The results of recent studies of the oxidative dissolution of transition metals in a liquid phase are generalised, and an analysis of the role of molecular oxygen and of the oxide film on the metal surface in oxidation processes in donor-acceptor organic media is proposed. The prospects of oxidative dissolution as a direct (single-stage) method of preparation of transition metal complexes are examined. 115 references.

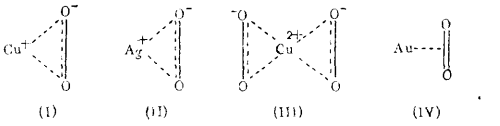
I. INTRODUCTION

The oxidative dissolution of transition metals in the liquid phase takes place by the reaction

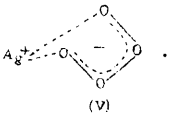
$$M^0 + Ox \xrightarrow[-ne]{mL} L_mM^{n+} + Red + P \qquad (1)$$

where M is the metal, Ox is the oxidiser, L is the complex former, Red is the reduced form of the oxidiser, and P are the products of the interaction between the components of the medium. Oxidative dissolution is an important topic in chemistry and in the chemical industry. It includes problems in catalysis, corrosion, and refining, in the analysis of metals and alloys, in extraction, and in the synthesis of complexes of various types[1]. Many problems in chemical energetics, ecology, and space technology are ultimately determined by metal oxidation processes.



Aqueous media containing inorganic acids, peroxides, and various related composition[2-6] are often used at present for oxidative dissolution. These systems are not always compatible with modern technology, and have some serious limitations (inadequate selectivity, reliance on toxic reagents, etc.). Requirements for non-aggressive and selective processes for the oxidation of metals in the liquid phase are increasing. One promising approach to the development of processes having the required characteristics is the use of non-aqueous media. Unlike the traditional processes in aqueous media, these have not so far been studied in detail.

Interesting influences of dipolar compounds having donor–acceptor properties on the rate and on the direction of chemical reactions have recently been reported: the effects are due to complex formation with organic or inorganic components[7,8]. The use of non-aqueous media allows the choice of a very wide range of donor–acceptor systems and can therefore lead to the development of processes for oxidative dissolution under mild conditions[9].



Whether a thermodynamically allowed oxidative metal dissolution process in a liquid phase can be realised, and the rate of the process in practice, are determined by a combination of factors: the nature of the metal and of the oxidiser, the composition of the medium and its donor–acceptor properties, and the state of the metal surface[10]. A real metal surface adsorbs mainly oxygen and water vapour[11]. Therefore an important feature of the process is that it takes place on the surface of an oxide layer. In this review we shall examine the problems arising from the influence of the surface oxide film and of the molecular oxygen on the oxidative dissolution of transition metals in donor–acceptor media, and we shall demonstrate the possibility of the single-stage preparation of transition metal complexes.

II. GAS-PHASE INTERACTION OF MOLECULAR OXYGEN WITH METALS

In order to characterise the interaction between molecular oxygen and a metal surface in a liquid phase, and the type of compound produced by this interaction, we must consider the reaction between metals and oxygen in the gas phase. The atoms of transition metals such as Ni, Cr, Cu, Ag, Au, Pd, Pt, Rh form complexes of the following types with molecular oxygen[12-14]:

Whereas a superoxide anion radical is produced by the interaction of O_2 with Ag and Cu [complexes (I)–(III)], the bond between the oxygen molecule and gold is of the "olefin" type, i.e. the resulting complex (IV) is of the π rather than of the σ type. The possibility of stabilising the bivalent state of the metal leads to the formation not only of $M^+O_2^{\cdot}$ [(I) and (II)] but also of *bis*(dioxygen) complexes such as $Cu^{2+}(O_2^{\cdot})_2$ (III), $Pd^{2+}(O_2^{\cdot})_2$, or in the case of silver (for which this possibility does not exist) we could have the tetra-oxygen complex $Ag^+(O_4^{\cdot})$ (V):

(V)

The formation of complexes of the type of (V) on a metal surface is unlikely for steric reasons. It has been suggested that $AgO_4^{\pm}$ or Ag_2O^{2-} can be formed on a silver surface [i.e. on $Ag(O_2)(ads)$] as a result of the dissociation of the O=O bond[15].

III. LIQUID-PHASE INTERACTION OF MOLECULAR OXYGEN WITH A METAL SURFACE

We have discussed[16] the role of the oxide film on the surface and that of molecular oxygen in the oxidative dissolution of transition metals. Donor–acceptor oxidising systems of two types were studied:

$$\text{DMSO} + \text{RX} \qquad (2)$$

where R = alkyl, H, or CCl_3, and X = Cl, Br, and

$$\text{DMFA} + CCl_4 \qquad (3)$$

In these expressions DMSO is dimethylsulphoxide, and DMFA is dimethylformamide. The system (2), unlike (3), can donate oxygen and thus produce an oxide film on the metal surface:

$$(CH_3)_2SO \rightarrow [O] + (CH_3)_2S.$$

Thus we know that the lower-valency complexes of titanium, molybdenum, and tungsten are effective deoxygenating agents because of the high thermodynamic stability of the M=O bond, and they can reduce $(CH_3)_2SO$ to $(CH_3)_2S$.[17]

We also showed[16] that the metals (M) can be classified into two groups according to their behaviour towards oxidation.

1. Metals which go into solution as complexes of the ionic $[L_pMX_n]_q[MX_m]$ or the neutral type $[L_pMX_m]$. No oxygen is included in these complexes. For the metals in this group, i.e. (Ti), Cr, Mn, Fe, Co, Ni, Cu, (Mo), Rh, Pd, Ag, Cd, (Ir), Pt, and Au, the dissociation energy of the metal–oxygen bond is $E_{MO} < 480$ kJ mole^{-1}.[18] For metals of the first transition series, and also Mo and Re, the rate of oxidative dissolution and the sublimation energy vary in opposite senses.

2. Metals for which the dissociation energy of the M=O bond is $E_{MO} > 480$ kJ mole^{-1} either do not dissolve or go into solution as oxo compounds of the type of $(L_pMO_nX_m)$. This group includes (Ti), V, Zr, Nb, Ru, Hf, Ta, W, (Mo), Re, Os, and (Ir). It was pointed out[18] that the heat of atomisation of O_2 ($E_{OO} = 498.7$ kJ mole^{-1}) lies in this energy range (480–500 kJ mole^{-1}), and therefore a stable M=O bond can be formed in the complexes of these metals.

The mechanism of the oxidative dissolution of the transition metals with the participation of oxygen is extremely complex, and not fully understood[8,9,19,20]. As in the mononuclear complexes of the transition metals with an O_2 molecule we can expect either a labile oxygen-containing molecular complex or a peroxo complex to be formed on the surface[21,22].

The presence of electrons on the oxygen π^* orbitals lowers the bond order in the resulting molecular ions $O_2^{\pm}$ and O_2^{2-}. Accordingly, the distance between the oxygen atoms increases in the series $O_2 < O_2^{\pm} < O_2^{2-}$, and the average energy of the bond decreases[22]. On metals with $E_{MO} \geq E_{OO}$ the states including $O_2^{\pm}$ and O_2^{2-} complexes will have a low stability, and the decomposition of molecular oxygen to form an oxide layer on the surface becomes possible.

The rate of dissolution of metals in the first transition series, and also Mo and Re, in systems (2) and (3) is found to be appreciable. Depending on the energy of the metal–oxygen bond formed on the metal surface by the adsorption of an oxygen molecule in the presence of a donor–acceptor system taking part in the formation of a molecular complex (MC)†, the formation of intermediates and of the final complexes can follow different mechanisms. An analysis of the metal–O_2–MC system has shown[26] that the complex can decompose on the surface either with regeneration of molecular oxygen (if $E_{-O_2-MC} < E_{O=O} > E_{MO}$) or with insertion of oxygen into the products. The formation of a stable oxide ($E_{MO} > E_{MX}$) suppresses this process. Thus, depending on the nature of the metal, oxygen can act as a catalyst (for a number of molecular complexes (MC) in the oxidation of Ag, Au, and Hg with $E_{MO} < 250$ kJ mole^{-1}), as a stoichiometric reactant (for most of the transition metals with $E_{MO} \cong 250$–630 kJ mole^{-1}), and lastly as an oxidative dissolution inhibitor (for Ti, Zr, Nb, Hf, Ta, and W, with $E_{MO} > 630$ kJ mole^{-1}).

We note that under real conditions (i.e. in a medium of coordinating solvents with donor–acceptor properties) dissolved oxygen forms reversible molecular complexes (for example, $C_6H_5N(CH_3)_2.O_2$ with dimethylaniline[27] and $(C_2H_5)_3N.O_2$ with triethylamine[28]), or associations (for example, $(H_2O)_n.O_2$ with water[29]). The energy degeneracy of the π^* orbitals of molecular oxygen is lifted in solution, but not enough for the paramagnetic properties to be lost. In the adsorption of solvated oxygen on the metal surface the splitting of the energy levels of the oxygen may be so large that singlet oxygen is formed: under these conditions changes in spin multiplicity become possible as a result of the change in the magnetic state of the metal atom (or ion)[30]. The transition $O_2(^3\Sigma) \rightarrow O_2(^1\Delta)$, requires an energy expenditure of ~96 kJ mole^{-1}.[31] Singlet oxygen acts as an electron donor towards strong electron acceptors[32], so that the energy consumed in the formation of a solvated molecule of singlet oxygen bound as a complex to the metal surface is compensated by the energy evolved by the addition of one electron to form an anion radical ($O_2 + e \rightarrow O_2^{\pm}$; $\Delta H^{\circ}_{298} = 63$–88 kJ mole^{-1}.[18–33]

The solvated superoxide ion can exist in two resonance-stabilised states: $O_2^{\pm}L \leftrightarrow O_2.L^{\pm}$ (for example $O_2^{\pm}Py \leftrightarrow O_2.Py^{\pm}$).[34] On the other hand, as we have already pointed out, the compounds which we are treating as "solvents" can form molecular complexes or associations (MC) or charge transfer complexes (CTC) with electron acceptors, for example $Py.SO_3$, $Py.Br_2$,[35] and $DMSO.SO_2$.[36]

We conclude from these results that the important role of molecular oxygen in metal oxidation processes reflects the ability of oxygen to interact with both the metal surface and the components of a donor–acceptor system.

IV. ROLE OF THE OXIDE FILM ON THE METAL SURFACE IN OXIDATIVE DISSOLUTION IN THE LIQUID PHASE

1. Formation of an Oxide Film

The electronic structure of the *d* metals is characterised by the presence of collectivised and of localised electrons. The properties of atoms on the surface of the transition metals play an important role in processes such as adsorption and catalysis, and thermo-electron emission.

The asymmetry of the attractive and repulsive forces towards neighbouring atoms of the crystal lattice gives the surface atoms a high reactivity, resulting from the tendency for the field of interaction forces to restore its symmetry. This tendency manifests itself in the formation of additional

† The molecular complexes are of the DMSO.RX and DMFA. $.CCl_4$ type. The formation of MC or associations and in some cases of an ion–radical salt (IRS) stimulated by the activated metal surface cannot be excluded[23–25].

bonds between the surface metal atoms and other atoms or molecules present on the surface. Complex formation on the surface lowers the thermodynamic potential of the system, and it is therefore an energetically favourable and spontaneous process. A study[37] by γ-resonance spectroscopy of the state of iron atoms on a polycrystalline tungsten surface has shown the presence of broken chemical bonds on the metal surface. This must lead to the formation of reactive centres at which relatively stable surface complexes (or even stable chemical compounds) can be formed.

Metal surfaces are covered with a thin layer of oxide (or, in the case of silver, of sulphide), approximately 100 Å thick. Though this layer is too thin to disguise the "metallic" sheen of the surface, there can be no doubt of its presence, and therefore all the processes known to occur on a metal surface have to take place on the surface of the corresponding oxides, which have the properties of semiconductors[38,39]. Only the oxides Au_2O_3, AgO, and Ag_2O_3 are thermodynamically unstable under normal conditions. On the surface of the precious metals gases such as oxygen and hydrogen form adsorption layers[40]. In some cases the heat of adsorption of oxygen at temperatures close to normal (i.e. the oxygen affinity) is higher than the heat of formation of the oxide: it has been suggested[41] that the thermodynamic properties of oxide films of thickness equivalent to one or a few unit cells of the crystal lattice are different from those of the massive oxides, and that the properties of chemisorbed oxygen are similar to those of oxygen in the thin oxides. The distinction between "chemisorbed oxygen" and "phase oxygen" is becoming blurred. Data on the heat of formation of oxides (expressed per mole of oxygen) and on the heat of adsorption of oxygen on various transition metals are given in Table 1.

Table 1. Heat of adsorption (ΔH_{ads}) of oxygen and heat of formation (ΔH) of transition metal oxides (kJ mole^{-2} O_2).[43,44]

Oxide	$-\Delta H$	$-\Delta H_{ads}$	Oxide	$-\Delta H$	$-\Delta H_{ads}$
Ag_2O	61.1	226.1	NiO	489.0	231.9—628.0
PdO	170.8	100.5	FeO	533.4	314.0
PtO_2	58.6	111.0	CoO	479.0	502.4
Cu_2O	333.7	343.3—502.4	WO	854.1	628.0—649.0

Benard[42] has classified all metals into four groups according to their oxygen affinity (ΔH°_{298}, kJ mole^{-1}): 1) $\Delta H^\circ_{298} < 210$ (the precious metals), 2) $\Delta H^\circ_{298} = 210$–$550$ (Cu, Fe, Ni, Co, ...), 3) $\Delta H^\circ_{298} = 550$–$840$ (Mn, Cr, Mo, W, ...), 4) $\Delta H^\circ_{298} > 840$ (Ti, Al, Si, ...). Oxides of the metals in the third and fourth of these groups are difficult to reduce.

The most probable configuration of the adsorption layer varies with the type of crystal plane of the metal, depending on the geometry of the lattice and on the number of bonds which can be formed between the metal and the adsorbed molecule. In the limit of the dissociative adsorption of oxygen the position of the adsorption centres is determined by the crystallographic orientation of the surface. On a close-packed surface, for example on the (111) plane of a face-centred cubic metal like Cu, the most stable adsorption centres are directly above the centres of gravity of groups of three adjacent atoms, and not above the atoms themselves[43] (see Fig.1). This important observation shows that coordination interaction can involve several surface atoms (or molecules): in other words, the conditions in this system are conducive to collective interactions.

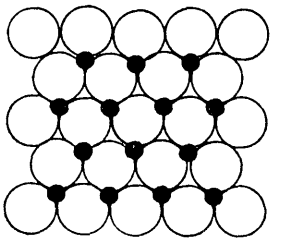


Figure 1. Coordination of the oxygen atoms during the dissociative adsorption of O_2 on the (111) face of a face-centred cubic metal (Cu).[42]

2. Properties of the Oxide Layer

The oxide systems of the transition metals include phases showing substantial deviations from the apparent stoichiometric composition. Typical of these are the homologous series of oxides in which the oxidation number of the metal is not a simple integer[39], for example the titanium oxides[45] Ti_nO_{2n-1} (n = 4–38) and the tungsten oxides[46] W_nO_{3n-2} and vanadium oxides[47] V_nO_{2n-1}, etc., where n is the number of metal atoms in the oxide.

In contrast to the separate amorphous or crystalline oxides, the oxide layers on a metal surface show a number of specific features# when examined as phases in their own right. Near the metal–oxide interface adjacent to the metal surface the oxide has n-type conductivity, i.e. the oxide is non-stoichiometric with an excess of metal. This produces an ohmic contact at the metal–oxide boundary (Table 2), since for most metals the electronic work function is lower than the work function of the oxide. As a result, under thermodynamic equilibrium conditions the oxide layer is enriched with electrons from the metal.

Some of the lower oxide phases of the transition metals, for example TiO,[49] and also the higher oxides of the platinum group metals, for example RuO_2, have a metallic conduction[50]. The possibility and the rate of the oxidation of the metal through the "outer" oxide surface are determined by the difference in work function between the metal and the oxide $\Delta\phi_{OM} = \phi_O - \phi_M$ (where ϕ_M is the electronic work function of the metal and ϕ_O is that of the oxide), and also by the activation energies for conduction (E_C) and for the diffusion of ions (E_d) in the oxide layer.

No direct relationship can be discerned between the $\Delta\phi_{OM}$ values (Table 2) and the ease of oxidation of metals. However, metals for which $\Delta\phi_{OM} \cong 1.0$–$2.5$ eV and the oxide has an energy gap $W \cong 1$–2 eV (like Mn and Cu) are more readily oxidised than metals with a smaller work function difference ($\Delta\phi_{OM} \cong 0$–1 eV) and a forbidden gap $W > 2$ eV (Ti, W). The relative positions of the energy levels of the metals and oxides are shown in Fig.2.

It has been shown[48] that the lower oxide of iron directly adjacent to the metal and structurally bound to it has a different stability (over thicknesses of the order of a few tens of Å units) than the same oxide in isolation from the metal surface.

Table 2. Physicochemical properties of the transition metal and their oxides[18,51-57].

Symbols: ϕ is the work function, $\Delta H^{\circ}_{f,298}$ is the sublimation energy, I is the ionisation energy, W is the width of the forbidden energy gap, and met. denotes metallic conduction. *The brackets denote a conductivity type not confirmed independently.

In general the rate-limiting step in the oxidation of metals whose oxides are electronic conductors is the breaking of bonds in the crystal lattice of the metal. If the oxide has a mixed (ionic–electronic) or an ionic conduction (as in Nb, Ta, and Zr) the transport of electrons through the oxide layer can be rate-limiting. Unfortunately, very little information is available on the activation energies for conduction and self-diffusion of metal ions in oxides containing metals in different states of oxidation.

Activation energies for conduction and metal diffusion in oxides measured at high temperatures are listed in Table 3. We can distinguish the group of electronic semiconductors (the oxides of Mn, Fe, Co, Ni, Cu) for which the activation energy for conduction is $E_{\sigma} < 83.7$–125.6 kJ mole^{-1} and the activation energy for the diffusion of the cation is $E_d < 210$ kJ mole^{-1}. Metals of this group show the characteristic relationship between the rate of oxidative dissolution and the sublimation energy of the metal[16]. In the case of the electronic semiconductors TiO_2, WO_3, and Ta_2O_5 and of the semiconductors of mixed or ionic type Nb_2O_5 and ZrO_2, which have relatively high values of E_{σ} (>83.7–125.6 kJ mole^{-1}) and of E_d (>209.3 kJ mole^{-1}), the oxidation of the metal is slow[16].

The stability of the oxide formed on the metal surface towards the replacement of oxygen by another counter-ion (for example, Cl^-) generated by electron transfer from the metal to the components of the donor–acceptor medium plays an important role in the oxidative dissolution of metals. Obviously, if the stability of the oxide is higher than that of the corresponding chloride (allowing for the effects of complex formation on the surface and in the solution) the dissolution will be suppressed.

Table 4 gives the standard heats of formation ΔH°_{298} of the chlorides and oxides of some transition metals. We note that the metals can be divided into two groups with respect to the relative stability of the corresponding oxides and chlorides (for the same degree of oxidation):

1) Co(III), Mn(IV), Cr(III), Fe(III), Mo(IV, VI), Ti(III, IV), V(III, IV, V), W(VI), Nb(V), Ta(V), Zr(IV), Rh(I, III), and Ru(IV) (chlorides less stable than oxides);

2) Ag(I), Au(I, III), Co(II), Ni(II), Mn(II), Pd(II), Cr(II), Fe(II), and V(II) (chlorides more stable than oxides).

The importance of the relative stability of the lower and the higher chlorides and oxides should be stressed. During the transfer of an electron from the metal to the oxide surface the metal ions in the oxide are reduced, and the stability of the oxides of the first group of metals decreases ("destabilisation" of the oxide layer): this improves the conduction properties of the layer, and the reactions leading to the formation of metal chlorides and their complexes become energetically preferred. If atmospheric oxygen is present in the system the degree of oxidation of the metal in the oxide layer increases, and the rate of formation of chlorides or oxide chlorides decreases. Under these conditions the rate of the oxidative dissolution process can be a function of the rate of the relevant rate-limiting step: either the supply (by diffusion) of oxygen to the surface or the dissolution of the oxide in the liquid phase containing chloride ions.

For the metals in the second group the characteristic reaction is the replacement of oxygen by chlorine: "stabilisation" of the oxide layer is produced by the oxidation of the metal ions by oxygen in the oxide layer, i.e. by the formation of higher oxides. This lowers the rate of the oxidation. The addition of oxygen to the donor–acceptor system suppresses the reaction in the first case and assists it in the second[9,16].

We note that the rate of dissolution of oxides depends less on the concentration of oxidiser than on the nature and concentration of the complex-forming ligand. For example, in spite of the relatively low concentration of proton oxidiser, the rate of dissolution of BeO is much greater in oxalic acid than in hydrochloric acid[66].

3. The Oxide Layer on the Surface of a Transition Metal as a Carrier of Electrons from the Metal to the Acceptor

Compounds of the transition metals such as the oxides have a characteristic valence band due to metal ions in an intermediate state of oxidation, for example M^{2+}, and not to O^{2-} ions, since the M^{2+} level is 5–8 eV higher than the O^{2-} level. In these compounds holes are formed more readily in the high

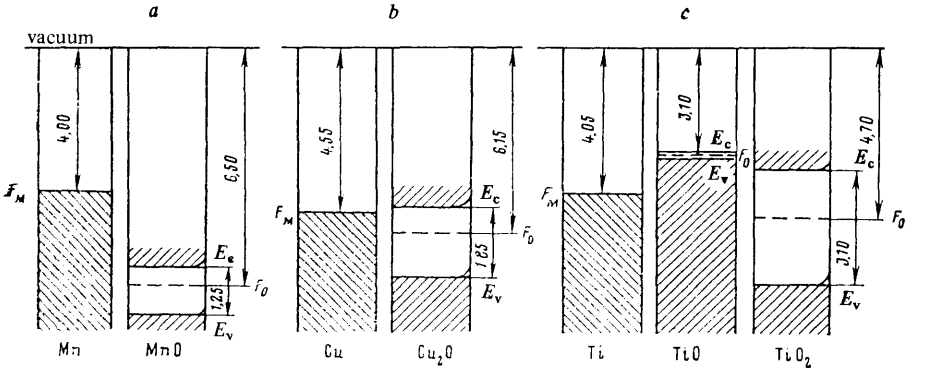

Figure 2. Energy level diagram (eV) for metals and their oxides: *a*) Mn/MnO, *b*) Cu/Cu_2O, *c*) $Ti/TiO/TiO_2$;[51-57] F_M and F_0 are the Fermi levels in the metal and the oxide, E_V and E_C are the edges of the valence and of the conduction band.

M^{2+} level or in the V'_M or V''_M levels (where V'_M and V''_M are vacancies with a negative and a double negative effective charge respectively). In any case, the emission of electrons from the M^{2+} level in transition metals[67] has an energy advantage equal to double the quantity $\Delta E_{OM} = E_O^{2-} - E_M^{2+}$. Thus, since the oxygen 2*p* band in transition metal oxides lies below the valance band of the metal, the first possible electron transition to give a polar state is (for nickel, say) from the Ni^{2+} ($3d^8$) to the Ni^+ ($3d^9$) band by the reaction[68]

$$Ni^{2+} + Ni^{2+} + h\nu \rightarrow Ni^{3+} + Ni^+ \qquad (4)$$

Table 3. Activation energies for conduction (E_σ) and for diffusion (E_d) of cations in metal oxides (kJ mole^{-1}).

Metal oxide	E_σ	E_d

Ta_2O_5 [65]	209.3	—

Notes: The width of the forbidden gap is 2.0 eV for ZrO_2 and 2.2 eV for Nb_2O_5,[57] with mixed conductivity; the energy gap for Ta_2O_5 is 3.6 eV.[57]

This transition is dipolar, and allowed by the selection rules[69], since it is from a $^3F(3d^8)$ to a $^2D(3d^9)$ state. On the other hand a transition from the $O^{2-}(2p^6\text{-}^1S)$ to the $Ni^+(^2D)$ band is either forbidden by the selection rules or (if treated as quadrupolar) it should have a much lower intensity[70].

Whereas reduction of a non-transition metal (M^{3+}) causes electrons to appear at the M^{2+} level, and oxidation produces holes in the O^{2-} band, in the oxides of transition metals (for example, in magnetite, Fe_3O_4) both processes are accommodated in the M^{2+} band, which is half-filled.

Table 4. Standard heats of formation ΔH°_{298} (kJ mole^{-1}) of the chlorides and oxides of the transition metals.

Chlorides	$-\Delta H^\circ_{298}$	Oxides	$-\Delta H^\circ_{298}$

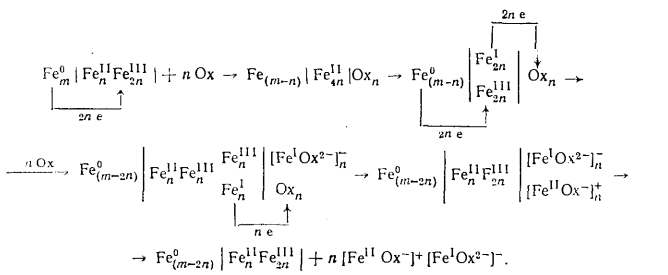
From these considerations we can formulate the main features of the oxidation of transition metals in the liquid phase with allowance for the catalytic role of the oxide film in the transfer of an electron from the metal to the oxidiser.

1. The oxide film on the metal surface acts as a catalyst§ for the oxidation of a transition metal in the liquid phase. Metal ions in the oxide film are reduced by the electrons flowing from the metal under the influence of the oxidiser¶ adsorbed on the surface. The adsorption of oxygen on the surface of a thin oxide layer produces a negative charge in the film. The outer surface of the oxide receives electrons both from the bulk of the film and from the metal, and the metal acquires a positive charge relative to the film[71]. Transition metals in a lower state of oxidation show a characteristic tendency to form metal–metal bonds, especially in the lower halides and oxides of Nb, Ta, Mo, W, and Re, though at least one such compound is known for every element of the *d* group[72]. We may assume that electron transfer is produced either by the formation of clusters in the lattice of transition-metal lower oxides containing M–M bonds with an energy similar to the bond energy of the transition metal lattice[73], or through the 2*p* band of the oxygen sublattice, which allows continuous exchange of electrons between the iron ions through the oxygen ions[74].

2. A metal atom incorporated into the crystal lattice loses enough electrons to convert it into its stable lower state of oxidation, for example

$$Cu^0 - e \rightarrow Cu^I; \quad Fe^0 - 2e \rightarrow Fe^{II}.$$

3. As a result of the donor–acceptor properties of the complex on the surface the reduction of the metal ions in the film is accompanied by a stimulated, synchronous transfer of electrons to the conduction band, yielding a pair of metal ions in states of oxidation differing by two units [see Eqn.(4)].[67,75] Since the postulate of a purely ionic bond in transition metal oxides is only a rough approximation we cannot exclude the interaction between the oxidiser and a virtual Mott exciton as the mechanism of this process. The formation of ions in different states of oxidation at very short distances apart may be equivalent to the formation of an active centre (which consists of a number of pairs of these ions, i.e. a cluster)[76].



4. Stabilisation of the excited state of the ions (or ion) is obtained by the transfer of one or two electrons from the surface of the oxide layer to the oxidiser, and depends on the nature of the latter (one-electron or two-electron acceptor).

5. Stabilisation of the counter-ions takes place through the formation of neutral complexes (for example, $[M^{n+}Ox_n^-]^0$, $[M^{2n+}Ox_n^{2-}]^0$), or of an ionic complex of the type $[M^{n+}Ox_{(n-m)}^-]_p^{m+} \cdot [M^{n+}Ox_{(n+p)}^-]_m^{-p}$ in the solvated state, which assists the diffusion of the complex into the solution.

6. Diffusion of an oxidised metal ion into the solution in the form of a neutral complex takes place when the stability of the complex is higher than the stability of the oxide on the surface, since this process requires the breaking of M–O bonds and formation of new M–Ox bonds.

7. Saturation of the free valencies of the oxygen atoms on the surface takes place through the diffusion of metal ions along vacancies in the layer by the replacement pressure ("crowdion") mechanism[77].

According to the proposed mechanism, the oxidation of metals can be described by the following scheme (in which the metal is a two-electron donor, iron (Fe^0), the oxidiser is a one-electron or two-electron acceptor, and the vertical lines denote the boundaries of the oxide phases):

In this process the oxidised state of the layer is regenerated. The scheme allows the formation of univalent iron, stabilised in an ionic complex by bivalent iron.

Evidently, further oxidation of the complex can take place in solution. However, further oxidation on the surface is also possible, giving Fe(II)–Fe(III) iron complexes of different valency in which the stabilisation of the bivalent iron[10] depends on the donor–acceptor properties of the solvent included as a ligand in the complex cation (for example, $[Fe^{II}(CH_3CN)_6].[Fe^{III}Cl_4]_2$) or in the complex anion (for example, *cis*-$[Fe^{III}Cl_2(DMSO)_4]_2[Fe^{II}Cl_4]$).

As the scheme shows, the active centre on which the oxidation takes place contains at least two metal atoms (or ions).

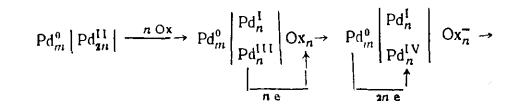
Inspection of the catalytic properties of oxide layers of the transition metals in the light of the above mechanism reveals the possibility (in principle) of selective oxidation of the transition metals. The basis of the selective oxidation process is the requirement of complementarity of the reaction† *with respect to the active centre*, i.e. the retention of the one- or two-electron mechanisms for the electron transfer to the oxidiser, irrespective of the number of electrons removed in the stabilisation of an atom from the crystal lattice of the metal. The realisation of this process depends on the properties of the complex on the metal surface (or on those of the oxide layer), i.e. on the possibility of redistributing the electron density in the surface complex by transferring one or two electrons. This redistribution leads to the decomposition of the complex, giving oxidised forms of the metal in solution in a lower state of oxidation than the ions on the metal surface (for example, those in the oxide layer). Several examples consistent with this interpretation of the role of the film on the metal surface can be quoted.

---

§ We shall use the term "catalyst" to denote a compound formed on the surface from the metal ion newly created in the oxidation process and from the O^{2-} ion set free, so that the "composition" of the compounds on the surface stays constant but its constituent metal ions are replaced.

¶ The term "oxidiser" (Ox) refers to a complex (or association) between the components of a donor–acceptor system in the liquid phase, for example $(DMFA)_n(RX)_m$.[23,24]

† A reaction is called complementary or non-complementary depending on whether the oxidation states of the oxidiser and of the reducer change by the same amount. The complementarity (or electronic correspondence) principle states that the replacement of a non-complementary by a complementary process leads to a faster reaction[78,79].



A study[80] of the cathodic reduction of oxide layers on an iron surface has shown that the outer layer of oxide contains ions in a higher state of oxidation, and that its oxygen content is higher than the stoichiometric composition Fe_2O_3 (oxide with an excess of cation vacancies).

We also know that the removal into an acid medium of the higher-valancy oxide from an iron surface involves the reductive dissolution rather than the direct dissolution of hematite and magnetite. A study of the solubility of the oxide Fe_2O_3 showed[81] that the direct action of acid on this oxide is slow, and gives Fe^{2+} ions in solution, though the oxide formally consists of Fe_2O_3. In a short-circuited model cell consisting of Fe_2O_3 and Fe^0 the iron was found to be the anode, and the oxide the cathode. Under these conditions the transfer of an electron from the metal to the oxide leads to the formation of structure defects of Fe^{3+} in the oxide lattice (i.e. to an increased concentration of Fe^{2+}). The appearance of Fe^{2+} ions upon dissolution of an oxide containing only Fe^{3+} is explained by assuming that the dissolution is confined to the structure defects. This explanation is consistent with our mechanism of electron transfer from the metal to the oxidiser through a layer of oxide.

It has been shown[82,83] that the transfer of an ion from the surface to the solution is assisted by a decrease in its valency. In the dissolution of precious metals in the presence of strong-field complexing ligands (for example, the dissolution of gold by the cyanide method with oxygen as the oxidiser, see p.12 of Ref.48) a layer of intermediate products is formed (mainly, the thermodynamically unstable[48] higher oxide of gold(III), Au_2O_3), and the cyanide complex of univalent gold goes into solution[2]. The thickness of this layer varies from 100 (on silver) to 1000 conventional monolayers (on copper), and depends on the concentration of cyanide and oxygen, on the rate of stirring, and on the temperature and duration of the reaction. It has been stressed[82,83] that the exact mechanism of action of these films is not understood, though their permeability to oxygen has been established. The rate of dissolution of the film itself plays an important part in the metal oxidation process.

A dynamic equilibrium is created on the surface, and the film adopts a constant thickness, depending on the conditions of the reaction[84].

The complementarity of the oxidation process with respect to the active centre which we have postulated can be further tested by considering the oxidation of a platinum group metal in which the metal is a two-electron donor (palladium) and the oxidiser is a one-electron acceptor:

As a rule the oxidation of Pd^0 with a two-electron acceptor produces a slower reaction, despite the fact that Pd^0 is a two-electron donor. The reaction follows a one-electron mechanism because the active centre formed on the surface is a one-electron donor.

The above considerations lead to the conclusion that the oxidation can be accelerated by adding to the system a compound able to act simultaneously as a one- and two-electron oxidiser and reducer[79]. Thus a much faster reaction is obtained by adding to the oxidation–reduction system a catalytic carrier which converts the one-electron electron-transfer mechanism into a two-electron mechanism (catalytic carrier, copper and iron ions (M); oxidiser, molecular oxygen)[85,86]:

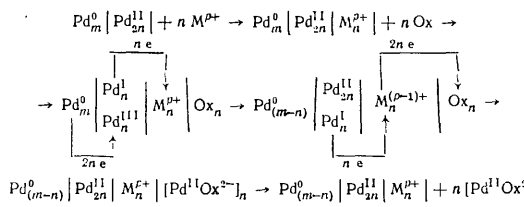


Table 5. Characteristics of electron transfer from a metal through an oxide layer to an oxidiser.

Surface reaction	Number of electrons*				E/E'	$\Delta E_i = E_i - E_i'$	Optimum conditions ($\Delta E_i < 0$)	Element	E_i/E_i'	ΔE_i, eV
	M^0	M^n	M^{n-1}	Ox						
$M^0 + 2M^n \rightarrow M^{2+} + 2M^{n-1}$ (5)	2	1	2	2	$\frac{W + I_0 + I_+ + I_{n-2} - I_{n-1}}{I_0 + I_+}$	$W + I_{n-2} - I_{n-1}$	$W < I_{n-1} - I_{n-2}$	Fe	$\frac{W + 9.7}{24.1}$	$W - 14.4$
$M^0 + M^n \rightarrow M^{2+} + M^{n-2}$ (6)	2	2	2	2	$\frac{W + I_0 + I_+ + \frac{1}{2}[I_{n-2} + I_{n-3}]}{I_0 + I_+ + I_{n-2}}$	$W + \frac{1}{2}[I_{n-3} - I_{n-2}]$	$W < \frac{1}{2}[I_{n-2} - I_{n-3}]$	Fe	$\frac{W + 36.15}{40.3}$	$W - 4.15$
$2M^0 + M^n \rightarrow 2M^+ + M^{n-2}$ (7)	1	2	1	1	$\frac{W + 2I_0 + I_{2+} - I_{n-1} + I_{n-2}}{I_0 + \frac{1}{2}[I_+ + I_{2+} - I_{n-1} - I_{n-2}]}$	$W + I_0 + \frac{1}{2}[I_{2+} - I_0 - I_{n-1} - I_{n-2}]$	$W < \frac{1}{2}[I_+ + I_{n-1} + I_{n-2} - I_{2+}] - I_0$	Au	$\frac{W - 2.1}{9.2}$	$W - 11.2$
$M^0 + M^n \rightarrow M^+ + M^{n-1}$ (8)	1	1	1	1	$\frac{W + I_0 + \frac{1}{2}[I_{n-1} - I_{n-2}]}{I_0}$	$W + \frac{1}{2}[I_{n-1} - I_{n-2}]$	$W < \frac{1}{2}[I_{n-2} - I_{n-1}]$	Au	$\frac{W + 13.95}{9.2}$	$W + 4.75$

Symbols: I_0 is the ionisation energy (eV) of the neutral unexcited atom by the reaction $M^0 \rightarrow M^+ + e$; I_+ is the ionisation energy (eV) of the singly charged (positive) unexcited metal ion by the reaction $M^+ \rightarrow M^{2+} + e$; $I_{(n-1)}$ is the ionisation energy (eV) of the unexcited metal ion with $(n - 1)$ positive charges by the reaction $M^{n-1} \rightarrow M^{n-2}$; W is the width of the forbidden energy gap (eV); E is the energy required for the electron transfer process with allowance for the formation of an electron–hole pair; E' is the same energy without the correction for the formation of an electron–hole pair.
*The numbers of electrons taking part in the catalytic process in the oxide layer are shown; M^0 is the metal (electron donor), M^n is the metal ion (electron acceptor), M^{n-1} is an active centre (electron donor), Ox is the electron acceptor in the liquid phase.

4. Role of the Surface Oxide Film as an Intermediate Electron Trap

The role of the surface as a direct participant in a chemical reaction, and in particular the metal oxidation reaction, includes the provision of a site for the localisation of free current carriers and excitons, since the Madelung constant (μ) on the surface is smaller than in the bulk, and therefore an electron–hole pair (or exciton) has a lower energy on the surface. In the case of an ionic cubic lattice we have $\mu = 1.74$ for the bulk and $\mu = 1.68$ for the surface, which is the cause of excition transport from the surface[97].

It can be shown that the oxidation of a metal covered with a layer of a semiconducting compound of variable composition and containing ions of the metal in different states of oxidation (e.g. an oxide) is energetically more favourable if it takes place through the formation of an electron–hole pair than by direct oxidation without preliminary excitation of the atoms (or ions). If all the other conditions stay the same (composition of the oxidation–reduction medium, composition of the layer on the metal surface, Madelung energy) two alternative paths are available for the oxidation of iron.

1) Oxidation through the formation of an electron–hole pair (in the case of a two-electron mechanism for the transport of electrons to the oxidiser):

a) reduction of Fe_3O_4 to FeO

$$Fe^0 + 2Fe^{3+},\ (Fe^{2+}) \rightarrow 3Fe^{2+},\ (Fe^{2+}) + E_v$$
$$E_v = I_0 + I_+ - 2I_{2+} = 7.9 + 16.2 + 2 \cdot 30.6 = -37.1\ \text{eV}$$

b) formation of an electron–hole pair

$$2Fe^{2+} \rightarrow Fe^+ + Fe^{3+} + W\ ,$$

where W is the width of the forbidden energy gap for FeO (Fe_3O_4) = 0.4 eV (see Table 2)

c) oxidation of Fe^+

$$Fe^+ \rightarrow Fe^{3+} + 2e + E_{OC}$$
$$E_{OC} = I_+ + I_{2+} = 16.2 + 30.6 = 46.8\ \text{eV}\ .$$

The total energy requirements of the first path are

$$E = E_v + W + E_{OC} = -37.1 + 0.4 + 46.8 = 10.1\ \text{eV}.$$

2) Oxidation without formation of an electron–hole pair, replacing the two-step process (b), (c) by the oxidation of two Fe^{2+} ions:

d) $$2Fe^{2+} \rightarrow 2Fe^{3+} + 2e + E'_{OC}$$
$$E'_{OC} = 2I_{2+} = 2 \cdot 30.6 = 61.2\ \text{eV}$$
$$E' = E_v + E'_{OC} = -37.1 + 61.2 = 24.1\ \text{eV}\ .$$

The gain in energy $\Delta E = E - E'$

$$\Delta E = 10.1 - 24.1 = -14.0\ \text{eV}.$$

In idealised limiting cases of oxidation in the absence of oxygen and of an oxide layer on the metal surface, or of a rate of dissolution of the oxide layer in the donor–acceptor medium greater than the rate of oxidation of the metal, the complex formed by the components of the liquid phase with the surface atoms of the metal can also be a catalyst for the oxidation process if it can be treated as a semiconductor. We can assume that the lower the activation energy for conduction and the energy gap in the complex, the more marked will be the catalytic effect.

Calculated values of the energy required for the electron transfer process in the film on a metal surface are shown in Table 5 for a one-electron (e.g. Au^0) and a two-electron donor metal (e.g. Fe^0), without allowance for the electron affinity of the oxidiser or for the solvation energies of the initial and the final products, which are assumed constant.

If the metal ions present in the film in a higher state of oxidation act as one-electron acceptors [for example, according to reaction (5)] the energy gain for iron (with $W = 0.4$ eV) is 14 eV.

If the metal ions in a higher state of oxidation act as a two-electron acceptor in the film [for example, by reaction (6)] the energy gain for iron becomes (W – 4.15) eV. Since $W \leq 3$ eV for semiconductors, in this case the energy gain is >1 eV. Comparing the electron transfer systems (5) and (6), assuming in both cases the formation of electron–hole pairs, we conclude that the first path offers an energy advantage:

$$\Delta E_{1,2} = E_1 - E_2 = {}^1/_2(I_{n-2} - I_{n-3}) - I_{n-1}\ .$$

For iron $\Delta E_{1,2} = -26.45$ eV, i.e. the one-electron reduction of the metal ion in the higher state of oxidation is preferred in this case. A similar analysis for gold suggests that reaction (7) is preferred to reaction (8) as an electron transfer path ($\Delta E_{3,4} = -16.05$ eV), whereas for a process not involving the formation of an electron–hole pair the two reactions are energetically equivalent ($E'_3 = E'_4$)#.

Our analysis justifies the following conclusions.

1) The transfer of an electron from the metal to the oxidiser through the surface film is energetically more favourable (if the film has semiconductor properties) than the "normal" transport process found in oxidation–reduction reactions in the liquid phase.

2) the most favourable process in terms of energy is the transfer of an electron through a layer of oxide with a very small decrease in the degree of oxidation of the metal ions in the layer [Table 5, Eqns.(5), (6), and (7), (8)].

V. ROLE OF SURFACE DEFECTS

A real surface differs from an idealised surface by perturbations in the periodicity of the structure, i.e. by the presence of surface defects[88]. The defects can participate directly in surface processes, since they can act as centres for the coordination of the components of the donor–acceptor medium. Vacancies in the cation sublattice may also play a part in the formation of electron–hole pairs by the quasi-chemical equation

$$V^0_M + V''_M \rightleftarrows (V'_M, h)^{\bullet} + (V'_M, e)'' \rightleftarrows 2V'_M + h + e$$

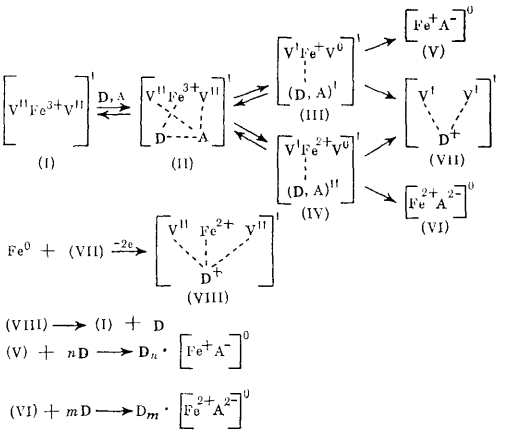
where V^0_M, V'_M, and V''_M are vacancies with a zero, a negative, and a double negative effective charge.

Transition metals containing *d* electrons and able to transfer electrons reversibly form characteristic associations (or complexes) of defects of the same kind because the attractive forces arising from quantum-mechanical exchange interaction are large enough to overcome the elastic and Coulombic interactions.

In the non-stiochiometric lower oxide of iron the holes, which are localised on iron ions as Fe^{3+}, can interact with the cation vacancies bearing an effective negative charge. This interaction leads to the formation of a composite complex defect: an interstitial ion bound to two vacancies, $[V'_{Fe}Fe^{3+}V''_{Fe}]'$. A complex with this configuration is more stable than the simple vacancy; it is a structure element of the phase $Fe_{3-y}O_4$ into

For gold $I_+ + I_2 - I_{n-1} - I_{n-2} = 0$ (see Table 5).

which $Fe_{1-y}O$ is converted when the critical metal deficit is exceeded. In these oxides the defects show long-range order, and the electrical conductivity is abnormally large (125 $Ohm^{-1}\,cm^{-1}$).[89] It has been suggested[90] that under these conditions the conductivity is due to the exchange of electrons between two adjacent iron ions (Fe^{2+} and Fe^{3+}). Evidently, analogous effects are possible in other oxide phases with a metal defect, $[M_{1-y}O]$, which include oxides with structure defects of the cation vacancy type[77] such as MnO, NiO, and Cu_2O.



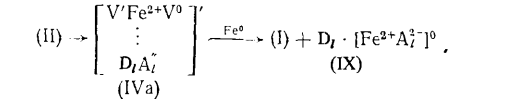
It has been shown that the active dissolution of iron covered with FeO involves an increase in the non-stoichiometry of the surface oxide and an increased concentration of surface defects: anion vacancies (Fe^{II} ions) and free electrons. Photoelectric polarisation measurements have established that the passivation of iron, copper, and silver is accompanied by changes in the surface oxide towards a stoichiometric composition, and by a decrease in the concentration of non-stoichiometric defects[88].

Experimental data[91,92] indicate the formation of the anion radicals ($Ox^{\pm}$) on the surface of metal oxides in the presence of acceptor molecules (O_2, SO_2, quinones). However, complex formation takes place mainly on charged surface defects (negatively ionised cation vacancies) rather than on ordinary lattice atoms, The assumption of charge transfer from an ionised defect to a molecule of the oxidiser is confirmed by the formation (for example, with benzoquinone or fluoranil) of charge-transfer complexes (CTC) of the same structure on both typical semiconductor (Ge, TiO_2, ZnO) and typical insulator surfaces (MgO, Al_2O_3).[93,94] For donor molecules the most probable coordination is on ordinary lattice atoms and on ions in interstitial sites.

Donor molecules (for example, triphenylamine) form cation radicals when adsorbed on zeolite surfaces, and acceptors such as tetracyanoethylene, trinitrobenzene (TNB), and *m*-dinitrobenzene form anion radicals. It is interesting to note that previous adsorption of donors (anthracene and perylene) on the zeolite causes a ten-fold increase in the number of TNB anion radicals as compared with the adsorption of TNB on a fresh zeolite surface[95]. Under these conditions an additional TNB anion radical is formed for every three anthracene or perylene cation radicals. This effect can be explained by the cooperative interaction of vacancies on a solid surface[95]. The adsorption of SO_2 and benzene leads to the formation of the corresponding ion radicals, i.e. $SO_2^{\pm}$ and $C_6H_6^{\pm}$. The adsorption of one oxygen molecule produces one perylene cation radical, but $O_2^{\pm}$ is not formed under these conditions. We interpret this as evidence of the cooperative nature of the interaction on the solid surface, since additional electron transport from the donor to the surface without involving an acceptor suggests a surface with a high capacity for electrons and controllable donor–acceptor properties.

Evidently, the formation of surface complexes in a donor–acceptor medium leads to electron transfer from the negative pole of the resulting dipolar MC (or CTC) to an ordinary lattice atom or ion, and from the vacancies to the positive end of the dipole. The formation of this coordination bond is accompanied by substantial changes in crystal field, with corresponding changes in the parameters of the defects, causing localisation of free carriers on the defects closest to the molecules held by coordination forces. This influences the strength of the bonds and the distortion in the complex, and weakens the intramolecular bonds of the MC. As a result of this coordination and collective interaction effect the localisation of holes near a metal ion in the lower state of oxidation and the emission of the ion from the surface into the liquid phase can take place within a unified quantum-mechanical system.

The participation of surface defects in complex formation with the oxidised form of the metal can be described (in the case of iron) by the following scheme:



In step (9) the complex (II) is formed on the surface. It includes the components of the oxidation–reduction system (the donor D and the acceptor A), the metal ion, and defects with double negative charges. This is followed by redistribution of the charge density in the complex, in which the charge on the active centre is retained. In the ground state the two components of the complex are bound by ion–dipole, hydrogen, and dispersion forces, and also (to a small extent) by electrostatic and covalent forces arising from electron transfer from DA to the metal. This transfer is largely determined by the electronegativity of the metal and also by the donor–acceptor properties and by the polarisability of the components of the medium (strictly speaking, of their associations) involved in complex formation on the surface. Depending on the relative stability of the complexes (III) and (IV), and on the donor–acceptor properties of DA, neutral complexes of univalent and of bivalent iron [(V) and (VI)] will diffuse into the solution. This stabilises the cation vacancy complex (VII) containing a positively ionised molecule of the donor [step (9)]. Two-electron transfer from a metal atom to the complex (VII) causes the donor to be transferred to the solution [steps (10) and (11)] and regenerates the active centre I.

This scheme ignores the redistribution of electron density in the complex on the surface, which can lead to a weakening of the intramolecular bonds and to the ejection of fragments of the donor (D_f) and of the acceptor (A_f) by the reaction

$$(II) \rightarrow D_f + A_f . \qquad (12)$$

Reaction (13) brings into the solution the complex (IX) between the metal and the decomposition products of the oxidation–reduction system:

The reaction

$$(II) \rightarrow (IVa) \rightarrow (I) + D_l + A_l \qquad (14)$$

causes catalytic conversion of the components of the donor–acceptor system: in other words, the metal surface can stimulate (or accelerate) the interaction between D and A with

formation of the fragments D_f, D_l, A_f, and A_l. This reaction path does not lead to oxidation of the metal, and may even suppress it.

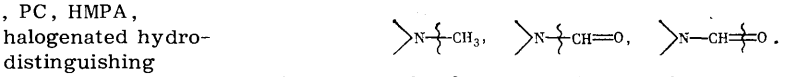
The possibility of controlling the direction of the interaction between a metal surface and the components of the liquid phase offers a real prospect of achieving selective oxidation of the transition metals.

VI. PROSPECTS OF OXIDATIVE DISSOLUTION AS A DIRECT METHOD OF SYNTHESIS OF TRANSITION METAL COMPLEXES IN THE LIQUID PHASE

The traditional methods of dissolving transition metals in a liquid phase, which give oxidised forms of the metal, rely on the use of aqueous media containing strong oxidising agents. The range of complexes which can be obtained in this type of system is very narrow, and the method is unsuitable for the direct (single-stage) synthesis of complexes by reaction (1).

Developments in the chemistry of the coordination compounds of transition metals have stimulated new approaches, based on non-aqueous aprotic media. The interest in these media stems mainly from the wide range of physicochemical properties which they offer: 1) their dielectric constants ε cover the range from 2.2 (1,4-dioxan) to 182 (*N*-methylformamide), 2) the dipole moments μ lie between 1.75 (tetrahydrofuran, THF) and 5.39 (hexamethyl phosphorotriamide, HMPA), 3) the region of existence of the liquid phase extends from −48.8 to +242 °C (for propylene glycol carbonate, PC), 4) these media offer specific donor–acceptor properties§, the *DN* varying from 2.7 (nitromethane) to 28.8 (HMPA) and the *AN* varying from 3.9 (diethyl ether) to 20.5 (nitromethane).

As we have shown[1], donor–acceptor systems containing dipolar aprotic compounds can be very effective in the oxidative dissolution of transition metals: dimethylsulphoxide, dimethylformamide, dimethylacetamide (DMA), tetramethylenesulphone (TMS), 2,4-dimethyltetramethylenesulphone (DMTMS), ethylene glycol carbonate (EC), PC, HMPA, acetonitrile (AN), benzonitrile (BN), and halogenated hydrocarbons (for example, CCl_4).[97] The most distinguishing feature of these organic solvents is their ability to form molecular complexes or associations[24]. This property also favours any thermodynamically allowed process¶ in which an easily polarisable solvent[104] acts as a bridging ligand and thus makes possible the transfer of an electron from the surface to an acceptor[25,105].



The oxidative dissolution of metals can yield two types of complex: neutral or ionic. The complexes may contain (as ligands) the components of the medium in their original state, or intermediate products formed by the interaction of these components[16,23,106].

1. Neutral complexes with an unchanged component as ligand. This case is most often met with copper, nickel, cobalt, molybdenum, and tungsten. Examples of complexes which have been synthesised in this way include the compounds L_2MX_2 (where M = Cu, Co, Ni) and $L_2MO_2X_2$ (where M = Mo, W), with X = halogen and L = DMFA, DMA, DMSO, and AN.

2. Ionic complexes with an unchanged component as ligand. Examples of complexes of this type which have been synthesised include the iron and cobalt compounds *cis*- and *trans*-$[Fe^{III}(DMFA)_4Cl_2][Fe^{III}Cl_4]$, $Fe^{III}(DMFA)_3Cl_2][Fe^{III}Cl_4]$, *cis*- and *trans*-$[Fe^{III}(DMSO)_4Cl_2]Cl$, $[Fe^{III}(DMSO)_3Cl_2].[Fe^{III}Cl_4]$, *trans*-$[Fe^{III}(DMSO)_4Cl_2][Fe^{III}Cl_4]$, *cis*-$[Fe^{III}.(DMSO)_4Cl_2]_2[Fe^{II}Cl_4]$, $[Fe^{III}(DMSO)_5Cl][Fe^{III}Cl_4]_2$, $[Fe^{II}(AN)_6][Fe^{III}Cl_4]_2$, $[Fe^{II}(BN)_6][Fe^{III}Cl_4]_2$, and $[Co^{II}.(DMSO)_6][Co^{II}Cl_4]$.

Further examples may be quoted to illustrate the special features of the direct method of synthesis. The metal being oxidised stimulates the interaction between the components of the oxidising system. The intermediates formed during the reaction are stabilised by ionic or coordination interaction with the metal ion. The possibility of including these "fragments" as ligands can lead to the formation of unusual complexes, both neutral and ionic. Thus by oxidising metals with a system containing DMSO the following complexes have been obtained: with iron, $[Fe^{III}(DMSO)_5Cl][Fe^{II}_2Cl_6O]$,[106] and with palladium $[(CH_3)_2S]_2PdBr_2$,[107] showing that the $>S \rightarrow O$ bond is broken. Stabilisation of the intermediates formed by this reaction is found also in the complex $[(CH_3S)_3C][Fe^{III}Cl_4]$ formed by the oxidation of iron during chlorination of cyclohexane in the DMSO + CCl_4 system: the H_3C-S bond is broken in this reaction[108].

It is interesting to note that in the dinuclear bridge complex [*cis*-$Cu(DMFA)_2Cl_2]_2$ formed during the oxidation of copper, one of the DMFA molecules bound to the copper atom through oxygen is in an anomalous state, all its bonds being longer than those of the other DMFA molecule in the *cis*-position. This suggests a weakening of the bonds as a result of complex formation, and the possibility of dissociation of the DMFA molecule into fragments under the influence of temperature and of the medium[106]. In fact, the following complexes containing fragments of the DMFA molecule have been isolated and characterised in DMFA systems[109,110]: $[(CH_3)_2.NCH\}_2CCl][Fe^{III}(DMFA)_6][Fe^{III}Cl_4]_4$ and $[CH_3NH_3]_4[Fe^{II}Cl_6].H_2O$. The reaction involves bond breaking as follows:

As an example of the potential use of this method we may consider the complex dimethyldibenzylammonium tetrabromopalladate, obtained[107] in the $C_6H_5CH_2Br$ + DMFA system. In this case the $>N-CHO$ bond in DMFA is broken, and stabilisation of the "fragments" $(CH_3)_2N-$ and $C_6H_5CH_2-$ takes place in the $[(CH_3)_2N(C_6H_5CH_2)_2]^+$ cation.

The use of chelating ligands in aprotic dipolar solvent–halogenated hydrocarbon systems widents the range of complexes which can be synthesised by this method. In the presence of α,α'-dipyridyl (α-dipy), dimethylglyoxime (DMGH), 8-oxyquinoline (8-oxin H), acetylacetone (acac H), cyclo-octa-1,5-diene (COD) the following complexes have been obtained: (α-dipy)$NiCl_2$, $Ni(DMG)_2$, $Co(8\text{-oxin})_2(H_2O)_2$, $Co(\alpha\text{-dipy})(acac)_2$, $H[Co(DMG)_2Cl_2]$, $Cu(DMG)_2$, $Cu(acac)_2$, $[Cu(COD)Cl]_2$, (α-dipy)$PdBr_2$, (α-dipy)$PtBr_4$, etc.[111,112] Another promising direction is the direct synthesis of transition metal complexes by catalytic oxidation with oxygen. This process has been demonstrated for a group of metals including some platinum group metals (Pd^0 and Pt^0) with which oxygen behaves as a "stoichiometric" reagent[16].

In the $M^0 + O_2 + HX + L + Kt$ system, where L = DMFA, pyridine (Py), pyridine oxide (PyO), AN, trimethylamine oxide $(CH_3)_3NO$, or the salt of an onium base ($>\overset{|}{N}X$, $\rightarrow SX$,

---

§ *DN* is the donor number and *AN* is the acceptor number on Gutman's scale[7,96].

¶ The Gibbs free energy (ΔG°_{298}) calculated for the reaction $Fe^0 + 2CCl_4 \rightarrow FeCl_2 + C_2Cl_6$ without allowing for complex formation is −229.4 kJ mole^{-1}.[98,103]

X = Cl, Br, I), and Kt = Fe, Cu, a series of palladium and platinum complexes has been synthesised. With [HX[> [L] ionic complexes were isolated in which the oxidised metal was in the anion, and the cation was produced from L by protonation (L = Py, PyO), hydrolysis (L = DMFA, AN), dissociation [L = $(C_2H_5)_3NHBr$, $(CH_3)_3SBr$], or protonation of the deoxygenated form of L[$(CH_3)_3NO \rightarrow (CH_3)_3N$ + [O]]. With [HX] < [L] neutral complexes were obtained, for example $(\alpha$-dipy$)PdCl_2$.[85,86]

---o0o---

Our study of the possible mechanisms of electron transfer from a metal to an oxidiser during the liquid-phase oxidative dissolution of transition metals, allowing for the semiconductor properties of the oxide layer, for the adsorption of molecular oxygen, and for the donor–acceptor interaction between the components of the medium has identified both complementary and non-complementary processes for the oxidation of metals in organic complex-forming media by which a wide range of coordination compounds can be synthesised.

The oxidative dissolution of transition metals in organic media and the direct synthesis of complexes are currently attracting intensive study from which interesting developments can be expected from the practical as well as the scientific aspect[113–115].

The Synthesis, Structure, and Reactions of 1,3-Oxathiacycloalkanes

D.L.Rakhmankulov, V.V.Zorin, F.N.Latypova, S.S.Zlomskii, and R.A.Karakhanov

Data concerning the methods of synthesis, structure, and properties of 1,3-oxathiacycloalkanes are discussed. The modern ideas about steric structure, reactivity, and mechanisms of the reactions of 1,3-oxathiacycloalkanes in the liquid phase are surveyed and described systematically.
The bibliography includes 102 references.

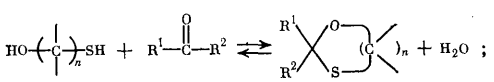
I. INTRODUCTION

The chemistry of 1,3-oxathiacycloalkanes has been developing vigorously during the last 10–15 years. These compounds proved to be of interest for stereochemical studies and are used in fine organic synthesis and in the synthesis of biologically active preparations.



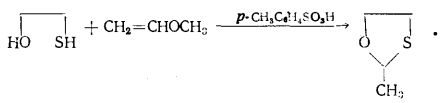
The problems associated with the chemistry of 1,3-oxathiacycloalkanes include selective methods of their synthesis from carbonyl compounds and mercaptoalkanols of different structure, the characteristics of their electronic and steric structure determined by the presence of oxygen and sulphur atoms in the 1- and 3-positions in the heterocycle, and their behaviour in reactions accompanied by the homolytic and heterolytic dissociation of the carbon–sulphur and carbon–oxygen bonds.

The aim of the present review is to give a systematic account and to survey the principal data concerning the synthesis, structure, and reactivity of 1,3-oxathiacycloalkanes in the liquid phase.

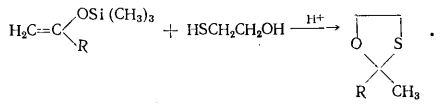
The gas-phase reactions of 1,3-oxathiacycloalkanes have been hardly investigated and the available data concern specific problems of heterogeneous catalysis and we have not considered them.

II. THE SYNTHESIS OF 1,3-OXATHIACYCLOALKANES

At the present time 1,3-oxathiacycloalkanes have been less thoroughly investigated than 1,3-dioxacycloalkanes and 1,3-oxazacycloalkanes. This is apparently due to the greater availability of diols and aminoalcohols compared with mercaptoalkanols. The vast majority of the 1,3-oxathiacycloalkanes described in the literature have been synthesised by the interaction of mercaptoalkanols with carbonyl compounds[1–21]:



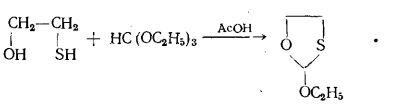
$n = 2, 3$.



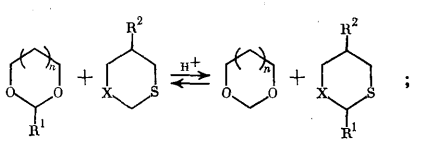
Various 1,3-oxathiolans[1–9] have been obtained by this method from 1,2-mercaptoalkanols and aldehydes or ketones[1–9] and 1,3-oxathianes have been obtained from 1,3-mercaptoalkanols[10–21].

Mercaptoalcohols condense in the presence of catalysts such as toluene-*p*-sulphonic acids, inorganic acids, and P_2O_5. Aldehydes and particularly formaldehyde give rise to 1,3-oxathiacycloalkanes in yields up to 90%, while in the case of ketones the yields are 30–70%.

Vinyl ethers can be used instead of carbonyl compounds[22,23]. Thus the condensation of mercaptoethanol with methyl vinyl ether yielded 2-methyl-1,3-oxathiolan[22]:



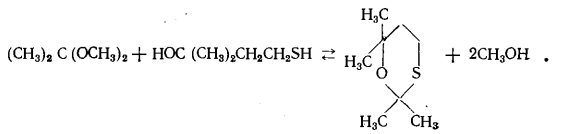
The reaction of trimethylsilyl vinyl ethers with 2-mercaptoethanol also leads to 1,3-oxathiolans[23]:



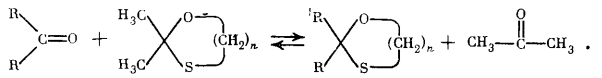
The yields reach 62–75% and are determined by the structure of the initial ether.

2-Ethoxy-1,3-oxathiolan has been synthesised by the reaction of 2-mercaptoethanol with ethyl orthoformate in the presence of acetic acid[24]:

2-Butyl-1,3-oxathiolan has been synthesised by the reaction of 2-ethoxy-1,3-oxathiolan with C_4H_9MgBr.[24]

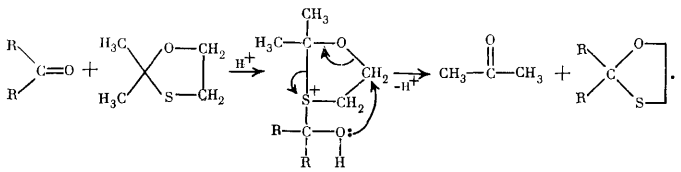


The possibility of obtaining 1,3-oxathianes as a result of the exchange reaction with 1,3-dioxacyclanes has been demonstrated[25–27]. This method makes it possible to obtain substituted 1,3-oxathianes which are difficult to synthesise by other methods:



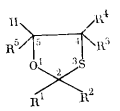
$n = 0, 1, 2$; X = O, S; $R^1 = CH_3$, C_2H_5, *n*-C_3H_7; $R^2 = H$, CH_3, iso-C_3H_7, iso-C_5H_{11}.

The yields are fairly high (79–95%). The reaction is catalysed by hydrochloric, sulphuric, and toluene-*p*-sulphonic acids and also by the KU-2 cation-exchange resin.



2,2,6,6-Tetramethyl-1,3-oxathiane has been obtained by the exchange acetalisation using the Dowex-50 catalyst[12]:

The synthesis of 2,2-disubstituted 1,3-oxathiacycloalkanes by the exchange reaction of 2,2-dimethyl-1,3-oxathiolan (or 2,2-dimethyl-1,3-oxathiane) with higher ketones has been described[1]:



The yields reach 90%. The following reaction mechanism has been proposed:

The properties of certain five- and six-membered 1,3-oxathiacycloalkanes are presented in Tables 1 and 2.

III. THE STRUCTURE OF 1,3-OXATHIACYCLOALKANES

1,3-Oxathiacycloalkanes proved to be of interest for structural and kinetic studies. Firstly, the ring in these compounds is asymmetric, which increases the number of isomers. Secondly, the conformational effects in these compounds differ significiantly from those in symmetrical 1,3-dioxoacyclanes, since the bond lengths differ greatly: the lengths of the C—S, C—C, and C—O bonds are 1.82, 1.54, and 1.43 Å respectively. Thirdly, the electronegativity of the sulphur atom is much lower than that of the oxygen atom. The structure of 1,3-oxathiacycloalkanes has been investigated by ^1H NMR and the acid-catalysed equilibrium method.

* Mixture of isomers.

1. The Stereochemistry of 1,3-Oxathiolans

The conformational analysis of five-membered rings has developed more slowly, despite their greater abundance in nature, than that of the corresponding six-membered rings. This is a consequence of the conformational mobility of the five-membered rings, for which there is a lower barrier to pseudorotation and a greater number of conformations with similar energies. The stereochemistry of 1,3-oxathiolans has been investigated by ^1H NMR[6,28-42].

It has been concluded[28,32,33] that the most probable conformation of 2-substituted 1,3-oxathiolans is that of a flexible "envelope". There is a possibility of nine different conformations, among which those with O (1 and 1a) or C^5 (2 and 2a) atoms on the "flap" are preferred and agree best with the

observed spin–spin coupling constants:

There is a possibility of the alternative half-chair conformations, where the C(4) or C(5) atoms and one of the heteroatoms lie respectively above and below the plane of the three other atoms; these conformations are in essence energetically equivalent to the corresponding conformations of the "envelope" type[32]. Three main factors determining the conformation of 2-substituted 1,3-oxathiolans have been pointed out[33]. The most important is the decrease of the *trans*-annular van der Waals interactions between the substituents at the C(2) atom and the methylene groups in the 4- and 5-positions. The second important factor is the minimisation of the torsional energies which is achieved when the heteroatom is in the β-position relative to the atom on the "flap" of the "envelope". The third factor is the increase in the size of the groups vibrating about the carbon atom on the "flap". This is attained in oxathiolans having conformations (1) and (2), which has been confirmed by calculations of the free energy change as a function of the changes in the torsional angles[33]. It has been shown that the conformational energy minima for oxathiolan and 2-methyloxathiolan are fairly close. The lowest pseudorotation energy is 12 kJ mol^{-1}.

Thus the conformational behaviour of 2-substituted 1,3-oxathiolans has been investigated in extremely great detail, although it is insufficient for the determination of the overall pattern of the conformational effects. The stereochemistry of 2,4- and 2,5-dialkyl-, 2,4,5-trialkyl-, and 2,4,4,5-tetraalkyl-1,3-oxathiolans has been investigated[6,29–31,37]. It has been confirmed that conformations (1) and (2) are most preferred. Certain thermodynamic constants of the isomeric equilibrium involving substituted 1,3-oxathiolans have also been determined (Table 3); the conformational energies of the alkyl substituents in the 2-position are in the range 5–8 kJ mol^{-1}.[28,36]

2. Stereochemistry of 1,3-Oxathianes

The structure of 1,3-oxathianes has been studied by ^{1}H NMR and by measuring their dipole moments[10,12,15,16,42–48]. The different bond lengths (1.41 Å for C–O, 1.54 Å for C–C, and 1.82 Å for C–S) and valence angles (110° for O–C–C, 111.7° for C–O–C, and 100° for C–S–C) in 1,3-oxathiane resulting in an unusual geometry of its ring. The "ether" part of the molecule (C^4–O–C^2) is more bent than the "thioether" part (C^6–S–C^2) and the axial valence angles are not rigorously parallel. The non-bonding 1,3-interactions are therefore appreciably weakened[10,12].

The main form of the 1,3-oxathiane ring is the chair conformation, although other conformations are also possible[12,48], the torsional and ring strains in 1,3-oxathianes having a greater influence on the energy parameters of different reactions than in the case of more symmetrical molecules[10,42–48]. Two conformations of the chair type are possible for 1,3-oxathianes[12]:

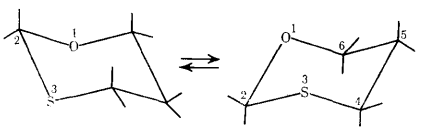

Table 4. Conformational energies* of axial alkyl groups in 1,3-oxathianes, 1,3-dioxanes, and 1,3-dithianes (kJ mol^{-1}).

* The values obtained from data for an acid-catalysed chemical equilibrium.

Table 5. Energies of the 1,3-diaxial interactions (H–CH_3, CH_3–heteroatom) in methyl-substituted 1,3-oxathianes, 1,3-dioxanes, and 1,3-dithianes (kJ mol^{-1})[12,39,42,43].

Compounds	Positions				
	2,4	2,6	4,6	5,4	5,6
1,3-Dioxane	8.5	8.5	3.7	2.0	2.0
1,3-Oxathiane	4.4	9.2	3.4	2.85	—
1,3-Dithiane	4.0	4.0	2.5	2.4	2.4

The free energies of ring inversion in certain *gem*-substituted derivatives are in the range 33.5–48.5 kJ mol^{-1}.[12] These values are quite usual for six-membered rings and are responsible for the ease of inversion close to room temperature. The energy parameters (Tables 4 and 5) show that the energies of the conformational interactions in the 1,3-oxathiane ring are intermediate between those of 1,3-dioxanes and 1,3-dithianes.

As mentioned above, the 1,3-oxathiane molecules exist preferentially in the chair conformation but, owing to the marked ring asymmetry, the chair is distorted and other conformations become possible[48] (Table 6).

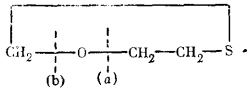

Table 6. Thermodynamic parameters of the chair–"twist" transformations in 1,3-diheterocycloalkanes[48].

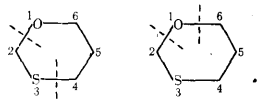
Compound	ΔG°, kJ mol^{-1}	ΔH°, kJ mol^{-1}	ΔS°, J mol^{-1} K^{-1}
1,3-Di-t-butylcyolohexane	21.3	25.0	13.4
1,3-Dioxane	33.3	35.9	9.2
1,3-Oxathiane	23.0	25.0	9.2
1,3-Dithiane	7.5	14.2	22.2

Since all four carbon atoms in the 1,3-oxathiane ring are magnetically non-equivalent, these compounds are convenient objects for studies by ^{13}C NMR. The results of ^{13}C NMR measurements for various methyl-substituted 1,3-oxathianes have been reported, the influence of substituents on the chemical shifts of the carbon atom signals have been discussed, and a comparative analysis with 1,3-dioxanes and cyclohexanes has been carried out[55]; the dependence of the influence of the substituents on the nature of the heteroatom has been demonstrated. The chemical shifts for 1,3-oxathianes are in the following ranges: 68–81 p.p.m. for C(2); 23–27 p.p.m. for C(4); 25–42 p.p.m. for C(5); 62–75 p.p.m. for C(6).[55] It has also been shown that the α-effect is very considerable for all the compounds investigated, the equatorial methyl group having a greater deshielding influence than the axial group; this effect is manifested to a greater extent in 1,3-oxathianes than in 1,3-dioxanes and cyclohexanes; the $|\delta|$- and $|j|$-effects are smaller.

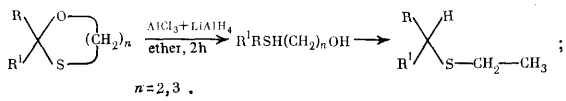


3. The Mass Spectra of 1,3-Oxathiolans and 1,3-Oxathianes

The fragmentation of 1,3-oxathiolans under the influence of electron impact has been investigated[51,52]. It has been found that, among all the possible ring fragmentation pathways, the decompositions (*a*) and (*b*) are the most probable:

It has been concluded that the dominant process (*a*) takes place as a result of the splitting off of an electron from the ring O atom despite the fact that the removal of a non-bonding electron from the S atom requires less energy. In substituted 1,3-oxathiolans the alkyl side group is eliminated from the 2-position more readily than from the 4- and 5-positions. The elimination of an H atom from the 2-, 4-, and 5-position is unlikely[51,52].

The characteristic features of the mass spectra of 1,3-oxathianes are a relatively high intensity of the molecular ion, the absence of metastable transitions, and the preferential shift of the charge to the sulphur-containing fragments[50]. There is a possibility of two main mechanisms of ring opening involving the dissociation of the C^4–S and C^6–O bonds:

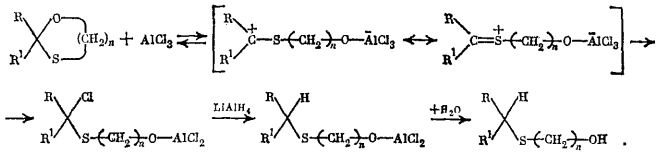


The intensity of the molecular ion peak diminishes with increase of the contribution by the 2-alkyl substituent[50].

IV. THE REACTIONS OF 1,3-OXATHIACYCLOALKANES

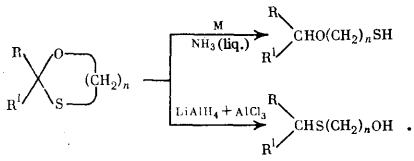
The reactions of 1,3-oxathiacycloalkanes have been comparatively little investigated. The heterolytic processes involving the opening of the 1,3-oxathiacycloalkane ring have been studied in greatest detail. Data have been obtained recently on the radical-chain reactions of compounds of this class.

1. Heterolytic Reactions of 1,3-Oxathiacycloalkanes



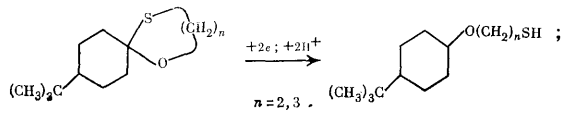
1,3-Oxathiolans and 1,3-oxathianes have been reduced[53,54] with lithium tetrahydroaluminate and aluminium chloride in ether:

$n=2,3$.



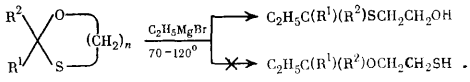
It has been shown that the reductive cleavage involves mainly the C–O bond. Thus the above reaction makes it possible to obtain thioethers from aldehydes and ketones.

On hydrogenolysis with a mixture of $LiAlH_4$ and BF_3 for 2 h, less than 1% of 1,3-oxathiolan reacted, while the $AlCl_3$ + $LiAlH_4$ mixture gives rise under the same conditions to 85–90% of hydrogenation products, mainly the hydroxythioether together with a small amount of a dialkyl sulphide. A mechanism involving the formation of a resonance-stabilised cation in the first stage has been proposed; on reaction with the nucleophilic chloride ion (from $AlCl_3$), this cation gives rise to an α-halogenothioether, which is readily reduced to the thioether[53]:

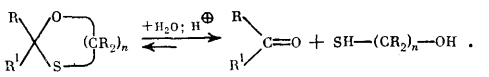


The study of the reductive cleavage of the 1,3-oxathiolan ring with a mixture of lithium tetrahydroaluminate and aluminium chloride or with boron trifluoride in ether[55] confirmed data[53,54] concerning the preferential opening of the 1,3-oxathiolan ring at the C–O bond and not the C–S bond (1,3-dithiolan does not undergo hydrogenolysis). The yields of the reduction products depend greatly on the order of mixing of the reactants. The addition of a Lewis acid to a mixture of oxathiolan and the hydride makes it possible to achieve better yields and to avoid the charring of the products and also permits reduction with the BF_3–$LiAlH_4$ system. The addition of a solution of a 1,3-oxathiacycloalkane to the $AlCl_3$–$LiAlH_4$ or BF_3–$LiAlH_4$ mixture[53,54] results in partial charring of the products in the former case and in the decomposition of $LiAlH_4$ even before it reacts with the oxathiacycloalkane in the latter case[55].

The cleavage of the oxathiacycloalkane ring at the C–S bond can be achieved when 1,3-oxathianes and 1,3-oxathiolans are treated with metals in liquid ammonia. In contrast to the effect of the $LiAlH_4$–$AlCl_3$ mixture, this results in the formation of the corresponding β- or γ-alkoxymercaptans[56–59]:

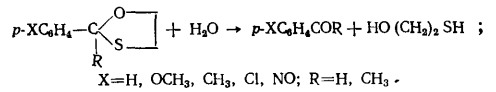


This reaction is widely used in peptide synthesis. Sometimes the reductive cleavage involves both bonds (C–O and C–S), which leads to sulphur-free products. Thus treatment of 2-methyl-2-phenyl-1,3-oxathiolan with sodium in liquid ammonia yields ethylbenzene as the main reaction product[59]. In general 1,3-oxathiolans with the phenyl substituent in the 2-position produce the corresponding alkylbenzenes on reduction[63]. The reduction of various substituted 1,3-oxathiolans and 1,3-oxathianes with metals in liquid ammonia has been studied. It has been shown that the reduction proceeds via the transfer of two electrons and the addition of a proton (from ammonia) to a carbon atom[57]:



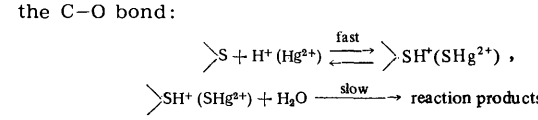
In the reactions of cyclic ketones the yields are 60–90%. For aldehyde derivatives, the yields of alkoxythiols are lower owing to the formation of thiols and olefins in side reactions[57]. The effectiveness of metals in the reduction decreases in the sequence Ca > Li > Na > K. The addition of proton-donating solvents (t-C_4H_9OH, C_2H_5OH) does not increase the yield of the reduction products. In the series of 1,3-oxathianes the yields are higher than for 1,3-oxathiolans.

The cleavage of 1,3-oxathiolans by a Grignard reagent has been investigated[59]:



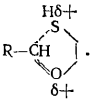
The reaction proceeds with dissociation of the C–O bond, i.e. via the first pathway. The reactivity of 1,3-oxathiolans increases in the sequence 1,3-oxathiolan < 2-ethyl-2-methyl-1,3-oxathiolan ≦ 2-propyl-1,3-oxathiolan ≦ 2-methyl-1,3-oxathiolan. The decrease of reactivity on passing from dioxolans to oxathiolans is associated with the increase of electron density at the C(2) atom[59].

1,3-Oxathiacycloalkanes react with water in the presence of acid catalysts to form the corresponding aldehydes (or ketones) and mercaptoalcohols[60–66]:



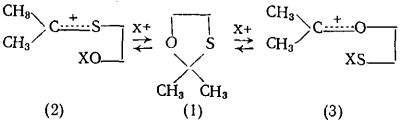
The hydrolysis of 1,3-oxathiolans has been studied in greatest detail, while extremely few data are available for 1,3-oxathianes.

The hydrolysis of 2-aryl-1,3-oxathiolans catalysed by the H_3O^+ and Hg^{2+} ions has been investigated[60]:



X=H, OCH_3, CH_3, Cl, NO; R=H, CH_3.

It has been shown that 2-aryl-1,3-oxathiolans hydrolyse more slowly than the corresponding 1,3-dioxolans. This has been explained by the fact that oxygen stabilises the α-carbenium ion more effectively than does sulphur[60]. On the basis of the study of the isotope effects and the determination of $\Delta H^{\neq}$ and $\Delta S^{\neq}$ for 1,3-oxathiolans relative to 1,3-dioxalans, it was concluded that the acid hydrolysis of 2-phenyl-1,3-oxathiolans proceeds via the $A2$ mechanism with rupture of the C–O bond:



The activation entropies for the hydrolysis of 1,3-oxathiolans are in the range from −17.8 to −24.4 e.u., which is less than the values for 2-phenyl-1,3-oxathiolan (−8.9 e.u.) and 2-methyl-2-phenyl-1,3-dioxolan (−8.9 e.u.), which have been shown to hydrolyse via the $A1$ mechanism and are close to the $\Delta S^{\neq}$ for 4,4,5,5-tetramethyl-2-phenyl-1,3-dioxolan (−14.2 e.u.), which has been shown to involve the $A2$ mechanism. The ratios k_D/k_H for 1,3-oxathiolans are also smaller than the values corresponding to the $A1$ mechanism.

The acid hydrolysis of 2-aryl-1,3-oxathiolans in HCl solutions in water and in a 50:50(%) dioxan–water mixture has been investigated[61]. The study of the isotope effect of the solvent and also the comparative analysis of 1,3-oxathiolans and 1,3-dioxolans led to the conclusion that the hydrolysis proceeds via the $A1$ mechanism with dissociation of the C–S bond and the formation of the intermediate ion:

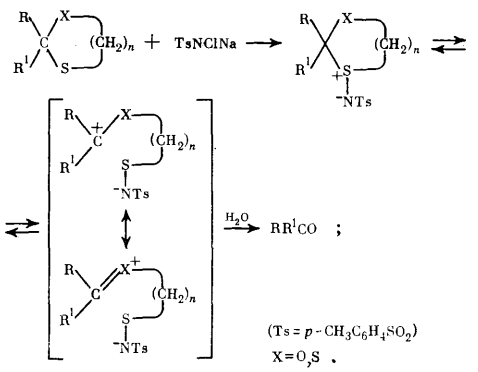
The isotope effect of the solvent ($k_D/k_H < 2$) is smaller than that usually observed for the $A1$ mechanism ($k_D/k_H > 2$). The low isotope effect of the solvent may be a result of the more intense protonation of the sulphur atom than the oxygen atom and this can be accounted for in its turn by the difference between the S–H and O–H bond lengths[61]. These conclusions have been confirmed by the comparative analysis of oxathiolans and the thioacetals $C_6H_5CH(OCH_3)SC_6H_4R$.[62]

The ^1H NMR study of 1,3-oxathiolans in a solution of the 1:1 FSO_3H + SbF_5 mixture in liquid SO_2 at −60 °C showed[63,64] that protonation leads mainly to the cation (2)(X=H), while the formation of the cation (3) (X=H) is unlikely:

(2) (1) (3)

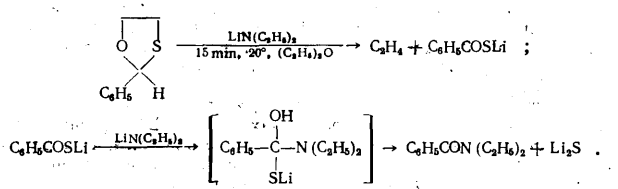
These results have been confirmed by the ^1H NMR study of 2,2-dimethyl-1,3-dithiolan under the same conditions. It was concluded that the hydrolysis of 1,3-oxathiolans proceeds with the dissociation of the C–O bond via the $A1$ mechanism. The preferential dissociation of the C–O bond on protonation and on formation of compound (6) in the kinetic stage can be explained mainly by the lower basicity of the S atom in relation to the proton compared with the O atom. It has been suggested that the intermediate product is formed without the participation of the nucleophile. The opening of the 1,3-oxathiolan rings on bromination has also been investigated[63,64]. It was shown that the basicity factor does not play here a major role and that in this instance there is a possibility of the dissociation of the C–O and C–S bonds with formation of the corresponding ions (6)(X=Br) and (7)(X=Br).

The study of the hydrolysis of 1,3-oxathiolan, 2-methyl-1,3-oxathiolan, and 2,2-dimethyloxathiolan in aqueous solutions of $HClO_4$ and $DClO_4$ showed[65] that the rate of reaction depends on the substituents in the 2-position. For 2-methyl-1,3-oxathiolan, it is approximately 2250 times higher than for the unsubstituted 1,3-oxathiolan and for 2,2-dimethyl-1,3-oxathiolan is 57 times higher than for 2-methyl-1,3-oxathiolan[71]. It is believed[65] that the hydrolysis proceeds via the *A*1 mechanism with dissociation of the C–O bond.



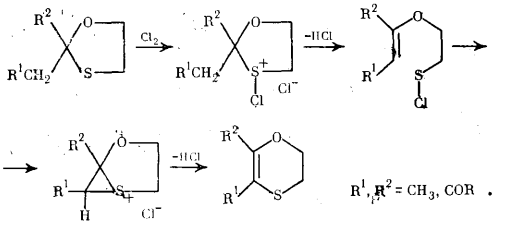
It is seen from the data considered that the mechanism of the hydrolysis of 1,3-oxathiolan has still not been determined unambiguously.

The hydrolysis of 2-substituted 1,3-oxathianes by $HClO_4$ in a H_2O/D_2O mixture has been studied[66] and it has been found that the relative rates of the acid hydrolysis of 1,3-oxathianes, 2-methyl-1,3-oxathiane, and 2,2-dimethyl-1,3-oxathiane are 1, 45, and 8×10^6 respectively. The rate of hydrolysis of 2-methyl-1,3-oxathiane proved to be much lower than was assumed. This can be explained by the fact that only the isomer with the axial conformation is hydrolysed; if account is taken of the mole fraction of the axial conformation, then the rate of hydrolysis of 2-methyl-1,3-oxathiane increases approximately by a factor of 300.[66] The hydrolysis of 1,3-oxathiacycloalkanes makes it possible to synthesise various aldehydes or ketones or to regenerate them when thioacetal or thioketal protecting groups are used.

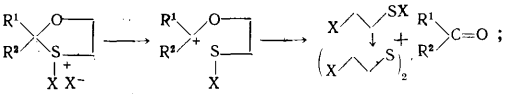


A convenient and rapid method of regenerating ketones and aldehydes by treating 1,3-oxathiacycloalkanes with chloramine T has been proposed[67,68]:

The reaction proceeds under mild conditions, the yields reaching 90–100%. Apart from the carbonyl compound, 2-hydroxyethyltoluene-p-sulphonimidosulphine-toluene-p-sulphonylimine and bis(2-hydroxyethyl) disulphide are formed (the latter product is obtained when less than 2 moles of chloramine T per mole of the oxathiolan are used in the reaction). The intermediate formation of a carboxonium ion has been postulated:

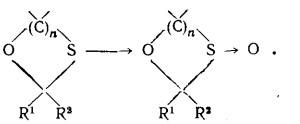


Olefins which are difficult to obtain by other methods can be synthesised by treating 1,3-oxathiacycloalkanes with alkaline reagents, for example, lithium dialkylamides. The reaction of 2-phenyl-1,3-oxathiolan with lithium diethylamide in ether has been studied in detail[69]:



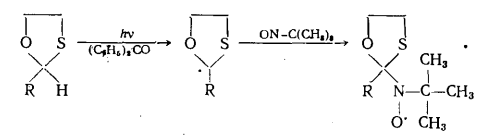
The yields of the olefins were nearly quantitative. Olefins can be obtained analogously also from the more readily available 1,3-dioxolans. However, olefins which are difficult to obtain, such as *trans*-cyclo-octene, *cis*- and *trans*-cyclo-octa-1,5-dienes, and also tetrasubstituted olefins can be synthesised more conveniently from 1,3-oxathiolans[69–71].

The chlorination of 1,3-oxathiolans having α-methylene groups leads to 5,6-dihydro-1,4-oxathi-ines[72–75]:



The reaction is carried out at low temperatures (between −20° and −70 °C) and the yields are 55–60%.

In the absence of α-methylene group, *C*-halogenation takes place instead. For example, the chlorination and bromination of certain substituted 1,3-oxathiolans lead to the formation of the corresponding ketones and disulphides[75]:

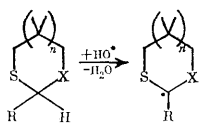


The oxidation of 1,3-oxathianes[75] and 1,3-oxathiolans[77,78] constitutes the main method of synthesis of cyclic sulphoxides:

The study of the oxidation of 1,3-dithiane and 1,3-oxathiane[76] showed that the content of isomers with an axial or equatorial SO group depends both on the cyclic sulphide being oxidised and on the oxidant. The content of the 1,3-oxathiane isomer with an axial SO group increases in the following sequence of oxidants: t-BuOCl > $NaIO_4$ > H_2O_2 > N_2O_4.

2. Homolytic Reactions of 1,3-Oxathiacycloalkanes and 1,3-Dithiacycloalkanes

When 1,3-oxathiacycloalkanes and 1,3-dithiacycloalkanes interact with sources of free radicals, the abstraction of hydrogen atoms results in the formation of 1,3-diheterocycloalkyl radicals. Thus the benzophenone-sensitised ultraviolet irradiation of 1,3-oxathiolans leads to the formation of 1,3-oxathia-2-cyclopentyl radicals, which in the presence of a spin-trapping agent (2-methyl-2-nitrosopropane) yield fairly stable spin-adducts (nitroxy-radicals) whose signals have been detected in the EPR spectra[79–82]:



Nitroxy-radicals containing 1,3-oxathia- and 1,3-dithia-2-cycloalkyl residues are formed on photolytic decomposition of t-butyl peroxide in 1,3-diheterocycloalkanes in the presence of 2-methyl-2-nitrosopropane[80–82]. The spectroscopic

characteristics of the nitroxy-radicals containing the 1,3-diheterocycloalkane residue show that the formation of radicals with an unpaired electron at the ring C(2) atom is the dominant process[79-82]. Consequently, under the conditions investigated (20–25 °C), the *t*-butoxy-radicals arising on photolysis of t-butyl peroxide attack very selectively the carbon–hydrogen bonds located between the two heteroatoms.

The increase of the hyperfine coupling constant a_n on passing from 1,3-dioxacycloalkane to 1,3-oxathia- and 1,3-dithia-cycloalkanes is evidently associated with the increase of electron density at the N atom of the nitroxy-group as a consequence of the decrease of the negative inductive effect following the replacement of the ring oxygen atoms by the less electronegative sulphur atoms[79-82]. In all the examples investigated the EPR spectra did not reveal signals due to nitroxy-radicals which might have been formed from the acyclic acylheteroalkyl radicals. This shows that the 1,3-oxathiacycloalkyl radicals do not undergo a rearrangement under the conditions investigated[79-82].

The structure of the radicals arising from 1,3-oxathia- and 1,3-dithiacycloalkanes under the influence of hydroxy- and t-butoxy-radicals has been studied directly[82,83,86-89]. When the hydroxy-radicals generated by the reaction Ti(III) + H_2O_2 → Ti(IV) + HO^- + $\dot{O}H$ react with 1,3-oxathia- and 1,3-dithiacycloalkanes in water at 25 °C, 1,3-dihetero-2-cycloalkyl radicals are formed more selectively (Table 7)[82,83,87], in contrast to 1,3-dioxacycloalkanes[84,85]:

n = 0, 1; X = O, S; R = H, CH_3, n-C_3H_7, $CH(CH_3)_2$.

Under the same conditions, cyclic acetals give rise to di- and mono-alkoxycycloalkyl radicals[82,84,85]. The replacement of the oxygen atom by the sulphur atom either greatly activates the hydrogen atom adjoining the two heteroatoms or increases the lifetime of the 1,3-dihetero-2-cycloalkyl radicals formed compared with other types of radicals.

An analogous picture has been observed in the interaction of sulphur-containing 1,3-oxaheterocycloalkanes with t-butoxy-radicals[89]. In the analysis of the EPR spectra and in the study of the configurations of sulphur-containing 1,3-dihetero-2-cycloalkyl radicals in combination with calculations by quantum-chemical methods[86-89], it was established that the sulphur atom exhibits a fairly large delocalising effect (~ 19% of the spin density) and flattens the pyramidal structure of the paramagnetic centre, which is characteristic of 1,3-dioxa-2-cycloalkyl radicals[85,90].

Thus the configuration of the tervalent carbon atom is flattened on passing from 1,3-dioxa-2-cycloalkyl radicals, via 1,3-oxathia-2-cycloalkyl radicals, to 1,3-dithia-2-cycloalkyl radicals.

1,3-Oxathia- and 1,3-dithia-cycloalkanes are extremely active donors of a hydrogen atom in the reaction with t-butoxy-radicals. The activities of 1,3-diheterocycloalkanes in the reaction involving the abstraction of a hydrogen atom by t-butoxy-radicals have been determined by the method of competing reactions[82,91,92]:

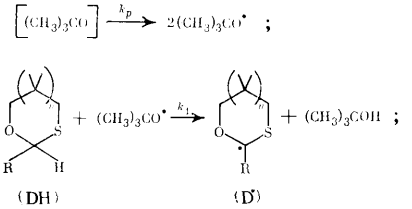
$$[(CH_3)_3CO]_2 \rightarrow 2(CH_3)_3CO^{\cdot};$$

$$(CH_3)_3CO^{\cdot} \begin{cases} \xrightarrow[+RH]{k_a} (CH_3)_3COH + R^{\cdot} \\ \xrightarrow{k_d} CH_3COCH_3 + CH_3^{\cdot} \end{cases}.$$

At a constant temperature the parameter k_a/k_d is a measure of the reactivity of 1,3-diheterocycloalkanes in the abstraction of a hydrogen atom by t-butoxy-radicals. At 130 °C the ratio k_a/k_d is 5.0–8.0 litre mol^{-1} for 1,3-oxathiacycloalkanes and 7.0–10.0 litre $mole^{-1}$ for the corresponding dithia-derivatives[82,91,92].

Table 7. EPR parameters of the radicals generated from 1,3-oxathia- and 1,3-dithia-cycloalkanes by treatment with hydroxy-radicals in water[79,83,87].

Radical	HFI constant, G			*g*-Factor
	$a_{\alpha\text{-H}}$	$a_{\beta\text{-H}}$	$a_{\gamma\text{-H}}$	
	—	16.6 (q)	0.5 (m)	2.0037
	—	15.5 (t)	0.5 (m)	2.0037
	—	15.2 (d)	0.5 (m)	2.0037
	—	17.7 (q)	0.5 (m)	2.0047
	—	9.0 (t)	0.5 (m)	2.0077
	5.1 (d)	—	1.1 (m)	2.0051
	14.4 (d)	—	1.0 (m)	2.0039
	13.5 (d)	—	1.3 (m)	2.0050
	15.2 (d)	—	1.5 (m)	2.0054

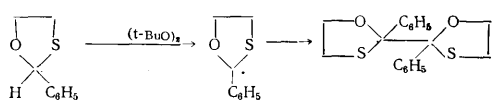


The increase of the reactivity of 1,3-diheterocycloalkanes as the oxygen atoms are substituted by sulphur atoms is common to five-, six-, and seven-membered rings. There is a greater increase of activity on passing from 1,3-dioxacycloalkanes to 1,3-oxathiacycloalkanes than on passing from 1,3-oxathiacycloalkanes to 1,3-dithiacycloalkanes. The alkyl substituents in 1,3-diheteroanalogues of cycloalkanes have little influence on their reactivity. The partial rate constants for the OCH(R)S and SCH(R)S (R = CH, n-C_3H_7, or iso-C_3H_7) fragments found by an additive scheme[92] are in the ranges $(k_a/k_d)^{130^\circ}_{OCH(R)S}$ = 5.3–8.2 litre mol^{-1} and $(k_a/k_d)_{SCH(R)S}$ = 6.3–9.6 litre mol^{-1} for heterocycles with different numbers of carbon atoms in the ring.

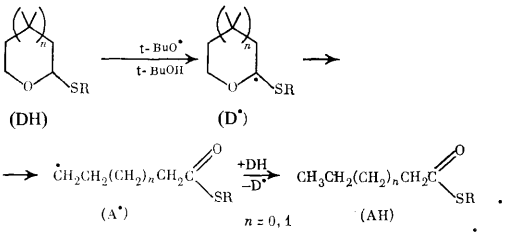
The partial contributions of the OCH(R)S and SCH(R)S groups are more than 80% of the effective rate constant and the hydrogen atom is therefore mainly abstracted at 130 °C from the carbon atom adjoining the two heteroatoms[82,92]. It

is striking that the following dependence of the reactivity on ring size is common to the oxygen- and sulphur-containing 1,3-diheterocycloalkanes: 1,3-diheterocyclohexanes < 1,3-diheterocycloheptanes < 1,3-diheterocyclopentanes[92].

The results have been interpreted[82,91,92] within the framework of ideas concerning the polar effects in the homolytic abstraction of a hydrogen atom by free radicals. Evidently the higher reactivity of 1,3-oxathia- and 1,3-dithia-cycloalkanes compared with that of 1,3-dioxacycloalkanes is due to a more favourable combination of polar factors in the transition state of the reaction involving the abstraction of a hydrogen atom by the electrophilic radical $(CH_3)_3CO^{\bullet}$[82,91,92].

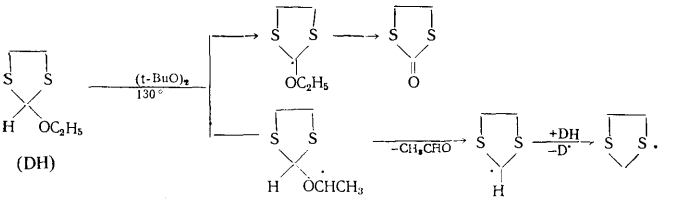


In the reaction initiated by t-butyl peroxide, 1,3-oxathiacycloalkanes are converted at 120–150 °C into esters of thiolocarboxylic acids[82,93]. The initial rate of formation of the thioesters varies linearly with the substrate concentration and is directly proportional to the square root of the initiator concentration[82,93], which suggested a radical-chain unbranched mechanism of the isomerisation of 1,3-oxathiacycloalkanes with quadratic chain termination by the rearranged radicals (A·):

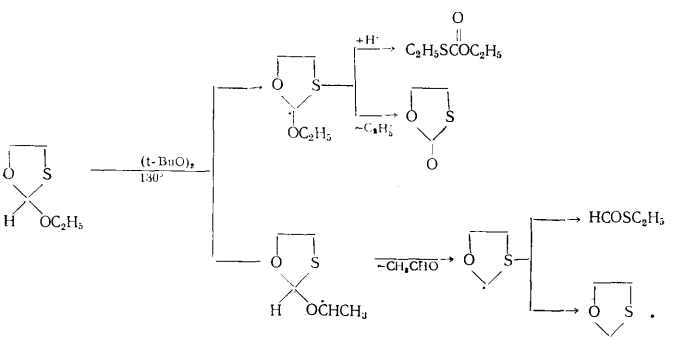


The rate-limiting stage of the reaction is the abstraction of a hydrogen atom from the substrate by the rearranged radical A·. The values of the kinetic parameter $(k_3/\sqrt{k_4})^{130^\circ}$ found, which are a measure of the reactivity of 1,3-oxathiacycloalkanes in the free radical isomerisation reaction, have shown[82,89] that 1,3-oxathiacycloalkanes are 2–3 times less reactive than 1,3-dioxacycloalkanes[82,93]. This was confirmed by the method of competing reactions[94].

The reduced reactivity of 1,3-oxathiacycloalkanes in the free radical isomerisation reaction compared with 1,3-dioxacycloalkanes is in direct contrast with their higher reactivity in the abstraction of a hydrogen atom by t-butoxy-radicals and is evidently associated with the less favourable combination of polar factors in the stage involving the abstraction of a hydrogen atom by the relatively nucleophilic carbon-centred acylheteroalkyl radical A· in the case where the ring contains a sulphur atom, which is less electronegative than oxygen.

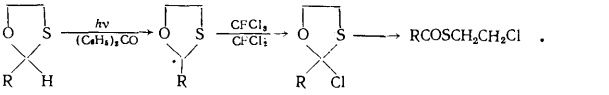


If the 1,3-oxathia-2-cycloalkyl radicals formed are fairly stable and do not undergo a unimolecular rearrangement, they recombine with formation of the corresponding dimeric product. Thus the reaction of 2-phenyl-1,3-oxathiolan with t-butyl peroxide at 130 °C results in the formation of a mixture of the *threo*- and *erythro*-isomers of bis-2-phenyl-1,3-oxathiolan[96]:

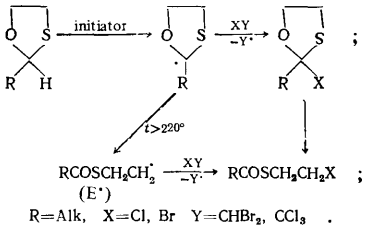


2-Alkylthiotetrahydropyrans and 2-alkylthiotetrahydrofurans isomerise analogously to 1,3-dithiolan[97–100]:

The reaction involving 2-ethoxy-1,3-dithiolan, in which only the cleavage products, namely ethylene dithiocarbonate and 1,3-dithiolan, are formed is somewhat more complex[101]:

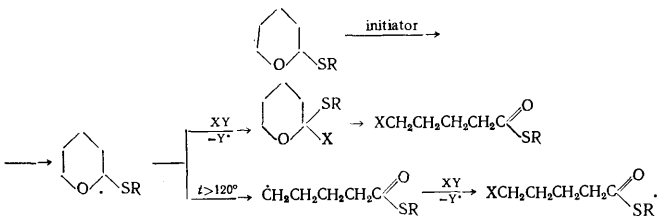


It has been suggested that the former product is formed via the 2-ethoxy-1,3-dithia-2-cyclopentyl radical and that the latter product arises as a result of the abstraction of a hydrogen atom from the α-position in the ethoxy-group via a stage involving the formation and fragmentation of the α-1,3-dithiacyclopentyl-2-hydroxyethyl radical[101]. Isomerisation and cleavage products are formed simultaneously from 2-ethoxy-1,3-oxathiolan[102]:

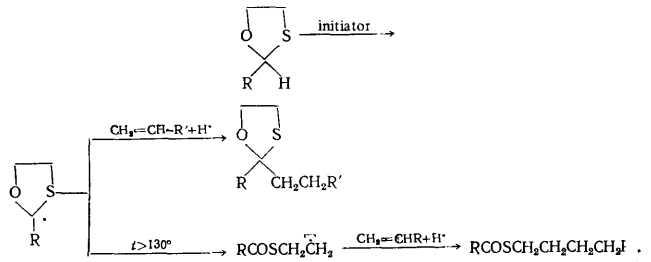


Linear and cyclic thiocarbonates are formed via the 2-ethoxy-1,3-oxathia-2-cyclopentyl radical and 1,3-oxathiolan and ethyl thioformate are formed via the 1,3-oxathiacyclopentyl-2-hydroxyethyl radical arising as a result of the abstraction of a hydrogen atom from the α-position in the ethoxy-group[102].

In polyhalogenomethanes in the presence of free-radical initiators, 1,3-oxathiolans are selectively converted into halogenothioethers, which has been attributed to the involvement of the solvent in the chain propagation stage[79,97–99]. Thus the photolysis of 2-alkyl-1,3-oxathiolans in $CFCl_3$ in the presence of benzophenone results in the formation of chloroethyl esters of thiolocarboxylic acids probably via the corresponding cyclic chlorides, which are unimolecularly converted into chlorothioethers under the reaction conditions:



In the reaction initiated by lauroyl peroxide (at 80 °C) or



t-butyl peroxide (at 120–150 °C) in polyhalogenomethanes (CCl_4, CCl_3Br, and $CHBr_3$) 1,3-oxathiolans are converted into chloro- and bromo-thioethers[98,99]

The authors[98,99] do not rule out the possibility of the formation of halogenothioethers at relatively high temperatures (> 120 °C) via a stage in which a halogen atom is obstructed by the rearranged acylthioethyl radical E·. Under analogous conditions (80–150 °C), 2-alkylthiotetrahydropyrans give rise to esters of δ-halogenothiolovaleric acids[99], whose formation can be represented as proceeding both via a cyclic halogeno-derivative and via a stage in which a halogen atom is obstructed by the rearranged radical E·:

On interaction with terminal olefins in the presence of radical initiators, 1,3-oxathiolans yield 2-alkyl-1,3-oxathiolans and alkyl thioacylates, whose formation is regarded as proceeding via a stage in which the 1,3-oxathia-2-cyclopentyl and the isomeric acylthioethyl radicals add to the double bond of the olefin[99]:

At relatively low temperatures (≤ 70°) only 2-alkyl-1,3-oxathiolans are formed[99]

---oOo---

On the basis of the data considered, one may reach definite conclusions concerning the methods of synthesis, structure, and types of reactions of 1,3-oxathiacycloalkanes.

The general and most effective methods of synthesis of 1,3-oxathiacycloalkanes involve acid-catalysed reactions of mercaptoalkanols with aldehydes, ketones, alkyl vinyl ethers, and orthoesters.

The main conformation of 1,3-oxathiolans is that of an inverted envelope. The 1,3-oxathiane ring exists preferentially in the chair conformation but the asymmetry of the ring gives rise to an increased probability of other conformations compared with 1,3-dioxanes.

The majority of the heterolytic reactions of 1,3-oxathiocycloalkanes proceed with the opening of the ring at the C–O or C–S bonds. Five-membered 1,3-oxathiacycloalkanes are the most reactive.

The high reactivity of the hydrogen atoms at the carbon atom linked to the two heteroatoms is responsible for the high selectivity of the attack by free radicals on the 2-position in the heterocycle. The mode of the homolytic reactions of substituted 1,3-oxathiacycloalkanes is therefore determined mainly by the rate of formation of the 1,3-oxathia-2-cycloalkyl radicals and the ability of the latter to participate in a unimolecular rearrangement with formation of a thioester, in addition to carbon–carbon double bonds, or in the abstraction of a halogen from polyhalogenoalkanes.

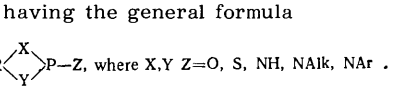
The Reactivity of 1,3,2-Diheterophospholans Containing a Tricoordinate Phosphorus Atom

M.A.Pudovik, V.V.Ovchinnikov, R.A.Cherkasov, and A.N.Pudovik



The results of studies on the reactivity of 1,3,2-di-heterophosphacycloalkanes containing a tricoordinate phosphorus atom carried out in recent years are examined and surveyed. Muchattention has been devoted to reactions leading to an increase of the coordination number of the ring phosphorus atom and also to exocyclic and endocyclic substitution reactions. The mechanisms and certain stereochemical characteristics of the reactions of cyclic phosphorus compounds are discussed. In a few instances the reactivities have been estimated quantitatively.
The bibliography includes 245 references.

I. INTRODUCTION

The characteristic features of the reactivity of cyclic compounds of tricoordinate phosphorus were noted previously in a review[1,2]. During the time which has elapsed since then, new interesting data have accumulated, supplementing and deepening the available information about the mechanisms of reactions of 1,3,2-diheterophospholans and 1,3,2-diheterophosphorinanes having the general formula

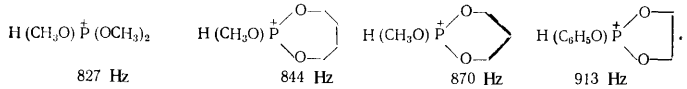
The description of these reactions is based on ideas about the structures of the intermediates or transition states involving an increase of the coordination number of the phosphorus atom. In many cases the reactivity of these compounds is explained from the standpoint of ring strain. Such inferences are based on the data accumulated hitherto on the cyclic phosphorus compounds: the steric structure of the ring itself and of the exocyclic substituent linked to it, the distribution of electron density in the molecule, the electronic situation at the phosphorus nucleus itself—the character of the hybridisation of its lone electron pair (LEP), and the strength of the phosphorus–heteroatom bond.

The steric structures of 1,3,2-diheterophospholans and 1,3,2-diheterophosphorinanes with a tervalent phosphorus atom have been studied in detail by various methods[3-5]. An important feature of the structure of five-membered phosphorus rings compared with the phosphorinane and acyclic analogues is a significantly reduced (93–100°) endocyclic X–P–Y angle. As a consequence of this, the electron density at the centre of the triad is reduced, which is clearly manifested by the deshielding of the phosphorus nucleus, according to ^{31}P NMR data, with decrease of ring size[6]. At the same time the LEP of phosphorus in such compounds has a reduced *p* character compared with the six-membered and acyclic derivatives with similar structures[7] and is therefore less reactive with respect to electrophiles. This factor is responsible for certain specific features of the reactivity of diheterophospholans. Many aspects of a purely synthetic type are not considered in this review. We thought it useful to deduce and as far as possible survey the characteristics of the reactivity of 1,3,2-diheterophosphacycloalkanes with a tervalent phosphorus atom, particular attention being devoted to compounds with a five-membered ring.

II. BASICITY AND COMPLEX FORMATION

Data concerning the ability of phosphorus-containing heterocycles to participate in nucleophilic reactions can be obtained from the analysis of the results of studies of the protonation of these compounds and of their tendency to form metal complexes.

It is known[8] that the introduction of electron-accepting substituents at a tricoordinate phosphorus atom reduces significantly the electron density at this atom, which entails a decrease of nucleophilic reactivity. An analogous effect is observed when phosphorus is incorporated in a ring. Thus the observed high ionisation potential of 1,3-butylene phosphorochloridite (9.90 eV) compared with diethyl phosphorochloridite (9.51 eV) may indicate a weakening of the interaction of the LEP of the phosphorus and oxygen atoms ($n_P - n_O$) on cyclisation[9]. In this respect, the absence of interaction between HCl and five-membered cyclic phosphorochloridites, obtained by the reaction

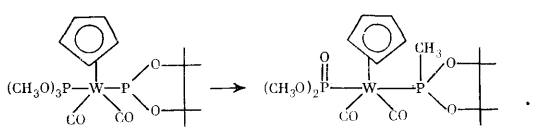


is also striking[10].

Acyclic and cyclic six-membered phosphorochloridites as well as 1,3,2-oxaza- or 1,3,2-diaza-phospholans are obtained only in the presence of hydrogen chloride acceptors[10]. While gaseous HCl does not interact with 2-chloro-1,3,2-dioxaphospholans, on replacement of the chlorine atom by an alkoxy-, alkyl, or dialkyl-amide group the tervalent phosphorus atom can be protonated[11].

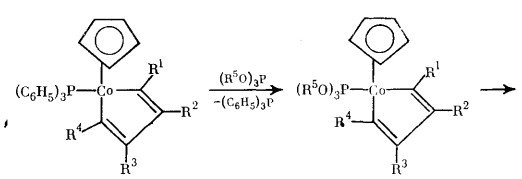
An important characteristic of the protonated phosphite is the constant $^1J_{PH}$, which is extremely sensitive to a change in the electronic and steric environment of phosphorus. The

increase of $^1J_{PH}$ on passing from acyclic to six- and five-membered cyclic as well as bicyclic protonated phosphites is consistent with the increase of the s character of the LEP of the phosphorus atom in the initial compounds[11,12]:

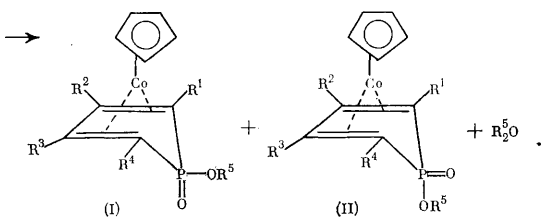


The results of the determination of the proton affinities and ionisation potentials of cyclic phosphites in the gas phase[13] also confirm the earlier conclusion that the basicity of the phosphorus atom decreases in the following sequence of phosphites: acyclic > six-membered > five-membered > bicyclic[14,15], which is associated with the increase of the ring strain in this sequence.

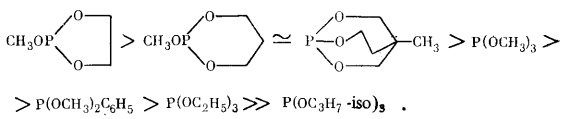
It has been suggested that the repulsion between the LEP of the oxygen and phosphorus atoms increases the energy of the highest occupied molecular orbital of the unshared electron pair of the phosphorus atom in an acyclic phosphite and its proton affinity. The inclusion of a phosphorus(III) atom in a five-membered ring alters the geometry of the pyramidal structure of the phosphorus atom and leads to strain in the cyclic system. As a consequence of this, the degree of hybridisation of the LEP in the ring phosphorus and oxygen atoms changes, their mutual repulsion diminishes, and the protophilic properties of the cyclic phosphite are diminished[13].



By virtue of the low basicity of phosphorus in dioxaphospholans, 1,2-phenylenephosphophosphorous acid exists in the condensed phase in a form with a tricoordinate phosphorus atom[16]. The presence of a small amount of a similar structure has been noted for the oxathiaphospholan analogue[17]; six-membered cyclic and acyclic diorganylphosphorous acids exist mainly as hydrophosphoryl derivatives $(RO)_2P(O)H$.



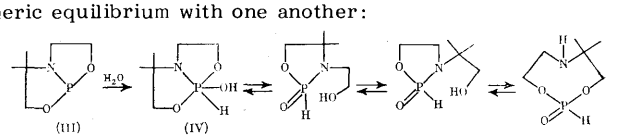
The reduced electron-donating capacity of the LEP of phosphorus in cyclic phosphites is also indicated by data demonstrating a lower stability of their complexes with phenols[18], BH_3, BF_3, and metals[19-21]. It is significant that the basicity of the phosphorus atom in phosphorinane structures and hence the stability of the adducts with BH_3 depend on the steric orientation of the LEP. Thus the equatorial electron pair in six-membered cyclic phosphites is less "basic" than the axial pair[9]. However, the formation of complexes of these compounds with Lewis acids leads to adducts in which the complex-forming agent is in the equatorial and apparently less sterically hindered position[20]. The cyclic phosphites in complexes can undergo intramolecular alkylation[22]:



The isomerisation of coordinated phosphites has been noted in substitution reactions proceeding via Scheme 1:[23]

Scheme 1

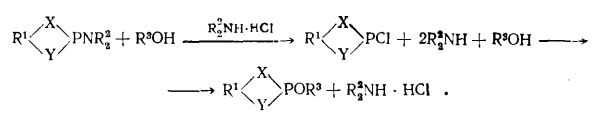
The use of cyclic phosphites in this reaction showed that at the triphenylphosphine substitution stage the rate of the process is independent of the nature of the phosphite. However, at the stage involving isomerisation of the phosphacyclopentadienyl derivatives (I) and (II) within the complex, the following phosphite activity series was found:



The above sequence can be explained by taking into account the fact that the isomerisation process proceeds via a transition stage with phosphorus(V),[23] in which there is a significant decrease of ring strain in cyclic phosphites. The small steric effect of cyclic dihydroxyalkylene groups compared with alkoxy-groups (particularly with an iso-structure)[23,24] also facilitates the reaction.

III. REACTIONS WITH COMPOUNDS CONTAINING A MOBILE HYDROGEN ATOM

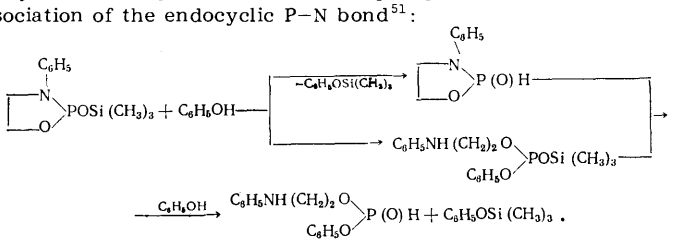
1. Water, Alcohols, and Phenols



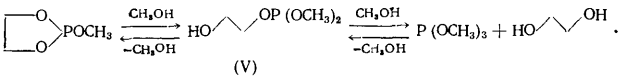
The interaction of cyclic phosphites with water and aqueous organic solvents is used widely as a convenient method of synthesis of 1,3,2-diheterophospholans and 1,3,2-diheterophosphorinanes containing the hydrophosphoryl group[25]. Dioxaphospholans[26,27] and oxazaphospholans[28] unsubstituted in the ring hydrolyse as a rule with ring opening, the hydrolysis being significantly accelerated by acid catalysts[29]. The presence of alkyl substituents at endocyclic carbon atoms greatly stabilises the cyclic fragment and hydrolysis takes place with retention of the ring[29-31]. In the low-temperature hydrolysis of condensed phosphoramidites (III),[32,33] the formation of the hydroxyphosphoranes (IV) was detected by ^{31}P NMR. These compounds are transformed further into derivatives of tetracoordinate phosphorus involved in a tautomeric equilibrium with one another:

The reactions of 1,3,2-diheterophospholans and 1,3,2-diheterophosphorinanes with alcohols, phenols, and glycols lead either to exocyclic substitution[34-41] or to the dissociation of one or both endocyclic phosphorus–heteroatom bonds[42-51]. There is also a possibility of the formation of monocyclic phosphoranes or spirophosphoranes with a P–H bond[52-55]; in many instances the reaction products are compounds of hexacoordinate phosphorus[56-59].

The study of the reactions of the amides of cyclic phosphorus acids with proton-donating reagents established the important role of acid catalysis[38,60-62]. Thus alcoholysis of phosphoramidites is accelerated by amine hydrochlorides,



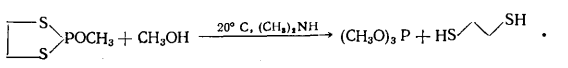
usually present as admixtures in the initial compound. This is accompanied by the intermediate formation of tervalent phosphorus chlorides which are readily esterified with regeneration of the catalyst[62]:



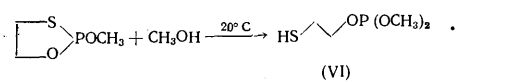
The acceleration of reactions of this type under the conditions of base catalysis has been noted[63].

The rates of the reactions of 2-dimethylamino-1,3,2-dioxaphospholan with phenol, butanol, and t-butyl alcohol in benzene increase with increase of the acidity of the hydroxylated reagent[38]. The reactivity of five-membered cyclic phosphoramidites in a non-catalysed reaction with butanol is significantly higher than that of the corresponding acyclic derivatives[38]; an increase of the number of alkyl substituents in the ring increases the reactivity of cyclic phosphoramidites in these reactions. The interpretation of the results is fairly difficult, particularly since it has been shown by kinetic studies[41] that the first stage of the alcoholysis involves complex formation between the alcohol and the phosphoramidite. According to the authors[41], this hinders comparison of the kinetic parameters of the reaction with the structures of the initial reactants.

The alcoholysis of 1,3,2-oxazaphospholans containing the exocyclic POSi group takes place simultaneously via two pathways—the desilylation of the initial phosphoramidite and dissociation of the endocyclic P–N bond[51]:

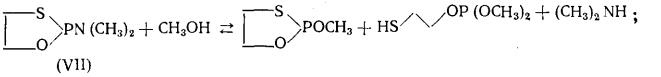


The P–N, P–O, and P–S bond strengths in 1,3,2-diheterophospholans unsubstituted in the carbon component of the ring and also the relative contributions of the *exo*- and *endo*-pathways of the methanolysis depend on different factors and in the first place on the temperature and acidity of the reaction medium and on the basic additives[47,48]. The methanolysis of 2-methoxy-1,3,2-dioxaphospholan does not take place in an alkaline medium; in the absence of bases, equilibrium involving the formation of the intermediate (V) with an open-chain structure has been noted[48]:

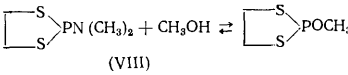


(V)

At 20 °C methanol does not interact with 2-methoxy-1,3,2-dithiaphospholan; the P–O bond is cleaved only at 80 °C in the presence of an excess of methanol. However, after the addition of catalytic amounts of dimethylamine, both P–S bonds of the heterocycle are readily ruptured even at room temperature[47]:

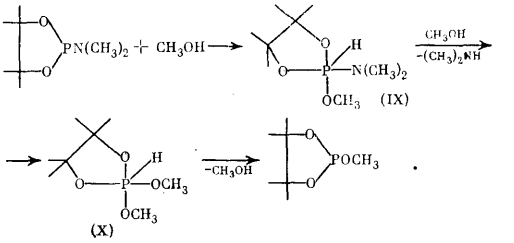


The use of oxathiaphospholan leads to the formation of β-mercaptoethyl dimethyl phosphite(VI):



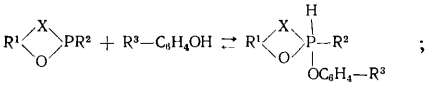
(VI)

The methanolysis of 2-dimethylamino-1,3,2-oxathia- and 2-dimethylamino-1,3,2-dithia-phospholans (VII) and (VIII) in the absence of basic additives is reversible[47]:



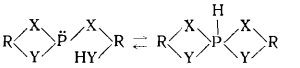
(VII)

(VIII)



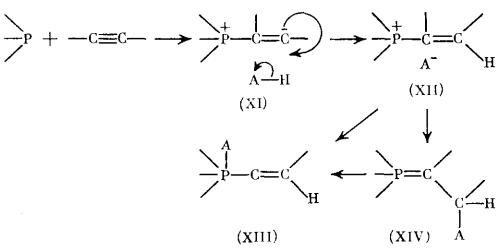
An increasing amount of data confirming that the alcoholysis of 1,3,2-diheterophospholans by alcohols and phenols involves the intermediate formation of structures of the phosphorane type with a P–H bond has been published recently[35,39,52–55]. The formation of the pentacoordinate intermediates (IX) and (X) in the reaction of 2-dimethylamino-4,4,5,5-tetramethyl-1,3,2-dioxaphospholan with methanol has been detected by ^{31}P NMR:[36]

(IX)



(X)

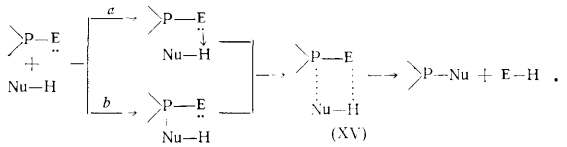
1,3,2-Dioxa- and 1,3,2-oxaza-phospholans react with substituted phenols also to form addition products which contain a pentacovalent phosphorus atom and are in equilibrium with the initial reactants[53,64]:



R^1=*o*-C_6H_4—, —$C(CH_3)_2C(CH_3)_2$—; R^2=Alk, Ar; R^3=*p*-NO_2, *p*-Cl, H, *p*-NH_2, *o*-NH_2; X=O, NH.

The formation of a phosphorane is favoured by a decrease of the temperature of the reaction mixture and an increase of the acidity of the phenol. It is believed[53] that the rate-determining stage in these reactions is the protonation of the phosphorus atom. An intramolecular version of such addition has been discovered in the case of 1,3,2-diheterophospholans containing functional groups with a mobile hydrogen atom in the β-position in the exocyclic substituent:

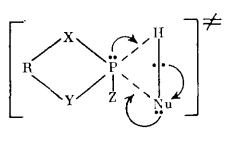
The position of this tautomeric equilibrium depends on the temperature, the nature of the solvent, the heteroatoms in the ring, and the nature of the substituents in the latter. Data on this question have been exhaustively described in a number of communications[65–71], although one should note that the thermodynamic characteristics of such processes, like those of many reactions of 1,3,2-diheterophosphacycloalkanes with proton donors, have not been described in the literature.



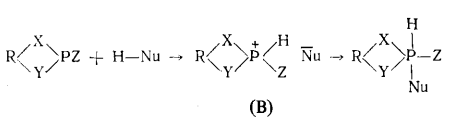
The course of the reactions of cyclic phosphites with alcohols in the presence of a third reactant—a compound with a C=C bond, was unexpected[54]:

(XI) (XII) (XIII) (XIV)

The dipolar ion (XI) formed in the first stage interacts with the proton-donating reactant A–H, leading to the phosphonium intermediate (XII) which is stabilised by being converted into the final phosphorane (XIII) either directly or via the unstable ylide (XIV).



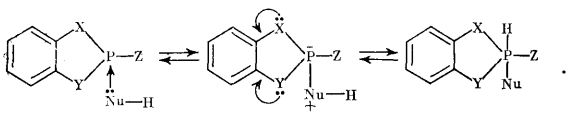
The available experimental data do not allow a single mechanism to be postulated for the interaction of 1,3,2-diheterophosphacycloalkanes with water, alcohols, and phenols. A number of workers have expressed the view that the substitution of an exocyclic group is an S_N2 process [with respect to phosphorus(III)] in which the reactivity of cyclic organophosphorus compounds depends on the ratio of the electronic and steric characteristics of the exchanging groups and also on the nature of the ring heteroatoms[61]. If the exocyclic substituent at the tervalent phosphorus atom is a group which is difficult to eliminate but is fairly basic, there is a possibility of electrophilic cooperation as a result of preliminary protonation (pathway *a*) or protonation after orientation of the nucleophile (pathway *b*):



(XV)

According to Mathis[37], these reactions can proceed via a four-centre cyclic transition (XV) or via the formation of the intermediate (XV) having a similar structure. Such association can take place also with participation of an endocyclic heteroatom[47], whereupon substitution occurs with ring opening.

On the other hand, the data presented in this Section show that, in the course of the reactions of 1,3,2-diheterophospholans with proton-donating reagents, intermediates with a pentacoordinate phosphorus atom probably play an important role. They can be formed via the 1,1-addition of a nucleophile to the tervalent phosphorus atom, or in a single stage via a three-centre transition stage (A), or in two stages via an ionic intermediate (B)†:

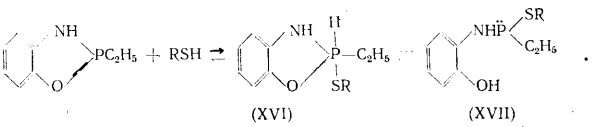


(A)

(B)

†Such reactions are classified in the literature as oxidative addition reactions[72,73].

In those cases where the electrophilicity of phosphorus is fairly high and the negative charge is effectively delocalised in the transition state (or in an anionic intermediate; for example, in benzodiheterophospholans), nucleophilic attack on the tervalent phosphorus atom can precede the proton transfer:



The possibility of the existence of cyclic anions with a tetracoordinate phosphorus atom has been demonstrated in a number of studies[74,75]. There is a possibility of base catalysis in reactions via this pathway[63]. The ability of the phosphorus atom in cyclic compounds to increase fairly readily its coordination number leads in many instances to products with a hexacoordinate phosphorus atom[56–59].

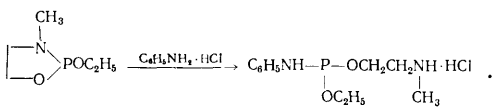
2. Mercaptans and Amines

In contrast to alcohols and phenols, mercaptans as a rule convert 1,3,2-diheterophospholans into thiophosphoryl compounds[76,77]. Only in rare instances are exocyclic groups at the tervalent phosphorus atom substituted by an alkylthio-group with retention of the coordination number[63]. The formation of cyclic phosphorothioic acids is observed on interaction of cyclic phosphites with hydrogen sulphide[78–80].

Depending on their structure, 1,3,2-oxazaphospholans react differently with mercaptans. Saturated heterocycles with an alkylene bridge in the molecule undergo "thionation" with retention of the cyclic fragment[63]. On the other hand, 4,5-benzo-1,3,2-oxazophospholans react with mercaptans to form addition products—monocyclic phosphoranes (XVI) with a P–H bond and a small amount of the isomeric phosphonamidothioites (XVII) with a tervalent phosphorus atom[55,81]. Compounds (XVI) and (XVII) are probably involved in a tautomeric equilibrium, which is displaced towards compound (XVI):

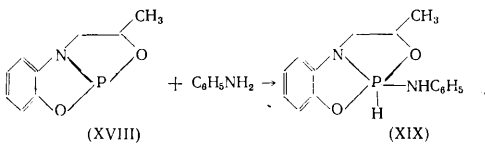
(XVI) (XVII)

The aminolysis of cyclic phosphorus(III) derivatives has been studied in greatest detail in relation to 1,3,2-dioxaphospholans having an exocyclic P–N bond[37]. The reactivity of cyclic phosphoramidites in transamidation is as a rule higher than that of their acyclic analogues and depends on the nature of the attacking and leaving amines. The rate of aminolysis increases with increasing basicity of the amine and the electrophilicity of the phosphorus atom in the sequence[82]



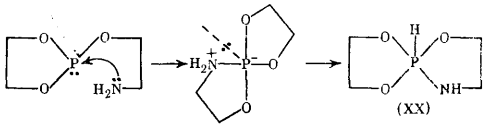
At the same time instances of the substitution of a more basic amine by a less basic amine in the presence of acid admixtures are known. The reactions take place in such cases in the three-component phosphoramidite–acid–amine system via the initial protonation of the phosphoramidite and subsequent formation of an anhydride, which interacts with the less basic amine to form transamidation products[62,83].

On the other hand, in a study of the transamidation of 2-dialkylamino-1,3,2-dioxa- and 1,3-dimethyl-1,3,2-diazaphosphorinanes, it was suggested that the following equilibrium obtains as a rule in the phosphoramidite–amine system[61]:

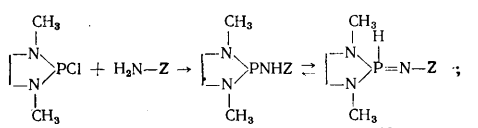


The role of added acid consists in shifting the equilibrium as a result of the binding of the more basic amine. However, this view is apparently valid only when equimolar amounts of the acid are used and does not explain the catalytic influence of the acid reactant on the course of these reactions.

The aminolysis of the endocyclic P–N bond in 1,3,2-oxazaphospholans takes place when aniline hydrochloride is used; in the absence of added additives, these reactions do not occur[84]:



The aminolysis of 1,3,2-diheterophospholans can also proceed via the intermediate formation of phosphoranes with a P–H bond[53]. The present authors have detected addition products of this type by ^{31}P NMR in a study of the interaction of bicyclic phosphoramidites with primary and secondary amines. After mixing the bicyclic compound (XVIII) with aniline at room temperature, a doublet signal was recorded in the ^{31}P NMR spectrum of the reaction mixture ($\delta_{^{31}P}$ = −54 p.p.m., $^1J_{PH}$ = 820 Hz); it refers to the phosphorane (XIX):

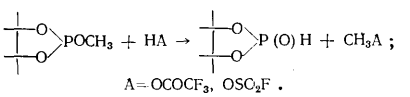


(XVIII) (XIX)

The reaction with diethylamine is accompanied by an exothermic effect and also leads to an addition product with a pentacoordinate phosphorus atom ($\delta_{^{31}P}$ = −42 p.p.m., $^1J_{PH}$ = 820 Hz). The increase of the rate of reaction in the sequence diphenylamine < ethylaniline < diethylamine suggests that in such cases there is nucleophilic attack on the tervalent phosphorus atom, which functions as the electrophilic reactant. An analogous mechanism must be assumed also in cyclisation reactions with formation of spirophosphoranes, for example, compound (XX):[2]

(XX)

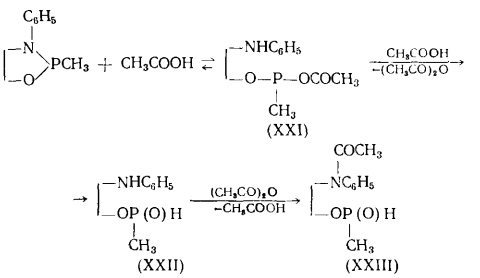
Products with an exocyclic secondary amino-group, which in many instances exist in the tautomeric imide form, have been obtained by the amination of 2-halogeno-1,3,2-diazaphospholans[85]:



Z=SO_2CF_3, $SO_2C_6H_4$–CH_3, P(S)$(OC_6H_5)_2$, P(S)$(C_6H_5)_2$.

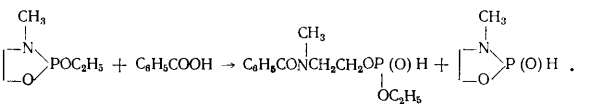
3. Acids

The reactions of 1,3,2-diheterophospholans and 1,3,2-diheterophosphorinanes with strong hydrogen donors, namely carboxylic[48,86–93], sulphonic[53,94,95], and phosphorus-containing acids[96–98], take place in several ways: with ring opening[87,89], with formation of phosphorane and spirophosphorane derivatives[90,91], with formation of disproportionation[48] and polymerisation[92,93] products, and with substitution of an exocyclic group[44,88,89].



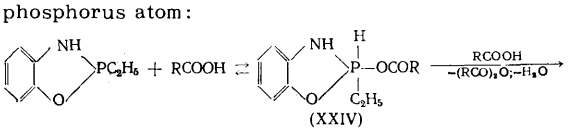
The interaction of the hydrate of toluene-*p*-sulphonic acid with substituted 1,3,2-oxazaphospholans and 1,3,2-oxazaphosphorinanes leads to products of the hydrolytic ring opening[94,95]. When equimolar proportions of the cyclic phosphite and trifluoroacetic or fluorosulphonic acids are used, the ring is not opened; in this case exocyclic dealkylation via the mechanism of the Arbuzov reaction is observed[11]:

A=$OCOCF_3$, OSO_2F .

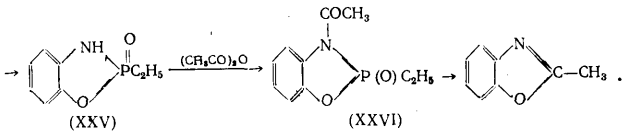


The reactions of strong phosphinic[96] and phosphinodithioic[97] acids with 1,3,2-diheterophosphorinanes resulted in the isolation of mixed anhydrides. The tricoordinate phosphorus atom in the ring of the latter was found to have a reduced nucleophilic reactivity.

The study of the interaction of carboxylic acids with 1,3,2-oxazaphospholans showed that, depending on the structure of the latter, the reactions can involve the nitrogen or phosphorus atom of the P–N ambident system. Protonation of the endocyclic nitrogen atom in saturated 1,3,2-oxazaphospholans leads to ring opening with formation of the phosphonite (XXI). As a result of acidolysis, the latter is converted into the hydrophosphoryl compound (XXII) and the acetic anhydride produced acetylates the amino-group with formation of the compound (XXIII):[89]

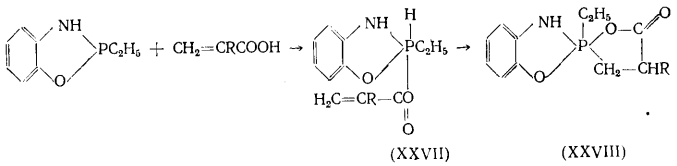


(XXI) (XXII) (XXIII)



The analogous reaction involving 2-alkoxy-3-alkyl-1,3,2-oxazaphospholans takes place simultaneously via two pathways with formation of linear and cyclic acid phosphites:

2-Ethyl-4,5-benzo-1,3,2-oxazaphospholan reacts with carboxylic acids under mild conditions to form products of the phosphorane type with a P–H bond [compounds (XXIV) [90,91]], which are further converted into compounds (XXV) with a tetracoordinate phosphorus atom. The rate of reaction increases with increase of the strength of the carboxylic acid. The first step in the interaction is probably protonation of the phosphorus atom:



(XXIV)

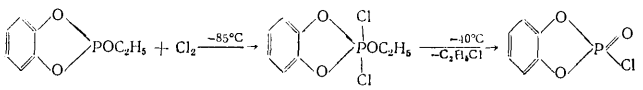
(XXV) (XXVI)

Acylation of the phosphonate (XXV) by acetic anhydride on heating leads to 2-methylbenzoxazole, formed from the acetylated oxazaphospholan (XXVI).

When α,β-unsaturated carboxylic acids are used, the phosphoranes (XXVII) formed initially are stabilised in a different manner—via intramolecular cyclisation with formation of the spirophosphoranes (XXVIII) with a P–C bond[91]:

(XXVII) (XXVIII)

Analogous reactions of 1,3,2-dioxaphospholans investigated previously lead to the formation of spirophosphoranes and polymeric products[92,93]. The formation of zwitter-ionic intermediates as the result of attack by a phosphonite molecule on the β-carbon atom of the unsaturated acid was postulated for this process[93] (see Section VIII below). However, one cannot rule out the possibility that initial protonation of the phosphorus atom is possible in these reactions too.



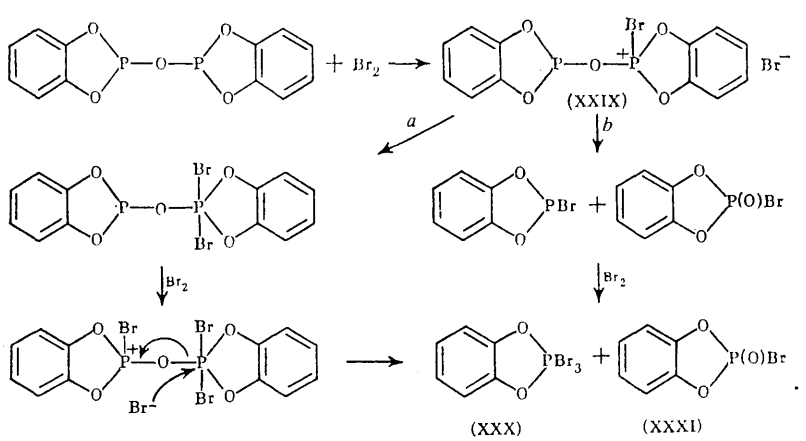
IV. BIPHILIC REACTIONS

Derivatives of tervalent phosphorus can exhibit in many instances a "biphilic" reactivity[99]. "Biphilicity" is understood as the ability of the phosphorus compound not only to supply electrons to the substrate with formation of a σ-bond but also to receive them at the same centre with formation of a σ- or π-bond. Reactions of this type were partly considered in the previous Section devoted to proton-donating reagents. It follows from the foregoing that "biphilic" reactions can be most usefully investigated in relation to cyclic systems in view of the relative stability of the intermediates formed; this makes it possible to investigate the intermediate stages in certain processes.

1. Reactions with Halogens

Depending on their structure, the halogenation of 1,3,2-diheterophospholans can proceed with ring opening and the formation of linear products[100] or it can lead to cyclic phosphates via the mechanism of the Arbuzov reaction[101–103]. In many instances it was possible to note the formation of adducts with a pentacoordinate phosphorus atom[101–106]. The initial formation of phosphonium salts of type (XXIX) has been assumed in these reactions[107]. They can be converted into the final products (XXX) and (XXXI) via two pathways: as a result of the attack by the halide ion on the phosphonium centre (pathway *a*) or as a result of the attack on another electrophilic centre of the molecule—the tervalent phosphorus atom (pathway *b*, Scheme 2):

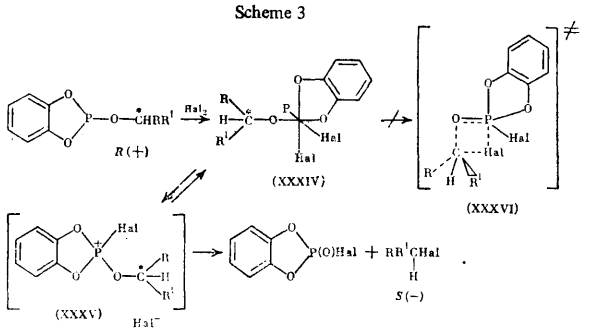
The chlorination of 2-alkoxy-4,5-benzo-1,3,2-dioxaphospholans in methylene chloride at −85 °C made it possible to detect the formation of the dichlorophosphorane (XXXII) which is converted into the cyclic phosphorochloridate (XXXIII) on raising the temperature to −40 °C:[108–110]



(XXXII) (XXXIII)

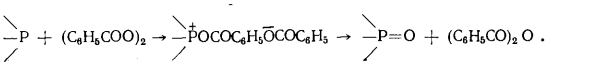
The analogous reaction of 4,5-benzo-1,3,2-dioxaphospholan, obtained from the optically active secondary *R*(+)-octyl alcohol, leads to a halogenoalkane with the *S*(−)-configuration[109]. This enabled the authors[109] to suggest that the process illustrated in Scheme 3 proceeds via a stage involving the formation of the dihalogenophosphorane (XXXIV), which is involved in a rapid equilibrium with the phosphonium salt (XXXV).

The dealkylation of the latter via the S_N2 mechanism leads to substitution at the chiral carbon atom with inversion of its configuration. The alternative mechanism with a four-centre transition stage (XXXVI) would lead to the retention of the configuration of the carbon atom in the exocyclic alkoxy-group.



Halogenation of oxazophospholans leads to the opening of the ring at the phosphorus–oxygen bond and the formation of phosphoramidochloridates[111]. The stereochemical result of the halogenation of *cis*- and *trans*-2-methoxy-1,3,2-dioxaphosphorinanes[112] depends on the nature of the halogen: chlorination takes place stereospecifically and bromination yields a mixture of diastereoisomeric products in which one or other diastereoisomer predominates.

Scheme 2

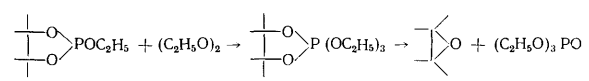


(XXIX) (XXX) (XXXI)

Scheme 3

2. Reactions with Peroxides, Disulphides, and Dithiocyanogen

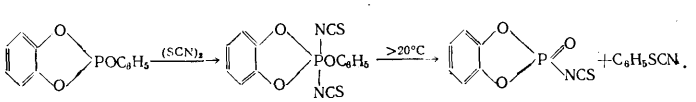
Cyclic and linear derivatives of tervalent phosphorus are characterised by a high reactivity in reactions with peroxides[113–115]. It has been suggested that the interaction with benzoyl peroxide takes place via the initial attack by the phosphorus atom on the peroxide oxygen with formation of the ion pair (XXXVII):



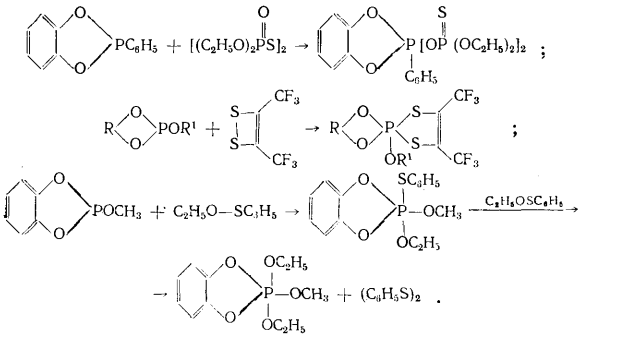
(XXXVII)

The sequence of changes in the reactivity of the cyclic phosphoramidites is analogous to that observed in the reactions with alkyl halides (see Section 5).

The results of a study of the reactions of cyclic phosphites with diethyl peroxide lead to a different conclusion[114]. The rate of this reaction increases in the sequence acyclic phosphites < dioxaphosphorinanes < dioxaphospholans.



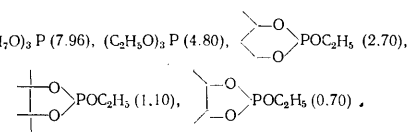
Among the phospholan derivatives, the 4,5-benzo-derivative, in which the phenylenedioxy-substituent exhibits powerful electron accepting properties, shows the highest reactivity. In addition, one should note the instability of the cyclic phosphoranes (XXXVIII) formed in the reaction:



(XXXVIII)

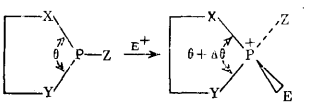
These results are consistent with the concept of the "biphilic" insertion of the phosphorus atom of the cyclic phosphite in the oxygen–oxygen bond of the peroxide. The 1,3,2-diazaphospholan analogues also react with diethyl peroxide to form the corresponding pentacoordinate compounds, but their stability is much lower than that of the intermediates with oxygen-containing rings[116].

A series of reactions accompanied by the "biphilic" insertion of tervalent phosphorus derivatives in the O–S and S–S bonds have been described in the literature. The reaction of 2-phenoxy-4,5-benzo-1,3,2-dioxaphospholan with dithiocyanogen[117] results in the formation of quinquevalent phosphorus compounds containing P–N bonds:



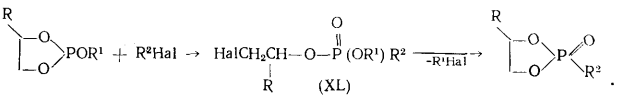
The formation of phosphorane derivatives is observed in the reactions of cyclic phosphites with disulphides[117–119] and compounds containing the O–S bonds[120]:

V. THE ARBUZOV REACTION. REARRANGEMENTS



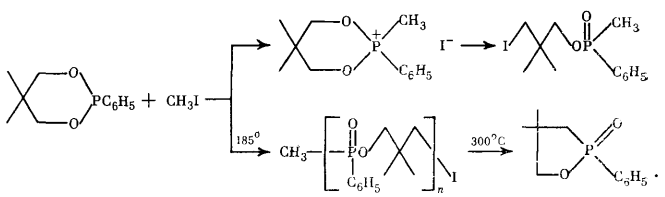
The study of the behaviour of cyclic esters of phosphorus acid in reactions with alkyl halides was initiated by Arbuzov in the 1950's.[121] The structure of the final products of this reaction depends on the ring size and the number and nature of its substituents. According to the results of differential thermal analysis[122], acyclic phosphites enter most readily into the Arbuzov reaction, while their 1,3,2-dioxaphosphorinane and 1,3,2-dioxaphospholan analogues react with greater difficulty. The increase of reactivity corresponds to the increase of electron density at the ring phosphorus atom[2,123].

A study of the comparative reactivities of tervalent phosphorus acid esters with respect to CH_3I established that, on passing from linear trialkyl phosphites to their six- and five-membered cyclic analogues, the rate constant diminishes[124]:



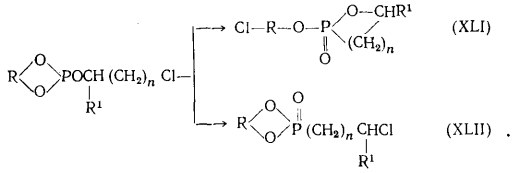
The values of $10^4\ k$ (litre $mol^{-1}\ s^{-1}$) are given in brackets.

The lower reactivity of phospholan derivatives in reactions with electrophiles E^+ is explained from the standpoint of the increasing ring strain ($\theta + \Delta\theta$) in the transition state, because the endocyclic angle increases from 93–98° to 109° in the intermediate (XXXIX) formed with a quaternised phosphorus atom[2,125]:



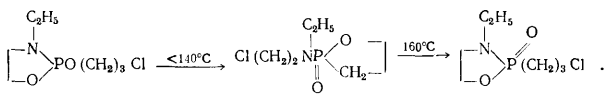
(XXXIX)

The Arbuzov reaction involving the esters of pinacol- and methoxymethylethylene-phosphorous acids as well as esters with six-membered rings proceeds without ring opening[126]. The reaction involving phosphites with cyclic arylene substituents takes place analogously[127,128]. Unsubstituted or monosubstituted phospholan systems tend to undergo ring opening[129–131], but there is also a possibility of the subsequent cyclisation of the intermediate linear phosphonate (XL):[132,133]

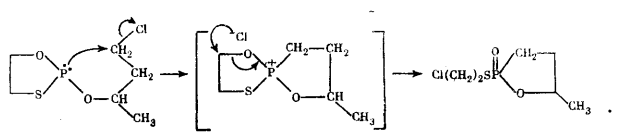


(XL)

In the reaction of methyl iodide with neopentylene phenylphosphonite[134], there is a possibility of "transcyclisation" at a high temperature with formation of an oxaphospholan derivative together with the usual Arbuzov reaction:



2-(ω-Halogenoalkoxy)-1,3,2-diheterophosphacycloalkanes, formed in the reaction of cyclic phosphorochlorodites with epoxyalkanes, undergo an unusual intramolecular version of the Arbuzov rearrangement[135-144]. The cyclic fragment of the initial phosphite can then be quoted or can be retained depending on the size of the ring, the nature and number of its substituents, and also the structure of the exocyclic halogenoalkyl component[137-145]:

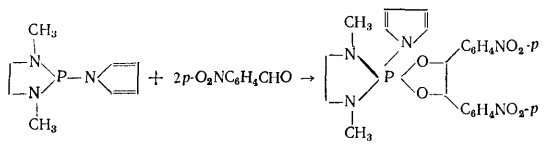


(XLI) (XLII).

In the majority of instances, intramolecular thermal isomerisation leads to a mixture of the isomeric compounds (XLI) and (XLII). The rearrangement of ethylene and 1,2-propylene phosphite results in the formation of both products; on the other hand, 2,3-butylene phosphites isomerise preferentially to compounds (XLII) with retention of the phospholan ring. The ratio of the isomers formed depends also on temperature. Thus 1,3,2-oxazophospholan (XLIII) isomerises at 140 °C to 1,2-oxaphospholan (XLIV) and an increase of the reaction temperature leads to "transcyclisation" with formation of a compound having the oxazaphospholan structure (XLV):[141]

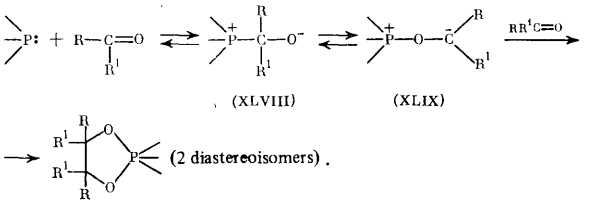
(XLIII) (XLIV) (XLV).

The ease of isomerisation depends on the nature of the branching of the exocyclic fragment. The introduction of the methyl group in the γ-position in the 3-chloroalkoxymoiety can fully suppress the intramolecular isomerisation of oxazaphospholans; the presence of the methyl group in the α-position facilitates the reaction[141]. These data are satisfactorily consistent with the S_N2 mechanism of the substitution of the halogen by a phosphorus atom at the terminal carbon atom. The rearrangement of the oxathiaphospholans (XLVI) is accompanied by ring opening at the C–O bond[140], probably via the attack by the chloride ion on the carbon of the unsubstituted oxathiaphospholan quasi-phosphonium intermediate (XLVII):



(XLVI) (XLVII).

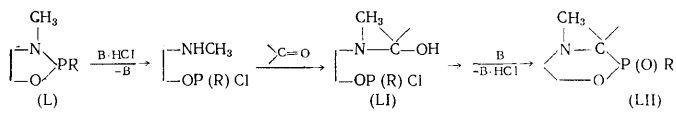
VI. REACTIONS WITH CARBONYL COMPOUNDS



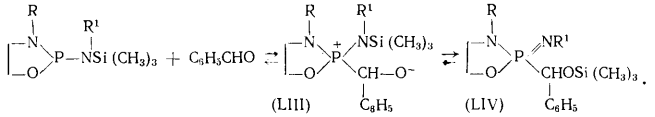
1. Aldehydes and Ketones

Data on the chemical reactions of alkylene phosphites with α-halogenoaldehydes and ketones have been published in a review[10] and will not be considered here. One should only note that α-chloroaldehydes interact with cyclic phosphites to form cyclic and acyclic products of the Perkow reaction, while α-chloroketones react both via the mechanism of the Arbuzov reaction and that of the Perkow reaction.

Various 1,3,2-diheterophospholans interact with aromatic aldehydes and ketones to form 1:2 adducts with the spirophosphorane structure[146-150]:



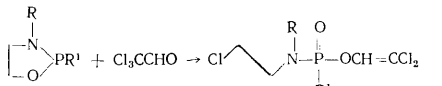
Apparently spiro-cyclisation takes place via the formation of intermediate dipolar structures (XLVIII) and (XLIX), which are converted into compounds with a pentacovalent phosphorus atom on reaction with a second molecule of the carbonyl reagent[1,151]:



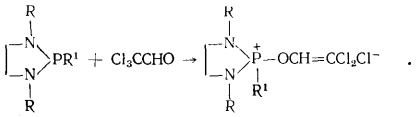
(XLVIII) (XLIX) (2 diastereoisomers).

The interaction of oxazaphospholans with aldehydes and ketones is frequently accompanied by the insertion of the latter in the P–N bond, ring expansion, and the formation of 1,4,2-oxazaphosphorinanes[152-156]. In these reactions there is acid catalysis due to an admixture of the hydrochlorides, frequently present in the initial cyclic phosphoramidites[157,158]. Under their influence, the initial dissociation of the P–N bond of the oxazaphospholan (L) takes place[159] and the resulting aminoalkyl phosphorochloridite or phosphonochloridite interacts with the carbonyl compound; the dehydrochlorination of the intermediate (LI) leads to the corresponding 1,4,2-oxazaphosphorinane (LII):

(L) (LI) (LII).



The reactions of carbonyl compounds with 1,3,2-oxazaphospholans containing the silylamino-group in the exocyclic fragment take place readily[160,161]:

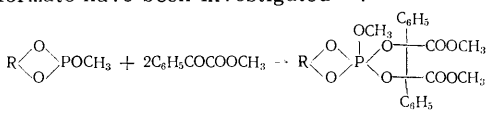


(LIII) (LIV).

The nucleophilic addition of the phosphorus(III) atom of the initial phosphoramidite to the carbonyl group leads to the formation of the dipolar ion (LIII), in which the trimethylsilyl group migrates to the oxy-anionic centre. The cyclic phosphonate (LIV) formed decomposes on heating into the initial component via a stage involving the formation of compound (LIII).[160]

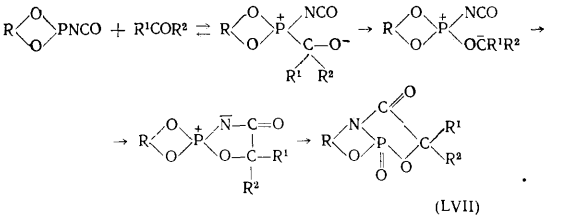
2-Alkoxy-1,3,2-oxaza- and 2-alkoxy-1,3,2-diaza-phospholans react differently with chloral. The formation of products with ring opening, namely β,β-dichlorovinyl phosphates (LV), is characteristic of the former[162], while the latter give rise to cyclic phosphonium chlorides (LVI):[163]

(LV)



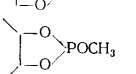
(LVI)

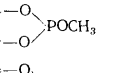
The study of the reactions of substituted 1,3,2-diheterophosphacycloalkanes with chloral and trichloroacetophenone[164] established that the overall sequence of the changes in the reactivity of cyclic phosphites in this process resembles that established in reactions of cyclic phosphites with alkyl halides[165] (see Section V): the reactivity decreases on passing from acyclic derivatives of tervalent phosphorus to their six- and five-membered cyclic analogues. This agrees with the idea that the rate-determining stage in such reactions involves the attack by the phosphorus atom on the carbon atom of the carbonyl group.



2. Activated Carbonyl and Dicarbonyl Compounds

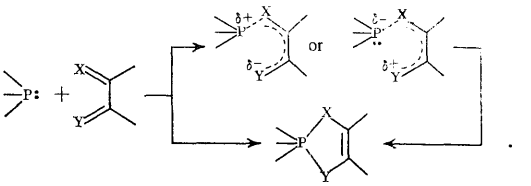
The reactions of trialkyl phosphites with carbonyl compounds activated by electron-accepting substituents can take place via two pathways[151]: at a low temperature with formation of predominantly pentacoordinate derivatives of phosphorus and at an elevated temperature with formation of the corresponding 2-substituted alkyl phosphonates. In contrast to linear phosphites, the cyclic analogues give rise as a rule to the thermodynamically stable spirophosphoranes. This is observed in the reactions of ethers and amides of alkylene phosphorous acids with esters of α-ketoacids[166] and of 1,3,2-diheterophospholans with phenylbenzoyldiimide[167,168] and the esters and the nitrile of benzoylformic acid[169,170]. The kinetics of the reactions of cyclic phosphites with methyl benzoylformate have been investigated[171]:





Despite the fact that two ester molecules participate in the reaction, the rate of the process is described by a second order kinetic equation (or first order with respect to each reactant) and the slowest stage is the formation of a dipolar ion of the type $\geq\overset{+}{P}-\underset{|}{C}-O^-$ (XLVIII).[171] The thermodynamic characteristics obtained (Table 1) make it possible to assign the five- and six-membered cyclic analogues to various reaction series: the reactivity of the phospholan derivatives is controlled by the entropy factor, while the reactions of phosphorinane derivatives are subject to control by the enthalpy factor.

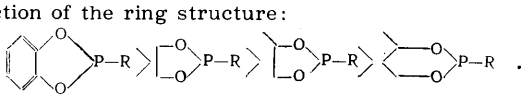
The products of the interaction of cyclic phosphoroisocyanatidites with the esters of pyruvic, benzoylformic, and α,β-di-oxobutyric acids and phenylglyoxal[172-174] are the corresponding hetero-derivatives of the bicyclo-octane and bicyclononane series (LVII):



(LVII)

Table 1. Kinetic parameters of the reactions of cyclic phosphites with benzoylformic acid ester at 50 °C.[171]

Phosphite	$10^4 k$, litre mol^{-1} s^{-1}	$\Delta H^{\neq}$, kJ mol^{-1}	$-\Delta S^{\neq}$, J mol^{-1} K^{-1}
	5.60	16.4	249.5
	9.10	19.3	236.9
	14.02	26.5	210.8
	1.69	5.9	292.7
	2.65	3.8	295.7

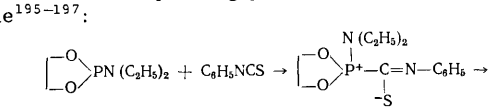


The interaction of cyclic derivatives of tervalent phosphorus with dicarbonyl and saturated carbonyl compounds has been examined in reviews[1,151,175]. 1,3,2-Diheterophospholans react with α,β-unsaturated compounds containing the N=N–C=O and N=C–C=O conjugated systems, which results in the formation of spirophosphorane structures[176-180].

Such processes resemble the cycloaddition reactions, which can proceed either via two stages or synchronously. The characteristics of such reactions are consistent with the mechanism of diene condensation with participation of cyclic phosphites[181-188]:

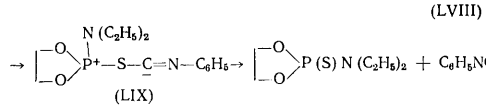
The rate of reaction depends mainly on the redistribution of electron density in the intermediate reaction complex, which results in the manifestation of the dominant influence of electronic or steric factors (Table 2).

The replacement of acyclic groups by cyclic groups increases significantly the rate and lowers the activation barrier to the reaction owing to the weak electron-donating influence of the 1,3,2-dioxaphospholan fragment compared with the two alkoxy-groups in the transition state. The activity series of cyclic phosphites in diene condensation[181,182] has been established as a function of the ring structure:



The data obtained most probably indicate nucleophilic attack by the unsaturated reactant; phosphorus then exhibits electrophilic properties[189]. The successive replacement of the oxygen atoms in the diheterophospholan fragment by sulphur apparently increases still further the electron-accepting character of this fragment and increases the rate of condensation[183].

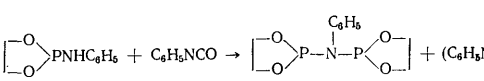
Table 2. Kinetic parameters of the condensation reactions between phosphorochloridites and isoprene[184].



Phosphorochloridite	$10^4 \cdot k$, litre mol^{-1} s^{-1}	E_a, kJ mol^{-1}	$-\Delta S^{\neq}$, J mol^{-1} K^{-1}
$(C_2H_5O)_2PCl$	0.012	92.8	100.8
	0.97	70.1	150.8
$C_2H_5OPCl_2$	1.26	82.3	116.8

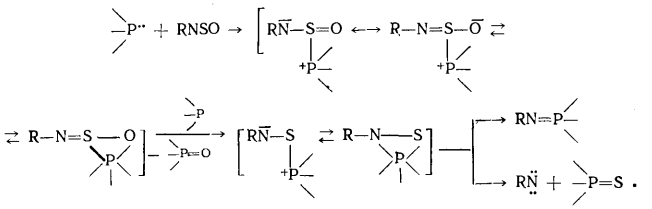
3. Reactions with Isocyanates, Carbon Dioxide, Their Thio-analogues, and Related Compounds

The "insertion reactions" involving isocyanates, isothiocyanates, carbon disulphide, carbon dioxide, and other heterocumulated reagents occupy a special place in the chemistry of tervalent phosphorus acid amides[190,191]. It has been suggested[192] that the reaction takes place via the insertion of the carbonyl reactant in the P–N bond in the ring with formation of an intermediate with a larger cyclic system than in the initial phosphite. However, it was shown subsequently[193,194] that two independent pathways can be followed in these reactions: insertion in the ring of the diheterophosphacycloalkane and its oxidation with formation of a compound having a tetrahedral phosphorus atom. In the interaction of cyclic phosphoramidites with isothiocyanates, dipolar ions with a P–C bond (LVIII) arise in the first stage and readily undergo the mercaptophosphonate–phosphorothioate rearrangement in the course of the reaction to the thiophosphonium intermediate (LIX); the final reaction products are the corresponding phosphoramidothioate and an isonitrile[195–197]:



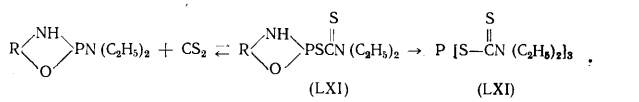
(LVIII)

(LIX)



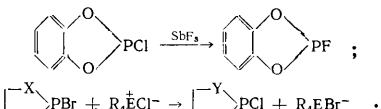
Cyclic phosphoramidites are oxidised analogously by isocyanates.

The presence of a mobile hydrogen atom in the exocyclic amino-group of the 1,3,2-dioxaphospholan permits its disproportionation in the reaction with isocyanate[197,198]:



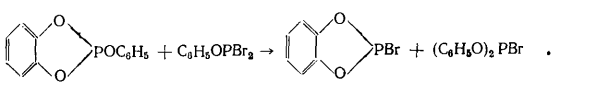
As a consequence of their low nucleophilic reactivity, 1,3,2-diheterophospholans are less reactive in reactions with substituted sulphenylamines than their open-chain analogues[199].

It has been suggested that the process begins with nucleophilic attack by the phosphorus atom on the electrophilic sulphur atom; in the subsequent stages the S–O and P–S bonds in the intermediates formed dissociate simultaneously or in succession. The final products of the reaction are the corresponding phosphoryl, thiophosphoryl, and imidophosphoryl derivatives:



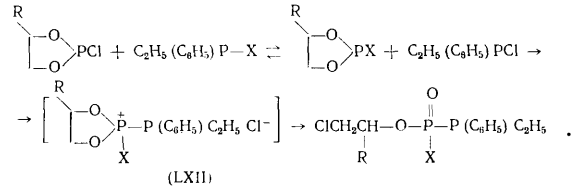
The stability of the products of the insertion of CS_2 and CO_2 in the exocyclic P–N bonds of 1,3,2-dioxaphosphorinanes[200], 1,3,2-oxathiaphospholans, 1,3,2-dithiaphospholans[201], and 1,3,2-oxazaphospholans[202] depends on the structure of the cyclic fragment. As a result of the interaction of carbon disulphide with amides containing a diheteroalkylene cyclic fragment (R = alkylene), stable thiocarbamoyl phosphorothioites (LX) are formed; the reaction of 4,5-benzo-1,3,2-oxazaphospholan (R = *o*-C_6H_4) takes place with subsequent disproportionation of the 1:1 adducts to tris(*N*,*N*-diethylthiocarbamoylthio)phosphine (LXI):

(LXI) (LXI)



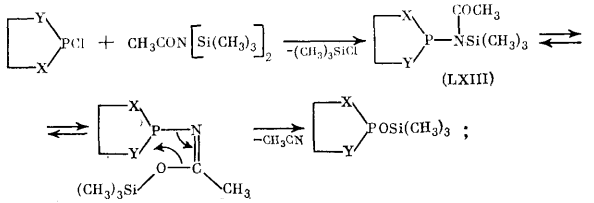
VII. SUBSTITUTION AT THE PHOSPHORUS ATOM ON TREATMENT WITH REAGENTS WITHOUT A MOBILE HYDROGEN ATOM

As already mentioned above, reactions accompanied by the substitution of the exocyclic group at the phosphorus atom are extremely characteristic of cyclic phosphorus derivatives. This is also characteristic of a series of reactions involving reagents without a proton. It has been established[203] that there is rapid intermolecular halogen exchange involving 2-chloro(bromo)-1,3,2-dioxa(oxaza)phospholans. The activation barrier to this process is 20.2 ± 4 kJ mol^{-1}, which agrees with the idea that the mechanism of the exchange involves a four-centre transition state of type (XV) without the preliminary ionisation of the phosphorus–halogen bonds. The exocyclic chlorine is readily substituted by fluorine on treatment with antimony trifluoride and bromine is substituted by chlorine on treatment with ammonium, phosphonium, and arsonium chlorides[204–206]:



X, Y=O, NR; R=Alk, Ar; E=N, P, As .

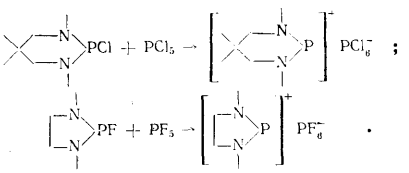
The exchange of substituents has been noted in reactions of the full cyclic esters of phosphorous acid[207,208]:



Similar exchange processes have been demonstrated also for cyclic phosphorochloridites when these react with trialkyl phosphites or phosphoramidites[209]. In a few instances these processes are accompanied by ring opening via a mechanism of the type of the Arbuzov rearrangement via an intermediate—the cyclic quasi-phosphonium salt (LXII):[210]

(LXII)

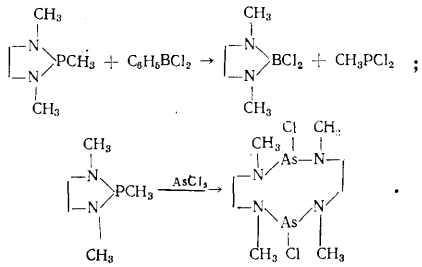
2-Halogeno-1,3,2-diheterophospholans are readily silylated by *N*,*N*-bis(trimethylsilyl)acetamide[211–214]:



(LXIII)

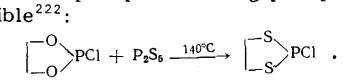
X, Y = O, NCH_3, NC_6H_5 .

During the reaction, the 2-(*N*-acetyl-*N*-trimethylsilylamino)-1,3,2-diheterophospholans (LXIII) formed initially decompose to the corresponding cyclic silyl phosphites. According to the results of differential thermal analysis, the reactivity of cyclic phosphorohalidites increases on passing from 1,3,2-diazaphospholan to the oxaza- and dioxa-derivatives, i.e. with increasing electrophilicity of the phosphorus atom[211].



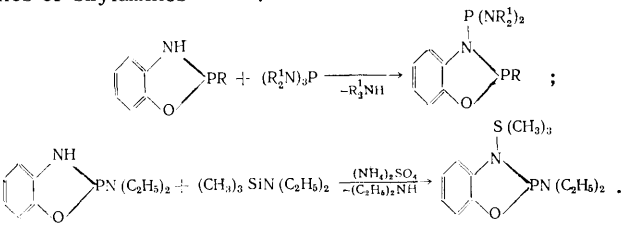
Compounds with a P–P bond can be obtained by treating 2-halogeno-1,3,2-diheterophosphacycloalkanes with metallic sodium[215,216].

Treatment of phosphorohalidites with Lewis acids leads to cyclic cations with a dicoordinate phosphorus atom[19,217]:

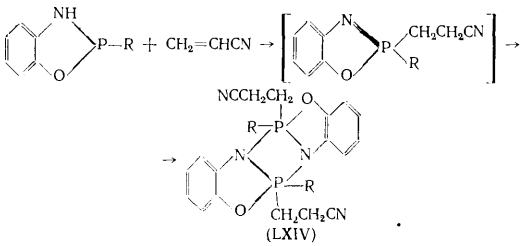


The formation of such compounds has been noted also in the formation of complexes by iron and manganese carbonyls or of fluoroboranes with 1,3,2-diazaphospholans[218–220].

The exchange of phosphorus for other heteroatoms is sometimes observed[205,221]:



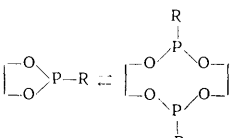
The replacement of the endocyclic oxygen atoms by sulphur in 2-chloro-1,3,2-dioxaphospholan using phosphorus pentasulphide is possible[222]:



The mechanisms of such reactions have not been determined in detail.

Substitution can take place not only at the phosphorus atom but also at the endocyclic nitrogen atom. 4,5-Benzo-1,3,2-oxazaphospholans readily exchange the mobile hydrogen atoms of the endocyclic amino-group in reactions with triaminophosphines or silylamines[223–229]:

2-Substituted 4,5-benzo-1,3,2-oxaza- and 4,5-benzo-1,3,2-diaza-phospholans readily add to unsaturated compounds with an activated double bond. The addition products formed initially are stabilised via dimerisation to diazadiphosphetidines (LXIV):[229–231]

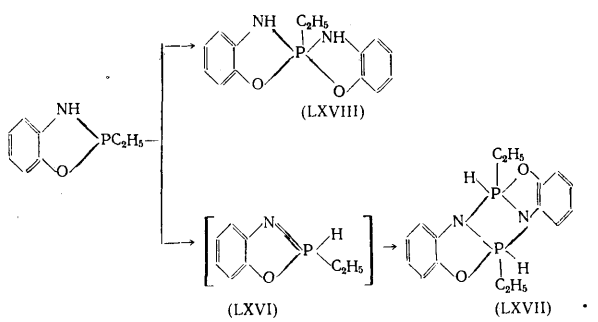


(LXIV)

VIII. RING EXPANSION. POLYMERISATION

In a number of instances cyclic derivatives of tricoordinate phosphorus are capable of spontaneous transformation into dimeric products or oligomers[232]. Thus on standing for a long time, 2-chloro-4,5-benzo-1,3,2-dioxaphospholan is irreversibly converted into oligomeric products, which regenerate the monomeric compound on distillation[233]. A similar reversible transformation of the monomeric 3-methyl-2-phenyl-1,3,2-oxazaphospholan has been noted[193].

The formation of dimers, trimers, and oligomers is particularly characteristic of unsubstituted cyclic derivatives of tervalent phosphorus in which the phosphorus atom is involved in an exocyclic P–C bond. Dioxaphospholans dimerise reversibly to ten-membered cyclic diphosphonites (LXV) in the presence of atmospheric moisture; furthermore, the formation of polymeric compounds is also observed under these conditions[233–237]:



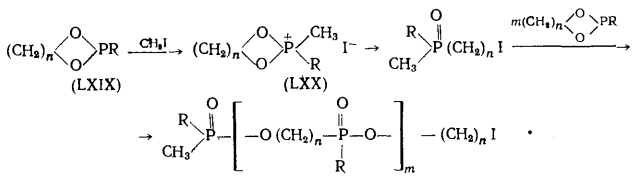
(LXV)

Dimeric derivatives with a similar structure are also formed from 1,3,2-oxazaphospholans[232]. Dimers of type (LXV) retain the properties of tricoordinate phosphorus derivatives —they are oxidised and combine with sulphur[238]. When both endocyclic oxygen atoms are replaced by nitrogen, phospholans lose their tendency to dimerise; ring expansion has not been observed also in the series of 1,3,2-dithiophospholans[236].

After prolonged storage, dioxaphosphorinanes give rise to cyclic dimers and trimers together with polymeric products[239]; in contrast to their five-membered cyclic analogues,

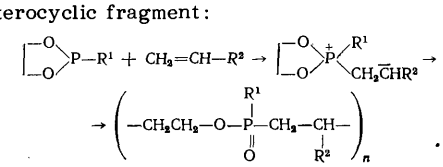
dithiaphosphorinane derivatives with tervalent phosphorus are irreversibly converted into 12-membered cyclic compounds[236].

The dimerisation of 2-ethyl-4,5-benzo-1,3,2-oxazaphospholan takes place in an unusual manner[240]. The phosphonoimidite (LXVI), formed as a result of prototropic isomerisation, dimerises to the diazadiphosphetidine (LXVII); the process is also accompanied by the symmetrisation of the initial phosphonite to give the spirophosphorane (LXVIII):



(LXVIII)

(LXVI) (LXVII)



When a ring oxygen atom is replaced by sulphur, the tautomeric prototropic transition does not take place and the formation of the phosphetidine ring is not observed; there is only a reversible transition to a compound having the spirophosphorane structure of type (LXVIII).[241]

The polymerisation and copolymerisation reactions of cyclic derivatives of phosphorus can be initiated by boron trifluoride, sulphuric acid, dimethyl sulphate, and bromocyanoacetamide[242]. The Arbuzov reaction of cyclic phosphites and phosphonites (LXIX) [244] with alkyl halides is used to synthesise oligomers with the phosphorus atom in the main chain; the reaction proceeds via the formation of the quasi-phosphonium salt (LXX), the opening of its ring, and interaction with the next molecule of the phosphacycloalkane:

(LXIX) (LXX)

The polycondensation of the dialkyl esters of phenyl- and ethyl-phosphinous acids with glycols takes place mainly via the intermediate formation of cyclic esters of phosphinous acid[245]. The copolymerisation of cyclic phosphorus(III) derivatives with a wide variety of electrophilic monomers, the so-called alternant polymerisation[93], begins with the formation of the dipolar ion (LXXI): the growth of the polymer chain involves the opening of the ring in the five-membered heterocyclic fragment:

α,β-Unsaturated carboxylic acids, their amides, and sulphonamides as well as ketones have been used as the unsaturated monomers[93].

The data presented in this review demonstrate the unusual reactivity of 1,3,2-diheterophospholans. The characteristics of the geometry of these molecules associated with the incorporation of a tervalent phosphorus atom in a strained five-membered ring alter the character of the hybridisation of the unshared electron pair of the phosphorus atom and weaken the nucleophilic properties of the phosphorus atom compared with acyclic phosphorus(III) derivatives. The distinct tendency of 1,3,2-diheterophospholans to participate in "biphilic" processes with increase of the coordinate number of the phosphorus atom is due to the same causes.

The wide variety of the chemical reactions characteristic of organic phosphorus(III) compounds is supplemented in the case of the cyclic esters, ester-amides, and amides by reactions with ring expansion, "transcyclisation", and spirocyclisation. The comparative instability of the unsubstituted five-membered phosphacycloalkanes containing a phosphorus(III) atom ensures the occurrence of oligomerisation processes, which make these cyclic organophosphorus substances similar to bifunctional monomers.

Advances in the Chemistry of Amidines

V.G.Granik

The review surveys data published during the period 1971-1981 on the synthesis and physicochemical and chemical properties of various types of amidine systems. Particular attention has been devoted to the use of amidines in the synthesis of heterocycles.
The bibliography includes 259 references.

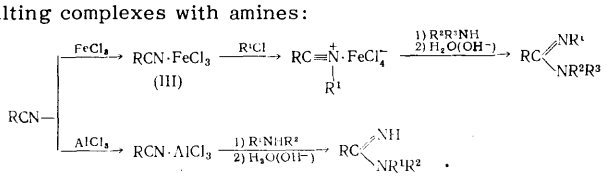
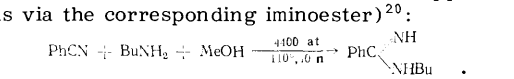
I. Introduction 377
II. Methods of synthesis 377
III. Structure and physicochemical properties 381
IV. Chemical properties 382

I. INTRODUCTION



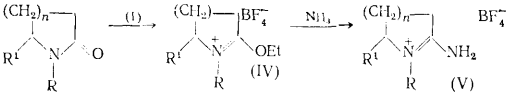
The chemistry of amidines has been recently attracting much attention by investigators in connection with their wide-scale employment in organic synthesis. The number of publications dealing with studies of the methods of synthesis and the properties of amidines has continuously increased and, despite the monograph published in 1975 [1] and a series of reviews dealing with various aspects of the chemistry of these compounds[2-7], most of the data published during the last decade have not been described in the review literature. The present review surveys new data on the synthesis, properties, and reactions of amidine systems of various types, particular attention being devoted to the application of amidines to the synthesis of heterocyclic compounds.

II. METHODS OF SYNTHESIS

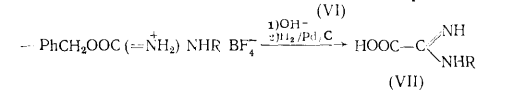


During the period considered, an extremely large number of studies dealing with the synthesis of various amidines were published. The traditional starting materials are nitriles, which are transformed into amidines via intermediate iminoesters. The latter are usually obtained by treatment with hydrogen chloride in alcohol and are then made to react with various amines[8-11]. Another method is based on the alkylation of nitriles with triethyloxonium tetrafluoroborate (I) followed by treatment of the nitrilium tetrafluoroborate salts (II) with amines[12,13]. A modification of this method involves the synthesis of nitrilium salts with the aid of methyl fluorosulphonate[14]:

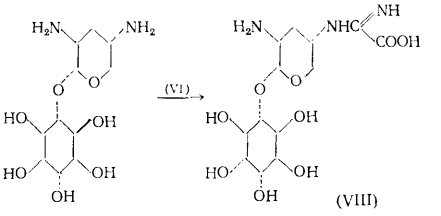
A general method of synthesis of various amidines is based on the reactions of nitriles with Lewis acids ($FeCl_3$ or $AlCl_3$ are usually employed)[15-19] followed by treatment of the resulting complexes with amines:



As can be seen from the scheme presented, the complexes of nitriles with iron(III) chloride can be alkylated by alkyl halides to form the corresponding *N*-substituted nitrilium salts, which can be transformed further into *N,N,N'*-trisubstituted amidines. An unusual method of synthesis of amidines at a high pressure is based on the reaction of nitriles with alcohols and amines (the reaction apparently proceeds via the corresponding iminoester)[20]:

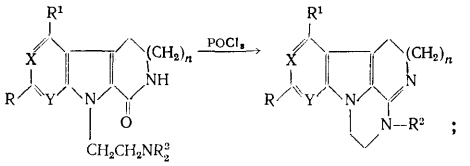


Nitriles can also interact with lithio-derivatives of arylamines[21]:



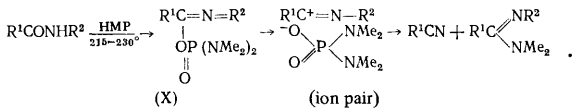
The synthesis of amidines from amides and thioamides is based on the preliminary activation of the amide functional group. Numerous reviews[22-27] dealing with such activation describe, in particular, also a considerable number of amidine syntheses. Such activation is usually achieved by alkylating amides with triethyloxonium tetrafluoroborate (or dimethyl sulphate)[12,28-30] or by acylation with reagents such as hexamethylphosphoramide (HMP),[31,32], phosphoryl chloride[33-35], phosphorus pentoxide[36], and acyl chlorides[37]. Thus the interaction of lactams with compound (I) [28] leads to the formation of the tetrafluoroborates (IV), which then readily react with ammonia to form amidinium salts (V). It is of interest to note that alkylation of 2-pyrrolidinone having a carbamoyl group in the 5-position [compound (IV, R = Me, $R^1 = CONH_2$, $n = 1$)] takes place selectively at the lactam carbonyl[28]:

The reaction involving compound (I) yielded the thioiminoester salt (VI)—the key compound in the method of synthesis of amidinoacids (VII):[29]



This method has been used in the synthesis of the antibiotic kasugamycin (VIII):[29]

It is of interest that only the equatorial amino-group reacts selectively with compound (VI).[29]



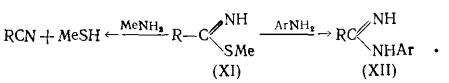
The activation of the amide functional group in tricyclic lactams of type (IX) made it possible to achieve their cyclisation to tetracyclic indole systems containing the amidine fragment[33,35]:

(IX)

X=Y=CH, R^1=R=H, X=Y=N, R^1=R=OH .

When amides are heated with HMP, nitriles and amidines are formed via the phosphorodiamidate derivative (X):[31]

(X) (ion pair)

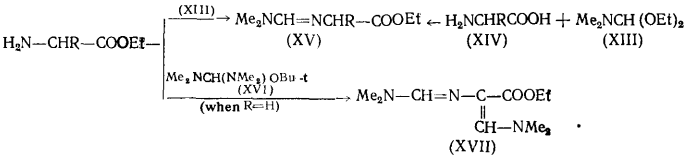


The reaction of an aromatic amine, formic acid, and HMP gives rise to amidines[32]:

$$ArNH_2 + HCOOH \xrightarrow{HMP} ArN{=}CH{-}NMe_2 .$$

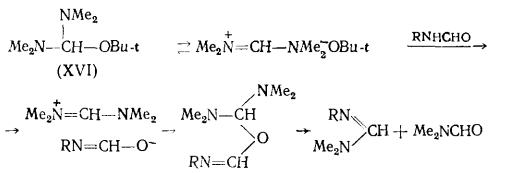
The interaction of acetanilides with dimethylformamide (DMF) in the presence of $POCl_3$, $SOCl_2$, PCl_3,[34] P_2O_5,[26] or *N,N*-diethylthiocarbamoyl chloride[37] leads to the corresponding amidines:

$$ArNHCOCH_3 + Me_2NCHO \xrightarrow{POCl_3\ (or\ PCl_3, SOCl_2, P_2O_5, Et_2NCSCl)} ArN{=}CH{-}NMe_2 .$$



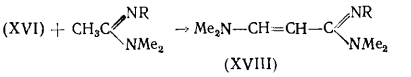
When thioiminoesters (XI) were used in the amidine synthesis, it was established that the esters react with aromatic amines to form the amidines (XII), while the reaction with highly basic amines proceeds with formation of nitriles[38]:

(XI) (XII)



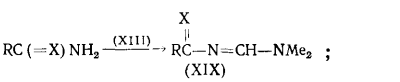
Schnur[38] was able to find a method of synthesis of amidines from compounds (XI) even with the aid of aliphatic amines, which makes it necessary to carry out the reaction in an acetate buffer solution.

Other types of activated amides—amide acetals, lactams, and related compounds, dichloromethyleneimmonium salts, and diethoxymethylammonium salts—are also widely used for the synthesis of amidines. The majority of studies of the amidine synthesis based on these compounds have been described in detail in reviews[25-27,39,40] and here we shall consider only those studies which were not included in the above reviews. A number of investigations were devoted to the synthesis of *N*-heteroarylamidines by the reaction of the acetals of DMF (XIII) and dimethylacetamide with heteroaromatice amines. Derivatives of *N*-pyrazinyl-2-formamidines[41], *N*-pyrimidinyl-2-formamidines[42], *N*-pyridyl-2-formamidines[42], *N*-purinyl-6-formamidines[43], *N*-pyrazolyl-3-formamidines[44], and *N*-pyrazolyl-3-acetamidines[44] were obtained via this procedure. The reaction of compound (XII) with aminoacids (XIV) is accompanied by alkylation and results in the formation of the amidinoesters (XV).[45] Compounds of the same type have also been obtained by the reaction of compound (XIII) with aminoacid esters[46]. When the more reactive aminal-ester (XVI) is used in this reaction, the enaminoamidines (XVII) are formed[46]:



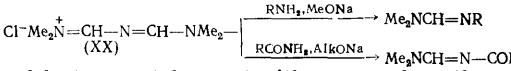
(XV) (XIV) (XIII) (XVI) (XVII)

The reaction of the aminal-ester (XVI) with secondary amides is of interest: *N,N*-disubstituted amides and amidines are formed in this instance. The authors suggested the following reaction mechanism[46]:



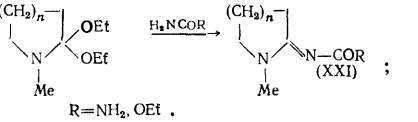
In the same study it was shown that the interaction of the aminal-ester (XVI) with acetamidine derivatives leads to the enaminoamidines (XVIII):[46]

(XVIII)



A series of studies have been published recently, according to which the acetal (XIII) readily reacts with primary amides and thioamides, which leads to the formation of acyl- or thioacyl-amidines (XIX)—interesting intermediates in various types of syntheses[47-49]:

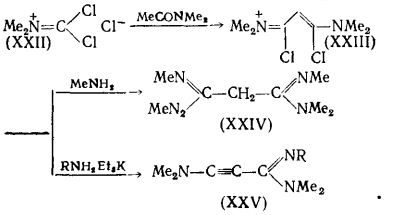
(XIX)



X = O, S .

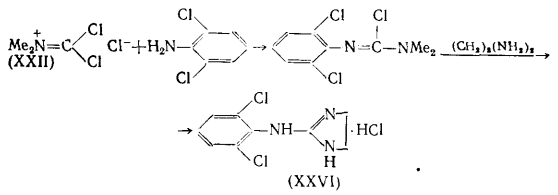
It has been shown[50] that the immonium salt (XX), obtained previously[51] by the reaction of DMF and cyanuric acid chloride, can be used successfully in the synthesis of amidines and acylamidines instead of the DMF acetal (XIII):

(XX)



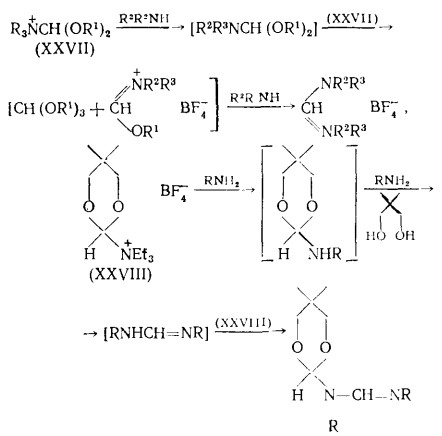
Amide and lactam acetals react with urea and urethane to form the corresponding *N*-carbamoyl- and *N*-ethoxycarbonylamidines (XXI).[52] We may note that the former form complexes with one or several urea molecules:

(XXI)



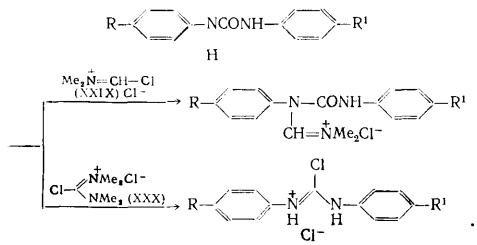
R=NH_2, OEt .

The interaction of dichloromethyleneimmonium chloride (XXII) with *N,N*-dimethylacetamide leads to the salt (XXIII) which can be converted into the diamidines (XXIV) or the ynaminoamidines (XXV), depending on the reaction conditions[53]:

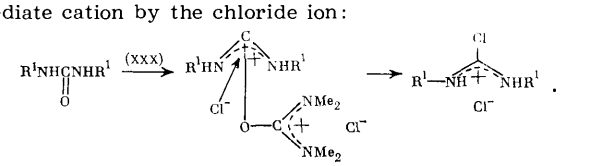


(XXII) (XXIII) (XXIV) (XXV)

A new synthesis of the valuable medicinal preparation clofelin (XXVI), based on the reaction of the immonium chloride (XXII) with 2,6-dichloroaniline involving the intermediate formation of chloroformamidine, was published recently[54]:

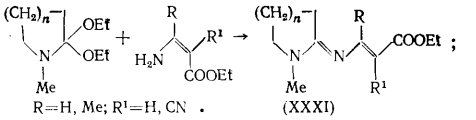


(XXVI)

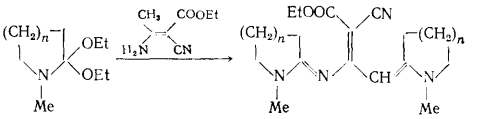


Certain chloroformamidines have been synthesised analogously from compound (XXIII) and different amines including heterocyclic amines[55,56]. A series of substituted formamidines have been synthesised by the reaction of the dialkoxymethylammonium salts (XXVII) and (XXVIII) with aliphatic amines[57,58]:

Processes involving the synthesis of formamidine derivatives by the reaction of diarylureas with chloromethylenedimethylammonium chloride (XXIX) and chlorodimethylaminomethylenedimethylammonium chloride (XXX) are closely related to the reactions described above[59]:



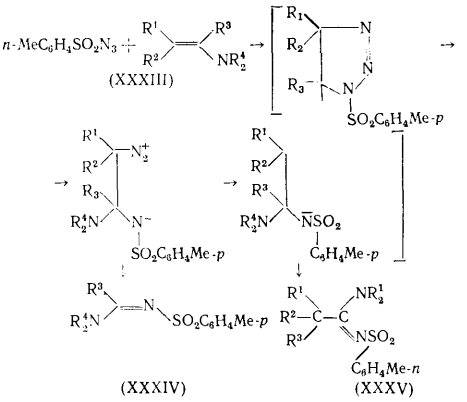
Tritschler and Kausz[57] believe that direct *N*-dimethylaminomethylenation takes place in the former case, while in the latter case it is impossible due to steric hindrance and the reaction involves oxygen with subsequent attack on the intermediate cation by the chloride ion:



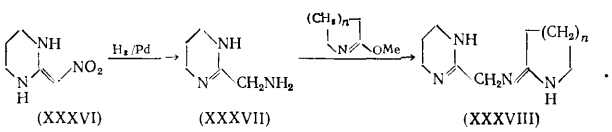
A number of pieces of experimental evidence supporting the above theoretical considerations have been published[59].

Amide and lactam acetals have also been used in the synthesis of an interesting class of organic compounds—enamidines, which have been used in a number of instances for the synthesis of condensed heterocycles (see below). The enamidines (XXXI) are formed readily and in high yields by the reaction of amide and lactam acetals with primary enamines[60,61], even weakly basic enamines such as aminomethylenecyanoacetic ester:

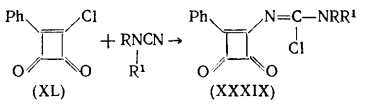
It is of interest to note that the reaction of amide and lactam acetals with β-amino-α-cyanocrotonic ester involves not only the amino-group but also the β-methyl group[61]:



Enamidines have also been synthesised[60,61] by the reaction of aryl cyanides with butyl-lithium or organomagnesium compounds[62,63]:

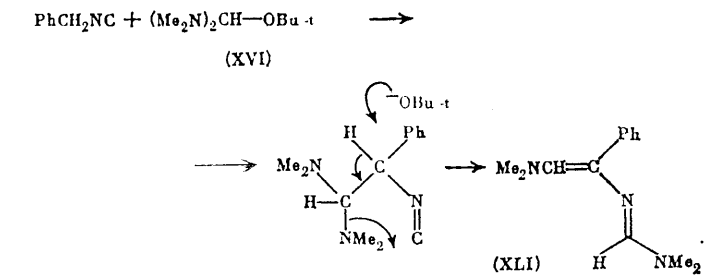


Substituted *sym*-triazines are formed as side products in this reaction[63]. Yet another mention of the synthesis of the enamidine (XXXII) has been made in a study[64] where it was obtained by the reaction of dimethyl acetylenedicarboxylate with formamidine at −10 °C:

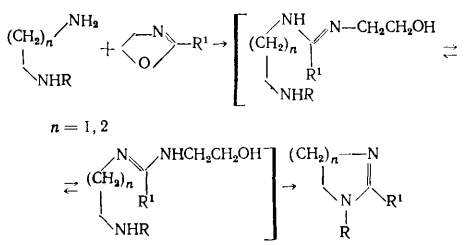


The reaction of the enamines (XXXIII) with toluene-*p*-sulphonyl azide proceeds in a very interesting manner—a mixture of the amidines (XXXIV) and (XXXV) is then formed[65]. It has been noted that, when R^1 and R^2 are alkyls (and not hydrogen atoms), the number of rearranged amidines (XXXV) increases, probably as a consequence of the ability of the alkyl group to stabilise the carbocationic centre:

Amidines (including cyclic amidines) can be obtained by the hydrogenation of nitroalkylenediamines (XXXVI). The bisamidines (XXVIII) have been synthesised from the aminomethylamidines (XXXVII) formed[66]:

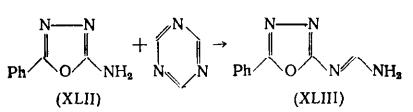


The reduction of carbodiimides with sodium tetrahydroborate[67] or of urea derivatives with lithium tetrahydroaluminate[68] leads to formamidine derivatives. Various formamidines can be synthesised from urea and thiourea derivatives. Thus chloroformamidines are formed when *N*,*N'*-dialkyl-*N*-heteroarylureas react with Ph_3P and CCl_4 [69] or on chlorination of *N*,*N'*-bis(arenesulphonyl)-*S*-methylisothioureas[70]. The chloroformamidine (XXXIX) is also formed on reaction of halogenocyclobutenedione (XL) with cyanamides[71]:



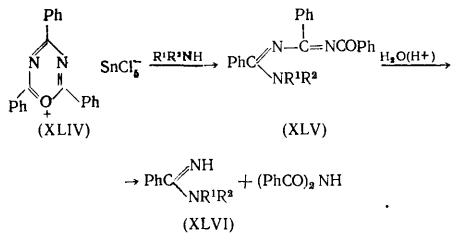
(XL) (XXXIX)

N-Hydroxyamidines have been obtained by the reaction of chloroimides with hydroxylamine[72,73] or by the reaction of substituted hydroximoyl chlorides with amines[74]. The reactions of isonitriles with sulphonamides[75], amines[76–78], and an aminal-ester[46] are used very frequently for the synthesis of amidines. One should note that it has been shown[76,77] that the reactions involving the addition of secondary amines to isonitriles take place stereospecifically with formation of *Z*-formamidines, which then rearrange to the thermodynamically more stable *E*-isomers. The interaction of the aminal-ester (XVI) with benzyl isocyanide involves the methylene unit with subsequent rearrangement[46] involving the formation of the amidine (XLI):

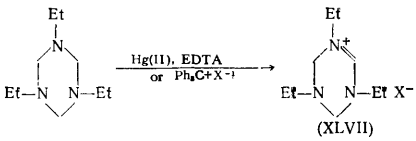


(XVI) (XLI)

A number of studies have been devoted to the synthesis of amidines using certain heterocyclic agents in the corresponding reactions. Thus the reaction of derivatives of ethylene- and propylene-diamines with Δ^2-1,3-oxazoline leads to cyclic amidines[79]:

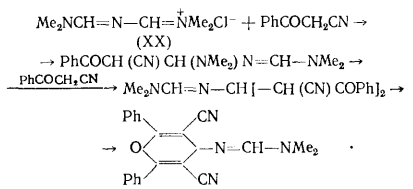


The reaction of 2-amino-5-phenyl-1,3,4-oxadiazole (XLII) with *sym*-triazine leads to the formamidine derivative (XLIII):[80]



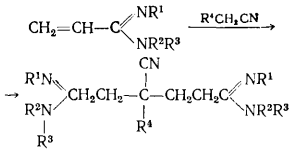
(XLII) (XLIII)

When 1,3,5-oxadiazinium salts (XLIV) react with amines, the products are *N*-(*N*-benzoylimino)benzylamidines (XLV), which hydrolyse in an acid medium to benzamidines (XLVI) and dibenzoylamine[81]:



(XLIV) (XLV) (XLVI)

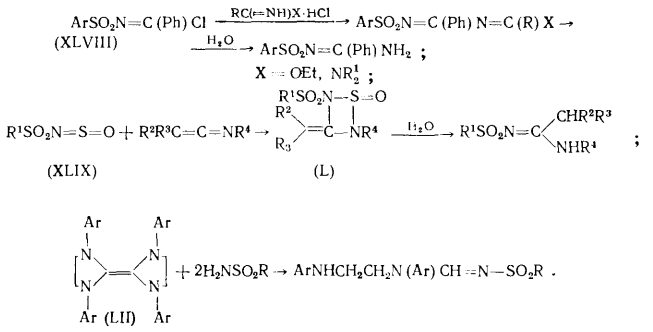
Cyclic amidinium salts (XLVII) can be obtained by oxidising *N*,*N'*,*N''*-triethylhexahydrotriazine or by treating it with $Ph_3C^+X^-$:[82]



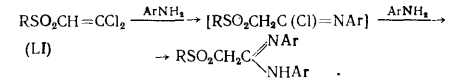
(XLVII)

It has been shown recently[83] that the immonium salt (XX) can be used to introduce the formamidine fragment into compounds with an active methylene unit:

It has been established in recent years that the amidinium group can be introduced into various organic compounds (amines, alcohols, compounds with an active methylene unit, and mercaptans) by the amidinoethylation reaction which is of the same type as the Michael reaction[84–87], for example:

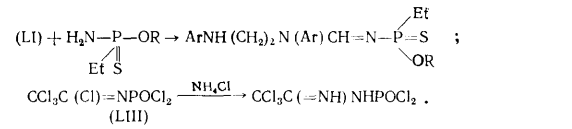


Derivatives of formamidine and homologous amidines are formed when alkali metal amides react with aldehydes in liquid ammonia[88] and *N*,*N'*-dimethylformamidine has been obtained by the thermal decomposition of potassium methylamide[89].



A series of studies have been devoted to the synthesis of amidines with sulphur-, phosphorus-, and silicon-containing substituents at the nitrogen atoms†. Thus sulphonylamidines have been synthesised by the reaction of arenesulphonylchloroimides (XLVIII) with iminoester (or amidine) hydrochlorides followed by the hydrolysis of the intermediate or imidoylamidines[90], by the reaction of *N*-sulphinylsulphonamides (XLIX) with keten imines via [2 + 2] cycloadditions

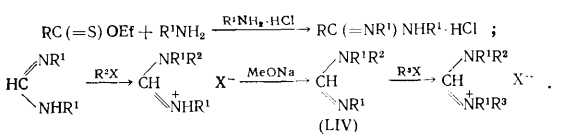
†See also the study[65] described earlier in this review, which was transferred to the section dealing with the synthesis of amidines from enamine compounds.



(L),[91] and by the reactions of sulphonamides with the ethylenetetramine (LI):[92]

The reaction of dichlorovinyl sulphones (LII) with aromatic amines takes place via the intermediate formation of chloroimides[93]:

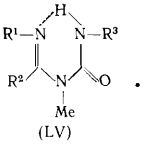
Phosphorus-containing amidines have been synthesised by the phosphorylation of the ethylenetetramine (LI) [92] and also by the reaction of the chloroimide (LIII) or related compounds with ammonium salts[94]:



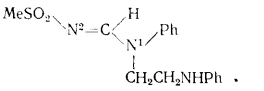
In addition, compounds of this type can be synthesised by the reaction of *N*-unsubstituted amidines with phosphorus halides[95,96]. *N*-Trimethylsilylamidines have been obtained analogously by the reaction of amidines with chlorotrimethylsilane; they are also formed in the reaction of trimethylsilylamine with butyl-lithium, followed by the treatment of the lithio-derivative with chloroimides[97].

Sulphinamidines, which are an interesting class of compounds, have been synthesised by the reactions of *N*,*N*-dichlorourea[98], *N*,*N*-dichloroamines[99], or *N*,*N*-dichloroamides of diphenoxyphosphoric acid[100] with sodium thiolates:

In conclusion of this section, we may point out two new syntheses of amidines, the first of which is based on the reaction of *O*-ethyl thioesters with amines in the presence of their hydrochlorides[101] and the second is based on the alkylation of di- and tri-substituted amidines[102]:

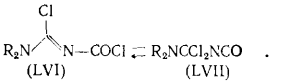


It is of interest that, when the trisubstituted amidines (LIV) are alkylated by the relatively unreactive alkyl halides, the alkylation may be accompanied by the abstraction of the elements of hydrogen halides from the alkyl halides to form the corresponding amidinium salts[101]:



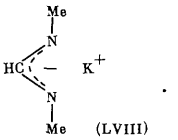
III. STRUCTURE AND PHYSICOCHEMICAL PROPERTIES

When the structure of amidines is considered, one must take into account the possibility of the prototropic "amidine" tautomerism due to proton transfer from one nitrogen atom to another. However, in many instances, it is possible to detect by physicochemical methods only one of the tautomeric forms. Thus it has been established by infrared spectroscopy for a series of cyclic amidines derived from 2-amino-Δ^1-piperideines that these compounds exist in the amino-form[103]. When there is an electron-accepting substituent at one of the nitrogen atoms, the tautomer in which the C=N bond is conjugated with this substituent usually predominates[75,95].



The study of the structure of *N*-carbamoylamidines (LV) by infrared spectroscopy made it possible to detect a strong intramolecular hydrogen bond in these compounds[104]:

The infrared spectra proved to be extremely useful also for the study of the hydrogen bonds between amidines and the solvent. Thus it has been established that formamidine derivatives form complexes of two types with chloroform: with participation of both the imino- and amino-nitrogen atoms[105], while in cyclic amidines[103] the hydrogen bond with $CHCl_3$ is formed only with participation of the ring nitrogen. Infrared spectra have also been used to elucidate the character of the coordination in boramidines[106]. The problem of the relative position of the substituents with respect to the C=N bond in amidines has attracted much attention. The *syn-anti* isomerisation in amidines of various types has been studied[107,108] by ^{1}H NMR. In the investigation of the addition of secondary amines to isonitriles[76,77] the authors concluded that *Z*-formamidines are formed initially and, being thermodynamically unstable, then rearrange to the *E*-isomers#. On the other hand, it has been stated[92] that stable *Z*- and *E*-isomeric *N*-sulphonylamidines have been isolated. However, subsequently, in a detailed study of their structures by infrared spectroscopic, ^{1}H NMR, and ^{13}C NMR methods, it was established that the substances isolated are rotational isomers relative to the C–N^1 bond[110]:



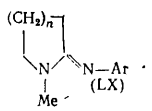
Interesting data have been obtained in a study[111] of the structure of *N*-chlorocarbonylchloroformamidines (LVI)—it was established that they are in equilibrium with the corresponding *N*,*N*-dialkylamino-1,1-dichloromethyl isocyanates (LVII):

A series of studies have been devoted to the hindered rotation relative to the C=N bond in amidines by ^{1}H NMR [108, 112–117]. The free energies of activation for the process ($\Delta G^{\neq}$) are usually not unduly high and, depending on the amidine structure, vary in the range 11–21 kcal mol^{-1}, the

#The assignment of amidines to the *Z*- or *E*-series can also be achieved by ^{13}C NMR.[109]

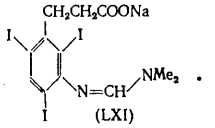
values for amidinium salts being appreciably higher[108]. It is of interest that the phenomenon of hindered rotation relative to the C=N bond could not be observed for the potassium salt of the amidine (LVIII):[112]

(LVIII)



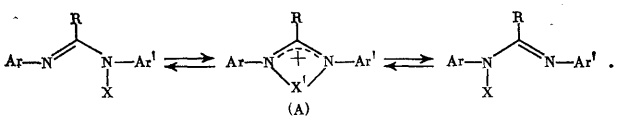
We may note that the "amidine" tautomerism was investigated in the same study by ^{1}H NMR and the thermodynamic parameters of the tautomeric equilibrium were obtained[112].

The position of the tautomeric equilibrium was estimated quantitatively by ultraviolet spectroscopy and by comparing the ionisation constants of certain amidines and model compounds[118,119]. It was shown that the equilibrium



(LIX)

involving the amidines (LIX), where Y is an electron-accepting substituent, is significantly displaced to the right and that $K_T \cong 30$ for Y = acyl and $K_T \cong 10^7$ for Y = SO_2R.[118] If Y is a substituted phenyl group, the equilibrium is not displaced quite so much and $K_T = 2.4$.[119] The ionisation constants of a series of cyclic amidines have been measured[120–122] and it has been shown that the pK_a depend significantly on the ring size§ and that the basicity decreases in the sequence $C_6 > C_7 > C_8 \cong C_5$.[122] The authors explain this phenomenon by conformational factors—for the six-membered ring there is a possibility of a planar configuration of the amidine fragment, which is energetically unfavourable for the five-, seven-, and eight-membered compounds due to the non-bonding interactions of the protons in the ring methylene groups[122]. The study of the ionisation constants of a series of amidines and of the correlation between the pK_a and the σ constants[124,125] led the authors to the conclusion that the values of ρ and in general the basicity of the amidines depend to a greater extent on the substituents at the imino-nitrogen atom than on the substituents at the amino-atom. The study of the protonation of 2-arylimino-1-azacycloalkanes (LX) showed[126] that it involves the exocyclic, imino-nitrogen atom:



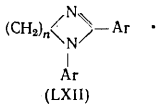
(LX)

The amidines (LX) are extremely strong bases (pK_a = 6.5–9.6), whose basicity also depends on the ring size[123,126]. On the basis of correlation analysis involving a comparison of the pK_a with the σ and σ^- constants, it was established in the above studies that the arene ring has been rotated relative to the C=N bond by approximately 50–60 °C. A similar rotation of the heteroaryl residue apparently occurs also in derivatives of *N*-(3-pyrazolyl)-amidines[44]. The high basicity of amidines is used in analytical chemistry for their quantitative analysis—one of the methods of analysis¶ of the radiocontrast agent bilimin (LXI) is its titration with $HClO_4$ in acetic acid[127]:

(LXI)

As already stated, the "amidine" tautomerism is due to proton transfer from one nitrogen atom of the triad to another. The 1,3-transfer of various groups within the amidine system, which has been studied by dynamic ^{1}H NMR [134–138] and by quantum-chemical calculations[139], is closely related to tautomerism of this type:

(A)



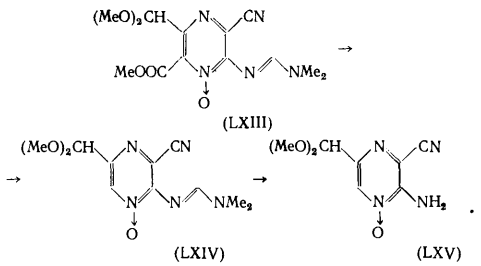
This reversible process has been studied for various substituents (X = acyl[134,138], 2,4-dinitrophenyl and picryl[135,138], or suphenyl[136,137]). Special experiments[134] estalbished that the 1,3-transfer process is intramolecular.

The energetic characteristics of the process depend on the structure of X and also on the structure of the substituents R, Ar, and Ar'. It is significant that the activation entropy $\Delta S^{\neq}$ for X = acyl is small and positive and that in such cases (A) is not a transition state but an intermediate. On the other hand, when X = SR^1, we have $\Delta S^{\neq} = -14$– -24 e.u., so that the transition state is more ordered than the ground state, which agrees with a structure of type (A). In the ^{1}H NMR studies of acyl- and sulphenyl-amidines at low temperatures, hindered rotation relative to the N–CO and N–S bonds respectively was observed.

IV. CHEMICAL PROPERTIES

1. Reactions With Nucleophiles and Electrophiles

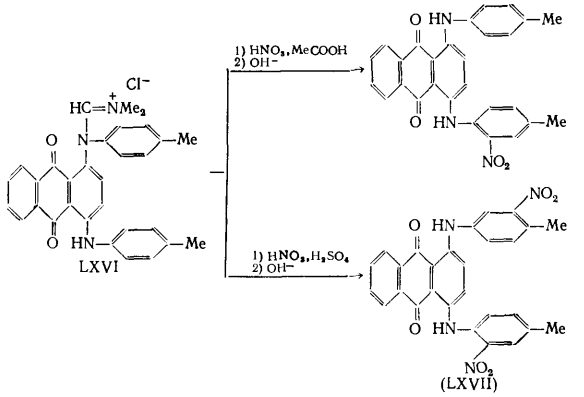
The simplest reaction of amidines or their salts with nucleophiles is their hydrolysis. The mechanism of the hydrolysis of amidines was studied in detail in a monograph[1] and new investigations[121,122,140] did not introduce significant changes into the existing ideas. Examination of the question of the influence of ring size on the rate of alkaline hydrolysis of the cyclic amidines (LXII) [122,123] enabled the authors to establish the following sequence of decreasing rate constants: $C_5 > C_6 > C_7 > C_8$:[122]



(LXII)

The authors attributed the highest rate of cleavage of compound (LXII, n = 2) to the strain in the five-membered ring, while the low rate of hydrolysis of seven- and eight-membered amidines is caused in their view by steric hindrance to the

§ For a review of the dependence of the properties of organic compounds on ring size, see Granik[123].



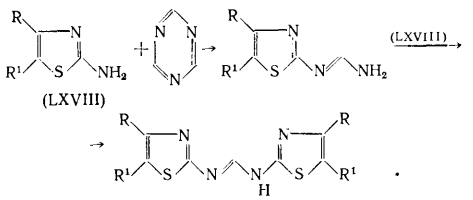
¶ In general amidines can be analysed quantitatively most effectively by titrating them as monoacidic bases. A study has been published recently[128], according to which certain amidines can also be analysed by gas–liquid chromatography (GLC).

attack by the hydroxide ion on these rings[122]. Comparison of the rates of the acid and alkaline hydrolysis of *N,N'*-dimethylformamidine showed that in an alkaline medium the process is significantly faster. An interesting study[41] of the conditions governing the retention and cleavage of the amidine group on hydrolysis as a function of the synthetic aim has been published recently. Thus it has been possible to hydrolyse selectively (and then decarboxylate) the methoxycarbonyl group of the substituted pyrazine (LXIII) without affecting the amidine group, by refluxing a solution of this compound in moist pyridine in the presence of lithium iodide. On the other hand, in the next stage it was necessary to remove selectively the formamidine group without involving the acetal group. The usual method, involving treatment with aqueous ammonia, proved to be unsuitable, since closure of the pyrimidine ring was observed under these conditions; acid hydrolysis in aqueous solution was also impossible owing to the dissociation of the acetal protecting group:

(LXIII) (LXIV) (LXV)

Taylor and Dumas[41] found an unexpected solution and obtained the amino-derivative (LXV) by keeping the formamidine (LXIV) in the 1:1 MeOH–$CH(OMe)_3$ mixture in the presence of $TsOH.H_2O$. In the case considered above, in order to protect the amino-group the latter was transformed into the formamidine group. This type of protection made it possible to solve the problem of the synthesis of mononitro- (or monobromo- and mono-*N*-acyl) derivatives of anthraquinone (LXVI):[141–143]

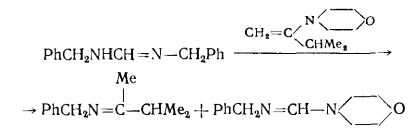
LXVI (LXVII)



The use of an amidinium protecting group with its subsequent hydrolysis permitted the synthesis of derivatives of type (LXVII), which are extremely difficult to obtain by other methods and which have *o*- and *m*-substituents in the symmetrical aryl substituents in the 1,4-positions in the anthraquinone ring[141]. The hydrolysis of the amidine fragment was the concluding stage in a new synthesis of imides[49]:

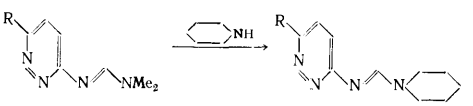
$$RCON{=}C(R^1)NMe_2 \xrightarrow{H_2O(MeCOOH)} RCONHCOR^1 .$$

The discussion of investigations of this kind must be completed by stating that the hydrolysis of cyclic amidines is a model reaction for the investigation of the enzymic transfer of single-carbon components[144,145]. This problem has been reviewed[146]. One of the extremely important reactions of amidines or their salts with nucleophiles, which is used as one of the stages in heterocyclic synthesis (see below), is the transamination reaction. The synthesis of *N,N'*-disubstituted amidines by means of this reaction has been described recently[147]:



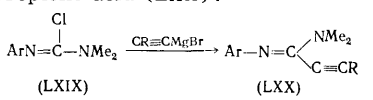
$$RC(=\overset{+}{N}H_2)NH_2Cl^- \xrightarrow{R^1NH_2} RC(=\overset{+}{N}HR^1)NH_2Cl^- \xrightarrow{R^1NH_2} RC(=\overset{+}{N}HR^1)NHR^1Cl^- .$$

The interaction of heterocyclic amines [for example, compound (LXVIII)] with *sym*-triazine is also accompanied by transamination[148]:



(LXVIII)

The reaction of amidines with tertiary enamines is extremely interesting—here too the final result is transamination[149]:

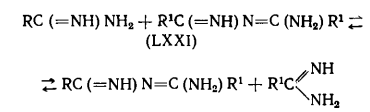


On heating, secondary amines are also capable of undergoing reactions of this type[150]:

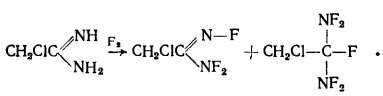
The study of the properties of *N*-anthraquinonylformamidines showed that they react with nucleophiles only in the protonated form[151]. Studies of the transamination of enamidines established that, instead of involving the amidine meso-carbon atom, the reaction takes place at the enamine α-position with formation of enamines (and not pyrimidines as might have been expected)[152]:

$$Me_2N{-}CH{=}N{-}CH{=}C(CN)COOEt \xrightarrow{RR^1NH} RR^1N{-}CH{=}C(CN)COOEt$$

Substituted chloroformamidines readily react with nucleophiles, forming guanidines of various types[55,56,71], urea derivatives[70], and *O*-alkylisoureas[154]. The interaction of the amidines (LXIX) with ethylmagnesium bromide leads to amidines of propiolic acid (LXX):[155]



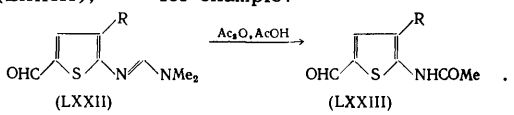
(LXIX) (LXX)



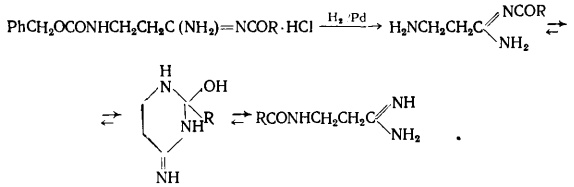
On treatment with sodium alkoxide at low temperatures, *N,N,N'*-trifluoroamidines yield a mixture of *N*-fluoroiminoesters and esters[156]:

$$RC(=NF)NF_2 \xrightarrow{EtONa,EtOH} RC(=NF)OEt + RCOOEt .$$

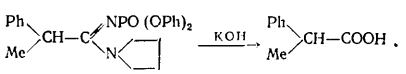
When amidines react with fairly strong C-acids, salts are formed[157]. The reaction is of first order with respect to both components. However, when the deutero-analogue of the C-acid instead of the C-acid itself is introduced into the reaction, complex kinetics, induced by numerous isotope exchange processes, are observed[157]. The exchange reactions involving imidoylamidines (LXXI) have been investigated by ^{19}F NMR,[158,159] for example:



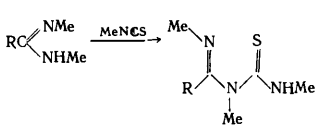
Among the reactions of amidines with electrophiles investigated in recent years, we may mention in the first place fluorination, which occurs mainly with formation of *N,N,N'*-trifluoro-derivatives[160], although in some cases products of the addition of fluorine to the C=N bond have also been isolated[160]:



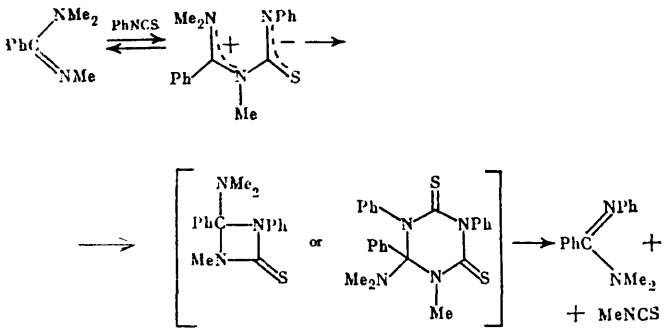
A series of investigations of the acylation of amidines have been made. *N*-Monosubstituted amidines are acylated by acyl chlorides at the substituted nitrogen atom[161]:



The acylation of *N*-heteroaryl-*N,N'*-dimethylformamidines (LXII) results in the formation of the corresonding acylamides (LXXIII),[42,162] for example:



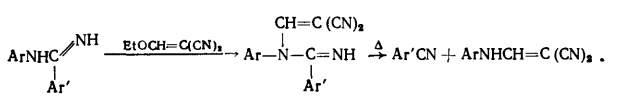
The acylation of compounds containing simultaneously the amino- and amidino-groups has been studied and an analytical method has been developed whereby it is possible to determine the position of the acyl group[163]. The observation[163] that the acyl group is transferred in acylaminoamidines is extremely interesting:



The acylation of *N*-dichlorophosphonylamidines by acyl chlorides takes place at the unsubstituted nitrogen atom[94]. Compounds substituted at a nitrogen atom by the $PO(OEt)_2$, PCl_3, and PCl_4 groups have also been synthesised by the reaction of amidines with triethyl phosphite[164] and phosphorus pentachloride[165,166]. Amidines substituted at a nitrogen atom by the phosphoric acid residue have served as starting materials in a new synthesis of substituted acetic acids[167]:

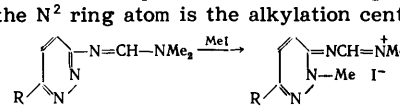
The interaction of amidines with alkyl isothiocyanates results in the formation of *N*-thiocarbamoylamidines[168,169]:

On the other hand, the exchange reaction

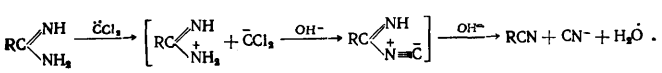


takes place when *N,N,N'*-trisubstituted amidines interact with aryl isothiocyanates[170]. The hypothesis of stringent steric requirements which must be met by the transition state is confirmed by the high negative entropy of activation (−36.1 e.u.).[170]

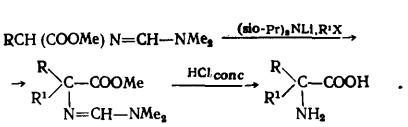
The study of the synthesis of fluorinated imidoylamidines by the reaction of amidines with nitriles is closely related to the above investigations[171]:



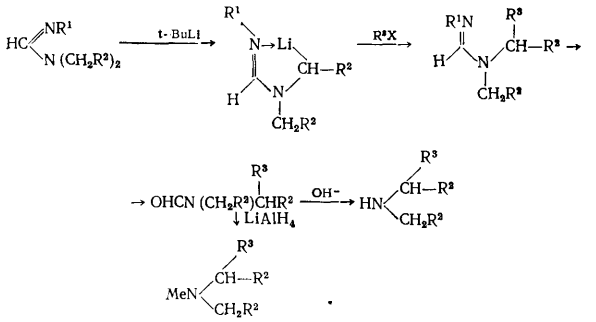
where R_F and R_F^1 are fluorinated groups. It is noteworthy that this reaction is extremely sensitive to the steric factor and that its rate decreases sharply with increase in the bulk of R_F^1.[171]



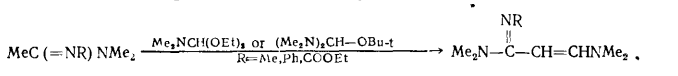
In a few studies of the alkylation of amidines having the NH group it has been shown that the reaction usually proceeds fairly smoothly. This is observed in the interaction of amidines with propiolic acid ester[172], alkyl halides[173] (in the latter case lithium salts of amidines have also been used), and ethoxymethylenemalononitrile[172,174]. We may note that the enamidines thus formed are cleaved to enamines and nitriles on heating[174]:



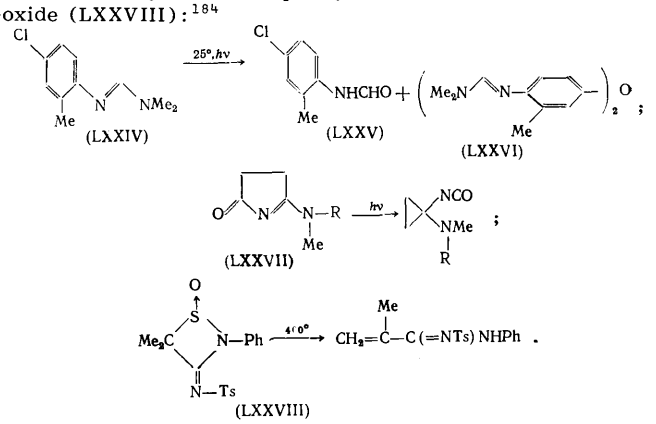
The alkylation of *N,N*-dimethyl-*N'*-(3-pyridazinyl)formamidine by methyl iodide takes place in an interesting manner—in this case the N^2 ring atom is the alkylation centre[150]:



Dichlorocarbene also attacks amidines at the unsubstituted nitrogen atom—the final result of the reaction (appearing under the conditions of phase-transfer catalysis) is a nitrile and a cyanide ion[175]:



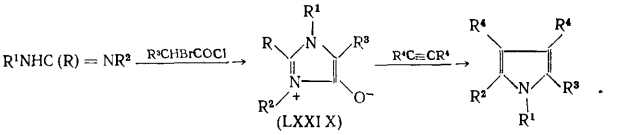
A new method of synthesis of α-substituted aminoacids based on the alkylation of *N,N,N'*-trisubstituted amidines has been published recently[45]:



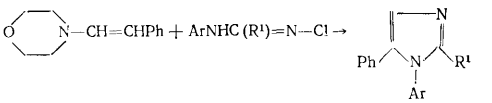
A new method of synthesis of α-substituted amines is also based on an analogous principle[176]:

In the studies of the reactions of amidines with electrophiles discussed above, the process involved either a nitrogen atom or a carbon atom of an alkyl group attached to a nitrogen atom. The possibility of the substitution of the protons of the methyl (methylene) group attached to the amidine meso-carbon atom† follows from a comparison of the electron-accepting influences of the iminoester and amidine functional groups[177]. The ability of amidines of type (LX) (see Section III above) to react with electrophiles at the α-$CH_3(CH_2)$ groups was first demonstrated in relation to the deuterium exchange reaction[177]. It was established that compounds (LX) exchange the ring α-protons for deuterons under mild conditions (CD_3OD, 20 °C) and that the exchange is accelerated in the presence of acid and basic catalysts[177]. The ring α-protons of enamidines (XXXI) (see Section II above) are also exchanged for deuterium albeit under more severe conditions[60]. A series of studies demonstrating that amide acetals and aminal-esters are capable of condensing via the methyl (methylene) group attached to the amidine meso-carbon atom have been published recently[46,52]:

In conclusion of this section, we may point to studies of the photolysis of *N*-(*p*-chloro-*o*-methylphenyl)-*N'*,*N'*-dimethylformamidine (LXXIV), which is converted into the corresponding formyl derivative (LXXV) and the bisamidinoester (LXXVI) on ultraviolet irradiation in water[182], the photochemical rearrangement of the cyclic amidine (LXXVII),[183] and the thermolysis of 3-sulphonylimino-1,2-thiazetidine 1-oxide (LXXVIII):[184]

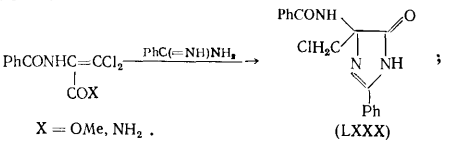


†This principle of the introduction of substituents into the α-$CH_3(CH_2)$ group, called the "principle of potential enaminisation", was also used in the study of the reactions of amide and lactam acetals and also various types of enamines with electrophiles and proved to be the most effective when applied in heterocyclic synthesis (see, for example, Refs.178–181).

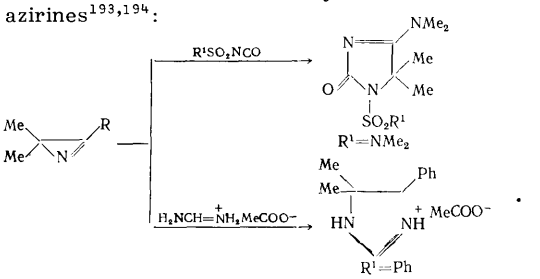


2. Heterocyclisation Reactions

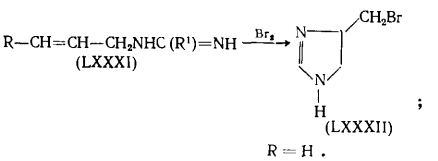
The synthesis of heterocycles using amidines is also based on their reactions with electrophiles or nucleophiles. However, bearing in mind the importance of this field of study, we thought it useful to consider the heterocyclisation reactions separately in their own section of the review.



Amidines have been the starting materials for the synthesis of a large group of five-membered heterocycles. Thus 2-dialkylamidino-2,4,5-triphenyl-2,3-dihydro-3-pyrrolones have been synthesised by the reaction of *N*,*N*-dialkylbenzamidines with diphenylcyclopropenone[185]. A number of studies have been made on the synthesis of the mesoionic compounds (LXXIX), which are converted into pyrroles on treatment with acetylenic derivatives[186–188]:

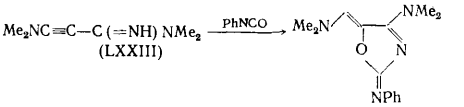


When tertiary enamines react with *N*-chloroamidines, imidazole derivatives are formed[189–191]:

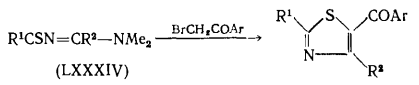


The imidazolones (LXXX) have been obtained by the reaction of α-carbamoyl (or ethoxycarbonyl)-β,β-dichloroenamides with amidines[192]:

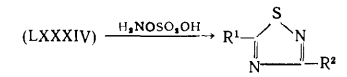
Imidazole derivatives have also been synthesised from substituted azirines[193,194]:



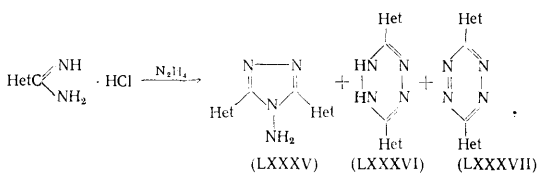
It has been established recently that the amidines (LXXXI), having an unsaturated group in the side chain, can be converted into the imidazolines (LXXXII):[195]



We may note that, when R = Ph in compound (LXXXI), tetrahydropyrimidine derivatives are formed[195].

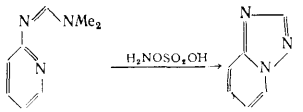


The reaction of ynaminoamidines (LXXXIII) with carbon dioxide or phenyl isocyanate has been used to synthesise oxazole derivatives[53]:

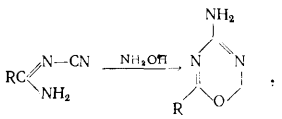


A preparatively convenient method of synthesis of substituted thiazoles is based on the reaction of thioacylamidines (LXXXIV) with α-bromoketones[196,197]:

The amidines (LXXXIV) are also used to synthesise thiadiazoles[48]:

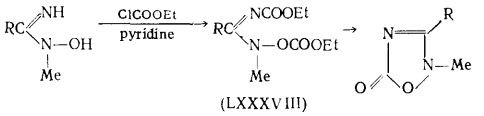


The same principle has been applied in the synthesis of triazole[47,52] and oxadiazole[47] derivatives: in these cases *N*-acylamidines[47] or *N*-ethoxycarbonylamidines[52] were made to react with hydrazine[47,52] and hydroxylamine[47]. An interesting synthesis of *N*-aminotetrazoles (LXXXV) and the tetrazines (LXXXVI) and (LXXXVII) is based on the interaction of heteroarylamidines with hydrazine[198]:



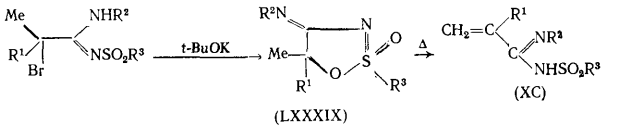
(LXXXV) (LXXXVI) (LXXXVII)

where Het = 2-furyl, 2-thienyl, 3-furyl, 3-thienyl, 2-selenophenyl, or 3-selenophenyl.



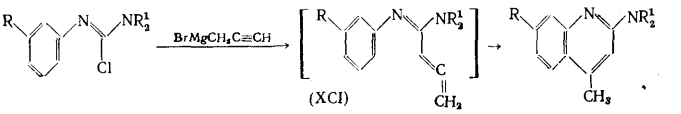
A new synthesis of condensed triazoles from *N*-(2-pyridyl)- and *N*-(1-isoquinolinyl)-formamidines has been published recently[199]:

N-Hydroxy- and *N*-cyano-amidines have been used in the synthesis of oxadiazoles[200]: in the former case amidines are made to react with bromocyanogen or trichloroacetic anhydride and in the latter with hydroxylamine:



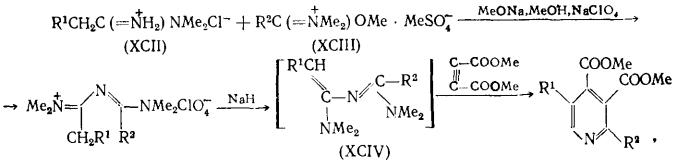
Another method of synthesis of oxadiazoles from *N*-hydroxyamidines consists in their interaction with chlorocarbonic ester and subsequent intramolecular cyclisation of the intermediate *O*,*N*-bisacyl derivative (LXXXVIII):[201]

(LXXXVIII)



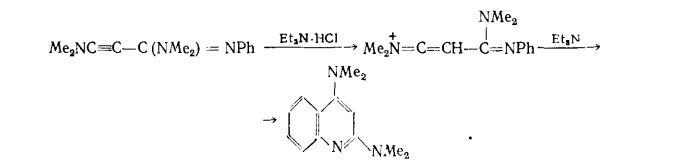
The conversion of α-bromo-*N*-sulphonylamidines into oxaisothiazolines (LXXXIX), which isomerise on heating to the enamidines (XC), has also been described[202]:

(LXXXIX) (XC)



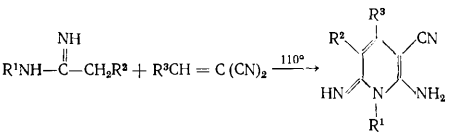
The employment of amidines in the synthesis of various six-membered, particularly pyridine, pyrimidine, and triazine, systems is even more promising.

The closure of the pyridine ring was achieved on reaction of chloroformamidines with ethynylmagnesium bromide or propargylmagnesium bromide[155]. In the latter case the process apparently proceeds via the intermediate formation of the allene (XCI):

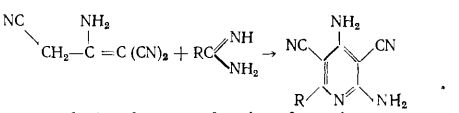


(XCI)

The reaction of the amidine salt (XCII) with the methyl sulphate complex (XCIII), followed by treatment of the intermediate enaminoamidine (XCIV) with acetylenedicarboxylic ester, also leads to the formation of a pyridine derivative[203]:

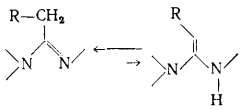


(XCII) (XCIII) (XCIV)

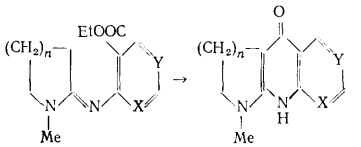


It has likewise been shown that the presence of the triple bond in the substituent at the meso-carbon atom of the amidine also makes it possible to achieve intramolecular cyclisation with formation of quinoline derivatives[204]:

A number of studies have been devoted to the synthesis of pyridines by the reactions of amidines with ylidenemalononitriles[205,206]:

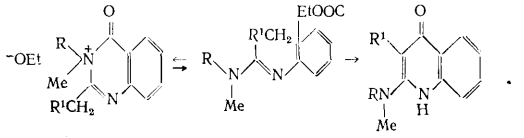


A reaction of a similar type also takes place between formamidine or acetamidine and the malononitrile dimer—in this case tetra- or penta-substituted pyridines are also formed[42]:

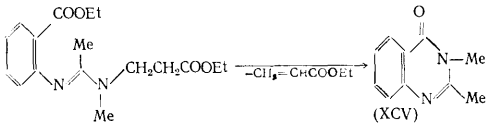


Another approach to the synthesis of various types of pyridine-containing heterocycles is based on the principle of potential "enaminisation" mentioned above (Section IV, subsection 1). The significance of this principle consists in the fact that the protons of the $CH_2(CH_3)$ groups attached to the amidine *meso*-carbon atom are fairly acidic and under certain conditions can be split off, creating thereby the basis for electrophilic substitution, for example, for deuterium exchange (see Section IV, subsection 1) or intramolecular cyclisations. There is then a possibility of the intermediate formation of enamines, although their appearance has not been detected experimentally#:

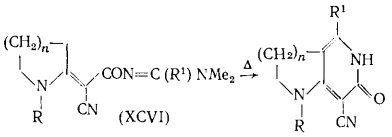
#In the study of the synthesis of pyridazines, definite evidence has been obtained quite recently in support of the occurrence of such amidine–enediamine tautomeric equilibrium (see below).



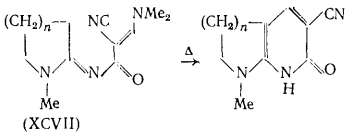
A number of syntheses of 4-pyridones, 4-quinolones and derivatives of pyrrolo-, pyrido-, and azepino-quinolines, pyrrolo-, pyrido-, and azepino-naphthyridines, and pyrrolo-, pyrido-, and azepino-pyrido[2,3-*d*]pyrimidines have been achieved using this approach[60,207-212]:



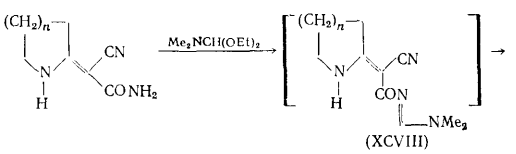
X=Y=CH; X=N, Y=CH, X=Y=N.



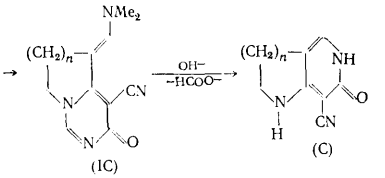
Reversible cyclisation at a nitrogen atom of the amidine system apparently takes place initially and the equilibrium is then displaced to the right as a result of the irreversible formation of a pyridone:



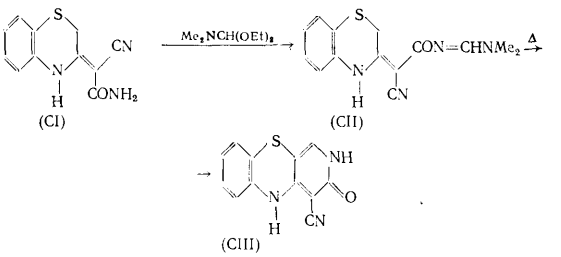
This hypothesis has been confirmed by the observation[209] that, when the substituent R can be split off in the form of a stable molecule, the only reaction product formed is a quinazolone derivative (XCV):[209]



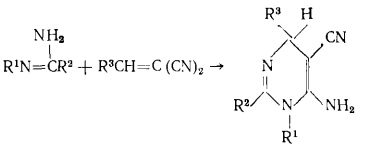
Enaminoacylamidines (XCVI) and (XCVII) proved to be an extremely promising class of compounds for the synthesis of various condensed pyridines[213-218]:

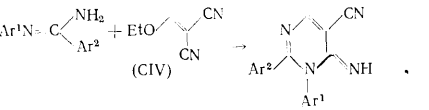


R=Me, $PhCH_2$, R¹=H, Me

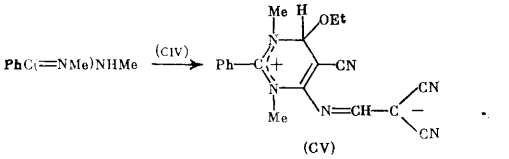


A study of the kinetics of both types of reaction showed that the rate of cyclisation is many times higher for compounds (XCVI) than for compounds (XCVII),[216] which corresponds to a more effective delocalisation of the positive charge in the amidine system compared with the enamine system. Enaminoacylamidines (XCVIII) are intermediates also in a new pyrimidine synthesis[215,217,219-223]:



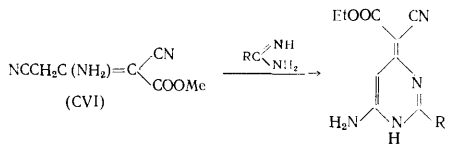


It is of interest that condensed pyrimidines (XCIV) behave similarly to cyclic amidines (see Section IV, subsection 1) and readily hydrolyse in an alkaline medium with elimination of formic acid[219,220] and recyclisation to 2-pyridone derivatives (C).[217,219-222] When the enaminoamide (CI) obtained from 2-benzothiazinone was used in the reaction, it was found that the intermediate acylamidine (CII) cyclises on heating to pyridobenzothiazine (CIII) and not to a pyrimidine derivative[223]:



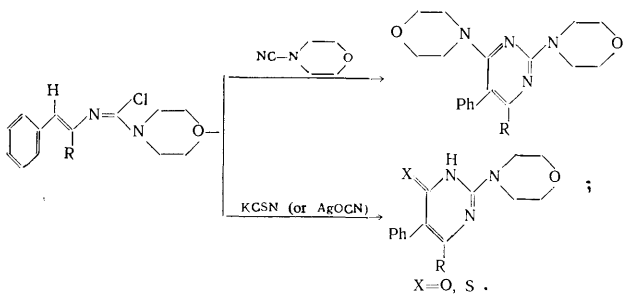
Pyrimidine derivatives are formed smoothly on interaction of amidines with various three-carbon components, such as dicarbonyl[224] and enaminocarbonyl[225,226] compounds as well as acetylenedicarboxylic ester[64]. Substituted pyrimidines are also formed when amidines react with various derivatives of 4-benzopyrone[227-229] or pyrylium salts[230]§. The reaction of amidines with ylidenemalononitriles leads to dihydropyrimidines[232,233]:

It has been shown[174] that the reaction of amidines having a primary amino-group with ethoxymethylenemalononitrile (CIV) takes place in the usual manner with formation of 4-iminopyrimidines:



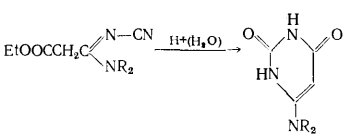
However, compound (CIV) reacts differently with *N*,*N'*-disubstituted amidines and the reaction product is in this case the zwitterionic 1:2 adduct (CV):[172]

(CV)



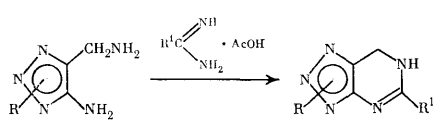
§ For a review of the transformations of oxygen-containing rings into pyrimidines under the influence of amidines (and guanidines), see Takagi and Hubert-Hebart[231].

The interaction of the codimer of malononitrile and cyanoacetic ester (CVI) with benzamidines and acetamidines (but not with formamidine—pyridines are formed in this instance) leads to derivatives of 4-methylenepyrimidine (CVII):[42]

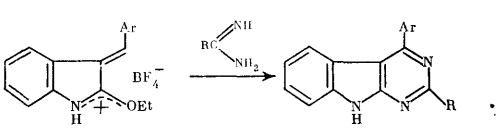


(CVI) (CVII)

Substituted chloroformamidines can be used successfully to synthesise substituted pyrimidine derivatives[234]. For this purpose, they are made to react with derivatives of cyanamide, silver isocyanate, or potassium isothiocyanate:

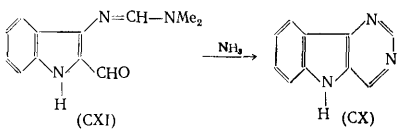


X=O, S.

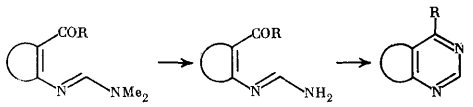


The salts of enaminoamidines can also serve as a source of pyrimidines, both directly (via their reaction with amidines[6]) and after their conversion into enaminoamidines of type (XCIV) (see above) followed by treatment with phenyl isothiocyanate[203]. A new synthesis of pyrimidine-2,4-diones by the intramolecular cyclisation of *N*-cyanoamidines has been published recently[235]:

Certain amidines have been used recently[236] as single-carbon components in the synthesis of condensed pyrimidines:

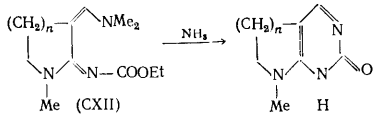


The presence of the amidine and carbamide functional groups in neighbouring positions ensures the possibility of the closure of the pyrimidine ring on interaction with formamide[237]. Pyrimidoindoles (CVIII) have been synthesised successfully by the reaction of amidines with tetrafluoroborate complexes (CIX):[238,239]



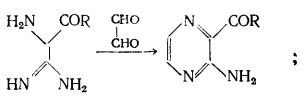
(CIX) (CVIII)

Pyrimidoindoles of another type (CX) have been synthesised by the reaction of the indolylamidine (CXI) with ammonia, primary amines, and hydroxylamine[240], for example:



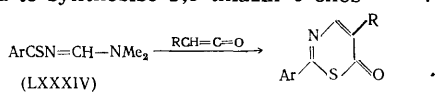
(CXI) (CX)

The first stage in pyrimidine synthesis of this type is usually transamination with subsequent cyclisation involving the participation of the adjacent carbonyl-containing group:



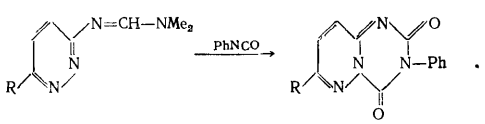
Anthrapyrimidines[151], pyrazolopyrimidines[152], and pyridopyrimidines[211] have been obtained by this method. A new synthesis of pyrimidines and derivatives of pyrrolo-, pyrido-, and azepino-[2,3-*d*]pyrimidines is based on the reaction of enaminoamidines of type (CXII) with ammonia[52]:

Me (CXII) Me H



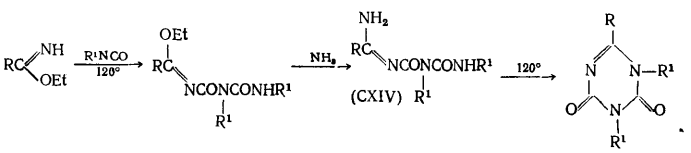
The aminoamidines (CXIII) have proved to be convenient starting materials for the synthesis of 2-amino-3-ethoxycarbonylpyrazines—important intermediates in the synthesis of pteridines[241,242].

(CXIII)



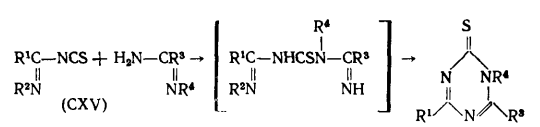
R=OEt, NH_2.

The *N*-thioacylamidines (LXXXIV) already mentioned above have been used to synthesise 1,3-thiazin-6-ones[197,243]:

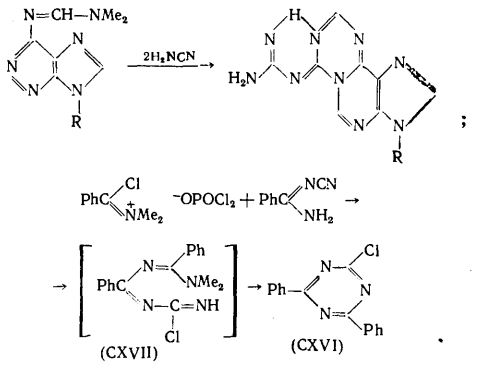


(LXXXIV)

Numerous studies have been devoted to the synthesis of triazine derivatives from amidines. The main bulk of these syntheses are associated with the use of various isocyanates and isothiocyanates, for example, phenyl isocyanates, as the second reaction component[150,244]—in these cases *N*-heteroarylamidines were introduced into the reaction:



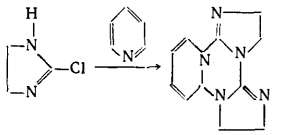
[1,2]-Adducts (triazinediones or triazinedithiones) are also formed when amidines react with benzenesulphonyl isocyanate[168] or methyl isothiocyanate[168,169]. The study of the synthesis of triazine derivatives by the intramolecular cyclisation of the amidine (CXIV), obtained by treating the corresponding iminoester with R^1CNO and then with ammonia[245], is related to these investigations:



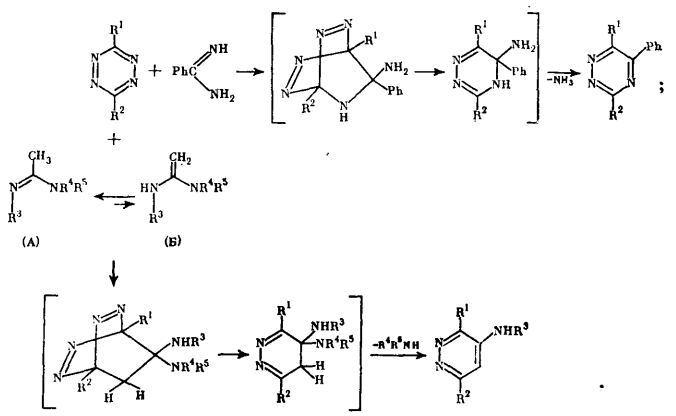
(CXIV)

sym-Triazinethiones have also been obtained by the reaction of iminoisothiocyanates (CXV) with amidines[246,247]:

(CXV)



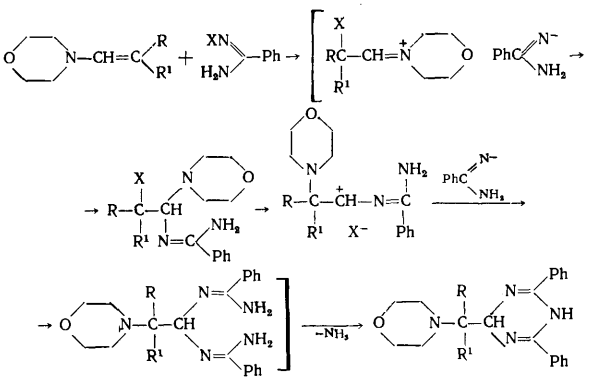
The reactions of amidines with cyanamide[43] and the reaction of *N*-cyanoamidines and complexes of amides with phosphoryl chloride[248] belong to another class of methods of synthesis of triazines:



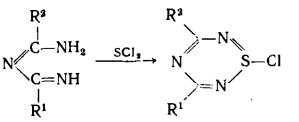
(CXVII) (CXVI)

The author does not explain why chlorotriazine (CXVI) is formed, but one can suppose that the intermediate chloroimide (CXVII) cyclises.

The triazine ring is also formed in the reaction of cyclic chloroformamidines with pyridine or quinoline[249]:

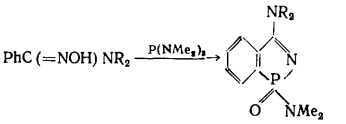


Amidines behave as dienophiles in reactions with tetrazines, which result in the formation of 1,2,4-triazines[250]. It is significant that, when *N*,*N*,*N'*-trisubstituted amidines are made to undergo an analogous reaction, pyridazines are produced[251]. The authors believe that this process is a consequence of the amidine–enediamine equilibrium (A ⇌ B) [215] (see also above):

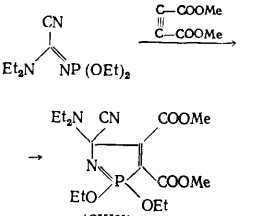


(A) (Б)

Finally we may note the interesting reaction of *N*-halogenoamidines with enamines via the mechanism[252]



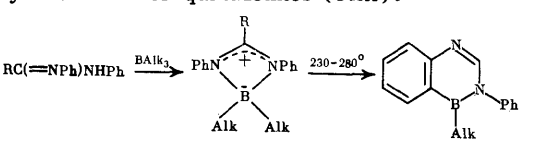
The 1,2,4,6-thiatriazine derivative (CXVIII) has been obtained by the reaction of imidoylamidines with sulphur dichloride[253]:



(CXVIII)

If *N*-arylamidines are introduced into a reaction of this kind, derivatives of 4-chloro-4-thiaquinazolines are formed[254].

In conclusion of this section, we may note studies devoted to the synthesis of phosphorus- and boron-containing heterocycles. The largest number of such studies have been made on phosphatriazines, which have been obtained by the reaction of *N*-cyanoamidines[255] or *N*-imidoylamidines[256] with phosphorus pentachloride, of trichlorophosphazo-compounds with amidines or *N*-dichlorophosphonylamidines[94], and also of *N*-hydroxyamidines with phosphines[257]. The last reaction involves *N*-hydroxyamidines unsubstituted at the second nitrogen atom. The reaction of the *N*-substituted compounds proceeds differently and a five-membered and not six-membered ring is formed[257]:



Phosphorus-containing amidines have been used in the synthesis of derivatives of azaphospholes (CXIX):[166]

(CXIX)

Since the review mentioned above[7] was devoted to boramidines, we shall mention only one recently published study on the synthesis of boraquinazolines (CXX):[258]

(CXX)

---o0o---

This review has dealt with the literature data on the chemistry of amidines and was not concerned with the results of studies on related systems, such as those comprising derivatives of guanidine, *O*- and *S*-substituted ureas, and thioureas. Only in a few instances does the review deal with the chemistry of amidinium salts, because a series of recently published reviews have described their properties[6,259]. Examination of data on the above types of compounds together with those on the chemistry of amidines is hardly possible within the framework of a single article.

Summarising the literature data, one may claim that the development of the chemistry of amidines has been responsible for the development of various fields of organic chemistry, in the first place the chemistry of heterocycles, and has proved extremely fruitful in both theoretical and practical respects.

Electronic Structure and the Chemical Bond in Non-stoichiometric Refractory Compounds of Transition Metals in Sub-groups IVa and Va

A.L.Ivanovskii, V.A.Gubanov, E.Z.Kurmaev, and G.P.Shveikin

Studies of the electronic structure and of the chemical bond in non-stoichiometric binary compounds based on the transition metals of sub-groups IVa and Va are systematically reviewed. The main phenomenological models are examined, and the results of calculations by band and by cluster models of the distribution of electron density are compared; changes in the chemical bond caused by the presence of point vacancies in the metalloid and in the metal sub-lattice are discussed. Calculated results are compared with the results of studies of non-stoichiometric compounds by X-ray emission and photoelectron spectroscopy methods, and with various physicochemical properties. The relative merits of the two approaches (using band and cluster models respectively) in studies of electronic processes associated with the formation of point vacancies in crystals are discussed. 159 references.

I. INTRODUCTION

Compounds of the transiton metals (TM) of sub-groups IVa and Va of the Periodic Table with the lighter s and p elements (carbon, nitrogen, oxygen) form a large class of substances with a number of unique physicochemical properties. They combine properties typical of covalently bonded crystals (high melting point, superior hardness, resistence to corrosion and radiation) with specific properties of electrical and thermal conduction, magnetism, and superconductivity[1-10].

The most striking feature of the monocarbides, mononitrides, and monoxides of the TM is their extensive homogeneity region, which allows the concentration of defects (point vacancies) in both sub-lattices to be varied by large amounts

without disrupting the original structure (type B1). Even in stoichiometric compositions the number of vacancies can be 15–25 at.%, increasing rapidly as the composition departs from the equi-atomic ratio: some compounds (for example, vanadium carbide) cannot be prepared in a strictly stoichiometric state under normal conditions. Furthermore in some binary compounds (VO_x, TiO_x, VC_x, etc.) the defects are partially ordered, with formation of defect clusters, and this can lead to the appearance of individual phases like V_6C_5, V_8C_7, $VO_{1.3}$, etc.[1-10]

Deviations from stoichiometry produce large changes in all the physicochemical properties of the compounds. Therefore the wide interest in the electronic structure of non-stoichiometric phases and in the electronic processes which accompany the formation of point vacancies in the crystal is not surprising.

A correct description of the electronic structure of non-stoichiometric phases (as opposed to that of an ideal crystal) should account for changes in the following properties: 1) the density of electronic states, 2) the position of the Fermi level, 3) the chemical bond near a defect. It should also correctly identify: 1) the nature of the vacancy states, their position in the overall energy spectrum, and the extent to which they are localised, and 2) the charge on the vacancies.

In this paper we shall attempt a systematic review of existing models of the electronic structure of MX_x binary compounds containing defects (where M is the metal and X is the non-metal), whether phenomenological or based on quantitative quantum-chemical calculations. We shall examine the relative merits of the different methods and approximations which have been used to describe the energy spectrum of electrons in the chemical bond of compounds with or without defects, and we shall compare them with data on MX_x compounds obtained by X-ray emission and photoelectron spectroscopy methods.

II. BAND AND CLUSTER MODELS USED IN THE CALCULATIONS OF THE ELECTRONIC STRUCTURE OF SOLIDS

Two alternative approaches to the calculation of the electronic structure of condensed phases are used at present: the band model and the cluster model. Both are based on the solution of the one-electron Schroedinger equation

$$\left\{-\frac{1}{2}\nabla^2 + V_{\text{coul}}(\mathbf{r}) + V_{\text{exch}}(\mathbf{r})\right\}\psi_j(\mathbf{r}) = \varepsilon_j\psi_j(\mathbf{r}) \qquad (1)$$

(where ∇^2 is the kinetic energy operator, $V_{\text{coul}}(\mathbf{r})$ is the coulombic potential energy of the electron, and $V_{\text{exch}}(\mathbf{r})$ is the exchange–correlation pontential), but they rely on radically different approximations.

In the energy band methods[11] special attention is paid to the properties of the energy spectrum arising from the presence of translational symmetry: the solid is treated as an infinitely large regular crystal. The wave function ψ_j is expressed as a combination of delocalised periodic functions of the Bloch type, and the electronic spectrum calculated in this way has continuous energy bands corresponding to the ground state of the ideal (defect-free) crystal, This approach is therefore useful for compounds which form bands (of any width), and it gives accurate values of the width and energy of the band. The characteristics which the band methods describe most correctly are those associated with delocalised electronic states (i.e. the kinetic properties).

The most serious weakness of this approach is that any deviation from the ideal crystal model (such as surfaces, impurities, defects, excited states, etc., which are found in the vast majority of real solids) will perturb the translational periodicity of the system and cause difficulties in the calculation of the energy bands in the disordered system.

Conversely, the molecular orbital cluster methods[12-14] describe the electronic structure as a set of discrete levels of energy ε_j, obtained by solving Eqn.(1) for a relatively small group of atoms (the cluster) chosen within the crystal. These methods retain the atomic orbital concept and rely on fairly simple computation schemes which are however applicable to compounds with crystal structures and compositions of any degree of complexity. Therefore the cluster methods are used mainly in calculations of electronic states and chemical bond effects in disordered solids containing defects, impurities, dislocations, etc. Cluster methods are most successful when applied to narrow-band crystals, and the most accurate results are obtained in calculations of characteristics associated with localised states.

One of the main shortcomings of the cluster approach is the difficulty of calculating kinetic parameters, and of describing wide-band systems.

Several independent methods are now available for band calculations (combined plane wave (CPW), orthogonalised plane wave (OPW), Green function, pseudo-potential methods, etc.) and for cluster calculations [semi-empirical or *ab initio* SCF MO LCAO methods, X_α-scattered wave (X_α-SW) methods, X_α-discrete variation (X_α-DV) methods, X_α-LCAO methods, etc.]. Since approximations have to be used even in non-empirical methods, and their validity may be doubtful, experimental tests of the results may be necessary. The most direct tests rely on X-ray emission and photoelectron spectroscopy. We shall therefore discuss the results of specific calculations in conjunction with relevant spectroscopic data in order to assess the validity of different models of the electronic structure of high-melting phases.

Before proceeding to our discussion of the electron energy spectrum (EES) of non-stoichiometric compounds we shall briefly examine the most important results relating to "complete" (i.e. ideal) binary phases, since these phases will be used later as reference systems when considering changes in electronic structure brought about by structural vacancies.

III. ELECTRONIC STRUCTURE AND THE CHEMICAL BOND IN STOICHIOMETRIC BINARY COMPOUNDS OF THE TRANSITION METALS

The earliest views on the electronic structure of high-melting compounds were formulated as two phenomenological models, each supported by a number of experimental facts[3,5,7-9]. According to the first of these models[15,16] interstitial phases can be treated as solid solutions of the metalloid in a matrix of the metal, where the main effects of chemical bonding arise from the collectivisation of the *d* electrons from the metal. The other model accounts for the hardness, refractoriness, and brittleness of these compounds by postulating a predominant contribution from covalent interactions between the metal and the metalloid[17-20].

The real structure of the EES of binary phases and the individual features of the electronic structure of particular compounds were successfully established by quantitative quantum-chemical calculations. Almost all the existing band and cluster methods have been applied to the calculation of the band structure of ideal binary compounds. The most important of these calculations are summarised in Table 1, which lists the methods applied to different materials and all the reported X-ray emission and photoelectron spectroscopy studies of these compounds.

Table 1. Bibliography of quantum-chemical calculations and X-ray emission (XE) and photoelectron spectroscopy (XPS) work on binary stoichiometric high-melting phases.

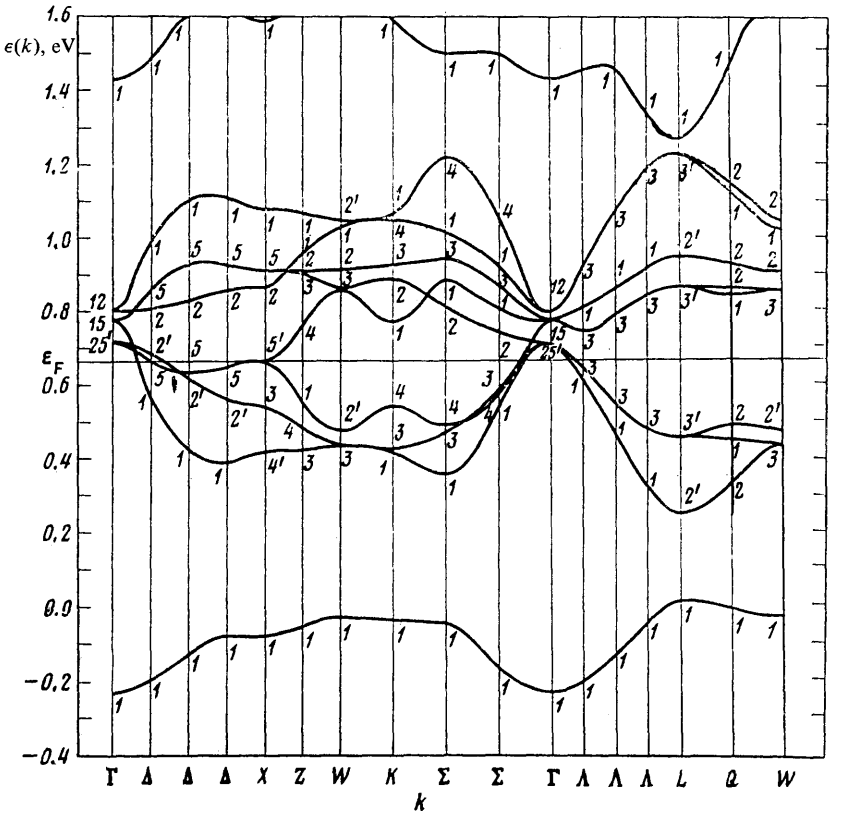

Figure 1. Band structure of titanium carbide (CPW calculation[36]).

The first calculation by Bilz[21] for TiC, TiN, and TiO by the strong bond method showed that the valence band of MX contains two sub-bands in which both M–X and M–M bonding can occur. However, the approximations used in that work[21] (such as the evaluation of two-centre integrals from data for the pure metals) led to some "averaging out" of the resulting band structure: this property was later put to use in the "quasi-rigid" band model, in which the general shape of the bands of the carbides, nitrides, and oxides of the *d* metals is assumed to be constant and only differences in the occupancy

of the energy bands (due to differences in the concentration of valence electrons between the different compounds) are considered.

Costa and Conte[22] confined their calculation for TiC to the *d* functions of the metal, which are split into t_{2g} and e_g components in the crystal field. They found that the M–M bond was stronger than in the pure metal, but their neglect of the Ti–C and C–C interactions makes this conclusion doubtful. This was pointed out by Lye and Logothetis[23], who evaluated the exchange integrals from spectroscopic data. In their band structure for TiC the e_g state of Ti was lower in energy than in the pure metal, giving a broad band of Ti–C interactions. This configuration of the bands should lead to high bond energies and to a melting point higher than that of titanium.

Conversely, in CPW calculations[24] for TiC, TiN, and TiO a transfer of charge in the opposite direction is obtained. The valence band is formed from the $2p(X)$ and the $3d$(Ti) states, and the Fermi level of TiC is found in a region of low density of electronic states $N(\varepsilon)$. As the atomic number z of the metalloid increases, the additional electrons populate the t_{2g} states in the metal, thus raising the level of ε_F. These results[24] were confirmed by an independent report[25] that charge (less than 1 electron) is transferred in the Ti → C direction.

Most of the calculations on binary MX phases were published during the 1970's and 1980's. Some special features of the EES of the IVa and Va carbides were established[26,27], but the $(n+1)p$ states of the metal were excluded from the basis without justification. Other workers[28–31] calculated the EES of TiC, ZrC, NbC, and NbN by an empirical pseudopotential method. The CPW method was used[32,33] to construct the band structure of Ti and V oxides, and also NbN. Ichara[34] calculated the EES for the monocarbides of the TM in sub-groups IVa and Va and obtained a density of states distribution in excellent agreement with the X-ray photoelectron spectra of the carbides.

The most accurate calculations in terms of band models for a wide range of MX binary compounds (M = Sc, Ti, V, Nb; X = C, N, O) by a self-consistent CPW method with an X_α exchange potential were reported by Neckel and coworkers[35–45].

The $\varepsilon(k)$ dispersion curves (Fig.1) calculated for titanium carbide by the SCF CPW method[36] show a valence band structure characteristic of this type of compound: a low-energy sub-band composed mainly of $2s$ (C) states and separated from the $3d$(Ti) and $2p$(C) mixed states by a gap of ~3 eV, followed by a sub-band of $3d$, $4s$ states of the metal and by a free $3d$, $4s$ band. The Fermi level lies in the overlap region of the p,d and d,s bands, which accounts for the metallic properties of these compounds.

The changes in the relative contributions from different states to the valence band in the carbide, nitride, and oxide series are shown in Fig.2 by the energy distribution of the partial densities of states $g_i(\varepsilon)$ for the MX compounds (M = Ti; X = C, N, O)[36]:

$$g(\varepsilon) = g_s^X(\varepsilon) + g_p^X(\varepsilon) + g_d^M(\varepsilon) .$$

Several problems in the methodology of applying local (cluster) models to the electronic properties of refractory compounds are discussed in Refs.58 and 59. It is stressed that the main features of the EES spectrum and the changes in the valence band in the carbide, nitride, and oxide series are accurately reflected by cluster calculations. Furthermore, the results from band and from cluster methods for the same level of approximation (CPW and X_α-SW) and using the same input parameters are not only qualitatively similar but they lead to quantitatively similar distributions of electrons in space and energy[59]. This confirms the validity of descriptions of the EES of high-melting compounds based on local models. The distribution of total charge density in MX crystals leads to the same conclusion: it can be inferred from X_α-DV calculations fro the $CTi_6C_{12}Ti_8$ cluster in titanium carbide[132] and from calculations for NbC and NbN by the pseudo-potential method[30].

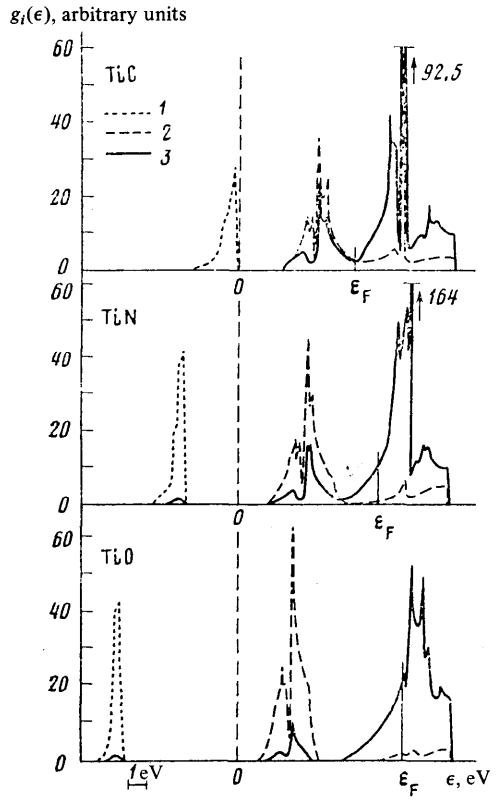

Figure 2. Partial densities of valency states[36] for TiX (X = C, N, O): *1*) and *2*) $2s$ and $2p$ states of X; *3*) $3d$ states of Ti.

The main features of the structure of the valence band and of the changes in this band for the series of binary compounds revealed by band[26–56] and by cluster calculations[57–71] can be summarised as follows.

1. The low-energy $2s$(X) band, which includes small contributions from the s, p, and d states of the metal, is broadened and shifted towards higher energies in the transition from oxides to carbides and from sub-group IVa to sub-group Va metals. For the carbides and nitrides of Hf and Ta (whose oxides with a B1 structure are unstable) the $4f$ states are found to be core states and practically unaffected by chemical bonding[55,56,63].

2. The band mainly responsible for valence bonding is formed by the strong mixing of the $2p$(X) and d(M) functions. It rapidly widens on going from oxides to carbides, and less rapidly on replacing the IVa by a Va sub-group metal. The overall covalency is higher in the Va than in the IVa metal compounds, and increases with the atomic weight of the metal within each sub-group.

3. The high-energy partially filled conduction band is mainly of the nd(M) type with a small contribution from $2p$(X), $(n+1)p$(M) and $(n+1)s$(M) functions, and it widens very rapidly on going from the oxide to the carbide. This is accompanied by a downards shift of ε_F and by a decrease in the density of states at the Fermi level $N(\varepsilon_F)$.

The redistribution of the individual atomic states during the formation of interstitial phases causes partial charge transfer between metal and non-metal atoms and contributes an ionic component to the chemical bond.

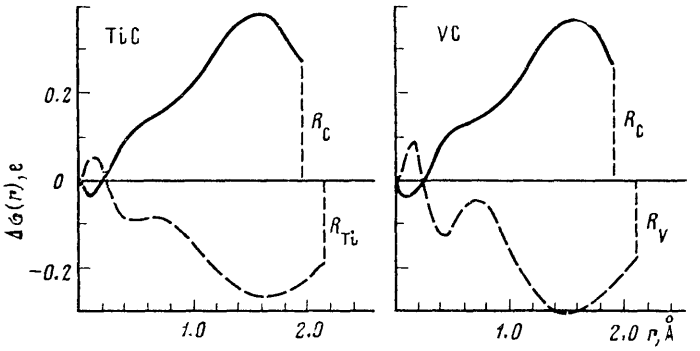

Figure 3. Difference between the crystal charge density (CPW) and the sum of the atomic charge densities in TiC and VC[36].

Strongly opposed views on the direction and magnitude of the charge transfer in MX compounds are held by different workers. Some[22,23] find that charge is transferred in the X → M direction. Others conclude from X-ray results[72,73] that the ionisation of the atoms in MX is very high (for example, almost +4 for Ti in TiC), and therefore they believe that the electrostatic energy is equivalent to ~90% of the cohesive energy of the crystal. However, the assertion[72,73] that the excess charges are strongly localised on the atoms is incompatible with most of the reported cluster and band calculations, with high-precision measurements by X-ray emission and photoelectron spectroscopy of the shifts in the internal levels for a wide range of carbides, nitrides, and oxides[36,37,53,54,57-70], and with the discussion in Section IV of this Review. Fig.3 shows the difference between the radial charge densities obtained in CPW calculations[36] for TiC and VC (σ_{cryst}) and as a superposition of the atomic densities (σ_{at}):

$$\Delta\sigma(r) = \sigma_{cryst}(r) - \sigma_{at}(r) .$$

In this case the excess of charge in the atomic spheres (i.e. the effective charge localisation on the atoms), given by

$$q^{eff} = Q_{cryst} - Q_{at} = \int_0^R \Delta\sigma(r)\,dr$$

is not large (~1e). There can be little doubt, at present, that charge transfer takes place in the M → X direction. The quantity q^{eff} increases slightly in the carbide, nitride, oxide sequence (see Table 2), thus increasing the coulombic contribution to the bond, but it remains much lower than the values postulated in the ionic model (+2, +3, and +4 for the metal in MO, MN, and Mc respectively).

By examining the atomic and the orbital composition of each type of state in the different energy ranges of the spectrum[35-37,57,59,63,64,69-71] it has been possible to identify the individual interatomic interactions and their relative contributions to the combined covalent-metallic-ionic bond found in high-melting phases. The crystal field causes splitting of the d(M) states, which become doubly (eg) or triply degenerate (t_{2g}). The t_{2g} states lying near ε_F are responsible for the M-M bond, and they are largely delocalised though they retain some thickening of the electron density in the M-M direction, characteristic of bonding interactions[62,63]. However, the system is diffuse and the M-M interaction is weak. The main chemical bonding effects are due to the strong interaction of the nd(M) and $2p$(X) functions, which forms interatomic bonds of σ and π type giving a three-dimensional network of orbitals with $eg(d_{x^2-y^2}, z^2)$ and $t_{2g}(d_{xy}, yz, xz)$ symmetry. As a result, the high-melting compounds are largely covalent, with a small ionic component in the bond.

Table 2. Orbital occupancies and charges (q^{eff}) on the metal atoms in the carbides, nitrides, and oxides of Ti, V, Zr, and Nb,[69-71]

Compound	$3d_\sigma$	$3d_\pi$	$3d$	q^{eff}	Compound	$4d_\sigma$	$4d_\pi$	$4d$	q^{eff}
TiC	0.85	0.44	2.97	0.50	ZrC	0.70	0.49	2.77	0.23
TiN	0.53	0.62	2.93	0.64	ZrN	0.42	0.71	2.89	0.42
TiO	0.31	0.79	3.02	0.78	«ZrO»	0.26	0.80	2.91	0.59
VC	0.97	0.70	4.05	0.39	NbC	0.78	0.79	3.95	0.24
VN	0.61	0.90	3.91	0.54	NbN	0.51	0.95	3.88	0.40
VO	0.35	1.05	3.96	0.67	NbO	0.34	1.14	4.10	0.54

The proportion of σ bonding is highest in titanium carbide, though the population of the π orbitals is double that of the σ orbitals. A marked redistribution of the occupancies of the t_{2g} and eg orbitals occurs in the carbide-nitride-oxide series, accompanied by a weakening of the σ bond (see Table 2). This results in destabilisation of the oxide lattice, making these compounds less refractory and less hard than the carbides[60,67,69-71].

These properties of the EES and of the charge distributions have been used to interpret X-ray emission[34,39,44,58-71] and photoelectron spectra[34,40,58-64,66,71] and appearance potential spectra[40], and also in studies of magnetic susceptibility[76], superconducting transition temperature[43], electronic specific heat[121,122], Hall coefficient[120], and Compton scatter profiles[74] for outlining the Fermi surface[34,75].

We should stress that all these calculations were for ideal, stoichiometric compounds, and in many cases (TiO, VO, VC, "ZrO") they were only model calculations.

IV. X-RAY EMISSION AND PHOTOELECTRON SPECTRA OF MX COMPOUNDS

Before attempting to describe the special features of the electronic spectrum of non-stoichiometric compounds we shall discuss the relationship between existing calculations for stoichiometric MX compounds and experimental data.

The experimental methods offering the most direct information on the distribution of electronic states over the whole depth of the valence band and on the energetics of the core levels are the spectroscopic X-ray photoelectron (XPS) and

X-ray emission spectroscopy (XE) methods. Spectral studies of most of the high-melting compounds discussed in this review have been reported (see Table 1). However, the extensive literature which has accumulated on this topic is literally "choked" with erroneous results: Zhurakovskii's recent monograph[126] is no exception. We shall not attempt to account fully for the inconsistencies in the experimental data, though the following general comments on the experimental problems of XE and XPS measurements on transition metal compounds may be helpful. On the one hand, errors in the calibration of the apparatus must lead to errors in the comparison of spectra from different series of components, and on the other hand errors can arise from differences in the surface layers of the samples electrically excited in the X-ray spectrometer.

Table 3. Bibliography of quantum-chemical calculations and X-ray emission and photoelectron spectroscopy work on non-stoichiometric compounds of the *d* metals.

The experimental results quoted in Tables 1–3 are those which we consider most relevant and useful to the present discussion. Interested readers wishing to examine the topic in more detail are referred to Zhurakovskii's monograph[126], which gives a full discussion of this type of work in the Soviet Union and abroad.

Measurements of the X-ray photoelectron spectra yield information on the density distribution of occupied electronic states over a wide range of energies[102] to the precision of the difference in photo-ionisation cross-section of the electronic sub-shells. The XPS spectra of the following compounds have been studied: TiC,[34,89,91–93] TiN,[92,94,95] VC,[34,90] ZrC,[34] NbC,[34,89,97] NbN,[97] NbO,[96] and HfC and TaC.[34] A series of XPS spectra for the valence band of *d* metal carbides has been obtained[34], and their parameters have been compared with CPW band calculations (Fig.4). Since the elements of the matrix which describes the transition probabilities in this energy region were assumed to be constant, the integral energy distribution of photoelectron intensity was compared directly with the calculated state densities. The relative intensity of peak II was found to increase in the TiC, ZrC, HfC series (Fig.4), and this was ascribed to the increase in the scattering cross-section of *d* electrons in the sequence 3*d*(Ti), 4*d*(Zr), 5*d*(Hf), since these electrons provide the main contribution to this part of the spectrum. Calculations based on the ionisation cross-sections of the sub-cells (after Scofield[103]) gave good agreement with experiment.

In the carbides of sub-group Va metals in the high-energy region we find a clear "outcrop" associated with the appearance of an additional *d* electron, and the relative intensity of peaks I and II increases with the atomic number of the metal (as in the carbides of sub-group IVa transition metals). Some of the difference between the theoretical and the experimental XPS spectrum of VC is due to the fact that stoichiometry was assumed in the calculation.

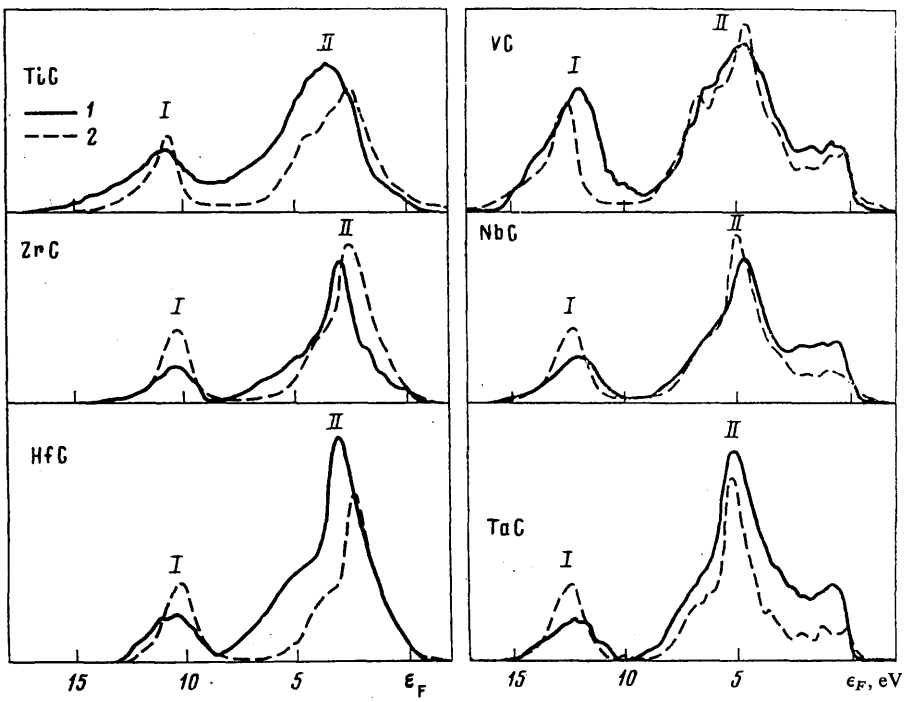

Figure 4. Experimental (*1*) and theoretical (*2*) XPS spectra of the carbides of transition metals in sub-groups IVa and Va.[34]

The relative advantages of band and cluster models for describing the XPS spectra have been discussed[58] in the case of TiC and VC. In the cluster approximation the spectrum was constructed by using the Gelius scheme[104], in which the intensities of the individual peaks (I_j) are defined in terms of the atomic photo-ionisation cross-sections σ_i:

$$I_j \sim \sum_i C_{ij}^2 \sigma_i ,$$

where C_{ij} are the coefficients of the MO in the LCAO expansion of the wave function. It was shown that the shape of the spectra for this class of compounds can be reproduced as accurately by the cluster approach as by band calculations if the bands are reasonably well localised.

As well as giving information on the structure of the valence band the XPS method can be used to measure the shifts in the core electron energy levels produced by the formation of mixed states in condensed phases, and it is an effective analytical technique for determining both the character of the chemical bond and the extent of charge transfer between the atoms[102].

Table 4 shows the changes in the energy ΔE of the inner levels of the carbides of the transition metals and the charges on the atoms (q^{eff}) calculated from data by Ramqvist[105] and Ichara[34]. We note that in all the carbides the shifts of the carbon levels are negative, and those of the metal levels are positive (relative to the energies of the corresponding levels in the neutral atoms). Thus a partial negative charge develops on the metalloid, and a partial positive charge on the metal. The discrepancy between the q^{eff} values obtained from data in Refs.34 and 105 is probably due to differences in surface preparation techniques in the two laboratories: in less carefully lapped surfaces[105] we expect a tendency for ΔE to increase.

Measurements[106] of the shifts of the 1*s*(N) and 2*p*(M) levels in the ScN, CrN, TiN, and VN series showed that in the nitrides also a small positive charge is localised on the metal atom, increasing from ScN to VN.

Table 4. Changes in the energies of core levels (ΔE, eV [105]) and in the ionic charges in TM carbides (q^{eff}). [34]

Carbide	$-\Delta E_C$	ΔE_M^*	q_M^{eff} (Ref.105)	$-q_C$	q_M	$\langle \lvert q_{C,M} \rvert \rangle^{**}$

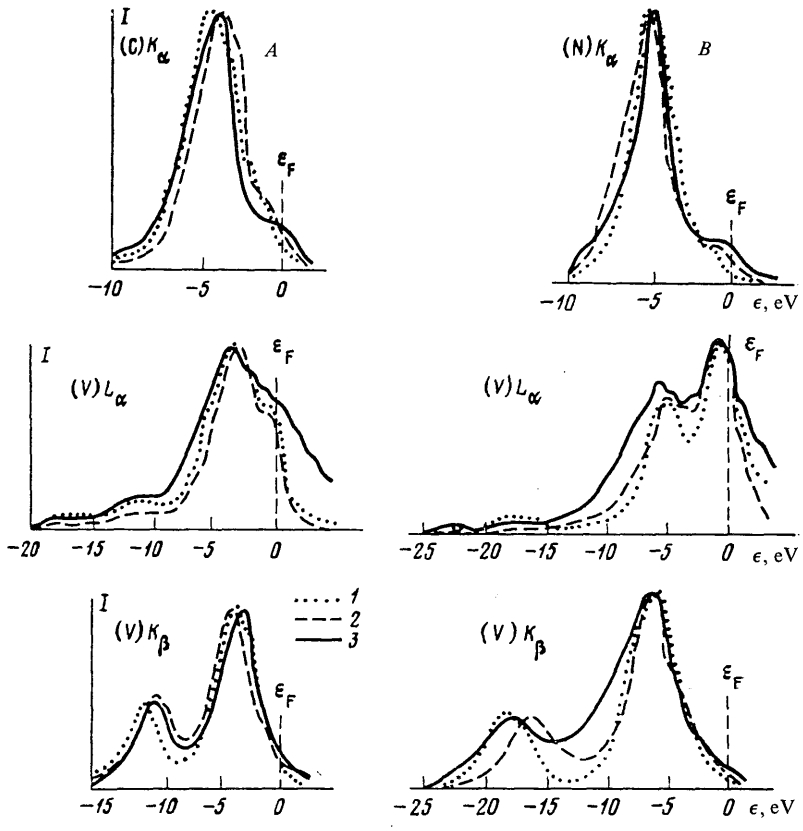

Figure 5. X-Ray emission spectra of VC (*A*) and VN (*B*): *1*) X_α-SW calculations, *2*) CPW calculations, *3*) experiment[59].

Direct calculations of the energy levels of the core electrons have been made by non-empirical X_α-SW and X_α-DV methods in a full basis for TiC, VO, and TiO.[107,108]. Allowance for relaxation effects (rearrangement of the electron shells under the influence of holes on the inner and valency levels) was made in Slater's transition state scheme[109]. Comparison of these results with the MO diagrams given by "unrelaxed" calculations shows that the valency states are almost unaffected, and that the uncorrected values can be used to calculate the energies of emission transitions. Relaxation effects become predominant for the inner levels, and by allowing for these effects we can calculate the absolute energies of the core levels in good agreement with XPS data.

More detailed information on the electronic energy spectra of high-melting compounds, including the configuration of the partial states of the individual components, can be obtained by the X-ray emission spectroscopy method[110]. Although the X-ray emission K, L, and M spectra of high-melting compounds have been observed by many workers (see Ref.10) their correct interpretation had to await the development of band calculations for TiC, TiN, and TiO,[24] and the identification of the long-wave satellites in the spectra of carbon, nitrogen, and oxygen compounds[81,111]. Even more exact interpretation of the XE spectra was made possible by cluster calculations[66,69,70].

In Fig.5 we show as an example the (C)$K\alpha$, (N)$K\alpha$, (V)L_{III}, and (V)$K\beta_5\beta''$ spectra of VC and VN [39] corresponding to the emitting transition $2p \rightarrow 1s$ (for C and N) and $3d, 4s \rightarrow 2p$ and $4p \rightarrow 1s$ (for V). By presenting these results on a unified energy scale with allowance for the different binding energies of the core electrons we find that a strong $2p$(X)–d(M) interaction occurs in all the compounds. The change from VC to VN affects most strongly the (V)L_{III} band: a high-energy element of structure is split off and produces a strong band, indicating an increased electron concentration in the nitride, with occupancy of the higher orbitals. In the (V)$K\beta_5\beta''$ spectrum of VN the $K\beta_5$ and $K\beta''$ sub-bands are significantly shifted towards longer waves, due to the decrease in the energy of the $2p$(N) and $2s$(N) states [as compared to the energy of the $2p$(C) and $2s$(C) states].

Correlations between the results of calculations by band methods and XE spectroscopy data are usually made in terms of the partial density of states $g(\varepsilon)$. The radial probabilities of emitting transitions have also been included in some calculations[39,44,112] of the intensities of XE spectra. The XE spectra calculated in this way for VC and VN by the X_α SW and CPW methods are shown in Fig.5. We note that (as in the XPS spectra) the main features of the XE spectra are satisfactorily described by small cluster calculations (both the position in energy of the maxima and their relative intensities), in full agreement with the results of CPW calculations[59].

The theoretical formulations[59–64,69–71] of the XE spectra of the carbides, nitrides, and oxides of Ti, V, Zr, Nb, Hf, and Ta allow a full interpretation of experimental data as well as the prediction of as yet unreported lines.

Thus the extensive applications of results from theoretical calculations and from spectroscopic investigations has yielded meaningful information on the EES and on the chemical interactions of high-melting compounds. As we shall show below, this approach has been successfully applied in studies of the rearrangement in space and energy of the electronic states caused by the appearance of structure defects.

V. ELECTRONIC STRUCTURE OF THE NON-STOICHIOMETRIC CARBIDES, NITRIDES, AND OXIDES OF THE *d* METALS

The marked effect of lattice vacancies on all the physicochemical properties of refractory compounds is well known[3–10]. Attempts to relate the observed dependences (of the property–defect density type) to changes in the electronic spectra led to the development of a number of qualitative models of the band structure in non-stoichiometric compounds, and stimulated some numerical calculations.

1. Phenomenological Models

The first attempt to allow for the effect of a variable concentration of vacancies on the EES of MX_x compounds relied on the rigid band model. It was assumed that the perturbation introduced by a vacancy into the crystal is generalised and does not affect the shape of the $N(\varepsilon)$ curve: only the occupancies are affected, depending on the concentration of valence electrons. By applying this postulate to calculations for stoichiometric TiC it was found[23] that an increase in the concentration of non-metal vacancies ($N_\square$) in the TiC_x compounds shifts the Fermi level towards the low-energy side of the spectrum, passing through a value (at the composition $TiC_{0.5}$) corrresponding to a maximum density of states in the bonding p–d band. We note that this conclusion is in sharp contrast with more recent XE [129,136,137,158] and XPS results [130,138,139], all of which imply a shift of ε_F in the opposite direction.

By using the same model Denker[113] explained the high equilibrium concentrations of vacancies in TiO_x in terms of the general decrease in the concentration of valence electrons (as compared to the stoichiometric composition), leading to a decrease in ε_F and in the total energy of the system and therefore to stabilisation of the structure. However, the neglect of the individual features of the band structure in particular compounds leads to the (generally incorrect) conclusion that any compound must be stabilised by the addition of vacancies.

Conversely, in the valence electron model[114] the defect is treated as a local perturbation of the electronic states in the crystal. When a non-metal atom is removed from an octahedral hole in the metallic matrix some of the previously screened M–M bonds become unscreened and can pass through the centre of the vacancy, and the d electrons set free by the breaking of the M–X bonds are accommodated in the high-energy local levels associated with the vacancy. As $N_\square$ increases, the local levels merge into a band: the result for the monocarbides of the IVa transition metals is a linear increase in ε_F, whereas for the monocarbides of metals in the Va sub-group a more complex dependence is obtained. Many changes in the kinetic and magnetic properties of monocarbides in their homogeneity region have been explained successfully by using this model[115].

Ichara's model[34], which is closely related to this theory[114], treats the EES of defect carbides as a superposition of the densities of states for the stoichiometric compound and for a hypothetic metal (with a face-centred cubic lattice) which forms clusters in the carbide structure by the conversion of carbon sites into carbon vacancies. The presence of strong M–M bonds in this case should lead to a stable value of ε_F.

Whereas the charge on the vacancy is not specified in the above models, Goodenough[116] proposed a model in which the vacancy carries a high charge (-2 for TiO_x) to compensate for the decrease in the Madelung energy in defect crystals, thus causing energy stabilisation of a substantial concentration of vacancies at equilibrium.

In the configurational electron localisation model[9] the main parameter used to define the electronic properties of the system is the statistical weight of an atom with stable configurations (SWASC), which is a measure of the deviation of the electronic configurations of the atoms in a stated compound

from the most stable configurations (i.e. free, half-filled, and completely filled). For the non-metal atoms in these compounds the stability of the bond is determined by the quasi-stable sp^3 configuration, whereas for the transition metals the maximum bond stabilisation corresponds to the d^5 configuration. The changes in the relative contributions of the various atomic states to the M–M and M–X bonds resulting from deviations from the stoichiometric composition are determined, according to this model, by the SWASC sp^3 and d^5. For example, for the compositions $TiC_{1.0}$ and $TiC_{0.67}$ semi-empirical estimates of these parameters give[117] 40.13 and 39.50% (SWASC sp^3) and 36 and 52% (SWASC d^5) respectively, indicating a weakening of the contribution from the p states to the strongest M–X bonds and a slight increase in strength of the M–M interactions in the defect carbides. These conclusions are qualitatively consistent with the development of metallic properties (increase in magnetic susceptibility, in low-temperature electronic specific heat, and in electrical conductivity) and with the decrease in micro-hardness and in T_f in carbides with a carbon deficit.

These phenomenological models of the electronic structure of non-stoichiometric phases offer a qualitative description of some of the experimentally observed variations in the physicochemical properties of MX compounds in their homogeneity region, but they cannot of course give any quantitative measure of the changes in the EES in space and energy: the parameters used in these models (such as the SWASC and the concentration of valence electrons) lend themselves only to the roughest qualitative estimates. Therefore the further development and quantification of our understanding of the nature of the chemical bond, of the interatomic interactions, and of the EES in these materials had to await the publication of correct quantumchemical calculations for individual compounds.

2. Calculations Using Band Models

Several calculations in which band methods are applied to non-stoichiometric compounds have been published (see Table 3). The first numerical calculation[119] by the strong bond method for TiC_x ($x = 1.0$, 0.8, 0.6) with explicit allowance for the presence of vacancies gave a Fermi level ε_F increasing with the concentration of defects in the non-metal sub-lattice. The next group of calculations for TiO_x,[120] VC_x, ZrC_x, and HfC_x,[34,121,122] relied on the virtual crystal approximation (*VC*-CPW), proposed by Schoen[123]. In this method allowance for the presence of vacancies was made by introducing functions of the concentration of vacancies into the expressions for the potential and for the matrix elements. The result was that the insertion of vacancies (whether in the metal or in the non-metal sub-lattice) does not produce new valency states which could be interpreted as vacancy levels[114] in any of the compounds examined. In a calculation[120] of the energy of formation of vacancies in TiO_x the difference between the bottom of the conduction band (which is fixed for all compositions) and ε_F was used as an average value of the energy for different compositions. This makes an oxide containing ~15% of vacancies in each sub-lattice the most stable composition[120]. It was also found[34] that as the concentration of X decreases, the energy of bands of the $2s$(X) and $2p$(X) type increases, but that of the d(M) type is relatively unaffected; the level ε_F decreases.

We should stress that these results were not confirmed by XPS measurements[34]: no significant shifts of the main spectral peaks were found, and an increase in the density of high-energy d states was noted. This inconsistency is due mainly to the use of ideal crystal potentials in the *VC*-CPW calculations for non-stoichiometric compounds[34,120–122], which is legitimate only for very low concentrations of vacancies.

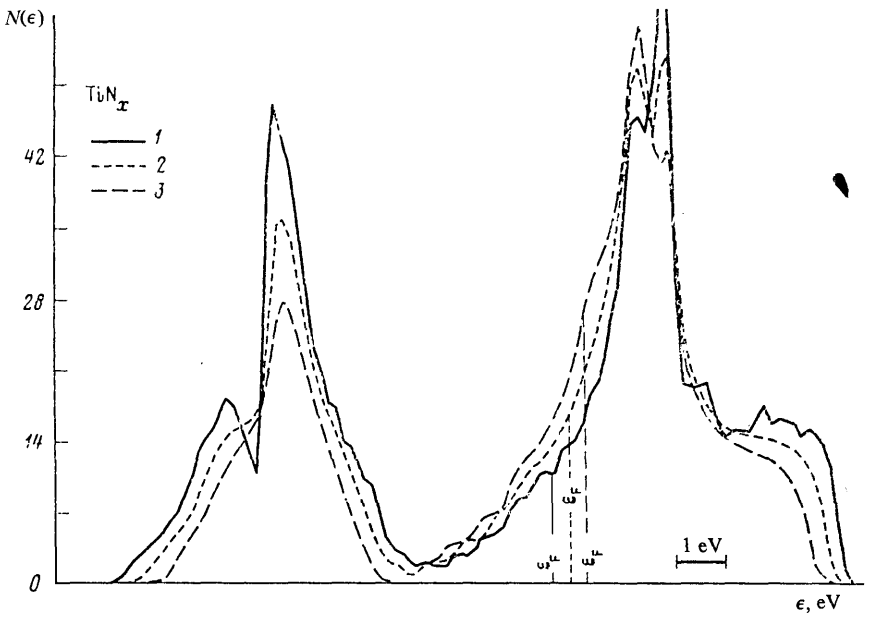

Figure 6. Full density of states in TiN_x; CP calculation[125] for $x = 0.0$ (*1*), 0.2 (*2*), and 0.4 (*3*).

This condition is not met in our case.

Calculations on TiC_x [124] and TiN_x [125] by the coherent potential (CP) method appear to be more reliable. In this work[124,125] the 2*s* states of C and N were excluded from the basis and assigned to the core states. An increase in $N_\square$ caused an increase in ε_F and a slight distortion of the energy dependence of the density of states (Fig.6). This is because an increase in $N_\square$ in TiC_x lowers the total number of carbon atoms in the *p* state, since $Np = 6-6_x$, whereas the number of expelled *p* electrons is $Npe = 2-2_x$. Under these conditions the Fermi level rises, and reaches the region of high density of states of the t_{2g} type. As a result $N(\varepsilon_F)$ also rises, as it does in the rigid band model, but for an entirely different reason, since in the rigid band model ε_F decreases, and the main contribution to $N(\varepsilon_F)$ comes from the e_g states.

Later calculations by the LCAO-CP method for NbC_x, TaC_x, and HfC_x ($0.7 \leq x \leq 1$) showed[127] that the spectra of sub-stoichiometric compounds do not contain any new structures identifiable as defect (vacancy) levels: the main effect is a small change in electron density $N(\varepsilon)$ as compared with the stoichiometric compounds, and the position in energy of the main $N(\varepsilon)$ spectral peaks stays almost constant, in contrast to earlier calculations[34,120-122]. In all the carbides ε_F moves upwards, the effect being most marked in HfC_x: $\Delta\varepsilon_F$ is 2.53 eV for $HfC_{0.7}$ as compared to 0.87 eV for $TaC_{0.7}$ and 0.72 eV for $NbC_{0.7}$. This is explained[127] in terms of the charge distributions in the carbides. In stoichiometric compositions a charge transfer of ~1*e* takes place in the M → C direction. Hence the removal of one C atom frees ~5 states, but only 4 electrons leave the crystal, so that 1 electron is transferred back to the metal and occupies its *d* band.

The parameters of the electronic structure of non-stoichiometric MX compounds calculated in this way[128] were used to calculate the energy of formation of defects in TiC and TiO. The formation of vacancies is due to the following common factors: 1) a change in the average energy of the bands, 2) the width of the band, 3) the creation of new levels of the defect type, 4) the position of the Fermi energy. A hypothetical binary compound AB was considered, with a band structure consisting of two bands (separated by an energy gap) corresponding to the states of the A and B components. It was shown[128] that the formation of vacancies in the sublattice of the atoms with lower electronic state energies can produce new (defect) levels with energies below ε_F, so that the total energy of the system is lowered by the transition of electrons to these new levels. This stabilising effect of the defect levels becomes more marked when ε_F rises as a result of an increase in $N_\square$. Under thse conditions the total

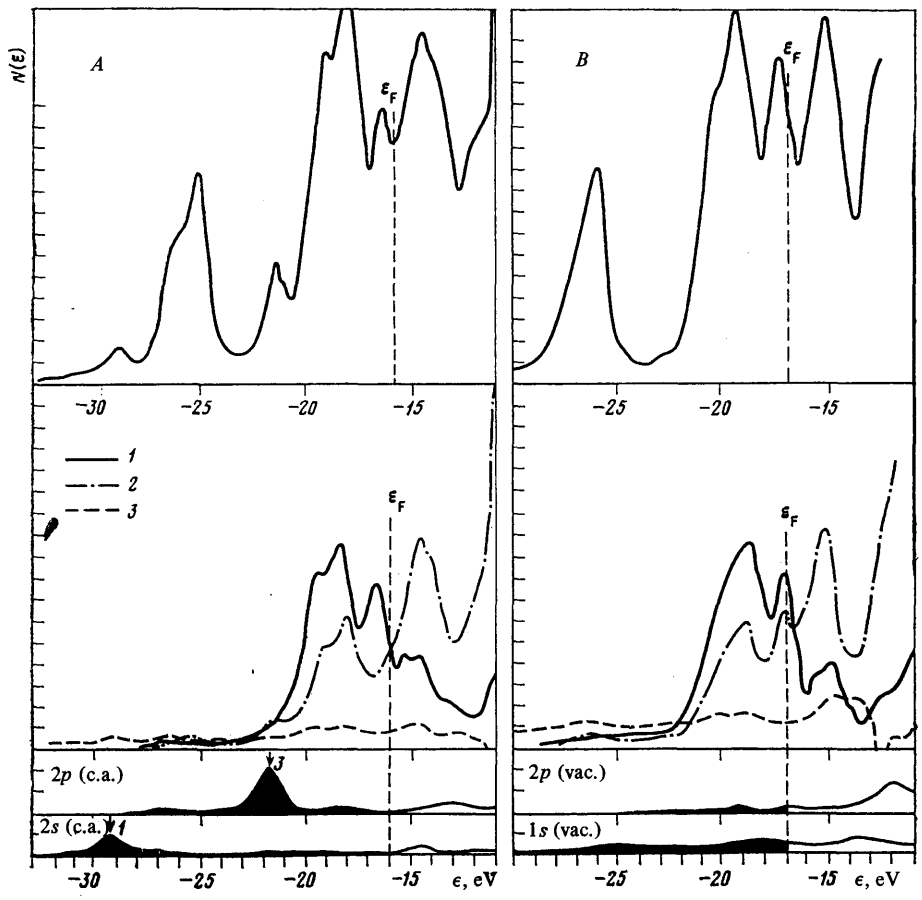

Figure 7. Full and partial densities of states in the stoichiometric cluster $CTi_6C_{12}Ti_8$ (*A*) and the defect cluster $\square Ti_6C_{12}Ti_8$ (*B*) used to model titanium carbide (X_α-DV method of calculation[132]): *1*) 2p(C), *2*) 3d(Ti), *3*) 4s + 4p(Ti). The lower outlines show the distribution of *s* and *p* states of the carbon central atom (c.a.) and of the vacancy (vac.).

energy of the system may go through a minimum at a certain concentration of vacancies, corresponding to the equilibrium concentration of defects. A calculation for TiC_x and TiO_x (by the Korringa–Kohn–Rostoker method in the averaged T matrix approximation) gave 0.0 ± 1.4 eV and 14 ± 1.4 eV respectively for the energies of formation of vacancies in TiC and TiO. Vacancy states lying below the Fermi level were found in the oxide but not in the carbide.

From the band calculations for MX_x compounds listed above[34,120–122,124,125,127,128] we may conclude that the general changes in band energetics and structure and in the position of the Fermi level are adequately described by this approach. However, problems concerning the rearrangement of the chemical bond in defect compounds and the nature of the vacancy states are largely unresolved. The solution of this type of problem, which basically arises from local changes in the electronic states close to a vacancy, was obtained by adopting cluster models.

3. Calculations by the Cluster Model

Several systematic calculations of the EES of carbides, nitrides, and lower oxides of the 3*d* and 4*d* metals (containing non-metal defects) by a semi-empirical SCF MO LCAO method in the cluster approximation have been reported[71, 129–131,136]. The vacancy was modelled by removing an X atom from the $[MX_6]$ fragment considered in the calculation (uncharged vacancy). As $N_\square$ was increased, the bands of $2s$(X) and $2p$(X) states became systematically narrower. The appearance of a vacancy is reflected most clearly by changes in the state of metal atoms in the immediate surroundings, since some of the *d* electrons genetically bound to these atoms are promoted to higher-energy levels, causing a sharp increase in the Fermi energy for compounds of metals in subgroup IVa. In compounds of the Va transition metals the shift of the Fermi level is much smaller.

The most important changes in the density of states take place near ε_F, because of the interaction[130,131] between nd and $(n+1)p$ orbitals of M in defect compounds. The occupancies also change, due to the increase in the charge of the cluster in the variable valency model. This model[129,136] assumes that the condition of overall electrical neutrality of the crystal can be applied to compounds of non-stoichiometric composition: $\sum_i x_i I_i = 0$, where x_i is degree of filling of the i-th sub-lattice, and I_i is the valency (state of charge) of its atoms. However, since (in TiC_x, for example) the carbon atoms keep the same surroundings, the valency of Ti should be lower in the non-stoichiometric than in the stoichiometric carbide in order to preserve the charge balance, and as a result the cluster containing vacancies acquires a partial negative charge. In this analysis the valency of the C atom is assumed constant, in keeping with the observed stability[139] of the $1s$(C) energy level in TiC_x.

This model was tested by comparing cluster calculations for sub-stoichiometric titanium carbides with the X-ray emission spectra[136]. Two variants of the calculation were described: for constant and for variable valency of the titanium respectively. In the latter case we observe the filling of the next higher metal *d* orbitals in the non-stoichiometric carbide, corresponding to the short-wave "outcrops" on the (Ti)L_α and (Ti)$K_{\beta 5 \beta''}$ bands of the emission spectrum of the $TiC_{0.65}$ sample. If constant valency of the Ti is assumed this effect is not found. The electronic energy spectra of NbC_x [133,134] and VN_x [134] compounds with non-metal defects have been studied by the X_α-SW method. The metalloid vacancy was modelled by an empty ("muffintin") sphere. The addition of a vacancy was found to raise the Fermi level by a small amount (~0.19 eV for NbC_x [133]). The changes in partial state densities arise from a slight redistribution of the states for the atoms adjacent to the vacancy and do not affect the more remote atoms, indicating a high level of localisation of the perturbations in the electronic distribution caused by individual vacancies. The rearrangement of the *d* states of the metal atoms nearest to the vacancies results in the appearance of a small charge in the sphere of the vacancy (0.7–0.8*e*), in contrast to the suggestion[116] that defects are highly charged. A new energy level, lying ~1.5 eV below ε_F, appears in the spectrum of occupied states.

The electronic nature of the vacancy in TiC_x has also been studied[132] by the non-empirical X_α-DV method. The calculation was carried out for a cluster of 27 atoms, using the pseudopotential from 96 external atoms as the boundary condition. Purely vacancy states were included in the basis in the form of 1s and 2p functions centred on the defect. These "vacancy" functions make a very small contribution to the filled band in the general spectrum of states (see Fig.7); since they are localised in the conduction band their perturbation is confined mainly to the spectrum of antibonding states. The change in structure of the states near the Fermi level following the introduction of a carbon vacancy has been ascribed[129–134] to the redistribution of the *d* states of the nearest metal atoms. Therefore the vacancy functions are localised (in space) within the first co-ordination sphere, and in energy well above ε_F (by 8–10 eV), and the presence of carbon vacancies does not produce any new occupied localised states.

As regards the charge on the vacancy, the additional electrons from the "broken" bonds are not captures by the vacancy (as shown by comparing the total charge density diagrams[132] for the integral and the defective cluster), and they fall into the 3*d* band of the metal instead. Similar conclusions are reached in calculations for clusters modelling vacancies in the metal sub-lattice[132]. Thus, since there is no marked localisation of the electrons on vacancies, the hypothesis of a continuously varying metal valency[129,130,136] in response to changes in the population of the 3*d* states caused by the formation of defects is confirmed.

We conclude that strict, non-empirical X_α-DV calculations have demonstrated the value of modelling the electronic structure of non-stoichiometric transition metal phases by extracting the appropriate atom from the fragment used in the calculation. They have also confirmed some earlier conclusions (see above) for other MX_x compounds which had been reached by semi-empirical MO LCAO methods[71,129–131,136].

VI. CALCULATION OF THE ELECTRONIC STRUCTURE OF NON-STOICHIOMETRIC COMPOUNDS FROM X-RAY EMISSION AND PHOTOELECTRON SPECTRA

For a long time the main problem in the study of non-stoichiometric MX_x compounds by XPS methods was the synthesis of sufficiently large single crystals (especially for studies of the valence bands). Therefore the early XPS measurements on non-stoichiometric compounds were limited to the effects produced by changes in the binding energy of the core levels [140,147]. XPS measurements of the valence bands became possible after the recent advances in the preparation of single crystals [which are so far limited to a few compounds, however (see Table 3)]. It was recently shown that almost metallic surfaces can be obtained by using hot-pressed samples of non-stoichiometric compounds[34,150], and that valence band studies by XPS are possible on these surfaces.

Let us examine the results of studies of MX_x compounds by XPS methods. Varying the composition of ZrC_x and TaC_x ($0.6 \leq x \leq 1.0$) did not produce substantial changes in the shape of the spectra[34]. Only some slight changes in the energy and width of peak II were noted (see Fig.8), together with a slight increase in the intensity of the "outcrop" on the short wavelength side of this peak, suggesting an increase in the occupancy of the t_{2g} band with decrease in the carbon content. We have already pointed out that this observation is inconsistent with the conclusions from VC-CPW calculations[34]. Conversely, by using the more strict CP method, changes in shape of the XPS peaks of NbC_x, HfC_x, and TaC_x consistent with experiment could be calculated[127]: in all these compounds an increase in $N_\square$ was found to produce a slight shift of the bands and a substantial increase in the sub-band close to ε_F (Fig.9).

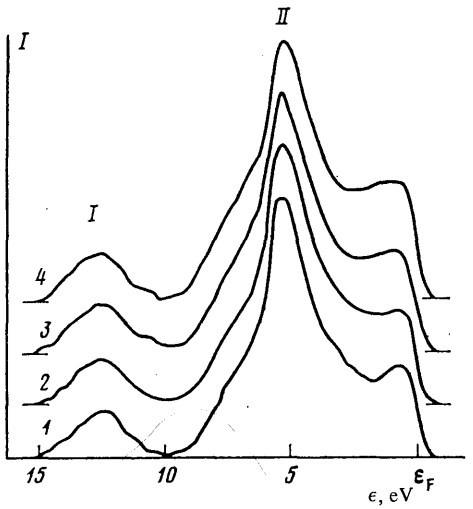

Figure 8. XPS peaks for the valence band of non-stoichiometric TaC_x [34] with the following x values: *1*) 1.0, *2*) 0.95, *3*) 0.9, *4*) 0.8.

A comparison[98] of the line shapes for $NbC_{0.98}$ and $NbC_{0.85}$ revealed a distinct new peak in the latter, located ~1.9 eV below ε_F, which was ascribed to the development of some p-type charge density localised in the sphere of the C vacancies[133].

The influence of variations in the number of defects on the XPS curve of TiC_x was studied by Johansson and coworkers[138,139]. They found that the half-width of the main peak, which reflects the range of p–d bonding, increases with $N_\square$. This effect was explained by MO (cluster) calculations[130] as an increased contribution from 3*d* electrons to the high-energy part of the filled band. Though this conclusion was confirmed by a special study[136] of the (Ti)L_α band in the X-ray emission spectra of carbon-deficient samples of TiC_x, the shape and the broadening of the reported XPS bands[138] need to be redetermined because the samples used in those measurements were contaminated with W which could have distorted the spectra because of its high 5d(W) electron photo-ionisation cross-section.

Table 5. Binding energy (ΔE) and chemical shifts (δ) of the core levels $3d_{5/2}$(Zr) and $4f_{7/2}$(Ta) in ZrC_x and TaC_x.[34]

ZrC_x			TaC_x		
1.0	179.3	0.4	1.0*	23.7	1.9
0.9	179.3	0.4	0.95	23.6	1.8
0.8	179.1	0.2	0.9	23.6	1.8
0.6	178.9	0.0	0.8	23.3	1.5
			0.7	23.3	1.5
			0.6	22.9	1.1

*For the 1s(C) level in TaC_x we have $\Delta E = 283.0$ eV and $\delta = -2.2$ eV; for the other levels 283.1 and −2.1 respectively. In the case of ZrC_x we have $\Delta E = 281.7$ eV and $\delta = -3.6$ eV for the 1s(C) state at all the values of x used in the work.

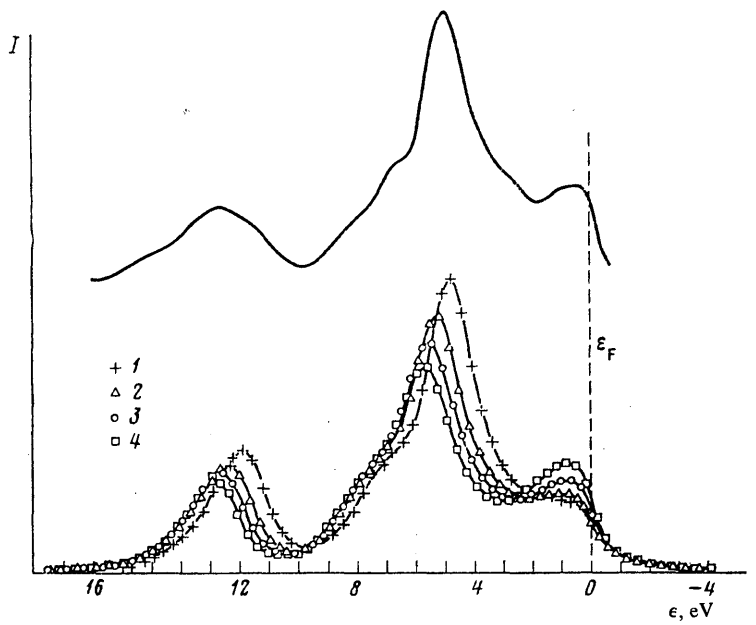

Figure 9. XPS spectra of TaC_x calculated[127] for x values of: *1*) 1.0, *2*) 0.9, *3*) 0.8, *4*) 0.7.

The photoelectron spectra of TiO_x [$x = 0.93$ or 1.15 (Ref.149), and $0.84 \leqslant x \leqslant 1.22$ (Ref.99)] showed a decrease in the intensity of the high-energy peak, which reflects mainly the 3d(Ti) states, with increasing oxygen content.

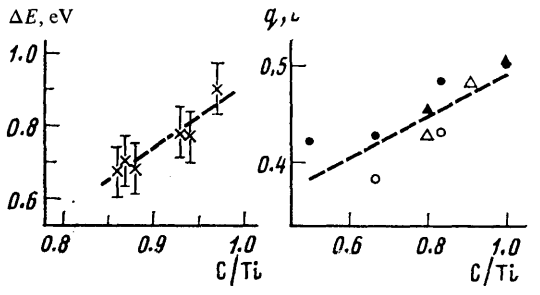

Figure 10. Shifts of ΔE for the $2p_{3/2}$(Ti) levels[139] and q^{eff} values for titanium[130] in TiC_x.

Interesting changes in the charge on the atoms in non-stoichiometric compounds were noted in measurements of the energy shifts of the inner levels of the X-ray photoelectron spectra of NbC_x,[148] NbN_x,[148] TiC_x,[138,139,147], and TaC_x and ZrC_x.[34] Shifts of the inner levels in low-carbon samples of TiC_x were also reported independently[140,147]. A systematic investigation of this effect[138,139] through the shift of the Ti $2p_{3/2}$ level showed a tendency for the shift to decrease as $N_\square$ increases (Fig.10), suggesting a change in the electronic configurations of the outer shells of Ti. Cluster calculations by the MO LCAO method[130] confirmed this. As Fig.10 shows, the effective charge q_{Ti} for clusters containing different numbers of vacancies decreases[130] as x decreases, denoting changes in the binding energy $E[2p_{3/2}(Ti)]$. Similar results have been reported[34] for ZrC_x and TaC_x (see Table 5). We note the fairly monotonic changes in the shifts $\Delta E[3d_{5/2}(Zr)]$ and $\Delta E[4f_{7/2}(Ta)]$, while the energy of the ls(C) levels remains practically constant: this can be ascribed to the constancy of the surroundings of the carbon atom in defect carbides, i.e. to the constant state of charge of the surroundings.

Attempts to examine the rearrangement of individual states in TiC_x as a function of N (by varying the energy of the exciting radiation) were inconclusive[139]. The use of X-ray emission spectroscopy methods seems more promising in this respect.

Most of the papers describing XE spectroscopic studies of the EES relate to non-stoichiometric oxides and carbides (see Table 3). For TiO_x ($x = 0.912$, 1.026, 1.19) the "centre of gravity" of the (O)$K\alpha$ band is shifted towards lower energies, and that of the (Ti)L_α band towards higher energies, by an increase in x, indicating[142] a decrease in charge density in the Ti and O spheres near ε_F and an increase in charge density in the deeper-lying states. Interesting rearrangements of the 4p(Ti) states have been observed[131] in a study of the (Ti)$K\beta_5\beta''$ spectra in TiO_x. In the region of non-stoichiometric compositions a high-energy structure element (K_{β_1}) was found, and its intensity was shown to increase with $N_\square$. The effect was interpreted[131] as a consequence of the 3d–4p mixing of the atomic orbitals of titanium on one lattice site, resulting from the lowering of the symmetry of the surroundings of the emitting atom produced by the formation of vacancies.

Direct confirmation of this conclusion was obtained in experiments with samples which had been exposed to high temperatures and pressures[131], in which the filling of vacancies (while retaining the overall composition $TiO_{0.88}$) caused a marked decrease in the intensity of the K_{β_1} sub-brand (see Fig.11). These results led to the recommendation[131] of X-ray emission as a method of calculating vacancy concentrations.

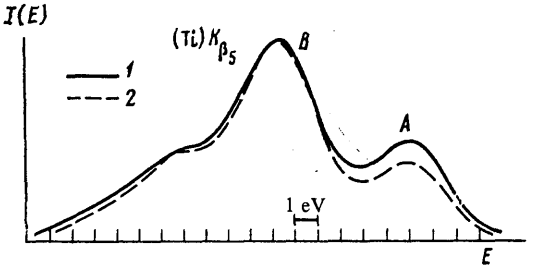

Figure 11. (Ti)K_{β_5} bands in the compound $TiO_{0.88}$: *1*) at normal pressure, *2*) at high pressure (90 kbar).[131]

The density of 3d(Ti) states near ε_F in titanium carbides is found to increase with $N_\square$ also from the behavour of the (Ti)L_α band[136,137], and direct confirmation of this increase has been obtained in cluster[129,136] and in band calculations[124]. A similar conclusion is reached from the shape of the (Nb)L spectra of NbC_x.[145] As regards the distribution of the 4p(Ti) states, identical Ti$K_{\beta_5}\beta''$ bands were observed for all the TiC_x compositions[126]. However, a more detailed study of $TiC_{1.0}$ and $TiC_{0.65}$ revealed[136] a clear $K^1\beta_5$ "outcrop" in the (Ti)K_{β_5} band of the non-stoichiometric compound which was absent in $TiC_{1.0}$ and can be interpreted as direct evidence of the appearance of 3d–4p interactions.

Far fewer studies of XE in non-stoichiometric nitrides have been reported. Nevertheless, existing X-ray emission L_α and $K_{\beta_5}\beta''$ spectra for compounds of composition TiN_x[142,158] and VN_x,[144,145] and calculations of the shape of the spectra by cluster (MO)[129] and band (CP) methods[125], suggest that the change in the valence band produced by an increase in the number of non-metal vacancies is the same for all the high-melting compounds of the transition metals: the density of d(M) states near the Fermi level increases, and the contribution from p(M) states (and also, in part, from the $2p$(X) electrons) also increases in this region. This conclusion is confirmed by the shape of the (X)K_α spectra of TiC_x, VC_x,[85,129,137], TiN_x, VN_x,[126,142,145] and TiO_x,[142,143] all of which develop a distinct "outcrop" on the short-wave side when $N_\square$ increases.

VII. THE CHEMICAL BOND IN NON-STOICHIOMETRIC MX_x COMPOUNDS

We shall now examine the changes in the chemical bond in non-stoichiometric compounds. As was pointed out above (Section III), in this class of compounds the bond is of a combined covalent–metallic–ionic type, and the existing descriptions differ in the relative contribution to the overall bond energy from the different types of interaction which they postulate.

Table 6. Populations (α) of the orbitals and of the interatomic bonds, and charges on the metal atoms, for some non-stoichiometric high-melting transition metal compounds[71,129].

Compound	$[MX_6]$ $(MX_{1.0})$					$[MX_6\square]$ $(MX_{0.856})$					$[MX_4\square_2]$ $(MX_{0.66})$				
	$(n+1)s$	$(n+1)p$	nd	q (M)	α (M – X)	$(n+1)s$	$(n+1)p$	nd	q (M)	α (M – X)	$(n+1)s$	$(n+1)p$	nd	q (M)	α (M – X)

Band calculations[119–122,124,125,127,128] suggest a number of conclusions on the change in relative contributions brought about by an increase in the number of defects. Thus an increase in the width and in the population of the metal d band[124,125,127,128] can be treated as a strengthening of the M–M interactions, whereas a narrowing of the $2p$(X) band is equivalent to a weakening of the interaction of the $2p$(X) and d(M) functions (the covalent component of the M–X bond).

A simple "energy diagram" of this type of redistribution can be produced[124] by noting that the breaking of M–C bonds produces an upward shift in energy of the d states of ~2.7 eV (in TiC_x), due to the $e_g \rightarrow t_{2g}$ ($d_\gamma \rightarrow d_\varepsilon$) transition. This increase in the occupancy ratio $N^M(t_{2g})/(N^M(e_g)$ (i.e. the strengthening of the M–M bond) caused by an increase in $N_\square$ has been ascribed[127] to charge transfer effects, arising from the reversion to the d_γ(M) band of the additional electron on the carbon atom when the latter is removed from the carbide lattice.

By far the most successful approaches in studies of the chemical bond are the cluster (MO) calculations, which offer a clear description of the origin and structure of the interactions between particles and allow the contributions from the different types of bond to be assessed quantitatively. The parameters of the electronic structure obtained from cluster MO calculations for a series of Ti, V, Zr, and Nb carbides, nitrides, and oxides[129] are listed in Table 6. We note that in both the stoichiometric and the non-stoichiometric compounds the main contribution to the chemical bond comes from the interaction between the nd functions of the metals and the $2p$ states of the ligands. As $N_\square$ increases, the occupancies of the individual M–X bonds also increase, but the total number of electrons involved in bond formation between the metal and the nearest ligands (expressed per metal atom) decreases from 2.45 for $TiC_{1.0}$ to 1.61 for $TiC_{0.5}$. Furthermore the addition of defects makes the electron density of individual bonds strongly anisotropic.

An increase in defect density rapidly lowers the charge (q^{eff}) localised on the atoms, thus making the role of the ionic component of the chemical bond even less important[117,129,130,132,136].

The changes in bond type brought about by a nearby vacancy are made clear by comparing the wave function diagrams for the σ and π types of interaction in stoichiometric and in non-stoichiometric titanium carbide[132]: this shows that the formation of a vacancy does not produce new bonds passing through the centre of the vacancy. The interactions between the states of the nearest metal atoms and those of the vacancy are quite complex, and they can be interpreted as a form of vacancy–metal π bonding. However, as the diagrams for the M–M interactions show[132], these bonds are the same as in the ideal carbide, and strong unscreened M–M bonds directed through the centre of the vacancy[114] are not formed.

Similar conclusions follow from cluster calculations modelling vacancies of metal atoms[132]: no electrons are localised on the vacancy, and no bonding states are created near the vacancy. Obviously, this explains the reported instability of metal vacancies in titanium carbide.

The changes in chemical bonding discussed above for the case of TiC_x apply also to other defect compounds of the MX_x type[129–131,135] (see Table 6).

In the carbide–nitride–oxide series the population of orbitals of the t_{2g} type increases (i.e. the M–M interaction increases), but the M–X bonds remain predominant over the whole of the homogeneity region (though their anisotropy increases). The total number of electrons localised on the M–X bonds decreases.

In the compounds of 4d metals (Zr, Nb), as in the stoichiometric compounds, the d(M)–$2p$(X) bond becomes stronger.

In the carbides of the sub-group Va transition metals various parameters (micro-hardness, thermal expansion coefficient, etc.) were found to have an extremum near the composition $MX_{0.8}$.[9,10,115].

These effects are probably related to the observed ordering of the vacancies[151–154] in MX_x. Evidently, more accurate descriptions can be expected from future calculations with clusters large enough to allow for ordering of the vacancies in the crystal structure.

VIII. THE ELECTRONIC STRUCTURE AND PHYSICOCHEMICAL PROPERTIES OF NON-STOICHIOMETRIC COMPOUNDS

Many studies of the physicochemical properties of high-melting compounds containing defects have been reported[3–10,115]. The results are usually interpreted in terms of simple qualitative models, and attempts to relate the observed changes to the parameters of the electronic structure, or indeed to calculate these parameters, are uncommon[127,129–136]. The only exception is the series of calculations (mentioned above) on XPS and XE spectra. This is due partly to the difficulty and complexity of strict quantum-chemical calculations of the electronic spectrum of defect phases, and partly to the difficulty of preparing samples with different vacancy concentrations while excluding microstructure effects (grains, domains, etc.) and chemical impurities, so that the observed differences in properties can be reliably ascribed to the different defect concentrations[3–10].

Nevertheless various correlations (of the electronic structure–property type) have been proposed[127,129–136,155,156]. To discuss these results we must examine first of all the method

used to calculate the EES of the compound. Depending on the specific features of the chemical bond and of the electronic structure, all the physicochemical properties which describe a high-melting phase can be classified into two groups[9]. The first includes the "lattice" properties such as micro-hardness (H_μ), T_f, atomisation energy, thermal expansion coefficient, etc. In the second group we classify all the magnetic and electrical properties determined by the distribution and concentration of high-energy delocalised *d* electrons. In this case calculations based on cluster (local) models are the most effective for describing the first group of properties, whereas approaches based on the band model are preferable for processes determined by the behaviour of almost fully collectivised electrons in a periodic crystal field.

Unfortunately, only a few qualitative comparisons have been possible so far, because of the very limited range of band calculations now available[127]: known anomalies in the phonon spectra of NbC_x and TaC_x can be explained by the redistribution of density of t_{2g} sub-bands, and the changes in $N(\varepsilon)$ can be shown to be qualitatively consistent with changes in T_S, ρ, the Hall coefficient, and the electronic specific heat.

More precise correlations have been possible by using the results of cluster calculations[129-136]. Changes in the "lattice" properties (decrease in T_f, H_μ, and atomisation energy accompanied by an increase in the amplitude of thermal vibrations $\sqrt{u^2}$ and in thermal expansion coefficient[157]) caused by an increase in $N_\square$ (Fig.12) are ascribed to the general weakening of the covalent M-X interaction resulting from the decrease in the total number of electrons localised on neighbouring M-X bonds and from the large increase in the anisotropy of individual bonds (see Table 6). The observed increase in magnetic susceptibility, and decrease in ρ, are consistent with the increase in the number of *d*-type electrons close to ε_F. In some calculations[129,131,132] the defects were assumed to be fully disordered. Long-range order[152-154] (with a type of ordering dependent of composition) should cause departures from monotonic dependences, as has in fact been observed for some of the parameters of the carbides of sub-group Va metals (see Fig.12).

The main weakness of the parameter (the overlap population) used by several workers[129-136] to explain the physicochemical properties of MX_x compounds is that it cannot be measured by direct experiment. An energy scheme developed[67] for calculating chemical bond stabilities in stoichiometric TiC, TiN, VC, and VN has confirmed earlier conclusions based on bond populations on the changes in bond energetics in this series of compounds. We can therefore expect these conclusions to be extended to energy effects in the bonds of non-stoichiometric compounds.

An interesting new application of EES calculations in the cluster model is in the interpretation of the NMR spectra of MX_x.[156] The observed parameters of the NMR spectra have been correlated with changes in overlap populations of different types (σ and π). Direct quantum-chemical calculations of the electric field gradient in VC_x, VN_x, and VO_x showed that at the nuclei this parameter is determined by valency contribution from the 3*d*(V) electrons. The calculated quadrupole interaction constants were in reasonably good agreement with experiment ($\nu_Q = 0.48$ and 0.164 MHz respectively for VO_x).

A calculation[134] by a non-empirical X_α-SW method gave a temperature (T_S) for the transition to the superconducting state in NbC_x and VN_x in qualitative agreement with the experimental value. These results justify the hope of substantial new progress in the application of cluster methods

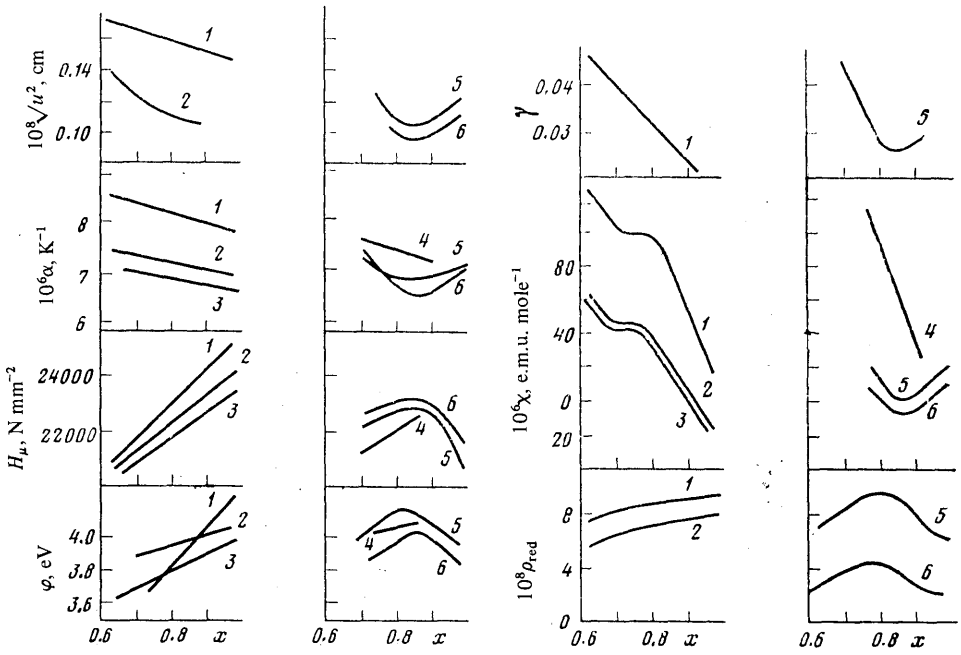

Figure 12. Changes in the amplitude of the thermal vibrations of the atoms ($\sqrt{u^2}$), thermal expansion coefficient (α), micro-hardness (H_μ), work function (ϕ), recombination coefficient of hydrogen atoms (γ), magnetic susceptibility (χ), and reduced electrical resistivity (ρ_{red}) in the homogeneity region of the carbides of: *1*) Ti, *2*) Zr, *3*) Hf, *4*) V, *5*) Nb, *6*) Ta.[9]

to the calculation of the physicochemical characteristics of defect phases.

---oOo---

Thus the basic models and methods of calculation developed so far are adequate for meaningful studies of the EES of defect phases over a wide range of vacancy concentrations. The main features of the rearrangements in the electronic structure and of inter-particle interactions in MX_x compounds have been established. Further developments in our understanding of the EES of defect phases should include defect ordering and double defect structures. Another important future goal is the assessment of the energy of rearrangements in the chemical bond caused by the creation of vacancies, which could be immediately translated into a description of the mechanism of structural phase changes in MX_x. By developing a new formalism, and by adding to the existing fund of calculations of independently measurable physicochemical properties in the homogeneity region, new impetus could be given to the development of theoretical models of defect states offering a prescribed set of properties.

Relation between the Nature of the Components of Titanium-containing Ziegler Systems and Their Activity and Stereospecificity in the Polymerisation of Dienes

N.G.Marina, Yu.B.Monakov, S.R.Rafikov, and V.I.Ponomarenko

Problems concerning the influence of ionic-coordination catalytic systems and of the structure of their individual components on their stereospecificity and activity in the polymerisation of dienes are considered in relation to titanium-containing catalysts. Modern ideas about the structure of the active centres and the factors determining their stereoregulating capacity are also examined.
The bibliography includes 153 references.

III. The structure of active centres and their stereoregulating capacity 419

I. INTRODUCTION

The development of studies on catalytic processes using systems of the Ziegler–Natta type opens up new possibilities for the separation of stereoregular polymers both by employing hitherto uninvestigated monomers and by varying widely the composition and conditions in the formation of the catalyst. The literature on this question is enormous particularly when patents are included. The titanium-containing catalytic systems, which have been most thoroughly investigated and have been most widely used, are convenient systems for examining the influence of the composition of the catalyst on the stereospecificity of the systems and their activity as well as certain kinetic characteristics of the polymerisation of dienes, primarily butadiene and isoprene. These data made it necessary to resort to modern ideas about the structure of the active centres and the factors determining their stereoregulating capacity.

II. THE INFLUENCE OF THE STRUCTURE OF THE COMPONENTS OF TITANIUM CATALYTIC SYSTEMS ON THE CHARACTERISTICS OF THE POLYMERISATION OF DIENES

It is known that, depending on the nature of the transition metal, the polymerisation of dienes in the presence of metal complex catalysts results in the formation of polymers with different stereoregularities. For example, the $TiCl_4$–AlR_3 system (Al : Ti ≅ 1) yields preferentially 1,4-*cis*-polyisoprene[1], while 1,4-*trans*-polyisoprene is formed in the presence of VCl_4–AlR_3.[2]

Catalytic systems based on the same transition metal are also capable of manifesting different stereospecificities. This is primarily because the metal in the active centres of the growing chains ($P-MX_n$) can exist in various valence states and can contain particular groups X at their reaction centre. The state of the active centre also changes when the polymorphic modification of the transition metal compound is varied. Allowance for these factors opens up wide possibilities for the regulation of the stereospecificity of catalytic systems[3] by altering the nature of the transition metal, its valence, and the structure of the ligand X. Thus it has been shown in relation to chromium-containing catalysts[4] that the variation of the ligands makes it possible to realise all the conceivable microstructures of polybutadiene and polyisoprene.

****The polymer chain consists predominantly of units of the given type.

Such universality is characteristic also of titanium-containing catalytic systems. Titanium systems of the Ziegler type make it possible to obtain highly stereoregular polybutadienes with all possible microstructures (Table 1) and a similar picture is also observed when organometallic titanium compounds are used (Table 2). There are as a rule no 1,2-units in polyisoprene obtained in the presence of titanium systems of the Ziegler type (Table 3). Up to 6–7% of 1,2-units is formed only with benzyl derivatives (Table 4).

With the exception of piperylene (Table 5), studies on the polymerisation of two conjugated dienes have not been systematic and have not embraced a wide range of catalytic systems. It is therefore difficult to infer the stereoregulating selectivity of titanium systems in relation to these monomers.

1. The Influence of the Ligand Environment at the Titanium Atom on the Stereospecificity and Activity of the Catalyst

There are at present no experimental data characterising the structure of the active centres of Ziegler catalysts but the specific features of the active centres can be inferred at least comparatively from the microstructures of the polydiene.

Table 1 shows that in the polymerisation of butadiene the titanium-containing system exhibits a high *cis*-regulating capacity only if it incorporates iodine and, for the optimum component ratio, the form in which this element is incorporated in the system is not very significant: in the initial titanium compound (TiI_4, TiI_2Cl_2), in the elemental form (I_2), or as part of the composition of other components (AlI_3, AlR_2I). The benzyl derivatives of titanium provide a remarkable example of the fact that the presence of iodine at the titanium atom in the active centre does not alone ensure a high *cis*-regulating capacity of the catalyst in the polymerisation of butadiene. Thus a sharp difference between the stereospecificities of R'_2TiI (91% of 1,4-*cis*-units) and $R'TiI_2$ (32% of 1,4-*cis*-units) has been observed[41]. It is extremely instructive that, when the $R'TiI_2—AlR_3$ system is judged on the basis of the microstructure of polybutadiene (Table 2), its active centres are apparently identical with those of the R'_2TiI catalyst.

The data on the microstructure of polybutadiene justify the hypothesis that, in all cases where iodine-containing Ziegler systems are used (Table 1), identical active centres are formed with iodine in the coordination sphere of the titanium atom. This is also confirmed by the results of the study of substances formed in the $TiI_4—AlR_3$ and $TiCl_4—I_2—AlR_3$ systems[58]. It has been observed that reduction and halogen exchange reactions take place in the ternary system and that the deposit contains organotitanium(III) iodide. When titanium tetrachloride is reduced by diethylaluminium bromide, the amount of bromine which is added to titanium is also appreciably greater than might have been expected on the basis of the statistical redistribution of the halogens[59]. The ease of replacement of chlorine at titanium by bromine or iodine has also been observed when $TiCl_3$ is treated with certain bromine- and iodine-containing compounds (AlI_3,

$AlRI_2$, AlR_2I, $AlBr_3$, $AlRBr_2$, and AlR_2Br), which is accompanied by a change in the stereospecificity of the action of the $TiCl_3$–AlR_2Cl system[60]. It has been suggested[61] that the ease of halogen exchange between $TiCl_4$ and AlR_2I is due to the fact that the larger titanium ion combines preferentially with the more polarisable (larger in size) iodide ion, while aluminium combines preferentially with the smaller halide ion (the chloride ion).

Judging from the microstructure of polydienes (Tables 1 and 3), such exchange reactions take place in those cases where the initial titanium compound in the catalytic system does not contain a halogen and is an alkoxide, an amide, or an acetylacetonate. Thus when the AlI_3, $AlBr_3$, and $AlCl_3$ additives are introduced into the $Ti(acac)_3$–AlR_3 system[15], the contents of the 1,4-*cis*-units in polybutadiene are 72, 64, and 53% respectively. These results confirm yet again the occurrence of exchange processes and the appearance of a halogen at the titanium atom in the active centre. Judging from the microstructure of polybutadienes[15], the exchange reactions leading to the formation of catalytic complexes based on titanium trihalides do not go to completion. One cannot rule out the simultaneous presence in the system of active centres of different types, particularly in the presence of $AlBr_3$ and $AlCl_3$, which can be inferred from the somewhat high number of 1,2-units in the polymer, characteristic of active centres formed on the basis of titanium compounds with a Ti–O bond.

For a titanium system ensuring a 1,4-*trans*-polymerisation of butadiene and isoprene, the presence of a halogen in a particular component is also obligatory. One should not the $TiCl_4$–AlR_3(Al : Ti > 2), α-, γ-, and δ-$TiCl_3$–AlR_3, and $TiCl_2$–AlR_3 systems, which are highly stereospecific in the *trans*-polymerisation of butadiene and isoprene. However, the appearance of such isotypical regulating capacity regardless of the nature of the monomer is by no means observed in all cases. Thus the $Ti(n\text{-}OR')_4$–$AlRCl_2$ (Al : Ti = 10) system leads to the formation of crystalline 1,4-*trans*-polybutadiene, whereas polyisoprene containing only 38% of the 1,4-*trans*-units is formed under the same conditions[16]. With decrease of the Al : Tl ratio to 4–6, the above system becomes *cis*-regulating in relation to isoprene and yields polybutadiene with a mixed microstructure.

Data on the chemical analysis and X-ray diffraction of the products of the reaction between $Ti(n\text{-}OR')_4$ and $AlRCl_2$ showed that, for Al : Ti = 4, the insoluble component consists almost entirely of β-$TiCl_3$ crystals[16]. NMR data have led to the conclusion that the exchange reaction $Ti(OR')_4 + AlRCl_2 \rightarrow TiCl_4 + AlR(OR')Cl$ takes place in the homogeneous phase and precedes the reduction of titanium. The EPR spectrum of the reaction mixture in which insoluble compounds have already been formed shows a broad signal with a *g*-factor of 1.959, which has been attributed to titanium(III) chloride with an adsorbed aluminium alkyl. Consequently, active centres identical in their structure to those in the $TiCl_4$–AlR_3. .(Al : Ti ≅ 1) catalytic system are formed in the $Ti(n\text{-}OR')_4$–$AlRCl_2$ system with the ratio Al : Ti ≅ 4. This is also supported by the microstructures of polybutadiene and polyisoprene formed in such cases.

An unusual feature of the $Ti(OR')_4$–$AlRCl_2$ systems consists in the dependence of their stereospecificity and the nature of the group OR' and the solvent[34]. Titanium tetraalkoxides with both linear and branched primary substituents form *cis*-regulating systems regardless of the nature of the solvent, while titanates with tertiary substituents lead to the formation of *trans*-polyisoprene. The most interesting results have been obtained for titanates with secondary substituents: *cis*-polyisoprene is formed in aliphatic solvents, while the use of aromatic solvents results in the inversion of the stereospecificity and the formation of *trans*-polyisoprene. The results of the study of these systems in various solvents by EPR have been interpreted[34] as evidence for the formation of crystalline α- or β-modifications of $TiCl_3$, because the structure of the titanates in solution (monomeric or polymeric form) is influenced both by the structure of the substituent OR' and by the nature of the solvent[62]. In all cases where the initial alkoxide has the polymeric form, 1,4-*cis*-polymerisation takes place and the monomeric alkoxides lead to the formation of 1,4-*trans*-polyisoprene. The Ti–Ti bonds are shorter for the polymeric form of the alkoxides and it is believed[34] that, after the reaction with $AlRCl_2$, the difference is maintained, which is consistent with various modifications of $TiCl_3$ in which the distances between the titanium atoms are 3.54 and 2.91 Å for the α- and β-forms respectively[63]. In other words, the "seed" for the formation of the α- and β-forms of $TiCl_3$ is already present in the initial solution of the alkoxide and predetermines the stereospecificity of the $Ti(OR')_4$–$AlRCl_2$ catalyst.

Presumably analogous $TiCl_3$ formation reactions occur also in the $Ti(NR'_2)_4$–$AlRCl_2$ systems[24].

The presence of a halogen at the titanium atom is not always obligatory for the formation of a polydiene having a predominantly 1,4-structure. Thus 1,3-pentadiene gives rise to an isotactic polymer containing mainly 1,4-*cis*-units in the presence of the $Ti(OR')_4$–AlR_3 systems[50]. On the other hand, the use of a titanium halide does not always ensure the formation of 1,4-polydiene either. The polymerisation of 4-methylpenta-1,3-diene in the presence of the $TiCl_4$–AlR_3 or α-$TiCl_3$–AlR_3 systems leads to the formation of a crystalline polymer having the 1,2-structure; the $Ti(OR')_4$–AlR_3 system likewise gives rise to the 1,2-polymer but this is amorphous[64].

Thus, while there is an abundance of different varieties of highly stereospecific titanium systems, the set of active centres formed (not only as regards the selectivity of their action but also their composition and structure) is apparently much narrower. The results which might have confirmed directly the identity of active centres in many systems are so far not available. Nevertheless data on the microstructures of polydienes, the interaction of the system components, and the compositions of the corresponding products justify this conclusion. The data accumulated on various titanium systems confirm yet again the view[65] that there are no "specialised" atoms or groups responsible for the stereospecificity in the polymerisation of dienes in the presence of metal complex catalysts. Because of this, catalytic systems in fact manifest a wide variety of stereoregulating capacities, particularly when the monomer is varied. This feature hinders significantly the search for ways of regulating the stereospecificity of these catalysts. Nevertheless, certain characteristics can be traced fairly clearly. In the first place this concerns the influence of halogens on the stereospecificity.

The nature of the halogen in the $TiHal_4$–AlR_3 systems determines the microstructure of polybutadiene: the content of *cis*-units is a maximum for iodine-containing systems and a minimum for fluorine-containing systems. The decrease in the number of *cis*-units is then caused by the increased amount of *trans*-structures, while the fraction of 1,2-units hardly changes. The stereoregulating capacity of monohalide derivatives of tetrabenzyltitanium also depends on the nature of the halogen. As in systems of the Ziegler type, the maximum number of *cis*-units are formed in the presence of iodine-containing derivatives (Table 2). However, in this case the decrease of the number of *cis*-units in the macrochains corresponding to the series of iodine-, bromine-, and chlorine-containing catalysts occurs primarily due to the increase of the fraction of 1,2-units. The absence of a halogen in titanium derivatives with a Ti–C bond (Table 2) leads to the formation of a polymer in which 1,2-units predominate

and, as can be seen from the microstructure of polybutadiene obtained in the presence of $(ClC_6H_4-CH_2)_4Ti$,[43] the preferential 1,2-combination of units requires the obligatory presence of the Ti–Hal bond. The introduction of chlorine into the aromatic ring also alters significantly the stereoregulating capacity of tetrabenzyltitanium. The results obtained in the polymerisation of butadiene in the presence of systems of the Ziegler type based on $TiCl_2(OCOCCl_3)_2$ and $TiCl_2(OCOCF_3)_2$ are also consistent with this[14]. The contents of the *cis*-units in the polymer are then 60 and 38% respectively, while the number of 1,2-units remains at the same level. Thus the halogen has an appreciable influence on the stereoregulating capacity of the catalyst by altering the electron density on titanium also when the latter is part of the titanium component but is not directly involved in a Ti–Hal bond.

One must note that the influence of the nature of the halogen on the stereospecificity of titanium systems in the polymerisation of butadienes differs somewhat from that in systems with other transition metals (V, Cr, Co, Ni, Mn, Fe). The effects of these metals (M) have been compared in the $M(acac)_n-AlR_3-AlX_3$ (X = Cl, Br, or I) systems; the content of 1,4-*cis*-units in polybutadiene increases in all cases, except for titanium, in the sequence Cl > Br > I, other conditions being equal[15]. It was established[15] that the content of 1,4-*cis*-units in polybutadiene obtained in the presence of titanium systems decreases linearly with increasing electron affinity (*eV*) of the halogen present in the system. In compounds of other metals (V, Cr, Co, Ni) a direct relation is observed between *eV* and the content of units with the *cis*-structure in polybutadiene. The unusual behaviour of titanium has also been noted[66] in the study of the NMR spectra of halide derivatives of biscyclopentadienyltitanium: the opposite sequence was observed for the halogens when the apparent energies of the abstraction of electrons from the titanium atom were estimated.

The data presented in Table 6 confirm that the influence of the halogen on the stereospecificity of ionic-coordination systems is varied and is determined by the nature of the transition metal. Only the stereospecificity of systems based on *f* elements is independent of the nature of the halogen.

Table 6. The influence of the nature of the halogen on the stereoregularity of the polybutadiene obtained in the presence of catalytic systems containing halogeno-derivatives of *d* and *f* elements.

Halogen	Content of 1,4-*cis*-units				
	Ti	Co [67]	Ni [67]	Nd [68]	U [69]
F	35	93	98	95.7	—
Cl	55	98	85	96.2	99.0
Br	85	91	80	96.8	98.5
I	95	50	10	96.7	98.5

Note. The microstructure of polybutadiene obtained in the presence of the $TiHal_4-AlR_3$ systems is indicated in accordance with the data in Table 1.
The numbers in square brackets denote references (Ed. of Translation).

Sharp differences between the microstructures of the polymer have not been observed as a function of the halogen in the polymerisation of isoprene in the presence of titanium systems of the Ziegler type. However, in the presence of tetrabenzyltitanium monohalide derivatives (Table 4) the overall variation of the number of units with the *cis*-structure in polyisoprene on passing from iodine-, to bromine-, and chlorine-containing derivatives is consistent with the relation observed in the polymerisation of butadiene in the presence of the same compound.

The replacement of the halogen atoms in $TiHal_4$ by substituents of another chemical type alters significantly the stereoregulating capacity of the catalytic systems. Individual examples of this are presented in Tables 1, 3, and 5. The replacement of the Ti–Hal bonds in the titanium component by Ti–O bonds increases the contribution of the 1,2-addition in polybutadiene. Thus the contents of the 1,2-units in the polymers for systems based on $TiCl_4$, $TiCl_2(OCOCH_3)_2$, and $TiCl(OCOCH_3)_3$ are 14, 21, and 42% respectively[14]. The same type of variation is manifested in the $TiCl_4$, $TiCl_2 \cdot (OC_4H_9)_2$, and $Ti(OC_4H_9)_4$ series—14, 48, and 73% of 1,2-units respectively[14]. A sharp decrease in the rate of polymerisation is observed in the series indicated. The step involving the addition of 1,2-units takes place approximately 300 times more slowly than for the 1,4-*cis*-units, which is indicated by a comparison of the rate constants for the chain propagation of polybutadiene when catalytic systems based on $Ti(OR')_4$ and TiI_2Cl_2 are used[70].

Data obtained for systems based on dichloroacetoxytitanium derivatives have shown that the content of 1,4-*cis*-units in polybutadiene diminishes with increase of the electronegativity of the acido-ligand[14]. An analogous picture has been noted also for titanium dichloride derivatives containing the anions of butyric acid or its chloro-derivatives. In all these cases the content of 1,4-*cis*-units diminishes due to the formation of *trans*-structures, while 1,2-addition in the chain is maintained at the same level regardless of the presence and nature of the halogen in the acido-ligands.

Presumably the change in the chemical nature of the substituents at the transition metal atom (and not the accompanying steric factors, which nevertheless must be taken into account) have in fact the primary influence on the catalytic characteristics of the active centres. Thus an increase in the length or bulk of the substituent of one chemical type at the titanium atom does not affect the stereospecificity of the catalyst[14,70]. It has been shown for the $Ti(OR')_4-AlR_3$ systems[70] that, when the substituents R' are varied within a homologous series, the microstructure of polybutadiene and the rate constant for chain propagation do not vary. The reactivity of the active centres is maintained, but the reactivity of the systems diminishes with increase in the size of R' as a result of the decrease of the number of these centres, the latter being related primarily to the steric hindrance in the interaction of the components of the catalytic system.

In considering the possibility of regulating the stereospecificity of catalytic systems of the ionic coordination type, one must also deal with results obtained in the study of these systems in the presence of modifying electron-donating additives. The nature of the variation of the stereospecificity of Ziegler systems following the introduction of an electron donor is determined by the nature of the transition metal. It has been shown for the $M(acac)_n-AlR_2Cl$ (M = V, Cr, Co, Ni, Ti) systems[19] that the influence of bases is most notable for the titanium systems; the extent of the changes in the microstructure is smallest when bases are introduced into a nickel-containing system.

The introduction of ethers, thioethers, and tertiary amines into the highly stereospecific *cis*-regulating TiI_4-AlR_3 system impairs the microstructure of polybutadiene as a result of the increase of the content of the 1,4-*trans*-unit, while the number of 1,2-units hardly changes[71,72]. The influence of ethers on the microstructure of the polymer varies in the sequence dimethyl ether > ethyl methyl ether > diethyl ether > dibutyl ether, which agrees with the variation of the capacity of the ethers for complex formation. A similar picture has been

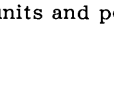
observed also after the introduction of electron donors into another *cis*-regulating system: $TiCl_4$–AlI_3–$AlHCl_2OR_2$.[9] The content of the *trans*-units in polybutadiene reaches 80% (without change in the content of the 1,2-structures) when amines are introduced into the $TiCl_4$–AlR_3 system[73], which gives rise to a polymer with a mixed microstructure in the absence of these additives. With the aid of electron donors, it is sometimes possible to achieve the almost complete inversion of the stereospecificity of the catalyst. Thus the addition of tetrahydrothiophen to the $TiCl_3.3AlI_3$–AlR_3 system leads to the formation of polybutadiene containing 88% of the 1,4-*trans*-units, while in the absence of a Lewis base the system exhibits a high *cis*-regulating capacity[74].

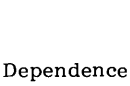
The addition of electron donors to systems based on titanium halides does not alter the ratio of the sums of 1,4-units and 1,2-units in the polybutadiene chain but drives the process towards a more intense formation of the 1,4-*trans*-units. On the basis of the concept of the *anti–syn* isomerisation of the terminal unit[75], it has been suggested that bases displace the equilibrium towards the formation of the *syn*-complex responsible for the appearance of units with the *trans*-structure in the chain.

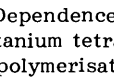
The influence of the structure of the electron donors on the stereospecificity of the $TiCl_4$–AlR_2 systems in the polymerisation of isoprene has been traced[76] in relation to a series of tetra-alkyldiamines and, by altering the amount of *N,N,N',N'*-tetramethyldiamino-4,4'-diphenylmethane, it has been possible to regulate smoothly the stereospecificity of the system.

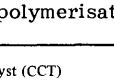
In contrast to the *cis*-regulating halogen-containing titanium systems of the Ziegler type, the addition of electron donors to tribenzyltitanium iodide in toluene enriches polybutadiene in the 1,2-units and polyisoprene in the 3,4-units[40,47].

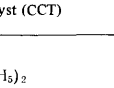
Table 7. Dependence of the stereospecificity of systems based on titanium tetrachloride on the nature of the cocatalyst in the polymerisation of isoprene.

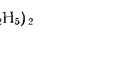


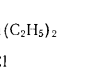


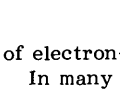












Cocatalyst (CCT)	CCT : $TiCl_4$	1,4-*cis*-units, %	Refs.
AlR_3	⩾1	95—99.5	[1, 6, 26, 27]
$AlH(Hal)_2 \cdot O(C_2H_5)_2$	1.5—2.2	95—96	[77]

2. The Influence of the Nature of the Organometallic Component on the Activity and Stereospecificity of the Catalyst

Mainly organic derivatives of Group I–III metals are used as the organometallic components (cocatalysts) in Ziegler systems. Despite the wide variety of cocatalysts, organoaluminium compounds (OAC) are most widely used in the polymerisation of butadiene and isoprene. Although the presence of a cocatalyst is not always obligatory for the occurrence of ionic-coordination polymerisation, it can have a significant influence on the process characteristics.

The microstructure of the polyisoprene obtained in the presence of titanium tetrachloride (Table 7) does not depend significantly on the nature of the organometallic compound, *cis*-polymerisation occurring in all cases. A distinctive feature of systems based on the OAC is their high catalytic activity combined with a high stereoregulating capacity (Tables 7 and 8).

Table 8. The influence of the nature of the organoaluminium compound on the microstructure of polydienes ($TiCl_4$ and TiI_2Cl_2 catalysts for isoprene and butadiene respectively)[91].

No.	OAC	Content of 1,4-*cis*-units, %	
		polybutadiene	polyisoprene
1	Al (iso-C_4H_9)$_3$	91	95
2	Al (C_7H_{15})$_3$	90	96
3	Al ($C_{10}H_{21}$)$_3$	90	96
4	Al ($C_{15}H_{31}$)$_3$	91	96
5		90	96
6		90	95
7		92	96
8		92	95
9		—	97
10		91	96

13	(iso-C_4H_9)$_2$Al—N (C_2H_5)$_2$	93	96
14		92	—
15		91	—
16		92	97
17	(iso-C_4H_9)$_2$Al—C≡C—C_6H_5	92	96

The role of electron-donating additives has been adequately elucidated. In many cases they (for example, water and alcohols) can react both with the transition metal compound and with the organometallic cocatalyst. On the other hand, the main cause of the effect of bases on the stereospecificity of the system is probably associated with their ability to be coordinated to the transition metal atom, to alter its ligand environment (electron density), and consequently to influence the reactivity of the active centre.

Aluminium tetrahydroborate and organomagnesium compounds are least stereospecific as cocatalysts in the polymerisation of isoprene. In their presence, low-molecular-weight polymers containing not more than 80% of *cis*-units are obtained. The polymerisation of butadiene in the presence of TiI_4, TiI_2Cl_2, and organomagnesium cocatalysts[92,93] involves the formation of polymers whose stereoregularity is as high as that of the polymers obtained using AlR_3. Organosilicon and organotin compounds occupy a special place among cocatalysts

(Table 7). They permit the use of a wide range of component ratios of the catalytic system, but the molecular weight of the polymers is low. Cocatalysts based on polyiminoalanes $[-AlH-NR-]_n$ [60] cause a rapid polymerisation of the diene and the polymers obtained under these conditions exhibit a high stereoregularity and have high molecular weights and a low content of the gel fraction. The activity of polyiminoalanes as cocatalysts in the polymerisation of isoprene in the presence of $TiCl_4$ depends on the structure of the group R, the greatest activity being attained for groups with a secondary carbon atom in the α- or β-position relative to the nitrogen atom.

More detailed data are available concerning the influence of the structure of the OAC on the characteristics of the catalytic systems for the polymerisation of dienes. In the first place one should note that a change in the structure (chain length, degree of branching, degree of cyclisation, and degree of unsaturation) of the hydrocarbon groups in AlR_3 does not entail a change in the stereospecificity of the catalytic system (as shown in experiments using titanium halides and tetraalkoxides[91,94–97]). The replacement of alkyl groups by groups containing heteroatoms (N, O, Si) is also not reflected in the microstructure of polydienes (Table 8). However, in contrast to their stereoregulating capacity, the activity of titanium systems in the polymerisation of both butadiene and isoprene depends significantly on the structure of the group in the organoaluminium component. The following main characteristic features have been discovered.

With increased length of the alkyl group within the limits of the homologous series of the OAC, the rate of polymerisation initially rises and then tends (Fig. 1) to a limiting value for OAC in which the chain length of the group exceeds C_{12}.[91,94–97] Here the region of catalytic activity shifts (Fig. 2) towards higher Al : Ti ratios with increase in the size of R.[91,96,97] AlR_3 with branched alkyl groups are more reactive than those with linear groups. However, among OAC with substituents having the iso-structure the activity also increases with increase of the number of carbon atoms in the group[94].

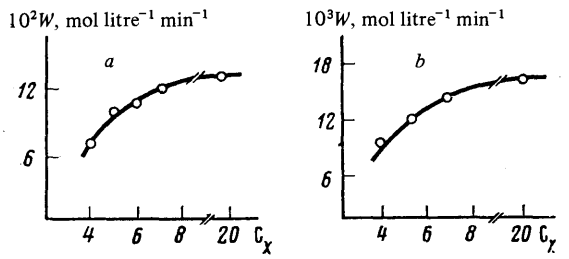

Figure 1. Dependence of the rate of polymerisation W of butadiene in the presence of TiI_2Cl_2–AlR_3 (*a*) and isoprene in the presence of $TiCl_4$–AlR_3 (*b*) on the number of carbon atoms C_X in the alkyl group R; solvent–toluene; t = 20 °C; $[TiI_2Cl_2] = 1.5 \times 10^{-3}$ M; $[TiCl_4] = 2.7 \times 10^{-3}$ M; $[C_4H_6]$ = 0.82 M; $[iso\text{-}C_5H_8]$ = 1.0 M.[91]

For the same number of carbon atoms, the rate of polymerisation is higher for aluminium trialkyls with linear substituents than for AlR_3 with cyclic substituents. With increase of the bulk of the cyclic substituent, the activity of the system falls. For the same number of carbon atoms in R, the rate of polymerisation is higher for AlR_3 with double bonds in the group than for saturated substituents, the presence of conjugated double bonds resulting in a still greater increase in the rate (Fig. 3).[91,97]

The replacement of alkyl groups in AlR_3 by substituents containing heteroatoms (N, O, Si) decreases the activity of the catalytic systems[91,97]. Consequently the increase in the activity of the titanium catalytic systems suggest the usefulness of employing organoaluminium compounds containing 8–10 carbon atoms in the hydrocarbon substituents and double bonds, in particular conjugated double bonds. It may be hoped that, when gel-immobilised OAC are used, it will be possible to increase still further the activity of the catalysts while retaining their high stereospecificity, particularly since a recent communication[98] confirms this possibility.

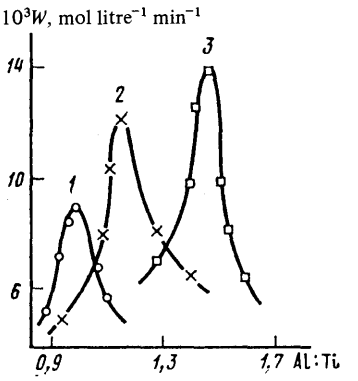

Figure 2. Dependence of the rate of polymerisation of isoprene on the Al : Ti ratio in the $TiCl_4$–AlR_3 systems with R = iso-C_4H_9 (curve *1*), n-C_7H_{15} (curve *2*), and n-$C_{10}H_{21}$ (curve *3*); solvent—toluene; $[TiCl_4] = 2.7 \times 10^{-3}$ M; [monomer] = 1.0 M; t = 20 °C.[91]

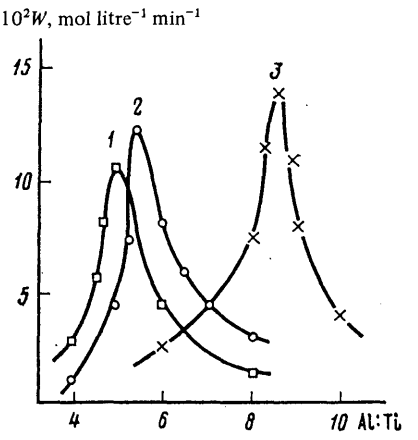

Figure 3. Dependence of the rate of polymerisation of butadiene in the presence of the TiI_2Cl_2–AlR_3 systems with different Al : Ti ratios on the structure of the group R:

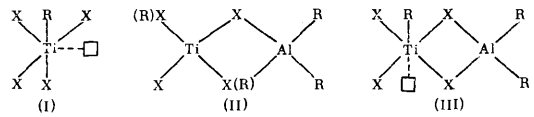
1)  2)  3) 

solvent—toluene; t = 20 °C; $[TiI_2Cl_2] = 1.5 \times 10^{-3}$ M; [monomer] = 0.82 M.[91]

Thus, when substituents at the aluminium atom in the cocatalysts are varied within the limits of a homologous series, the stereospecificity of ionic-coordination systems remains constant in the polymerisation of dienes, but their activity changes, as in the case where substituents are varied similarly at a transition metal atom. Such variation results in the formation of active centres with identical structures and reactivities. This is supported, apart from the microstructure data, by the following facts. The form of the EPR spectra of the reaction product in the TiI_2Cl_2–AlR_3 and $Ti(OR')_4$–AlR_3 systems is independent of the length of the group R.[96] The activation energy for the chain propagation reaction is likewise independent of the length and structure of the hydrocarbon group in the polymerisation of isoprene in the presence of $TiCl_4$–AlR_3 and amounts to 5–6 kcal mol^{-1}.[91,99] All the changes in the activity of the catalytic systems associated with the differences between the structures of the substituent in the OAC and unaccompanied by a change in the microstructures of the polymers are due to the different concentrations of the active centres, while the reactivity of these centres (k_p) remains unchanged (Table 9).

Table 9. The influence of the structure of AlR_3 on the rate constant for the propagation reaction (k_p), the content of active centres (C_a), and the constant for chain transfer to AlR_3 (k_o^{Al}) in the polymerisation of butadiene and isoprene in the presence of the titanium-containing $TiHal_4$–AlR_3 systems (solvent—toluene; t = 25 °C).[97]

Reaction conditions	AlR_3	$10^{-3}k_p$, litre mol^{-1} min^{-1}	$C_a/C_{Ti}\cdot10^2$	$10^{-3}k_o^{Al}$ litre mol^{-1} min^{-1}
TiI_2Cl_2; Al:Ti = 7, butadiene	Al (iso-C_4H_9)$_3$	7.4	1.5	3.4
	Al (–C_2H_4– )$_3$	7.4	3.6	1.5
$TiCl_4$; Al:Ti = 1.1; isoprene	Al (iso-C_4H_9)$_3$	1.0	0.3	0.2
	Al (–C_2H_4– )$_3$	1.0	0.7	0.1
	Al ()$_3$	1.0	1.0	0.1



The increased molecular weights of the polydienes when higher AlR_3 are used are associated with the increase of the macrochain propagation time as a result of the decrease of the constant for chain transfer to AlR_3 with increase in R (Table 9).

III. THE STRUCTURE OF ACTIVE CENTRES AND THEIR STEREOREGULATING CAPACITY

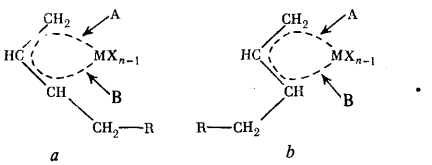
The study of the mechanism of the stereospecific polymerisation of dienes is related directly to the structure of the active centres.

It is generally accepted that polymerisation involves the transition metal–carbon bond and that the cocatalyst plays the role of a complex-forming agent, a reductant, and an alkylating agent. However, the question whether or not the organometallic compound is incorporated in the composition of the active centre for polymerisation, i.e. the question of the mono- or bi-metallic structure of the active centres, still remains controversial.

There exists a view[100–103] that the active centre (I) includes only the alkylated transition metal compound. However, this structure of the active centre does not explain the influence of the nature of the organometallic compounds on the stereospecificity of the catalytic systems.

□ - vacant site, X-ligand, R-alkyl group

The bimetallic structure of the active centres (II) presupposes an important role of the organometallic compounds in their creation[104–107], a more important role than simple stabilisation of the alkylated transition metal compound via halide bridges[108,109]. Thus Minsker and co-workers[106,107,110] demonstrated by quantum-chemical calculations the high probability of the propagation of the polymer chain with participation of the $\overset{-}{Al}$–R–$\overset{\delta+}{Ti}$ group, while Cossee's mechanism[101,102] presupposes chain propagation solely via the Ti–R bond. It is believed[106,107,110] that the OAC coordinated to the titanium compounds is directly involved in the addition of the monomer to the growing chain via the simultaneous electrophilic (from the side of the Ti atom) and nucleophilic (from the side of the Al atom) attack on the monomer.



In conformity with the schematic representation of the active centre (III), the propagation of the polymer chain takes place at the transition metal, while the aluminium compound is one of the ligands of the transition metal[111–113]. According to Avdeev et al.[112], the OAC, present in the second coordination sphere of the transition metal, cannot influence appreciably the reactivity of the active centre in this case. Thus the third type of active centres, where the leading role of the transition metal compound is assumed, also takes into account the appreciable role of the OAC in the formation and stabilisation of the active centres. Active centres of type (III) made it possible to explain[114] why the reactivity of the active centres is independent of the nature of the OAC in the ionic-coordination polymerisation of α-olefins. Our set of investigations[91,97,99], using a large number of aluminium trialkyls of different structures, showed that active centres of type (III) are most probably formed also in the polymerisation of dienes, since the reactivity of the active centres of titanium systems is independent of the structure of the organoaluminium component.

Although the hypothesis that the structure of the active centres in the polymerisation of dienes is modelled by the π-allyl complexes of transition metals is generally accepted, the question of the causes of stereoregulation, i.e. of the factors responsible for the formation of polydiene macrochains with 1,4-*cis*-, 1,4-*trans*-, 1,2-, or 3,4-units remains controversial. Two concepts predominate in the literature on this topic.

The concept of the *cis*–*trans* geometrical control[115–117] takes into account the presence of two double bonds in the conjugated dienes. If the diene is coordinated to the active centre via two double bonds, then its subsequent incorporation in the growing chain entails the formation of a unit with the 1,4-*cis*-configuration. For the monodentate coordination of the diene, it is possible to obtain polymers containing 1,4-*trans*- or 1,2-units. Thus the coordination of the monomer and hence the stereoregularity of the polymer depend on the matrix effect of the catalyst. Active centres with a single vacancy (a single coordination site), for example α-$TiCl_3$, permit the possibility of employing only one double bond of the diene in the *S*-*trans*-form, while on centres with two vacancies (for example, the crystal lattice of β-$TiCl_3$), the diene molecules can be coordinated using either one or

two double bonds (the *S-cis*-form)[118]. Furukawa[65] suggested that the microstructure of the polydienes, determined by the mode of coordination of the monomer, depends on the electron density at the transition metal atom. The probability of the mono- and bi-dentate coordination of the monomer is determined, according to Furukawa[119], by the difference between the energy levels of the orbitals of the transition metal involved in bonding with the π-orbitals of the diene and the highest occupied orbitals of the latter. In conformity with the proposed mechanism, 1,4-*cis*-polydienes are obtained when the energy levels of the bonding orbitals of the metal and the highest occupied orbitals of the monomer are close to one another; when there is a large difference between the energy levels, polymers with the 1,2- or 1,4-*trans*-structures are formed. The electronegativity of the ligands, which influences the positions of the energy levels of the transition metal orbitals, is an important stereoregulation factor.

According to the other concept, the stereoregularity of the polymer chain is determined by the π-alkenyl polymer–transition metal linkage and not the coordination of the monomer to the active centre, *the* anti-form *a* corresponding to *cis*-addition and the *syn*-form *b* corresponding to the *trans*-units:

a *b*

It is believed[116,119] that the *anti–syn* orientation should depend on the coordinating capacity of the double bond adjoining the π-alkenyl linkage at the end of the macromolecule (i.e. on the penultimate double bond), while the geometrical configuration of the π-alkenyl end of the growing chain is unimportant. However, the stereospecificity of the action of the catalyst has been attributed[75,120–125] to the configuration of the π-alkenyl unit of the growing chain. This version is supported by data obtained in a study[126] where it was shown by ^{1}H NMR that there is only a very slight possibility of the coordination of the penultimate double bonds of the growing chain.

According to a number of investigations[75,122,124,125], a conjugated diene always behaves as bidentate ligand, which is favoured by energy factors for conjugated dienes, and the primary steps involving the addition of the monomer therefore lead solely to the *anti*-configuration of the π-alkenyl centre. The content of the 1,4-*cis*- or 1,4-*trans*-structures is determined by the ratio of the rates of chain propagation and *anti–syn* isomerisation of the active centre: a higher rate of chain propagation results in the formation of a polymer with the 1,4-*cis*-structure of the units on insertion of the monomer in the π-alkenyl linkage of the *anti*-complex formed initially, while at low rates of chain propagation the role of the *anti–syn* isomerisation reaction of the active centres increases and the thermodynamically more stable *syn*-π-complexes, giving rise to units with a 1,4-*trans*-structure, are formed. Such interconversions of the structures take place fairly readily for simple compounds[127]; the *anti–syn* isomerisation of the π-alkenyl complexes of certain transition metals has been observed also in the polymerisation of dienes[128–131], the rate of reaction depending on the structure of the alkyl substituent in the diene.

The coordinated diene molecule can enter the growing chain either from side A, whereupon polymer chains with 1,4-units are formed, or from side B, which leads to the formation of polymers with a 1,2-structure of the units.

Very little is known about the factors directing the stereospecific polymerisation towards the formation of the 1,4- or 1,2(3,4)-polymer, nevertheless experimental data show indirectly that these factors may depend both on the monomer and on the catalyst. Thus comparison of the results of the polymerisation of butadiene and 4-methylpenta-1,3-diene in the presence of α-$TiCl_3$–AlR_3 showed[132] that in both cases the monomer is inserted in the same Ti–C bond of the π-allyl complex at the end of the chain, which contains the least substituted and hence the most reactive carbon atom. However, this approach cannot explain the formation of 1,2-polybutadiene. On the grounds that in the majority of polybutadienes in which the 1,2-units predominate, including those obtained in the presence of $Ti(OR')_4$–AlR_3, the residual units have almost exclusively the 1,4-*cis*-structure, the authors[132] believe that the monomer in these systems is always coordinated as a bidentate ligand and the π-allyl complex at the end of the chain has the *anti*-structure. However, in such systems one assumes a geometry of the catalytic complex such that the terminal, carbon atom of the coordinated monomer can be closer (at a distance equal to a single bond length) to the more substituted although less reactive third carbon atom in the π-allyl group. As a result of this, the monomer is inserted preferentially in the B direction and 1,2-polybutadiene is formed.

This approach, which takes into account the rigorously steric, geometrical characteristics of the active centre, should apparently be regarded as useful. Indeed the presence of bulky substituents at the titanium atom promotes in all cases and, what is most important, independently of their chemical nature the appearance of 1,2-units in the polybutadiene chain. The greater the number of such ligands at the titanium atom, the larger the fraction of 1,2-junctions. This is indicated by the results of the polymerisation of butadiene in the presence of catalytic systems consisting of $Ti(OR')_4$,[25,70] $Ti(NR_2)_4$,[24] $TiCl_2(indenyl)_2$,[14] $TiCl_2(fluorenyl)_2$,[14] $TiCl_2(OR')_2$,[14] and $TiCl_2(OCOR')_2$ [14] in combination with AlR_3.

The causes of the formation of a polymer with a mixed microstructure can be accounted for also by factors other than the *anti–syn*-isomerisation of the active centre, a difference in the modes of incorporation of the monomer in the growing chain, or an alteration of the geometry of the catalytic complex. The question whether the polymerisation involving the formation of polydienes with a mixed microstructure occurs on the same active centres or on non-identical active centres with different activities and stereospecificities still remains open. The latter possibility is not ruled out if only because even when the Al : Ti ratio is altered only slightly in systems based on titanium halides, the microstructure of the polydienes begins to change. Unfortunately, there are almost no literature data which would make it possible to follow the qualitative and quantitative variation of the active centres as a function of the component ratio in catalytic systems. Thus it has been shown in a study[133] of the polymerisation of butadiene in the presence of TiI_4–$Al(iso\text{-}C_4H_9)_3$ that the propagation rate constant increases sharply when the Al : Ti ratio is raised from 1.5 to 5.5, but a clear-cut correlation between the concentration of active centres and the Al : Ti ratio was not found.

Nevertheless, certain results can be interpreted only on the assumption of the simultaneous presence in a particular system of active centres of different types and with different reactivities. Thus the separation of the products of the polymerisation of butadiene in the presence of $TiCl_4$–AlR_3 by extraction with different solvents made it possible to isolate from the overall reaction mass a highly stereoregular 1,4-*cis*-polybutadiene[134]. In the polymerisation in the presence of β-$TiCl_3$ the formation of two polymers separable by extraction (1,4-*cis*-, and 1,4-*trans*-polybutadienes) in comparable

amounts was also noted[135]. Even when highly stereospecific catalytic systems such as TiI_2Cl_2–AlR_3 (monomer = butadiene) and $TiCl_4$–AlR_3 (monomer = isoprene) were used, an increase of the content of the 1,4-*cis*-units was observed in all the fractions of rubbers with increase in the molecular weight of the fraction; a particularly marked decrease of the amount of *cis*-units is observed in the region of molecular weights below 20000.[27] This phenomenon is regarded as a consequence of the presence in the catalyst of different active centres with different propagation and *anti–syn* isomerisation constants, polymers with a higher molecular weight and a higher content of 1,4-*cis*-units being formed on the more active centres. It is believed[136] that EPR data confirm the hypothesis of the existence of two forms of active centres in iodine-containing titanium systems: monomeric paramagnetic centres with a high catalytic activity lead to the formation of a high-molecular-weight 1,4-*cis*-polydiene, while associated diamagnetic centres are much less reactive and the decrease of the content of the 1,4-*cis*-units in the polymer probably depends on them.

One can therefore assume that the significant difference between the stereoregulating capacities of the $TiCl_4$–AlR_3 system ($Al:Ti \geq 1$) in the polymerisation of butadiene and isoprene is due to the fact that in the case of butadiene the polymerisation takes place simultaneously on two types of active centres (*cis*- and *trans*-regulating), which in fact leads to a mixed microstructure of the polymer. On the other hand, the polymerisation of isoprene hardly takes place on the less active *trans*-regulating centres (if only by virtue of the steric hindrance to coordination) and the entire polymerisation process occurs on the *cis*-regulating active centres. Quantum-chemical calculations[137,138] agree with these ideas.

It is difficult to obtain experimental data on the structure and the active centres in ionic-coordination polymerisation of dienes because of their high sensitivity to impurities, the complexity of their composition, and their low concentrations. Thus the degree of conversion of the initial titanium halide into the catalytically active compounds by its reaction with AlR_3 does not exceed several per cent[70,91,97,99,133,139–142]. This parameter is even lower (<1%) for systems based on titanium alkoxides[70,143].

The lack of experimental data on the structure of the active centres is partly compensated by quantum-chemical studies. The relevant calculations have the following aspects: the nature of the metal–monomer and metal–alkyl bonds, the coordination of the monomer to the active centre, and its insertion in the metal–carbon bond. There have been almost no detailed calculations of the structure of the active centres for the polymerisation of dienes in the presence of Ziegler–Natta catalyst and of the potential energy surfaces for the addition of the diene to the active centre (of the kind carried out, for example, for α-olefins[110,112,114,144]).

Quantum-chemical calculations on the anionic polymerisation of dienes in the presence of organometallic derivatives of alkali metals modelling the structure of the terminal unit of the growing macromolecule linked to the transition metal have been published in a number of communications[145–150] and a computer study of the formation of active centres and of the mechanism of the polymerisation of α-olefins and dienes in the presence of heterogeneous Ziegler–Natta catalysts has been described[137]. According to calculations[137], the role of the organometallic compound MR consists in building up the crystal lattice of the catalyst, in the formation of a Ti–R–M bridge bond, and in the formation of an unusual structure of the active centre by the groups R and the metal atoms ("tunnel"), which has an orienting effect at the monomer coordination stage.

Attention has been concentrated in semiempirical[114] and non-empirical[151] calculations on the estimation of the electronic structures of various titanium–aluminium–olefin complexes and their alteration in the addition of the olefin to the Ti–C bond. As a rule, the choice of the model of the active centre is based on the available experimental data. Models of active centres have been obtained by the computer calculation of the random absorption of AlR_3 on the surface of $TiCl_3$ crystals in only a few studies[110,137,151]; this made it possible to predict different forms of active centres and to select the most probable.

A hypothesis concerning the mechanism of catalytic polymerisation is impossible without the elucidation of the nature of the lability of the transition metal–carbon bond. In terms of this aspect, the data of L'vovskii and Erusalimskii[152,153], who investigated the equilibrium properties and the electronic nature of the lability of the Ti–C σ-bond in a series of alkyl halide derivatives of quadrivalent titanium, are of great interest. L'vovskii used the unrestricted version of the Hartree–Fock–Roothaan (UHFR) for quantum-chemical calculations and compared it with the restricted version (RHFR) in the CNDO approximation. Calculations on the homolytic dissociation of the Ti–C bonds in $TiCl_3CH_3$ and the Al–C bonds in $AlCl_2CH_3$ by the UHFR method showed[153] that there is a very much smaller energy barrier to the dissociation of the Ti–C bond than to the dissociation of the Al–C bond. The electronic correlation has a much greater influence on the lability of the Ti–C bond and this influence is determined mainly by the properties of the *d* orbitals of the transition metal[153], which explains the difference between the energy barriers to the homolytic dissociation of the Ti–C and Al–C bonds. It is also of interest to note that calculations[153] indicate an increase of the energy barrier to the dissociation of the Ti–C bonds in the sequence $TiCl_3C_2H_5 < TiCl_3CH_3 < (\eta^5\text{-Cp})_2.TiClCH_3$, which agrees with the variation of the thermal stability of these compounds.

However, all the known calculations on reaction pathways have been carried out within the framework of the RHFR method, where, in the light of the results of L'vovskii and Erusalimskii[152,153], some caution is needed in assessing the energy barriers obtained and hence also the correctness of the choice of both the rate-limiting stage and the single- and two-stage mechanisms of chain propagation.

---o0o---

The general level of the results achieved at the present time in the field of the ionic-coordination polymerisation of dienes is fairly high. Extensive experimental data have accumulated on various aspects of this field and further studies are being vigorously prosecuted. However, despite the advances made, the state of knowledge on a number of questions is still merely empirical. A particular consequence of the lack of a profound theoretical basis is that new catalytic systems are selected, as regards both composition and the formation conditions, by a purely experimental procedure. In view of the complexity of the physicochemical picture of the formation and functioning of the active centres, the characteristic features of the polymerisation of a particular diene in the presence of a given transition metal cannot always be extended to other systems and other monomers. This applies in the first place to the stereospecificity of the action of ionic-coordination systems, which is indicated by the analysis of the literature data presented in this review. On the other hand, one can assume, on the basis of modern ideas about the structure of the active centres, that the lack of an effect by the structure of the organoaluminium component on the stereospecificity of the titanium system apparently obtains

also in other systems of the Ziegler type. As regards the question of the influence of the structure of the OAC on the activity of the systems, the characteristics discovered for the titanium systems can hardly hold in all other cases in view of the wide variety of the functions of the organoaluminium compound in the Ziegler system, particularly when account is taken of their reducing and alkylating capacities.

Thus there is an evident necessity for further studies designed to accumulate new experimental facts which would serve as a basis for the development of methods for the specific control of processes involving the stereospecific polymerisation of dienes.

Thermochemistry of Haloethanes

V.P.Kolesov and T.S.Papina

Data on the thermochemistry of haloethanes are surveyed. The most reliable standard enthalpies of formation of 37 haloethanes are recommended on the basis of a critical analysis of the experimental results published up to 1980 inclusive (and partly in 1981). The constants of a computational scheme for the estimation of the enthalpies of formation of hitherto uninvestigated haloethanes have been evaluated by the method of least squares. The enthalpies of formation of 210 haloethanes containing H, F, Cl, and Br have been calculated with the aid of these constants.
The bibliography includes 131 references.

VI. Conclusion 435

I. INTRODUCTION

Organohalogen compounds are widely used in many branches of the national economy. The study of their thermochemical properties is of great practical and theoretical importance[1,2]. Studies[3,4] in which the available experimental data were analysed and recommendations were made concerning the estimation of the standard enthalpies of formation of hitherto uninvestigated compounds were devoted to the thermochemistry of halomethanes and also organofluorine compounds with three or more carbon atoms. No similar investigations have been published on the thermochemistry of haloethanes.

However, haloethanes occupy a very important place in modern chemistry and technology. They are used as cooling agents, aerosol propellants, flame inhibitors, solvents, etc. Some of them have found applications in medicine and as effective anaesthetics. Many representatives of the haloethanes are the final or intermediate products in large-scale manufacturing processes (CF_2ClCF_2Cl, C_2F_5Cl, CH_3CHF_2, CF_2BrCF_2Br, etc.[5]). In this connection detailed analysis of the present state of the thermochemistry of haloethanes is urgently required. Its practical value is determined primarily by the need to have reliable thermochemical data for calculations on technological processes. The study of the influence of the nature and number of substituent atoms on the energetic properties of molecules with similar compositions and structures is of theoretical interest.

There are few experimental enthalpies of formation of haloethanes and they are frequently contradictory. While the total number of known haloethanes is 630, the enthalpies of formation of only 30 compounds of this class can be found in the handbooks published in recent years[6-9]. Furthermore, the discrepancies between the values of ΔH_f° adopted from different sources (for example, for CF_2ClCF_2Cl and $CF_2Br.CHFCl$) reach up to 50–60 kJ mol^{-1}.

During recent years many new data, which have not yet been incorporated in handbooks, have been published on the enthalpies of formation of haloethanes. Thus the enthalpies of formation of 9 compounds which had not been investigated previously were determined: CH_2ClCCl_3, CH_2CF_2Cl, $CH_3CF_2.Br$, $CF_3CH_2.Br$, $CH_3CHClBr$, CH_2ClCH_2Br, $CF_3CHClBr$, $CF_2.ICF_2I$, CH_3CF_2I. The enthalpies of formation of certain substances for which previous data had been contradictory were redetermined (CF_2ClCF_2Cl, $CF_2ClCFCl_2$, $CF_2BrCHFCl$). Significant errors in the results of previous studies were discovered and eliminated in these measurements. New determinations of the enthalpies of formation of certain haloethanes (CH_3CH_2Cl, CH_3CHCl_2, $CH_2ClCHCl_2$, $CHCl_2CHCl_2$) made it possible to revise previous recommendations.

In addition the values of ΔH_f° for a whole series of haloethanes should be recalculated and significantly modified because their calculation involves the use of the ΔH_f° for compounds whose values have been fundamentally redetermined in recent years. For example, a new determination of the enthalpy of formation of chlorotrifluoroethylene[10] led to a sharp change in the values of ΔH_f° for CH_2FCHF_2 and $CF_2.BrCFClBr$, which were calculated from the enthalpies of hydrogenation[11] and bromination[12] of $CF_2=CFCl$. Certain enthalpies of formation of substances in the gaseous state have been revised as a result of new determinations of the enthalpies of vaporisation.

The publication in recent years of a large number of experimental ΔH_f° makes it timely and necessary to re-examine the set of enthalpies of formation of haloethanes. This paper surveys the present state of the thermochemistry of haloethanes. The methods of experimental determination and the possibility of the approximate calculation of the enthalpies of formation of haloethanes are briefly characterised. All the available experimental literature data for the ΔH_f° for haloethanes published up to 1980 inclusive (and partly in 1981) are examined and analysed. The most reliable ΔH_f° for 37 compounds are recommended on the basis of this analysis. The enthalpies of formation of all the 210 possible bromochlorofluoroethanes have been calculated by Bernstein's method[13,14] from the selected experimental ΔH_f° for haloethanes containing H, F, Cl, and Br atoms. The inadequate number of experimental enthalpies of formation of iodoethanes at present precludes a similar calculation for all haloethanes including the iodo-derivatives.

II. UNITS OF MEASUREMENT AND KEY AND AUXILIARY QUANTITIES

In conformity with the International System of Units ("SI"), all the thermodynamic quantities in the present review are expressed in joules. The initial data and the data in handbooks expressed in kcal were recalculated on the basis of the relation 1 cal = 4.1840 J.[15] The atomic weights were adopted

in accordance with a IUPAC publication[16]. The enthalpies of formation of haloethanes were calculated using the following ΔH_f° (kJ mol^{-1})[17] included in the unique system of key quantities adopted by the Committee on Numerical Data for Science and Engineering (CODATA):

Compound	CO_2 (gas)	H_2O (liq.)	F^- (aq.)	Cl^- (aq.)	Br_2 (gas)
ΔH^0_f	−393,51±0,13	−285.830±±0.042	−335,35±0.65	−167,08±0,088	30.91±0,11
Compound	I_2(gas)	HCl (gas)	HBr (gas)	HI (gas)	
ΔH^0_f	62.421±0.08	−92,31±0,13	−36,38±0,17	26,36±0.8	

All the values of ΔH_f° indicated in this review and derived from handbooks or original communications have been recalculated on the basis of these key quantities. The enthalpies of dilution of HF solutions were taken from Johnson et al.[18] and the enthalpies of dilution of HCl solutions were taken from the Tables of Cox et al.[19] The heat capacities of the pure substances (except where stipulated otherwise) were taken from a handbook[7] and the heat capacities of solutions were taken from Parker[20].

In the calculation of the enthalpies of reaction from the equilibrium constants, the thermodynamic functions quoted by Glushko[21] were used. Apart from the above key quantities, in the calculation of the ΔH_f° for certain haloethanes it is also necessary to know the enthalpies of formation of ethylene or its halogeno-derivatives.

The enthalpy of formation of chlorotrifluoroethylene, $\Delta H_f^\circ[C_2F_3Cl(gas)] = -515.1 \pm 3.4$ kJ mol^{-1}, was taken from a recent study[10]; the reasons for its selection are given below (in Section III). The enthalpy of formation of vinyl bromide, $\Delta H_f^\circ[C_2H_3Br(gas)] = 79.3 \pm 1.9$ kJ mol^{-1}, was taken from a handbook[9] where it was recommended on the basis of the enthalpy of hydrogenation of C_2H_3Br to C_2H_6 measured by Lacher et al.[22] The enthalpies of formation of all the remaining haloethylenes were taken from Glushko's handbook[21]. All the recommended values in two handbooks[9,21] were calculated on the basis of the same system of key quantities which was adopted in the present study and their employment does not therefore impair the mutual consistency of the enthalpies of formation. The values $\Delta H_f^\circ[C_2H_4(gas)] = 52.4 \pm 0.5$ kJ mol^{-1} and $\Delta H_f^\circ[C_2F_4(gas)] = -659.5 \pm 2.5$ kJ mol^{-1} have been recommended[21] on the basis of reliable experimental data of several workers. The quantity $\Delta H_f^\circ[C_2H_3Cl(gas)] = 23.0 \pm 2.1$ kJ mol^{-1} was adopted on the basis of measurements of the enthalpy of polymerisation of liquid C_2H_3Cl,[23] the enthalpy of formation of the polymer[24], and the enthalpy of vaporisation of $CH_2 = CHCl$ quoted by Glushko[7]. The quantity $\Delta H_f^\circ[1,1\text{-}C_2H_2Cl_2(gas)] = 2.3 \pm 1.4$ kJ mol^{-1} is based on precise calorimetric measurements of the enthalpy of formation[24,25] and the enthalpy of vaporisation[26].

The enthalpies of formation of *cis*- and *trans*-1,2-$C_2H_2Cl_2$. .(gas) have been found[21] by adjusting the enthalpies of formation of the liquid isomers[27] for consistency with the enthalpies of vaporisation measured in several studies and on the basis of an investigation of the *cis*–*trans* isomerisation equilibrium[28–30]. This led to $\Delta H_f^\circ = 4.1 \pm 1.0$ and 6.1 ± 1.0 kJ mol^{-1} for *cis*- and *trans*-$C_2H_2Cl_2$(gas) respectively. The enthalpies of formation of tri- and tetra-chloroethylenes have been calculated[21] from measurements[27] of their enthalpies of combustion in the liquid state using the enthalpies of vaporisation measured calorimetrically[31]: $\Delta H_f^\circ[C_2HCl_3(gas)] = -4.1 \pm 1.2$ kJ mol^{-1} and $\Delta H_f^\circ[C_2Cl_4(gas)] = -11.0 \pm 2.1$ kJ mol^{-1}. The quantity $\Delta H_f^\circ[1,1\text{-}C_2F_2Cl_2(gas)] = -338 \pm 11$ kJ mol^{-1} has been recommended on the basis of measurements[11] of the enthalpies of hydrogenation of 1,1-$C_2F_2Cl_2$ to 1,1-$C_2H_4F_2$ in the gas phase and the enthalpy of formation of gaseous 1,1-$C_2H_4F_2$ determined by Kolesov et al.[32]

Among the ΔH_f° for haloethylenes indicated, the most reliable are those for C_2H_4, C_2F_4, 1,1-$C_2H_2Cl_2$, and C_2F_3Cl. The majority of other ΔH_f° for haloethylenes have been determined with a relatively low accuracy and their use for the calculation of the ΔH_f° for haloethanes therefore introduces a considerable additional error and is as a rule undesirable.

III. METHODS FOR THE DETERMINATION OF THE ENTHALPIES OF FORMATION OF HALOETHANES

All the experimental methods for the determination of the enthalpies of formation of haloethanes described in the literature can be divided, with very rare exceptions, into two large groups: calorimetric measurements and determination of equilibrium constants. The most important results for this range of substances have been undoubtedly obtained by calorimetric methods, among which the most universal is the method of combustion in a bomb calorimeter. When it is used to determine the ΔH_f° for organohalogen compounds, particularly those with a high halogen content, complications arise due to the low specific energy of combustion of the substances, the complex composition and high corrosion activity of the combustion products, and the occurrence of side reactions. These complications can be partly overcome by employing special apparatus (for example, calorimeters with rotating bombs lined with platinum), auxiliary substances, reductants, careful analysis of the combustion products, etc.; however, all these procedures undoubtedly complicate the method and have an unfavourable effect on the accuracy of the measurements[33,34]. Furthermore, in view of the low specific energy of the combustion of many haloethanes, more stringent requirements must be imposed on the purity of the test specimens.

However, despite these complications, the method of combustion in a bomb has many valuable advantages (in the first place the fact that the apparatus and method have been thoroughly developed and comprehensively tested, the high accuracy of the calorimetric measurements, and the possibility of careful analysis of the combustion products in both gaseous and condensed phases). The fact that the method of determination of the combustion energies in calorimeters with a rotating bomb has been significantly improved in recent years is also important.

In the Laboratory of Thermochemistry at Moscow State University, the method was modernised by increasing the accuracy of the measurement of the temperature and temperature control, by careful study of the processes occurring in the bomb, and partly by employing new more accurate methods of analysis of the combustion products. The changes introduced into the method have already been described[35,36].

The improvements in the method of determination of the energy of combustion in rotating bomb calorimeters made it possible to apply it to the study of new groups of haloethanes: compounds containing different halogen atoms (for example, $CF_3CHClBr$ and $CF_2BrCHFCl$), gaseous and volatile Freons (CF_2ClCF_2Cl and $CF_2ClCFCl_2$), etc.

The determination of the energies of combustion of gaseous haloethanes in a bomb calorimeter involves additional complications, since, as usual, the entire gas does not react and the amount of combusted substance can be determined only from the results of the analysis of the combustion products[37]. The method of combustion of gases in a calorimeter with a burner at a pressure close to atmospheric yields more accurate results[38,39]. However, this method is applicable only to compounds with a low halogen content, mainly to monochloroalkanes[38]. At the present time the majority of enthalpies of combustion of gaseous haloethanes have been obtained by combustion in a bomb.

The method of combustion in the liquefied state in a bomb calorimeter of substances which are gaseous at room temperature, developed recently, is extremely valuable for the

investigation of haloethanes[10,36]. Its principal advantage is almost complete combustion of the test substances. A specially designed crucible container has been used for the liquefaction and combustion of such substances. The method has been developed in a series of calorimetric experiments on the determination of the energies of combustion of chlorotrifluoroethylene[10]. $\Delta H_f^\circ[CF_2 = CFCl(gas)] = -515.1 \pm 3.4$ kJ mol^{-1} has been obtained. Previous determinations of this quantity by measuring the enthalpies of reactions with alkali metals yielded markedly divergent results: -502.3,[40] -549.1,[41] and -565.5 kJ mol^{-1}.[42] The reliability of the determination of $\Delta H_f^\circ[CF_2 = CFCl(gas)]$ obtained in the above study[10] is confirmed by the similarity of the values found by two other procedures: on the basis of the experimental[43] enthalpy of combustion of $CF_2ClCFCl_2$ using the enthalpies of chlorination[44] of chlorotrifluoroethylene, which yielded $\Delta H_f^\circ[CF_2 = CFCl(gas)] = -522.0 \pm 3.4$ kJ mol^{-1}, and also the experimental[45] enthalpy of combustion of $CF_2BrCHFCl$ and the experimental[46] enthalpy of hydrobromination of chlorotrifluoroethylene, which yielded $\Delta H_f^\circ[CF_2 = CFCl(gas)] = -509.5 \pm 5.6$ kJ mol^{-1}. The method developed by Erastov and Kolesov[10] leads to extensive possibilities for the investigation of the thermochemical properties of substances which are not fully combusted in the bomb in the gaseous state.

The results of measurements of the enthalpies of the catalytic halogenation, hydrohalogenation, and hydrogenation of ethylene and its halogeno-derivatives in the gaseous state are frequently used for the calculation of the ΔH_f° of haloethanes. A whole series of such measurements have been carried out by Lacher and co-workers[11,12,22,44,46-50] in a specially designed isothermal calorimeter of the compensation type. In these investigations a fairly high reproducibility of the experimental results was achieved (usually to within ~ 0.5–1.0 kJ mol^{-1}). However, significant systematic discrepancies with data obtained by other methods were also observed in certain cases and it was therefore suggested that the catalyst employed is insufficiently inert[39]. Calculation of ΔH_f° for haloethanes from the data of Lacher and co-workers as a rule requires the knowledge of the ΔH_f° for other organohalogen compounds (for example, haloethylenes).

In order to determine the enthalpies of formation of gaseous chlorofluorocarbons (including chlorofluoroethanes), the method of measurement of the enthalpies of reaction of these compounds with alkali metals has been frequently used[3,40-42]. The reactions are initiated by an electric arc whose energy has to be measured accurately. This method is less accurate than the determination of the heats of combustion owing to the complexity of the composition of the products formed and the need to introduce numerous corrections[3]. The ΔH_f° for haloethanes have been sometimes determined by measuring the enthalpies of reactions which can be achieved only for a few compounds. Thus $\Delta H_f^\circ(C_2F_6)$ has been determined by measuring the enthalpy of the reaction of hexafluoroethane with nitrogen trifluoride[51]. Other cases are examined in Section IV.

Numerous enthalpies of formation of haloethanes have been obtained by measuring the equilibrium constants. The enthalpy of reaction is related to the equilibrium constant by the familiar expression

$$\Delta H_T^0 = -RT \ln K_p + T\Delta S_T^0 \ . \qquad (1)$$

Having measured K_p at several temperatures and having assumed that ΔH_T° and ΔS_T° are constant in the experimental temperature range, it is possible to find the ΔH_T° from the temperature variation of ln K_p (the method of the Second Law of Thermodynamics). If the entropies of the reactants are known, a more accurate calculation of ΔH_T° by the direct substitution of ΔS_T° in Eqn.(1) is possible (the method of the Third Law of Thermodynamics); in principle, it is then sufficient to measure the equilibrium constant at a single temperature. The similarity of the values of ΔH° found on the basis of the Second and Third Laws of Thermodynamics usually indicates the absence of systematic errors from the experimental data. The necessary conditions for the determination of reliable enthalpies of reaction from the study of equilibria are an accurate measurement of the concentrations and (or) pressures of the reactants, careful monitoring of the attainment of the state of equilibrium and, in calculations based on the Second Law, also a fairly wide temperature range of the measurements. In a highly sophisticated experiment, the results of the determination of the enthalpies of reaction by measuring the equilibrium constants are frequently not inferior in their accuracy and reliability to the results of calorimetric measurements.

IV. ANALYSIS OF EXPERIMENTAL DATA AND SELECTION OF THE RECOMMENDED ENTHALPIES OF FORMATION

Ethane

The bibliography of studies on the determination of ΔH_f° for ethane has already been published[7,21]. The most reliable measurements of the enthalpies of combustion of gaseous ethane in a flow calorimeter were carried out by Rossini[52] and Pittam and Pilcher[53]. The amount of combusted ethane was determined by analysing the combustion products for H_2O[52] and CO_2.[53] The values of $\Delta H_f^\circ[C_2H_6(gas)]$ obtained are similar: -84.73 ± 0.48 kJ mol^{-1} [52] and -83.87 ± 0.24 kJ mol^{-1},[55] but the difference between them is nevertheless outside the limits of error. Pittam and Pilcher[53] used a purer specimen than that in Rossini's investigation[52]. However, in the latter study[52] the heat capacity of the calorimeter was determined by measuring the electrical energy, while Pittam and Pilcher found it from the heat of combustion of hydrogen, which renders their results dependent on their latter quantity; it was taken from Rossini's determinations. $\Delta H_f^\circ[C_2H_6.(gas)] = -84.0 \pm 0.4$ kJ mol^{-1} is recommended. It agrees with the value adopted by Glushko[21] as a result of the joint treatment of Rossini's[52] and Pittam and Pilcher's[53] data and the results of studies[54-56] in which the enthalpies of formation and hydrogenation of ethylene were measured.

Hexafluoroethane

The enthalpy of formation of hexafluoroethane has been determined by different methods: by measuring the enthalpy of the reaction of C_2F_6 with potassium[51] or nitrogen trifluoride[51]:

$$C_2F_6\,(gas) + {}^2/_3NF_3\,(gas) \rightarrow 2CF_4\,(gas) + {}^1/_2N_2\,(gas) \qquad (2)$$

and by investigating the equilibria in the reactions[57]

$$C_2F_6\,(gas) + Br_2\,(gas) \rightleftarrows 2CF_3Br\,(gas) \qquad (3)$$

or[58]

$$2CF_3CN\,(gas) \rightleftarrows C_2F_6\,(gas) + C_2N_2\,(gas)\ . \qquad (4)$$

The result obtained by Kirkbride and Davidson[41] is doubtful, since they did not characterise the purity of the substances and did not introduce all the necessary corrections for side reactions. The most reliable value has been obtained[21] by adjusting for mutual consistency the thermochemical data for reactions involving C_2F_6, CF_3Br, CF_3I, CF_3Cl, and CHF_3, including reactions (2)–(4): $\Delta H_f^\circ[C_2F_6(gas)] = -1344.0 \pm 4.0$ kJ mol^{-1}.

1,1-Difluoroethane

The enthalpy of combustion of gaseous CH_3CHF_2 in a bomb calorimeter has been determined[32]: $\Delta H_C^\circ = -1219.6 \pm 8.4$ kJ mol^{-1}. Mass-spectrometric analysis of the combustion products failed to reveal the presence of any fluoro-derivatives, except for a small amount of CH_3CHF_2 which had not reacted. Calculation of the enthalpy of formation using the key quantities adopted above leads to $\Delta H_f^\circ[CH_3CHF_2(gas)] = -497.0 \pm 8.5$ kJ mol^{-1}. Lacher et al.[11] measured ΔH° for the hydrogenation of $CF_2 = CCl_2$ with formation of CH_3CHF_2. However, these data were not used to calculate $\Delta H_f^\circ(CF_2 = CCl_2)$ (see Section II).

1,1,1-Trifluoroethane

The enthalpy of combustion of gaseous 1,1,1-trifluoroethane has been measured[59]: $\Delta H_C^\circ[CH_3CF_3(gas)] = -1008.3 \pm 1.7$ kJ mol^{-1}. A correction for adjustment to the standard state was not applied[59]; we calculated it on the basis of the calorimetric experimental data presented in the above study[59] and found it to be 4 ± 2 kJ mol^{-1}. When account is taken of this correction, we obtain $\Delta H_f^\circ[CH_3CF_3(gas)] = -748.7 \pm 3.2$ kJ mol^{-1}. A very similar value was obtained[60] by calculation from the dissociation energy of the C–C bond in 1,1,1-trifluoroethane found from kinetic data for the dehydrofluorination of CH_3CF_3: $\Delta H_f^\circ[CH_3CF_3(gas)] = -747.3$ kJ mol^{-1}. This method is much less accurate than that employed by Kolesov and Martynov[59].

1,1,2-Trifluoroethane

Lacher et al.[11] measured the enthalpy of hydrogenation of chlorotrifluoroethylene at 401 K:

$$CF_2 = CFCl\,(gas) + 2H_2\,(gas) \rightarrow CH_2FCHF_2\,(gas) + HCl\,(gas). \qquad (5)$$

They found $\Delta H_{401}^\circ(5) = -271.6$ kJ. After adjustment to the standard temperature, we obtain $\Delta H_{298}^\circ(5) = -268.2$ kJ, whence $\Delta H_f^\circ[CH_2FCHF_2(gas)] = -691 \pm 10$ kJ mol^{-1}. The error was estimated approximately in view of the lack of the necessary information in the above study[11] for its calculation.

Hexachloroethane

Berthelot[61] determined the enthalpy of combustion of hexachloroethane by an obsolete method which did not ensure the complete reduction of chlorine. Smith et al.[27] used the "quartz spiral" method and showed that it makes it possible to measure the heats of combustion of organochlorine compounds with an accuracy close to that of measurements in a rotating bomb calorimeter. They recalculated the results obtained previously by this method after introducing a series of necessary corrections. However, an important disadvantage of the study of Smith et al.,[27] which lowers the reliability of the determinations, is the absence of data on the purities of the test substances. Furthermore, the influence of impurities on the measurements of ΔH_C° is particularly marked for compounds with a high chlorine content. The data of Smith et al.[27]† for hexachloroethane yield $\Delta H_f^\circ[C_2Cl_6(cryst.,$ orthorhomb.$)] = -198.4 \pm 2$ kJ mol^{-1}. Taking into account the enthalpy of sublimation ($\Delta H_{s,298}^\circ = 60.7 \pm 4.2$ kJ mol^{-1}[7,21]), we find $\Delta H_f^\circ[C_2Cl_6(gas)] = -137.7 \pm 4.7$ kJ mol^{-1}. The accuracy of the enthalpy of sublimation of hexachloroethane is likewise low. The value of $\Delta H_{s,298}^\circ$ was calculated by Glushko[7,21] as the sum of three experimental quantities: the enthalpy of vaporisation of C_2Cl_6(cryst.,triclin.) and the enthalpies of fusion of the triclinic and orthorhombic modifications. Thus the value of $\Delta H_f^\circ[C_2Cl_6(gas)]$ found from the data of Smith et al.[27] cannot be regarded as sufficiently reliable.

Kirkbride[63] measured the enthalpy of chlorination of liquid tetrachloroethylene and the enthalpy of solution of C_2Cl_6 in C_2Cl_4, whence he found $\Delta H_{298}^\circ(6) = -155.2$ kJ for the reaction

$$C_2Cl_4\,(liq.) + Cl_2\,(gas) = C_2Cl_6\,(cryst.). \qquad (6)$$

$\Delta H_f^\circ[C_2Cl_6(gas)] = -145.2$ kJ mol^{-1} corresponds to the value. Kirkbride's study[63] was not precise; the slowness of the chlorination reaction made it necessary to introduce several large corrections which were not determined with adequate accuracy. His result must therefore be regarded as merely approximate.

The equilibrium in the gas-phase catalytic reaction

$$C_2Cl_4\,(gas) + Cl_2\,(gas) \rightleftarrows C_2Cl_6\,(gas). \qquad (7)$$

has been investigated[64–67]. We calculated $\Delta H_{298}^\circ(7) = -127.0$ kJ in accordance with the Third Law of Thermodynamics from the equilibrium constant measured[64,65] at 776 K, whence $\Delta H_f^\circ[C_2Cl_6(gas)] = -138.0$ kJ mol^{-1}. The equilibrium constants were measured[66,67] at three temperatures in the range 773–873 K and the enthalpy of reaction (7) has been found from the temperature variation of K_p: $\Delta H_{853}^\circ(7) = -130.5$ kJ. Adjustment to the standard temperature leads to $\Delta H_{298}^\circ(7) = -136.9$ kJ. Calculation of the enthalpy of reaction (7) in accordance with the Third Law of Thermodynamics yields three similar values: −139.7, −140.0, and −140.1 kJ. Using the average $\Delta H_{298}^\circ(7) = -139.9$ kJ, we obtain $\Delta H_f^\circ[C_2Cl_6(gas)] = -150.9$ kJ mol^{-1}. The results of the calculation of $\Delta H_{298}(7)$ by two methods from the data of Bushneva and co-workers[66,67] agree satisfactorily. However, in the calculation of $\Delta H_f^\circ(C_2Cl_6)$ it is necessary to employ the value of $\Delta H_f^\circ(C_2Cl_4)$ determined by Smith et al.,[27] the deficiencies of whose work were mentioned above.

Thus it is difficult to recommend a reliable value of $\Delta H_f^\circ[C_2Cl_6(gas)]$ on the basis of the available experimental data. Its calculated value is presented below (Section VI).

Chloroethane

Several workers[39,68–70] determined ΔH_C° for gaseous chloroethane in a calorimeter with a burner. Studies of Berthelot[68] and Thomsen[69] are only of historical interest. The precision of the method used by Casey and Fordham[70] was not high: the calorimeter was calibrated against the heat of combustion of a known volume of hydrogen; there is a large fraction of ballast heat due to the combustion of hydrogen in the mixture with chloroethane; quantitative characteristics of the purity of the reactants are not given. Casey and Fordham[70] obtained $\Delta H_f^\circ[C_2H_5Cl(gas)] = -100 \pm 10$ kJ mol^{-1}. The most reliable data are those of Fletcher and Pilcher[39] who used pure specimens and carried out a careful analysis of the combustion products. They obtained $\Delta H_C^\circ[C_2H_5Cl(gas)] = -1413.05 \pm 0.59$ kJ mol^{-1}, which corresponds to $\Delta H_f^\circ[C_2H_5Cl.(gas)] = 112.2 \pm 0.7$ kJ mol^{-1}.

Similar results were obtained from the results of a study of the equilibrium reaction

$$C_2H_4\,(gas) + HCl\,(gas) \rightleftarrows C_2H_5Cl\,(gas) \qquad (8)$$

† All the values of ΔH_C° for chloroethanes quoted by Smith et al.[27] were measured at 292 K; in the present review they have been adjusted to the standard temperature. The heat capacity of C_2Cl_6 was taken from Rossini et al.[62] and those of all the remaining substances were taken from Glushko's handbook[7].

by Lane et al.[71] (at 722–754 K) and Howlett[72] (at 448–528 K). Lane et al.[71] obtained $\Delta H^\circ_{743}(8) = 74.98$ kJ on the basis of the Third Law of Thermodynamics and Howlett[72] obtained $\Delta H^\circ_{463}(8) = -72.97$ kJ on the basis of the Second Law of Thermodynamics. Hence, after adjustment to 298 K, we obtain $\Delta H^\circ_f[C_2H_5Cl(gas)] = -110.8 \pm 2$ and -111.1 ± 2 kJ mol^{-1} respectively. An earlier and less accurate study[73] of equilibrium (8) yielded $\Delta H^\circ_f[C_2H_5Cl(gas)] = -96.0$ kJ mol^{-1}. Measurements of Lacher and co-workers[7,48] of the enthalpy of hydrogenation of chloroethane at 521 K ($\Delta H_r = -71.80$ kJ mol^{-1}) lead to $\Delta H^\circ_f[C_2H_5Cl(gas)] = 106.7$ kJ mol^{-1} after adjustment to the standard temperature. The value obtained by Fletcher and Pilcher[39] is recommended: $\Delta H^\circ_f[C_2H_5Cl.(gas)] = -112.2 \pm 0.7$ kJ mol^{-1}.

1,1-Dichloroethane

Thomsen's study[69] involving the measurement of the enthalpy of combustion of CH_3CHCl_2 is merely of historical interest. Later measurements of ΔH°_C yielded $\Delta H^\circ_f[CH_3CHCl_2.(liq.)] = 158.3 \pm 0.9$ kJ mol^{-1} or (when account is taken of the enthalpy of evaporation $\Delta H^\circ_{v,298} = 31.00 \pm 0.04$ kJ mol^{-1} [7]), $\Delta H^\circ_f[CH_3CHCl_2(gas)] = -127.3 \pm 0.9$ kJ mol^{-1} were obtained[27]. Lacher et al.[50] determined ΔH for reaction

$$CH_3CHCl_2\,(gas) + 2H_2\,(gas) \rightarrow C_2H_6\,(gas) + 2HCl\,(gas) \qquad (9)$$

at 523 K. Their data yield $\Delta H^\circ_{298}(9) = -139.9 \pm 2.5$ kJ and $\Delta H^\circ_f[CH_3CHCl_2(gas)] = -128.8 \pm 2.6$ kJ mol^{-1}. The results of Smith et al.[27] and Lacher et al.[50] are similar and yet it is difficult to regard them as reliable. Thus the sign of ΔH for the isomerisation of dichloroethane which follows from the values of $\Delta H^\circ_f[C_2H_4Cl_2(gas)]$ found in the above studies[27,50] conflicts with that determined directly[74] (see below). The purity of the CH_3CHCl_2 specimen used by Lacher et al.[50] was low (99% according to chromatographic analysis); the method used to check that the reaction proceeds unambiguously is not indicated. Smith et al.[27] totally fail to give any information about the purity of the specimen.

More reliable data were obtained by Levanova et al.[75] in the study of the equilibria

$$CH_3CHCl_2\,(gas) \rightleftarrows CH_2{=}CHCl\,(gas) + HCl\,(gas) \qquad (10)$$

and

$$CH_2{=}CHCl\,(gas) + HCl\,(gas) \rightleftarrows CH_3CHCl_2\,(liq.) \qquad (11)$$

in the temperature ranges 403–438 K and 293–323 K respectively. They calculated $\Delta H^\circ_{420}(10) = 61.7$ kJ and $\Delta H^\circ_{308}(11) = -92.7$ kJ on the basis of the Second Law of Thermodynamics; $\Delta S^\circ_{420}(10) = 144.3$ kJ mol^{-1} K^{-1} and $\Delta S^\circ_{308}(11) = -238.9$ J mol^{-1} K^{-1}. Adjustment to the standard temperature yields $\Delta H^\circ_{298}(10) = 60.9$ kJ, whence follows $\Delta H^\circ_f[CH_3CHCl_2(gas)] = -130.2$ kJ mol^{-1}; $\Delta H^\circ_f[CH_3CHCl_2(gas)] = -131.0$ kJ mol^{-1} corresponds to $\Delta H^\circ_{298}(11)$. The similarity of the ΔH°_f found from the ΔH for reactions (10) and (11) indicates the absence of significant systematic errors.

Another confirmation of the validity of the results of Levanova et al.[75] is the satisfactory agreement between the experimental $\Delta S^\circ(10)$ and $\Delta S^\circ(11)$ and those calculated from the data in Glushko's handbook[7]: $\Delta S^\circ_{420}(10) = 148.4$ J mol^{-1} K^{-1} and $\Delta S^\circ_{298}(11) = -239.0$ J mol^{-1} K^{-1}. The average of the two values of ΔH°_f found by Levanova et al.[75] is recommended, i.e. $\Delta H^\circ_f[CH_3CHCl_2(gas)] = -130.6 \pm 3.0$ kJ mol^{-1}. The error was estimated by analogy with the results of the study of equilibria in other investigations by the same workers.

1,2-Dichloroethane

The values of ΔH°_C for 1,2-dichloroethane have been determined[69,76] but their accuracy is low. The enthalpies of combustion of liquid CH_2ClCH_2Cl found by Smith et al.[27] lead to $\Delta H^\circ_f[CH_2ClCH_2Cl(liq.)] = -158.9 \pm 0.8$ kJ mol^{-1}. When account is taken of the enthalpy of evaporation $\Delta H^\circ_{v,298} = 35.4 \pm 0.4$ kJ mol^{-1},[7] we obtain $\Delta H^\circ_f[CH_3CHCl_2(gas)] = 123.5 \pm 0.9$ kJ mol^{-1}. Later determinations[24,77] of $\Delta H^\circ_C(CH_2ClCH_2Cl)$ lead to $\Delta H^\circ_f[CH_2ClCH_2Cl(gas)] = -129.5 \pm 1.6$ and -134.1 ± 1.2 kJ mol^{-1} respectively.

The enthalpy of the reaction

$$CH_2ClCH_2Cl\,(gas) + 2H_2\,(gas) \rightarrow C_2H_6\,(gas) + 2HCl\,(gas) \qquad (12)$$

found by Lacher et al.[50] at 523 K leads to $\Delta H^\circ_{298}(12) = -142.1 \pm 2.5$ kJ and $\Delta H^\circ_f[CH_2ClCH_2Cl(gas)] = -126.6 \pm 2.6$ kJ mol^{-1} after adjustment to the standard temperature. As in the hydrogenation of 1,1-dichloroethane (see above), the specimen employed by Lacher et al.[50] was not highly pure (99%) and the absence of side reactions was not confirmed.

Conn et al.[78] determined ΔH° for the chlorination of ethylene in the gas phase at 355 K: $\Delta H^\circ_r = -182.6 \pm 0.6$ kJ mol^{-1}. After adjustment to 298 K, their data lead to $\Delta H^\circ_f[CH_2ClCH_2.Cl(gas)] = -130.4 \pm 0.8$ kJ mol^{-1}. The studies of Sinke and Stull[24], Hu and Sinke[77], and Conn et al.[78] were carried out by well tested methods using fairly pure specimens. However, one must note that the results of Hu and Sinke[24] and Conn et al.,[78] like those of Smith et al.[27] and Lacher et al.,[50] conflict with the determination[74] of ΔH for the isomerisation reaction

$$CH_3CHCl_2 \rightleftarrows CH_2ClCH_2Cl \qquad (13)$$

[$\Delta H^\circ_{385}(13) = -9.6 \pm 1.4$ kJ was obtained]. The latter value was found by the joint treatment of the results of measurements of K_p in the liquid and gas phases and is only approximate. Nevertheless its sign and approximate value must be taken into account in selecting the ΔH°_f for 1,2-dichloroethane. On the basis of these considerations, preference must be given to the data of Hu and Sinke[77], who determined ΔH°_C by the most reliable method—in a rotating bomb calorimeter, and $\Delta H^\circ_f[CH_2ClCH_2Cl(gas)] = -134.1 \pm 1.2$ kJ mol^{-1} must be adopted.

1,1,1-Trichloroethane

The enthalpy of combustion of 1,1,1-trichloroethane in rotating bomb calorimeters has been measured by a number of workers[25,77,79]. It has been shown[79] that the result obtained previously, namely $\Delta H^\circ_f[CH_3CCl_3(gas)] = -138.3$ kJ mol^{-1},[77] was erroneous owing to the inadequate purity of the specimen. In two investigations[25,79] the purities of the specimens were extremely high (99.99 and 99.96 mole % respectively). Both studies were carried out using a thoroughly tested method. The values of ΔH°_C from the above investigations[25,79] together with $\Delta H^\circ_{v,298}(CH_3CCl_3) = 32.47 \pm 0.07$[80] yield $\Delta H^\circ_f[CH_3CCl_3(gas)] = -142.1 \pm 1.4$ kJ mol^{-1}[25] and -146.1 ± 1.1 kJ mol^{-1}.[79] Hu et al.[79] also investigated the equilibrium

$$CH_2{=}CCl_2\,(gas) + HCl\,(gas) \rightleftarrows CH_3CCl_3\,(gas) \qquad (14)$$

at 348–399 K and obtained $\Delta H^\circ_{298}(14) = -54.6 \pm 8$ kJ on the basis of the Third Law of Thermodynamics. Hence we find $\Delta H^\circ_f[CH_3CCl_3(gas)] = -144.6 \pm 1.7$ kJ mol^{-1}.

The equilibrium in the hydrochlorination of 1,1-dichloroethylene in chlorobenzene at 293–353 K has been studied by Levanova et al.[81] They found $\Delta H^\circ_{323} = -56.9 \pm 2$ kJ mol^{-1}, from which follows $\Delta H^\circ_f[CH_3CCl_3(gas)] = -141.0 \pm 2.4$ kJ

mol^{-1}, its accuracy being lower than that of the results of other investigations[25,79], since no account has been taken of the enthalpy of solution of $CH_2=CCl_2$ and CH_3CCl_3 in chlorobenzene.

The weighted average of the most reliable results[25,79] presented above is recommended: $\Delta H_f^\circ[CH_3CCl_3(gas)] = -144.6 \pm 0.8$ kJ mol^{-1}.

1,1,2-Trichloroethane

Kirkbride[63] measured the enthalpy of the reaction

$$CH_2ClCH_2Cl\ (liq.) + Cl_2\ (gas) \rightarrow CH_2ClCHCl_2\ (liq.) + HCl\ (gas) \qquad (15)$$

and found $\Delta H_{298}^\circ(15) = -116.3$ kJ. Using the value of $\Delta H_f^\circ(CH_2ClCH_2Cl)$ adopted above, we obtain $\Delta H_f^\circ[CH_2ClCHCl_2.(liq.)] = -193.5$ kJ mol^{-1}. Kirkbride[63] introduced fairly large corrections for the dissolution of HCl, the evaporation of dichloroethane, etc., which had not been measured with adequate accuracy; no check was made to make sure that side reactions do not occur. His result must therefore be regarded as only approximate.

Levanova et al.[82] investigated the equilibria in the hydrochlorination of *cis*- and *trans*-dichloroethylenes in solution in tetrachloroethane. Without taking into account the heats of solution, we obtain from these results $\Delta H_f^\circ[CH_2ClCHCl_2.(liq.)] = -179.9$ and -181.9 kJ mol^{-1}. The result based on the study of the equilibrium in the isomerisation reaction

$$CH_2ClCHCl_2\ (liq.) \rightleftarrows CH_3CCl_3\ (liq.) \qquad (16)$$

at 373–473 K is more reliable[82]. Calculation based on the Second Law of Thermodynamics yielded $\Delta H_{423}^\circ(16) = 8.4 \pm 1.7$ kJ. Hence, having adopted $\Delta C_p(liq.) = \Delta C_p(gas) = 3.8$ J mol^{-1} K^{-1} [17]# in view of the lack of data for $C_p[CH_2.ClCHCl_2(liq.)]$, we find $\Delta H_{298}^\circ(16) = 7.9 \pm 1.7$ kJ and $\Delta H_f^\circ.[CH_2ClCHCl_2(liq.)] = -185.0 \pm 1.9$ kJ mol^{-1}. Taking into account the enthalpy of evaporation $\Delta H_{v,298}^\circ = 40.28 \pm 0.06$ kJ mol^{-1},[80] we have $\Delta H_f^\circ[CH_2ClCHCl_2(gas)] = -144.7 \pm 1.9$ kJ mol^{-1}.

1,1,1,2-Tetrachloroethane

The enthalpy of combustion of liquid CH_2ClCCl_3 (purity 99.95 mole %) has been measured[83] in a tantalum rotating bomb calorimeter and $\Delta H_c^\circ[CH_2ClCCl_3(liq.)] = -973.90 \pm 1.28$ kJ mol^{-1} was obtained. This leads to $\Delta H_f^\circ[CH_2ClCCl_3(liq.)] = -193.45 \pm 1.35$ kJ mol^{-1}; taking into account $\Delta H_{v,298}^\circ = 41.1 \pm 0.2$ kJ mol^{-1},[83] we find that $\Delta H_f^\circ[CH_2ClClCCl_3(gas)] = 152.3 \pm 1.4$ kJ mol^{-1}.

Levanova et al.[84] found $\Delta H_{333}^\circ = 45.4 \pm 0.4$ kJ mol^{-1} from the temperature variation of the equilibrium constants for the dehydrochlorination of 1,1,1,2-tetrachloroethane. Hence we obtain $\Delta H_{r,298}^\circ = 44.0 \pm 0.4$ kJ mol^{-1} and $\Delta H_f^\circ[CH_2ClCCl_3.(gas)] = -133.3$ kJ mol^{-1}. This result is less accurate than the data of Gundry and Head[83].

1,1,2,2-Tetrachloroethane

Smith et al.[27] determined the enthalpy of combustion of 1,1,2,2-tetrachloroethane: $\Delta H_c^\circ = -970.0 \pm 1.4$ kJ mol^{-1}. From this data, we obtain $\Delta H_f^\circ[CHCl_2CHCl_2(liq.)] = 193.0 \pm 1.5$ kJ mol^{-1} or (taking into account the enthalpy of evaporation $\Delta H_{v,298}^\circ = 45.78 \pm 0.16$ kJ mol^{-1} [80]) $\Delta H_f^\circ[CHCl_2CHCl_2.(gas)] = -147.2 \pm 1.5$ kJ mol^{-1}. The ΔH° for the chlorination of *cis*-dichloroethylene measured by Kirkbride[63] leads to a similar value: $\Delta H_f^\circ[CHCl_2CHCl_2(gas)] = -148.2$ kJ mol^{-1}. More reliable results were obtained in a study[67] where the equilibrium constants of the isomerisation reaction

$$CHCl_2CHCl_2\ (liq.) \rightleftarrows CH_2ClCCl_3\ (liq.) \qquad (17)$$

were measured at three temperatures in the range 453–493 K and the enthalpy of reaction (17) was calculated on the basis of the Second Law of Thermodynamics; $\Delta H_{473}^\circ(17) = 10.0 \pm 2.6$ kJ was obtained. Having adopted $\Delta C_p(liq.) = \Delta C_p(gas) = 2.1$ J mol^{-1} K^{-1} [7] for adjustment to 298 K (in view of the lack of the heat capacity of liquid CH_2ClCCl_3), we obtain $\Delta H_{298}^\circ(17) = 9.7 \pm 2.6$ kJ. Together with the value of $\Delta H_f^\circ.[CH_2ClCl_3(liq.)]$ quoted above, this yields $\Delta H_f^\circ[CHCl_2CHCl_2.(liq.)] = -203.1 \pm 3.0$ kJ mol^{-1} or $\Delta H_f^\circ[CHCl_2CHCl_2(gas)] = -157.3 \pm 3.0$ kJ mol^{-1}.

Pentachloroethane

The enthalpy of combustion of pentachloroethane measured by Smith et al.,[27] namely $\Delta H_c^\circ = -858.9 \pm 2.5$ kJ mol^{-1}, leads to $\Delta H_f^\circ[C_2HCl_5(liq.)] = -183.5 \pm 2.6$ kJ mol^{-1}. The enthalpy of chlorination of trichloroethylene $\Delta H_r = -150.6$ kJ mol^{-1} obtained by Kirkbride[63] leads to $\Delta H_f^\circ[C_2HCl_5(liq.)] = -188.7$ kJ mol^{-1}.

Bushneva[67] and Levanova et al.[85] determined the equilibrium constants of the catalytic reaction

$$C_2HCl_5\ (soln) \rightleftarrows HCl\ (gas) + C_2Cl_4\ (soln) \qquad (18)$$

at 363–383 K and found $\Delta H_{373}^\circ(18) = 45.1 \pm 4.5$ kJ on the basis of the Second Law of Thermodynamics. Adjustment to the standard temperature yields $\Delta H_{298}^\circ(18) = 48.1 \pm 4.5$ kJ, whence $\Delta H_f^\circ[C_2HCl_5(liq.)] = -191.4 \pm 5$ kJ mol^{-1}.

The deficiencies of the studies of Smith et al.[27] and Kirkbride[63] were already noted above [see the discussion of the value of $\Delta H_f^\circ(C_2Cl_6)$]. The accuracy of the determination of $\Delta H_f^\circ[C_2HCl_5(liq.)]$ in the above investigations[67,85] is also low as a consequence of the narrow temperature range in the measurements of K_p, the lack of enthalpies of solution for C_2Cl_4 and C_2HCl_5, and the use of an insufficiently reliable value of $\Delta H_f^\circ[C_2Cl_4(gas)]$, determined from the data of Smith et al. (see Section II).

The ΔH_f° for gaseous pentachloroethane were found to be -137.9 kJ mol^{-1},[27] -143.1 kJ mol^{-1},[63] and -145.8 kJ mol^{-1}.[67,85] Their reliability is reduced also as a consequence of the use of $\Delta H_{v,298}^\circ(C_2HCl_5) = 45.6$ kJ mol^{-1}, quoted by Kirkbride without indicating the error and the method of measurement. The calculated $\Delta H_f^\circ[C_2HCl_5(gas)]$ is therefore recommended below (see Section VI).

1,2-Dichlorotetrafluoroethane

The values of $\Delta H_f^\circ[CF_2ClCF_2Cl(gas)]$ calculated from the ΔH° for the reactions of CF_2ClCF_2Cl with potassium[41] or sodium[86] are -920.8 and -968.5 kJ mol^{-1} respectively. This discrepancy is probably due to complications arising in the determination of ΔH for reactions with alkali metals.

The measurements of the enthalpy of chlorination of tetrafluoroethylene by Lacher et al.[47] lead to $\Delta H_f^\circ[CF_2ClCF_2Cl.(gas)] = -899.4$ kJ mol^{-1}. The recommended value is based on the enthalpy of combustion of gaseous 1,2-dichlorotetrafluoroethane measured in a rotating bomb calorimeter[87]. The purity of the specimen was 99.8 mole %; a correction was

$\Delta C_p(liq.)$ and $\Delta C_p(gas)$ for dichloroethane isomers do not differ within the limits of experimental errors[7].

applied for the 0.2 mole % C_2F_5Cl impurity. $\Delta H_c^\circ[CF_2ClCF_2Cl.(gas)] = -624.7 \pm 3.6$ kJ mol^{-1} was obtained, whence follows $\Delta H_f^\circ[CF_2ClCF_2Cl(gas)] = -925.5 \pm 4.3$ kJ mol^{-1}.

1,1,2-Trichlorotrifluoroethane

The enthalpy of combustion of $CF_2ClCFCl_2$ was determined by Erastov et al.[43] The measurements were performed in two rotating bomb calorimeters, three specimens with purities of 99.60, 99.85, and 99.91 mole % were used, and the combustion products were carefully analysed. $\Delta H_f^\circ[CF_2Cl.CFCl_2(liq.)] = -755.0 \pm 2.8$ kJ mol^{-1} corresponds to the $\Delta H_c^\circ[CF_2ClCFCl_2(liq.)] = -641.6 \pm 1.9$ kJ mol^{-1} measured[43]. When account is taken of the enthalpy of evaporation $\Delta H_{v,298}^\circ = 28.2 \pm 0.4$ kJ mol^{-1},[88] we find $\Delta H_f^\circ[CF_2ClCFCl_2(gas)] = -726.8 \pm 2.8$ kJ mol^{-1}. When the enthalpy of formation $\Delta H_f^\circ.[CF_2=CFCl(gas)]$ quoted above is used, the result of Erastov et al.[43] agree satisfactorily with the enthalpy of chlorination of chlorotrifluoroethylene obtained by Lacher et al.[44]

The quantity $\Delta H_f^\circ[CF_2ClCFCl_2(gas)] = -781.9$ kJ mol^{-1}, calculated from the measurements of ΔH° for the reaction of $CF_2ClCFCl_2$ with sodium[86], is less reliable.

Tetrachloro-1,1-difluoroethane

The enthalpy of chlorination of 1,1-dichlorodifluoroethylene $\Delta H_{363} = -171.9$ kJ mol^{-1}, to which corresponds $\Delta H_f^\circ[CF_2Cl.CCl_3(gas)] = 510$ kJ mol^{-1}, has been measured[44]. It is noteworthy that the value of $\Delta H_f^\circ[CF_2=CCl_2(gas)] = -338 \pm 11$ kJ mol^{-1} (see Section II) employed in this calculation is not very reliable. The value of ΔH° obtained[44] for the chlorination reaction also gives rise to some doubts, since it deviates from the general relations for the ΔH° for the chlorination of fluoro- and chloro-ethylenes[89].

The value based on the measurement of the enthalpy of combustion of tetrachloro-1,1-difluoroethane (purity 99.6 mole %) in a rotating bomb calorimeter is more reliable[90]; it amounts to $\Delta H_c^\circ[CF_2ClCCl_2(cryst.)] = -670.5 \pm 3.5$ kJ mol^{-1}, whence follows $\Delta H_f^\circ[CF_2ClCCl_3(cryst.)] = -569.8 \pm 3.8$ kJ mol^{-1}. When account is taken of the enthalpy of fusion ($\Delta H_{m,298}^\circ = 3.3 \pm 0.4$ kJ mol^{-1} [90]) and the enthalpy of evaporation ($\Delta H_{v,298}^\circ = 40.7 \pm 1.9$ kJ mol^{-1}) of tetrachloro-1,1-difluoroethane, we obtain $\Delta H_f^\circ[CF_2ClCCl_3(gas)] = -525.8 \pm 4.3$ kJ mol^{-1}.

1-Chloro-1-fluoroethane

The enthalpy of combustion of two specimens of gaseous CH_3CHFCl (with purities of 99.78 and 99.93 mole %) were measured[91] in a rotating bomb calorimeter. $\Delta H_f^\circ[CH_3CHFCl.(gas)] = -313.4 \pm 2.6$ kJ mol^{-1} corresponds to the $\Delta H_c^\circ = -1247.75 \pm 2.5$ kJ mol^{-1} obtained.

1-Chloro-1,1-difluoroethane

The enthalpy of combustion of gaseous CH_3CF_2Cl (99.90 mole % pure) has been measured[92] in a rotating bomb calorimeter: $\Delta H_c^\circ = -1061.1 \pm 5.0$ kJ mol^{-1}. Hence follows $\Delta H_f^\circ.[CH_3CF_2Cl(gas)] = -536.2 \pm 5.2$ kJ mol^{-1}.

Bromoethane

The early determinations[68,69] of ΔH° for the combustion of bromoethane are of only historical interest. Lane et al.[71] investigated the equilibrium in the hydrobromination of ethylene at 515–573 K and calculated $\Delta H_{r,544}^\circ = -80.3 \pm 1.3$ kJ mol^{-1} on the basis of the Second Law of Thermodynamics. After adjustment to the standard temperature, we obtain $\Delta H_{r,298}^\circ = -78.2 \pm 1.3$ kJ mol^{-1} and $\Delta H_f^\circ[C_2H_5Br(gas)] = -62.2 \pm 1.4$ kJ mol^{-1}. The enthalpy of hydrogenation of bromoethane has been measured[49] at 523 K; it amounts to $\Delta H_r^\circ = -62.05 \pm 1.1$ kJ mol^{-1}, whence $\Delta H_{r,298} = -59.51 \pm 1.1$ kJ mol^{-1}. Using the value of $\Delta H_f^\circ[C_2H_6(gas)]$ recommended above, we obtain $\Delta H_f^\circ[C_2H_5Br(gas)] = -60.9 \pm 1.2$ kJ mol^{-1}. The values of ΔH_f° derived from the investigations of Fowell et al.[49] and Lane et al.[71] agree satisfactorily; their weighted mean, i.e. $\Delta H_f^\circ[C_2H_5Br(gas)] = -61.5 \pm 1.0$ kJ mol^{-1}, can be adopted as the most probable.

Ashcroft et al.[93] determined ΔH° for the reaction of C_2H_5Br with lithium hydride and found that the heat of the reaction

$$C_2H_5Br\,(liq.) + {}^1/_2H_2\,(gas) \rightarrow C_2H_6\,(gas) + {}^1/_2Br_2\,(liq.) \qquad (19)$$

is $\Delta H_{328}^\circ(19) = 11.7 \pm 6.3$ kJ. Hence follows $\Delta H_f^\circ[C_2H_5Br.(liq.)] = -95.7 \pm 6.3$ kJ mol^{-1}; bearing in mind that $\Delta H_{v,298}^\circ = 27.91 \pm 0.21$ kJ mol^{-1},[7] we obtain $\Delta H_f^\circ[C_2H_5Br(gas)] = -67.8 \pm 6.3$ kJ mol^{-1}. This value does not conflict with that recommended above but is less accurate.

1,1- and 1,2-Dibromoethanes

Berthelot's data[94] for the enthalpy of bromination of ethylene and also those of Kablukov and Perel'man[76] for the enthalpy of combustion of 1,2-dibromoethane in a static bomb calorimeter are now obsolete.

Measurements of the enthalpy of combustion of liquid CH_2BrCH_2Br in rocking[95] and rotating[96] bomb calorimeters lead to $\Delta H_f^\circ[CH_2BrCH_2Br(gas)] = -52.3$ and -22.4 kJ mol^{-1} respectively when account is taken of $\Delta H_{v,298}^\circ(CH_2BrCH_2Br) = 41.8 \pm 0.4$ kJ mol^{-1}.[7] The large discrepancy between them may be explained by the presence of impurities in the test specimens whose purities were not characterised in the above investigations[95,96].

Conn et al.[78] determined the enthalpy of bromination of ethylene (with a purity of 99.98 mole %) in the gas phase at 355 K; it proved to be -121.6 ± 1.3 kJ mol^{-1}. After adjustment to 298 K, we obtain $\Delta H_{r,298}^\circ = 121.9 \pm 1.3$ kJ mol^{-1}, whence follows $\Delta H_f^\circ[CH_2BrCH_2Br(gas)] = -38.6 \pm 1.4$ kJ mol^{-1}.

Levanova et al.[97] measured the equilibrium constants of the reactions

$$CH_3CHBr_2\,(gas) \rightleftarrows CH_2=CHBr\,(gas) + HBr\,(gas), \qquad (20)$$

$$CH_2BrCH_2Br\,(gas) \rightleftarrows CH_2=CHBr\,(gas) + HBr\,(gas), \qquad (21)$$

$$CH_3CHBr_2\,(gas) \rightleftarrows CH_2BrCH_2Br\,(gas) \qquad (22)$$

at temperatures in the range 404–520 K and calculated the following values on the basis of the Second Law of Thermodynamics: $\Delta H_{425}^\circ(20) = 70.3 \pm 2.5$ kJ, $\Delta H_{448}^\circ(21) = 79.9 \pm 1.7$ kJ, and $\Delta H_{485}^\circ(22) = -12.1 \pm 1.3$ kJ. Adopting $\Delta C_p = 0$ in reactions (20)–(22) owing to the lack of data for $C_p(CH_3.CHBr_2)$ and also in view of the low value of $\Delta C_p(21) = 0.1$ J mol^{-1} K^{-1},[7] we obtain $\Delta H_f^\circ[CH_3CHBr_2(gas)] = -27.4 \pm 3.2$ kJ mol^{-1} and $\Delta H_f^\circ[CH_2BrCH_2Br(gas)] = -37.0 \pm 6$ kJ mol^{-1} from the ΔH° for reactions (20) and (21).

Izmailov et al.[98] investigated the equilibrium in the isomerisation of dibromoethane in the liquid phase at 363–698 K and calculated the enthalpy of isomerisation as 528 K on the basis

of the Second Law of Thermodynamics, which proved to be -13.0 ± 0.5 kJ mol^{-1}. Adopting $\Delta C_p = 0$ and using the value of $\Delta H^\circ_{v,298}(CH_2BrCH_2Br)$[7] quoted above as well as the value $\Delta H^\circ_{v,298}(CH_3CHBr_2) = 39.3$ kJ mol^{-1} calculated by the Klages equation[99], we obtain $\Delta H^\circ_{298}(22) = -10.5 \pm 5.0$ kJ for the gas phase. The error takes into account the approximate nature of the calculation. The results of the determination of the enthalpies of formation of 1,1- and 1,2-dibromoethanes as well as the enthalpies of their isomerisation found in a number of studies[78,97,98] agree with one another (within the limits of the errors). Joint least squares treatment of the five results indicated, taking into account their statistical weights, yielded the following recommended values: $\Delta H^\circ_f[CH_3CHBr_2.(gas)] = -26.7 \pm 1.9$ kJ mol^{-1} and $\Delta H^\circ_f[CH_2BrCH_2Br(gas)] = -38.3 \pm 1.2$ kJ mol^{-1}.

1,2-Dibromotetrafluoroethane

Lacher et al.[12] measured the enthalpy of bromination of gaseous tetrafluoroethylene at 376 K and found it to be -161.0 ± 3.0 kJ mol^{-1}. Using $C_p[CF_2BrCF_2Br(gas)] = 119.8$ J mol^{-1} K^{-1}, estimated from the heat capacities[7] of C_2F_6 and C_2Br_6, we obtain $\Delta H_{r,298} = -161.3 \pm 3.0$ kJ mol^{-1}, whence follows $\Delta H^\circ_f[CF_2BrCF_2Br(gas)] = -789.9 \pm 4.0$ kJ mol^{-1}.

1-Bromo-1,1-difluoroethane

Pickard and Rodgers[100] measured the equilibrium constant of the reaction

$$CH_3CF_2Br\ (gas) + I_2\ (gas) \rightleftarrows CH_3CF_2I\ (gas) + IBr\ (gas) \qquad (23)$$

at 581–622 K and found [having estimated $\Delta S^\circ(23)$ and $\Delta C_p(23)$ by the method of group contributions] $\Delta H^\circ_{298}(23) = 42.7 \pm 0.8$ kJ. Adopting $\Delta H^\circ_f[IBr(gas)] = 40.80 \pm 0.14$ kJ mol^{-1} [21] and $\Delta H^\circ_f[CH_3CF_2I(gas)] = -410.0 \pm 8.5$ kJ mol^{-1} (see below), we obtain $\Delta H^\circ_f[CH_3CF_2Br(gas)] = -474.3 \pm 8.5$ kJ mol^{-1}.

Bromo-1,1,1-trifluoroethane

Buckley et al.[101] investigated the equilibrium

$$CF_3CH_2Br\ (gas) + I_2\ (gas) \rightleftarrows CF_3CH_2I\ (gas) + IBr\ (gas) \qquad (24)$$

in the range 614–726 K and calculated $\Delta H^\circ_{298}(24) = 27.6 \pm 2.1$ kJ on the basis of the Third Law of Thermodynamics using the thermodynamic functions of haloethanes taken from Ford[102]. Taking into account $\Delta H^\circ_f[CF_3CH_2I(gas)] = -648.6 \pm 3.9$ kJ mol^{-1} (see below), we obtain $\Delta H^\circ_f[CF_3CH_2Br(gas)] = -697.8 \pm 4.4$ kJ mol^{-1}.

Bromo-1,1,2,2-Tetrafluoroethane

Lacher et al.[46] measured the enthalpy of hydrobromination of gaseous perfluoroethylene and found $\Delta H^\circ_{r,367} = -137.7 \pm 0.9$ kJ mol^{-1}. Adopting $C_p[CHF_2CF_2Br(gas)] = 104.2$ J mol^{-1} K^{-1}, we find $\Delta H^\circ_{r,298} = -137.3 \pm 1$ kJ mol^{-1} and $\Delta H^\circ_f[CHF_2.CF_2Br(gas)] = -833.2 \pm 2.7$ kJ mol^{-1} from a comparison of the C_p for C_2H_6, C_2F_6, and C_2Br_6.[7]

1-Bromo-1-chloroethane

Bushneva et al.[103] investigated the equilibria in the thermocatalytic reactions of 1-bromo-1-chloroethane in the gas phase at 443–523 K and calculated the enthalpies of the following three reactions on the basis of the Second Law of Thermodynamics:

$$2CH_3CHClBr \rightleftarrows CH_3CHCl_2 + CH_3CHBr_2\ , \qquad (25)$$

$$CH_3CHClBr \rightleftarrows CH_2{=}CHCl + HBr\ , \qquad (26)$$

$$CH_3CHClBr \rightleftarrows CH_2{=}CHBr + HCl\ . \qquad (27)$$

They obtained $\Delta H^\circ_{483}(25) = 8.0 \pm 0.4$ kJ, $\Delta H^\circ_{483}(26) = 70.7 \pm 0.8$ kJ, and $\Delta H^\circ_{483}(27) = 66.1 \pm 1.7$ kJ. The above values were not adjusted to 298 K because of the lack of data for $C_p(CH_3CHClBr)$, but an approximate estimate of ΔC_p in reactions (25)–(27) showed that the difference between the values of ΔH°_{298} and ΔH°_{483} is less than the experimental error. Using the enthalpies of formation of chloro- and bromo-ethylenes quoted in Section II of the present review and also the ΔH°_f recommended above for CH_3CHCl_2 and CH_3CHBr_2, we obtain three values of $\Delta H^\circ_f[CH_3CHClBr(gas)]$: -82.6 ± 3.6, -84.1 ± 2.3, and -79.1 ± 3.4 kJ mol^{-1}. Their mean is recommended: $\Delta H^\circ_f[CH_3CHClBr(gas)] = -82.5$ kJ mol^{-1}. The error indicated takes into account the complexity of the composition of the equilibrium mixture and the actual discrepancies between the three results obtained[103].

1-Bromo-2-chloroethane

Bushneva et al.[104] found the enthalpies of the following reactions from measurements of their K_p at 483–523 K:

$$2CH_2ClCH_2Br\ (gas) \rightleftarrows CH_2ClCH_2Cl\ (gas) + CH_2BrCH_2Br\ (gas), \qquad (28)$$

$$CH_2ClCH_2Br\ (gas) \rightleftarrows CH_2{=}CHCl\ (gas) + HBr\ (gas), \qquad (29)$$

$$CH_2ClCH_2Br\ (gas) \rightleftarrows CH_2{=}CHBr\ (gas) + HCl\ (gas). \qquad (30)$$

They obtained $\Delta H^\circ_{503}(28) = 3.7 \pm 0.4$ kJ, $\Delta H^\circ_{503}(29) = 77.8 \pm 2.5$ kJ, and $\Delta H^\circ_{503}(30) = 69.0 \pm 2.1$ kJ. Neglecting the adjustment to the standard temperature, we obtain from these enthalpies three values of $\Delta H^\circ_f[CH_2ClCH_2Br(gas)]$: -88.1 ± 1.7, -91.2 ± 3.3, and -82.0 ± 2.8 kJ mol^{-1}. As in the case of 1-bromo-1-chloroethane, their average is recommended: $\Delta H^\circ_f[CH_2ClCH_2Br(gas)] = -87 \pm 5$ kJ mol^{-1}.

1,2-Dibromo-1,2-dichloroethane

Müller and Schumacher[105] determined the enthalpy of bromination of gaseous *trans*-dichloroethylene from the temperature dependence of the equilibrium constant in the range 343–373 K and obtained $\Delta H_{r,358} = -72.4 \pm 6$ kJ mol^{-1}. Using $C_p(CHClBrCHClBr) = 112.3$ J mol^{-1} K^{-1} estimated from the heat capacities of C_2H_6, C_2Cl_6, and C_2Br_6 quoted by Glushko[7], we find $\Delta H^\circ_{r,298} = -73.0 \pm 6$ kJ mol^{-1}, whence $\Delta H^\circ_f[CHClBr.CHClBr(gas)] = -36 \pm 6$ kJ mol^{-1}.

1,2-Dibromo-2-chloro-1,1,2-trifluoroethane

Lacher et al.[12] measured the enthalpy of bromination of gaseous chlorotrifluoroethylene: $\Delta H^\circ_{r,376} = -132.2 \pm 1.3$ kJ mol^{-1}. $C_p(CF_2BrCFClBr) = 124.9$ J mol^{-1} K^{-1} was adopted (from a comparison of the heat capacities of C_2F_6, C_2Cl_6, and C_2Br_6 quoted by Glushko[7]) in order to adjust the above quantities to 298 K. This yields $\Delta H^\circ_{r,298} = -132.6 \pm 1.3$ kJ mol^{-1}, whence follows $\Delta H^\circ_f[CF_2BrCFClBr(gas)] = -616.8 \pm 3.7$ kJ mol^{-1}.

1-Bromo-1-chloro-2,2,2-trifluoroethane

The enthalpy of combustion of 1-bromo-1-chloro-2,2,2-trifluoroethane, measured in a rotating bomb calorimeter[45], amounts to $\Delta H_c^\circ = -761.6 \pm 3.2$ kJ mol^{-1}. Hence $\Delta H_f^\circ[CF_3.CHClBr(liq.)] = -729.6 \pm 3.8$ kJ mol^{-1}. Taking into account the enthalpy of evaporation $\Delta H_{v,298}(CF_3CHClBr) = 29.69 \pm 0.1$ kJ mol^{-1} (the mean of two calorimetric determinations[45,106]), we obtain $\Delta H_f^\circ[CF_3CHClBr(gas)] = -699.9 \pm 3.8$ kJ mol^{-1}.

1-Bromo-2-chloro-1,1,2-trifluoroethane

The enthalpy of combustion of $CF_2BrCHFCl$ has been determined in a rotating bomb calorimeter at $\Delta H_c^\circ = -806.3 \pm 5.2$ kJ mol^{-1}.[45] Hence $\Delta H_f^\circ[CF_2BrCHFCl(liq.)] = -684.8 \pm 5.6$ kJ mol^{-1} or, when account is taken of the enthalpy of evaporation $\Delta H_{v,298}^\circ(CF_2BrCHFCl) = 30.15 \pm 0.1$ kJ mol^{-1},[107] one can obtain $\Delta H_f^\circ[CF_2BrCHFCl(gas)] = -654.7 \pm 5.6$ kJ mol^{-1}. The value found agrees with the measured[46] enthalpy of hydrobromination of chlorotrifluoroethylene when $\Delta H_f^\circ.[CF_2=CFCl(gas)] = 515.1 \pm 3.4$ kJ mol^{-1}, taken from Erastov and Kolesov[10], is used.

1-Bromo-2,2-dichloro-1,1-difluoroethane

Lacher et al.[46] measured the enthalpy of hydrobromination of 1,1-dichloro-2,2-difluoroethylene and obtained $\Delta H_{r,367} = 96.4 \pm 0.5$ kJ mol^{-1}. Having estimated $C_p(CF_2BrCHCl_2) = 114.1$ J mol^{-1} K^{-1} (from a comparison of the C_p for C_2H_6, C_2F_6, C_2Cl_6, and C_2Br_6 quoted by Glushko[7]), we find $\Delta H_{r,298}^\circ = -96.3$ kJ mol^{-1} and $\Delta H_f^\circ[CF_2BrCHCl_2(gas)] = -471 \pm 11$ kJ mol^{-1}.

The Difference between the Enthalpies of Formation of Bromoperfluoroethane and Pentafluoroethane

The equilibrium in the gas-phase reaction

$$C_2HF_5 + Br_2 \rightleftarrows C_2F_5Br + HBr \qquad (31)$$

was investigated[108,109] at temperatures in the range 632–860 K and $\Delta H_{746}^\circ(31) = -24.2 \pm 0.7$ kJ was found from the temperature variation of K_p. Buckley et al.[110] calculated $\Delta H_{298}^\circ(31) = -31.4 \pm 0.4$ kJ from the data of Coomber and Whittle[108] and Ferguson and Whittle[109] on the basis of the Third Law of Thermodynamics using the thermodynamic functions of C_2HF_5 and C_2F_5Br from Ford's dissertation[102]. The difference $\Delta H_f^\circ[C_2F_5Br(gas)] - \Delta H_f^\circ[C_2HF_5(gas)] = 35.9 \pm 0.5$ kJ mol^{-1} corresponds to the above value.

The Difference between the Enthalpies of Formation of Bromo- and Chloro-Perfluoroethanes

Coomber and Whittle[111] investigated the equilibrium

$$C_2F_5Br\,(gas) + Cl_2\,(gas) \rightleftarrows C_2F_5Cl\,(gas) + BrCl\,(gas) \qquad (32)$$

at 738–833 K and calculated $\Delta H_{785}^\circ(32) = -43.3 \pm 1.1$ kJ on the basis of the Second Law of Thermodynamics. Buckley et al.[110] calculated from the same data $\Delta H_{298}^\circ(32) = -39.75 \pm 0.4$ kJ on the basis of the Third Law of Thermodynamics. Hence we find the difference $\Delta H_f^\circ[C_2F_5Br(gas)] - \Delta H_f^\circ[C_2F_5Cl.(gas)] = 54.5 \pm 0.4$ kJ mol^{-1}.

Iodoethane

Measurements of the enthalpy of combustion of iodoethane by Thomsen[69] and Berthelot[112] as well as the determination of the ΔH of the substitution of iodine by bromine in iodoethane[68] are at present only of historical interest. Springall and White[113] determined the enthalpy of combustion of liquid iodoethane and obtained $\Delta H_c^\circ = -1466.5 \pm 2.1$ kJ mol^{-1}; hence $\Delta H_f^\circ[C_2H_5I(liq.)] = -35.1 \pm 2.1$ kJ mol^{-1} and, when account is taken of $\Delta H_{v,298}^\circ(C_2H_5I) = 32.2 \pm 0.4$ kJ mol^{-1},[7] we obtain $\Delta H_f^\circ[C_2H_5I(gas)] = -2.9 \pm 2.1$ kJ mol^{-1}. One should note that Springall and White[113] give no information about the purity of the specimen, the results of the analysis of the combustion products, and the number of experiments.

Carson et al.[114] measured the enthalpies of iodination of solutions of diethylzinc and diethylcadmium in benzene and ether respectively and also the enthalpies of solution of iodine in benzene and ether. Neglecting the enthalpies of solution of iodoethane in benzene and ether and using the values of ΔH_f° for diethylzinc, diethylcadmium, and the corresponding metal iodides adopted by Glushko[7], we obtain from these data two values of $\Delta H_f^\circ[C_2H_5I(liq.)]$, which are respectively -40.6 and -39.7 kJ mol^{-1}. Their reliability is reduced owing to the inadequately rigorous allowance for the heats of side reactions.

Ashcroft et al.[93] measured the enthalpy of reduction of ethyl iodide by lithium hydride in an ethereal solution of lithium tetrahydroaluminate, whence the heat of the reaction

$$C_2H_5I\,(liq.) + {}^1/_2H_2\,(gas) = C_2H_6\,(gas) + {}^1/_2I_2\,(cryst.) \qquad (33)$$

was found to be $\Delta H_{298}^\circ(33) = -44.3 \pm 0.7$ kJ. This value leads to $\Delta H_f^\circ[C_2H_5I(liq.)] = -39.7 \pm 0.8$ kJ mol^{-1} and $\Delta H_f^\circ.[C_2H_5I(gas)] = -7.5 \pm 0.9$ kJ mol^{-1}. We believe that this latter value is the most reliable.

1,2-Di-iodoethane

The equilibrium constants of the reaction

$$CH_2ICH_2I\,(gas) \rightleftarrows C_2H_4\,(gas) + I_2\,(gas) \qquad (34)$$

have been measured[115–118] at 282–476 K). The results of Mooney and Ludlam[115] are doubtful, since their measurements were performed at I_2 and $C_2H_4I_2$ concentrations close to saturation. The other data[116–118] agree satisfactorily. Benson and Amano[118] subjected them to a joint treatment on the basis of the Second Law of Thermodynamics and obtained $\Delta H_{380}^\circ(34) = 48.12 \pm 0.84$ kJ. Adjustment to the standard temperature leads to $\Delta H_{298}^\circ(34) = 48.16 \pm 0.84$ kJ, whence $\Delta H_f^\circ[CH_2ICH_2I(gas)] = 66.7 \pm 1.0$ kJ mol^{-1}.

Tetrafluoro-1,2-di-iodoethane

Wu and Rodgers[119] investigated the equilibrium

$$CF_2{=}CF_2\,(gas) + I_2\,(gas) \rightleftarrows CF_2ICF_2I\,(gas) \qquad (35)$$

at 477–562 K and calculated $\Delta H_{520}^\circ(35) = -66.5 \pm 2.1$ kJ on the basis of the Second Law of Thermodynamics. Adjustment to 298 K, which the authors carried out themselves[119], led to $\Delta H_{298}^\circ(35) = -69.5 \pm 2.1$ kJ. Hence it follows that $\Delta H_f^\circ[CF_2I.CF_2I(gas)] = -666.6 \pm 3.3$ kJ mol^{-1}.

1,1-Difluoro-1-iodoethane

Pickard and Rodgers[100] quote the difference between the enthalpies of formation of 1,1-difluoro-1-iodoethane and 1,1-difluoroethane given previously in Pickard's dissertation[120]:

$[\Delta H_f^0(CH_3CF_2I\ (gas)) - \Delta H_f^0(CH_3CHF_2\ (gas))]_{298} = 87.0 \pm 0.8$ kJ mol^{-1}

Using the value of $\Delta H_f^\circ(CH_3CHF_2)$ recommended above, we find $\Delta H_f^\circ[CH_3CF_2I(gas)] = -410.0 \pm 8.5$ kJ mol^{-1}.

1,1,1-Trifluoroiodoethane

Wu and Rodgers[121] measured the equilibrium constant of the reaction

$$CF_3CH_3\,(r) + I_2\,(r) \rightleftarrows CF_3CH_2I\,(r) + HI\,(r) \qquad (36)$$

at 730–775 K. Having estimated the entropies of haloethanes, the above workers[121] calculated $\Delta H_{298}^\circ(36) = 64.0 \pm 2.1$ kJ on the basis of the Third Law of Thermodynamics. Hence, taking into account the value of $\Delta H_f^\circ[CH_3CF_3(gas)]$ recommended above, we obtain $\Delta H_f^\circ[CF_3CH_2I(gas)] = -648.6 \pm 3.9$ kJ mol^{-1}.

1-Bromo-2-Iodoethane

Berthelot[68] measured the enthalpy of the reaction

$$CH_2ICH_2I\ (cryst.) + Br_2\ (liq.) = CH_2BrCH_2I\ (cryst.) + BrI\ (cryst.) \qquad (37)$$

and obtained $\Delta H(37) = -58.2$ kJ. In view of the lack of more accurate measurements of $\Delta H_f^\circ(CH_2BrCH_2I)$, we calculated this quantity from Berthelot's data[68]. Using $\Delta H_f^\circ[IBr(cryst.)] = -10.33$ kJ mol^{-1} and $\Delta H_{S,298}^\circ(CH_2ICH_2I) = 66.9$ kJ mol^{-1} taken from Glushko's handbook[7] as well as the value of $\Delta H_f^\circ[CH_2I.CH_2I(gas)]$ recommended above, we find $\Delta H_f^\circ[CH_2ICH_2Br.(cryst.)] = -48.1$ kJ mol^{-1}. Adopting $\Delta H_{S,298}^\circ(CH_2BrCH_2I) = 60.3$ kJ mol^{-1} [the mean of the two values of $\Delta H_{S,298}^\circ(CH_2I.CH_2I)$ presented above and $\Delta H_{S,283}^\circ(CH_2BrCH_2Br) = 53.6$ kJ mol^{-1}[7]], we obtain $\Delta H_f^\circ[CH_2BrCH_2I(gas)] = 12.2$ kJ mol^{-1}; this value is only approximate.

The Difference between the Enthalpies of Formation of Iodo- and Bromo-perfluoroethanes

Buckley et al.[110] studied the equilibrium

$$C_2F_5Br + I_2 \rightleftarrows C_2F_5I + IBr \qquad (38)$$

in the gas phase at 618–667 K. Using the thermodynamic functions of haloethanes calculated by Ford[102], Buckley et al.[110] obtained $\Delta H_{298}^\circ(38) = 38.5 \pm 0.8$ kJ. Hence we obtain the difference $\Delta H_f^\circ[C_2F_5I(gas)] - \Delta H_f^\circ[C_2F_5Br(gas)] = 60.1 \pm 0.8$ kJ mol^{-1}.

V. ESTIMATION OF THE ENTHALPIES OF FORMATION OF HALOETHANES

Among the numerous additive methods whereby the enthalpies of formation of organic compounds can be calculated approximately, only a few have been used to estimate the ΔH_f° of haloethanes. The enthalpies of formation were usually estimated only for a small number of haloethanes. All the haloethanes were never embraced by a single computational scheme sufficiently accurate in relation to this particular group of substances.

Rodgers[122] used Zahn's method[123] for the calculation of the enthalpies of formation of chlorofluorocarbons and evaluated six constants of the additive scheme whereby it is possible to calculate the ΔH_f° for only ten haloethanes. Furthermore some of the experimental ΔH_f° used by Rodgers[122] to calculate the constants are now obsolete. The attempt by Lacher and Skinner[124] to apply Allen's scheme[125] to fluoro- and chloro-derivatives of methane and ethane did not yield satisfactory results owing to the small number of experimental data available at the time. Later Gasteiger et al.[126] used Allen's scheme to estimate the enthalpies of formation of haloalkanes having at their disposal more extensive experimental data. Constants were found for the calculation of the ΔH_f° for mono- and poly-chloro-substituted hydrocarbons and also mono-fluoro-, monobromo-, and monoiodo-derivatives; only a small proportion of the haloethanes are included in the above groups of substances.

The "incremental" method used by Andreevskii et al.[127] for fluoroalkanes makes it possible to calculate the enthalpies of formation of substances containing substituent atoms of only two types. Benson et al.[128], who proposed the method of "group contributions" for the calculation of ΔH_f°, evaluated the contributions of 12 halogen-containing groups with the aid of which it is possible in principle to find the enthalpies of formation of 78 haloethanes. However, it has been noted by several workers[60,128] that the method of group contributions leads to highly distorted estimates for compounds containing adjacent groups with sharply different polarities, which is in fact a characteristic feature of a large number of haloethanes.

According to the scheme developed by Somayajulu and Zwolinski[129,130], the enthalpies of formation of haloethanes are calculated as sums of contributions corresponding to the interactions in sets of three atoms linked to a single carbon atom and to "excess" vicinal interactions. Somayajulu and Zwolinskii[130] quote constants whereby it is possible to estimate the ΔH_f° for 78 haloethanes, but some of the experimental ΔH_f° used in their study have now been modified. The calculation of the constants of the scheme of Somayajulu and Zwolinski constitutes a fairly cumbersome procedure in view of the need to calculate the number of sets of three atoms and vicinal interactions.

Bernstein[13,14] proposed a method for the estimation of the enthalpies of formation based on the allowance for the pair interactions of all the atoms in the molecule both linked and not linked by chemical bonds. In the estimation of the ΔH_f° for haloethanes in Bernstein's later study[14], the initial scheme was simplified: the group $-CH_3$ was regarded as one of the substituents in methane and the enthalpies of formation of haloethanes not containing the CH_3 group were calculated as the sums of the contributions of two substituted methyl groups. In this approach no account was taken of the fairly intense interactions of the substituents in haloethanes located at different carbon atoms. This simplification, made in view of the limited number of experimental data, led to a significant decrease of the accuracy of the estimate. Discrepancies are particularly large between the ΔH_f° calculated by Bernstein[14] and subsequently determined experimentally for fluoroethanes.

Nevertheless the method proposed by Bernstein is in principle extremely promising for compounds with a short carbon chain and different substituents, since it makes it possible to estimate the enthalpies of formation with a satisfactory accuracy using a comparatively small number of constants in the computational formulae. In combination with modern experimental data, this method has been applied successfully to the estimation of ΔH_f° for halomethanes[8,21] and fluoroethylenes[21].

In the present review Bernstein's method was used for the approximate calculation of the enthalpies of formation of haloethanes. Since the experimental data accumulated at the present time make it possible to take into account all the pair interactions of the atoms in haloethanes (except in the case of iodo-derivatives) and in order to facilitate calculations,

the computational formulae were modified compared with those proposed by Bernstein[13,14].

The enthalpy of formation of a haloethane containing substituents of only two types (X and Y) can be represented, according to Bernstein, by the sum of the following contributions: $P(CC)_1$, $P(CX)_1$, $P(CY)_1$, $P(CX)_2$, $P(CY)_2$, $P(XX)_2$, $P(YY)_2$, $P(XY)_2$, $P(XX)_3$, $P(YY)_3$, and $P(XY)_3$. Subscript 1 refers to a pair of atoms connected by chemical bond, subscript 2 refers to atoms linked by two bonds, and subscript 3 refers to atoms joined by three bonds. Since the numbers of contributions are not linearly independent, they can be reduced to the following four constants of the computational scheme:

$$[CX]_1 = {}^1/_6 P(CC)_1 + P(CX)_1 + P(CX)_2 + P(XX)_2 + {}^3/_2 P(XX)_3 , \quad (39)$$

$$[CY]_1 = {}^1/_6 P(CC)_1 + P(CY)_1 + P(CY)_2 + P(YY)_2 + {}^3/_2 P(YY)_3 , \quad (40)$$

$$[XY]_2 = P(XY)_2 - {}^1/_2 [P(XX)_2 + P(YY)_2] , \quad (41)$$

$$[XY]_3 = P(XY)_3 - {}^1/_2 [P(XX)_3 + P(YY)_3] . \quad (42)$$

The linear combinations (39–(42) were selected so that the evaluation of ΔH_f° requires the calculation of only the number of bonds between carbon atoms and substituents and the number of interactions between unlike substituent atoms.

Table 1. Experimental and calculated enthalpies of formation of haloethanes at 298.15 K.

* References are given only to studies which served as a basis for the recommended ΔH_f°.

** Here and henceforth the experimental values regarded as unreliable are given in brackets.

For example, the enthalpy of formation of 1,1,2-trifluoroethane can be represented by the following sum:

$$\Delta H_f^\circ(CH_2FCHF_2) = 3[CH]_1 + 3[CF]_1 + 4[HF]_2 + 5[HF]_3 .$$

Thus, in order to calculate the ΔH_f° for ten haloethanes having the composition $C_2X_{6-n}Y_n$ (where $0 \leq n \leq 6$), it is necessary to know four constants. When a third substituent (Z) is introduced, a further five constants must be added: $[CZ]_1$, $[XZ]_2$, $[XZ]_3$, $[YZ]_2$, and $[YZ]_3$, which are defined by relations analogous to Eqns.(39)–(42); having calculated them, it is possible to evaluate the enthalpies of formation of 55 haloethanes having the composition $C_2X_{6-m-n}Y_mZ_n$. When there are substituents of four types, 16 constants are necessary to estimate the ΔH_f° for 210 compounds. When a fifth substituent is introduced, the number of haloethanes increases to 630 and the number of constants rises to 25.

The available set of experimental data makes it possible to calculate the 16 constants necessary to estimate the ΔH_f° for ethanes containing H, F, Cl, and Br. The following numerical constants (in kJ mol^{-1}) were found by the method of least squares from the recommended experimental values listed in Table 1 (with the exception of ΔH_f° for C_2Cl_6 and C_2HCl_5 as well as iodoethanes): $[CH]_1 = -14.488$, $[CF]_1 = -223.266$, $[CCl]_1 = -23.897$, $[CBr]_1 = +33.523$, $[HF]_2 = +12.858$, $[HF]_3 = -3.444$, $[HCl]_2 = -3.916$, $[HCl]_3 = -3.151$, $[HBr]_2 = -6.880$, $[HBr]_3 = -3.672$, $[FCl]_2 = +2.920$, $[FCl]_3 = +1.018$, $[FBr]_2 = +7.675$, $[FBr]_3 = -1.351$, $[ClBr]_2 = -1.273$, and $[ClBr]_3 = +1.448$. These constants were used to estimate the enthalpies of formation of bromoethanes listed in Tables 1 and 2.

It is noteworthy that the recommended values of ΔH_f° for haloethanes containing only H, F, and Cl are as a rule the most reliable: the availability of numerous experimental data made it possible to select the most accurate values confirmed by several workers. In this connection, it is possible to obtain also more accurate estimates of ΔH_f° for ethanes containing H, F, and Cl. For this purpose, 17 experimental values of ΔH_f° for ethanes containing H, F, and Cl (except for C_2Cl_6 and C_2HCl_5) were treated by the method of least squares, which yielded the following nine constants (in kJ): $[CH]_1 = -13.859$, $[CF]_1 = -224.190$, $[CCl]_1 = -24.915$, $[HF]_2 = +10.786$, $[HF]_3 = -3.401$, $[HCl]_2 = -4.038$, $[HCl]_3 = -2.952$, $[FCl]_2 = +2.753$, and $[FCl]_3 = +2.444$. The enthalpies of formation of chlorofluoroethanes listed in Tables 1 and 3 were calculated with the aid of the above constants.

The nine constants for the estimation of ΔH_f° for ethanes containing H, F, and I or the 16 constants for the estimation of ΔH_f° for ethanes with H, F, Br, and I can also be found in principle from the available experimental data (Table 1). However, the number of experimental values of ΔH_f° for iodoethanes which serve as reference values for the calculation of constants referring to interactions of the iodine atom with other atoms, namely $[CI]_1$, $[HI]_2$, $[HI]_3$, $[FI]_2$, etc., is equal to the number of the required constants and such a system of equations would be ill-founded. Further accumulation of experimental data is therefore necessary for the estimation of the unknown ΔH_f° for iodoethanes.

VI. CONCLUSION

The calculated ΔH_f° for haloethanes are compared in Table 1 with the recommended experimental values. The average discrepancy between the experimental and calculated values for chlorofluoroethanes is 1.9 kJ mol^{-1}, while for the bromo-derivatives it is much higher (5.3 kJ mol^{-1}), which was to be expected in view of the lower accuracy of the experimental

data. Comparison of the experimental and calculated values (Table 1) suggests that the errors of the estimated ΔH_f° for ethanes containing H, F, and Cl (Table 3) do not exceed 5–10 kJ mol^{-1}, while those for bromine-containing ethanes (Table 2) are not more than 20–25 kJ mol^{-1}.

Table 2. Calculated enthalpies of formation of bromoethanes (kJ mol^{-1}) at 298.15 K.

The calculated ΔH_f° obey certain relations noted previously. Thus there is a sharp increase of $|\Delta H_f^\circ|$ in the series $C_2H_{6-n}F_n$, $C_2Cl_{6-n}F_n$, $C_2Br_{6-n}F_n$ as fluorine atoms accumulate at the same carbon atom, as in the case of other organofluorine compounds[3,89,131]. In the $C_2H_{6-n}Cl_n$ series there is also an increase of ΔH_f° with increase of n, but there is a maximum at $n = 4$. A similar picture has been noted for chloromethanes where the maximum value of $|\Delta H_f^\circ|$ corresponds to $CHCl_3$.[3]

On successive replacement of hydrogen by bromine in the $C_2H_{6-n}Br_n$ series, a more rapid increase of ΔH_f° is observed than would have been the case for a linear relation between ΔH_f° and n. This is also characteristic of bromomethanes[3].

Table 3. Calculated enthalpies of formation of chlorofluoroethanes (kJ mol^{-1}) at 298.15 K.

No.	Compound	$-\Delta H_f^0$ (gas)	No.	Compound	$-\Delta H_f^0$ (gas)

Further development of the thermochemistry of haloethanes involves the accumulation of reliable experimental data. Thus very few values of ΔH_f° are available at present for iodoethanes and there are no data whatever for haloethanes containing Cl and I. The number of known values of ΔH_f° for bromoethanes is clearly inadequate and the reliability of some of the available data is low. As regards the haloethanes containing H, F, and C atoms, which are of greatest importance in practice, some of the values measured previously (for example, for C_2Cl_6, and C_2HCl_5) must also be checked experimentally and the number of reliable experimental data must be increased. All these considerations will permit an improvement in the accuracy of the estimates of ΔH_f° and will give rise to more reliable thermochemical parameters for all haloethanes.

Diazotisation of Weakly Basic Aromatic and Heterocyclic Amines in Strongly Acid Media

T.I.Godovikova, O.A.Rakitin, and L.I.Khmel'nitskii

The review is devoted to the diazotisation of weakly basic aromatic amines. The methods of synthesis of diazonium salts based on these amines by non-traditional methods are examined. Data on the mechanism of the diazotisation reaction in strongly acid media are surveyed. Reactions of diazonium salts leading to the synthesis of new compounds are presented. The bibliography includes 75 references.

I. INTRODUCTION

The diazotisation reaction has been known for a long time in organic chemistry. Diazotisation in weakly acid aqueous solutions has been particularly thoroughly investigated. Diazonium salts, used to synthesise a wide variety of different classes of compounds, are obtained in this way from strongly and moderately basic amines. Thus all possible azo-products, including azo-dyes, have been synthesised by a reaction without evolution of nitrogen. Reactions with evolution of nitrogen lead to functional derivatives of aromatic compounds. The reaction involving the substitution of the diazo-group by a metal has been developed by the school of Academician A.N.Nesmeyanov.

The diazotisation of weakly basic amines, which in the present review are understood as aromatic amines containing electronegative groups in the nucleus, has been much less well studied. The diazotisation of such compounds is as a rule carried out in strongly acid media. There are a number of reasons for this. The most inert amines, such as 2,4,6-trinitroaniline[1] or 6-bromo-2,4-dinitroaniline[2], are not diazotised under other conditions. Many diazonium salts containing strongly electronegative substituents, for example, 2,4,6-trinitrobenzenediazonium[3] or 3-carboxypyrazole-4-diazonium[4] sulphates are stable only in concentrated acids, decomposing on dilution with water, frequently with substitution of the diazo-group by the hydroxy-group[4]. A high acid concentration hinders, as a result of the protonation of the amino-group, the formation of 1,3-disubstituted triazenes from the diazonium salt and the initial amine in the course of the reaction[5-8].

The range of reactions of the diazonium salts obtained from weakly basic amines is limited, which we believe to be due to the inadequate attention devoted to the diazotisation of such amines.

The necessity to analyse the literature data and to describe them systematically has arisen in view of the possibility of employing weakly basic amines in the diazotisation reaction, which can lead to the synthesis of many substances of practical value which are otherwise difficult to obtain.

II. THE MECHANISM OF DIAZOTISATION IN STRONGLY ACID MEDIA

The present understanding of the diazotisation reaction of aromatic and heterocyclic amines is based on the consideration of four stages in the process[9,10]:

$$ArNH_2 + NOX \rightleftarrows ArNH_2^{\oplus}NO + X^{\ominus}, \quad (1)$$

$$ArNH_2NO^{\oplus} \underset{+H^{\oplus}}{\overset{-H^{\oplus}}{\rightleftarrows}} ArNHNO, \quad (2)$$

$$ArNHNO \rightleftarrows Ar{-}N{=}N{-}OH, \quad (3)$$

$$Ar{-}N{=}N{-}OH \begin{cases} \xrightarrow{HX} ArN_2^{\oplus}X^{\ominus} + H_2O, \\ \longrightarrow ArN_2^{\oplus}OH^{\ominus}. \end{cases} \quad (4)$$

In diazotisation in dilute acid solutions the rate-determining stage is the first—involving reaction with the nitrosating agent NOX with formation of a nitrosoammonium ion, which, being a strong acid[11], is readily deprotonated to the nitrosoamine. It is extremely probable that both stages can occur simultaneously.

In the third stage the nitrosoamine undergoes a tautomeric rearrangement to the diazohydrate†, which instantaneously gives rise to the diazonium cation [stage (4)].

The reaction in a strongly acid medium is distinguished by a high reactivity of the diazotising agent and a high rate of nitrosation. Nitrosonium sulphate (nitrosylsulphuric acid), which consists of ionic components, is usually employed as the nitrosating agent[12]. The generation of active nitrosonium cations has been demonstrated by ultraviolet spectroscopy of solutions in sulphuric acid[13]:

$$HNO_2 + 2H_2SO_4 \rightleftarrows NO^{\oplus} + H_3O^{\oplus} + 2HSO_4^{\ominus}.$$

In terms of its activity, the nitrosonium cation exceeds all known nitrosating agents[9]:

$$NO^{\ominus} > \begin{matrix} H \\ H \end{matrix}\!\!>\!O^{\oplus}{-}NO > BrNO > ONONO > HONO.$$

Kinetic studies have shown that in a strongly acid medium the *N*-nitrosation stage does not determine the reaction rate. It has been suggested[14] that an arylamine is rapidly nitrosated to give a low equilibrium concentration of the nitrosoammonium ion, which is converted into the diazonium ion with a slow transfer and elimination of protons. These two stages determine the rate of diazotisation in a strongly acid medium.

With increase of the acidity of the medium, the equilibrium concentration of the nitrosoammonium ion and the rate of loss of a proton diminish.

† Not isolated hitherto[9].

It is noteworthy that the formation of nitrosoammonium salts is possible also in reactions with weak acids, for example, in the reaction of nitrous acid with acetic acid or acetic anhydride[15]:

$$HNO_2 + AcOY \rightleftarrows AcONO + HOY ;$$
$$AcONO \rightleftarrows NO^{\oplus}AcO^{\ominus} ;$$
$$Y=H, Ac .$$

The unexpectedly high activity of nitrosonium acetate in the diazotisation reaction has been noted[15].

III. METHODS OF SYNTHESIS OF DIAZONIUM SALTS

Weakly basic aromatic and heterocyclic amines are usually diazotised in concentrated sulphuric acid, a mixture of sulphuric and phosphoric acids, a mixture of sulphuric and acetic acids, and also in concentrated nitric acid.

1. Diazotisation in Concentrated Sulphuric Acid

Diazotisation in concentrated sulphuric acid is suitable only for weakly basic amines. Aromatic amines with a high basicity are either precipitated from sulphuric acid in the form of salts (for example, aniline[16]) or are nitrosated in the *p*-position in the ring (for example, α-naphthylamine, *m*-toluidine, and *m*-anisidine[1]).

The diazotisation is as a rule carried out in the following manner. The amine is added with stirring and cooling to a solution of nitrosylsulphuric acid in sulphuric acid, prepared by the method of Fierz-David and Blangley[17], and the reaction mixture is then allowed to stand for the required time. The diazonium salt is either precipitated with ether or is made to undergo further reactions in concentrated sulphuric acid.

The time required for the complete diazotisation depends on the structure of the amine. Table 1 presents data on the diazotisation of weakly basic amines in concentrated sulphuric acid.

Table 1. Diazotisation of amines in sulphuric acid.

p-Phenylenediamine	—	[24]**
2-Methyl-3,5-dinitroaniline	—	[25]

* Total diazotisation time.
** A bisdiazonium salt is formed.

The rate of diazotisation can be increased by diluting sulphuric acid with water[1]. However, this procedure is limited by the solubility of amines[21] and also by the decomposition of certain diazonium salts, for example 2,4,6-trinitrobenzenediazonium sulphate[3].

It has been noted[26] that the diazotisation of nitroanilines in concentrated sulphuric acid requires certain precautions: the reaction mixtures are very explosive in the case of dinitroanilines.

2. Diazotisation in a Mixture of Sulphuric and Acetic Acids

Weakly basic amines are diazotised successfully and at a high rate in a mixture of sulphuric and acetic acids. There are two methods, developed by Hodgson and co-workers, whereby the reaction can be carried out, depending on the solubility of the amine in acetic acid.

A. When the amine is soluble in acetic acid, its solution is added to the sulphuric acid solution of nitrosylsulphuric acid and care is taken to avoid the formation of a precipitate of the amine sulphate[27,28]. For example, *o*-phenylenediamine[27] and 4-nitro-1-naphthylamine[29] are diazotised in this way.

B. If the amine is sparingly soluble in acetic acid, it is recommended that it be initially dissolved in the sulphuric acid solution of nitrosylsulphuric acid and that an approximately equal amount of acetic acid is then added, as in the diazotisation of 1,6-dinitro-2-naphthylamine[30] or *p*-aminobenzaldehyde[31].

A list of weakly basic aromatic and heterocyclic amines, diazotised by the first and second methods in a mixture of sulphuric and acetic acids, is given in Table 2.

The method of diazotisation in acetic acid is used quite widely; it makes it possible to diazotise successfully not only weakly basic but also strongly basic aromatic and heterocyclic amines, provided that they do not decompose in sulphuric acid.

Table 2. Diazotisation of amines in a mixture of sulphuric and acetic acids.

4-t-Butyl-1-nitroaniline	A	[40]

Diazonium sulphates can be isolated in the solid state by precipitation with ether or by other suitable solvents[41-43].

The relatively high freezing point of acetic acid, even in solution in sulphuric acid, must be regarded as a disadvantage of this method. If it is necessary to carry out the reaction at a low temperature, a mixture of acetic and propionic acid is used, for example, in the diazotisation of ethyl 5-aminothiophen-2-carboxylate[44].

3. Diazotisation in a Mixture of Sulphuric and Phosphoric Acid

The method of diazotisation in a mixture of sulphuric and phosphoric acids was developed by Schoutissen for weakly basic aromatic amines and diamines[16,31,35,45]. Diazotisation in a mixture of sulphuric and phosphoric acid takes place much more rapidly than in sulphuric acid alone. As in a mixture of sulphuric and acetic acids, the reaction is carried out by two methods: (1) a solution of the amine in sulphuric acid is added to a solution of nitrosylsulphuric acid in sulphuric acid; (2) phosphoric acid is added to a solution of the amine and nitrosylsulphuric acid in sulphuric acid.

Table 3 gives a list of the weakly basic aromatic and heterocyclic amines which have been diazotised by this method. The advantages of the method include the possibility of working at low temperatures.

Table 3. Diazotisation of amines in a mixture of sulphuric and phosphoric acids.

** Bisdiazonium salts are formed.

4. Diazotisation in Concentrated Nitric Acid

It has been shown[50,51] that certain amines can be smoothly diazotised in concentrated nitric acid. The reaction takes place much faster than in concentrated sulphuric acid and is actually faster than in mixtures of sulphuric acid with acetic or phosphoric acid. The diazotisation frequently reaches completion after several minutes, which can be explained by the high solvent power of concentrated nitric acid.

Despite these advantages, the method is used rarely, because there is a risk that part of the amine is nitrated before being diazotised[52,53].

The reaction in nitric acid is carried out using different diazotising agents. Thus 2,6-nitro-4-toluidine is diazotised by nitrous oxides[50]; 4-amino-3,5-dibromobenzoic acid is diazotised with potassium nitrite[54]; 3,4,5-tri-iodoaniline is diazotised with sodium nitrite[55]; 2-methyl-3,5-dinitroaniline[25] and 13-aminobenzanthrone[56] are diazotised with nitrosylsulphuric acid formed when potassium thiosulphate is introduced into nitric acid. It is noteworthy that the diazotised amine is nitrated very slowly[56] owing to the powerful negative mesomeric effect of the diazo-group[57].

5. Diazotisation in Organic Solvents

This method is used fairly rarely for weakly basic amines. Thus 6-bromo-2,4-dinitroaniline[2] is diazotised by a mixture of nitrosylsulphuric and formic acids in tetrahydrothiophen 1,1-dioxide, while 2,4,6-trinitroaniline[16] is diazotised by a mixture of nitrosylsulphuric and phosphoric acids in nitrobenzene.

It has been reported[58] that 2,4,6-trinitroaniline can be smoothly diazotised by nitrosylsulphuric acid in a mixture of pyridine and sulphuric acid and the product of the azo-coupling of the diazonium salt with β-naphthol was actually isolated. Later, when an attempt was made to confirm this investigation, it was established[59] that diazotisation does not take place in this instance and that the so-called "product of the azo-coupling reaction" is an equimolar adduct of β-naphthol and picramide.

The attempt to obtain diazonium salts from 2,4,6-trichloro- and 2,4,6-tribromoanilines with the aid of nitrosylsulphuric acid in ethanol[18] should also be mentioned: after the decomposition of the reaction mass, only the corresponding diaryltriazenes were isolated, which indicates a low rate of diazotisation.

The question of the limits of the applicability of the reaction is obscure and the possibility of the diazotisation of weakly basic amines in organic solvents must be elucidated in each individual instance.

Thus weakly basic aromatic and heterocyclic amines can be most conveniently diazotised by nitrosylsulphuric acid in a mixture of concentrated sulphuric and phosphoric ($d = 1.7$) or acetic acids. Phosphoric acid mixtures make it possible to carry out the reaction at a low temperature. Other diazotising mixtures are rarely employed.

IV. REACTIONS OF DIAZONIUM SALTS

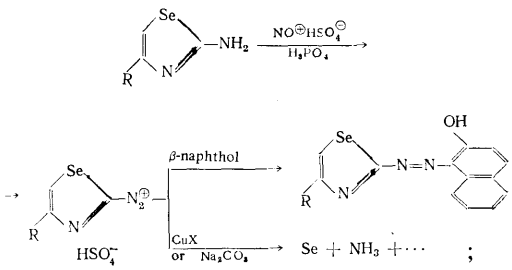
The reactions of diazonium ions have been investigated for a very long time. Various reactions of diazonium salts, leading to compounds which cannot be obtained by other methods, are known.

There exist several classifications of the reactions of diazonium ions. The most complete modern classification was devised by Zollinger[60] in 1973.

The present review deals only with those reactions which are known for diazonium salts obtained from weakly basic aromatic and heterocyclic amines by diazotisation in strongly acid media. They are frequently divided into three types:

1. Reactions involving addition to the β-atom of the diazo-group (azo-coupling with electron-donating π-electron systems, the formation of triazenes and azido-derivatives);
2. reactions with heterolytic dissociation of the bond between the ring carbon atom and a nitrogen atom of the diazo-group (hydrolysis);
3. reactions with homolytic dissociation of the same bond (substitution by halogen-, nitro-, and cyano-groups and reduction of diazonium salts).

1. Azo-Coupling with π-Electron Systems

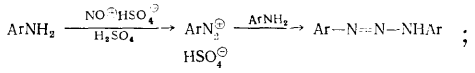


One of the most characteristic reactions of diazonium salts is that of azo-coupling. The azo-coupling reaction is usually carried out in nearly neutral media, because in an acid medium the amines and the phenols employed as the azo-components are protonated and to a large extent lose their activity.

The reaction is accelerated when the arenediazonium cation contains one or several electron-accepting groups. Thus the 2,4,6-trinitrobenzenediazonium ion reacts even with a relatively inactive azo-component such as mesitylene[61].

When the diazonium salts are difficult or impossible to obtain in the solid state or in an aqueous solution of moderate acidity, their azo-coupling is carried out in strongly acid

solutions by adding the azo-component in the solid state or in solution in pyridine[16] or methylene chloride[62]. β-Naphthol or phenol are usually employed as the azo-component. The precipitate of the azo-coupling product is usually bright red.

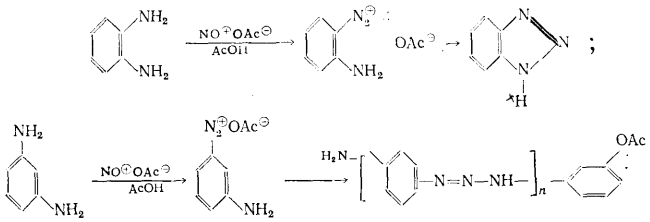


Among the chemical methods, this reaction constitutes the most reliable procedure for the detection of diazonium salts. In many cases the presence of diazonium salts is tested by the azo-coupling reaction. Thus the formation of diazonium salts in the diazotisation of 2-amino-1,3-selenazoles by a mixture of nitrosylsulphuric and phosphoric acids was confirmed solely by the reaction with β-naphthol, while the interaction with other reagents leads only to decomposition products[43]:

R=H, Ph .

2. The Formation of Triazenes

Triazenes are usually formed on diazotisation of amines (particularly weakly basic amines) in a weakly acid medium. The use of strong acids, prevents this reaction. If the diazotisation has not been carried out to completion or additional amine is introduced into the reaction mass which has fully reacted, there is a possibility of the formation of 1,3-disubstituted triazenes when the strongly acid solutions are poured into water[18]:



$ArNH_2$ = 2,4,6-trichloro- or 2,4,6-tribromo-aniline;

$ArNH_2$ = 1,2,4,5-tetrachloro-, 2,3,4,6-tetrachloro-, 2,4,5-trichloro-aniline, etc.

It is particularly important to take this reaction into account in the decomposition of monodiazonium salts obtained from diamines. This entails the formation of both cyclic (from *o*-phenylenediamines) and linear triazenes[7,63]:

3. The Formation of Azido-Derivatives

Diazonium salts interact with ammonia, hydrazine and many of their derivatives, such as hydroxylamine, arenesulphonamides, phenylhydrazine, and aromatic acid hydrazides with formation of azides.

However, these methods are applicable to weakly basic or neutral solutions of diazonium salts, because in strong acids ammonia and hydrazine derivatives are protonated and do not react with diazonium cations.

For weakly basic amines, the most common reaction of diazonium salts is that with hydrazoic acid and its salt. The yields of azidoarenes are high, frequently nearly quantitative:

For example, 1-azido-4-trifluoromethyl-2-nitrobenzene, 1-azido-4-formyl-2-nitrobenzene, 1-azido-4-fluoro-2-nitrobenzene[19], and 1-azido-4,6-dibromo-2-nitrobenzene[32] are obtained in this way.

In the case of 2,2′-diaminoazobenzene and 2,4,6-triaminomesitylene it is possible to introduce two[64] or three[65] azido-groups respectively.

4. Substitution by the Hydroxy-Group

Virtually all diazonium salts react with water, exchanging the diazo-group for a hydroxyl. For diazonium salts obtained from weakly basic amines, this reaction can actually interfere with its normal reactions and can compete with the reaction involving substitution under the influence of other nucleophiles[3,4].

Strongly acid solutions of diazonium salts obtained from weakly basic amines are decomposed by being poured into water, as in the case of 3-carboxypyrazole-2-diazonium sulphate[4], or into a solution of copper sulphate, as in the case of 2,3,4,5-tetrachlorobenzenediazonium sulphate[22]. When necessary, dilute solutions of diazonium salts are refluxed. For example, *p*-hydroxybenzaldehyde[31] and 2- and 4-hydroxyquinolines[23] are obtained in this way.

5. Substitution by the Chloro-, Bromo-, Nitro-, and Cyano-Groups (The Sandmeyer Reaction)

When a solution of a diazonium salt is treated with an appropriate nucleophile X^- (X = Cl, Br, NO_2, or CN) in the presence of a copper catalyst, the diazo-group is replaced by the chloro-, bromo-, cyano-, or nitro-group. The catalyst can consist of metallic copper, copper(I) oxide, copper(II) oxide, or copper(II) sulphate as well as copper(I) salts (the chloride, bromide, and cyanide).

The Sandmeyer reaction is carried out as a rule in a neutral or weakly acid medium. The diazonium salts obtained from weakly basic amines by diazotisation in strongly acid media are also decomposed by being poured into a solution of the corresponding nucleophile in the presence of the copper catalyst.

The substitution by chlorine (or bromine) is usually carried out by adding a solution of copper(I) chloride (bromide) in hydrochloric (hydrobromic) acid to a solution of the diazonium salt.

Nitro-compounds are best obtained with preliminary precipitation of the diazonium salt from strongly acid solutions with ether.

The reaction involving the substitution of the diazo-group by the cyano-group is rarely used. It is usually carried out in a rigorously neutral medium by adding a solution of an alkali metal cyanide and copper sulphate (copper monocyanide is sometimes used). For example, *o*-, *m*-, and *p*-nitroanilines[66], 3-aminopyridine, and 5-amino-2-methylpyridine[67] are diazotised in this way.

Data for the Sandmeyer reaction of hydrochloric acid solutions of diazonium salts are presented in Table 4.

The Sandmeyer reaction does not occur when the competing hydrolytic reaction proceeds at a higher rate, as for 2-carboxypyrazolediazonium sulphate[4], or when the heterocycle is ruptured[46].

Table 4. The Sandmeyer reaction for weakly basic aromatic and heterocyclic amines.

Amine	Diazotising mixture	Substituting anion	Decompn. mixture	Refs.
2,3-Dinitroaniline	$NOHSO_4+H_3PO_4$	$Cl^{\ominus}$	HCl+CuCl	[47]

6. Substitution by Iodine

The substitution of the diazo-group by iodine does not require the presence of copper catalysts. It takes place when strongly acid solutions of diazonium salts are poured into a solution of potassium iodide. A list of weakly basic amines which have been made to undergo this reaction is presented in Table 5.

7. Substitution by Hydrogen (Reduction)

Diazonium salts can be reduced with the aid of many reagents. The most common are alcohol and hypophosphorous acid. (In relation to the initial amine, this reaction is referred to as deamination.)

Diazonium salts obtained from weakly basic amines such as 2,4-dinitrotoluidine[50] and 5-t-butyl-2-nitroaniline[40] are usually reduced by heating with ethanol. Copper catalysts are sometimes used, for example, copper(II) oxide for *o*-, *m*-, and *p*-nitroanilines, 2,4-dinitronaphthylamine, and 2,5-dichloroaniline[33] or copper sulphate for 2,6-dibromo-4-carboxyaniline[54].

2,4,6-Trinitroaniline can be conveniently deaminated with hypophosphorous acid[75].

Summarising the above discussion, one may say that the diazonium salts obtained from weakly basic amines in strongly acid media are capable of undergoing various reactions both with and without the evolution of molecular nitrogen. The reactions without the evolution of a nitrogen molecule (azo-coupling and the formation of triazenes) as a rule take place readily. The methods for the substitution of the diazo-group by various functional groups have been developed less fully owing to the low stability of the diazonium salts in aqueous media.

Three-membered Organophosphorus Heterocycles

Yu.G.Gololobov, N.I.Gusar', and A.S.Tarasevich

The methods of synthesis, structural characteristics, and properties of compounds with three-membered rings and containing at least one phosphorus atom and one carbon atom, including bicyclic and tricyclic compounds, are examined. The bibliography includes 76 references.

I. INTRODUCTION

Three-membered rings occupy a special position in theoretical and applied organic chemistry as a consequence of characteristic features of orbital hybridisation, the high angular strain, and the consequent ease of ring opening or expansion. The introduction of a heteroatom into a three-membered ring lowers the molecular symmetry and results in the non-equivalence of the angles and bonds, expressed to the greatest extent in the case of a ring containing a phosphorus atom.

It is noteworthy that compounds with three-membered phosphorus-containing heterocycles (phosphirans) have been studied comparatively little, since they have been obtained only very recently. In the monograph of Kirby and Warren[1], the English edition of which was published in 1967, it is still stated that "stable three-membered rings containing phosphorus are unknown except for the elemental phosphorus P_4. However, they can arise as intermediates or in transiton states...".[2,3] The intermediate formation of unstable compounds with a three-membered phosphorus-containing ring was invoked to account for the mechanism of formation of reaction products and has also been postulated in a number of other studies[4-10], while the synthesis of relatively stable phosphirans and element-substituted phosphirans as well as the study of their properties have been described as a rule only during the last decade.

Baudler's review[11], devoted to compounds with three-membered rings consisting solely of phosphorus atoms, or of two phosphorus atoms and a single carbon, silicon, germanium, arsenic, boron, or sulphur atom, or of two arsenic atoms and a single phosphorus atom, i.e. in most cases referring to inorganic rings, was published in 1980. The present review deals solely with three-membered phosphorus-containing rings with at least one carbon atom, so that the data presented constitute an organic supplement to Baudler's review[11].

Data on the synthesis and NMR spectra of phosphirans containing only phosphorus and carbon atoms are also considered in Quin's monograph[12] devoted to P-C heterocycles.

II. SYNTHESIS

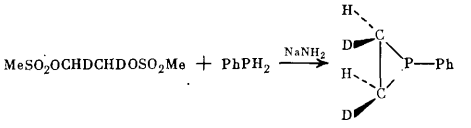
1. Rings with Tetracoordinate Phosphorus

The simplest compound, the unsubstituted phosphiran, was the first to be synthesised among compounds containing a three-membered heterocycle with a phosphorus atom and a P-C bond. In their study of the reaction of α,ω-dihalogenoalkanes with alkali metal phosphides in liquid ammonia, which was undertaken with the aim of synthesising α,ω-diphosphinoalkanes, Wagner and co-workers[13,14] unexpectedly observed that, when 1,2-dichloroethane is used, the product is phosphiran or 1-methylphosphiran. According to Wagner et al.[14], this course of the reaction can be explained by the fact that the hydrogen linked to the phosphorus atom in the intermediate formed on substitution of the first chlorine atom in dichloroethane readily exchanges for the metal on treatment with sodium phosphide or methylphosphide, which then leads to cyclic products:

$$ClCH_2CH_2Cl \xrightarrow[-Cl^-]{RPH^-} ClCH_2CH_2PHR \xrightarrow[-RPH_2]{RPH^-} \rightarrow ClCH_2CH_2\bar{P}R \xrightarrow[-Cl^-]{} \underset{\diagdown P \diagup}{CH_2—CH_2} \; ;$$

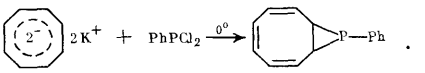
$$\underset{R}{|}$$

R=H, Me .



Wagner's method proved to be of general validity for the synthesis of C- and P-substituted phosphirans. The use of other 1,2-dichloroalkanes and monosubstituted sodium phosphides in this reaction made it possible to obtain a series of 1-alkyl(aryl)- and 2-alkyl-phosphirans in yields of 25-60%.[15] According to ^1H NMR data, 2-alkylphosphirans are then obtained in the form of a mixture of *cis*- and *trans*-isomers. In order to investigate the properties of phosphirans and to establish their structural characteristics (see Section III), various isotope-substituted phosphirans were synthesised. Thus the interaction of sodium dideuterophosphide with dichloroethane in liquid trideuteroammonia[16] or hexamethylphosphoramide[15,17] led to 1-deuterophosphiran; 2-deuterophosphiran[15,17], 2,2,3,3-tetradeuterophosphiran[16] and [^{13}C]phosphiran[15,17] were synthesised analogously by the reaction of monodeuterodichloroethane, perdeuterodichloroethane, and [^{13}C]dichloroethane respectively with sodium phosphide in liquid ammonia. The phosphirans were isolated by fractional vacuum condensation. The structures of the products were determined from infrared spectroscopic, ^1H and ^{31}P NMR, and mass-spectrometric data, and also from ebullioscopic determinations of their molecular weights.

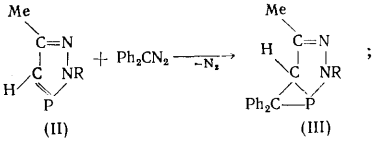
An unusual version of the reaction described above involves the interaction of 2-bromoethyldibromophosphine with lithium tetrahydroaluminate in the diethyl ether of diethylene glycol. Evidently the initial products in this case are the corresponding phosphine, which then cyclises intramolecularly to a three-membered ring[14]. Apart from the phosphiran, ethylphosphine, phosphine, and ethylene are formed under these conditions:



$$BrCH_2CH_2PBr_2 \xrightarrow{LiAlH_4} \underset{\diagdown P \diagup}{CH_2—CH_2} + EtPH_2 + C_2H_4 + PH_3 \; .$$

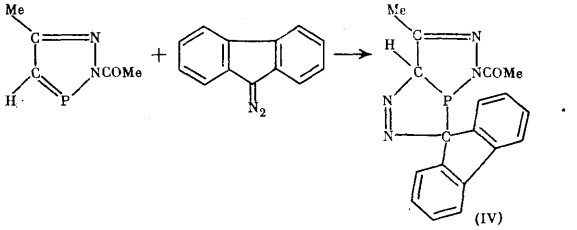
$$\underset{H}{|}$$

The cyclisation of 1,2-disubstituted ethanes can take place not only as a result of the elimination of the halogen from the carbon atom, the methanesulphonyloxy-substituent also being capable of functioning as the leaving group. For example, in the presence of sodium amide, phenylphosphine interacts with 1,2-dideutero-1,2-bis(methanesulphonyloxy)ethane to form *cis*-2,3-dideutero-1-phenylphosphiran[18]:



When readily eliminated halogen atoms are present at the phosphorus atom, the phosphorus compound can be involved in the synthesis of phosphirans as an electrophile. Thus 9-phenyl-9-phosphabicyclo[6.1.0]nona-2,4,6-triene (I) has been obtained by the condensation of the dipotassium salt of cyclo-octatetraene with dichlorophenylphosphine under mild conditions[19,20]:

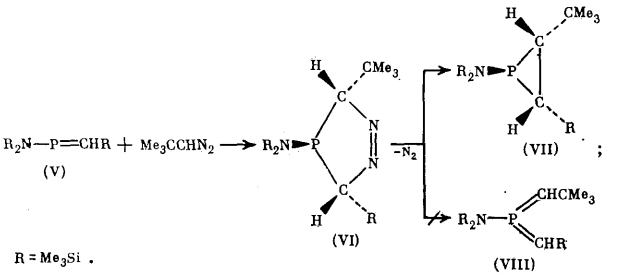
(I)



Arbuzov and co-workers recently described a method for the formation of the phosphiran ring with a tervalent phosphorus atom, which consists in the addition of diphenyldiazomethane to the P=C bond in compounds with dicoordinate phosphorus[21,22]. In this case the phosphorus atom is shared by two rings. The products are crystalline substances (III) with high melting points and some of the highest thermal stabilities among compounds with a phosphiran ring. Their structure has been confirmed by infrared spectroscopy and ^{1}H and ^{31}P NMR, by determining their molecular weights, and by a series of reactions:

(II) (III)

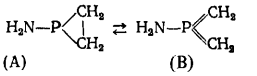
R=Ph, MeCO .



Despite the conditions being varied, products containing the phosphiran ring are not formed in the analogous interaction of the diazaphosphole (II, R=MeCO) with 9-diazofluorene. However, when the reaction is carried out in pentane or hexane, the adduct (IV) is produced in almost quantitative yield, its formation suggesting that diazoalkanes add to the P=C bond in diazaphospholes (II) via the 1,3-cycloaddition mechanism and not via a carbene[23]:

(IV)

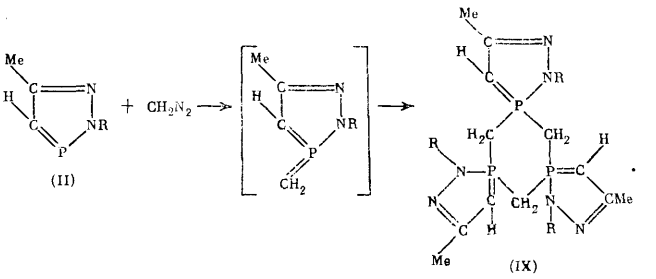
The interaction of 2,2-dimethyldiazopropane with a noncyclic derivative of dicoordinate phosphorus (V) also leads to a stable 1,3-cycloaddition product, namely 3-trimethylsilyl-4-[bis(trimethylsilyl)amino]-5-t-butyl-1,2,4λ^3-diazaphospholine (VI). However, on heating *in vacuo* at temperatures between 80° and 120 °C, the diazaphospholine (VI) splits off nitrogen and gives rise to the corresponding phosphiran (VIII), whose configuration has been postulated on the basis of spectroscopic data.



The possibility of the formation of aminodimethylenephosphine (VIII) has also been postulated in the decomposition of the diazaphospholine (VI).

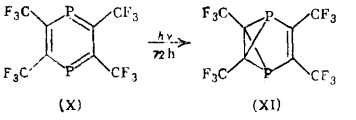
(V) (VI) (VII) (VIII)

R = Me_3Si .



However, calculation of the energy surface for the valence isomerisation of the model structure

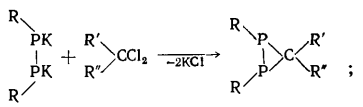
(A) (B)



by the MINDO/3 method showed that the cyclic form (A) is more favourable by 22 kcal $mole^{-1}$ than the dimethylenephosphine form (B) and that the A⇌B transition has a comparatively high energy barrier[24].

A similar dimethylenephosphino-derivative, analogous to compound (VIII), is apparently formed as an intermediate in the reaction of 1,2,3-diazaphospholes with diazomethane, since the products are not phosphirans but three-dimensional compounds (IX):

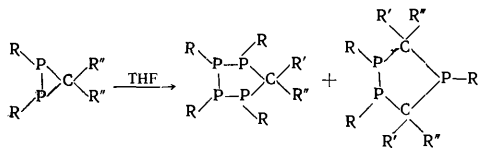
(II) (IX)



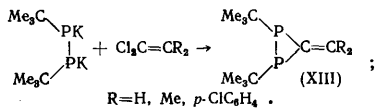
When 2,3,5,6-tetrakis(trifluoromethyl)1,4-diphosphabenzene (X) is illuminated for a long time, the product is a tricyclic compound containing two phosphiran rings with tervalent phosphorus—2,3,5,6-tetrakis(trifluoromethyl)-1,4-diphosphatricyclo[3.1.0.$0^{4,6}$]hex-2-ene (XI). This compound is the first representative of the analogues of benzvalene with heteroatoms in the ring[25-27]:

(X) (XI)

Three-membered rings with two phosphorus atoms, namely diphosphirans (XII), were obtained for the first time by the reaction of the dipotassium salts of symmetrical dialkyl(aryl)-diphosphines with geminal dichloroalkanes in pentane or toluene at −30 °C.[11,28,29]. Their formation reaction can be regarded as an unusual version of the Wagner synthesis of



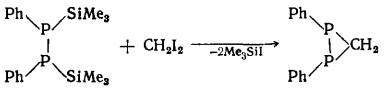
phosphirans, since in this case too the halogen at the saturated carbon atom undergoes nucleophilic substitution by the phosphide anion:



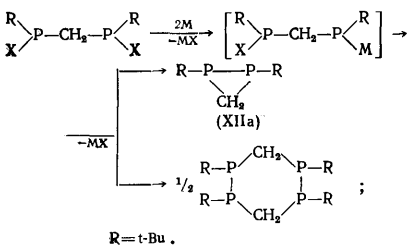
(XII)

R = t-Bu, R′, R″=H, Me; R=Ph, R′, R″=Me .

It is of interest that, when this reaction is carried out in tetrahydrofuran (THF), five-membered and not three-membered phosphorus-containing heterocycles are produced[29], which has been explained by a rapid rearrangement of the diphosphirans in the more polar solvent[11]:



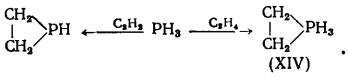
Diphosphirans (XIII) having an exocyclic C=C bond have been obtained by the reaction of 1,2-di-t-butyl-1,2-dipotassio-diphosphine with 1,1-dichloro-olefines as well as geminal dichloroalkanes[11]:



(XIII)

R=H, Me, *p*-ClC$_6$H$_4$.

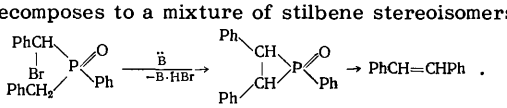
The reaction of 1,2-bis(trimethylsilyl)-1,2-diphenyldiphopshine with di-iodomethane in THF at −30°C apparently also leads to 1,2-diphenyldiphosphiran[28], since a signal in the appropriate region appears in the ^{31}P NMR spectrum:



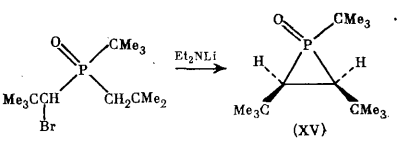
1,2-Di-t-butyldiphosphiran (XIIa) has also been obtained by the intramolecular 1,3-cyclisation of the corresponding *P,P*-dihalogenodiphosphinomethane by treatment with a liquid potassium–sodium alloy at temperatures between 0° and 10 °C (yet another version of the Wagner reaction). Diphosphiran is then obtained in the form of a mixture with a dimer—1,2,-4,5-tetra-t-butyl-1,2,4,5-tetraphosphacyclohexane—and constitutes 80% of the mixture. The diphosphiran could not be detected in the analogous reaction of *P,P*-dihalogenodiphosphinomethane with isopropyl groups at the phosphorus atoms—the corresponding tetraphosphacyclohexane is formed immediately[30]:

R=t-Bu .

Thus the most general methods of synthesis of phosphirans with tervalent phosphorus are different versions of the interactions of alkali metal phosphides with compounds containing two readily removed groups (a halogen or the methanesulphonyloxy-group) in the 1,2- or 1,1-positions and also the addition of diazoalkanes to compounds of dicoordinate phosphorus, which has also been used to synthesise phosphirans with tetracoordinate phosphorus and with a nitrogen atom in the phosphiran ring (see below). Other syntheses known at present have been described only in relation to individual examples. The theoretical possibility of yet another method of synthesis of unsubstituted phosphirans as well as the synthesis of a phosphiran with a pentacoordinate phosphorus atom [structure (XIV)] as a result of the addition of phosphine to acetylene and ethylene respectively has been predicted on the basis of the analysis of Woodward–Hoffman correlation diagrams:



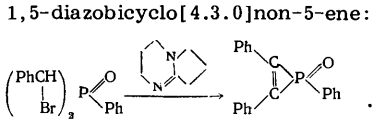
(XIV)



The authors believe that the first reaction can occur in the ground state, while the second takes place on photochemical oxidation of the molecules and also under the conditions of acid and base catalysis. Substitution of the hydrogen atoms in the phosphine by more electronegative groups should impair the energetics of the formation of the phosphiran ring[31]. However, hitherto this synthesis has not been realised.

2. Rings with Tetracoordinate Phosphorus

Only one method of synthesis of phosphiran oxides has been described so far. It involves the 1,3-cyclisation under the influence of a base of acyclic oxides containing a halogen atom in the α-position in one of the substituents at the phosphorus atom and a mobile hydrogen atom in the α-position in the other substituent. Thus 1,3-elimination of hydrogen halide from α-bromobenzylphenylbenzylphosphine oxide results in the formation of 1,2,3-triphenylphosphiran oxide, which decomposes to a mixture of stilbene stereoisomers[32]:



A stable phosphiran oxide (XV) with the *cis*-configuration and containing three t-butyl groups has been obtained recently as a result of an analogous cyclisation[33,34]. The configuration of the product has been proposed on the basis of ^{1}H and ^{13}C NMR data:

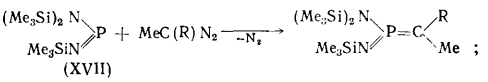
(XV)

It has been reported[32,35] that 1,2,3-triphenylphosphiran oxide (XVI) has been obtained as a result of the analogous cyclisation of bis(α-bromobenzyl)phenylphosphine oxide on treatment with 1,5-diazobicyclo[4.3.0]non-5-ene:

(XVI)

However, the formation of this phosphiran oxide has been refuted[36] on the basis of the physical and spectroscopic characteristics of the product obtained on repeating the above reaction, although one should note that the infrared and mass spectra of the compounds synthesised by the two groups of investigators are different.

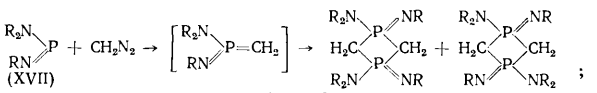
Nevertheless the possibility, in principle, of the existence of compounds with a phosphiren ring forming an aromatic system as a consequence of delocalisation of the $p\pi$ electrons of the double bonds via $p_\pi - d_\pi$ conjugation, has been considered in a study[37] whose authors concluded that fairly stable phosphirenium salts and phosphiren oxides (analogues of cyclopropenone) exist:



Like the analogous compounds with the C = P–N group (see above), compounds of dicoordinate phosphorus with the N = P–N group are capable of reacting with diazoalkanes although via a somewhat different mechanism. For example, the addition of diazomethane to bis(trimethylsilyl)aminotrimethylsilyliminophosphine (XVII) leads to 1-bis(trimethylsilyl)amino-1-trimethylsilyliminophosphiran (XVII)—a representative of phosphirans with an exocyclic phosphazo-group[38]:

(XVII) (XVIII) ;

R = Me_3Si .

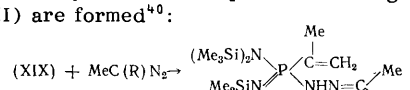


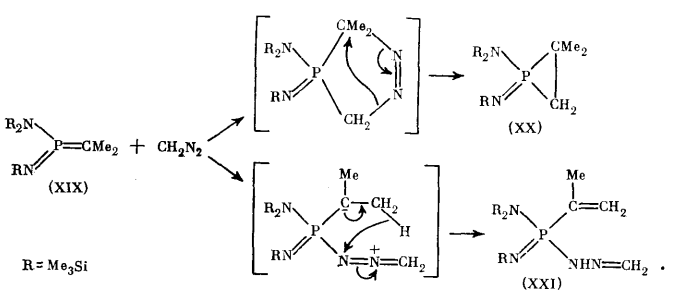
The intermediate formation of an ylide with a tricoordinate phosphorus atom is confirmed by the fact that the reaction of the aminoiminophosphine (XVII) with other diazoalkanes stops at the ylide stage. The ylides are stable for steric reasons, as suggested by Niecke and Wildredt[39]:

(XVII)

R = Me, Et, iso-Pr, t-Bu .

In addition, when the conditions of the reaction between the phosphine (XVII) and diazomethane are modified somewhat, a mixture of isomeric diphosphetans, which are cyclic dimers of the intermediate phosphazoylide, is formed[40]:



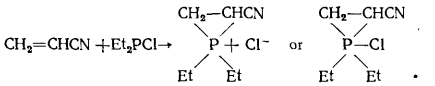


(XVII)

R = Me_3Si .

When diazomethane adds to the iminomethylenephosphine (XIX), the product is, as in the formation reaction of compound (XVIII), a compound (XX) with a phosphiran ring together with an acyclic compound (XXI) (in proportions of 7 : 3).[40]

The addition of α-alkyldiazoethanes to the iminoethylenephosphine (XIX) takes place, as in the case of compound (XVII), without cyclisation and products analogous to compound (XXI) are formed[40]:



(XIX) (XX) (XXI)

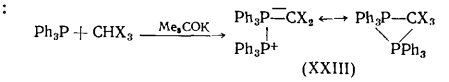
R = Me_3Si .

3. Rings with Pentacoordinate Phosphorus

When chlorodiethylphosphine was made to add to acrylonitrile, a crystalline very hygroscopic substance was obtained. On the basis of infrared and ^1H NMR spectra as well as the study of its hydrolysis products, it was assumed to have the structure of 2-cyano-1,1-diethylphosphiranium or a derivative of pentacoordinate phosphorus—1-chloro-2-cyano-1,1-diethylphosphiran (XXII)[41]:

(XXII)

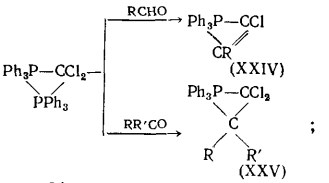
The formation of this compound is the only example of the 1,2-addition of a chlorophosphine to an activated olefinic bond. However, one should note that the interaction of chlorodiethylphosphine with acrylic and methacrylic acids and their chlorides also results in the formation of hygroscopic crystalline adducts. Whether these compounds are products of the 1,2-addition of the phosphine to the C = O bond is unknown, since their structure has not been investigated[42].



Even in the presence of antimony pentachloride, chlorodiphenylphosphine does not react with acrylonitrile[41].

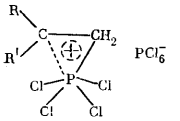
The intermediate formation of compounds with pentacoordinate phosphorus containing a phosphiran ring is postulated in the reactions of 1-phenylphosphiran with 3,3,4-trimethyldioxetan and 3,4-bis(trifluoromethyl)dithietan[18,43] (see Section IV).

The products of the reactions of triorganylphosphines with ethoxyacetylene may contain a phosphiren ring with pentacoordinate phosphorus[7]:



When triphenylphosphine reacted with chloroform or bromoform and potassium t-butoxide in proportions of 2 : 1 : 1, high-melting products (XXIII), having the structure of diphosphirans or betaines (XXIII), were obtained. The reaction of the chloro-compound (XXIII, X = Cl) with a series of aldehydes is accompanied by the elimination of a hydrogen chloride molecule and leads to products to which the structure of phosphirens (XXIV) was attributed. In the reactions involving benzophenone and 2-methoxybenzaldehyde, compounds (XXV) with a saturated phosphiran ring are obtained. Their structure has been postulated on the grounds that their infrared spectra contain absorption bands at frequencies characteristic of the three-membered phosphorus-containing ring[44–46]:

(XXIII)

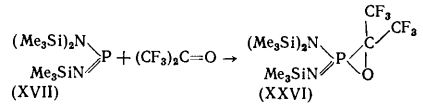


R = Ph, Pr, 2-MeC_6H_4, 2-HOC_6H_4, 2-$NO_3C_6H_4$, PhCH = CH

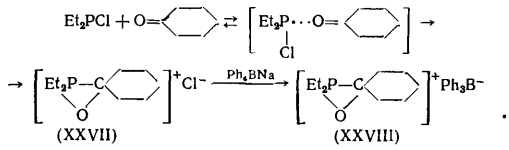
(XXIV) (XXV)

R, R′ = Ph; R = H, R′ = 2-$MeOC_6H_4$.

The structure of a three-centre epiphosphiran cation[47] of the type

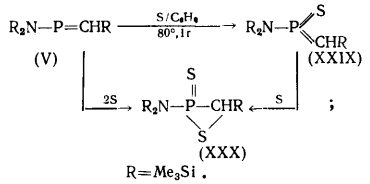


has been attributed to the transition state in the reactions of alkenes with phosphorus pentachloride.

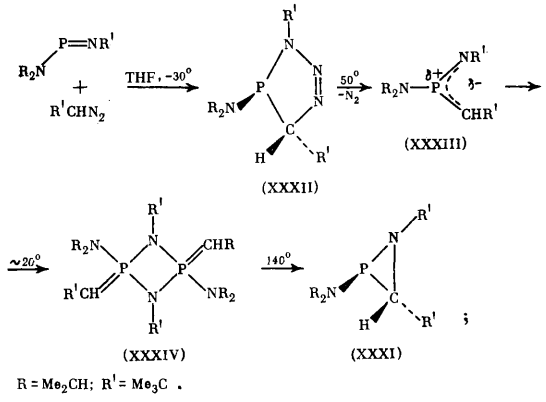


4. Element-substituted Phosphirans

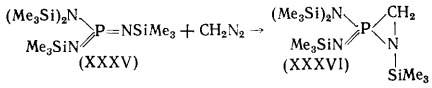
Element-substituted phosphirans, whose three-membered ring contains, apart from phosphorus and carbon atoms, also oxygen, sulphur, or nitrogen atoms, are very few. The possibility of the intermediate formation of unstable compounds with an oxaphosphiran ring has been postulated in considering the mechanisms of reactions important in the chemistry of organophosphorus compounds such as that of trialkyl phosphites with α-diketones[8] or α-halogenoketones[9].



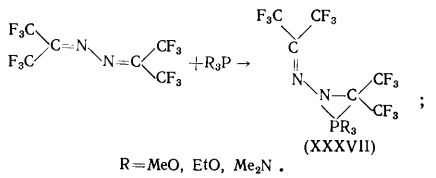
The first stable oxaphosphiran derivative (XXVI) was obtained only recently[48] as a result of the addition of hexafluoroacetone to the aminoiminophosphine (XVII). As in the reaction with diazomethane, only the phosphorus atom of (XVII) is involved in the reaction with hexafluoroacetone:



A crystalline compound, which is unstable in air and has the structure of a substituted oxaphosphiranium salt (XXVII), was isolated from the mixture of the products of the reaction of chlorodiethylphosphine with cyclohexanone. The more stable oxaphosphiranium salt (XXVIII) was obtained in the exchange of the anion of the chloride (XXVII)[49]:



When an equivalent amount of sulphur adds to the aminomethylenephosphine (V), the corresponding sulphide (XXIX) is obtained together with a small amount of the thiaphosphiran (XXX), characterised by hydrogen, phosphorus, carbon, and silicon NMR data; the preferential formation of the sulphide (XXIX) shows that the thiaphosphiran ring is closed as the result of the addition of sulphur to the P=C bond of the sulphide and not the initial phosphine (V). The phosphine (V) reacts with two equivalents of sulphur to give a quantitative yield of the thiaphosphiran (XXX), which is the first representative of this heterocyclic system[50]:



The interaction of t-butyliminodi-isopropylaminophosphine with 2,2-dimethyldiazopropane leads ultimately to 1,3-di-t-butyl-2-di-isopropylaminoazaphosphiridine (XXXI). The formation of compound (XXXI) completes the chain of transformations of the intermediates having structures (XXXII), (XXXIII), and (XXXIV), which were isolated in a pure state and characterised by ^{1}H, ^{13}C, and ^{31}P NMR data[51]:

In contrast to the P=N bond of the aminoiminophosphine (XVII) containing dicoordinate phosphorus, the analogous bond in the aminodi-iminophosphine (XXXV), containing tricoordinate phosphorus, is capable of the 1,2-addition reaction with diazomethane resulting in the formation of the azaphosphiridine (XXXVI), which is stable in the absence of moisture almost indefinitely[38]:

The addition of phosphorous acid derivatives to hexafluoroacetone azine takes place at only one C=N bond with formation of thermally stable azaphosphiridines (XXXVII) with a pentacoordinate phosphorus atom. Their structure has been postulated on the basis of infrared spectroscopic, ^{19}F and ^{13}C NMR and mass-spectrometric data[52]:

III. STRUCTURE AND PHYSICAL PROPERTIES

The structure of compounds with a three-membered ring containing phosphorus has been of evident interest to chemists and the determination of the structural parameters of such compounds was therefore begun almost immediately after the synthesis of phosphiran and its first homologues.

The microwave spectra of phosphiran, [^{13}C]phosphiran, *cis*- and *trans*-2-deuterophosphirans, and 1-deuterophosphiran were investigated, which made it possible to determine the bond lengths and angles in the phosphiran molecule, the result being presented in the Table. The dipole moment of phosphiran is 1.12 D.

The structure of crystalline 4-methyl-2,6,6-triphenyl-1-phospha-2,3-diazabicyclo[3.1.0]hex-3-ene (III, R=Ph), containing the phosphiran ring combined with the 1,2,3-diazaphospholan ring, was determined by X-ray diffraction[54]. It was found that the phosphorus atom has a distorted pyramidal configuration in this compound and that the plane of the three-membered ring makes an angle of 108.4° with the almost flat five-membered ring. The P–C bond lengths and the angle at the phosphorus atom in the phosphiran ring proved to be somewhat greater than the values in the Table.

Comparison with dimethylphosphine, which is an acyclic analogue of phosphiran and has $r(P-C) = 1.853$ Å, $r(P-H) = 1.445$ Å, $\alpha(CPC) = 99°12'$, and $\alpha(HPC) = 96°30'$,[55] shows that ring closure decreases the valence angles at the phosphorus atom and leads to a corresponding increase in the length of its endocyclic bonds. This effect is responsible for the increase of the *p* character in the bonds involving the phosphorus atom and of the *s* character of its unshared electron pair. Indeed, an independent estimate of the amount of *s* character of the hybrid atomic orbital of phosphorus in the P–H bond from the spin–spin coupling constant $^1J_{HP}$ yielded 5.3% for phosphiran, which is lower than the corresponding value for Me_2PH (6.5%).[17]

The bond lengths (*r*, Å) and angles (α, deg) in cyclopropane and its heteroanalogues XC_2H_4.[53]

Bond or angle	X					
	CH_2	NH	O	SiH_2	PH	S
r(C—C)	1.510	1.480	1.472	1.520	1.502	1.492
r(C—H)	1.088	1.082	1.082	1.081	1.093	1.078
r(C—X)	1.510	1.488	1.436	1.826	1.867	1.819
r(X—H)	1.088	1.000	—	1.480	1.428	—
α(CXC)	60.0	60.0	61.4	49.2	47.4	48.5
α(HCH)	115.1	116.7	116.6	120.0	114.4	116.0
α(C—CH_2)	150	159.4	159.5	143.9	149.5	151.7
α(HXC_2)	117.6	112.0	—	120.0	95.7	—
α(XCC)	60.0	60.2	59.2	65.4	66.3	65.8

In conformity with this, it has been noted[33] that the formation of a phosphiran ring with a phosphoryl group is accompanied by a decrease of the spin–spin coupling in the endocyclic P–C bonds and an upfield shift of the signal in the ^{31}P NMR spectrum. The stretching vibration frequency of the P=O bond increases under these conditions.

An interesting feature of the molecular structure of phosphiran is the fact that the *cis*-hydrogen atom of the methylene group is more remote from the phosphorus atom by 0.035 Å than the *trans*-hydrogen atom, while the angle between the CH bond and the plane of the ring is greater by 2.2° in the case of the *cis*-atom[17]. In order to elucidate the cause of this phenomenon, a microwave spectroscopic study was made of *cis*- and *trans*-2-methylphosphirans[56]. In this case too the substituent at the carbon atom in the *cis*-isomer is somewhat more remote from the phosphorus atom than in the *trans*-isomer, but the barriers to internal rotation in these isomers differ insignificantly, which is difficult to reconcile with the possible interaction through space between the proton at the phosphorus atom and the substituents at the carbon atoms of the phosphiran ring. The difference between the free energies of the isomeric 2-methylphosphirans, which is a measure of the stability of the isomeric forms, is also small ($\Delta F_{200K} = 0.13$ kcal mol^{-1}; *F* is lower for the *trans*-isomer). This also indicates the absence of an appreciable interaction through space. On the other hand, analysis of the change in the density matrix obtained by the extended Hückel method with adjustment for self-consistency with respect to charges[57] shows that all the atoms of the phosphiran molecule, including the methylene protons, are involved in the inversion of the phosphorus pyramid. This demonstrates the occurrence of an explicit interaction of the methylene protons with the proton at the phosphorus atom. Estimation of the barrier to inversion from the change in the orbital population yielded 39.9 kcal mol^{-1}, which is much larger than the analogous change for aziridine and agrees well with the usually observed high barriers in acyclic phosphorus compounds.

The calculation of the barriers to pyramidal inversion by the specially parametrised semiempirical CNDO/2 method without taking into account the *d* orbitals yielded a still higher value of phosphiran: 80.4 kcal mol^{-1}. The inclusion of the inverted centre in a small ring increases the barrier to inversion because of the corresponding increase in *s* character of the unshared electron pair of the heteroatom. In particular, it has been shown that the barrier increases in the series of phosphorus compounds investigated: trimethylphosphine < 1-methylphospholan < 1-methylphosphetan < phosphiran[58].

The phosphiran molecule provides an excellent possibility for the observation of the stretching vibrations of the C–P–C linkages in a small strained ring and the influence of this ring on the vibration frequency of the P–H bond. A study of the infrared spectra of phosphiran, 1-deuterophosphiran, and 2,2,3,3-tetradeuterophosphiran in the gas phase and of the Raman spectrum of phosphiran in the liquid phase has been reported[16]. The observed bands were identified on the basis of the frequency shifts in the deuterated derivatives, the data for the polarisation of the Raman lines, the contours of the infrared bands for the gas phase, and the characteristic group frequencies. Two bands were assigned to symmetrical vibrations of the P–C bonds in the ring: at 598.1 and 656.7 cm^{-1}. They have undergone a bathochromic shift relative to the analogous stretching vibrations in dimethylphosphine (664 and 710 cm^{-1}).

The 2291.4 cm^{-1} band in the spectrum of gaseous phosphiran was assigned to the stretching vibrations of the P–H bond; bearing in mind that the analogous band in the spectrum of dimethylphosphine is observed in the region of 2290 cm^{-1}, it was concluded[16] that the three-membered ring has an insignificant influence on the frequency of these vibrations. On the other hand, the deformation vibrations of the P–H bond in the gas phase (769 and 680.4 cm^{-1}) are observed at lower frequencies than those known for the analogous acyclic phosphorus compounds. For example, the corresponding band in the dimethylphosphine spectrum is in the region of 1146 cm^{-1}.[59]

In contrast to aziridine, where the frequency of the out-of-plane deformation vibrations of the N–H bond is higher than the frequency of the corresponding in-plane vibrations, in phosphiran the above relation is reversed from the analogous vibrations of the P–H bond[60]. This is undoubtedly caused by the smaller valence angles at the heteroatom in phosphiran (Table 1), as a result of which the steric hindrance to the displacement of the heteroatom proton from the symmetry plane is much smaller than the hindrance to the deformations within this plane.

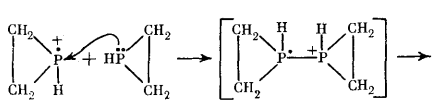
The inversion barrier in phosphiran, estimated from the calculated force field of the molecule, is 33 kcal mol^{-1}.[60]

The thermodynamic functions of phosphiran have been calculated in terms of the rigid rotator–harmonic oscillator approximation[60]. They differ appreciably from the values obtained in another study[61] in terms of the analogous approximation but on the basis of an assignment of the infrared bands of phosphiran and related molecules differing somewhat from that described above[62].

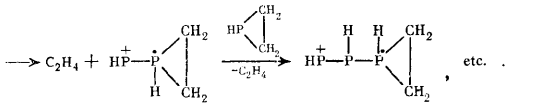
A ^{31}P NMR study[14] showed that the phosphiran spectrum consists of a doublet with the centre at −341 p.p.m. relative to 80% phosphoric acid. The chemical shift of phosphorus thus proved to be the highest upfield shift among the values reported for phosphines. The spin–spin coupling constant $^1J_{PH} = 155$ Hz is unusually small. Each component of the doublet is split in a complex manner by interaction with the

methylene proton. A qualitative description of the proton NMR spectrum is also given.

The ^{31}P NMR spectra of substituted phosphirans yield additional evidence for their configurational stability. The existence of the *cis*- and *trans*-isomers of 2-ethylphosphiran has been demonstrated[15] by the presence in the spectrum of two doublets with different chemical shifts and slightly different spin–spin coupling constants $^1J_{PH}$. The more pronounced upfield character of the ^{31}P chemical shifts and their greater sensitivity to structural changes in substituted phosphirans compared with the analogous secondary and tertiary phosphines have also been noted.

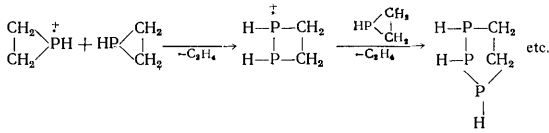


The chemical shifts in the ^{13}C NMR spectrum and the spin–spin coupling constants for 1-phenylphosphiran have been published[63]. The changes in these quantities with increase of the number of endocyclic C–C bonds and on ring opening are discussed in the same communication.



The results of mass-spectrometric studies of different types of phosphirans have been described: phosphirans with tricoordinate and tetracoordinate phosphorus, diphosphirans, element-substituted phosphirans, and others[15,29,64]. In all cases the spectra contain peaks due to molecular ions which are the most intense for monosubtituted phosphirans with tervalent phosphorus. The fragmentation of unsubstituted phosphiran and 1-deuterophosphiran is believed[15] to begin apparently with successive abstraction of the hydrogen atoms linked to the carbon atoms, while the P–H or P–D bonds remain unaffected. The introduction of methyl substituents into the molecule alters the preferred mode of fragmentation[15]. The mass spectra of all phosphirans with one phosphorus atom in the ring and of element-substituted phosphirans contain the peak of the fragment formed on rupture of both endocyclic phosphorus bonds. The fragmentation of 3,3-disubstituted 1,2-di-t-butyldiphosphirans takes place via the elimination of the t-butyl groups and their substitution by protons with subsequent formation of the $(M-C_4H_8)^+$ and $(M-2C_4H_8)^+$ ions[29].

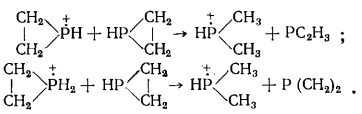
The mass spectrum and the ion–molecule reactions of phosphiran and its mixtures with ammonia and deutero-, dideutero-, and trideutero-ammonia were also investigated by ionic cyclotron resonance spectrometry[64]. It was confirmed (see also Baudler and Saykowski[29]) that the most intense primary ions are the molecular ion M^+, the ions formed following the elimination of protons from the carbon atoms, $(M-2H)^+$ and $(M-3H)^+$, and also an ion with *m/e* 45 (PCH_2^+ or $HPCH^+$). There is no dominant secondary ion, as in the case of acyclic methylphosphines, and several ions in approximately equal proportions are formed. Another characteristic feature of phosphiran, found in the study of the influence of pressure (10^{-4}–10^{-6} mmHg) on the ionic ratios, proved to be a sharp decrease of the relative content of the molecular ions with increase of pressure (for methylphosphines, pressure has almost no influence on the content of the molecular ion).



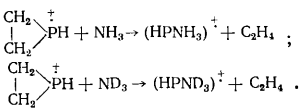
The ion–molecule reactions of phosphiran proceed mainly in three ways.

(a) The transfer of the P–H fragment from phosphiran to the molecular ion with evolution of ethylene and the formation of $R(PH)_n^+$ ions (where R = 1-phosphiranyl, $n = 1$–3), having an open phosphorus-containing chain or, which is more likely, having the structure of cyclic compounds with large rings formed as a result of the insertion of the P–H groups in the ring:

or



(b) The formation of protonated ions:



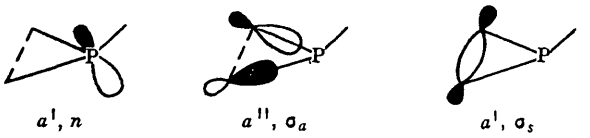
The determination of the rate constant for this reaction showed that phosphiran is protonated much more slowly than dimethylphosphine ($k = 0.54$ and 1.4×10^{-7} litre mole^{-1} s^{-1} respectively). The presence of the three-membered ring has a retarding influence on the rate of reaction (see Section IV).

(c) Ring decomposition:

The reaction of ammonia and deuteroammonia with the molecular ion of phosphiran for an electron energy of 11 eV also entails the transfer of the P–H fragment and this process is not accompanied by deuterium exchange:

The reactions with NHD_2 and NH_2D take place analogously.

For an electron energy of approximately 15 eV and above, there is additiional abstraction of the proton or deuterium, for example:



On the grounds that the molecular ion of phosphiran as well as the neutral molecule undergo PH transfer, it is concluded that the cyclic structure is retained in the molecular ion.

The interaction of phosphiran with the PH_3^+ radical-ion also proceeds as PH transfer with formation of the $P_2H_4^+$ radical-ion.

The relative stabilities of the cyclic onium ions $C_2H_4X^+$ have been investigated[65]. The study of the equilibrium $C_2H_4X^+ + HY \rightleftharpoons C_2H_4Y^+ + HX$ by the method of ionic cyclotron resonance made it possible to set up the series of increasing relative stabilities of ions for the following X: OH < Cl < Br < CH, $PH_2 < NH_2$.

The influence of angular strain in phosphiran on its electronic properties is of great interest to investigators. The study of the basicity and the ionisation potentials of phosphiran in relation to dimethylphosphine proved to be fruitful. The experimental photoelectron spectra of these compounds have been discussed[66] on the basis of *ab initio* quantum-chemical calculations. The removal of electrons from the highest occupied molecular orbitals with a′, a″, and a′ symmetries corresponds to the first three ionisation potentials of phosphiran and dimethylphosphiran. The orbital (*n*) with the highest energy is characterised by the dominant contribution of the unshared electron pair of the phosphorus atom

and the next two orbitals are characterised by the antisymmetric (σ_a) and symmetrical (σ_s) combinations of the *p* orbitals of the carbon atoms (Fig.1).

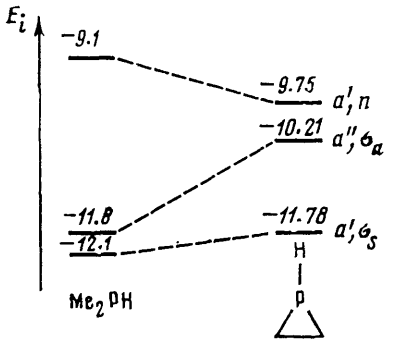


Figure 1. Correlation diagram for the orbital energies (in eV) of the three highest occupied molecular orbitals of dimethylphosphine and phosphiran[66].

The formation of the ring lowers the energy of the *n* molecular orbital by 15.4 kcal mol^{-1}. The stabilisation of this molecular orbital can be to a large extent accounted for by the enhanced *s* character of the unshared electron pair of the phosphorus atom in the three-membered ring. The repulsion of the electrons in the P–C σ-bonds increases with decrease of the C–P–C angle. The corresponding shift of electron density from P to C renders the phosphorus atom more positive, which also promotes the stabilisation of the *n* molecular orbital. The symmetrical combination of the π_{CH_2} orbitals of the two methylene groups is more strongly bonding than the symmetrical combination of the π_{CH_3} orbitals in dimethylphosphine. The hyperconjugation in phosphiran therefore destabilises the *n* molecular orbital to a lesser extent than in dimethylphosphine.

The lower-energy σ_a and σ_s orbitals are localised mainly at the carbon atoms. The shift of electron density from the P atom to C with decrease of the C–P–C angle, mentioned above, should destabilise both these orbitals. The mutual approach of carbon atoms enhances both the antibonding and the bonding interactions between them. As a result, the σ_a molecular orbital is most destabilised, while the energy level of the σ_s molecular orbital hardly changes.

The proton affinity of phosphiran is lower by 23.2 kcal mol^{-1} than that of dimethylphosphine[66]. The explanation is that, compared with the unstrained tetrahedral phosphorus atom in phosphonium salts, the angular strain in the protonated phosphiran is much greater than in its acyclic analogue. The enhanced *s* character of the unshared electron pair of the phosphorus atom in phosphiran and the shift of electron density in the P–C bonds from P to C also play an appreciable role.

Photoelectron spectroscopy combined with semiempirical quantum-chemical calculations has been used to investigate the electronic structures of three-membered heterocycles containing more than one phosphorus atom[67].

Investigators were naturally interested in the structural characteristics and physical properties of phosphiran relative to other known three-membered heterocycles which are derivatives of elements in Period II and III in Mendeleev's Table. This Table shows a steady decrease of the C–C bond length with increase of the atomic number of the element within the limits of each Period. This effect has been explained[68] by regarding the XC_2H_4 heterocycle as a donor–acceptor complex of ethylene C_2H_4 in the ground state and the fragment X in the valence state with the $(np_x)^2$ $(np_z)^0$ configuration of the endocyclic heteroatom ($n = 2$ or 3) (Fig.2).

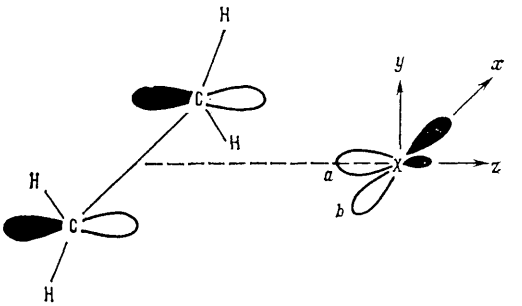

Figure 2. The heterocycle XC_2H_4 in the form of the $C_2H_4 + X$ donor–acceptor complex.

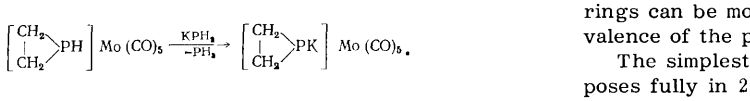
The C–C bond is weakened as a result of the transfer of electron density from the occupied *b* orbital of the fragment X (*yz* symmetry plane) to the vacant π* orbital of C_2H_4 and from the occupied π orbital of C_2H_4 to the vacant *a* orbital of X. The degree of such transfer is determined mainly by the energy levels of the *a* and *b* orbitals of X. Calculation of these levels by the *ab initio* SCF-MO method yielded a satisfactory explanation even for the non-uniformity of the shortening of the C–C bond within each Period.

Calculation of certain structural parameters of three-membered heterocycles, including phosphiran and the phosphiranium ion by the MNDO method without taking into account the *d* orbitals was used by Dewar and Ford[69] to set up the "π-complex character" series for these rings. The above authors expressed the view that, depending on the electronegativity and other properties of X, the compounds XC_2H_4 can constitute a continuous series, at one end of which there are the "classical" three-membered rings of the type of cyclopropane, while at the other there are π-complexes of the olefin–transition metal type. In the latter the intramolecular transfer of electron density from C_2H_4 to X greatly exceeds the reverse transfer. On the basis of the calculation of several criteria for the estimation of the "π-complex character" of the compounds XC_2H_4, series based on decreasing "π-complex character" of the heterocycles were established. Since compounds with X = PH and SiH_2 were found to be at the very end of this series, even beyond CH_2, phosphiran and siliran must be classified as the most typical "classical" three-membered rings in which electron transfer from X to C_2H_4 is the dominant feature.

It has been shown[53] that the C–C bond length in a three-membered heterocycle is determined mainly by the transfer of electron density from the *b* orbital of X to the π* orbital of ethylene. Increase of the electronegativity of X diminishes the effect of such transfer. As a result, the C–C bond is shortened and the angle β between the axis of this

bond and the normal to any of the CH_2 planes increases. The corresponding quantum-chemical calculations have shown that the overlap population of the C–C bond then increases and that of the X–C bond diminishes.



Several studies have been devoted to calculations on hypothetical molecules, which have not as yet been obtained, incorporating a three-membered phosphorus-containing ring, in particular cyclic spiro-compounds with a bridgehead phosphorus atom. A qualitative examination of the interaction of the *p* orbitals of the carbon atoms with the *d* orbitals of the phosphorus atom in symmetrical compounds with two mutually perpendicular rings[70] permits the conclusion that some of these systems are stable. Analogous systems have been considered quantitatively in a study[71] where the geometries and heats of formation of the individual spiro-compounds were calculated by the MINDO/3 method with minimisation of the total energy. The relative instability of these compounds is explained by the high energy level of the highest occupied molecular orbital and hence by their high reactivity towards electrophiles. Stabilisation can be achieved by the addition of electron-accepting groups to the central atom. The inclusion of the 3*d* orbitals of the phosphorus atom in the calculation greatly reduces the level of the highest occupied molecular orbital, thereby increasing the stability of the entire bicyclic system.

Thus the study of the structural characteristics and physical properties of compounds containing the phosphiran ring is being continued using all modern experimental and computational methods.

IV. CHEMICAL PROPERTIES

1. The Acidity of Phosphiran and Its Derivatives

Since direct measurements of the acidity of P-unsubstituted phosphirans have not been made, the conclusion that the mobility of the hydrogen atom linked to phosphorus is low can be reached only at a qualitative level on the basis of attempts to carry out exchange reactions. When phosphiran is treated with potassium in liquid ammonia or with ethyl-lithium in ether, hydrogen is not evolved. Nor does the exchange reaction occur with potassium phosphide in dimethyl ether. Such exchange does take place, however, in a complex of phosphiran with molybdenum carbonyl, i.e. pentacarbonylphosphiranmolybdenum(0), approximately 80% of the calculated amount of phosphine being evolved[72]:

^{1}H NMR data have shown that in methanol there is no rapid exchange of the hydrogen atom attached to phosphorus for the methanol protons[14]. Thus in this respect phosphiran does not differ from acyclic secondary phosphines[73].

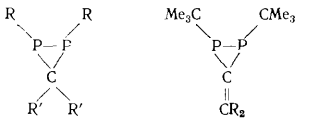
2. The Basicity of Phosphiran and Its Derivatives

The few available literature data show that the phosphorus atom in the three-membered ring is much less basic than in acyclic phosphine and than the nitrogen atom in a similar ring. For example, the calculated potential energies of atomic interactions[57] have shown that the density of the free electron pair of the phosphorus atom in phosphiran is delocalised over the carbon atoms of the ring to a much greater extent than the electron density of nitrogen in aziridine. Only 62.3% of the free electron pair density is localised at the phosphorus atom, in contrast to the 76.3% at the nitrogen atom of aziridine.

This type of delocalisation is even more pronounced in 1-methylphosphiran, where only 57.1% of the free electron pair density remains at the phosphorus atom and Petersen and Brisotti[57] suggested that this compound should be the weakest base among the compounds which they examined (apart from those indicated, they also investigated 1-methyl- and 1-chloro-aziridines), provided that the basicity is correlated with the localisation of electron density at the heteroatom.

Comparison of the properties of the heteroatom in phosphiran and other three-membered rings containing elements in the Second and Third Periods (C, N, O, S, and Si) on the basis of quantum-chemical calculations by the CNDO method[53] showed that, with increase of the atomic number of the element, there is a systematic increase of the negative charge on the heteroatom in each Period and its decrease in each Group of the Periodic System. Thus the charge on the phosphorus atom of phosphiran is much less negative than on the nitrogen atom of aziridine (+0.109 and −0.167 respectively) and on the sulphur atom in thi-iran (−0.103), but is less positive than on the silicon atom in siliran (+0.316).

The decrease of the basicity of the heteroatom on passing from acyclic compounds to three-membered heterocycles is a general property, as shown by studies of the basicity of rings with N, O, S, and P heteroatoms and also of dimethyl-substituted acyclic compounds of these elements (Me_2NH, Me_2O, Me_2S, and Me_2PH) by ion cyclotron resonance[66]. The decrease of proton affinity is explained by the increase of the amount of s character of the orbtials of the free electron pair of the heteroatom and by the redistribution of electron density in the C–X bond as well as the increase of the angular strain on protonation, since this should entail a transition from a pyramidal to a tetrahedral angle. The influence of angular strain is the dominant factor in phosphiran, which has the smallest C–X–C angle. On passing from dimethylphosphine to phosphiran, a particularly sharp decrease of basicity is observed (the difference between proton affinities is in this instance 23.2 kcal mol^{-1}, while for the N, O, and S analogues it is only 3–5 kcal mol^{-1}).

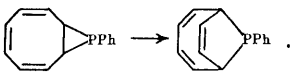


3. The Opening of the Three-membered Ring

(a) *Thermolysis of the phosphiran ring.* The high ring strain, which is a characteristic property of rings with three and four members, is also manifested in phosphirans, whose rings can be more or less readily opened depending on the valence of the phosphorus and the nature of the substituents.

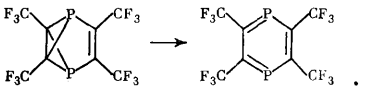
The simplest phosphiran is thermally unstable and decomposes fully in 24 h even at room temperature on storage without a solvent, giving rise to ethylphosphine (15%), ethylene (6%), and an involatile viscous liquid. The decomposition in methanol at room temperature is slow[14].

The diphosphirans with tervalent phosphorus known at the present time showed a tendency towards dimerisation with formation of 1,2,4,5-tetraphosphacyclohexanes. The thermal stability of diphosphirans of this type depends on the bulk of the substituents and increases appreciably even on substitution of the hydrogen atoms at a ring carbon atom by methyl groups. Thus the conclusion that the heterocycle (XII, R = Ph, R′ = H) is formed also on interaction of 1,2-diphenyl-1,2-bis(trimethylsilyl)diphosphine with di-iodomethane at −30 °C was based solely on the appearance of a weak signal in the ^{31}P NMR spectrum of the reaction mixture with a chemical shift characteristic of the phosphorus atom in a three-membered ring, whereas compound (XII, R = Ph,



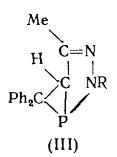
R′ = Me) can be obtained at −30 °C in a yield of approximately 10% and is stable in benzene at this temperature for several days[28]. The still more stable diphosphirans (XII, R = t-Bu) can be vacuum-distilled at approximately 30 °C without decomposition. However, whereas the diphosphiran (XIIa) dimerises at room temperature in a pure form in several hours (more slowly in solution and at −78 °C the dimerisation ceases [29,30]), compound (XII, R = t-Bu, R′ = Me) can be maintained at room temperature in an inert gas atmosphere for months and can be briefly heated to as much as 200 °C without visible decomposition; in air the last two compounds both rapidly oxidise without igniting[29]. On the other hand, the diphosphiran (XII, R = iso-Pr, R′ = H) cannot be obtained at all—the six-membered dimer is formed immediately[30]:

(XII) (XIII)



An analogous behaviour has been observed also for diphosphirans (XIII) with an exocyclic C = C bond. The methylenediphosphiran (XIII, R = H) begins to decompose in the reaction mixture already at −50 °C, so that it was possible to obtain it only with a purity of 70%, whereas its analogues with methyl or *p*-chlorophenyl groups are comparatively stable and have been isolated in a pure form by high-vacuum distillation or fractional cyrstallisation[11].

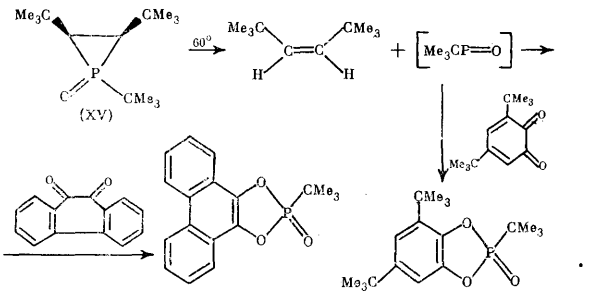
The bicyclic phosphiran with condensed rings 9-phenyl-9-phosphabicyclo[6.1.0]nona-2,4,6-triene can be stored in an inert atmosphere with cooling over a period of one year almost without changes, but, on raising the temperature the three-membered ring expands with formation of 9-phenyl-9-phosphabicyclo[4.2.1]nona-2,4,7-triene (XXXVIII), which has been isolated in a high yield[19,20]:



(I) (XXXVIII)

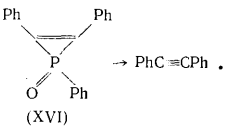
When the phosphorus analogue of benzvalene, which is stable at room temperature, is heated or illuminated with light from a low-pressure mercury lamp (λ = 2537 Å), it is reconverted into a 1,4-diphosphabenzene derivative (X) by a sigmatropic rearrangement (in hexafluorobenzene at −198 °C the half-life of the reaction is approximately 75 min[25,27]):

(XI) (X)



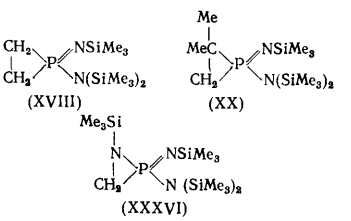
Despite the presence of tervalent phosphorus in the three-membered ring, derivatives of 1-phospha-2,3-diazabicyclo-[3.1.0]hex-3-ene exhibit an appreciable thermal stability, melting without decomposition at 135° and 145 °C [for R = Ph and MeCO respectively][21].

(III)
R=Ph, MeCO



In the search for a quantitative approach to the problem of the comparative stabilities of the three-membered rings XC_2H_4 (X = CH_2, O, NH, PH, PH_3, or S), a group of Romanian investigators[31] calculated the enthalpies of decyclisation of the above compounds in several ways by an additive scheme using the tabulated bond energies and found that the ring with X = PH_3 has the highest positive enthalpy of decyclisation, i.e. derivatives of phosphiran with a pentavalent phosphorus atom, which had not yet been obtained at the time of the publication of the above study, should be resistant to thermal ring opening. Experimental data have shown that the stability of the ring depends on the structural features of each specific compound.

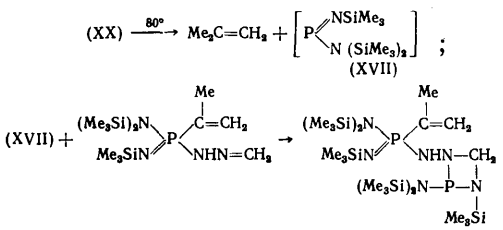
For example, *cis*-1,2,3-tri-t-butylphosphiran oxide (XV) is stable at room temperature but decomposes on heating in perdeuterobenzene at 60 °C, giving a quantitative yield of *cis*-2,2,5,5,-tetramethylhex-3-ene, i.e. the thermolysis is stereospecific. The second decomposition product, the unstable t-butylphosphinidene oxide with a dicoordinate phosphorus atom, cannot be detected when the thermolysis of the oxide (XV) is carried out in the presence of 1,2-bis-(trimethylsilyl)acetylene, 2,3-dimethylbutadiene, diacetyl, benzil, or *N*-(2,2-dimethylpropylidene)-t-butylamine, but 2-t-butylphenanthro[9,10-*d*]-1,3,2-dioxaphosphole oxide was obtained in 50% yield in the presence of 9,10-phenanthrenequinone, while 2,4,6-tri-t-butylbenzo-1,3,2-dioxaphosphole oxide is formed in a quantitative yield in the presence of 3,5-di-t-butyl-*o*-benzoquinone, which confirms the formation of a species with a dicoordinate phosphorus atom[32]:



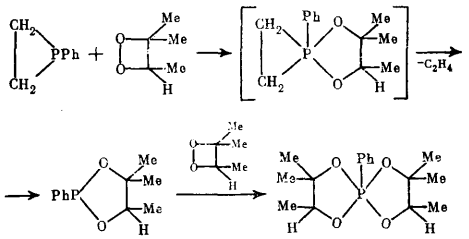
(XV)

1-Oxo-1,2,3-triphenylphosphiren (XVI) is cleaved analogously at 120 °C *in vacuo* (10^{-5}–10^{-6} mmHg), forming diphenylacetylene[35]:

(XVI)

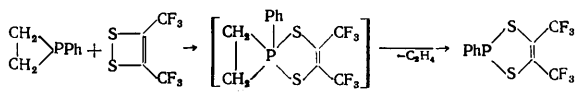


The positive influence of the steric shielding of the molecule on the thermal stability of the ring can be clearly traced in phosphirans with an exocyclic phosphazo-group and bulky substituents. Thus 1-[bis(trimethylsilyl)amino]-1-trimethylsilyliminophosphiran (XVIII), unsubstituted in the 2- and 3-positions, decomposes fairly rapidly at room temperature[38], while its analogue (XX) with two methyl groups in the 2-position[40] and the azaphosphiridine (XXXVI) with a bulky trimethylsilyl group at the ring nitrogen atom[38] are stable at room temperature:



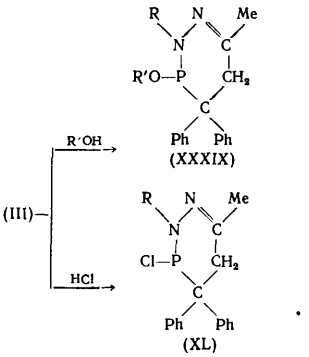
(XVIII) (XX)

(XXXVI)

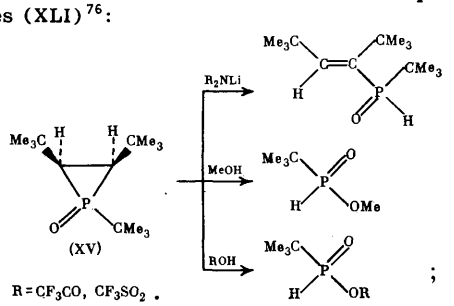


On heating to 80 °C, the phosphiran (XX) decomposes to 2-methylprop-1-ene, which has been characterised by infrared spectroscopic data, and the aminoiminophosphine (XVII), which undergoes further reactions as a result of the addition to the second product formed on synthesis of compound (XX):

In cyclic spirophosphoranes with a pentacoordinate phosphorus atom a three-membered phosphorus-containing ring has a low thermal stability. For example, in the reaction of 1-phenylphosphiran with 2,3,3-trimethyldioxetan, a cyclic spirophosphorane can be detected at −80 °C by ^{31}P NMR. At the above temperature the spectrum of the reaction mixture remains unchanged in the course of two weeks, but, on raising the temperature, ethylene is evolved and the signal assigned to the resonance of the phosphorus nucleus of the phosphorane with the three-membered phosphorus-containing ring disappears[43]:

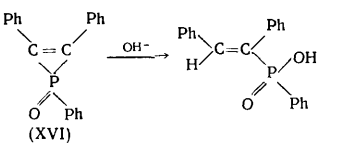


When 1-phenylphosphiran was treated with 3,4-bis(trifluoromethyl)dithieten at −78 °C, only ethylene and 2-phenyl-4,5-bis(trifluoromethyl)-1,3,2,-dithiaphospholen were obtained, i.e. the intermediate cyclic spirophosphorane decomposes even at this low temperature[18,74]:



The decomposition proceeds via a concerted and not a two-stage mechanism, since the reaction involving *cis*-2,3-dideutero-1-phenylphosphiran yields, 1,2-dideuteroethylene containing mainly the *cis*-isomer (95 : 5).[18]

(b) *Ring opening on treatment with chemical reagents.* The phosphiran ring of the unsubstituted compound is rapidly decomposed by acidic and basic agents. Even at reduced temperatures, phosphiran is rapidly decomposed by hydrogen chloride, giving rise to 90% of ethylene, 20% of phosphine, 5% of ethylphosphine, and a yellow solid which is mainly a polymeric phosphine[14]. On interaction with sulphur dioxide at 0 °C, ethylene and a polymeric product are also formed[75]. The interaction of phosphiran with potassium in liquid ammonia gives rise, as a result of ring cleavage, to a mixture of the anions of a series of phosphines. Rupture of the phosphiran ring also occurs on treatment with methyl-lithium in ether[72].

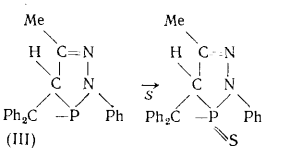


On heating with alcohols or on treatment with hydrogen chloride, the three-membered ring is also cleaved in derivatives of 1-phospha-2,3-diazabicyclo[3.1.0]hex-3-ene and the monocylic compounds (XXXIX) and (XL) are formed[22]. Under these conditions the P–C bond ruptured is that whose approach by the reagent apparently involves the smallest steric hindrance:

On the other hand, *cis*-1,2,3-tri-t-butylphosphiran oxide is very stable at room temperature in concentrated hydrochloric acid, trifluoroacetic acid, and trifluoromethanesulphonic acid and also in concentrated aqueous alkali, being decomposed only slowly by lithium diethylamide or piperidide with formation of t-butyl(1,2,-di-t-butylvinyl)phosphine oxide[34]. In boiling methanol the oxide (XV) is converted in 20 h into the monomethyl ester of t-butylphosphonous acid[33], while its thermolysis in trifluoroacetic or trifluoromethanesulphonic acid results in conversion into the corresponding anhydrides (XLI)[76]:

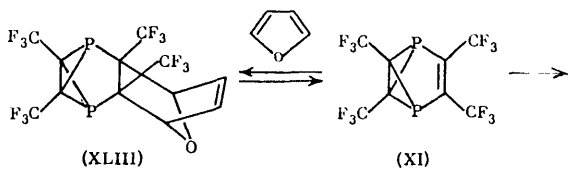
Hydrolysis of 1,2,3-triphenylphosphiren oxide by an aqueous solution of sodium hydroxide to phenyl(1,2-diphenylvinyl)phosphinic acid confirms the structure of this phosphiren derivative[35]:

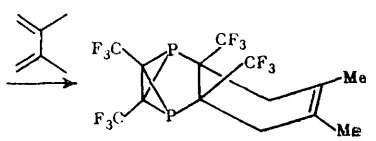
2-Cyano-1,1-diethylphosphiranium chloride is converted on hydrolysis into a mixture of 2-cyanoethyl(diethyl)phosphine and diethylphosphinic acid, which is difficult to separate[41].



4. Reactions Occurring with Retention of the Phosphiran Ring

When phosphiran reacts with the *N*-methylpyridinium salt of pentacarbonylmolybdenum iodide, a molybdenum complex is formed in which phosphiran is one of the ligands, namely pentacarbonylphosphiranmolybdenum(0):

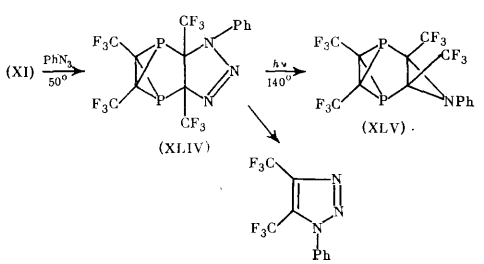




Phosphiran can displace also other ligands from molybdenum complexes: for example, pentacarbonylnorbornadienemolybdenum(0) and tricarbonylcyclohexatrienemolybdenum(0) give rise respectively to tetracarbonylbis(phosphiran)molybdenum(0) and tricarbonyltris(phosphiran)molybdenum(0). The complexes have been characterised by ^{1}H and ^{31}P NMR data[72]

The addition of sulphur to a derivative of 1-phospha-2,3-diazabicyclo[3.1.0]hex-3-ene also takes place with retention of the three-membered ring and has given rise to the first representative of a phosphiran with a P–S bond[22]:

The phosphorus analogue of benzvalene (XI) is capable of entering into the Diels–Alder reaction as the dienophile, forming, for example, with 2,3-dimethylbutadiene, the adduct (XLII), to which the *exo*-configuration has been attributed by analogy with the adduct obtained from benzvalene. Reaction with furan results in the formation of an equilibrium mixture of the initial compound (XI) and the adduct (XLIII):



(XLII)

When the adduct is dissolved in n-pentane, a solution is obtained whose ^{19}F NMR spectrum reveals the presence of compound (XI), equilibrium being established extremely rapidly at 70 °C.

Phenyl azide also adds to the double bond of the tricyclic compound (XI), giving the adduct (XLIV) with an additional triazoline ring, which evolves nitrogen on photolysis or heating at 140 °C and is converted into diphosphabenzvalenoaziridine (XLV); it has been shown by ^{19}F NMR that the initial compound (XI) is then obtained together with compound (XLV). Chromatography on silica gel entails the decomposition of this adduct (XLIV) with formation of 1-phenyl-4,5-bis(trifluoromethyl)triazole[27]:

---oOo---

The chemistry of heterocyclic phosphorus compounds is now passing through a period of vigorous development. The present review has dealt with the results of studies on three-membered organophosphorus heterocycles. It is of interest to examine the synthesis and properties of four-membered phosphorus-containing heterocycles.

Phenyl-substituted Polyheteroarylenes

V.V.Korshak and A.L.Rusanov

The fundamental methods of synthesis of polyheteroarylenes containing phenyl substituents in the heterocycles, formed in the course of the polycyclocondensation process, are examined. The influence of the phenyl substituents on the principal characteristics of the polyheteroarylenes is analysed. The likely usefulness of the introduction of phenyl substituents into polyheteroarylenes, in the sense of increasing their solubility, thermoplasticity, and resistance to thermal oxidation, is demonstrated.
The bibliography includes 112 references.

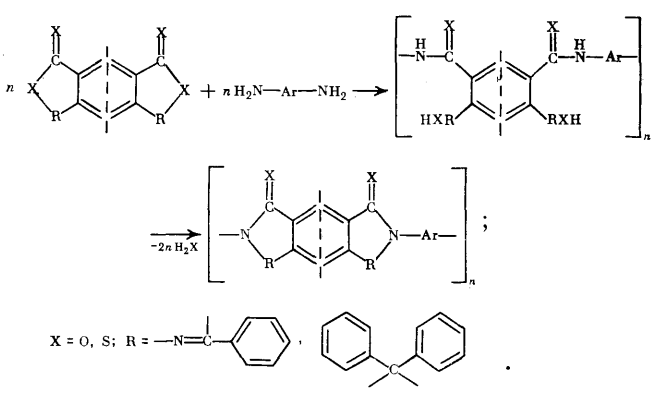
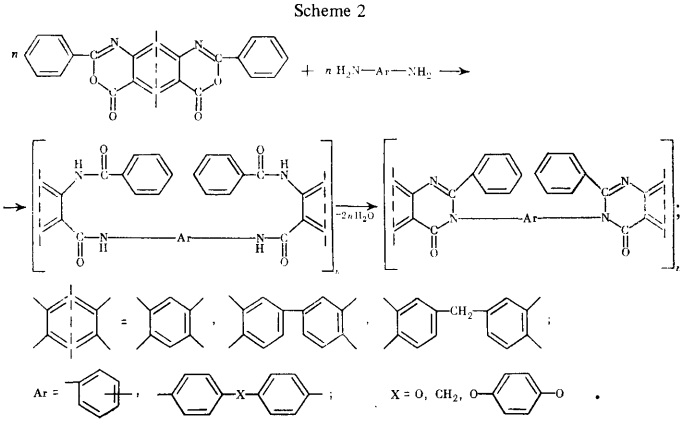
I. INTRODUCTION



The development of a number of fields of modern technology has led to the necessity of synthesising thermostable polymeric materials and hence new thermostable polymers. Numerous studies designed to synthesise thermostable macromolecular compounds, both in the USSR and abroad, have resulted in the development of a series of organoelemental[1,2] and aromatic carbochain polymers[1,3-8], but aromatic polymers containing various heterocycles in the main macromolecular chains, namely polyheteroarylenes, have come to be most widely used[1,3,4,6,7,9,10-12].

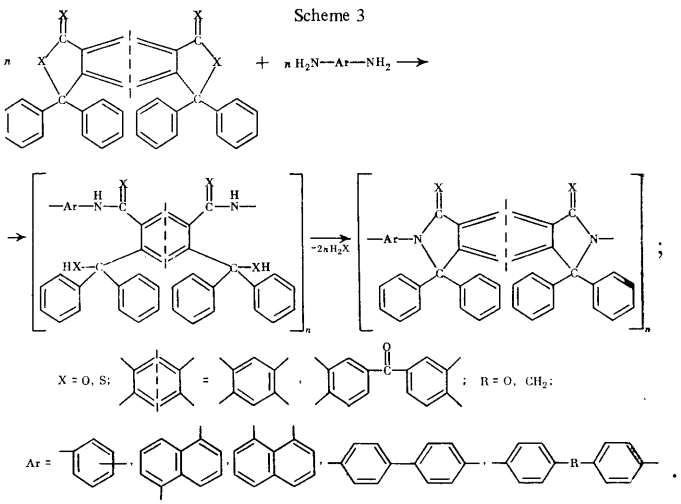
One of the achievements in the chemistry of polyheteroarylenes has been the development of multistage methods of their synthesis in which the first stages are carried out under mild conditions, the resulting prepolymers are isolated and used to make the required articles, after which thermal cyclisation is carried out directly in the finished article[1,4,9]. This approach has been used widely and successfully in the synthesis of polyimides[13,14], polyazoles, and polybenzazoles[15-18] and also a series of other polyheteroarylenes. Together with unquestionable advantages, the multistage method of synthesis of polyheteroarylene suffers from a series of significant disadvantages, among which the main one is the instability of the prepolymers[13,14] and also the lack of technological procedures for the thermal cyclisation processes and the impossibility of secondary processing of the polyheteroarylenes. As a result, in the middle 1960s a tendency arose in the chemistry of polyheteroarylenes to impart to these systems solubility in organic solvents in the final stage. Solubility in inorganic solvents and hence improved capacity for being converted into articles can be imparted to polyheteroarylenes in various ways—by introducing "hinged" groups into the main chain of the macromolecules, by synthesising macromolecules with the most asymmetric structure possible[3,19], and by synthesising polymers with bulky side groups—the "card" polymers[20-22]. However, the approach involving the introduction of phenyl side groups into the polyheteroarylenes, i.e. the synthesis of phenyl-substituted polyheteroarylenes, has come to be most widely employed. Phenyl substituents can be introduced by using monomers containing phenyl groups either in fragments which do not change in the course of the polycyclisation reaction[23,24] or in functional groups or fragments involved in the formation of the heterocycle. Phenyl substituted polyheteroarylenes obtained by the second of the above two procedures will be examined in this review.

II. PHENYLATED ANALOGUES OF POLYIMIDES



A large group of reactions involving the synthesis of phenyl-substituted polyheteroarylenes, obtained from monomers containing phenyl substituents in functional groups, can be represented by a general scheme similar to that for the synthesis of polyimides[13,14], i.e. involving the interaction of cyclic electrophilic monomers with diamines accompanied by ring opening and subsequent cyclodehydration of the resulting *o*-substituted polyamides (Scheme 1).

Scheme 1

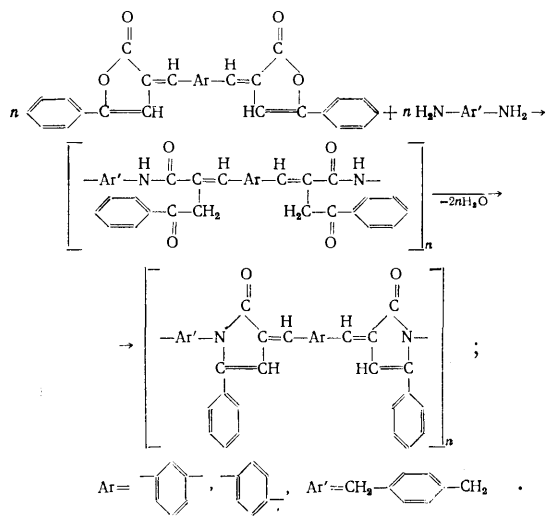


The first polyheteroarylenes obtained in accordance with Scheme 1 were phenyl-substituted polyquinazolinones, whose synthesis was achieved by the interaction of bis(2-phenylbenzoxazin-4-ones) with aromatic diamines[25–29] in accordance with Scheme 2.

Scheme 2

The reduced electrophilic reactivity of bis(2-phenylbenzoxazinones) compared with the dianhydrides of tetracarboxylic acids[30] necessitates the synthesis of phenyl-substituted polyquinazolinones under the conditions of high-temperature polycyclocondensation in polyphosphoric acid (PPA) or phenolic solvents[25–29]. The fact that the polycyclocondensation processes are carried out at 200° ± 20 °C combined with the ease of formation of six-membered heterocyclic systems makes it virtually impossible to isolate the intermediate poly(*o*-benzamido)amides and results in the occurrence of cyclisation reactions under the conditions of polymer chain propagation reactions. It is most useful to employ di(4-aminophenyl) ether and di(4-aminophenyl)methane as aromatic diamines. These substances are the most basic in the series of aromatic diamines[31]. Furthermore, the presence of "hinged" groups in these compounds determines the enhanced flexibility of the macromolecules obtained on their basis. Phenyl-substituted polyquinazolinones synthesised from these diamines are soluble in acid and phenolic solvents and are highly viscous, which makes it possible to prepare strong elastic films on their basis. Phenyl-substituted polyquinazolinones exhibit a comparatively high thermal stability—according to the results of dynamic thermogravimetric analysis (DTGA), the polymers do not undergo degradation in air up to 420 °C.

Scheme 3



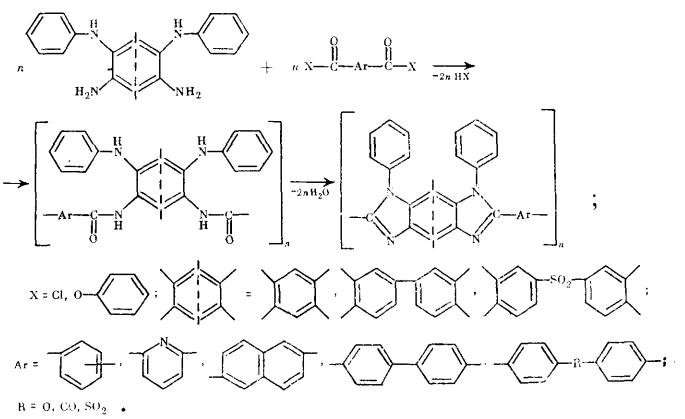
Phenylated polyimidines have been obtained by the reaction of phenylated phthalides[32–35] or their thio-analogues[33] with aromatic diamines in accordance with Scheme 3.

Like benzoxazinones, phthalides are comparatively weakly electrophilic[36,37] and react with amines, particularly aromatic amines, extremely slowly even in the presence of two phenyl substituents in the 3-position of the phthalide ring. For this reason, phenylated polyimidines are synthesised in accordance with Scheme 3 at high temperatures (180–350 °C), which precludes in its turn the isolation of the intermediate *o*-substituted polyamides and polythioamides. Regardless of whether the polyimidines were synthesised in the melt or in solvents, for example in PPA, nitrobenzene, biphenyl, dixylylethane, trichlorobenzene, or *m*-cresol, the polymers obtained have comparatively low viscosity characteristics (the maximum value of η_{log} of their solutions did not exceed 0.3 dl g^{-1}). At the same time the polyimidines were readily soluble in organic solvents—$CHCl_3$, dimethylformamide (DMF), and CCl_4—and exhibited a high thermal stability, losing 10% of the initial mass at 400–525 °C in air and at 450–560 °C in an inert medium[32–35]. These advantages of polyimidines are responsible for the interest in the synthesis of high-molecular-weight systems of this type. One of the possible ways of solving the problem of such synthesis consists in the employment as monomers of thio-analogues of phthalide compounds more reactive than the oxo-compounds[33].

Products similar in structure and properties to the polymers obtained in accordance with Scheme 3 were synthesised by the homocondensation of 6-amino-3,3-diphenylphthalide[38] and 3-(*p*-aminophenyl)-3-phenylphthalide[39] in PPA, nitrobenzene, trichlorobenzene, or dixylylethane.

The synthesis of phenylated polypyrrolinones by the reaction of 2,2-diphenyl-substituted bis(but-3-en-4-olides) with diamines[40] (Scheme 4) is fairly closely related to the reactions described in a general form by Scheme 1.

Scheme 4

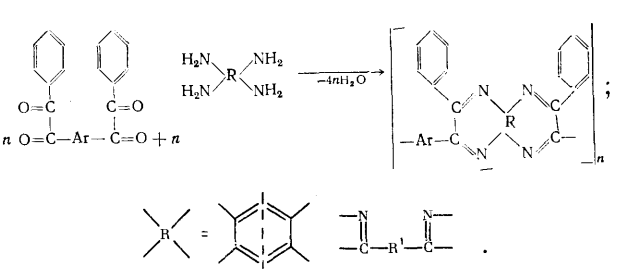


The first stage of the process at a low temperature in *m*-cresol led to the formation of polyamides with keto-side groups. When the process was carried out at 80 °C in the presence of acid catalysts (H_3BO_3, HCl, or CH_3COOH) or at 160 °C in the absence of catalysts, phenyl-substituted polypyrrolinones were obtained. Both polyamides with keto-substituents and phenylated polypyrrolinones are soluble in polar solvents (*m*-cresol, nitrobenzene, and DMF), but their viscosity characteristics are low (the maximum η_{log} of their solutions do not exceed 0.5 dl g^{-1}) and they have a low thermal stability, which makes these systems less interesting.

III. PHENYLATED POLYBENZAZOLES, POLYTRIAZINES, AND POLYQUINOXALINES

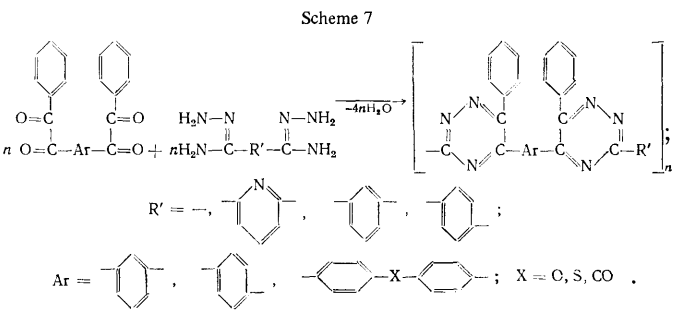
Together with the synthesis of phenyl-substituted polyheteroarylenes by reactions analogous to those used in the synthesis of polyimides, the synthesis of phenyl-substituted polybenzazoles in accordance with the general scheme for the synthesis of these systems[16-18], has attracted the attention of investigators. In the series of phenyl-substituted polybenzazoles, the synthesis of poly(*N*-phenyl)benzimidazoles in accordance with Scheme 5 has attracted most attention[28,41-53].

Scheme 5



The first studies designed to obtain poly(*N*-phenyl)-benzimidazoles were associated with the reaction of bis(*N*-phenol-*o*-phenylenediamines) with the diphenyl esters of dicarboxylic acid; the process was carried out initially in the melt and was followed by the subsequent high-temperature additional cyclisation of the solid mass *in vacuo* (the Marvel reaction" [41-44]). The poly(*N*-phenyl)benzimidazoles obtained were distinguished by relatively low viscosity characteristics (the η_{int} of 0.5% solutions in HCOOH at 25 °C were in the range 0.64–0.86 dl g^{-1}),[44] which precluded the formation from them of articles with effective deformation-strength characteristics.

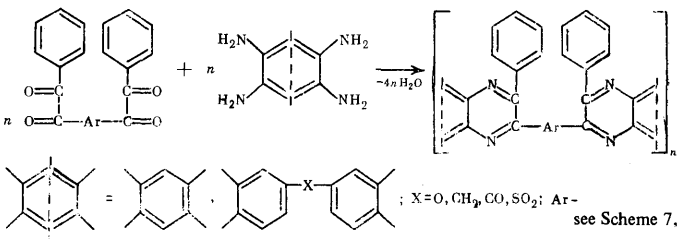
In order to increase the viscosity characteristics and hence the molecular weights of these polymers, attempts were made to synthesise poly(*N*-phenyl)benzimidazoles by a two-stage process. The first stage involved the interaction of bis(*N*-phenyl-*o*-phenylenediamines) with the dichlorides of dicarboxylic acids under the conditions of low-temperature polycondensation in dipolar aprotic solvents[28,42-52]. The second stage involved the cyclisation of poly(*o*-phenylamino)-amides under the conditions of thermal solid-phase polycyclisation[42-52]. When the synthesis of poly(*o*-aminophenyl)amides is carried out in amide solvents[28,45-49], high-molecular-weight systems, forming strong elastic films, are obtained; polymers with still higher molecular weights are formed when the polycondensation is carried out in sulpholan[51,52], which does not enter into side reactions with aromatic dicarboxylic acid dichlorides. The poly(*o*-aminophenyl)amides are usually cyclised to poly(*N*-phenyl)benzimidazoles by the solid-phase heat treatment of these systems[45-52]; this results in the formation of high-molecular-weight film-forming products which are soluble in acid and phenolic solvents. The cyclisation can also be achieved in PPA [45-47] or, more effectively, by adding hydrogen chloride or other acid catalysts to the reaction solutions of poly(*o*-aminophenyl)amides and then heating the latter at 160–170 °C.[28,45-47] Unfortunately the catalytic polycyclisation of poly(*o*-aminophenyl)amides has not come to be widely used, although there is no doubt about the likely usefulness of the method.



Detailed comparison of the properties of poly(*N*-phenyl)-benzimidazoles and unsubstituted polybenzimidazoles[42,53] showed that the introduction of phenyl substituents improves the solubility of the polymers and their resistance to thermo-oxidative degradation with the simultaneous decrease of their softening temperatures and thermal stability in an inert medium. The latter factor is due to the ease of abstraction of the phenyl substituents from the nitrogen atoms of the benzimidazole ring as a consequence of the lack of conjugation between the heterocycle and the substituent[53,54]. In the light of these data, the synthesis of polyheteroarylenes containing phenyl substituents at a carbon atom is preferable. A large family of such polymers has been obtained as a result of the reaction of tetrafunctional nucleophilic compounds (bis-*o*-phenylenediamines[55] and dicarboxylic acid bis-amidrazones[55,56]) with bisphenylglyoxalyl derivatives[55,57] in accordance with the general Scheme 6.

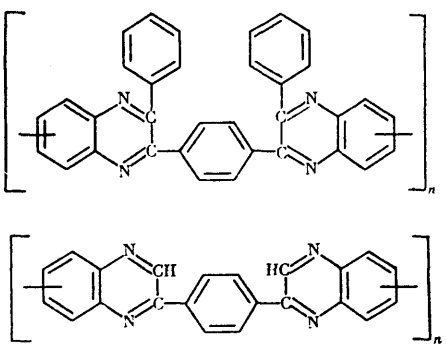
Scheme 6

The interaction of dicarboxylic acids bisamidrazones with bisphenylglyoxalyl derivatives in accordance with reaction (7) results in the formation of poly-*asym*-triazines[57-70].



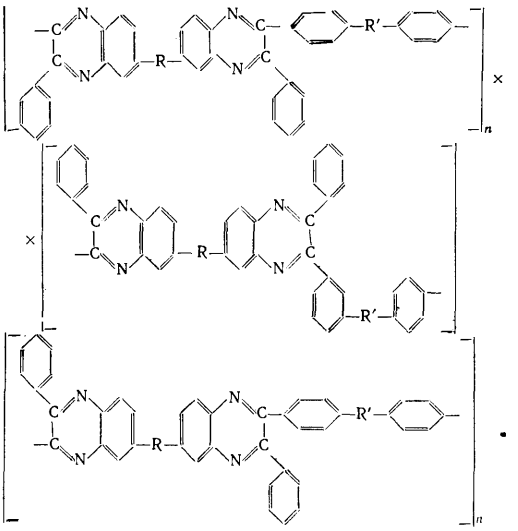
Scheme 7

The synthesis of poly-*asym*-triazines takes place smoothly in *m*-cresol and a number of other solvents even at room temperature. Fully aromatic phenylated poly-*asym*-triazines are characterised, depending on their structure, by a high or limited solubility in acid and phenolic solvents and also in chloroform, dimethyl sulphoxide (DMSO), dimethylacetamide (DMA), and other dipolar aprotic solvents. These polymers have high viscosities and hence high molecular weights which determine the possibility of preparing from them films, adhesives, and binders for glass plastics[63,66] capable of being used for a long time at 260 °C. Poly-*asym*-triazines soften at 270–330 °C and, in contast to unsubstituted poly-1,2,4-triazines, are characterised by a comparatively high resistance to isothermal thermal ageing in air, because the most thermostable representatives of this class of polyheteroarylenes lose 20–25% of the initial mass in 45 h at 290 °C. Polyphenylquinoxalines, which are the products of the interaction of bis(*o*-phenylenediamines) with bisphenylglyoxalyl



derivatives[57,71,72] in accordance with Scheme 8, are even more thermostable.

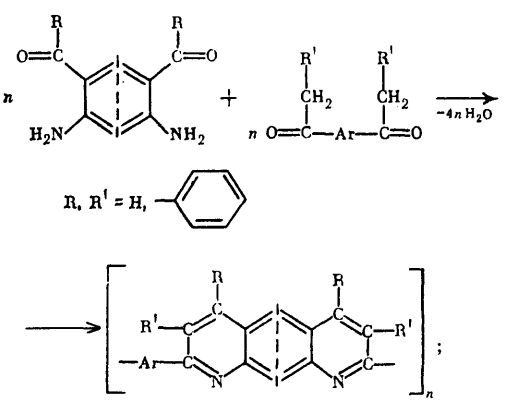
Scheme 8



see Scheme 7.

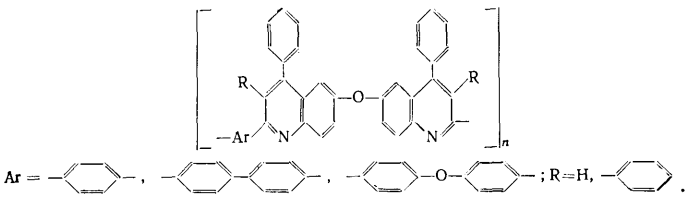
In the series of phenylated polyheteroarylenes these polymers have attracted most attention. A number of careful reviews have been devoted to problems of their synthesis, their properties, and the materials based on them[57,71,72]. We shall therefore not analyse these data in detail. We shall only mention that, like polyphenyl-*asym*-triazines, polyphenylquinoxalines are obtained under very mild conditions. Thus, the polycyclocondensation is carried out at room temperature in phenolic solvents or in chlorinated hydrocarbons. The ease of formation of the quinoxaline ring is responsible for the almost complete absence of uncyclised fragments from these polymers, which, in combination with the high stability of individual heterocyclic compounds of this type, determines the high thermal and chemical stability of polyphenylquinoxalines. These properties of the above systems, combined with their high molecular weights and ready solubility in phenolic solvents, *N*-methyl-2-pyrrolidinone (NP), and chloroform, are responsible for the undoubted practical value of polyphenylquinoxalines, which can be used as binders in reinforced plastics[73,74], adhesives[73], films[72], fibres[72], and other polymeric materials capable of being employed for a long time at 320 °C. In full analogy with polyphenyl-*asym*-triazines, polyphenylquinoxalines also exhibit a higher resistance to thermal oxidation than their unsubstituted analogues. Thus comparison of the thermo-oxidative stabilities of polyphenylquinoxaline based on 3,3'-diaminobenzidine and 1,4-bis(phenylglyoxalyl)benzene and its non-phenylated analogue[75] showed that they lose respectively 6 and 50% of the initial mass at 400 °C in the course of 200 h.

The most significant disadvantage of polyphenylquinoxalines is their high thermoplasticity due to the "isomeric heterounit" structure of these systems: the macromolecules of polyphenylquinoxalines contain isomeric 2,2'-, 3,3'-, and 2,3'-substituted phenylquinoxaline fragments:



The relative amounts of these fragments in polyphenylquinoxaline macromolecules depend on the nature of the monomers employed. Despite the fact that the interaction of the most nucleophilic amino-groups of bis(*o*-phenylenediamines) with the most electrophilic carbonyl groups of bis(α-diketones) or the interaction of the least nuclephilic amino-groups of bis(*o*-phenylenediamines) with the least electrophilic groups of bis(α-diketones) is most likely, the "isomeric heterounit" structure is characteristic of all polyphenylquinoxalines without exception. As a result, all the known polyphenylquinoxalines proved to be amorphous and the attempts to synthesise ordered systems of this type were unsuccessful[72]. In the search for phenylated polyheteroarylenes free from "isomeric heterounit" structures, a number of investigators turned to polycyclocondensation reactions based on the Friedlaender reaction[76].

IV. PHENYL-SUBSTITUTED POLYHETEROARYLENES OBTAINED BY THE FRIEDLAENDER REACTION

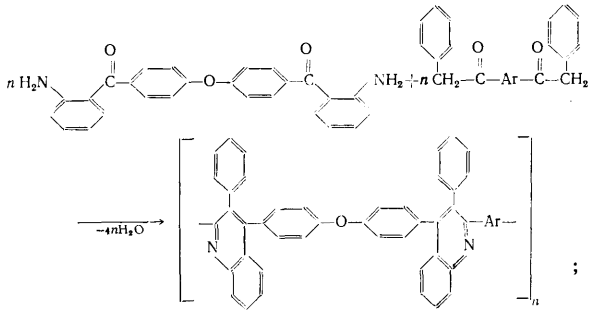


The classical version of this reaction consists in the condensation of *o*-aminocarbonyl compounds with ketomethylene products[76].

A number of phenyl-substituted polymers containing 2,6-quinoline and anthrazoline fragments in the main macromolecular chains have been synthesised by the reaction of diaminodicarbonyl compounds with aromatic diacetyl and diphenylacetyl compounds (Scheme 9).

Scheme 9

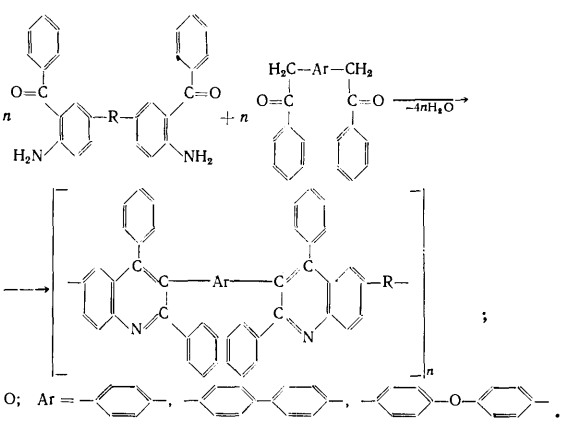
In particular the interaction of di(4-amino-3-benzoylphenyl)-ether with bis(α-ketomethylene) compounds in mixtures of *m*-cresol with PPA and P_2O_5 and 130–140 °C yielded a series of poly-2,6-quinolines[77–80] having the general formula



The polymers dissolve in *m*-cresol and chloroform and their intrinsic viscosities are in the range 0.6–4.1 dl g^{-1}. Their glass points are 260–350 °C and their melting points, corresponding to a ~20% degree of crystallinity, are in the range 450–480 °C. The temperatures of the onset of the degradation of poly(2,6-quinolines) are 530–545 °C in air and 530 ° to 570 °C in nitrogen according to DTGA data. Under the conditions of isothermal thermal ageing, polyquinoline based on di(4-acetylphenyl) ether, the least thermostable of the polymers synthesised, did not undergo degradation for 100 h at 300 °C, while after 100 h at 371 °C its mass diminished by 48%.[81]

In the series of polyanthrazolines obtained by the reaction of 4,6-diaminoisophthalaldehyde[80,82,83] and 4,6-dibenzoyl-1,3-phenylenediamine[84] with aromatic diacetyl and diphenacetyl compounds, the greatest interest attaches to systems based on 4,6-dibenzoyl-1,3-phenylenediamine—these are polymers soluble in *m*-cresol, HCOOH, and MP and having η_{log} up to 1.25 dl g^{-1}. According to DTGA data, these polyanthrazolines decompose at 500–550 °C in air and at 530–600 °C in an inert medium.

Poly(2,4-quinolines), which are isomeric with the poly(2,6-quinolines) described above, have been obtained by the reaction of di[4-(2-aminobenzoyl)phenyl] ether with diphenacetyl monomers[85] in accordance with Scheme 10.



Scheme 10

They are soluble in *m*-cresol and have intrinsic viscosities of 0.26–0.57 in this solvent.

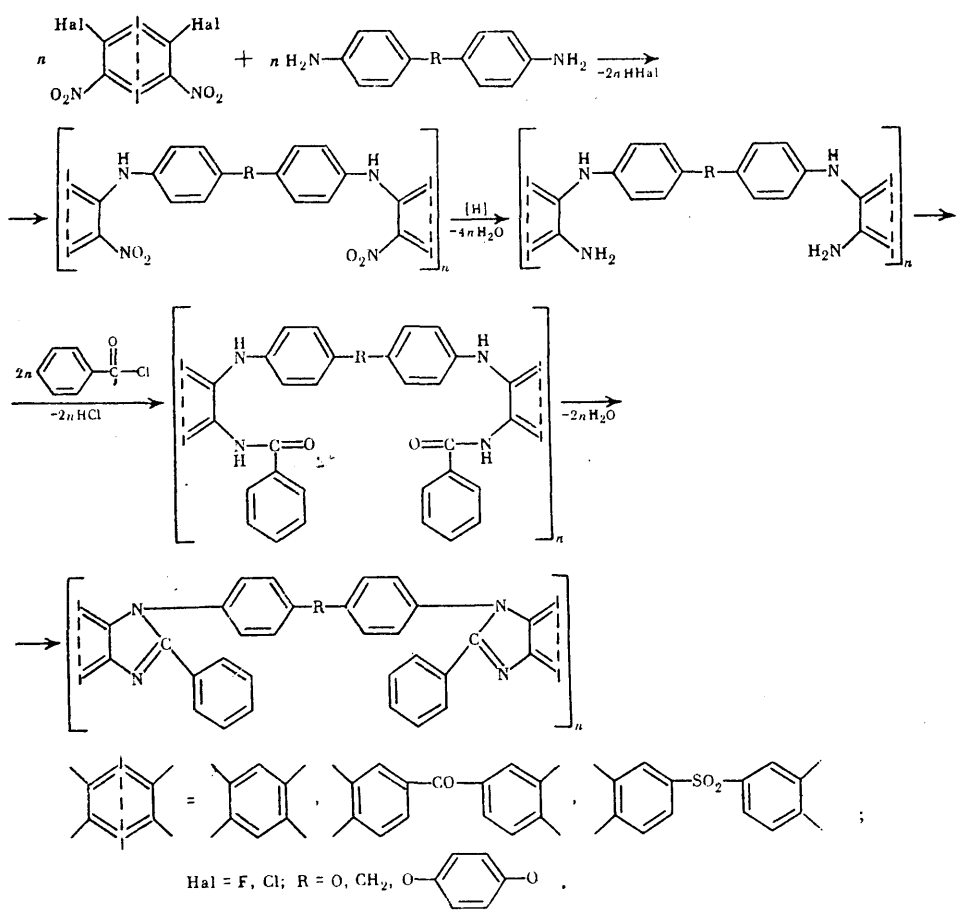
When aromatic diacetyl and diphenacetyl compounds are replaced by diphenacyl monomers of the type of 4,4'-diphenacylbiphenyl, di(4-phenacylphenyl) ether, and 1,4-diphenacylbenzene and on interaction of these products with di(4-amino-3-benzoylphenyl) ether and 4,4'-diamino-3,3'-dibenzoylbiphenyl, phenylated poly(3,6-quinolines) were obtained[86] (Scheme 11).

Scheme 11

Like the phenylated polyquinolines examined above, these polymers are soluble in *m*-cresol, chloroform, and tetrachloroethane and have intrinsic viscosities of 0.5–3.6. Their thermal characteristics are comparable to those of the polyquinolines considered above. Overall, phenyl-substituted polyquinolines and polyanthrazolines have higher softening temperature than polyphenylquinoxalines, but in this case the introduction of phenyl groups significantly increases the thermoplasticity of polyheteroarylenes.

Yet another group of reactions which lead to extensive possibilities for the synthesis of phenyl-substituted polyheteroarylenes consist of modified reductive polyheterocyclisation processes[87].

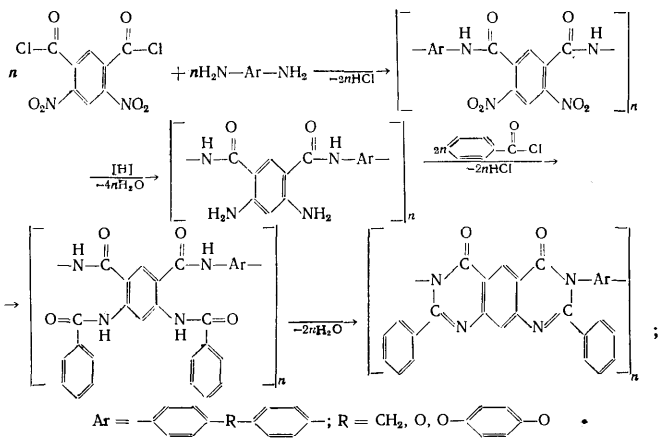
V. PHENYL-SUBSTITUTED POLYHETEROARYLENES OBTAINED BY A MODIFIED REDUCTIVE POLYHETEROCYCLISATION REACTION



These processes were used successfully for the first time to synthesise *C*-phenyl-substituted polybenzimidazoles, including the interaction of activated bis(*o*-nitro)halogenoarylenes with reactive aromatic diamines[88–94], the reduction of the nitro-groups in the resulting poly(*o*-nitro)amines to the amino-groups[88–92,95], the benzoylation of the latter[88–92,95], and catalytic polycyclisation of the poly(*o*-benzamido)amines formed to poly(*C*-phenyl)benzimidazoles[88–92,96] (Scheme 12).

Such polyphenylbenzimidazole are most usefully synthesised in a single-stage process, i.e. without isolation of the intermediate polymeric structures[88–92], in MP and using as a source of hydrogen and as a polycyclisation catalyst the hydrogen halide evolved as a side product in combination with metals. The employment of a catalyst makes it possible to carry out this process at relatively low temperatures (160–170 °C), eliminating thereby the risk of all possible secondary cross-linking degradation, etc. reactions.

In the series of poly(*C*-phenyl)benzimidazoles, polymers based on di(4-chloro-3-nitrophenyl) sulphone and di(4-aminophenyl) ether or di(4-aminophenyl)methane—readily available and at the same time reactive compounds— are of greatest interest. These polymers have high viscosities, are readily soluble in phenols and amide solvents, and have higher thermal stabilities than the poly(*N*-phenyl)benzimidazoles, which are similar to them in structure (see above).



High quality carbon plastics, capable of being used for a long time at 250–300 °C, have been obtained from these polymers[87]. A significant disadvantage of these systems is their low softening temperatures (300–320 °C), which are responsible for their thermoplasticity at elevated temperatures.

Scheme 12

Somewhat higher softening temperatures are characteristic of phenylated polyquinazolinones obtained by the method of modified reductive polyheterocyclisation[97,98], involving the interaction of the dichloride of 4,6-dinitroisophthalic acid with activated aromatic diamines, the reduction of the *o*-nitro-substituents in the resulting polyamides to the amino-groups, benzoylation of the latter, and catalytic cyclisation of the poly(*o*-benzimido)amides formed (Scheme 13).

Scheme 13

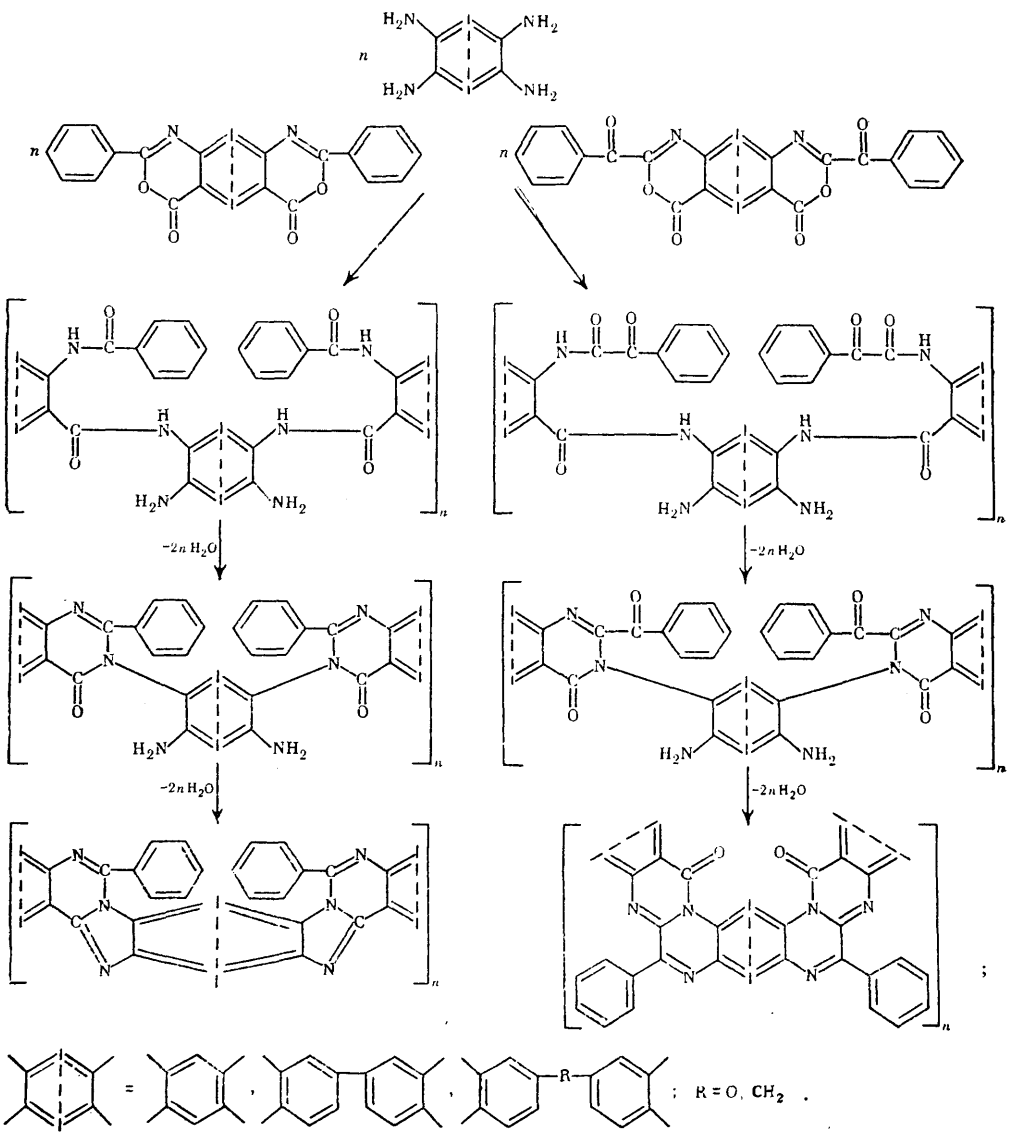
The poly(2-phenyl)quinazolinones obtained in this way do not contain unreduced nitro-groups and uncyclised fragments according to the infrared spectroscopic data for the polymers and model compounds. The polymers synthesised are soluble at room temperature in strong acids and phenols and on heating in dipolar and aprotic solvents. The viscosities η_{int} of poly(2-phenyl)quinazolinones are 1.02–1.21 dl g^{-1}, which makes it possible to obtain from these systems strong ($\sigma \leq 1200$ kg cm^{-2}) and fairly elastic ($\varepsilon \geq 12\%$) films. According to DTGA data and the results of isothermal thermogravimetric analysis (ITGA), the thermal stability of these polymers is comparable to that of identical systems obtained by the usual (see above) method[26].

The properties of phenylated and unsubstituted polyheteroarylenes have been by no means compared in all the systems examined above. However, analysis of the available data and systematic arrangement of the results scattered throughout the literature show that in the vast majority of cases the introduction of phenyl substituents into polyheteroarylenes leads to the following results:

1) the improvement of the solubility of polyheteroarylenes in organic solvents;

2) an increase of the resistance of polyheteroarylenes to thermo-oxidative degradation;

3) a decrease of the softening temperatures and hence an increase of the thermoplasticity of polyheteroarylenes.



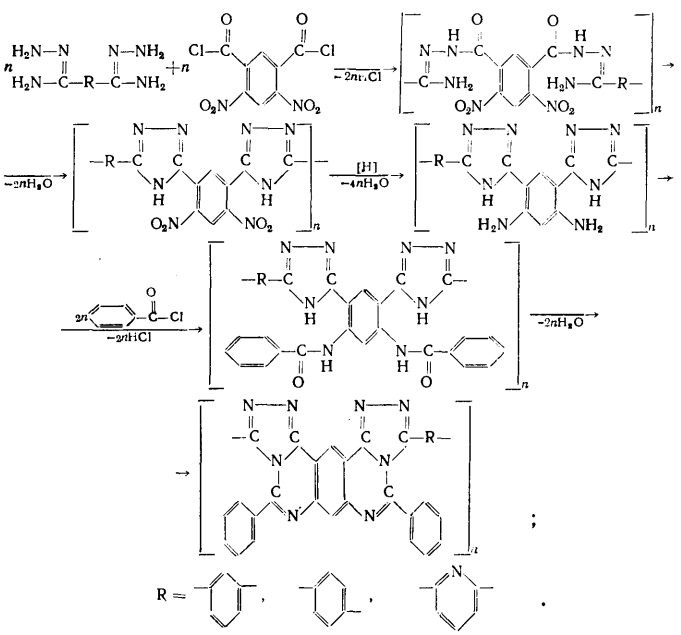
The latter factor facilitates the conversion of polyheteroarylenes into articles, but it limits the temperature ranges in which materials based on polyheteroarylenes can be used. As

a result, the synthesis of phenylated ladder polyheteroarylenes, i.e. systems containing highly condensed aromatic heterocycles in the main chains of the macromolecules, have become one of the most vigorously developing fields in the chemistry of phenyl-substituted polyheteroarylenes[99–101].

VI. PHENYLATED LADDER POLYHETEROARYLENES

The use by Hedberg et al. of aromatic tetra-amines with condensed rings, namely 2,3,7,8-tetra-aminodibenzofuran, 2,3,7,8-tetra-aminophenazine, 1,2,5,6-tetraminoanthraquinone, 2,3,11,12-tetra-aminodiquinoxalino[2,3-*e*: 2′,3′-1]pyrene, and 2,3,8,9-tetra-aminodiquinoxalino[2,3-*e*: 2′,3′-1]cyclopentanepentone for the synthesis of polyphenylquinoxalines[102] led to the formation of polymers soluble in *m*-cresol and at the same time having glass points exceeding 400 °C. Other examples of the synthesis of phenylated ladder polyheteroarylenes are reactions involving the formation of polyphenylquinoxalinoquinazolines[103] and polyphenylbenzimidazoquinazolines[104–106] by the reaction of aromatic bis(*o*-phenylenediamines) with bis(2-phenylbenzoxazin-4-ones) and 6,6′-(2-benzoylbenzoxazin-4-one) in accordance with Scheme 14.

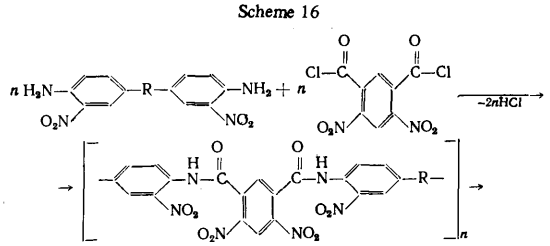
Scheme 14



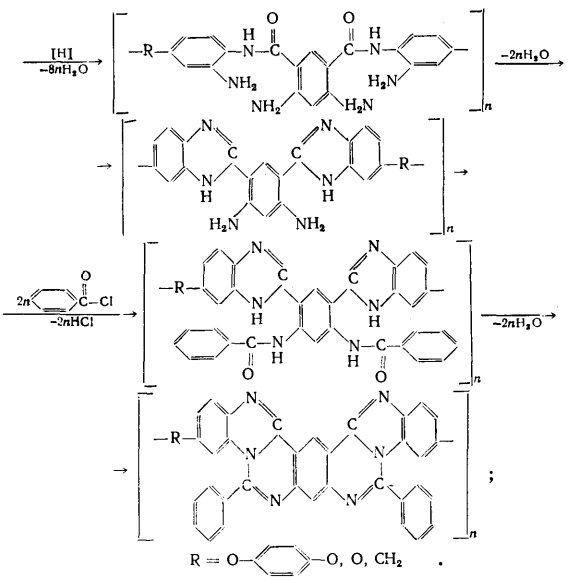
These reactions have been carried out in the melt, in phenolic solvents, or in PPA at elevated temperatures and led directly to the required polymeric structures without the isolation of intermediate systems. The polymers were soluble in acid and phenolic solvents and had a comparatively high thermal stability and heat resistance, but their viscosities (η_{int} up to 0.85) were insufficient to permit the preparation on their basis of materials with acceptable deformation-strength properties.

A number of phenylated ladder polyheteroarylenes have been obtained by the methods of modified and combined reductive polyheterocyclisation[87].

Phenylated polybenzo[di(*S*-triazolopyrimidines)], isomeric with previously known polymers, were obtained in the reaction of the dichloride of 4,6-dinitroisophthalic acid with the bisamidrazones of dicarboxylic acids and in the subsequent reactions of the resulting poly(*o*-nitro)aroylamidrazones[107, 108,109,110] (Scheme 15).



Scheme 15



The presence of phenyl side groups and the relatively mild conditions of the polycyclisation processes are responsible for the solubility of the resulting polymers in acid solvents (H_2SO_4 and CF_3COOH) and the 3 : 1 trichloroethane (TCE)–phenol mixture and for their partial solubility in hot MP. A comparative study of the thermal stabilities of polybenzo[di-(*S*-triazolopyrimidines)], synthesised by modified reductive polyheterocyclisation and by the two-stage method[109,110], showed that these systems are comparable.

When various bis(*o*-nitroanilines) were used as the comonomers of the dichloride of 4,6-dinitroisophthalic acid, phenyl-substituted polybenzo[di(pyrimidinobenzimidazoles)] were obtained[111,112] (Scheme 16).

Scheme 16

Phenyl substituents combined with mild conditions of the polycyclisation processes are responsible for the solubility of the polymers in the 3 : 1 TCE–phenol mixture, H_2SO_4, and CF_3COOH. The thermal stabilities of polybenzo[di(pyrimidinobenzimidazoles)] obtained by reductive polyheterocyclisation are comparable under ITGA conditions with those of polymers obtained by the two-stage method[109,110].

The softening temperature of polybenzo[di(*S*-triazolopyrimidines)] and polybenzo[di(pyrimidinobenzimidazoles)] are in the range 350–420 °C, depending on the structure of the polymers.

---o0o---

The introduction of phenyl substituents into polyheteroarylenes constitutes a reliable and effective method of increasing the solubility of the polymers and their overall capacity for being converted into articles. By varying the structure of the main macromolecular chains, it is possible to obtain phenyl-substituted polyheteroarylenes with softening temperatures from 250° to 400 °C and to generate a wide assortment of polymers of interest for the preparation of thermostable polymeric materials.

Thermophysical Properties of Irradiated Polymers

B.A.Briskman

The effect of ionising radiation on the specific heat, thermal conductivity, thermal diffusivity, and density of partially crystalline (polyethylene, polypropylene, polytetrafluoro-ethylene) and of amorphous polymers (polystyrene, poly(methyl methacrylate)) is discussed. Analytical models of the mechanism of heat conduction, and the development of anisotropic thermal conductivity in amorphous polymers, are examined. The influence of ionising radiation on the thermophysical properties of composite materials is analysed. 79 references.

I. INTRODUCTION

Information about the influence of ionising radiation on the thermophysical characteristics of polymeric materials is important, for two reasons. Firstly, because the thermal state of constructional materials used in the new technologies in the presence of powerful ionising radiations is determined by the thermal constants of these materials, and secondly because the structure of the polymer can be inferred from the temperature and dose dependence of the thermal conductivity and (even more directly) of the specific heat. Thus information on the phonon mechanism of energy transfer in polymers and on the phase composition of the partially crystallised materials can be obtained from the changes in thermal conductivity λ. Measurements of the specific heat c_p of solid polymers have been used to study molecular mobility, relaxation processes, phase transitions, etc.; the high precision of calorimetric methods over a wide temperature range ensures that the information is unambiguous.

In spite of the importance of the influence of ionising radiation on the thermophysical properties of polymers, very few experimental data have been published on this topic (compared, for example, with the number of data on radiation effects on the mechanical and dielectric properties of the same materials). This may be due to the practical difficulty of measuring λ, c_p, and the thermal diffusivity coefficient a, and to the shortage of apparatus offering adequate precision. Another reason is that marked changes in thermophysical properties are observed only for very high absorbed doses of radiation (up to tens of Mrad). This causes practical difficulties and necessitates the use of fairly powerful radiation sources.

Results so far reported indicate a large difference between the radiation effects in crystalline and in amorphous polymers. Published data on the effects of ionising radiation on the specific heat c_p, the thermal conductivity λ, the density ρ, the degree of crystallinity x, and the melting point will therefore be reviewed separately for partially crystalline and for amorphous polymers.

II. PARTIALLY CRYSTALLINE POLYMERS

There are two important differences between simple solids and solid linear polymers: the chemical structure of the polymers is far more complex, and their physical structure is often metastable, and variable for a given chemical structure. This makes the thermal properties of the polymers a function of the thermal history of the sample, and also of the heating rate (in dynamic experiments). Because of the strong influence of the thermal history on the structure of polymers, both amorphous and crystalline, most of the discrepancies in published data on radiation interaction with polymers can be explained by differences in morphology between the different samples.

1. Polyethylene

a) *Specific heat of polyethylene.* Though the specific heat of polyethylene (PE) has been studied over a wide range of temperature in many laboratories (see, for example, reviews in Refs.1 and 2), relatively little work has been done on the effect of irradiation on c_p[3-5]. Radiation effects on c_p have been studied only above 20 °C. Thus, PE of PE-500 grade with an initial density of 915 kg m^{-3} and c_p = 1.91 kJ kg^{-1} K^{-1} has been irradiated[4] with γ quanta from a ^{60}Co source up to a dose of 6.1 Mrad. The irradiation temperature T_i and the measurement temperature T_m were both ~ 30 °C. As the dose was increased, c_p fell monotonically to 1.45 kJ kg^{-1} K^{-1}. This decrease in specific heat was ascribed[4] to the formation of cross-links between the linear macromolecules, which lowers the number of internal degrees of freedom.

High-pressure PE (c_p = 918 kg m^{-3}) was irradiated[5] in air with ^{60}Co γ quanta at a dose rate of 7.5 rad s^{-1} and T_i = 40 °C to give a range of absorbed dose up to 50 Mrad. Each sample was subjected to at least two heating runs (heating rate ~ 1K min^{-1}). The temperature dependence of c_p between 20 and 70 °C was linear for the PE samples which had not

been irradiated. Beyond this range the increase of c_p becomes much steeper, suggesting the onset of melting of the crystalline phase. The melting point (T_f) was found to be 110 °C. In the range 110–113 °C a large exothermic effect was observed, and c_p fell steeply from ~ 11.0 to ~ 1.6 kJ kg^{-1} K^{-1}. Further heating to 120 °C increased c_p to 2.5 kJ kg^{-1} K^{-1}. Repeated heating of the same sample (using the cycle: first heating to 90 °C, cooling, second heating to 140 °C) lowers the melting peak (observed in the second heating period) by 2 K. In the region of 95 °C a pre-melting effect occurs during the second heating: a sharp increase in c_p from 3.7 to 6.5 kJ kg^{-1} K^{-1} followed by a decrease to 5.1 kJ kg^{-1} K^{-1}. Very similar effects are observed for c_p in irradiated samples (Fig. 1a–1c). The position of the c_p maximum on the successive curves of the repeated heating cycle coincides with the maximum heating temperature of the preceding run. This phenomenon persists until all the crystals initially present in the sample have been melted.

A large number of melting peaks on the curve of c_p against T for PE was reported also in Ref. 6. An increase in the absorbed dose caused a marked decrease in the height of the main melting peak: at 30 Mrad the peak became diffuse, and at 50 Mrad it disappeared completely. The pre-melting peaks disappeared at doses greater than 10 Mrad, and the 110–120 °C exothermic effects disappeared at doses greater than 5 Mrad. At the same time as the heat of melting, the melting point T_f also decreases (as shown by the coordinate of the specific heat maximum).

The initial model used to explain the changes in thermophysical properties of partially crystalline polymers is usually the classical two-phase model[7–9], even though the structure of polyethylene is quite different from that of an ideal two-phase system, and the presence of marked relaxation processes in PE (pre-melting region) is well recognised. Godovskii[10] has criticised the hypothesis of a crystalline phase embedded in an amorphous matrix.

According to published data on the temperature dependence of c_p, the melting processes can extend over the temperature region 80–113 °C. This is evidence of a wide range of crystallite sizes, each crystalline formation having its own melting point. The "boundary melting" effect discussed in Ref. 11 may also be partly responsible for the wide melting range of these materials.

The nature of the non-equilibrium melting process is determined by the previous history of the sample: the situation is further complicated by the possibility of new partial crystallisation at a stage during the melting process when the temperature is quite high and the relative amount of crystalline phase is substantially decreased. This possibility is confirmed by the exothermic effects in the pre-melting region of both the irradiated and the non-irradiated PE.[5] When the system reaches a high enough temperature all the crystals suddenly melt. A similar phenomenon was observed in a study[12] of the thermodynamic behaviour of PE single crystals. The gradual flattening out of the $c_p = f(T)$ curve with increase in the absorbed dose is obviously caused by a

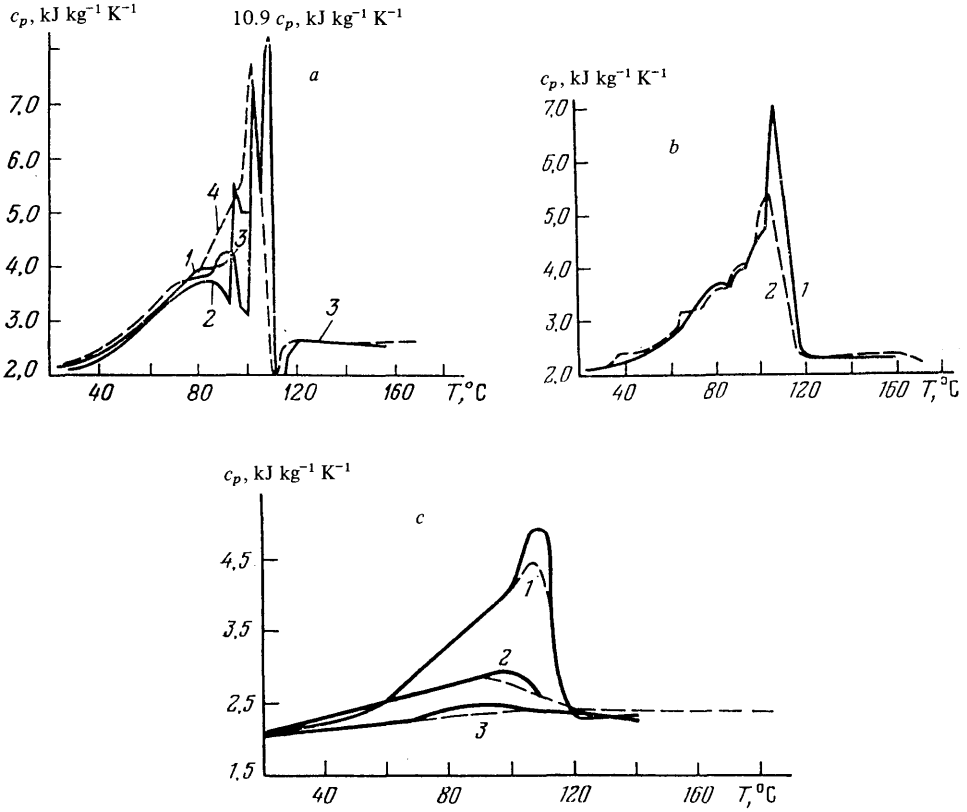

Figure 1. Temperature dependence of the specific heat of high-pressure polyethylene. (*a*) 2 Mrad dose, heated to different temperature: 1) 90, 2) 100, 3) 150, 4) 160 °C. (*b*) 5 Mrad dose: 1) first heating, 2) second heating. (*c*) different doses: 1) 10, 2) 30, 3) 50 Mrad (full lines denote first heating, broken lines second heating[5]).

decrease in crystallinity. The characteristic decrease in T_f and in the c_p maximum observed in all the samples subjected to heating cycles may be due to a decrease in size of the crystallites formed in the polyethylene during the cooling period.

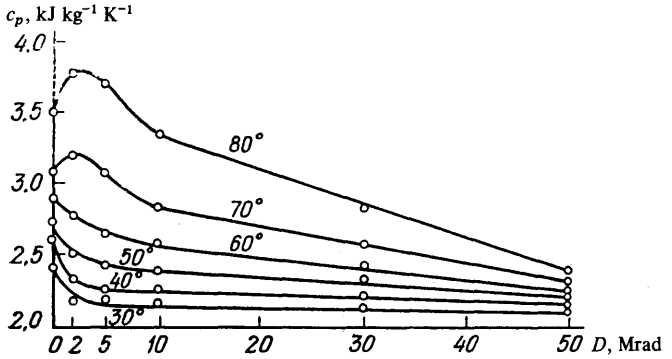

Figure 2. Dependence of the specific heat of high-pressure polyethylene on the dose of radiation for different measurement temperatures[5].

Plots of c_p against the absorbed dose are shown in Fig.2 for different measurement temperatures T_m.[5] In the 30–50 °C temperature range the parameter c_p decreases monotonically as the dose increases, but at and above 70 °C it goes through a maximum at D = 2 Mrad. Since c_p is higher for an amorphous than for a crystalline PE phase[13], the decrease in crystallinity produced by the irradiation should make the specific heat vary in the same sense as the dose. However, when the PE molecules become cross-linked the increased rigidity of the system (or, in other words, the loss of internal degrees of freedom) causes c_p to decrease. Evidently, at 30–50 °C the cross-linking process predominates over the amorphisation process for the whole range of doses. At T_m = 70 °C (and above) the intensification of the melting process increases the relative amount of amorphous phase, and the specific heat can therefore increase for doses up to ~ 2 Mrad, but at higher levels of cross-linking c_p begins to decrease with increasing dose.

Some of the published data on the effect of radiation-induced cross-linking on T_f in PE crystals are contradictory. Both a decrease in T_f with increase of dose[14] and an almost constant T_f[15] have been reported. Ushakov and co-workers[16] irradiated low-pressure PE samples (LPP) in the solid state (T_i = 45–50 °C) and as melts (T_i = 130–140 °C). In the solid samples T_f fell from 135 to 118 °C for a dose of ~ 5.5 Mrad, rising again to 124 °C at a dose of 11 Mrad, whereas irradiation in the melt lowered T_f to 50 °C even at a dose of 5.5–6 Mrad. For high-pressure polyethylene (HPP) at T_i = 45–50 °C the melting point T_f goes through a minimum as the dose increases (~ 107 °C for D = 6 Mrad), and then rises again to its original value (113 °C for D = 11 Mrad). As was stated above, T_f for HPP has been found[5] to decrease from 110 to 106 °C as the dose is increased to D = 10 Mrad. The maximum T_f value for the diffuse endothermic peak at a dose of 30 Mrad was 100 °C.

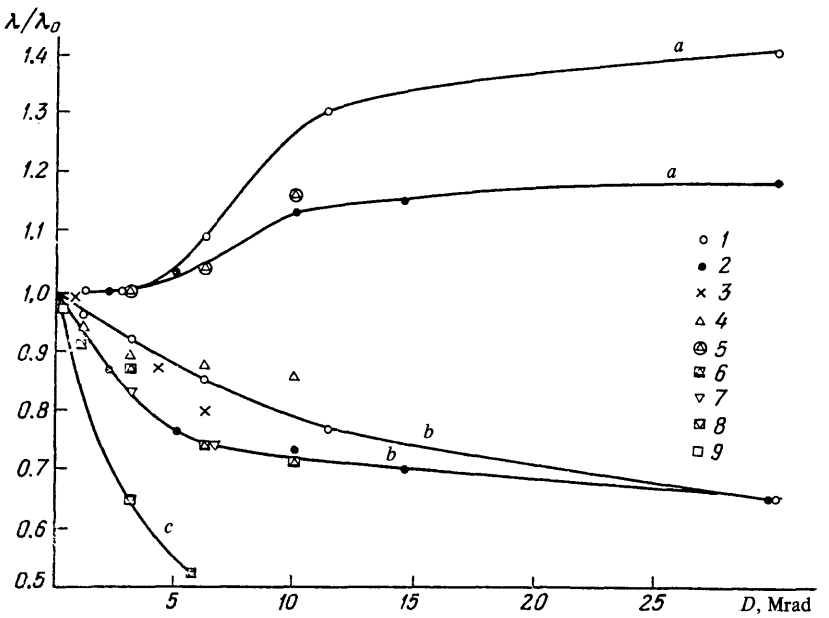

Figure 3. Relative thermal conductivity of polyethylene as a function of dose of radiation for different measurement temperatures [30 °C (*a*), 150 °C (*b*), and −150 °C (*c*)]. HPP: 1) from Ref.17, 2) from Ref.19, 3) from Ref.4, 4) from Ref.18, 5) from Ref.18, 6) from Ref.18; LPP: 7) from Ref.18, 8) from Ref.18, 9) from Ref.9.

Radiation-induced cross-linking causes a decrease in the degree of crystallinity and in the size of the crystallites, which lowers T_f, but on the other hand it also imposes some molecular order within each crystal, as shown by measurements of double refraction in spherulites of irradiated PE.[16] This local ordering effect causes an increase in T_f. As a result, the real behaviour of T_f in particular samples of PE becomes a function of the initial crystallinity and of the irradiation temperature.

The decrease in T_f to 105 °C in the second heating run (mentioned above) is practically constant for doses up to 10 Mrad.[5] PE has a "memory", and when the sample is cooled new crystals are formed on the original sites, but these are smaller as a result of cross-linking in the crystalline phase and they melt at lower temperatures. Since the thermal conditions for recrystallisation are approximately the same in different samples, we can expect constant values of the crystallite size and therefore also of T_f.

b) Thermal conductivity and density of polyethylene. As in the case of the specific heat, the effect of irradiation on the thermal conductivity λ of polyethylene is largely determined by the irradiation conditions and by the initial crystallinity of the polymer. Studies of radiation effects on λ in PE are mentioned in several papers[3,4,9,17-19]. Since λ is higher in a crystalline than in an amorphous phase (the mean free path of phonons being longer in crystals than in amorphous phases, where it is limited by the disordered arrangement of the atoms to a value of the same order as the interatomic distance) we can expect a decrease in λ in irradiated polyethylene. But at the same time the cross-linking of the molecular chains increases the packing density of the macromolecules, thus increasing the effective mean free path of the phonons, i.e. increasing λ. As a result, the behaviour of the thermal conductivity in irradiated samples depends on the relative magnitude of these competing processes.

Data on the relative changes in λ for HPP and LPP as a function of dose of radiation are shown in Fig.3. Some workers[4,9] irradiated their samples with γ quanta at T_i = 30 °C, others[18] used an electron beam (E = 1 MeV) giving a dose rate of 1.7 krad s^{-1} and absorbed doses up to 10 Mrad. In Refs.17 and 19 mixed radiation from a reactor was used at T_i = 80 °C. In Fig.3 curves *a* and *b* are drawn through the experimental points of Refs.17 and 19 for T_m values of 150 and 30 °C respectively, and curve *c* is drawn through the points of Ref.9 (T_m = −150 °C, LPP). The difference between the results from Refs.17 and 19 may be due to differences in the crystallinity of the initial samples. In the range of measurement temperatures (T_m) from −150 to 80 °C the λ value of polyethylene decreases as the absorbed dose is increased to ~ 20 Mrad (see Fig.4 below), indicating amorphisation of the polymer by the radiation. A gradually increasing contribution from radiation-induced cross-linking effects eventually stops the changes in λ, assisted by the increasing contribution from degradation processes. At the higher measurement temperatures ($T_m > T_f$) the crystallinity of the sample is low (or zero). Therefore the changes in λ due to radiation-induced cross-linking become more marked. However, the processes responsible for changes in λ are gradually inhibited by polymer degradation effects.

The influence of dose on λ at $T < T_f$ is more marked below the glass transition temperature (T_g) than in the region $T_g < T < T_f$. From the standpoint of the two-phase model this is explained by the strong temperature dependence of the thermal conductivity of the crystalline phase ($\lambda_{cr} \propto 1/T$) as compared to that of the amorphous phase (λ_a). As a result, the difference $\lambda_{cr} - \lambda_a$ increases sharply as the temperature falls. Under these conditions the effect of the dose of radiation, which lowers the crystallinity, becomes much stronger.

The effect of the irradiation temperature T_i on the changes in λ in polyethylene is shown in Fig.4, using data from Ref.19. We should note that a visual examination of the cross-section of samples irradiated at T_i = 80 °C (dose rate P = 200 rad s^{-1}) revealed small pores when the dose exceeded 2 Mrad, whilst at higher doses even cracks were observed. The number and size of these defects increased with the dose, suggesting gas evolution during irradiation. At T_i = 30 °C (P = 13 rad s^{-1}) the gaseous hydrolysis products can diffuse into the surroundings without producing large internal stresses. It is clear from Fig.4 that though the curves for two series of measurements at different irradiation temperatures have the same shape, the absolute values of λ are 15–20% lower for T_i = 80 °C than for T_i = 30 °C. This is due to differences in crystallinity and porosity between the samples. As the temperature of the sample increases, the degree of crystallinity decreases, and the thermal resistance of the pores decreases because of the increasing contribution from radiative heat transfer[20]. The net result is a decrease in the difference between the λ values for two series of experiments as a function of dose for T_i above 80 °C. Thus for T_i = 30 °C and a dose of 23 Mrad the difference between the λ values is 19%, and for T_i = 100 °C it is 8%.

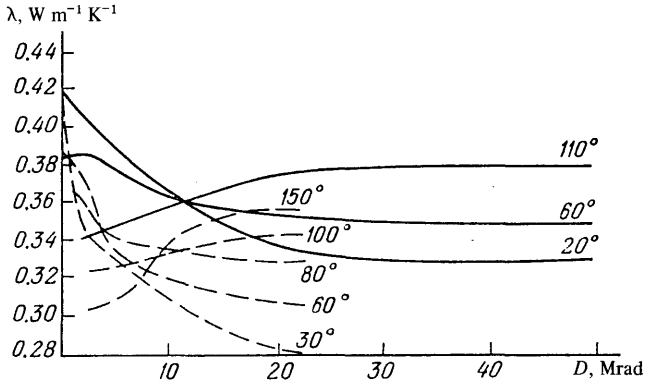

Figure 4. Dependence of the thermal conductivity of high-pressure polyethylene on the dose of radiation for different measurement temperatures (full curves for T_i = 30 °C, broken curves for T_i = 80 °C[19]).

A high initial crystallinity results in a steeper dose dependence of the λ value of polyethylene. Thus[9] even at a dose of 0.3 Mrad the λ value of polyethylene of density ρ = 947 kg m^{-3} is decreased by 3%. The difference in the behaviour of λ between HPP and LPP is clearly shown in Fig.3.

The thermal conductivity of polymers is known to be closely correlated with their density, since an increase in density causes an increase in the phonon mean free path, and hence in λ. Evidently, changes in density induced by radiation should also depend on the irradiation temperature. It has been shown[21] that irradiation of HPP with doses of up to 20 Mrad produces a minimum on the $\rho = f(D)$ curve at D = 5 Mrad (T_m = 20 °C), while the density increases monotonically from ρ = 780 to ρ = 890 kg m^{-3} at D = 20 Mrad (T_m = 150 °C). Data[17,19,22] on the effect of irradiation temperature (T_i) on the shape of the $\rho = f(D)$ curves for HPP are shown in Fig.5. In every case the temperature of the sample during the measurement (T_m) was 20 °C.

Analogous results were obtained[23] by using mixed (gamma and neutron) radiation at T_i = 80 °C. In this case the density minimum was obtained at a dose of 4–5 Mrad. On the other hand, measurements for T_i = 30 °C gave a monotonic increase in ρ with dose of radiation[4] from the initial value of 915 kg m^{-3} to 1005 kg m^{-3} for D = 6.1 Mrad.

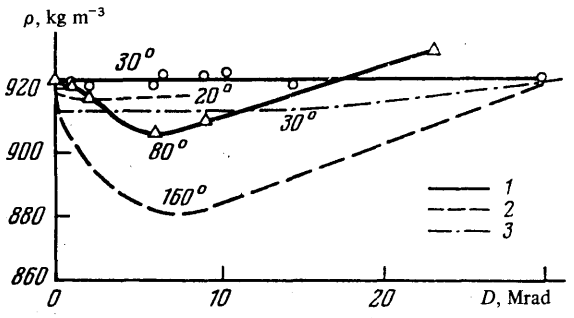

Figure 5. Density of high-pressure polyethylene against dose of radiation for different irradiation temperatures: 1) from Ref.19, 2) from Ref.22, 3) from Ref.17.

The mechanism of the change in density of polyethylene is exactly the same as that described above for the thermal conductivity. For relatively low values of T_i (20–30 °C) the amorphisation of the PE (which causes ρ to decrease, since $\rho_{cr} > \rho_a$) is largely compensated by the radiation-induced cross-linking. Under these conditions ρ either remains constant over a wide range of doses or increases slightly. An increase in T_i causes a large increase in the rate of amorphisation without a proportionate increase in cross-linking. The result is a decrease in ρ for polyethylene irradiated with doses up to 5 Mrad, followed by an increase.

The presence of a minimum on the $\rho = f(D)$ curve for T_i = 160 °C (T_f) is due to partial recrystallisation of the sample during the cooling period after irradiation. A monotonic increase in density with dose of radiation for T_i = 150 °C can be obtained[21] by very slow (near-equilibrium) cooling of the sample after irradiation, or by using a preliminary anneal.

Table 1. Thermal diffusivity of irradiated polyethylene[19].

D, Mrad	$10^7 a$, m^2 s^{-1}			D, Mrad	$10^7 a$, m^2 s^{-1}		
	20° C	40° C	80° C		20° C	40° C	80° C
0	2.00	1.71	1.13	10	1.90	1.88	1.21
2	1.99	1.85	1.15	20	1.74	1.79	1.33
5	1.94	1.91	1.18	30	1.69	1.74	1.41

c) *Thermal diffusivity of polyethylene.* Table 1 gives the thermal diffusivity values (a) of irradiated PE, calculated by the formula $a = \lambda/c\rho$ from the results of Ref.19 for T_i = 30 °C. According to Samoilov[4], radiation-induced changes in the thermal diffusivity of PE measured at $T_m \approx 20$ °C are undetectable for doses up to 6 Mrad. This is not inconsistent with the previous results[19], since the change in a found for the same range of radiation doses with T_m = 20 °C was less than 5%. The dependence of a on the absorbed dose is determined mainly by the behaviour of the thermal conductivity characteristics.

d) *Thermophysical properties of the amorphous phase, and crystallinity of polyethylene.* Our calculations of these properties[24] were based on the two-phase model of PE. Since cross-linking under the influence of radiation occurs mainly in the amorphous phase, the thermophysical characteristics of the crystalline phase were assumed to be constant.

The temperature dependence of the specific heat of the crystalline phase (c_{cr}) and of the amorphous phase (c_a) in non-irradiated PE was calculated as in Ref.8; the corresponding values of λ_{cr} and λ_a have been reported previously[25,7], and also those of ρ_{cr} and ρ_a.[26] The calculations of λ_a were carried out[7] with samples having different initial levels of crystallinity (x). In our experiments[24] changes in x were carried out by irradiation, using published data[5,19,20].

The parameter x was measured[24] either from the specific heat of polyethylene irradiated at T_i = 30 °C or from the density of PE for T_i = 80 °C. The values of $c_{cr} = f(T)$ used in the calculations[24], taken from Refs.7–9, are internally consistent and very reliable.

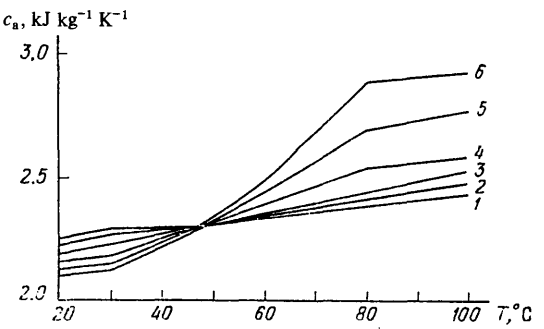

Figure 6. Temperature dependence of the specific heat of the amorphous phase of polyethylene for different doses of radiation[24]: 1) 0, 2) 2, 3) 5, 4) 10, 5) 20, 6) 30 Mrad; T_i = 30 °C.

The method of determining the specific heat c_a of irradiated PE consisted in a linear extrapolation of the experimental plot of c_p for PE samples fully amorphised by irradiation to the value c_a for D = 0.[8] The dose of radiation corresponding to full amorphisation of polyethylene was taken to be 30 Mrad. It was found (Fig.6) that in the range of doses between 0 and 30 Mrad and for T_m less than ~ 50 °C the c_a values decrease with dose as a result of radiation-induced cross-linking (by 10% at T_m = 20 °C). For T_m = 50–100 °C on the other hand the c_a values increase with dose (by 20% at T_m = 100 °C). In this region of temperature the predominant role is played by the decreased rigidity of the amorphous matrix resulting from the breakdown of the crystals.

Exact determination of the degree of crystallinity x of polymers is often difficult. The most accurate (though laborious) method is the calculation of x from calorimetric data, using the expression

$$c = c_a[1 - x(T)] + c_{cr}\, x(T) + \Delta H \partial x/\partial T, \qquad (1)$$

where ΔH is the heat of melting of the polymer. Most workers[8,27] ignore the dependence of x on T and use the simplified expression

$$c = c_a(1 - x) + c_{cr} \cdot x,$$

which can lead to serious errors at high temperatures. Shimchuk and co-workers[28] used Eqn.(1), but they avoided solving the differential equation by making the substitution

$$c = c_{cr}\, x + (1 - x)c_a + b\Delta H$$
$$x = a - b(T - T_f);\ b = -\mathrm{d}x/\mathrm{d}T\ .$$

In the differentiation of the expression for x the non-linear terms were ignored[28], because their effect is appreciable only at high temperatures. Because of these assumptions the melting point of the crystals was incorrectly calculated as 80 °C.

To determine $x = f(D,T)$ we have re-written Eqn.(1) as[24]

$$\frac{\partial x(D,T)}{\partial T} + \frac{1}{\Delta H}[c_a(D,T) - c_{cr}(T)]\, x(D,T) = [c_a(D,T) - c(D,T)]\frac{1}{\Delta H} \qquad (2)$$

with the boundary condition $x = 0$ for $T = T_f = \phi(D)$. The parameter ΔH for PE was found to be 277 J g^{-1} (according to Refs.8 and 29), 275 J g^{-1} (Ref.30), and 271 or 280 ± 9 J g^{-1} (Ref.31). In the solution of Eqn.(2) a value of ΔH = 276 J g^{-1} was used.

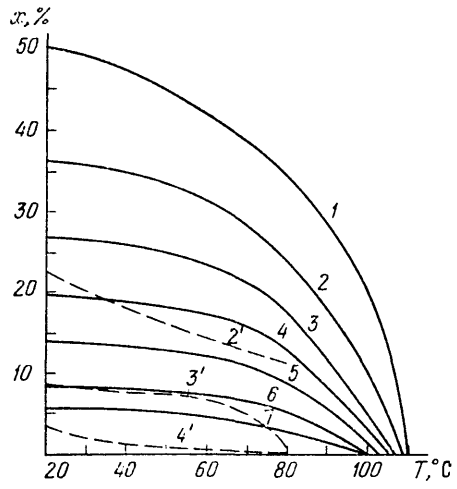

Figure 7. Temperature dependence of the crystallinity of polyethylene for different doses of radiation: 1) 0, 2) and 2') 2, 3) and 3') 5, 4) and 4') 10, 5) 15, 6) 20, 7) 25 Mrad (full lines T_i = 30 °C, broken lines T_i = 80 °C[24]).

The results (Fig.7) of our numerical integration[24] of Eqn.(2) show that the degree of crystallinity of PE decreases at temperatures above T_m = 30 °C (full curves, T_i = 30 °C). The behaviour of x for D = 0 is consistent with earlier results[32,33] and confirms the general validity of our method[24].

The $x = f(D)$ dependence shown in Fig.7 agrees on the whole with the results[21] obtained by Nikitina for 20 °C. The only exception is the dose for full amorphisation, which Nikitina gives as 20 Mrad.

It has been reported[34] that when HPP with an initial crystallinity of 50% is irradiated with a dose of up to 2 krad the x value falls to 33%, rising again to 50% for a dose of 1 Mrad before decreasing once again. The temporary restoration of the crystallinity during irradiation is ascribed to the photochemical breaking of the distorted bonds in the keto groups formed by irradiation in air. It is suggested[34] that in this case some of the units can be accommodated in the crystalline lattice. However, this hypothesis is not confirmed by our results.

The degree of crystallinity can be calculated from the densities ρ or from the specific volumes v of the separate phases: the crystallinity by weight is given by the formula

$$x = \frac{v_a - v}{v_a - v_{cr}} = \frac{\rho_{cr}}{\rho}\frac{\rho - \rho_a}{\rho_{cr} - \rho_a} = \frac{1 - \rho_a/\rho}{1 - \rho_a/\rho_{cr}}$$

and the crystallinity by volume by the formula

$$\gamma = \frac{\rho - \rho_a}{\rho_{cr} - \rho_a} = \frac{\rho}{\rho_a}\, x \qquad (3)$$

Table 2. Density of the amorphous phase of polyethylene.

T_m, °C	ρ_a, kg m^{-3}	
	(Ref.24)	(Ref.26)
20	855	855
40	842	842
60	830	829
80	818	817

The density of the amorphous phase ρ_a can be determined by extrapolating to room temperature the ρ values measured at $T > T_f$. Ross[23] obtained a ρ_a value of 877 kg m^{-3} at T_m = 20 °C for HPP irradiated to D = 4 Mrad by extrapolation to D = 0, and 853 kg m^{-3} for non-irradiated HPP. By using Eqn.(3) for T_i = 30 °C, and data on crystallinity obtained in Ref.24, we have calculated[24] the $\rho_a = f(D,T)$ dependence (see Fig.8, full lines). Over the whole range of radiation doses (up to 30 Mrad) ρ_a increases with dose as a result of radiation-induced cross-linking. The increment $\Delta\rho_a$ for a dose of 30 Mrad is 8–10%. In the range of T_m = 20–80 °C the parameter ρ_a decreases monotonically with temperature for all doses of radiation, and the temperature coefficient is practically independent of the dose (~ 6 × 10^{-4} K^{-1}). The ρ_a value for non-irradiated PE agrees very well with published data[26] (see Table 2). The results of Ross mentioned above[23] on the ρ_a value of irradiated HPP are also consistent with our calculation[24], confirming the validity of the proposed method for calculating crystallinity and for determining the $c_a(D)$ relationship[24].

To calculate the ρ_a values of HPP irradiated at T_i = 80 °C we used[24] a linear extrapolation of the experimental densities ρ for D = 10–15 Mrad (corresponding to complete amorphisation of the PE) to D = 0. The ρ_a values obtained in this way (Fig.8, broken curves) are higher than the ρ_a values for T_i = 30 °C, the largest difference corresponding to the measurement temperature T_m = 80 °C. This dependence of the density ρ_a on the irradiation temperature is probably due

to an increase in the yield of radiation-induced cross-links, which has been found[35,36] to increase four-fold as the irradiation temperature is varied from −196 to +73 °C.

By combining these values of ρ_a with Eqn.(3) we calculated the degrees of crystallinity $x(D,T)$ for T_i = 80 °C (shown in Fig.7 as broken curves). As could have been expected, the crystallinity of PE decreases steeply as the irradiation temperature is increased.

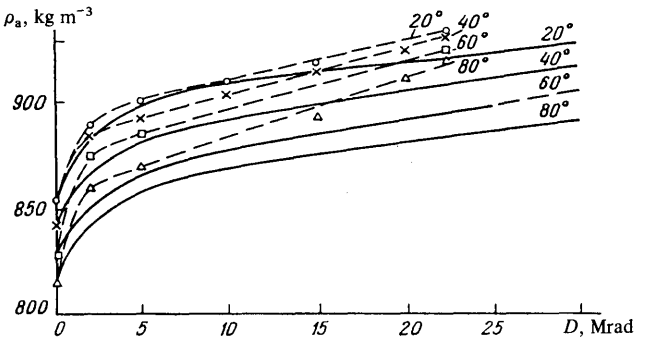

Figure 8. Density of the amorphous phase of polyethylene against dose of radiation for different measurement temperatures: full lines for T_i = 30 °C, broken lines for T_i = 80 °C[24].

The thermal conductivity λ_a of the amorphous phase of non-irradiated PE has been discussed in many papers[7,37-40], usually in terms of the two-phase Maxwell–Eucken model:

$$\lambda = \frac{2\lambda_a + \lambda_{cr} + 2\gamma(\lambda_{cr} - \lambda_a)}{2\lambda_a + \lambda_{cr} - \gamma(\lambda_{cr} - \lambda_a)}\lambda_a \quad . \qquad (4)$$

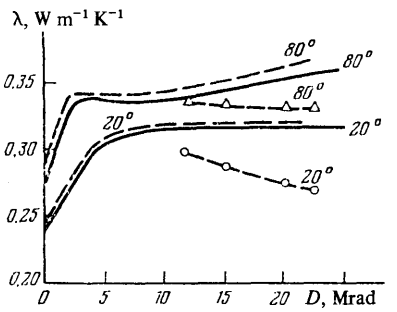

Figure 9. Thermal conductivity of the amorphous phase of polyethylene against dose of radiation for different measurement temperatures: full lines for T_i = 30 °C, broken lines for T_i = 80 °C. The broken lines with experimental points are for samples containing pores (T_i = 80 °C)[24].

Some workers[41,42] have used the Bruggeman model[43] and the Cheng–Vachon model[44] to determine the thermal conductivity of two-phase solid systems. It has been shown[7] that λ_a increases with temperature up to the glass transition temperature T_g = −20 °C, and decreases slightly at higher temperatures. This type of temperature dependence of λ_a has been explained by postulating[7] a constant value of the volume crystallinity γ. However, the same type of $\lambda_a = f(T)$ dependence is obtained[37] even allowing for the temperature dependence of γ. A different model[9] of the disposition of the crystallites in the amorphous matrix gave λ_a values lower than those of Ref.7 without affecting the shape of the temperature dependence. The decrease of λ_a with increase of temperature above T_g is explained[39] in terms of the increased free volume of the molecules. A proposed[40] generalised relationship between λ_a and the fractional free volume for amorphous polymers at temperatures above T_g implies a decrease in λ_a with increase in temperature (we note that data from Ref.7 were used for PE in these calculations). On the other hand, Hattory found[38] that λ_a for PE increases monotonically in the range 20–100 °C, and he explained this by postulating excitation of micro-Brownian motion of the polymer molecules at temperatures above T_g. Similar conclusions were reached by other workers[45,46].

We have calculated[24] the effect of irradiation on λ_a for irradiation temperatures of 30 and 80 °C, using the Maxwell–Eucken model [Eqn.(4)] with the x values given in Fig.5 and λ_{cr} values from Ref.7. Increasing the dose to 5 Mrad produced a marked increase in λ_a (15%). Beyond this point λ_a increased more slowly (see Fig.9). The $\lambda_a = f(D)$ curve is identical in shape to $\lambda = f(D)$ for almost completely amorphous PE at T_m = 110 °C (see Fig.4).

Table 3. Effect of porosity on the thermal conductivity of amorphous polyethylene[24].

T_m, °C	$(1 - \lambda_{ae}/\lambda_a) \times 100$, %	
	D = 12 Mrad	D = 13 Mrad
20	6.0	16.0
40	5.8	13.0
60	5.3	11.4
80	4.1	9.8

The λ_a values for T_i = 80 °C could not be determined by this method because the samples of irradiated PE were found to be porous. It was argued[24] that for a given dose of radiation the ratio λ_a/ρ_a must be independent of the irradiation temperature, since the same mechanism was assumed to apply to both radiation-induced changes. The λ_a values obtained in this way were 2–4% higher than those for T_i = 30 °C: they correspond to the thermal conductivity which would be observed in samples without pores. By comparing these results with experimental data for λ_a (T_i = 80 °C) obtained at doses greater than ~ 10–12 Mrad (λ_{ae}), and therefore with almost fully amorphised PE, the influence of pores and cracks on λ_a was determined (see Table 3). The effect of porosity increases with dose of radiation and decreases with temperature.

It follows from those results[24] that an increase of T_m from 20 to 80 °C increases λ_a by 10%, which agrees with some published results[38,45,46] but not with others[7,9,37,39]. Evidently, in practice the dependence of λ_a on T_m is determined by the relative importance of two processes: the increase in free volume and the micro-Brownian motion of the sections of the polymer chain.

We have calculated the reliability of these results by allowing for the experimental error. Our analysis showed that if the measurement error of λ is ±4% the Maxwell–Eucken model

(like many other models) cannot give a reliable indication of the variation of λ_a with temperature, since the changes in this parameter between 20 and 80 °C are only 5–15% and lie within the uncertainty limits of the calculation. We must therefore conclude that the nature of the temperature dependence of λ_a in PE is still a live issue.

Nevertheless the gradual damping of the increase of λ_a produced by an increase in the absorbed dose[24] seems to support the micro-Brownian motion mechanism, since an increase in the number of radiation-induced cross-links should suppress this motion more rapidly than it lowers the molecular free volume.

2. Polytetrafluoro-ethylene

a) Density and crystallinity of polytetrafluoro-ethylene. Polytetrafluoro-ethylene (PTFE) is a partially crystalline polymer in which the degree of crystallinity (unlike that of PE) is increased by irradiation, even with small doses. This behaviour is explained by assuming the formation of molecular fragments (during the radiation-induced degradation) which can combine to form small crystallites[74,48]. Quantitative results on the increase in crystallinity caused by irradiation have been published by various workers[19,49–52]. The following dependence of the density ρ (kg m^{-3}) on the crystallinity x has been proposed[53]

$$\rho = 2000 + 300\,x \ .$$

Table 4. Density and crystallinity of polytetrafluoro-ethylene.

* Data for two samples with different initial densities.
** Irradiated *in vacuo*.
*** Irradiated in air. Density measured by i.r. spectroscopy.

Data on the effect of irradiation with γ quanta from ^{60}Co on the density and crystallinity of PTFE (for $T_m \cong 20$ °C) are given in Table 4. According to Ferse and co-workers[52] the volume of the pores produced in the samples by the irradiation was 0.57% for a dose of 10 krad and 1.4% for a dose of 40 krad. The melting point of PTFE decreases (as the dose of radiation is increased) from 340 °C for $D = 0$ to 334 °C for $D = 10$ krad and 314 °C for $D = 1$ Mrad[51]. This decrease in T_f is discussed by the authors in terms of an increase in the density of radiation-induced cross-links.

b) Thermal conductivity of polytetrafluoro-ethylene. Radiation-induced change in λ for PTFE have been observed[19,49]. It was found[49] that λ is practically independent of T_m between 10 and 180 °C, with a value close to 0.27 W m^{-1} K^{-1}. Small changes in λ were observed at $T_1 = 20$ °C and $T_2 = 125$ °C, and ascribed to a phase transition of the first kind in the crystal lattice of PTFE (T_1) and to relaxation processes in the amorphous phase (T_2). Irradiation with γ quanta from ^{60}Co to a dose of 1.9 Mrad (dose rate ~ 24 rad s^{-1}) gave a decrease in λ by 8%. At the same time T_1 fell by 1 K for $D = 0.05$ Mrad and by 14 K for $D = 1.9$ Mrad, while T_2 increased.

The changes in λ in PTFE can be explained by the two-phase model of a polymer. The λ value for the crystalline phase increases with temperature[7], since in complex crystals (like those of PTFE) the mean free path of phonons L is comparable to the mean free path for the amorphous phase. This can explain[7] the similarity between the temperature dependences of λ_{cr} and of λ_a. The relationship between λ_{cr} and λ_a for PTFE has been expressed in terms of the corresponding densities[54] as

$$d\lambda/\lambda = 5{,}8\ d\rho/\rho \ .$$

Since $\lambda_{cr} > \lambda_a$, the λ values for PTFE should increase with the degree of crystallinity, as has indeed been reported[53]. A decrease in λ on irradiation, accompanied by an increase in crystallinity, has been ascribed to porosity effects[49].

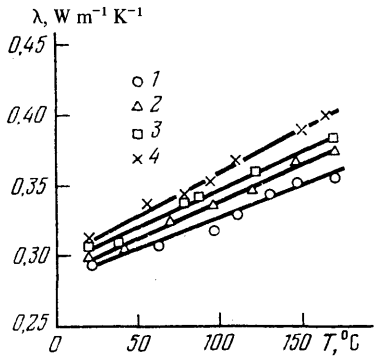

Figure 10. Temperature dependence of the thermal conductivity of polytetrafluoro-ethylene for different doses (D, Mrad): 1) 0, 2) 0.04, 3) 0.17, 4) 1.26[19].

A 6–12% increase in λ, depending on the measurement temperature, has also been observed[19] (as expected) in PTFE irradiated with γ quanta from ^{60}Co to a dose of 1.26 Mrad at a dose rate of ~ 8 rad s^{-1}. At the same time, and in contrast to earlier work[49], a monotonic increase of λ by 20–25% in the temperature range 20–170 °C was observed[19] in both non-irradiated and irradiated samples (Fig. 10).

The problem of the temperature dependence of λ in polytetrafluoro-ethylene is not yet fully resolved. Some workers[45,49,55,56] found λ to be practically independent of temperature, whereas others[19,57,58] noted an increase of λ with temperature above 0 °C. Irradiation produces an increase in λ.

3. Polypropylene

Tomlinson and Kline[59] have reported the effect of γ radiation (^{60}Co) on the density and specific heat of isotactic polypropylene (PP) at temperatures between 0 and 160 °C, doses up to 18 Mrad, and a dose rate of 26 rad s^{-1}. The initial crystallinity of the samples (x_0) was 60%.

The λ value of non-irradiated PP samples increases from 0.188 W m^{-1} K^{-1} at 0 °C to 0.200 W m^{-1} K^{-1} at 80 °C before decreasing monotonically to 0.130 W m^{-1} K^{-1} at 160 °C (Fig.11). Melting occurs in the range 127–167 °C; the melting peak corresponds to a temperature of 161 °C.

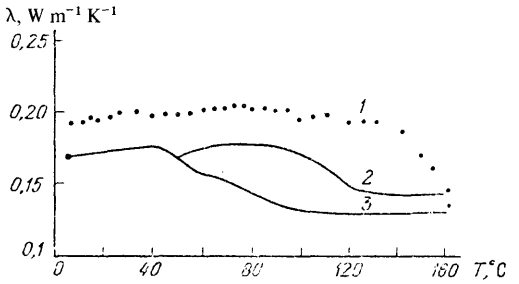

Figure 11. Temperature dependence of the thermal conductivity of polypropylene for different doses (D, Mrad): 1) 0, 2) 6, 3) 18[59].

Irradiation of PP causes breakdown of the crystals. The crystallinity is determined from the area under the exothermic melting peaks as x = 44% for D = 6 Mrad and x = 9% for D = 18 Mrad. Repeated heating does not affect the x value for D = 0, but it lowers the crystallinity from 44 to 14% for D = 6 Mrad and from 9% to 0 for D = 18 Mrad. These changes in crystallinity suggest a decrease in the size of the crystallites with increase in the dose of radiation, and this hypothesis is confirmed by the shift of the melting peak from 161 to 105 °C for D = 6 Mrad and to 63 °C for D = 18 Mrad. The density of PP at 20 °C decreases from 907 for D = 0 to 889 kg m^{-3} for D = 18 Mrad.

As in polyethylene, the λ value of PP decreases with dose of radiation. The maximum change in λ is 30%, and occurs at ~ 100 °C. At temperatures above T_m = 120 °C the thermal conductivity of irradiated samples becomes practically independent of temperature.

III. AMORPHOUS POLYMERS

The extent of radiation-induced changes in the thermophysical characteristics of amorphous polymers is determined mainly by the relative rates of radiation-induced cross-linking and degradation processes respectively. In polymers with a low radiation yield of cross-links, like polystyrene, we cannot expect marked changes in thermal properties. Polymers which suffer degradation under the influence of radiation, like poly(methyl methacrylate), will show changes in these properties: for example, a decrease in thermal conductivity.

1. Polystyrene

a) Specific heat of polystyrene. The specific heat of polystyrene (PS) at helium temperatures has been studied[60] with 2–16 Mrad doses of radiation consisting of 80 MeV electrons. In the calculation of the radiation-induced changes by the continuum model the effect expected from the deformation of the acoustic phonon spectrum was less than 0.5%: the effect actually found amounted to 25%.

The following is a possible mechanism for the change in c_p under the influence of irradiation. An important contribution to the low-temperature specific heat of amorphous polymers comes from low-frequency constrained vibrations of chain segments in regions of the sample where the density is less than the average value. The contribution from these vibrations may be decreased by radiation-induced cross-linking either through a decrease in the number of the segments or through an increase in their average vibration frequency. The radiation effect calculated by adopting this mechanism was 35%, i.e. fairly close to the experimental value.

We have studied[5] the effect of radiation on the specific heat of atactic PS at 30–200 °C with doses of up to 50 Mrad of mixed gamma and neutron radiation at a dose rate of 36 rad s^{-1}. At least up to 80 °C the specific heat of PS was found to be independent of the absorbed dose. The dispersion of the specific heat values for a confidence level of 95% was 0.7% at 30 °C and 1.8% at 80 °C. This result is not unexpected in view of the small distortion of the acoustic phonon spectrum.

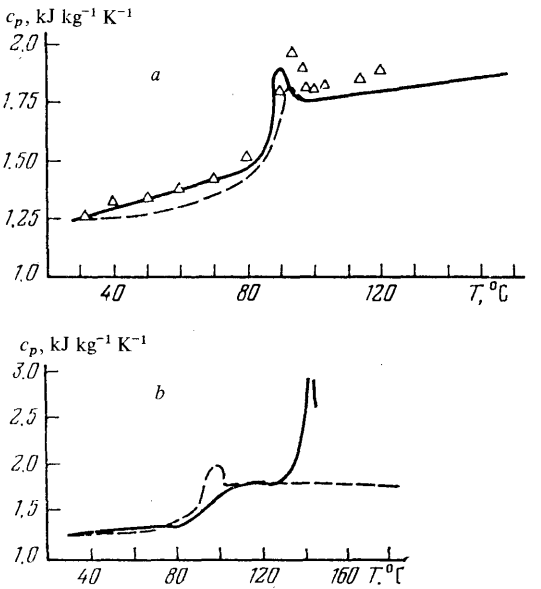

Figure 12. Temperature dependence of the specific heat of polystyrene: (*a*) D = 0, full curve first and second heating, broken curve third heating[5], experimental points from Ref.61; (*b*) D = 2.5 Mrad, full curve first heating, broken curve second heating[5].

Large radiation effects were obtained in the region of the thermal phase changes. Non-irradiated PS shows a sharp rise in c_p from 1.48 to 1.90 J g^{-1} K^{-1} at the glass transition temperature T_g = 87 °C (the average temperature of the glass formation region). These results[5] are fully consistent with earlier reports[61] (see Fig.12*a*). Other reports[62,63] of relaxation transition in the region of 50 °C were not confirmed[5,61].

Irradiation with a dose of 2.5 Mrad (Fig.12*b*) converts the maximum of c_p into a sharp break in the $c_p = f(T)$ curve, and increases T_g from 87 to 93 °C. Further irradiation produces a further increase in T_g (see Table 5).

Clearly defined high-temperature transitions, similar to the endothermic melting peak, were found[5] in samples irradiated with doses greater than 2.5 Mrad. The temperature (T_t) of these effects increased with dose (Table 5). In repeated heating runs the high-temperature effects had disappeared, and they could not be restored by any form of heat treatment.

Table 5. Temperatures of phase transitions in polystyrene[5].

D, Mrad	0	2.5	4.4	10	21	27	50
T_g, °C	87	93	90	97	94	97	102
T_t, °C	—	142	144	146	174	178	192

The presence of this transition in atactic non-irradiated PS was demonstrated[64] by various physicochemical methods including dilatometry, calorimetry, and X-ray diffraction. The transition temperature T_t lies between 115 and 225 °C, depending on the molecular weight of the PS. The appearance of the transition depends also on the heating rate. At low heating rates the transition may be shifted towards T_g, and overlap the glass formation process. In some samples of PS[5,61,65] this transition was not detectable for $D = 0$ because of the low heating rate used (≤ 1 K min^{-1}).

Boyer has pointed out[64] that T_t corresponds to the transition from one amorphous state (characterised by constrained rotations, due to interactions with neighbouring polymer chains) to another amorphous state (in which rotations are relatively free). This type of transition should be present in all amorphous polymers. At low molecular weights the two transitions (T_g and T_t) merge into one, and they can be resolved only if the molecular weight is of the order of 10^4. Unlike the glass formation process, which involves polymer segments of 50–100 carbon atoms, the high-temperature transition relies on the displacement of a whole polymer chain, made possible by the increase in the free volume and in the mobility of the polymer chains produced by changes in the position of their centre of gravity. In support of this model Boyer quotes the fact that the transition is suppressed by cross-linking the polymer (for example, in natural rubber or in polybutadiene).

The observation[5] of the high-temperature transition in irradiated PS at low heating rates, and of the disappearance of this transition in duplicated heating runs, is incompatible to some extent with the Boyer model. We suggest the following possible explanations: 1) the breakdown of relatively dense ordered regions of the quasi-crystal type formed during irradiation, whose size (and melting point) increase with dose, causing the transition temperature to increase; 2) relaxation of the mechanical stresses produced by the irradiation and therefore increasing with dose; 3) evaporation of liquid radiolysis products or the sudden ejection of gaseous products, whose diffusion is hindered under normal conditions.

A surprising analogy is noted between the dependence[5] of T_g and T_t on the dose of radiation (Table 5) and their dependence on the molecular weight of the PS[66]. Fox and Flory have shown[66] that T_g and T_t increase monotonically with the molecular weight, reaching values of $T_g = 100$ °C and $T_t = 192$ °C for $M = 360000$. Thus the radiation-induced cross-linking of PS appears to be equivalent to an increase in molecular weight from the point of view of the mechanism of the high-temperature transitions.

b) Thermal conductivity and density of polystyrene. According to the Klemens theory[67] of the thermal conductivity of amorphous materials the coefficient λ at low temperatures in these materials is determined by longitudinal acoustic phonons, whose mean free path L is determined by scattering phenomena associated with the elastic disordering of the amorphous solid structure. At low temperatures the characteristic wave lengths of the emitted phonons (and therefore also the L values) are much greater than the size of the disordered regions. From this point of view the formation of transverse bonds in the PS as a result of radiation-induced cross-linking will only produce additional point defects in an already disordered structure, and it should not have a marked effect on λ, as long as the average distance between cross-linking points remains greater than the wave length of the phonons (~ 10 Å).

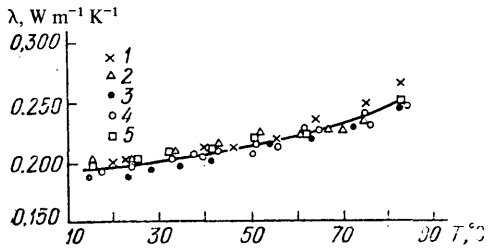

Figure 13. Temperature dependence of the thermal conductivity of polystyrene for different doses (D, Mrad): 1) 0, 2) 2.5, 3) 10, 4) 21, 5) 27[19].

Since the radiation yield of cross-links is small in PS, large changes in λ cannot be expected, even for large doses. Thus, no changes in λ could be detected (within experimental error) with doses of 2–16 Mrad at helium temperatures[60] and with a dose of 27 Mrad at 16–85 °C.[19] On the other hand, an increase in temperature from 16 to 85 °C increases the λ value of polystyrene by 24% (Fig.13). A small increase in the density of PS (by 0.6% at 20 °C) has been noted[19]: clearly, this cannot cause a large change in λ. The distortion of the spectrum of acoustic phonons caused by the transition from helium temperatures to the region of 50–100 °C is clearly insufficient to make the L value comparable with the distance between cross-linking points.

2. Poly(methyl methacrylate)

Poly(methyl methacrylate) (PMMA) is one of the polymers which are degraded by radiation. Therefore we can expect (from the above considerations) relatively small changes in λ for fairly high doses of radiation.

Knappe and Yamamoto[18] studied λ in PMMA by using samples cross-linked with triallyl cyanurate (TAC) or samples of PMMA irradiated to doses of 20 Mrad at a dose rate of 17 krad s^{-1}. For a 10% weight fraction of TAC the molecular weight of PMMA fell from 3.2×10^4 to 8.2×10^3 and the density rose from 1184 to 1191 kg m^{-3}, giving a maximum increase in λ of 10%.

Irradiation of the PMMA to a dose of 1 Mrad had no effect on λ. At a dose of 2 Mrad and T_i = 25 °C the λ value fell by 5–6%. The degradation of the polymer is shown by the decrease in molecular weight (22800 at a dose of 1 Mrad and 10700 at a dose of 2 Mrad). This decrease in molecular weight increases the number of end-groups of macromolecular chains, corresponding to an increase in the relative number of van der Waals bonds, i.e. to a decrease in λ.

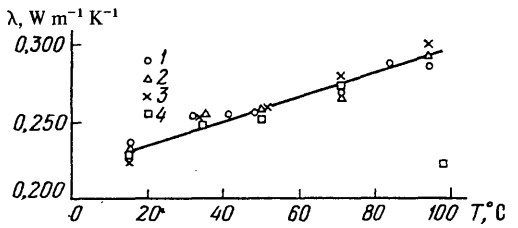

Figure 14. Temperature dependence of the thermal conductivity of poly(methyl methacrylate) for different doses (D, Mrad): 1) 0, 2) 0.1, 3) 0.3, 4) 0.6[19].

These results were confirmed by measurements in our laboratory[19], in which PMMA was irradiated with γ quanta from ^{60}Co to doses of 0.09 and 0.57 Mrad at a dose rate of 3.6 rad s^{-1}. The λ values measured at 18–98 °C increase with temperature by 25% and are independent of dose (Fig.14). At 98 °C a dose of 0.57 Mrad produces marked frothing which causes a sharp drop in λ.

IV. ANALYTICAL MODELS OF HEAT CONDUCTION MECHANISMS

In order to predict radiation effects on the thermophysical properties of polymers we need analytical models which adequately describe the observed changes in these properties.

In some early descriptions[68,69] of the thermal conductivity of amorphous materials the polymer was treated as a series network of elementary thermal resistances corresponding to chemical and to van der Waals types of bonding between atoms. The standard Debye formula for phonon heat conduction was used. According to the elastic constants of these bonds, the thermal conductivity along the main polymer chain is 10 times greater than between chains.

For a series network of thermal resistances equivalent to a cross-linked polymer with n carbon atoms in the chain between the cross-linking points the parameter λ_c can be expressed as

$$\frac{1}{\lambda_c} = \frac{1}{3}\left(1+\frac{r}{2}\right)\frac{1}{\lambda_1} + \frac{1}{3}\left(2-\frac{r}{2}\right)\frac{1}{\lambda_2} + \frac{1}{3n}\left(\frac{1}{\lambda_2}-\frac{1}{\lambda_1}\right),$$

where λ_1 and λ_2 are the coefficients for the thermal conduction along the chain and between chains respectively, and $r = (M_n/M_c - 1)/n$ is the cross-linking parameter. (M_n is the number-average molecular weight before cross-linking, and M_c is the molecular weight of the chain portions between cross-links.)

For a cross-linked polymer it seems more logical to postulate a series–parallel equivalent network of thermal resistances. If we assume that the radiation effects appear mainly in the cross-links between polymer chains we can confine the changes in thermal resistance to the direction perpendicular to the chains. Under these conditions we can write[18]

$$\lambda_c = 3\frac{\frac{r}{4}\lambda_1 + \left(1-\frac{r}{4}\right)\lambda_2}{\left(\frac{r}{4}+2\right)\lambda_1 + \left(1-\frac{r}{4}\right)\lambda_2}\lambda_1 . \qquad (5)$$

A comparison[18] of calculation and experiment for irradiated polyethylene above the melting point of the crystals and for poly(methyl methacrylate) chemically cross-linked with triallyl cyanurate showed that the λ_c values given by the formulae for series or parallel connection lie well below the experimental values. Calculation by formula (5) gives much better agreement with experiment, though the discrepancy increases with the degree of cross-linking.

One possible reason for the discrepancy is the use of too rough an approximation for the parameter r, by taking the limit

$$r = \lim_{n\to\infty}\left(\frac{M_n/M_c - 1}{n}\right) = \frac{M_g}{M_c},$$

where M_g is the molecular weight of a monomer unit in the chain. It could be useful to determine the absolute values of λ_1 and λ_2 from experimental data for both irradiated and non-irradiated polymers, and to use these values in tests of the various models of thermal conductivity.

V. ANISOTROPY OF THERMAL CONDUCTIVITY

It is clear from the above discussion that crystalline or partially crystalline polymers can show changes in thermal properties on irradiation as a result of changes in phase composition. For amorphous polymers, or for the amorphous phase of partially crystallised polymers, the radiation effect depends on the number of the resulting radiation-induced cross-links and on the extent of degradation of the material. When the yield of cross-links is quite high, for example in the amorphous phase of polyethylene, the radiation effects are substantial. When the yield of cross-links is low (for example, in polystyrene) radiation-induced changes in thermal conductivity are not detected, and in easily degraded materials (for example, poly(methyl methacrylate) and thermal conductivity decreases. At the same time chemical cross-linking of the polymer chains causes λ to increase.

It is interesting to compare the effect of transverse links between the polymer molecules on the λ value of the polymer with anisotropy effects in the thermal conductivity of polymers. The basic reason for anisotropy in the thermal properties of polymers is the difference between the transport of heat along the macromolecular chains and the transport between the chains. Thermal vibrations in the macromolecule are transmitted much more rapidly along the main covalent bonds than along the side bonds. Intermolecular heat transfer in an amorphous polymer is characterised by a definite potential barrier (or thermal resistance) which opposes the transfer of thermal impulse created by the van der Waals interaction forces.

Experimental data (for polystyrene, poly(methyl methacrylate), poly(vinyl chloride), and polycarbonate) on the stretch (η) of oriented polymers gave the following relationship between λ and the thermal expansion coefficient β[2]:

$$\frac{\lambda_\eta}{\lambda_0} = 0.8\frac{\beta_\eta}{\beta_0} + 0.2,$$

where the subscript "η" denotes a stretched polymer. As η is increased, both λ and β increase linearly in the stretch direction, and in the transverse direction both parameters

decrease. The smallest anisotropy is found in polystyrene, and the largest in polycarbonate. The longer (or bulkier) the side-groups in the main chain, the less marked is the anisotropy.

By interpreting the cross-linking of polymer chains as an increase in size of the side-groups in the macromolecule we can establish an analogy between the radiation-induced cross-linking and the mechanical deformation of a polymer, i.e. we can compare the absence of radiation effects on the λ value of an amorphous polymer with the absence of anisotropy in its properties. Conversely, strong radiation effects on λ suggest that anisotropy can be expected. Thus, the anisotropy of λ and β is found[2] to be much more marked in PMMA than in PS. Similar effects from cross-linking (radiation-induced in PS[19,60] and chemical in PMMA[18]) have been obtained for the thermal conductivity of these materials.

If our hypothesis is valid it offers a practically useful corollary: dilatometric measurements of the linear expansion coefficient of non-irradiated polymers could be a valuable tool in studies of radiation effects in the thermal conductivity of polymeric amorphous materials. Clearly, in the absence of substantial anisotropy in the β values the need for radiation experiments disappears.

VI. COMPOSITE MATERIALS

Whereas the polymers considered above are to some extent model materials, for which an analysis of the radiation effects can be fairly reliable, in the case of the practically very important composite materials a comparable analysis is often impossible in our present knowledge of the mechanism of physicochemical phenomena in polymers. The main difficulties arise from the structural complexity of the polymers, from the frequent lack of information on the properties of the separate components, from the non-additivity of those properties, etc.

Dosimetry can present a very difficult problem in composite systems. If the particle size of the components is of the order of a tenth of a millimetre or less in a system where electronic equilibrium is not reached, irradiation with γ quanta or with fast electrons[70] leads to a substantial redistribution of the absorbed energy between substances with different effective atomic number Z, while retaining the overall balance: the dose absorbed by the substance with the smaller value of Z increases, and the dose absorbed by the substance with the larger value of Z decreases. As a result the conventional calculation of average radiation dose can be seriously misleading, since some components of the composite are almost invariably "over-irradiated" while others are "under-irradiated". The magnitude of this effect can reach several tens of per cent, and in some cases 100%, depending on the type (and spectrum) of the radiation.

Evidently, the only prospect of a realistic prediction of radiation-induced changes in the thermophysical properties of composite materials lies in an extensive study of model substances, in the characterisation of the radiation-induced changes in these substances, and in the development of a unified theory of radiation effects on thermophysical properties, followed by application of the results to composite materials and detailed experimental tests of theoretical predictions.

Published experimental data on radiation effects in the thermophysical properties of these materials relate to the thermal conductivity of the composites VK-9 and Kriosil[71]. The VK-9 resin is a compound of the epoxide oligomer ED-20 and polyamide PO-300, and Kriosil consists of the organosilicon polymer DFMKr, the low-molecular polyamide L-20, boron nitride, and Aerosil. Irradiation was carried out with γ quanta from ^{60}Co at 30 °C in air, or in a reactor at 50 °C. The results of our study of VK-9 are summarised in Table 6, those for Kriosil in Table 7.

The radiation-induced changes in these composites were analysed by the two-phase model for partially crystalline polymers, using Eqn.(4). In order to establish whether the decrease in the thermal conductivity of VK-9 on irradiation is due to amorphisation of the partially crystalline polyamide or to degradation of one or both polymers we calculated the λ and λ_a/λ values of the polyamide from published data[72].

Table 6. Thermal conductivity of VK-9, W m^{-1} K^{-1}.[71]

D, Mrad	−100° C	0° C	100° C	180° C
0	0.210	0.231	0.260	0.289
1	0.202	0.224	0.251	0.282
3	0.197	0.219	0.248	0.276
10	0.188	0.219	0.245	0.269
20	0.151	0.186	0.224	0.248

Table 7. Thermal conductivity of Kriosil, W m^{-1} K^{-1}.[71]

D, Mrad	−100° C	0° C	100° C	180° C
0	0.570	0.728	0.810	0.859
1	0.514	0.686	0.748	0.796
2.2	0.500	0.656	0.720	0.756
6.6	0.479	0.600	0.665	0.693
10	0.431	0.576	0.632	0.659
20	0.369	0.479	0.528	0.583

The experimentally observed change in λ for VK-9 at a dose of 20 Mrad is 1.3–2.3 times greater than the change corresponding to full amorphisation of the polyamide (allowing for its proportion by weight in the compound). An analysis of the density of different polyamides as a function of crystallinity, and a study of the changes in density of VK-9 as a function of dose, showed that the amorphisation of the polyamide is far from complete even at a dose of 20 Mrad. It follows that the degradation of the VK-9 resin under the influence of radiation makes a significant contribution to the observed changes in λ. However, further work is needed to determine whether both polymers are degraded or only one, and to what extent.

At temperatures near −50 °C the $\lambda = f(T)$ curves show maxima which gradually decrease as the dose is increased. These maxima disappear at a dose of 20 Mrad. They appear to be related to the glass transition in the components of the polymer. This suppression of a phase transition of the second kind has been observed previously, for example in the specific heat of irradiated polystyrene[5]. A possible explanation is the formation of micro-inhomogeneities during irradiation, each new structure having its own glass transition temperature. The result is a "smearing out" of the phase transition in temperature.

The amorphous polymers (organosilicon polymer and polyamide) in Kriosil are typical of the polymers which are degraded by irradiation. We know[73] that in filled polymers the rate of radiation-induced degradation is much higher than in unfilled organosilicon vulcanised materials, possibly as a result of the stress concentration on the chains in contact with the filler particles. It is clear from the decrease of the

λ value of Kriosil with increase in the dose of radiation (Table 7) that in this system the cross-linking processes cannot compete with the degradation processes. The monotonic decrease in density of Kriosil with dose of radiation (by 12%) is also consistent with the degradation hypothesis.

We note that whereas in Kriosil the magnitude of the radiation effects is almost independent of the temperature at which λ is measured, in the case of VK-9 the change in λ at -100 °C is almost double that at +100 °C. This may be due to the large difference between λ_{cr} and λ_a for the polyamide ($\lambda_{cr}/\lambda_a = 2.0$ at -100 °C and 1.68 at +50 °C), or to a difference in their temperature dependence. Whereas the relationship obtained by Eucken[25] for low-molecular crystals ($\lambda_{cr} \propto 1/T$) applies in our case, the parameter λ_a increases with temperature up to the glass transition point and then slowly decreases.

In both composites the radiation effects were unaffected by the type of radiation used.

VII. REVERSIBLE EFFECTS ON THE THERMOPHYSICAL PROPERTIES

Reversible effects include changes in the properties of polymers initiated by irradiation but which disappear as soon as the irradiation is stopped. These effects can be very strong in the dielectric (and in some of the mechanical) properties of polymers, but as far as the writer is aware no such observations have been reported for the thermophysical properties. This may be due, at least in part, to the practical difficulty of this type of work.

Indirect evidence for the absence of reversible effects in the thermal conductivity of polyethylene comes from our relaxometer[70] study of the components of the absorption from nuclear reactors. The detector of the relaxometer was a rectangular polyethylene prism 50 × 50 mm in cross-section and 150 mm long. From the thermal conductivity coefficients of polyethylene measured after irradiation the temperature fields in the cross-section of the prism were calculated: the results agreed well with those of irradiation experiments at 50–100 °C with doses of up to 10 Mrad and dose rates between 13 and 55 rad s^{-1}.

Radiation-induced gas evolution is a possible reason for the appearance of reversible effects in the specific heat of polymers. At high enough dose rates the pressure of gaseous radiolysis products (mainly hydrocarbons) in the microvolumes of irradiated samples can reach several MPa. On reaching a particular pressure, depending on the mechanical strength of the polymer, the irradiation temperature, etc., the sample develops microscopic cracks and pores. This process continues as long as the absorbed dose continues to increase. The polytropic emission of radiolysis gases involves a decrease in temperature according to the laws of thermodynamics, and therefore it should lead to a change in the "apparent" specific heat of the material. This mechanism may be more easily observed for irradiation temperatures below 0 °C, when the polymers are less plastic.

No reversible effects were noted within experimental error (±5%) in our recent measurements of the specific heat of polyethylene and Kriosil irradiated at 20–90 °C and dose rates of 5.5–11 rad s^{-1} to a dose of 2 Mrad. According to our model these effects (if they exist) can be expected only for doses and dose rates an order of magnitude higher than those used in these experiments†.

† Essentially reversible effects were observed in very recent experiments on the specific heat of polyvinylformal (see B.A.Briskman. et al., Vysokomol.Soed., in press).

VIII. STORED ENERGY OF IONISING RADIATIONS

The analytical prediction of the effect of radiation on the properties of polymers, including their thermophysical properties, requires a knowledge of the energy balance of the interaction between the ionising radiation and the substance.

During the interaction of γ quanta, electrons, or neutrons with the substance being irradiated most of the energy of the secondary electrons or charged heavy particles is dissipated through intermediate forms of excited or ionised atoms and molecules. In the majority of materials the ionisation energy is rapidly converted into heat by recombination processes. However, some of the energy absorbed during irradiation is not converted into heat: this is usually called the stored energy ΔW. Storage can occur, for example, by the formation of crystal defects. In polymers a very important form of energy storage is the generation of cross-links between polymer chains.

Most of the published experimental data on ΔW are estimates of the upper limit of this parameter, obtained from dosimetric measurements directly within the material. The following is a list of the relative values of ΔW for polyethylene (as a percentage of the total energy absorption) obtained in different laboratories: ΔW (%) = 3,[74] 2,[75] 3.7,[76] 0.7,[77] 4,[78] and 3.8%[79].

Weimer[78] found that in polyethylene and for doses up to 1 krad the predominant reaction is exothermic, with a maximum heat evolution at the beginning of the irradiation which accounts for more than 20% of the energy in the absorbed dose. At doses in the region of 1 krad the exothermic reaction is replaced by an endothermic reaction (with energy storage); at a dose of 2 krad the parameter ΔW reaches 4%, and stays constant at higher doses. Polystyrene also shows a characteristic exothermic reaction[78], but when the dose exceed 2 krad, $\Delta W = 0$. In a plastic equivalent to biological tissue with effective atomic number Z proton irradiation gave[76] $\Delta W = 4.2 \pm 0.3\%$. Sabel and co-workers[79] used X-radiation of 30 keV energy and obtained the following values of ΔW: 2.31 ± 0.78% for poly(methyl methacrylate), 6.95 ± 0.94% for polyamide, 2.01 ± 0.68% for poly(vinyl chloride), and 4.08 ± 0.55% for Shonka-plastic. The exothermic effect reported[78] for PE was not observed in this work[79], but it was observed for PMMA.

Differences in stored energy for different types of radiation have not been reported. Though the selectivity of the interaction of different types of radiation with the thermophysical properties of polymers has not been specifically examined, we have no reason to expect any marked differences, especially at temperatures above 0 °C.

---o0o---

From this analysis of the work published so far we may conclude that further studies of the thermophysical properties of irradiated polymers should be aimed at the following problems: 1) the creation of a basic theory of the effects of radiation on the thermophysical properties; 2) the study of likely reversible effects in these properties; 3) the study of the selectivity of interactions with different types of radiation; 4) the extension of the range of model polymers and of the range of characteristics for which detailed information is available. In particular, we need data on the behaviour of the linear thermal expansion coefficients.

The solution of these problems should allow the prediction of the after-effects of radiation on the thermophysical properties of polymers, including composite materials, which is currently of interest in both pure and applied science.

Chemical X-Ray Fluorescence Trace Analysis

F.I.Lobanov, I.M.Yanovskaya, and N.V.Makarov

The results of recently published work on the determination of traces of elements by X-ray fluorescence (XRF), combined with chemical methods of separation and concentration, have been reviewed. The application of various combinations of XRF with precipitation, sorption, and extraction has been described. The combined XRF method can be used to determine traces of elements in natural and industrial materials.
The bibliography contains 84 references.

III. X-ray fluorescence analysis combined with ion exchange and sorption 486
IV. Combination of X-ray fluorescence analysis with extraction 487

I. INTRODUCTION

In the determination of traces of elements by X-ray fluorescence (XRF), there are several ways of increasing the sensitivity. One is by improving the quality of the apparatus and by using new and more sensitive X-ray spectrometers. This method is not always possible, however, and often does not give the desired results. Thus in a large number of recent studies, the sensitivity of XRF analysis has been increased by preliminary physicochemical and chemical concentration of the elements being determined. Concentration combined with XRF is also convenient in that specimens of uniform composition and form are obtained; this eliminates the complex calculations required to take account of matrix effects.

The following methods are used for concentration in chemical analysis: extraction, sorption, precipitation, evaporation, electrochemical methods, crystallisation processes, zone fusion, and various others[1]. Only those methods of concentration giving specimens convenient for XRF spectrometry are combined with XRF, however.

II. COMBINATION OF X-RAY FLUORESCENCE ANALYSIS WITH PRECIPITATION

The combination of precipitation with XRF determination gives good results, since preliminary separation and selective precipitation make it possible to separate traces of elements from a matrix and also from elements giving interfering spectral lines. On the other hand, the precipitated elements are uniformly distributed in the light matrix of the emitter on a comparatively large surface, increasing the accuracy and sensitivity of the determination.

In an examination of the results of studies based on the combination of precipitation with XRF, mention must first be made of a paper published in 1963 by Luke[21], who showed that this combined method makes it possible to determine traces of 69 elements in organic and inorganic materials, and examined in detail the problems associated with the precipitation, coprecipitation, and filtration of the precipitates, the influence of interfering ions, the use of different precipitants (carbamate, Cupferron, NH_3, H_2S, phenylfluorone); the conditions for the chemical separation of 25 elements and their X-ray analysis were also examined. Luke showed that the method is fairly rapid and sensitive, and makes it possible to determine 2×10^{-8} g Ni, Ti, and Sc; 10^{-7} g Ca, Cu, Fe, Co, and Zn; and 10^{-6} g of a number of other elements.

Another fundamental paper in this field was published by Hirokawa[3], who clearly showed that the combination of XRF with concentration by precipitation is effective and has a high sensitivity. Other studies in this field can be formally divided into two groups, involving the use of inorganic or organic compounds.

1. The Use of Inorganic Precipitants

Traces of elements are usually precipitated as the sulphides, sulphates, or hydroxides. Precipitates of inorganic salts and hydroxides are readily analysed by XRF. It should be borne in mind, however, that possible agglomeration of the precipitate may lead to distortion of the surface of the emitter, with an undesirable effect on the results of the analysis. To prevent this phenomenon, it is recommended that sulphide precipitates be filtered immediately after precipitation. The precipitation of inorganic compounds is widely used for the XRF determination of traces of many elements.

Thus, in the analysis of metallic aluminium for traces of Cu, Fe, Mn, Zn, and Co, the precipitation of these elements as the sulphides made it possible to determine their concentrations at the 10^{-4}% level[4].

An interesting method for determining Hg, Ag, Cu, Bi, Pb, Cd, Se, Te, Zn, Co, and Ni in aqueous solutions is based on the filtration of the solution through a thin layer of zinc and manganese sulphides; the metals listed form less soluble sulphides, and remain in the precipitate, which is then analysed by XRF.[5] In addition to traditional methods of precipitating metals as the sulphides, their determination in precipitates of hydroxides[6-8], oxides[9], and sulphates[10] is also used. The detection limit of elements such as Pb, Nb, Ta, and W in steels and alloys is ~0.002%.[6,10]

The XRF analysis of the precipitates obtained is carried out using an external standard, and the reference specimens are prepared as the same precipitates. In addition to external standards, internal standards can also be used. Thus in the determination of U, Np, Pu, and Am,[7] the internal standards added to the solution are Y and Sc, which are then precipitated together with the other elements using NH_4OH.

Uranium has been determined[11] at the 10^{-4}% level after precipitating as barium diuranate; the precipitate was sorbed not on the polycarbonate membrane usually employed, but on an Ag membrane filter. This lowered considerably the minimum quantity of uranium detectable, as a result of the excitation of the fluorescent emission of uranium not only by the primary radiation of the X-ray tube but also by the secondary emission from the silver support.

Precipitation is being used successfully to determine not only heavy metals but also various light elements. Thus phosphorus can be determined in purified copper at the level of 5×10^{-4}% in a 5 g specimen with preliminary precipitation of phosphorus by ammonium molybdate[8]. The quantity of phosphorus can be determined from the fluorescent emission of phosphorus and molybdenum. The determination of parts per million of chlorides in various silver catalyst specimens has been described[12]. Good results can be achieved by coprecipitating traces of elements with iron[13,14] and cobalt[15] hydroxides; the method described above is used to prepare the emitters.

2. The Use of Organic Precipitants

Most of the work based on a combination of precipitation with the XRF determination of elements has been carried out using organic precipitants[16]. Mention must first be made of those studies where heavy metals have been precipitated using sodium and ammonium carbamates.

Thus sodium diethyldithiocarbamate has been used to determine traces of Cu, Zn, Hg, and Fe in salt solutions[17,18] and of Cu, Zn, Cd, and Pb in aqueous solutions[8], to determine the principal components of Mn,Zn- and Ni,Zn,Co-ferrites[19], in the multi-element analysis of sedimentary and other rocks[20], and to determine low concentrations of Mn and Fe in titanium[21]. Kessler and co-workers[22,23] used titanium diethyldithiocarbamate to coprecipitate traces of transition metals. Japanese workers have determined traces of Cu, Zn, Fe, and Ni in pure aluminium and magnesium by precipitating with ammonium pyrrolidine-1-dithiocarbamate; the XRF analysis of the precipitate was carried out using an external standard. For this purpose, selenium was added as internal standard to the solution[24]. The concentrations of Fe, Co, Cu, Zn, Cd, and Pb in water at the 10^{-9}% level were determined by coprecipitating these metals with Mo pyrrolidinethiocarbamate complex carrier[25]. Cr, Cu, Zn, As, and Se in water at the 10^{-7}% level was determined similarly, except that the carrier used to coprecipitate these elements was the Fe pyrrolidinedithiocarbamate complex[26].

Methods have also been described for determining heavy metals by coprecipitating with polyvinylpyrrolidone and thionalide[27], by precipitating as salts of glycollic acid[28], and by coprecipitating Co and Ni with iron hydroxide using hexamethylenetetramine[29].

Traces of tungsten in iron, molybdenum, and titanium have been determined by precipitating the tungsten with phenylfluorone solution after dissolving the metal specimen[30]. A method has also been proposed for the simultaneous XRF determination of Nb, Zn, and Ta at the 10^{-2}% level after precipitating with phenylarsonic acid[31]. It has been shown possible to determine transition metals after precipitating them with 1-(2-pyridylazo)-2-naphthol[32]. Standard XRF methods for determining Fe at the 10^{-4}% level include its determination after precipitating with 1-(2-pyridylazo)-2-naphthol[33].

In the determination of traces of Al, Fe, and Ti in different gypsum specimens, the metals were precipitated by Cupferron from acidic solutions (pH 3.5–3.7) after dissolving the gypsum by fusing with H_3BO_3 and Na_2CO_3 followed by solution in H_2SO_4.[82] This method gives good reproducibility, the coefficient of variation does not exceed 2.6%, and the minimum detectable quantities of Al, Fe, and Ti are 0.15, 0.58, and 0.15 μg respectively.

Sometimes, not one but several precipitants are used to precipitate micro-quantities of metals. In those cases where both precipitants are organic reagents, however, multiple precipitation may not take place, since the first precipitant forms complexes and prevents the precipitation of some elements by the second precipitant. This effect can be observed when Cupferron and phenylfluorone are used in succession. On the other hand, a successful combination of reagents gives good results.

Thus traces of Mn, Fe, Ni, Cu, Zn, Cd, Sm, Hg, and Pb have been coprecipitated from solutions using a mixture of 1,10-phenanthroline and sodium tetraphenylborate in the ratio 1:1.[34] Tetraphenylborate is also used to precipitate K and Rb.[20,35] In all the procedures described, the precipitates were filtered through microporous membranes or compact filters, and the specimens obtained in this way were studied by XRF spectrometry. A special apparatus has been developed for the selective electrodeposition of Ni, Cu, and Zn, and the XRF analysis of the deposit[36].

Thus the combination of precipitation and XRF determination is rapid, sensitive, accurate, and, which is most important, universal. It is necessary, however, to remember the possible errors, associated with incomplete precipitation of the elements to be determined or the coprecipitation of elements which interfere with one another in the XRF determination, and also the marked difference between the actual and theoretical density of the precipitate. Examples of the combination of XRF with precipitation are given in Table 1.

Table 1. Examples of combined XRF analysis and precipitation.

No.	Precipitant	Material	Elements determined	Refs.
1	Sodium diethyldithiocarbamate	salt solutions	Cu, Zn, Hg, Fe^{3+} (0,01—10 mg litre^{-1})	[17, 18]
2	ditto	water, pH 5.5	Cu, Zn, Cd, Pd	[8]
3	»	ferrites	Mn, Zn, Ni, Co, Fe (~ 5 μg)	[19]
4	»	water, pH 8.0–8.2	transition metals	[22, 23]
5	»	titanium, pH 7–9	Mn, Fe (50–100 μg)	[21]
6	»	ores and sedimentary rocks	Ti, Mn, Fe, Ni, Cu Zn, Pb, As, Sr	[20]
7	Ammonium molybdate	purified copper	P ($3 \cdot 10^{-4}$%)	[8]
8	$La(NO_3)_3 + NH_4OH$	crude copper	As, Bi, Fe, Pb, Sb, Te, Sn	[8]
9	*	solutions	Ni, Cu, Zn ($1 \cdot 10^{-100}$%)	[36]
10	Sodium tetraphenylborate	water	K (0.1–1000 μg)	[35]
11	1,10-Phenanthroline + Na tetraphenylborate (1:1)	water, pH 4–6	Mn, Fe, Ni, Cu, Zn, Cd, Sn, Hg, Pb, Co	[34]
12	1-(2-Pyridylazo)-2-naphthol	water, pH 10	Cu, Zn, Fe, Co, Ni (0,1—0.5 μg in 50 ml)	[32]
13	Pyridylazonaphthol	molybdenum, pH 10	Fe ($5{,}6 \cdot 10^{-4}$—$5 \cdot 10^{-3}$%)	[33]
14	Phenylarsonic acid	steel	Nb, Zr (0,01%)	[31]
15	Phenylfluorone	iron, 1% H_2SO_4 solution		[30]
16	Glycollic acid	organic material, water, pH 4.7–5.0	Hg, Ni, Pb, Se, As, Cd, Cu, Fe, Zn ($5 \cdot 10^{-6}$—$2{,}5 \cdot 10^{-5}$%)	[28]
17	Polyvinylpyrrolidone-thionalide	water, pH 4	Sn, Te, Hg, Pb (30—600 μg litre^{-1})	[27]
18	Ammonium pyrrolidinedithiocarbamate	water, pH 4	Cr, Cu, Zn, As, Se (10^{-7}%)	[26]
19	ditto	water	Fe, Co, Cu, Zn, Pb (10^{-9}%)	[25]
20	»	water	Cu, Zn, Fe, Ni, Mg, Al (< 50 μg)	[24]
21	NH_4OH	RuO_2	Th (0,1—1,2%)	[9]
22	ditto	water	U, Np, Pu, Am (0.05 μg)	[7]
23	»	Cu (metal), pH 9–10, Fe^{3+} ions	Bi	[14]
24	»	pH 8.5, Fe^{3+} ions	Zn, Cu, Pb, Mn (10—75 μg)	[13]
25	Na_2S	aluminium	Fe, Mn, Zn, Cu (10^{-4}%)	[4]
26	ZnS+MnS	water	Hg, Ag, Cu, Bi, Pb, Cd, Sn, As, Se, Tl, Zn, Co, Ni	[5]
27	H_2SO_4	steel, Ba^{2+} ions	Pb (0,02—0,5%)	[10]
28	H_2SO_3	Fe alloys	Nb, Ta, W ($2 \cdot 10^{-3}$%)	[6]
29	NaOH	molybdenum	Zr, Ti (10^{-8}—10^{-7} r)	[15]
30	Cupferron	gypsum, pH 3.5–3.7	Fe, Al, Ti	[82]
31	8-Quinolinol	water, activated carbon	heavy metals	[38]
32	8-Quinolinol	water, pH 8, activated carbon	ditto	[39]

III. X-RAY FLUORESCENCE ANALYSIS COMBINED WITH ION EXCHANGE AND SORPTION

In 1977, Leyden[37] reviewed XRF methods for determining metal ions in water specimens with preliminary concentration[37]. The most promising methods of concentration were sorption methods, particularly those using special filters and membranes with immobilised ionogenic groups. All the work reviewed[37] can be divided into two groups. The first involved the sorption of the metals or their complexes on activated carbon, or ion-exchange concentration on a resin. The concentrates obtained were generally subjected to further treatment to obtain an emitter convenient for XRF. The second group involved the use of ion-exchange membranes and paper, and in this case the concentrate was obtained in a form suitable for the XRF determination of the elements.

1. The Use of Ion Exchange Resins and Activated Carbon

The sorption of metal chelates on activated carbon is well known. This property has been used by a number of workers to concentrate heavy metal oxinates on activated carbon with subsequent XRF determination of the metals in the concentrate[38–40,80]. The authors cited not only developed a quantitative method for determining Mn, Fe, Co, Ni, Cu, Zn, and Al in waters of different types but also found the quantitative characteristics of the dependence of the distribution of the complexes of these elements with 8-quinolinol on various factors (pH, reagent concentration, metal concentration, etc., and also the presence of large quantities of alkali and alkaline earth metal ions in the solution).

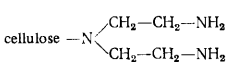
Transition metals are often concentrated using the commercially available ion exchanger Chelex-100 (a complexing ion-exchange resin of the ketoimine–carboxylate type). This resin has been used to determine uranium in ground water[41]. A weighed specimen of the resin was placed in a previously acidified solution of the water being analysed, after which the resin with the sorbed uranium was filtered off on a membrane filter, dried, and compressed with a binding agent (Somarmix) on a boric acid support. The disc obtained in this way was used for the XRF analysis; the uranium detection limit was 2×10^{-7}%. Ca^{2+}, Ti^{3+}, Cr^{3+}, Mn^{2+}, Fe^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, As^{3+}, and Br^- were determined similarly in solutions containing these elements at concentrations of 5×10^{-6} to 5×10^{-4}%.[42]

In some cases, however, a dynamic method of ion-exchange concentration is more convenient. For example, Cu and Ni have been determined at the 0.5–5 μg litre^{-1} level, and Zn at the 4–15 μg litre^{-1} level in sea water[43]. The sea water was passed through a column of resin, after which the resin with the sorbed ions was compressed to form a disc. The minimum detectable quantities of Cu, Ni, and Zn are 0.3, 0.1, and 0.1 μg litre^{-1} respectively. A similar method has been used[44] to determine traces of a number of elements in various materials.

An interesting method for determining lead and mercury[45] using diethyldithiocarbamate on a support of Chromosorb W-DMCS gives 100% concentration. The detection limits for cadmium and mercury are 0.08 μg and 1.7 μg respectively[45].

Several papers in this field have been published in the Soviet literature. An X-ray–radiometric method, combined with ion-exchange concentration, has been used to determine noble metals (gold, rhenium, and silver);[49] the detection limit was 0.1–0.01 mg litre^{-1}. In the determination of Cu, Zn, Cd, and Pb in sewage[81], the metals were concentrated using the strongly acidic monofunctional KU2×8 cation exchange resin.

Amberlite IRA-400 in the Cl form has been used to determine low concentrations of uranium [$(0.2–5) \times 10^{-4}$%] in carbonate–bicarbonate solutions. To prepare the emitter, the resin with the sorbed uranium was filtered off and distributed in a uniform layer on a Mylar film fixed in a special holder[48].

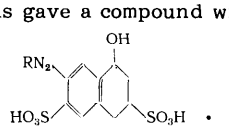


In the development of this trend in XRF, research workers are now using new and more selective sorbents. Japanese workers have developed a method for determining microgram quantities of metals by XRF combined with extraction from solutions by chelating functional groups immobilised on SiO_2.[47] A whole series of new sorbents have been prepared and studied in detail, together with the conditions for the extraction of Hg, Cu, Zn, Ni, Pb, Eu, and Mn as the preliminary concentration stage in XRF analysis[80]. A disadvantage of sorbents of this type is their instability in concentrated acids and alkalies.

Substituted cellulose powder containing 1-(2-hydroxyphenylazo)-2-naphthol or 4-(2-pyridylazo)resorcinol groups has also been proposed for concentrating metals in XRF analysis[45]. The combination of ion-exchange concentration on a column and XRF determination of the elements in the resin phase is not very convenient, however, since the preparation of a suitable emitter for XRF spectrometry is very tedious, and introduces additional errors, and the use of loose resin specimens for spectrometry lowers considerably the sensitivity of the determination and the accuracy of the analysis, as a result of the increase in the standard deviation, associated with the nonuniformity of the particles.

2. The Use of Ion Exchange Papers and Membranes

In XRF analysis, increasing use is now being made of analysis by a thin layer technique, since it makes it possible to avoid matrix effects. Work in which elements are concentrated using paper impregnated with an ion-exchange resin, and different types of filters containing complex-forming groups, is therefore of considerable interest.



A method of obtaining filters of this kind, capable of concentrating transition and alkaline earth metals, has been described[50]. Chlorodihydroxycellulose (obtained by the reaction of $POCl_3$ with Whatman-41 cellulose) was treated with diethylenetriamine or iminodiacetonitrile, followed by reduction. This gave a chelating ion-exchange filter:

which was used successfully in XRF analysis.

Filters of this type are also available commercially, for example Chelex-100 and Acropore-SN, with diameter 47 mm, containing chelating iminodiacetic acid groups[51]. Thus uranium in ground water has been determined using Chelex-100 [52] and Whatman R-81 [53] filters, and also a filter containing 20% SiO_2, modified by silylation with N-β-ethylaminopropyltrimethoxysilane[54]. The uranium detection limit reached 0.3 μg.

Traces (2.5 ppm.) of Fe, Cu, Zn, Sr, and Hg have been isolated from water using specially prepared cellulose filters[55]. The chromotropic functional group was introduced into the cellulose as follows: *p*-aminophenylcellulose (RNH_2) was first prepared, after which RNH_2 was treated with a mixture of HCl and $NaNO_2$ to give $RN_2^+Cl^-$, to which chromotropic acid was added. This gave a compound with a capacity of 0.2 mmole g^{-1}:

As already noted, ion-exchange filters are being used increasingly in XRF analysis. The number of studies in this field has increased sharply in recent years. The method is used in the analysis of water and in the analysis of various organic and inorganic materials after decomposition. One of the most interesting studies describes the determination of calcium and strontium in mineral waters[56]. The mineral water was passed eight times through a Whatman SA-2 filter impregnated with a cation exchange resin. The XRF spectrum was excited using the ^{109}Cd isotope. The detection limit according to the 3σ criterion is 7×10^{-5}–2×10^{-3}% for calcium, and 5×10^{-6}–2×10^{-4}% for strontium.

Traces of Cr, Fe, Cu, Zn, Sr, Cd, and Ba in surface waters have been determined using Amberlite NR-120 ion-exchange paper[57]. Similar methods have been used to determine Hg in water[58], osmium and ruthenium in the presence of large quantities of Cu, Fe, and Ni[59], the lanthanides[60], gold and silver in metallic copper[61], V, Cu, Fe, and Ni in mineral oils[62], and a number of other elements[63]. It should not be concluded, however, that the combination of ion-exchange separation on a filter with an XRF determination is suitable only for determining cations. The method has been used for the quantitative determination of sulphates[64]; the solution is passed through a filter of SB-2 anion-exchange resin, with subsequent XRF determination of sulphur.

The methodology of a study of the determination of copper and silver in pure lead[65] differs from that of the above studies. To separate Pb, the dissolved specimen is passed through a column of Chromosorb W-HP impregnated with a solution of dithizone in *o*-dichlorobenzene, and the silver and copper ions remaining in solution are concentrated on 2.5 cm diameter discs of SERVA-SB-2 ion-exchange paper as the complexes $[AgI_4]^{3-}$ and $[CuI_4]^{2-}$. Silver and copper are determined by XRF.

Table 2. The use of ion-exchange filters and membranes for preliminary concentration in XRF analysis.

No.	Filter	Material	Elements determined	Refs.
1	Chelex-100	water, pH 7–8	heavy metals	[51]
2	Chelex-100	water	U ($0{,}5 \cdot 10^{-7}$%)	[52]
3	Chelex-100	water, pH 2.5	U (0.3 μg)	[53]
4	Paper impregnated with $AgNO_3$	steel	Se (10 μg)	[66]
5	SB-2	lead	Ag, Cu (0.2 μg)	[65]
6	SB-2	fuel	SO_4^{2-} (1%)	[64]
7	SB-2	water, pH 0.3	Os, Ru	[59]
8	SB-2	water	Hg (1 μg in 50 ml)	[58]
9	Chromatographic paper	water	Cs, Ba, Ln, Ag, Zn, Fe, Hg (10^{-7} g)	[63]
10	Ion-exchange membrane	mineral oils	V, Cu, Fe, Ni (10^{-4}%)	[62]
11	Ion-exchange membrane	copper	Au, Ag (100 μg)	[61]
12	SA-2	metals	Ln (10 μg)	[60]
13	Amberlite HP-120	water	Cr, Fe, Cu, Zn, Sr, Cd, Ba (1–$3 \cdot 10^{-4}$%)	[57]
14	SA-2	water	Ca ($7 \cdot 10^{-5}$%), Sr ($5 \cdot 10^{-7}$%)	[56]
15	Cellulose with the chromotropic group	water pH 4–7	heavy metals (1×10^{-5}%)	[55]
16	Cellulose with amino-groups	water	Ln	[50]

Paper can be impregnated not only with an ion-exchange resin but also simply with solutions capable of absorbing substances liberated as gaseous products. Thus Japanese workers have proposed a method for determining selenium in steels, based on its liberation as H_2Se and fixing on paper impregnated with silver nitrate[66]. When the liberation of H_2Se was complete, the paper was used as the emitter in the XRF determination (see Table 2).

Although the use of ion-exchange filters and membranes is attractive, they generally have a low capacity, which is inconvenient in the analysis of solutions with a large salt background.

IV. COMBINATION OF X-RAY FLUORESCENCE ANALYSIS WITH EXTRACTION

The combination of the XRF determination with concentration by extraction is of interest, because of the speed and simplicity of the extraction concentration. Both liquid extraction and extraction by low-melting organic substances are now used.

1. Liquid Extraction

One of the first studies in this field dealt with the determination of transition metals at concentrations of 10^{-8}–10^{-6}%.[67] The metals were extracted as the diethyldithiocarbamate complexes by carbon tetrachloride. Polystyrene was then added to the extract, and the mixture evaporated on a Mylar film under an infrared lamp. This film was then analysed by XRF.

Later, a more complex method of preparing the specimen was used to determine V, Cr, Mn, Fe, Co, Ni, Cu, and Zn in sea water[68]. The elements to be determined were separated as the pyrrolidinedithiocarbamates by treating with methyl isobutyl ketone, and then transferred to nitric acid solution and sorbed on cellulose powder, which was compressed to form a disc. The reference specimens were prepared similarly from standard solutions. The elements listed could be determined at concentrations of 0.1 μg litre^{-1}.

Micro-quantities of palladium in titanium alloys have been determined by extracting palladium diethyldithiocarbamate with chloroform[69]. The emitter was prepared by impregnating a 15 mm diameter filter-paper disc with the extract. A similar method was used to determine technetium in waste products from nuclear fuel production[70], and uranium and neptunium in metallic plutonium[71].

In the Soviet literature, the determination of micro-quantities of tantalum in technetium solutions[72] and of zirconium and hafnium in heat-resistant alloys[73] by a combination of liquid extraction and XRF determination of the metals in the extract has been described.

Leyden[74] determined phosphorus in natural waters at concentrations of 10^{-7}% using selective extraction by ethyl acetate as molybdophosphoric acid. Phosphorus was determined using the Mo K_α line. This indirect determination of light elements from the emission of heavier elements is opening up a new and promising field in the XRF analysis of light elements.

2. Extraction by Low-Melting Organic Substances

Increasing use is now being made of low-melting organic extracting agents, and solutions of extracting agents in low-melting organic solvents. The combination of high-temperature extraction with XRF analysis of the extract is particularly promising, since when the extraction mixture is cooled, the solid organic phase is obtained directly in a form suitable for spectrometry. This property has been used in the determination of Cr, Fe, Co, Ni, and Cu in fresh water after extraction by molten 8-quinolinol at 98 °C.[75]

One of the most widely used low-melting solvents is naphthalene[76] or its mixtures with other organic substances[77]. The use of naphthalene as extracting agent, however, does

not make it possible to determine elements whose XRF analysis requires a vacuum. Another disadvantage of working with naphthalene is the low viscosity of its solutions, which causes difficulty in the separation of phases with markedly different quantities. It is much more convenient to use as the organic phase a mixture of C_{17}–C_{20} aliphatic acids.

Micro-quantities of Cr, Mn, Fe, Co, Ni, Cu, and Zn have been extracted by a solution of 1-phenyl-3-methyl-4-benzoylpyrazolone-5 in a molten mixture of aliphatic acids[78]. A similar procedure has been used[79] to determine bismuth in various materials with preliminary extraction by dithizone or 2,3,4-trihydroxy-4'-chlorobenzene (sic). Japanese workers have concentrated Co, Fe, Ni, Cu, Zn, Pb, Bi, and Cd by extracting their pyrrolidinedithiocarbamate complexes into molten stearyl alcohol[83]. The chelates of all these metals except iron are transferred quantitatively to the organic phase at pH 5. The extraction of iron is not complete, since its chelates are unstable at high temperatures.

Extraction by low-melting organic substances provides an approach to the solution of the problem of the standardisation and unification of the XRF determination of traces of elements in various natural and industrial materials. The combination of the individual solution of the specimen to be analysed with subsequent extraction by low-melting organic substances and the production of an emitter from the solidified extract makes it possible to obtain a standardised matrix which is independent of the previous history of the substance being determined.

The general questions of the metrology of chemical XRF analysis have been examined in detail[84]. An analysis of the dependence of the relative standard deviation $S_{r,\,c}$ on the concentration $c_{min,\,p}$ showed that preliminary concentration makes it possible not only to lower $c_{min,\,p}$ but also to increase the reproducibility of the results at low concentrations. The use of low-melting extracting agents makes it possible to lower the random and systematic errors in the analysis by eliminating matrix effects and making possible the construction of universal calibration characteristics. If the low-melting extracting agent contains only light atoms, it is possible to reduce to a minimum the effects of absorption and selective excitation. On the other hand, if it is necessary to produce very thin saturated layers, it is possible to use low-melting extracting agents containing heavy atoms, for example bromine. The use of hetero-organic compounds with a known concentration of the reference element makes it possible to increase considerably the accuracy of the determination using an internal standard.

It should be emphasised again that chemical XRF analysis is finding increasing application in the analysis of water and in the analysis of other most varied materials (steels, alloys, and organic and biological materials). In the analysis of solid substances, concentration is preceded by solution.

The choice of the optimum method of concentration is determined by the conditions of the analysis, interfering elements, and the accuracy and sensitivity required in each specific case.

As already noted, an advantage of the methods described, compared with traditional non-destructive XRF methods, is that the preliminary decomposition and concentration of the specimen makes it possible to eliminate the corrections for matrix effects and non-uniformity of composition and particle size. On the other hand, the combination of chemical methods of concentration with the XRF determination of elements in the concentrates makes it possible to avoid the restrictions associated with the chemical nature of the elements being determined (the superposition of colours in photometry, etc.), and does not require preliminary separation of the elements.

Thus the combination of XRF with various chemical and physicochemical methods of concentration is a promising development in the determination of traces of elements.

Chromatography in a Gas-Colloid System

S.I.Kirsh, R.N.Martynyuk, N.T.Karabanov, and M.S.Vigdergauz

The results of the study of colloidal systems based on highly dispersed adsorbents and colloidal solutions of polymers as universal stationary phases for gas chromatography have been analysed. Particular attention has been paid to the regular features of retention on colloidal sorbents and the estimation of their selectivity and thermal stability. Possible fields of analytical application (the separation of mixtures of organic and organometallic compounds, trace analysis, and capillary chromatography) have been examined.
The bibliography contains 70 references.

I. INTRODUCTION

In practical gas chromatography (GC), increasing use is being made of sorbents combining the properties of solvents and adsorbents. The use of sorbents operating under intermediate adsorption–absorption conditions extends gas-chromatographic analysis chiefly by making it possible to control the selective properties of the chromatographic packing by changing the relationship between the contributions of solution and adsorption in the overall retention. The use of sorbents with controllable selectivity makes it possible to reduce considerably the range of stationary phases (SP) for gas chromatography.

Sorbents of the intermediate type include: 1) macroporous carbon adsorbents, modified by liquid phases, of the Carbochrome or Carbopak type, 2) macroporous silica adsorbents, modified by liquid phases, of the Silochrome or Spherosil type, 3) porous polymers, modified by liquid phases, of the Porapak or Polysorb type, 4) adsorbents with stationary liquids chemically bound on the surface (graft sorbents of the Durapak type), 5) organic derivatives of clays (Bentones) on an inert solid carrier, 6) liquid crystals on an inert solid carrier, and 7) colloidal systems on an inert solid carrier.

Adsorption–absorption chromatography using modified Silochromes and graphitised carbon black[1-3], the use of modified polymers in gas chromatography[4], problems of chromatography on Bentone columns[5-7], analytical and physicochemical aspects of chromatography in a gas–liquid crystal system[8], and graft sorbents[9] have already been reviewed.

The modification of adsorbents by a liquid phase makes it possible to control the selectivity, eliminates the asymmetry of the peaks due to polar substances, and in the case of carbon black increases the mechanical strength of the sorbent. Usually, with increase in the quantity of stationary phase on the adsorbent carrier, the efficiency increases up to the formation of a monolayer, after which it decreases as a result of a decrease in the rate of mass exchange[2]. This restricts the range of the selectivity of modified adsorbents suitable for practical application, and naturally reduces the range of analytical problems that can be solved using a given adsorbent–modifier system.

Bentones belong to the class of intermediate sorbents because of the mixed mechanism of the interaction of the sorbates with adsorption centres on the one hand and with organic groups on the other. Since liquid crystals show simultaneously (within a short temperature range) the properties of both liquids and solids, they also act as intermediate sorbents. It should be noted that both Bentones and liquid crystals, which have a high selectivity with respect to structural isomers, have a moderate group selectivity.

Colloidal systems (colloids) in the most general sense are systems in which substances are subdivided to give very small particles (10^{-4}–10^{-7} cm). A necessary condition for the colloidal state of a system is the insolubility of one phase in the other. The existence of a physical surface between the phases, that is the heterogeneous character of colloids, represents the basic difference between them and true homogeneous solutions. From the molecular-kinetic properties typical of polymer solutions (low osmotic pressure, little diffusion of the macromolecules, and their inability to pass through a semi-permeable partition in dialysis), they must be classified as colloidal systems. This similarity is related to the fact that the dimensions of the particles, which determine the properties of the solutions of both types, are similar to one another and much greater than those of ordinary molecules.

A chromatographic study of a binary squalane–stearonitrile mixture[10] confirmed the suggestion that micelles exist in mixtures of non-polar liquids with nitriles. Thus these and similar binary liquid phases are colloidal.

Of the wide range of types of colloidal system, classified according to the state of aggregation of the dispersed phase and the dispersion medium, the systems formed by a solid and an organic liquid, that is organosols and gels of highly dispersed adsorbents and polymers, are of greatest interest from the present viewpoint. The use of these systems as sorbents is attractive because it is possible, by changing the composition, to vary smoothly the sorption characteristics of the packing in a range from the properties of the liquid to the properties of the solid, which is difficult in the classical form of gas chromatography on modified adsorbents.

If organic derivatives of clays are regarded as one-dimensional colloids in view of the "colloidal" dimensions of the particles in one of three directions[11], then Bentones were essentially the first colloidal systems to find gas-chromatographic application. Bentones mixed with liquid phases form stable colloidal systems[12]. It has been suggested[13] that on

treatment with a silicone oil, the crystal lattice of Bentone-34 is deformed, and the mixture becomes a thixotropic gel. Modified Bentones have been widely used in the analysis of aromatic isomers[5-7].

Colloidal systems can be obtained by introducing an appropriate filler into viscous organic liquids. The first examples of these stationary phases were silicone greases[14]. The influence of the silica fillers in high-vacuum silicone grease on the value of the retention has been studied[15]. Pecsok and Vary[16], working with dispersions of metallophthalocyanines in silicone oil, were among the first to demonstrate clearly the advantages of the directed use of adsorption effects in gas–liquid chromatography. It subsequently appeared appropriate to carry out detailed studies of the chromatographic properties and analytical possibilities of colloidal sorbents.

The present review examines two types of colloidal system as SP for gas chromatography—colloidal solutions of polymers and colloidal systems based on highly dispersed adsorbents. Studies carried out by the authors have shown that these stationary phases make it possible to control the selectivity of chromatographic separation over a wide range, and hence to solve a large number of analytical problems.

II. REGULAR FEATURES OF RETENTION ON COLLOIDAL SORBENTS

1. Preparation of Colloidal Sorbents

The method of preparing sorbents with colloidal polymer solutions as stationary phases is protected by a patent[17] and has been described in a number of papers[18-21]. Dispersions of macromolecular compounds corresponding to the colloidal state were obtained by the aggregation of the macromolecules in the solution by the introduction of a high-boiling liquid modifier. When the solvent was evaporated and an inert carrier added to the heated mass (80–100 °C), the solid surface was covered by aggregates of molecules of the colloidal system. Polyvinyl alcohol (PVA), polystyrene (PS), and low-pressure polyethylene (PE) were used as polymeric components. Polyethylene glycol-400 (PEG-400), dinonyl phthalate (DNP), and squalane were used as modifiers.

Ultrasonic dispersal† has been used to prepare colloidal SP based on highly dispersed adsorbents[22-26]. The Aerosil (highly dispersed silicon dioxide) or PM-15 grade carbon black was introduced into solutions of the organic liquid squalane, PEG-400, PEG-40000, polymethylsiloxane (PMS-100), or polymethylphenylsiloxane (PMPS), after which the prepared suspension was deposited on inert solid carriers. Since the particle size of the fillers used lay in the colloidal range ($\sim 10^{-5}$–10^{-6} cm), the systems based on them are colloidal. An apparatus for continuous vigorous shaking has been used to increase the thermal stability of stationary phases by adding solid highly dispersed binding agents of the Aerosil or graphitised carbon black type[27]. There is no difference between the filling of capillary columns by colloidal stationary phases[28] and that in ordinary gas–liquid chromatography.

†A similar method has been used to obtain stable coatings in capillary chromatography (see section VI).

2. Influence of the Composition of the Colloidal Stationary Phase on the Retention of Polar and Non-polar Compounds

A necessary condition for the successful gas-chromatographic analysis of a mixture is the correct choice of sorbent. The use of binary or multiple systems makes it possible to vary smoothly the selectivity of the chromatographic separation and hence to carry out a directed search for the sorbent with the optimum properties. The dependence of the elution characteristics of the components of the mixture being analysed on the composition of the combined stationary phase provides a basis for the solution of this problem. For the usual mixed liquid phases, these relationships in most cases are linear. A characteristic feature of colloidal systems is the presence of breaks and extremal points on the plots of $\lg V_g$ against composition (V_g is the specific retention volume). Anomalies in the retention process are due to specific interaction between the components of the system, and also adsorption factors.

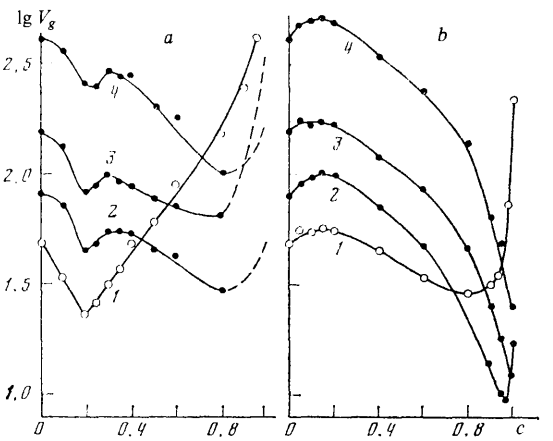

Figure 1. Dependence of the retention on the composition of colloidal SP; PEG-400–Aerosil (*a*) and PEG-400–carbon black (*b*); *1*) nonane, *2*) benzene, *3*) ethanol, *4*) nitromethane[22,25].

The dependence of the retention on the composition of colloidal SP containing highly dispersed adsorbents is given in Fig. 1 (*c* is the mass fraction of the adsorbent). The curves corresponding to the retention of alkanes on columns containing a PEG-400–Aerosil system have a minimum at $c = 0.2$.[22,26] This composition corresponds to the conversion of the colloid from the free-dispersed state (sol) into the bound-dispersed gel-like state. This agrees with data obtained by the workers who developed the Soviet Aerosil[29], and is confirmed by electron-microscope studies[26]. In addition to this minimum at $c = 0.2$ for polar compounds, there is another deeper minimum corresponding to $c = 0.8$. At this component ratio, the contribution of solution is appreciable. A higher concentration of Aerosil corresponds to a sharp increase in the retention volume, due to adsorption on the gas–Aerosil surface with the production of asymmetric peaks. The position of the extremal points on the $\lg V_g$–composition curves for the PEG-400–carbon black system[25] corresponds to the same

component ratio as in the PEG-400–Aerosil system. The colloidal conversion is accompanied by the maximum retention for this system, however.

Thus the form of the extremal point is determined by the nature of the interaction between the components of the colloidal stationary phase, since the glycol is able to form hydrogen bonds with the Aerosil, whereas its interaction with the carbon black involves chiefly non-specific forces. Fig.1 also shows that by introducing a highly dispersed carrier into the stationary phase, it is possible to change smoothly the retention of the substances being analysed, as far as a change in the order of their elution.

For the organic PS–squalane system (Fig.2), the retention characteristics pass through a maximum at equal proportions of the modifier and the polymer, indicating an interaction between the components of the colloidal stationary phase at this component ratio. The extremal points on the graph giving the dependence of the retention on composition for the PE–PEG-400 system are not so sharp as those for the sorbent based on polystyrene. Here also, however, change in the ratio of the components of the stationary phase can be used to control the selectivity of the column in the analysis of organic compounds of various classes. The sharp increase in the retention of polar sorbates on going from the pure polymer to the mixture with a small quantity of the glycol is apparently due to the influence of the adsorption factor[30].

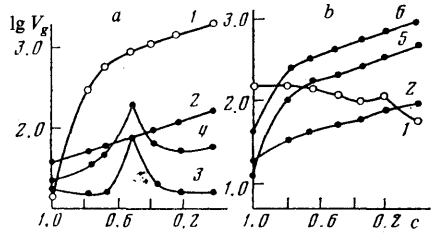

Figure 2. Dependence of the retention on the composition of colloidal SP; PS–squalane (*a*) and PE–PEG-400 (*b*); *1*) nonane, *2*) benzene, *3*) ethanol, *4*) methyl ethyl ketone, *5*) nitromethane, *6*) pyridine[18,19].

In a study of the absolute retention of benzene, allyl iodide, and chlorobenzene on the mole fraction (x_A) of strearonitrile in squalane, maxima were observed at x_A = 0.1–0.2.[10] In the opinion of the authors cited, this was due to the formation of micelles in this system.

Thus for practically all colloidal systems, the plot of the logarithm of the retention volume against the quantitative ratio of the phases is non-linear. The presence of breaks and extremal points on these curves is determined by the nature of the interaction between the components of the system, and adsorption factors. Change in the composition of the colloidal sorbent over a wide range makes it possible to control the sorption characteristics of the chromatographic packing.

3. Influence of Temperature on Retention by Colloidal Stationary Phases

The temperature of the column (T), together with the composition of the sorbent, provides an efficient means of controlling the selectivity of a chromatographic separation. This is particularly true of systems containing polymers or liquid crystals, that is materials which change their phase state in the range of temperatures used in gas-chromatographic analysis.

It is known[31] that

$$\lg V_g = A + B/T \quad . \qquad (1)$$

The coefficient A is related to the entropy of sorption, and the coefficient B is the enthalpy component. A change in the nature of the sorption in the range of the temperatures of the phase transformation of the polymer for polar and non-polar sorbates leads to a change in the absolute values of the constants A and B in Eqn.(1), leading to distortion of the plot of the logarithm of the retention volume against the reciprocal of the absolute temperature (Fig.3).[21] These distortions are observed chiefly for non-polar or weakly polar compounds (alkanes and aromatic hydrocarbons). This indicates that the modifier makes the predominant contribution to the retention of polar compounds (PS–PEG-400 system) and that there is no specific interaction between sorbates and the PE–squalane sorbent. For colloidal solutions of polystyrene and polyvinyl alcohol in squalane, the opposite picture is observed. Increase in the concentration of the polymer in the binary stationary phase leads to more clearly defined breaks on these curves for compounds whose retention is determined by the polymeric component.

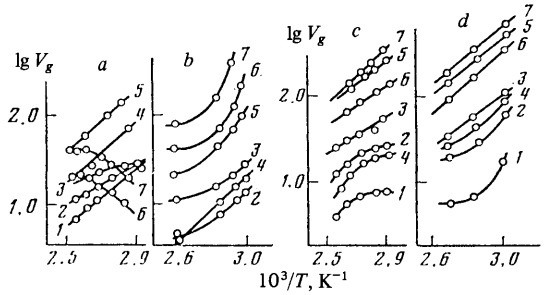

Figure 3. Plot of the retention against the reciprocal of the absolute temperature of the column; *a*) PS–PEG-400 (c = 0.67), *b*) PE-squalane (c = 0.2), *c*) PS–squalane (c = 0.4), *d*) PVA–squalane (c = 0.6); *1*) ethanol, *2*) methyl ethyl ketone (MEK), *3*) benzene, *4*) nitromethane, *5*) pyridine, *6*) n-nonane, *7*) n-decane[18,19].

A change in the selectivity of the column in the range of the temperatures of the phase transformation is particularly characteristic of the PS–PEG-400 system. When polystyrene changes from the vitreous to the highly elastic state (~100 °C), the retention of alkanes increases to such an extent that the peak of nonane is "displaced" into the middle of the chromatogram, passing in front of ethanol, methyl ethyl ketone, nitromethane, and pyridine. Thus the use of colloidal solutions of polymers as stationary phases makes it possible to control the selectivity of the chromatographic column in the temperature range of the change in the phase state of the polymer without replacing the sorbent.

A study of the temperature dependence of the retention for the colloidal stationary phases PEG-400–Aerosil and squalane–Aerosil# established[22,26] that for all sorbates they are linear,

#Here and subsequently, the squalene–Aerosil and squalane–carbon black systems are systems with the addition of 15% PEG-400 relative to the mass of Aerosil and 1.5% relative to the mass of carbon black.

since the phase state of the components does not change in the temperature range studied. The plot of the retention volume against the reciprocal of the temperature for a PEG-40000–Aerosil sorbent has been studied[24,26]. The graphs show breaks in the absence of the adsorbent, and at a relative concentration of the adsorbent $c = 0.1$ and 0.2. As with polymer solutions, the deviations from the linear relationship characterise the change from the adsorption of the substances being analysed on the surface of the solid polymer to solution, due to the diffusion of the molecules into the depth of the liquid polymer film, leading to an increase in the capacity of the sorbent. The increase in retention takes place before equilibrium absorption is reached. As the Aerosil is added to the polymer, the inflection on the retention curve gradually decreases, and it disappears completely at $c = 0.3$. An interesting feature is that the sorbent with this composition shows the strongest specific adsorption properties[24].

4. Influence of Adsorption Factors on Retention by Colloidal Stationary Phases

As already noted, the marked deviation from linearity shown by the dependence of the retention characteristics of the sorbates on the composition of the binary colloidal phase may be due to adsorption phenomena. Retention in a gas–colloid system is determined by solution in the liquid phase (the dispersion medium of the colloid), adsorption on the surface of the colloidal particles of the polymer or adsorbent (the disperse phase of the colloid), and also adsorption at the boundaries between the phases. The influence of these factors on retention has been studied[20,21,23,26].

Since the stationary phases were deposited on fairly inert silanised carriers in quantities of more than 10%, adsorption at the gas–solid carrier and liquid–solid carrier boundaries could be neglected. For the description of the adsorption effects on colloidal organic phases[20,21], an equation was proposed, relating the specific retention volume (V_g) to the distribution and adsorption constants

$$\frac{V_{g,p}}{s} = \frac{\Gamma}{s}\frac{W}{g + g_c} + \Gamma_1 \qquad (2)$$

where $V_{g,p}$ is the specific retention volume per gram of packing, $cm^3\ g^{-1}$; s the surface area of 1 g of the colloid, cm^2; Γ the coefficient of sorption by the colloid, $(g\ cm^{-3}/g\ cm^{-3})$; Γ_1 the coefficient of adsorption on the gas-colloid surface, cm; W the volume of colloidal solution in the column, cm^3; g its mass, g; and $g + g_c$ the mass of packing, g.

Since the coefficients of adsorption of polar and non-polar sorbates at the gas–colloid surface for systems containing highly dispersed adsorbents are negligible[23], the sorption by these sorbents was calculated using the equation[26]:

$$V_{g,p} = \Gamma\frac{W}{g + g_c} \quad . \qquad (3)$$

Eqns.(2) and (3) are applicable for systems containing a small quantity of a disperse phase and consisting of colloidal solutions or sols. The quantity Γ in Eqn.(2) characterises the adsorption by the colloidal particles of the polymer[20,21]:

$$\Gamma W/(g + g_c) = \Gamma_m W_m/(g + g_c) + \Gamma_m\Gamma_s s_{pl,p} \qquad (4)$$

where W_m is the volume of the modifier in the column, cm^3; $s_{pl,p}$ the surface area of the colloidal particles of the polymer, calculated for 1 g of packing, $cm^2\ g^{-1}$; Γ_s the coefficient of adsorption on the surface of the colloidal particles, cm; and Γ_m the distribution coefficient between the pure modifier and the gas phase, $(g\ cm^{-3})/(g\ cm^{-3})$.

Eqn.(4) gives

$$\frac{\Gamma}{\rho}\frac{\Pi}{\Pi + 100} = \frac{\Gamma_m}{\rho_m}\frac{1 - c}{1 + 100/\Pi} + \Gamma_m\Gamma_s s_{pl,p} \qquad (5)$$

where Π is the percentage impregnation of the solid carrier by the colloid; ρ the density of the colloid, $g\ cm^{-3}$; ρ_m the density of the modifier, $g\ cm^{-3}$; and c the mass fraction of the polymer in the mixture with the modifier.

The relationship

$$\frac{\Gamma}{\rho} = \Gamma_m\left[\frac{1 - c}{\rho_m} + \Gamma_s\left(1 + \frac{100}{\Pi}\right)s_{pl,p}\right] \qquad (6)$$

can then be brought to an equation of the form

$$\frac{\Gamma}{\rho} = \Gamma_m\left[\frac{1 - c}{\rho_m} + \Gamma_s s_{pl,pl}c\right] \qquad (7)$$

($s_{pl,\,pl}$ is the surface area of the particles, calculated for 1 g of polymer, $cm^2\ g^{-1}$).

If Γ_m is known from the data obtained using the pure modifier, it is possible to calculate $\Gamma_s s_{pl,\,pl}$, that is the adsorption by 1 g of polymer present in the colloidal state.

With increase in the proportion of the dispersed phase, the colloidal solution is converted into a gel-like state. The system loses its flow properties as a result of the agglomeration of the micro-particles to give a coagulation structure. The overall surface area of the sorbent increases. In the general case it may be assumed that the retention of the compounds being analysed for these systems is determined by the sorption by the gel. Thus

$$V_{g,p} = \Gamma_g s_g \qquad (8)$$

where Γ_g is the coefficient of sorption by the gel, cm; and s_g the surface area of the gel for 1 g of packing, $cm^2\ g^{-1}$.

The contributions of solution and adsorption to the total retention on organic colloidal sorbents can be estimated from Eqn.(4).[20] When colloidal systems containing highly dispersed adsorbents are used, part of the modifier does not take part in the sorption process, but is used up in suppressing the active centres of the solid carrier. Thus with allowance for this characteristic feature of these systems,

$$V_N = \Gamma_m(W_m - W'_m) + \Gamma_m\Gamma_a s_a \qquad (9)$$

where V_N is the effective retention volume, cm^3; Γ_a the coefficient of adsorption on the surface of the adsorbent in the colloidal state, cm; s_a its surface area, cm^2; and W'_m the volume of the modifier not taking part in the sorption process, cm^3.

The proportion of the modifier W'_m corresponds to the ratio of the components of the system at which the change to adsorption on the surface of the adsorbent takes place. This change corresponds to the retention minima on the plots of $\lg V_g$ against composition in the range of high values of c. Thus for the PEG-400–Aerosil system (Fig.1), $W'_m = 0.25g_a/\rho_m$ (g_a is the mass of highly-dispersed adsorbent in the column for the composition $c = 0.8$).

It can be shown that $g_a = W_m\rho c/(1 - c)$, so that $W'_m = 0.25W_m c/(1 - c)$. By analogy with the PEG-400–Aerosil system, for the PEG-400–carbon black system $W'_m = 0.015W_m c/(1 - c)$.

The use of these relationships for the quantitative estimation of the factors determining retention showed[20,21,26] that change in the composition of the colloidal stationary phases, and in the case of polymer solutions change in the temperature of the column, leads to a change in the ratio between the contributions of adsorption and absorption forces to the overall retention. This makes it possible to control the selectivity of separation and elution times of substances being analysed.

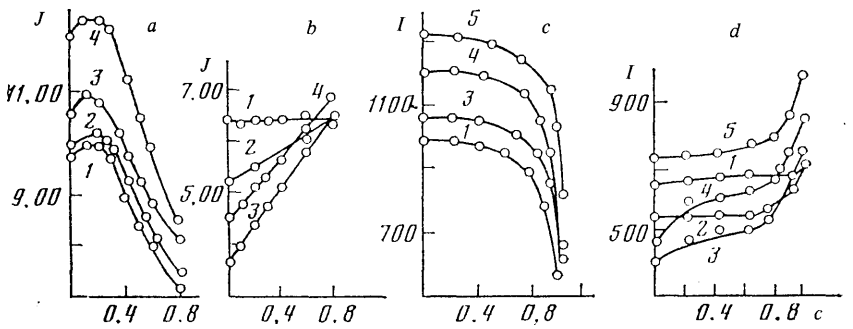

Figure 4. Dependence of the retention indices on the composition of colloidal SP: *a*) PEG-400–Aerosil, *b*) squalane–Aerosil, *c*) PEG-400–carbon black, *d*) squalane–carbon black; *1*) benzene, *2*) MEK, *3*) ethanol, *4*) nitromethane, *5*) pyridine[22,25].

III. SELECTIVITY OF COLLOIDAL STATIONARY PHASES

The range of stationary phases for GC on the world market includes more than 900 products. In spite of this, cases are frequently encountered where no known phase gives the required separation. These "selectivity gaps" are observed particularly in the selection of sorbents for the analysis of multi-component mixtures. The choice of sorbent is facilitated considerably by using different kinds of combined stationary phase, in particular colloidal systems.

1. Indices of Retention on Colloidal Sorbents

A convenient characteristic of the selectivity of a stationary phase towards a definite class of compound is provided by the logarithmic retention indices (Kovats indices) of a given substance *I* belonging to this class[32,33]. Its linear analogue *J* [33,34] is simpler in calculations. These data can be used to classify sorbents according to their polarity, and also to estimate the range of change in selectivity using combined sorbents.

Figs.4*a* and 4*b* [22,25] give the dependence of the linear retention index on the composition of colloidal stationary phases based on Aerosil. For the PEG-400–Aerosil system, the *J* curves for all the sorbates studied show maxima at the composition corresponding to the conversion of the sol to the gel. For the squalane–Aerosil system, the dependence of *J* on *c* is practically linear. The relative error in the determination of the linear retention indices did not exceed ±0.04 index unit. As a result of the change in the nature of the interaction on going from the PEG-400–Aerosil sorbent containing 20% adsorbent to the sorbent containing 80% adsorbent, the linear retention index of benzene, methyl ethyl ketone, and ethanol can be changed by 3 units, which corresponds to 300 units of the Kovats index, and that of nitromethane can be changed by 3.7 units (370 units). On pure squalane, ethanol is eluted before butane, and on a squalane–Aerosil sorbent with $c = 0.8$ it is eluted after hexane.

The dependence of the logarithmic retention index on the composition of stationary phases containing carbon black has been studied[25,26] (Figs.4*c* and 4*d*). In contrast to the PEG-400–Aerosil system, the change from the sol to the gel for the colloid containing carbon black is not accompanied by a maximum on the graph, since the interaction of polar and non-polar sorbates with the non-specific adsorbent involves dispersion forces. The greatest decrease in the retention indices begins at a carbon black concentration of 60% in its mixtures with the glycol. A different picture is observed for the squalane–carbon black system. Thus for ethanol and nitromethane, substances which tend to undergo strong specific interactions with a carbon black surface treated with a small quantity of glycol, breaks are observed on the curves at a low concentration of a highly dispersed filler. On going from the sorbent with $c = 0.2$ to the sorbent with $c = 0.985$ in the PEG-400-carbon black system, the retention indices can be changed by 280 units for benzene, by 300 units for ethanol, and by 370 units for nitromethane. On squalane, the retention index of methyl ethyl ketone is 140 units greater than that of ethanol, and on squalane containing 90% modified carbon black, the retention index of ethanol is 16 units greater than that of methyl ethyl ketone.

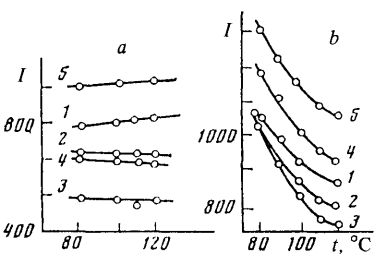

Figure 5. Dependence of the retention indices on the column temperature; *a*) PS–squalane ($c = 0.5$); PS–PEG-400 ($c = 0.5$).[21] See Fig.4 for numbering of sorbates.

Fig.5 [21] gives the temperature dependence of the Kovats indices of standard sorbates on polymeric colloidal phases. The greatest temperature "displacement of the indices" is observed for the PS–PEG-400 system. In this case the index of benzene, for example, in the range 80–100 °C decreases from 1005 units to 870 units, due to the increase in the retention of alkanes in the region of the phase transformation of polystyrene. For other colloidal solutions of polymers, the changes in *I* with change in the column temperature are slight. Thus for the PS–squalane system in the same temperature range, it changes by only 10 units (from 690 to 700).

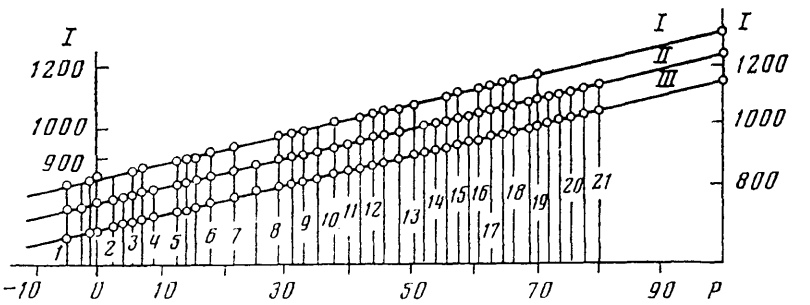

Figure 6. Dependence of the retention indices of ethylbenzene (*I*), toluene (*II*), and benzene (*III*) on the conditional chromatographic polarity[20,21]. For the numbering of the phases see Table 1.

2. Conditional Chromatographic Polarity of Colloidal Sorbents

The selection of the sorbent for the separation of a specific pair of components or a mixture of substances belonging to the same class is simplified considerably if its conditional chromatographic polarity *P*, a characteristic of the phase determined by the presence of groups other than alkyl groups, is known. According to Rohrschneider[35], who first proposed this approach to the selection of sorbents and their classification according to polarity, *P* is given by the expression

$$P = \frac{\lg r_2 - \lg r}{\lg r_2 - \lg r_1} \qquad (10)$$

where r_1 and r_2 are the ratios of the retention volumes of butadiene and butane on squalane ($P = 0$) and on β,β'-hydroxydipropionitrile ($P = 100$), and r is the corresponding ratio on the sorbent being studied.

The relative retention can be replaced by the retention indices for, for example, aromatic hydrocarbons[36]. In this case, the graphical expression of the conditional chromatographic polarity involves plotting *P* against the retention index. These plots can be used to predict the retention times of the substances being analysed and to select a sorbent with the optimum selectivity. Fig.6 gives the graph[20,21] for determining the conditional chromatographic polarity of colloidal solutions of polymers. The position of the point corresponding to the stationary phase on the abscissa was determined from the retention indices of benzene, toluene, and ethylbenzene. Table 1 gives colloidal systems in order of increasing conditional chromatographic polarity, with the column temperatures, composition, and percentage impregnation.

The change in the conditional polarity with change in the percentage impregnation of the carrier is apparently related to the sorption of the substances being analysed on the surface of the colloidal particles. The selectivity of colloidal binary phases may also be changed under the influence of the temperature factor, and if vitrification of the less polar component takes place, the decrease in its sorptive capacity leads to an increase in the overall polarity of the colloidal phases.

Fig.6 and Table 1 show that, using only six components (three polymers and three stationary liquids), it is possible, by varying their qualitative and quantitative composition, the percentage impregnation of the carrier, and the column temperature, to obtain a fairly wide range of conditional chromatographic polarity (from −5 units to 80 units). The smooth change in the properties of the colloidal systems based on polymers makes it possible to select the required phase for the solution of a specific analytical problem.

Table 1. Dependence of the conditional polarity (*P*) of colloidal polymer phases on the column temperature (*t*), the composition of the stationary phase (*c*), and the percentage impregnation (П).[20]

Phase No.	System	*t*, °C	*c*	П	*P*

3. Rohrschneider's Polarity Factors for Colloidal Sorbents

Polarity factors have recently been used to characterise the selective properties of sorbents. These factors represent the differences in the retention indices ΔI of standard sorbates of different chemical character on columns with the stationary phase being studied and a non-polar liquid, for example squalane. The Rohrschneider polarity factors[37], that is the values of $\Delta I/100$ for benzene (*x*), ethanol (*y*), methyl ethyl ketone (*z*), nitromethane (*u*), and pyridine (*s*), have been calculated for the colloidal sorbents studied[20–22, 24–26] (see Table 2). These quantities make it possible to characterise in more detail the intermolecular interactions between the sorbent and the substance being analysed, and the set of values of the polarity factors provides as it were a sorbent "specification", which makes it possible to evaluate

its suitability for solving a particular separation problem. The values of the polarity factors and the overall conditional polarity of colloidal organic systems depend on the composition of the stationary phase, the percentage impregnation of the solid carrier, and the column temperature (see also Fig.7). The nature of the change in the polarity coefficients is on the whole analogous to that of the change in the overall conditional polarity (P). The change in the polarity coefficients with change in the percentage impregnation of the carrier characterises the relative contribution of adsorption and absorption factors to the retention of the corresponding standards, compared with the relative contribution of these factors to the retention of alkanes (Fig.7).

Table 2. Polarity factors of colloidal systems based on polystyrene at 100 °C and П = 25%.

System	Solutions in PEG-400					Solutions in squalane			
c	0.2	0.3	0.5	0.67	0.8	0.2	0.5	0.6	0.8

s	5.65	5.28	4.52	4.28	3.66	0.58	1.07	1.37	1.51

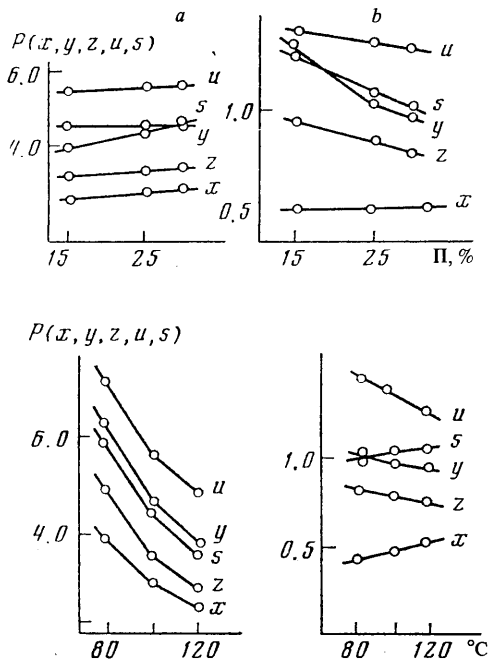

Figure 7. Dependence of the polarity factors of colloidal SP on the percentage impregnation and the column temperature: *a*) PS–PEG-400 (c = 0.67); *b*) PS–squalane (c = 0.5).[21]

The relationships given in Fig.7 can be used to select the optimum conditions for separating components of different classes. For example, to achieve the most selective separation of amines and aromatic hydrocarbons on colloidal solutions of PS in PEG-400, it is necessary to work at low column temperatures and maximum impregnation of the carrier by the liquid phase. To separate amines from nitromethane, the opposite relationship in these experiment parameters is preferred, since this case is characterised by the greatest difference in the polarity factors x and s, which play the most important role in the separation of components of these classes.

Table 3 gives the values of the polarity factors for colloidal stationary phases containing highly dispersed adsorbents. The sorbents studied are arranged in order of increasing constant x, the most universal characteristic of chromatographic polarity.

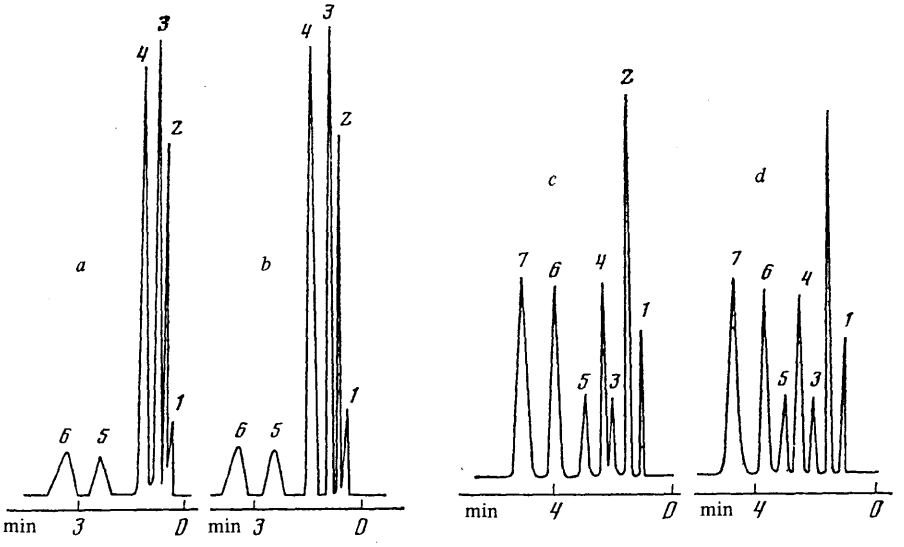

Figure 8. Chromatograms obtained for synthetic mixtures on ordinary (*a*,*c*) and colloidal (*b*,*d*) SP having similar polarity factors; 120 °C; Solid carrier Celite-545: *a*) SE-30, *b*) PS–squalane (*c* = 0.2); *1*) propionaldehyde, 2) thiophene, 3) n-octane, 4) o-xylene, 5) n-octanol, 6) o-cresyl acetate; *c*) Reoplex-400, PS–PEG-400 (*c* = 0.5); *1*) n-pentane, 2) acetone, 3) chloroform, 4) toluene, 5) dioxan, 6) n-butanol, 7) isopentyl alcohol[20,21].

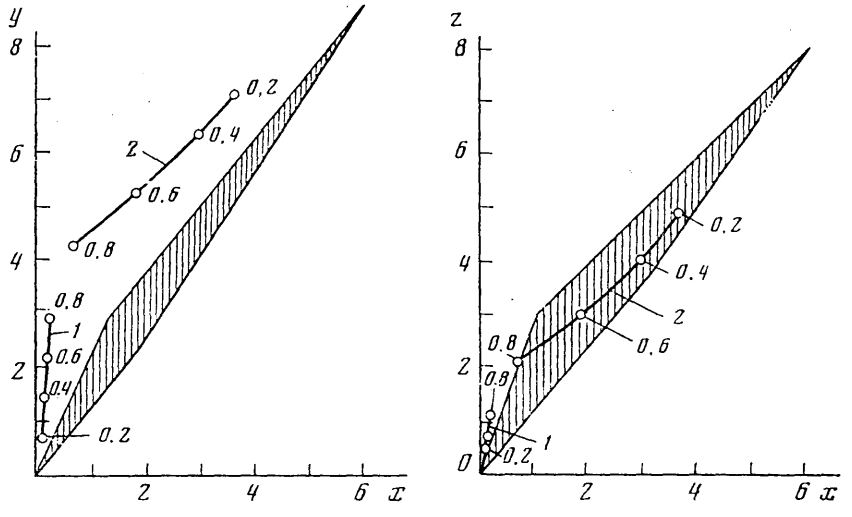

Figure 9. Dependence of the polarity factors y and *z* on the polarity factor *x*: *1*) PEG-400–Aerosil (*c* = 0.2, 0.4, 0.6, 0.8), 2) squalane–Aerosil (*c* = 0.2, 0.4, 0.6, 0.8) (the range of stationary phases studied by Rohrschneider[37] is hatched).[39]

The data in Table 3 can be used to select a sorbent with optimum selective properties on the basis of available materials produced by Soviet industry. The data given show that the use of colloidal stationary phases based on Aerosil and carbon black and a few modifiers makes it possible to obtain a set of sorbents covering a fairly wide range of polarity. Thus the polarity factor *y*, characterising the retention of ethanol, can be changed gradually from 0 on pure squalane to 6.96 on a PEG-400–Aerosil sorbent with *c* = 0.2 [1,2,3-tris(β-cyanoethoxy)propane], which has the highest polarity factors among known stationary phases (*y* = 8.71).

Knowing the Rohrschneider polarity factors, it is possible to replace one stationary phase by another with similar values of the polarity constants. Table 4 gives the values of the polarity factors of standard and colloidal stationary phases with similar selective properties[26]. The values of the polarity factors for the colloidal sorbents were obtained at 60 °C. The data on the separation on the standard stationary phases were taken from a monograph[38]. Thus without resorting to

the use of expensive SP difficult to obtain, it is possible to achieve a similar separation on a colloidal sorbent with a definite component ratio.

A similar comparison of standard stationary phases with the colloidal organic systems PS–PEG-400 and PS–squalane has been carried out[20]. As an example illustrating the possibility of replacing the stationary phases usually employed by colloidal phases, Fig.8 gives identical chromatograms for mixtures of compounds with different structures.

Graphs giving the relationship between the composition of a binary colloidal system and the polarity factor have been published[39] (Fig.9). The colloidal systems examined have higher polarity factors y than the usual stationary liquids studied by Rohrschneider[37]. Thus colloidal sorbents not only provide an alternative, but also may ensure an original combination of polarity factors.

IV. EFFICIENCY OF COLUMNS WITH COLLOIDAL SORBENTS

To estimate the efficiency of columns with solutions of polymers as stationary phases, and also to take account of various factors influencing the spreading of the zones of the components being separated, the following characteristics have been used[20,21]: the height equivalent to a theoretical plate (H) and the height equivalent to a theoretical plate with infinite increase in the retention time (H_∞):[6]

$$H_\infty = Lb/5.545 \qquad (11)$$

where L is the column length, and b is a constant from the equation relating the half-width of the peak and the retention time ($\tau_{0.5} = a + bt_R$). The set of values of H and H_∞ can characterise the efficiency of a chromatographic column for the separation of mixtures including weakly sorbed and strongly sorbed components, that is it can indicate the limiting possibilities provided by the stationary phase being studied.

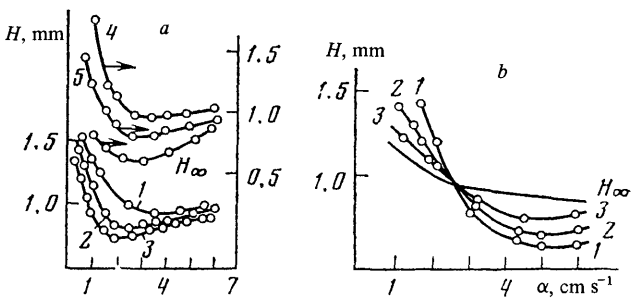

Figure 10. Relationship between the height equivalent to the theoretical plate and the linear velocity of the carrier gas at $\Pi = 15\%$ (*a*) and $\Pi = 3\%$ (*b*); PS–squalane ($c = 0.5$): *1*) hexane, *2*) heptane, *3*) nonane, *4*) benzene, *5*) toluene[20,21].

The regular features of the dependence of the efficiency of columns with colloidal stationary phases on the carrier-gas velocity, on the composition of the binary phase, and on the percentage impregnation of the carrier have been studied for a gel of polystyrene in squalane[20,21] (Fig.10). The nature of the change in the efficiency on going from one sorbent to another depends on the mechanism responsible for the broadening. The efficiency of columns with organic colloids in which the polymer is present in the liquid state is identical to that of columns with the pure modifier[20,21].

The efficiency of colloidal stationary phases based on highly dispersed adsorbents has been studied[26]. As noted above (see Fig.1), the sorptive capacities of the sorbents studied may differ considerably from one another, so that to estimate and compare their efficiencies it is appropriate to use the quantity $N = 5.545(t'_R/\tau_{0.5})^2$—the number of effective theoretical plates ($t'_R = t_R - t_0$ is the reduced retention time, and t_0 is the retention time of the non-sorbed gas). According to the data in Table 5, the efficiency of the stationary phase remains practically unchanged when a highly dispersed adsorbent is introduced into it, although in principle, a slight increase as a result of the decrease in the thickness of the liquid film should be expected[26]. Account must be taken, however, of the fact that the change to filled systems which have a higher viscosity than the pure modifiers leads to a decrease in efficiency. Thus in the final analysis, the values of N for a number of compounds are approximately the same on the individual liquid phase and on the liquid phase containing added adsorbents.

Table 5. Values of N for organic compounds on colloidal stationary phases[26].

Sorbate	PEG-400	PEG-400–Aerosil ($c = 0.2$)	PEG-400–carbon black ($c = 0.2$)
Nonane	680	670	660
Benzene	750	750	750
Methyl ethyl ketone	980	980	970
Ethanol	880	870	880
Nitromethane	690	700	690

The study of the dependence of the height equivalent to a theoretical plate on the carrier-gas velocity showed that, beginning from $V_a = 30$ cm^3 min^{-1}, the efficiency of a column with a colloidal sorbent depends little on the carrier-gas consumption for both organic and organometallic compounds[26]. Thus by using these sorbents it is possible to work in a fairly wide range of carrier-gas velocities without significant deterioration in the quality of the separation.

V. THERMAL STABILITY OF COLLOIDAL SORBENTS

One of the fundamental properties of a sorbent is its thermal stability. The limiting working temperature of sorbents can be determined in three ways: by recording the loss of liquid phase when the column is heated in a stream of carrier gas[40], by thermal analysis[41,42], and from the change in the background ion current with increase in the column temperature[43].

The most objective estimate of the thermal properties of chromatographic packing is given by thermal analysis, since in addition to the determination of the start of the mass loss from the form of the differential thermal curves, it is possible to deduce the nature of the processes responsible for the volatilisation of the stationary phase. The published thermal analysis curves[21] show that for colloidal polymeric phases, the temperatures of the start of mass losses and the start of the thermal effect generally coincide. This indicates that the changes in the mass of the colloidal stationary phases take place without significant thermal effects, and can be attributed to volatilisation.

Comparison of the upper temperature limits for colloidal stationary phases (Table 6) and the stationary phases usually employed in gas chromatography shows[19] that the thermal stability of the colloidal systems is equal to that of the individual modifiers and stationary liquids with similar polarity.

Table 6. Maximum working temperatures of colloidal phases, determined by extrapolation (medium—nitrogen, c' is the concentration of the vapour of the stationary phase in the carrier gas, g ml^{-1}).[21]

Stationary phase	$c'=10^{-6}$	$c'=10^{-7}$	$c'=10^{-8}$
PS–squalane (c = 0.9)	230	210	192
PS–PEG-400 (c = 0.8)	205	130	70
PS + 0.01% PEG-400	240	225	210

Although the addition of a polymer has no significant influence on the thermal characteristics of stationary phases, the addition of solid highly dispersed materials leads to an appreciable decrease in volatility. In the opinion of some authors[27,43], the effect is due to the binding of molecules of the liquid in the field of the adsorption forces of the active filler. For a high degree of dispersion and a sufficient quantity of highly dispersed material, all of the liquid phase is bound by adsorption, leading to a decrease in its volatility.

From the experimental data, it was concluded[27,43] that the stabilisation of stationary phases by Aerosil makes it possible to increase the maximum working temperature of the columns by 40–50 K, and makes it possible to increase the sensitivity of the chromatographic analysis using a flame ionisation detector by factors of 5–10, to increase the period of service of the columns, and to increase the accuracy of the treatment of the chromatograms by decreasing the distortion of the zero line.

Table 7. Values of K, $\bar{\Delta}$, and λ for colloidal and ordinary phases with similar polarity[20].

Mixture analysed	Stationary phase	t°, C	P	K	$\bar{\Delta}$	λ
1. Products of the catalytic dehydrogenation of butenes (acetone, acetic acid, acrylic acid, maleic anhydride)	25% PS in squalane (c = 0.4)	150	25	4.48	0.225	5.4
	25% Octoil-S	150	23	1.20	0.166	2.21
2. Products of the catalytic synthesis of isoprene (hexane, hexenes, hydropyrans, unsaturated alcohols, dimethyldioxan)	30% PS in dinonyl phthalate (c = 0.5)	100	26	1.00	0.182	3.64
	25% DNP	100	24	0.80	0.091	2.46
	15% PMPS-4	100	24	2.00	0.040	2;32
3. Aromatic hydrocarbons (benzene, toluene, cresyl acetates, naphthalene, ethylbenzene)	25% PS in squalane (c = 0.08)	150	10	2.10	0.059	3.10
	25% Apiezon L	150	9	3.48	0.040	2.32
4. C_2–C_{11} n-alcohols	25% PS in PEG-400 (c = 0.67)	180	58	1.10	0.085	0.91
	25 PEG-20000	180	64	1.43	0.032	0.71
5. C_1–C_6 aliphatic acids	25% PS in DNP (c = 0.2)	150	25	2.15	0.462	3.30
	DS-550 silicone oil	150	23	0.605	0.132	0.61
6. C_{10}–C_{24} n-alkanes	15% PS	250	62	1.00	0.704	2.08
	15% PEG-2000	250	64	1.10	1.157	1.60

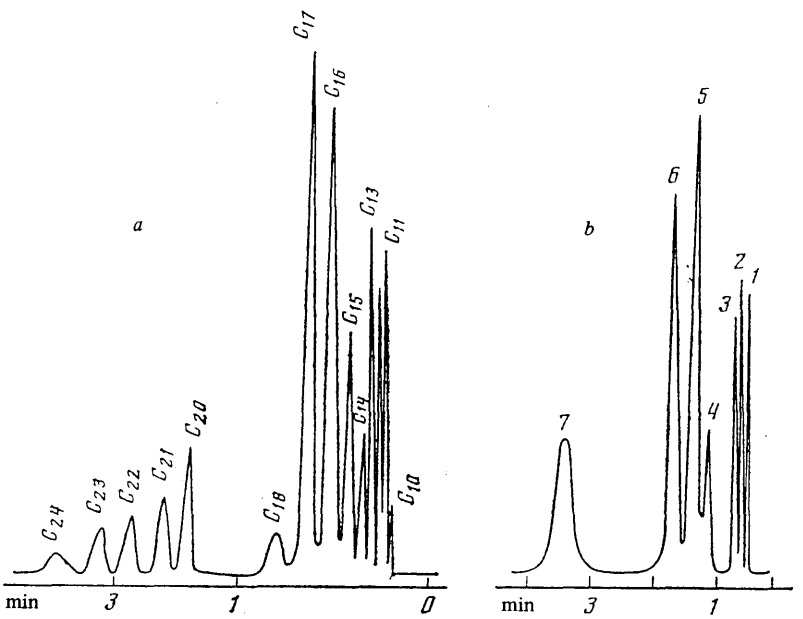

Figure 11. Chromatograms of mixtures of C_{10}–C_{24} n-alkanes (after the recording of the C_{18} peak, the diagram chart speed was decreased by a factor of 3) (*a*) and aromatic hydrocarbons and their derivatives (*b*): *1*) benzene, *2*) toluene, *3*) ethylbenzene, *4*) m-cresyl acetate, *5*) o-cresyl acetate, *6*) naphthalene, *7*) biphenyl[21].

A comparison of the thermographic curves obtained on a thermal analysis apparatus for PMS-100–Aerosil systems (c = 0.5) and for pure PMS-100, and also a study of the dependence of the mass losses by these sorbents on the time of passage of the carrier gas at 250 °C, showed that stationary phases stabilised by Aerosil have a higher thermal stability than the pure liquids[26].

VI. PRACTICAL APPLICATIONS OF CHROMATOGRAPHY IN A GAS–COLLOID SYSTEM

The universal character of colloidal stationary phases makes it possible to use them for the analysis of various organic and organometallic materials. As examples illustrating the possibilities provided by these sorbents, the conditions for the separation of various mixtures of direct practical interest are described below. In all cases, the colloidal stationary phases containing the highly dispersed adsorbents were deposited on silanised Chromaton. The solid carrier for the polymeric colloidal systems (except where otherwise indicated) was silanised Celite-545. In those cases where there is no reference to the source, the examples of the use of the sorbents developed were taken from Refs.21 and 26.

1. Analysis of Organic Compounds

Hydrocarbons. The low sorptive capacity of polymers makes it possible to use them to determine high-boiling substances at temperatures appreciably below the boiling points of the components being studied. Thus a mixture of C_{10}–C_{24} n-alkanes has been analysed on a column with polystyrene as stationary phase (Fig.11*a*) at 250 °C [b.p.(C_{24}) = 421 °C].[20] The response coefficient (Table 7) was greater by factors of ~6 and ~4 respectively than those on columns with Apiezon-L and polyphenylmethylsiloxane, usually employed in the analysis of n-alkanes. The time required for the analysis of the mixture of C_{10}–C_{24} n-alkanes was 5 min on the colloidal phase, and 30 min on Apiezon-L, for identical experimental conditions. A mixture of aromatic hydrocarbons and their derivatives was separated using a solution of polystyrene in squalane (c = 0.8) at 150 °C (Fig.11*b*).

Alcohols. The possibilities provided by the use of gas–liquid and gas–adsorption chromatography for the separation of high-boiling polar substances are limited by the low thermal stability of the polar liquid phases and the insufficient uniformity of the surface of most adsorbents, which leads to asymmetry of the peaks. The separation of C_2–C_{10} alcohols (boiling point of n-decanol 213 °C) on a column with the stationary phase PS–PEG-400 (c = 0.67) at 130 °C (Fig.12*a*) is therefore of interest.

Aliphatic acids. The analysis of free aliphatic acids (without conversion to the esters) on the usual stationary phases and diatomite carriers is extremely difficult, because of strong adsorption phenomena and the marked asymmetry of the peaks. Colloidal polymeric phases have been used for the direct separation of synthetic mixtures of C_1–C_6 aliphatic acids[20]. Fig.12*b* shows that the peaks of the acids are fairly symmetrical, and the analysis time is short (4 min). The conditions of the chromatographic separation were as follows: a 120 × 0.3 cm column was filled with a colloidal solution (15%) of polystyrene in dinonyl phthalate (c = 0.2) on silanised Chromosorb-W; 160 °C; nitrogen velocity 30 ml min^{-1}; specimen volume 0.025 μlitre.

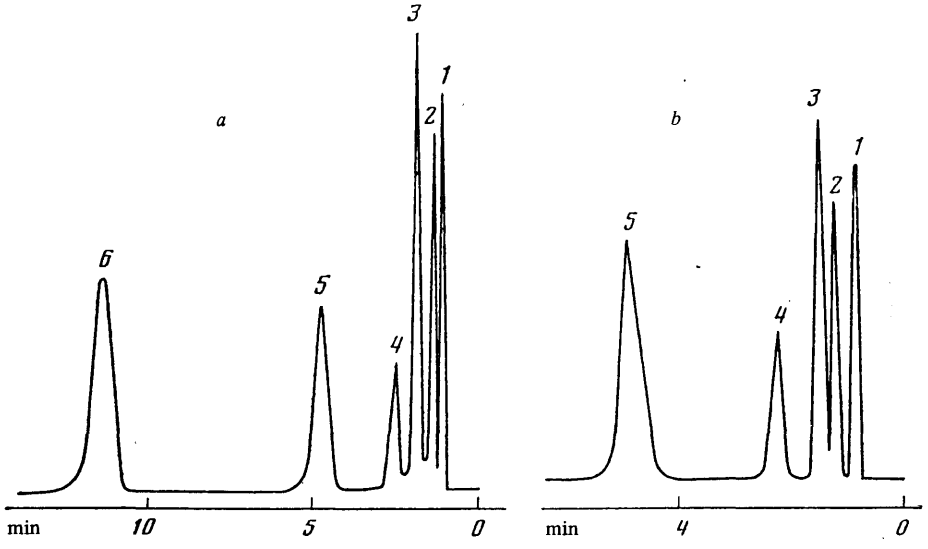

Figure 12. Chromatograms of mixtures of C_2–C_{10} n-alcohols (*a*): *1*) ethanol, *2*) propanol, *3*) butanol, *4*) pentanol, *5*) heptanol, *6*) decanol; and C_1–C_6 aliphatic acids (*b*): *1*) acetic, *2*) n-propionic, *3*) isobutyric, *4*) isovaleric, *5*) n-hexanoic.[21]

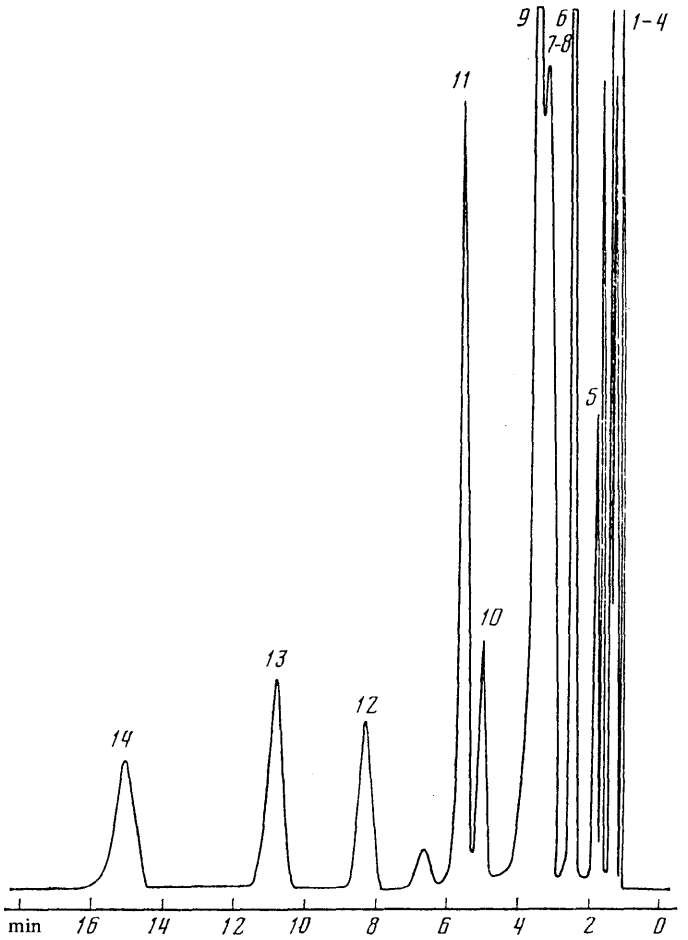

Figure 13. Chromatogram of petrol from the oxidative cracking of petroleum, boiling up to 100 °C: *1*) pentane, *2*) hexane, *3*) hexane, *4*) heptane, *5*) heptene, *6*) acetone, *7*) butyraldehyde, *8*) methyl ethyl ketone, *9*) benzene, *10*) ethanol, *11*) toluene, *12*) n-propanol, *13*) isobutyl alcohol, *14*) n-butanol[26].

Petrol from the oxidative cracking of petroleum. This petrol (fraction up to 100 °C), in addition to alkanes and aromatic hydrocarbons, contains oxygen compounds. It is difficult to separate this multicomponent mixture on an individual stationary phase. The largest number of peaks with a sufficiently regular distribution on the chromatogram was obtained using the colloidal system PEG-400–Aerosil (c = 0.5), deposited on a solid carrier in quantities of 20%. The chromatogram (Fig.13) shows that this sorbent makes it possible to separate the hydrocarbons from one another and from oxygen-containing compounds under isothermal conditions (column temperature 80 °C) on a column of length 2 m at a carrier-gas velocity of 40 ml min^{-1}. The colloidal sorbent had the following Rohrschneider characteristics: x = 2.37, y = 5.72, z = 3.51, and u = 6.12.

Products of the catalytic synthesis of acrylonitrile. The analysis of the highly dilute aqueous solutions is possible on a two-metre column using the stationary phase PS–PEG-400 (c = 0.67) at 100 °C and a carrier-gas velocity of 40 ml min^{-1} (Fig.14*a*).[20]

Mixture of moist air with hydrogen sulphide and ammonia. Symmetrical peaks for these substances (Fig.14*b*) are obtained using a colloidal solution of PS in PEG-400 (c = 0.3), deposited (in quantities of 30%) on Chromosorb-W (column length 2 m). The analysis is carried out initially at 50 °C, and after the ammonia peak has passed, the temperature of the thermostat is raised to 100 °C to achieve rapid elution of water.

Solution of t-butyl hydroperoxide and its decomposition products in chlorobenzene. Colloidal systems containing PM-15 carbon black have been used to analyse peroxides with a low thermal and catalytic stability[25]. t-Butyl hydroperoxide and its decomposition products have been separated[44] on a 120 × 0.4 cm column at 50 °C and a carrier-gas velocity of 70 ml min^{-1}, using dinonyl phthalate (30%) on Celite-545 as sorbent. By using a packing consisting of 20% of the system PEG-400–carbon black (c = 0.95) on the carrier, without changing the other parameters of the experiment, it was possible to decrease the time required for the analysis of the solution to 5 min (Fig.15*a*).

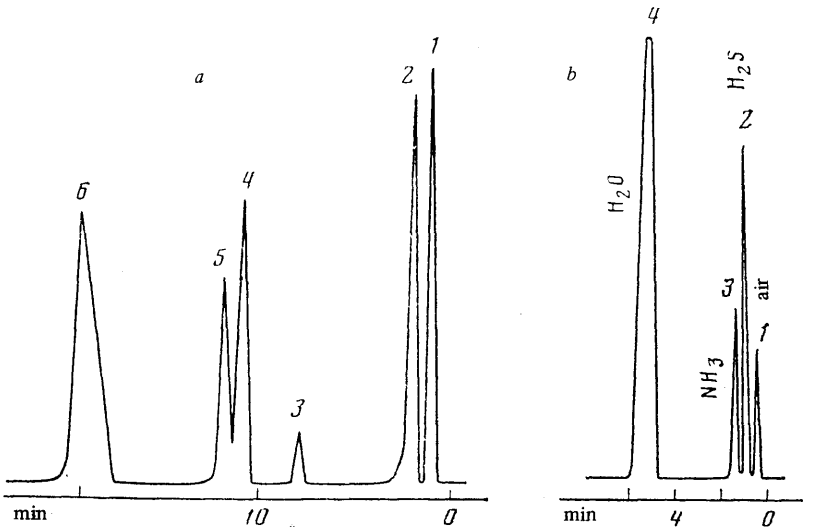

Figure 14. Chromatograms of mixtures of the products of the catalytic synthesis of acrylonitrile (AN) (*a*): *1*) air, *2*) ammonia, *3*) acrolein, *4*) AN, *5*) acetonitrile, *6*) water; and of moist air containing hydrogen sulphide and ammonia (*b*).[20,21]

Products of the catalytic dehydrogenation of butenes. The gas-chromatographic analysis of these products in the presence of large quantities of water has been carried out on a column of length 1.2 m containing a 25% colloidal solution of polystyrene in PEG-400 (c = 0.4) at 150 °C. On this sorbent, all the components were clearly separated, with completely symmetrical peaks (Fig.15*b*).

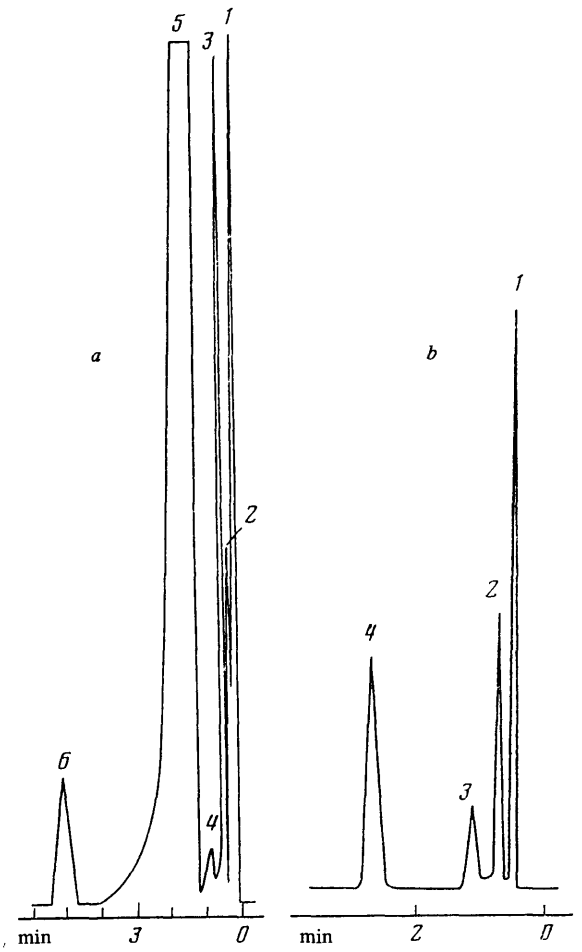

Figure 15. Chromatograms of mixtures of the products of the catalytic dehydrogenation of butenes (*a*): *1*) acetone, *2*) acetic acid, *3*) acrylic acid, *4*) maleic anhydride; and of a solution of t-butyl hydroperoxide and its decomposition products in chlorobenzene (*b*): *1*) acetone, *2*) methanol, *3*) t-butyl alcohol, *4*) di-t-butyl peroxide, *5*) chlorobenzene, *6*) t-butyl hydroperoxide[21,24].

Trace analysis. Conditions have been found for the gas-chromatographic determination of traces of biphenyl in diphenylamine, and of β-chloronaphthalene in naphthalene at 170 °C on the sorbent PEG-40000–Aerosil (c = 0.6).[26] The study of these solid solutions is of interest for the theory and practice of the production of semiconducting elements. Micro-analytical and spectral methods for the analysis of these systems are tedious and have a low sensitivity. The use of gas chromatography with colloidal sorbents has made it possible to lower the level of the quantitative determination of the impurity to 10^{-4}–10^{-5}% in the first case, and to 10^{-1} to 10^{-2}% in the second. The results of the determination of impurities in 1-ethyltricycloheptane-3-one[26] have been used to estimate the purity of the material for the precise study of its thermodynamic properties.

The results of the analysis of various synthetic mixtures and catalysates on ordinary and colloidal phases with similar polarity are given in Table 7. The following characteristics were used in the comparison of their selectivity: the degree of separation of the least effectively separated pair (K), the uniformity criterion ($\bar{\Delta}$), and the response coefficient (λ) [6]

$$\bar{\Delta} = n_c \tau K/t \qquad (12)$$

where n_c is the number of peaks, τ the width of the least broadened peak, and t the analysis time.

The response coefficient λ was calculated from the equation

$$\lambda = n_c K^2/t \ . \qquad (13)$$

Table 7 shows that the values of λ for the colloidal polymeric phases are higher than those for the ordinary phases. In the analysis of n-alcohols, PEG-20M gives a slightly better separation (K = 1.43) than the colloidal phase PS–PEG-400 (K = 1.10). If the decisive factor is the analysis time, however, it is necessary to compare the values of λ, and in this case the second phase is preferred.

Colloidal solutions of polymers have another significant advantage over the usual stationary phases: increase in temperature leads to a simultaneous increase in their selectivity and efficiency for the mixtures of substances examined, and this makes it possible to decrease the analysis time considerably without deterioration in the quality of the separation. Thus for example, the pair of substances most difficult to separate on the individual phase PEG-400 are not separated at all when the column temperature is increased from 100 °C to 120 °C, whereas under these conditions, the selectivity of columns with a colloidal stationary phase is increased by a factor of 1.1–1.4, leading to complete separation of the components being analysed[21].

2. Analysis of Organometallic Compounds

Most substances containing a metal–carbon bond are reactive and unstable to heat, and this makes it difficult to develop gas-chromatographic methods for determining organometallic compounds (OMC) and impurities in them. Thus in addition to the necessary resolving power, the chromatographic packing should have a low capacity, to ensure that the analysis can be carried out at low temperatures, and should be chemically inert with respect to the substances being analysed. These requirements are not satisfied by all liquid phases and adsorbents. Silicone stationary phases are fairly inert and hydrophobic, which is particularly important in work with readily hydrolysed compounds, and these phases have found extensive application in the gas-chromatographic analysis of OMC. Thus in a fairly complete review[45], more than 60% of all the examples of the analysis of OMC involved the use of stationary phases of the SE-30 and E-301 type. In the Soviet Union, the analogue of these SP with similar chromatographic polarity is the polymethylsiloxane liquid PMS-100.

The regular features of the chromatographic retention of alkanes and aromatic hydrocarbons by colloidal stationary phases based on PMS-100 and Aerosil have been studied[46]. It was shown that the addition of highly dispersed silica to the silicone stationary phase leads to a decrease in the specific retention volumes of heptane, benzene, biphenyl, and their derivatives. At the same time, the retention indices of aromatic compounds increase, and the selectivity of the

sorbent as a whole increases. Thus on going from the pure silicone to the sorbent with $c = 0.8$, the logarithmic retention index increases by 200 units for benzene, by 225 units for bibenzyl, and by 275 units for stilbene. Thus the possibility of achieving a smooth decrease in the sorptive capacity with an increase in the selectivity of chemically inert silicone SP by the dispersal of highly dispersed fillers in them facilitates the solution of the problem of separating and analysing OMC.

It is possible in principle to analyse a mixture of bis(arene) π-complexes of chromium (trade name Barkhos liquid) on silanised Chromaton with 6% of the colloidal system PMS-100–Aerosil ($c = 0.2$).[47] A clear-cut separation of organochromium compounds with boiling points of 315–340 °C was achieved on a 100 × 0.4 cm column at 185 °C (Fig.16). In earlier studies[48,49], Barkhos liquid was analysed at 200 °C and above. Even a slight decrease in temperature in the analysis of unstable compounds in order to decrease their decomposition in the column is theoretically and practically justified[50]. A decrease in the temperature of the experiment generally leads to an increase in the selectivity of separation. This makes it possible, by decreasing the length of the column, to reduce the analysis time, and this also leads to a decrease in the decomposition of the unstable specimen[51].

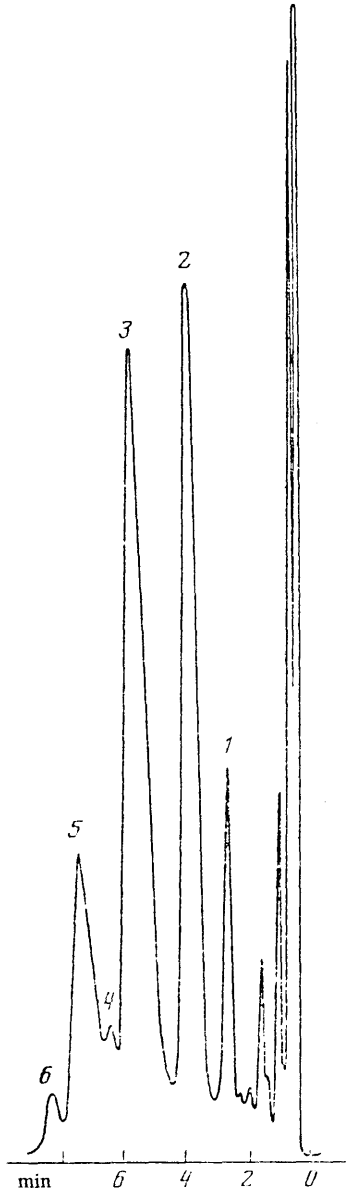

Figure 16. Chromatogram of a mixture of bis-arene π-complexes of chromium: *1*) benzene(ethylbenzene)chromium, *2*) bis(ethylbenzene)chromium, *3*) (ethylbenzene)(diethylbenzene)chromium, *4*) not identified, *5*) bis(diethylbenzene)chromium, *6*) not identified; SP—6% of the system PMS-100–Aerosil ($c = 0.2$); 100 × 0.4 cm column, 185 °C, carrier-gas velocity (hydrogen) 70 ml min^{-1}.[26]

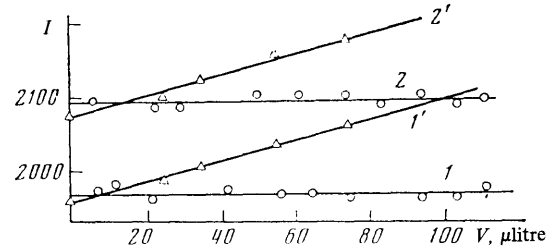

Figure 17. Dependence of the retention index on the quantity of organochromium liquid Barkhos added to the column: *1*, *2*) SP—6% of the system PMS-100–Aerosil ($c = 6$), 150 °C; *1'*, *2'*) SP—6% PMS-100, 200 °C; *1*, *1'*) bis(ethylbenzene)chromium, *2*, *2'*) (ethylbenzene)(diethylbenzene)chromium[53].

A subsequent study[52] of the dependence of the retention of the principal components of Barkhos liquid [bis(ethylbenzene)chromium and (ethylbenzene)(diethylbenzene)chromium] on the composition of the binary PMS-100–Aerosil system showed that the replacement of the silicone by the highly dispersed adsorbent, as in the case of hydrocarbons, leads to a decrease in the time required for the analysis of the organometallic compounds studied, and to an increase in the selectivity of their separation. On the basis of the observed regular features, it was suggested that the chromatographic analysis of Barkhos liquid be carried out on a column containing 6% of the colloidal system PMS-100–Aerosil ($c = 0.6$) at 150 °C, which lowered the temperature of the analysis by 35 K.[53] The usual method of lowering the temperature of the analysis by reducing saturation of the solid carrier with pure silicone does not work in this case because of the low selectivity of the lightly loaded column[53,54].

The advantage of carrying out the analysis at lower temperatures (by using a colloidal sorbent) is confirmed by the dependence of the retention indices of the OMC analysed on the number of specimens introduced into the chromatograph and expressed as the total quantity of Barkhos liquid passed through the column (volume of one specimen, 2 μlitre) (Fig.17). Fig.17 shows that on prolonged operation with a sorbent of 6% PMS-100 on Chromaton at 200 °C, there is a monotonic increase in the retention index, indicating the formation in the course of the analysis of a new stationary phase consisting of PMS-100 and the decomposition products of Barkhos liquid. This is also indicated by the almost complete change in the colour of the packing along the entire length of the column after the introduction of a total of 70 μlitre of the organochromium liquid. When 6% of the colloidal system PMS-100–Aerosil ($c = 0.6$) on the same carrier was used at 150 °C, however, the retention index and the colour of the sorbent along the entire length of the column remained practically unchanged during repeated analyses.

Colloidal SP based on Aerosil and PMS-100 have also been used to separate the organometallic compounds of the group VI elements[26,53,55]. The relative retention volumes and logarithmic retention indices have been determined[26] for arenetricarbonyl complexes of chromium (Table 8) and the hexacarbonyls of chromium, molybdenum, and tungsten at 50 °C on PMS-100–Aerosil (c = 0.4):

Compound	Chromium hexacarbonyl	Molybdenum hexacarbonyl	Tungsten hexacarbonyl
V^{rel}	1.00	2.03	4.14
I	746	826	903

Table 8. Chromatographic characteristics of the retention of chromium arenetricarbonyls (column temperature 170 °C).[53]

Compound	V^{rel}		I	
	SE-30 [56]	PMS-1000-aerosil (c = 0.4)	SE-30 [56]	PMS-100-aerosil (c = 0.4)
Benzenetricarbonylchromium	1.00	1.00	1595	1621
Toluenetricarbonylchromium	1.21	1.68	1604	1744
Mesitylenetricarbonylchromium	1.67	2.09	1722	1794
Anisoletricarbonylchromium	2.03	2.60	1805	1853
(Ethyl benzoate)tricarbonyl-chromium	2.58	3.24	1876	1906

The relative retention volumes and retention indices of all the arenetricarbonyls are greater on the column with the colloidal sorbent than on the column with SE-30. Thus in addition to dispersion interaction, the retention of the sorbates involves specific forces determined by the interaction of the carbonyl groups of the compounds studied with the Aerosil surface. The calculated retention indices can be used to identify metal carbonyls.

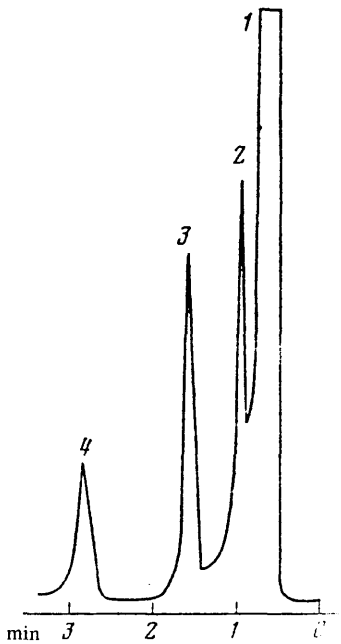

Figure 18. Chromatogram of the separation of group VI metal hexacarbonyls: *1*) chloroform, *2*) chromium hexacarbonyl, *3*) molybdenum hexacarbonyl, *4*) tungsten hexacarbonyl, SP—6% of the system PMS-100–Aerosil (c = 0.4), 200 × 0.3 cm column, 50 °C, carrier-gas velocity (hydrogen) 50 ml min^{-1}.[53]

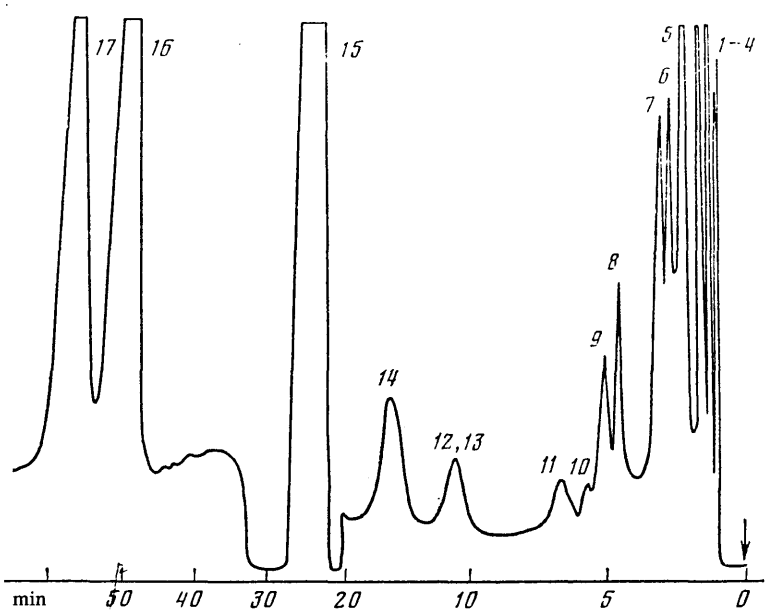

Figure 19. Chromatogram of impurities in tetraethyllead: *1*) ethane, *2*) butane, *3*) hexane, *4*) ethyl chloride, *5*) methylheptane, *6*) octane, *7*) octene, *8*) nonane, *9*) nonyne, *10*) nonadiene, *11*) benzene, *12*) ethanol, *13*) toluene, *14*) s-butyl alcohol, *15*) tetraethyllead, *16*) isobutyltriethyllead, *17*) n-butyltriethyllead, SP—20% of the system PEG-400–Aerosil (c = 0.3), 200 × 0.3 cm column, 70 °C, carrier-gas velocity (nitrogen) 20 ml min^{-1}, specimen volume 0.5 μlitre, instrument scale 10^{-11} A, recorder chart speed 600 mm h^{-1} for peaks *1–14*, 240 mm h^{-1} for peaks *15–17*.[58]

The use of the colloidal sorbent made it possible to separate the hexacarbonyls of chromium, molybdenum, and tungsten at 50 °C in 3 min (Fig.18).[53] In other studies[57], a similar mixture was separated at 90 °C in 7 min.

A stationary phase consisting of the binary system PEG-400–Aerosil (c = 0.3) has been proposed for the gas-chromatographic determination of impurities in tetraethyl-lead at the 10^{-4}–10^{-5} vol.% level[26,58,59]. It is possible to detect ~20 impurities of different chemical character (Fig.19). In the analysis, 90% of the principal component was directed past the flame ionisation detector, ensuring its stable operation.

These examples show that the gas-chromatographic analysis of organic and organometallic compounds can be carried out successfully using colloidal SP based on standard highly dispersed adsorbents or polymers. The possibility of controlling the sorptive properties, the high separating power, the symmetry of the peaks due to polar substances, the low retention times of high-boiling reactive compounds of low stability, the possibility of analysing impurities and micro-impurities, and their ready availability indicate the promising possibilities provided by the use of these colloidal sorbents in gas-chromatographic practice.

3. Colloidal Systems in Capillary Chromatography

Capillary chromatograms are being used increasingly in scientific-research and factory laboratories. They have a higher specific permeability than packed columns, and this makes it possible to carry out separations on long columns with a low pressure drop. Long column lengths combined with a high efficiency of separation ensure high separating power. Capillary chromatography is therefore being used to solve the most complex problems of separation in analytical chemistry[60–62]. Capillary columns, however, have a lower selectivity than packed columns. This can be seen from Eqn.(14), relating the selectivity of a column K_S [not to be confused with the selectivity of the stationary phase $k_S = (\Gamma_2 - \Gamma_1)(\Gamma_2 + \Gamma_1)$] with respect to two components being separated to the Henry coefficients Γ_1 and Γ_2 and the ratio of the volumes occupied by the gas and liquid phases in the column ($\varkappa$ and $\varkappa_1$ respectively):

$$K_s = 2\,\frac{(\Gamma_2\varkappa_1 + \varkappa) - (\Gamma_1\varkappa_1 + \varkappa)}{(\Gamma_2\varkappa_1 + \varkappa) + (\Gamma_1\varkappa_1 + \varkappa)} = 2\,\frac{\Gamma_2 - \Gamma_1}{\Gamma_2 + \Gamma_1 + 2\varkappa/\varkappa_1}\ . \qquad (14)$$

Packed columns usually have values of $\varkappa/\varkappa_1$ in the range 5–35, and capillary columns values in the range 50–15000. The latter are therefore less selective, and to achieve the same separation, the number of theoretical plates in them must be 10–100 times that for packed columns[60]. The change to adsorption–absorption sorbents obviously makes it possible to decrease $\varkappa/\varkappa_1$ and to bring the selectivity of capillary columns close to that of packed columns.

Since metallic capillary columns are gradually being displaced by glass columns, the interest in these sorbents is increasing to an even greater extent, since the effective use of glass columns is largely determined by their internal surface, which should ensure effective wetting of the glass capillary by the liquid phase. Special treatment makes it possible to increase both the wettability of the glass and its absorptive power. Various methods for producing intermediate coatings in capillary columns have been described[2,60–62]; analysis of these results shows that good operating characteristics can be obtained using columns with a layer of highly dispersed material, deposited on the wall of the capillary at the same time as the liquid phase. To avoid blocking of the capillary tubes when the suspension is introduced and to produce a uniform coating, the particle size of the solid filler cannot exceed 10^{-6} cm, that is it should be at the colloidal level.

Colloidal components as intermediate layers have been used and studied by Blumer[63,64] and Horning and co-workers[65–68]. Blumer[63,64] established that Aerosil treated with trimethylsilane (trade name Silanox-101) shows hydrophobic properties and forms stable suspensions in many solvents. Its dispersions in organic binding agents at a low concentration of the solid phase form thixotropic gels and adhere firmly to the surface of metal, glass, and polymers, making it possible to obtain a thin mechanically strong film of the stationary phase. Intermediate porous layers have been obtained by preparing a mixture of 0.2–0.5 g of the liquid phase (Apiezon-L, PEG-20M, FFAP, Emulphor, SE-30) in 10 ml of a solvent (methylene chloride, chloroform, or their mixtures with methanol) and 0.4–0.65 g of Silanox. Before the column was filled, the suspension was dispersed for 30 s in an ultrasonic bath. To predict qualitatively the efficiency of a column with this coating, a clean polished metal plate was wet with the prepared suspension. A smooth mechanically strong coating ensures good column operating conditions, whereas a dense granular surface with cracks and fractures after drying leads to a decrease in efficiency or to blocking of the capillary. To obtain thick porous layers, the suspension was introduced at a comparatively high rate (80 cm s^{-1}).[64] These columns have been used to separate mixtures of C_{16} to C_{18} methyl esters, normal alcohols, and homologues of benzene. For a specimen volume of 0.05 μlitre and HETT (height equivalent to a theoretical plate) = 1–1.3 mm, the separation time was several minutes.

Horning and co-workers[65,66], using intermediate layers with Silanox, obtained heat-resistant high-resolution glass columns suitable for the analysis of biological mixtures (steroids, acids, essential oils, and medicinal metabolites). Columns of length 60 m at 100–300 °C have given an efficiency of up to 100000 theoretical plates. A highly dispersed filler (6–10 μm), uniformly distributed in a surface film, prevented the formation of micro-droplets and breakdown of the stationary phase when the column was heated and cooled. The suspension was prepared by adding 2 g of Silanox to a solution of 0.5 g of SE-30 in 10 ml of CCl_4. To increase the sensitivity of the Silanox suspension, it was recommended that a solvent with a high density be used, or that a surface-active agent, for example benzyltriphenylphosphonium chloride, be added to the solution. The rate of passage of the suspension through the column was 5 cm s^{-1}. After drying for 3 h in a stream of nitrogen, the capillary column was covered with a basic layer of the stationary phase SE-30.

Glass capillary columns with heat-resistant polar phases have been described[67,68]. In the first stage, 20 m non-silanised borosilicate capillaries were wet with 1 ml of a suspension (0.1 g of the polar phase, 1 g of Silanox, and 100 ml of Silanox) (sic. Ed.of Translation), previously treated in an ultrasonic bath. The polar phase was then deposited on to the thin layer of suspension. A suspension of Silanox in a solution of the polymer of phenyl ether and phenyl sulphone (PZ-176) has been used to obtain a coating which makes it possible for a capillary column to operate at temperatures above 300 °C, and to separate the methyl esters of polyunsaturated aliphatic acids[75].

Longer columns (150 m) containing Silanox have been filled[69] by depositing intermediate coatings from a solution of 40 mg of the surface-active agent Igepol SO-880 in 10 ml of CCl_4 with the addition of 200 mg of Silanox. To increase the stability, the colloidal solution was placed for several minutes in a high-frequency furnace. The proposed method gives glass capillary columns with efficiencies of 437000–165000 theoretical plates. Their preparation is time-consuming, however (1 week).

A method for depositing colloidal intermediate layers to obtain polar capillary columns has been developed[70]. The stabilising additive was finely divided silica treated with benzyltriphenylphosphonium chloride (Cabosil), with particle size 15 nm and specific surface 190 $m^2 g^{-1}$. The suspension (0.3 g OV-225, 0.3 g silica, and 50 ml CCl_4) was treated in an ultrasonic bath and then passed through the column at a rate of 4–5 cm s^{-1}. An additional layer of OV-225 was deposited dynamically from a 10% solution in toluene. The thicknesses of the colloidal coating and the film of stationary phase, determined using the scanning electron microscope, were 0.3 μm and 0.4–1.2 μm respectively. The high stability of the film was attributed[70] to the porosity of the structure and the rheological properties of the intermediate layer. The proposed capillary columns have been used to separate mixtures of pesticides and steroid derivatives.

In the works cited, colloidal systems based on highly dispersed adsorbents were used as supports for the basic separating layer of stationary phase. The intermediate coating essentially increases the stability and capacity of the capillary column. The possible direct use of colloidal systems as stationary phases in capillary chromatography is also of interest, however.

Copper columns of length 25 m, containing as stationary phase a mixture of PEG-400 and Aerosil in the ratio 4 : 1, were recently described[28]. The suspensions were prepared in methanol solution. The separating characteristics of columns filled with pure PEG (column 1) and the colloidal stationary phase PEG-400–Aerosil (c = 0.2) (column 2) were compared. The quality of the columns was estimated from the number of theoretical plates N, the selectivity coefficient of the column K_S, and from the chromatograms of mixtures of organic compounds. Table 9 shows that, while giving almost the same efficiency, the columns containing the colloid are more selective in the separation of alcohols and hydrocarbons.

Table 9. Selectivity coefficients of the capillary columns 1 (N = 169000) and 2 (N = 162000).[28]

Substance	Column 1	Column 2
Methanol–ethanol	0.050	0.240
Ethanol–isopropyl alcohol	0.025	0.128
Ethanol–n-propanol	0.342	0.462
Decane–undecane	0.292	0.522
Benzene–decane	0.074	0.204

Thus the use of colloidal systems as intermediate stabilising layers and as stationary phases is extending considerably the possibilities provided by capillary chromatography, the most effective method of separating complex mixtures.

VII. FUTURE DEVELOPMENT OF CHROMATOGRAPHY IN A GAS–COLLOID SYSTEM

The analytical possibilities provided by chromatography in a gas–colloid system have not been exhausted. In the future, the extension of the range of application of colloidal sorbents already developed, and the production of new sorbents based on components which have not yet been studied chromatographically, can be expected. Some possible ranges of application and properties of colloidal stationary phases indicating their promising possibilities are described below.

The possibility of the extensive control of the selectivity, and the high thermal stability and availability of colloidal sorbents, can be used successfully to solve problems associated with the separation of multicomponent mixtures of substances belonging to different classes, in the analysis and trace concentrations, in analysis under programmed-temperature conditions, and in chromatographic–mass-spectrometric studies. The same properties, and the possibility of achieving a high capacity with a significant saving of stationary liquid phase, makes the use of colloidal sorbents promising in preparative chromatography. Colloidal stationary phases are used extensively in capillary chromatography, because of their high separating power and good operating characteristics. The possibility of lowering the temperature of the analysis by decreasing the capacity of the sorbent without a deterioration in the separating characteristics of the column, ensured by the use of colloidal systems, may be useful in the chromatographic analysis of compounds unstable to heat. The addition to the liquid phase of colloidal particles forming complexes with the compounds being analysed is promising in connection with the production of super-selective sorbents.

Among the important developments extending the possibilities provided by gas chromatography on colloidal sorbents is the use as fillers of higher dispersed adsorbents with chemically grafted organic groups, colloidal metals, and organometallic complexes, which make it possible to obtain heat-resistant sorbents with different selectivities. The development of analytical chromatography in a gas–colloid system will undoubtedly stimulate the use of gas chromatography as an effective method for studying colloidal systems. Reverse gas chromatography can be used to study sol–gel transitions, to determine the disjoining pressure and heats of displacement, to study adsorption at the boundary between a dispersed phase and the dispersion medium, etc. At the same time, the use of rheological methods and infrared and NMR spectroscopy will make possible a theoretically well-founded approach to the production and study of new colloidal sorbents for gas chromatography.

Uranium Phosphates

L.V.Kobets and D.S.Umreiko

The methods of preparation, stability in solution and in the solid state, and composition of the crystalline hydrates of uranyl and uranium(IV) orthophosphates and condensed phosphates have been reviewed. The structures of these compounds have been discussed; they are three-dimensional polymers with a uranyl-phosphate framework.
The polymerisation of the phosphate anion on thermal decomposition has been discussed. Condensed uranyl polyphosphates are unstable when kept, and are capable of undergoing dehydration, the extent of which increases with increase in the length of the phosphate chain and increase in the uranium concentration.
The bibliography contains 199 references.

I. INTRODUCTION

There is now a large amount of experimental and theoretical data on phosphates. The wide variety of these compounds is due to the high reactivity of the PO_4^{3-} group, and also the possibility of various combinations of phosphates. Phosphates have been the subject of a number of monographs[1-3] and reviews[4-6], in which the preparation, structural analysis, and spectral and thermal properties have been summarised. There are few publications, however, which systematise data on the phosphates of one element or several elements with similar properties, including orthophosphates and condensed phosphates (such as, for example, that devoted to the phosphates of quadrivalent metals[6]).

Extensive data on uranium phosphates have now accumulated, and require reviewing. The uranium compounds are mainly uranyl complexes containing the UO_2^{2+} group, of the oxo-group type MO_2^{2+} and MO^{2+}, which show a number of common structural and physicochemical properties.

In the present review, an attempt has been made to systematise available data on uranium phosphates. This has been done before, but the studies were incomplete. For example, in Ref.7, uranyl phosphates were examined from the viewpoint of the stability of their crystalline hydrates under isobaric conditions, and in Ref.8 the crystal chemistry of uranium minerals, including phosphorus-containing minerals, was discussed.

In the number of forms and variety of minerals, the class of uranyl phosphates is fairly representative[8]. Of 200 known minerals, it includes about 20 types, which can be divided into three crystal-chemical groups, on the basis of the $UO_2:PO_4$ ratio.

I. $UO_2:PO_4 = 1:1$ — autenite–meta-autenite or uranium phosphate micas.

II. $UO_2:PO_4 > 1$ — phosphuranylite.

III. $UO_2:PO_4 < 1$ — parsonsite.

The first group of minerals is made up of double uranyl phosphates with the alkali and alkaline earth metals, Cu, Mn,

Al, Fe, and hydrogen. The crystals of the minerals of the first group have a layer structure. The structure of meta-autenite $Ca[(UO_2)_2(PO_4)_2].6H_2O$ was studied in Ref.9, and later confirmed in Ref.10.

The second group includes minerals in which the ratio $UO_2:PO_4$ is most frequently 3:2 or 4:3. The crystal-chemical formulae of the minerals of this group have not been finally established, with the exception of dumontite $Ca(UO_2)_2(PO_4)_2.10H_2O$ and phosphuranylite $Pb(UO_2)_4(PO_4)_2(OH)_2.3H_2O$.[11] This group of minerals probably also includes the recently described phuralumite $Al_2(OH)_2(PO_4)_2(UO_2)_3(OH)_6.10H_2O$ and upalite $Al(UO_2)_3(PO_4)_2(OH)_3$,[12,13] whose structures are analogous to that of dumontite, and consist of $[(OH)_2(PO_4)_2.(UO_2)_3]_n$ layers. The crystal-chemical structures of the minerals of the parsonsite group have not yet been established.

Although considerable progress has been made in the crystal chemistry of uranium compounds, a number of problems relating to phosphorus-containing minerals have not yet been resolved. These include the question of the form in which uranium is present in the minerals, how to ensure the reliable determination of the $UO_2:PO_4$ ratio (errors in the determination of this ratio often lead to incorrect descriptions of chemical formulae), and how to systematise the nomenclature of the compounds. Since the study of minerals is often made difficult by such factors as the presence of impurities, the isomorphous replacement of elements, a low concentration of uranium, etc., the study of synthetic analogues of the natural compounds may help considerably in the determination of the degree of hydration and the form in which uranium is present in the compounds, and in establishing the regular features of the binding of the metal in different groups of atoms inside and outside the coordination sphere.

II. URANIUM ORTHOPHOSPHATES

1. Behaviour in Solution

The preparation of uranyl orthophosphates was the subject of lively discussion for a long time (until the nineteen-sixties). Some authors believed that the normal phosphate could not be isolated[14], and others that the dihydrogen phosphate could not be obtained[15]. The preparation of the compounds $P_2O_5.2UO_3.H_2O$, $P_2O_5.3UO_3$, and $P_2O_5.UO_3.2H_2O$, corresponding to the monohydrogen phosphate, the normal phosphate, and the dihydrogen phosphate, was reported[16]. It was noted that the composition of the precipitates is influenced by the $UO_3:P_2O_5$ ratio in the solution. The conditions of formation of uranium orthophosphate were studied most systematically by Schreyer and Baes[17,18], who examined the solubility of uranyl orthophosphates in phosphoric and perchloric acid solutions over a wide concentration range (0.001–15 M). They identified three stable phases at the following phosphoric acid concentrations:

$$[(UO_2)_3(PO_4)_2\cdot 6H_2O] < 0.014\,[PO_4^{3-}]\ M$$
$$[UO_2HPO_4\cdot 4H_2O] = (0.014 \div 6.1)\,[PO_4^{3-}]\ M$$
$$[UO_2(H_2PO_4)_2\cdot 3H_2O] > 6.1\,[PO_4^{3-}]\ M\ .$$

The dependence of the solubility of $UO_2HPO_4.4H_2O$ on the acid and salt concentrations was studied[18]. The existence in solution of the complexes $UO_2H_2PO_4^+$ and $UO_2H_3PO_4^{2+}$ was postulated.

Studies in solutions of constant ionic strength[19] confirmed the existence of the first complex, with formation constant 15.5, and also of $UO_2(H_2PO_4)_2$ and $UO_2(H_2PO_4)_2.H_3PO_4$ at PO_4^{3-} concentrations of ~ 1 M and 10 M respectively; their formation constants are 21.8 and 10.2 respectively. The solution of $UO_2HPO_4.4H_2O$ in perchloric acid (unlike that in phosphoric acid) is incongruent, depends on the surface area of the substance, and takes place via the formation of the sparingly soluble normal orthophosphate[20].

Pavkovic and co-workers[21,22] returned to the question of the formation and stability of orthophosphates in phosphoric acid solutions in a study of the precipitation and dissociation of complexes in aqueous solutions of phosphoric acid (2×10^{-6}–6 M) and uranyl nitrate (3×10^{6}–0.5 M). In an excess of the latter, the only product is the normal orthophosphate, which is present in equilibrium with solutions with a total PO_4^{3-} concentration of 3×10^{-3} M or less. Prolonged treatment of the normal orthophosphate (more than 24 d) converts it into the monohydrogen phosphate; the PO_4^{3-} concentration should be greater than 1.5×10^{-6} M. An important feature of this work[21,22] was the determination of the equilibrium conditions for the formation of the normal orthophosphate and the monohydrogen orthophosphate.

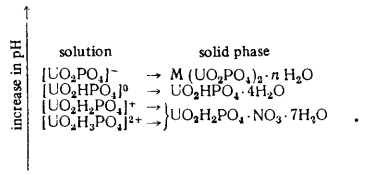
Comparison of the data of Refs.17 and 21 shows that they differ considerably at low and high phosphoric acid concentrations, and agree in the range 2×10^{-2}–2 M. The conversion of hydrogen phosphates into the normal phosphate is a common phenomenon, whereas the reverse process is comparatively rare. This characteristic feature of uranyl orthophosphates was noted by other workers[23], who converted the natural analogue trogerite $(UO_2)_3(PO_4)_2$ into the monohydrogen orthophosphate by keeping it in the equilibrium solution for six months. The normal phosphate is stable in air, whereas the monohydrogen phosphate is converted into the normal phosphate[16]. The compound $UO_2HPO_4.4H_2O$ is also stable when kept, and no changes were detected visually or by physicochemical methods in a specimen kept for 5 years. The best proof of its stability is the fact that it exists in nature as the mineral "hydrogen meta-autenite".

The synthesis from aqueous solutions of the so-called double uranyl phosphates containing other metal cations in addition to UO_2^{2+} is most complicated. A number of Soviet workers[24–26] have shown that normal and double phosphates may be formed under these conditions. The composition of the products depends on the concentration of the original solutions and the pH of the medium.

An attempt has been made to determine the relationship between the chemistry of the precipitation of the acidic, normal, and double orthophosphates[26,27]. A study of the conditions of precipitation of $NH_4UO_2PO_4$[26] showed that the reaction products may be normal ammonium orthophosphate and ammonium phosphatouranate, depending on the U:P ratio and the pH of the medium. A mechanism was proposed[26] for the formation of the phosphatouranate, including several stages. The uranyl ion is regarded primarily as the hydrolysed species $UO_2(OH)^+$,[28] so that formation of the normal orthophosphate is possible:

$$2UO_2(OH)^+ + UO_2^{2+} + 2HPO_4^{2-} + 4H_2O \rightarrow (UO_2)_3(PO_4)_2\cdot 6H_2O$$

$(UO_2)_3(PO_4)_2$ then reacts with the ammonium ion, giving a complex ammonium phosphatouranate



$$2(UO_2)_3(PO_4)_2\cdot 6H_2O + 2NH_4^+ \rightarrow (NH_4)_2(UO_2)_5(PO_4)_4\cdot 6H_2O + UO_2^{2+} + 6H_2O\ .$$

In an excess of ammonium phosphate, it is converted into $NH_4UO_2PO_4$:

$$(NH_4)_2(UO_2)_5(PO_4)_4\cdot 6H_2O + 3NH_4^+ + HPO_4^{2-} + 9H_2O \rightarrow 5NH_4UO_2PO_4\cdot 3H_2O\ .$$

It is believed[26] that the same reactions take place when uranyl salts are titrated with different phosphates (Na, K, Ca, etc.). It is suggested that the $(UO_2)_5(PO_4)_4^{2-}$ group is very stable, and forms part of a number of minerals. For a ratio U:P = 1:1, the following pH dependence of the stability

of the complexes was proposed:

Analysis of the data in Ref.26 reveals a number of discrepancies. First of all, it is not clear how the formation of ammonium phosphatouranate can be preceded by the formation of two compounds — $(UO_2)_3(PO_4)_2$, which is the least soluble uranyl orthophosphate (Table 1), and also a product containing the $(UO_2)_5(PO_4)_4^{2-}$ group, assumed[26] to be extremely stable—which are converted into ammonium phosphatouranate merely by titration. The statement[26] that $(UO_2)_5(PO_4)_4^{2-}$ is present in various minerals, in particular phosphuranylite, was not confirmed by later structural studies[11]. The dependence of the composition of the reaction products on the pH of the medium was also noted in Ref.29. Weigel and Hoffmann[7] regarded all double phosphates and hence minerals of uranium(VI) as salts of $HUO_2PO_4.4H_2O$ in which hydrogen is replaced by alkali and alkaline earth metals according to the schemes:

$$HUO_2PO_4 + M^+ \rightarrow MUO_2PO_4 + H^+$$
$$2HUO_2PO_4 + M^{2+} \rightarrow M(UO_2PO_4)_2 + 2H^+ \quad .$$

Table 1. Solubility products (SP) of uranyl orthophosphates.

Phosphate	SP	Refs.	Phosphate	SP	Refs.
UO_2HPO_4	$3{,}5 \cdot 10^{-12}$	[32]	$NH_4UO_2PO_4$	$4{,}36 \cdot 10^{-27}$	[33]

The difficulties of obtaining double uranyl phosphates were avoided[29] by treating powdered uranyl monohydrogen phosphate with 4 *N* solutions of the corresponding metal chlorides.

The conditions of preparation and solubility of uranyl orthophosphates have been studied by a number of authors[30–34,36–38]. Data on the solubility of uranyl orthophosphates are summarised in Table 1. The solubility of double uranyl phosphates with the alkali metals decreases in the order Na > Cs > K > Rb > NH_4, and that for bivalent metals in the order Zn ≅ Co ≅ Ni > Ca > Sr > Ba ≧ Cu.

2. Crystalline Hydrates of Uranyl Orthophosphates

In solubility studies, the composition of the crystalline hydrates is generally not discussed, and in the study of the physicochemical properties of solid specimens, the data obtained by different authors on the water concentration do not agree. Thus for the normal orthophosphate, the formation of $(UO_2)_3(PO_4)_2.6H_2O$,[17] and heptahydrate[16], and the trihydrate[24] has been reported. Methods for synthesising the hexa- and tetrahydrates have also been proposed[17,39]. For the monohydrogen orthophosphate, there is more agreement between different authors, who assign to it the composition $UO_2HPO_4.4H_2O$ (except for a report of the hydrate $UO_2HPO_4.2.5H_2O$[40]). The compositions of the crystalline hydrates of double uranyl phosphates differ considerably. The stability ranges of the crystalline hydrates with respect to isobaric thermal decomposition with a constant partial pressure of water vapour above the crystalline hydrates have been determined[7] (Table 2).

Table 2. Compositions of the crystalline hydrates of uranyl orthophosphates and the temperature range of their stability at a water vapour pressure of 92.5 ± 0.5 mmHg[7].

Original orthophosphate	Number of moles of water					
	6	4	3	2	1	0
$UO_2HPO_4 \cdot 4H_2O$	—	20—50	—	60—80	90—160	>170
$(UO_2)_3(PO_4)_2 \cdot 4H_2O$	—	20—120	—	—	160—220	>300
$LiUO_2PO_4 \cdot 4H_2O$	—	20—70	80—120	120—170	—	>190
$NaUO_2PO_4 \cdot 3H_2O$	—	—	20—70	—	90—160	>170
$KUO_2PO_4 \cdot 3H_2O$	—	—	20—70	—	(0,5 H_2O; 80—150)	>100
$NH_4UO_2PO_4 \cdot 3H_2O$	—	—	20—80	—	(0,5 H_2O; 130—140)	>140
$Mg(UO_2PO_4)_2 \cdot 9H_2O$	100	110	—	120—170	180—200	>230
$Ca(UO_2PO_4)_2 \cdot 10H_2O$	—	110	—	140—200	—	>240
$Sr(UO_2PO_4)_2 \cdot 8H_2O$	75—105	—	—	110—190	—	>200
$Ba(UO_2PO_4)_2 \cdot 8H_2O$	~60—70	—	—	100—180	—	>200

The processes of thermal dehydration of uranyl orthophosphates, in spite of differences in the data reported by different authors, can be examined from the simplified viewpoint of the formation of intermediate hydrates and anhydrous salts, and differ only in the stepwise character of the removal of water and the temperature ranges. This is confirmed by data on the dehydration of the monohydrogen orthophosphate. It has been reported[16] that $UO_2HPO_4.2H_2O$ is formed when the tetrahydrate is heated, and is stable up to 110°; the anhydrous phosphate exists in the range 150—500°. In Ref.41, the loss of 3.5 moles of water was observed in the range 30—180°, and complete dehydration at 230—250°. In Ref.42, three moles of water were removed up to 60°, to give the monohydrate, stable in the range 60—120°. In Ref.40, it is claimed that all the water of crystallisation is lost at 170°. Finally, in Ref.43 it is reported that 2.5 moles of water are lost at 60—70°, and all the water of crystallisation at ~220°. Published data on the dehydration of the normal and double phosphates are equally contradictory[16,29,39,44].

3. Uranium(IV) Orthophosphates

The synthesis of uranium(IV) phosphates has been described in detail[6], and these compounds will be discussed only briefly.

Attempts to prepare uranium(IV) orthophosphates were reported in the early nineteen-hundreds. Colani[45] described orthophosphates to which he assigned the compositions $U(HPO_4)_2.5H_2O$, $U_3(PO_4)_4.UCl_4.HCl$, and $M_2U(PO_4)_2$ (M = Na, K). They were obtained by fusing UO_2 with metaphosphates or pyrophosphates in molten alkali metal chlorides.

The synthesis and solubility of the monohydrogen orthophosphate were later studied by Schreyer[46], who isolated the gelatinous compound $U(HPO_4)_2.4H_2O$. When the compound was kept in equilibrium with phosphoric acid, it was converted into the hexahydrate, and at an H_3PO_4 concentration greater than 9.8 M into $U(HPO_4)_2.H_3PO_4.H_2O$. Blumenthal[47] reported the preparation of the hydrates $U(HPO_4)_2.2H_2O$ and $U(HPO_4)_2.5H_2O$. Moskvin and co-workers[48] studied the solubility of $U(HPO_4)_2.4H_2O$ in phosphoric acid solution, and found that it passes through a maximum due to the formation of the undissociated form of $U(HPO_4)_2$. The stability constants of the complexes $U(HPO_4)^{2+}$, $U(HPO_4)_2$, $U(HPO_4)_3^{2-}$, and $U(HPO_4)_4^{4-}$ were determined; $\lg \beta = 12.0$, 22.0, 30.6, and 38.6 respectively.

The problem of the synthesis of the normal orthophosphate has not been resolved. It was noted above that in Ref.45 the normal phosphate could not be obtained by the reaction of solutions of UCl_4 and trisodium phosphate, whereas in Refs.49 and 50 it is stated that this compound is formed and is stable at 800°, and in Ref.51 it was found to be stable to 900–1200°. In Ref.39 it was shown that the normal orthophosphate does not exist at 600°, and the product, which has the same U:P ratio, is a mixture of the pyrophosphate and uranium dioxide.

Uranium orthophosphates with the general formula $MU_2(PO_4)_3$ (M = Na, K) are said to be obtained by the reaction of the uranium oxides UO_2 and UO_3 with zirconium pyrophosphate is molten sodium and sodium chlorides, and also by the reaction of the melts with uranium monohydrogen phosphate in an inert atmosphere according to the scheme[52]:

$$U(HPO_4)_2 + NaCl \xrightarrow{850°} NaU_2(PO_4)_3$$
$$U(HPO_4)_2 + KCl \xrightarrow{750°} KU_2(PO_4)_3 \quad .$$

4. Conditions of Preparation

In Ref.53, the phosphate $UO_2HPO_4.4H_2O$ was synthesised by the method of Schreyer and Baes[17], and had the composition given by this formula. The ranges of stability of its crystalline hydrated formed at room temperature were determined by keeping the specimens under equilibrium conditions at different saturated water vapour pressures. The tetrahydrate is stable down to pressures of 0.15 mmHg, the monohydrate exists at lower pressures, and the hydrates are interconvertible. The products with two and three water molecules are mixtures of the mono- and tetrahydrates. Thus the existence of the hydrate $UO_2HPO_4.2.5H_2O$[40] appears unlikely. A noteworthy feature of the interconversion of the crystalline hydrates is the rearrangement of the crystal structure, which involves the intermediate formation of an amorphous product which subsequently crystallises to give the new phase. This effect was detected by X-ray diffraction and thermal analysis, which showed the appearance of an exothermic effect on the DTA curve at 70° during the dehydration of the monohydrogen orthophosphate[53].

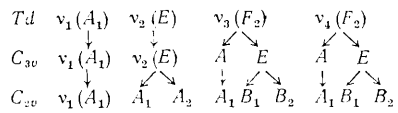
In Ref.54, the normal orthophosphate was obtained by various methods[17,24,39], including hydrothermal synthesis (Table 3). In the latter, an equimolar mixture of 0.1 M solutions of uranyl nitrates or stoichiometric quantities of UO_3 and 0.1 M H_3PO_4[54] were placed in ampoules, sealed, and kept at 150° for 3–4 d. The X-ray diffraction patterns of the products obtained under hydrothermal conditions and by hydrolysis of uranyl monohydrogen orthophosphate coincide, but do not agree with the data of Ref.55. The reaction of uranyl nitrate with Na_2HPO_4[24] gave a precipitate with the composition $NaUO_2PO_4.3H_2O$ (Table 3). Dilute (0.01 M) solutions of uranyl nitrate and phosphoric acid give the amorphous normal orthophosphate, which binds ~ 6 moles of water; it is stable in air, but in a dry atmosphere it gradually loses water to give the tetrahydrate. Crystalline $(UO_2)_3(PO_4)_2.4H_2O$ is stable at room temperature at different water vapour pressures in the range 0–12 mmHg.

Table 3. Compositions of uranyl orthophosphates obtained by different methods.

No.	Synthesis conditions	Concentration of the components in the solid phase, %				Composition
		U	P_2O_5	Na	H_2O	
1	0.001 M $UO_2(NO_3)_2$ and H_3PO_4; 25 °C (Ref.17)	63.4	13.2	—	9.7	$(UO_2)_3(PO_4)_2 \cdot 6H_2O$
2	Ditto (Ref.17)	62.4	12.5	—	6.9	$(UO_2)_3(PO_4)_2 \cdot 6,3H_2O$
3	Hydrothermal synthesis, 0.1 M $UO_2(NO_3)_2$ and H_3PO_4; 150 °C, 72 h (Ref.54)	66.8	13.4	—	6.9	$(UO_2)_3(PO_4)_2 \cdot 4H_2O$
4	Hydrothermal synthesis, 0.1 M UO_3 and H_3PO_4 (U:P = 3:2); 150 °C, 72 h (Ref.54)	65.9	13.6	—	6.5	$(UO_2)_3(PO_4)_2 \cdot 4H_2O$
5	Hydrolysis of $UO_2HPO_4.4H_2O$ by water; 100 °C, 2 h (Ref.39)	67.1	13.7	—	6.8	$(UO_2)_3(PO_4)_2 \cdot 4H_2O$
6	0.001 M $UO_2(NO_3)_2$ and 0.015 M Na_2HPO_4; 25 °C (Ref.24)	53.4	15.6	4.0	12.5	$NaUO_2PO_4 \cdot 3H_2O$
7	0.01 M $UO_2(NO_3)_2$ and 0.15 M Na_2HPO_4; 25 °C (ref.24)	52.9	16.3	4.2	12.9	$NaUO_2PO_4 \cdot 3H_2O$
8	Hydrolysis of $NH_4UO_2PO_4.3H_2O$ by boiling with 0.8 M HNO_3 (Ref.17)	54.2	16.9	—	12.3	$NH_4UO_2PO_4 \cdot 3H_2O$

To obtain double uranyl phosphates, it is necessary to maintain strictly definite pH values in the solutions. Thus ammonium uranyl phosphate $NH_4UO_2PO_4.3H_2O$ can be obtained only at pH 4.6–4.8 from solutions of uranyl acetate and diammonium hydrogen phosphate[56]. In Ref.57 it was found that in the NH_3–UO_2–H_3PO_4–H_2O system there exist two uranyl phosphates, containing 3.8% and 8.8% NH_3 respectively.

The compound $U(HPO_4)_2.4H_2O$ obtained by the method of Ref.48 is a gelatinous product which does not crystallise on prolonged standing (20–30 d) in the equilibrium solutions at room temperature and higher temperatures[58]. To improve the mechanical properties of the product, it was salted-out with organic solvents. Best results were obtained using isopropyl alcohol in the ratio reduced solution:alcohol ≅ 1:4.[58] Although the precipitate obtained was amorphous towards X-rays, it was readily filtered, washed, and dried. Hydrates containing more or less than $4H_2O$ of crystallisation could not be obtained by the methods of Refs.46 and 47. Hydrates with 2.5 and 1.5 moles of water are obtained by keeping $U(HPO_4)_2.4H_2O$ under equilibrium conditions at different saturated H_2O vapour pressures. The tetrahydrate is stable down to p_{H_2O} = 5 mmHg, $U(HPO_4)_2.2.5H_2O$ is stable in the range 4–2 mmHg, and $U(HPO_4)_2.1.5H_2O$ is stable at lower water vapour pressures.



To resolve the question of the possibility of obtaining the normal orthophosphate[58], the conditions of its synthesis according to Ref.49 from solutions of UCl_4 and trisodium phosphate with subsequent heating of the precipitates to 600° were reproduced. At pH > 6, the precipitate is uranium hydroxide, and in acidic solutions, either the monohydrogen phosphate or chloride phosphates containing 58.6% U, 20.1% P_2O_5, 6.1% Cl, and 8.4% H_2O are formed; when the latter were heated at 600°, the product had a composition close to that of $U_3(HPO_4)_4$ (64.3% U, 23.6% P_2O_5), but consisted of a

mixture of the ortho- and pyrophosphates and uranium dioxide. The normal phosphate could not be obtained by the prolonged hydrolysis of $U(HPO_4)_2.4H_2O$ (20 d) at high temperatures. Thus the normal orthophosphate cannot be obtained, and products with a similar composition have been erroneously assumed to be normal uranium(IV) phosphate.

5. Physicochemical Properties

Until comparatively recently, there were few published papers on this topic[31,40,59,60]. A simplified interpretation of the bands in the infrared spectrum, involving their assignment to various vibrations of the uranyl ion and its overtones and combination tones, was carried out in Ref.59. The other papers do not give a detailed assignment of the bands of all the groups in the compound, and do not discuss the wavenumbers of the water vibrations, which make a significant contribution to the spectra of uranium complexes.

The characteristic ranges of absorption by each of the groups in uranyl orthophosphates are well known[3,61-63]. The free orthophosphate ion has a tetrahedral configuration, and has four fundamental vibrations with wavenumbers $\nu_1(A_1)$ ~ 940 cm^{-1}, $\nu_2(E)$ ~ 420 cm^{-1}, $\nu_3(F_2)$ ~ 1020 cm^{-1}, and $\nu_4(F_2)$ ~ 560 cm^{-1}, of which the two triply degenerate vibrations are infrared active[3,62]. On coordination to a metal, the symmetry of the PO_4^{3-} ion may be lowered from T_d to C_{3v} or C_{2v}, accompanied by the following changes in the spectral characteristics:

The infrared spectrum of $UO_2HPO_4.4H_2O$ in the range of the $\nu_3(F_2)$ vibrations shows two strong bands with maxima at 990 cm^{-1} and 1105 cm^{-1}; the $\nu_4(F_2)$ band is also split into two components. Thus the symmetry of the distorted phosphate tetrahedron is close to C_{3v}[64,65] (Table 4).

The ν(OH) stretching region contains a strong broad band with a maximum at about 3300 cm^{-1}, which merges with the band at 2200 cm^{-1}, and the $\delta(H_2O)$ region contains two bands, at 1640 cm^{-1} and 1750 cm^{-1}. From the broad bands of medium strength at 1750 cm^{-1} and 2200 cm^{-1}, it was first assumed that part of the water in the compound is present as hydroxonium ions H_3O^+,[66-68], formed by the transfer of protons from HPO_4^{2-} to H_2O. Evidence in support of this assumption was provided by the absence of δ(POH) absorption at 1200 cm^{-1} and 2400 cm^{-1}.[62,69]

A study of the ^1H NMR spectra of $UO_2HPO_4.4H_2O$,[70] however, showed the absence of the bands of width 10–15 G and 20 G characteristic of water of crystallisation and hydroxonium ions respectively[71-74]. Instead, the spectrum shows one narrow band of width only 0.1 G, which with decrease in temperature becomes broader, while retaining its singlet structure. This narrow line corresponds to weakly bound water molecules and protons with a high diffusion mobility, indicating that the proton is hydrated by water molecules to give the oxonium group $H_9O_4^+$. The criterion used to distinguish H_3O^+ and more complex oxonium groups was the absence of the totally symmetric deformations of H_3O^+ in the Raman spectra in the region of ~ 1200 cm^{-1}.[75] The extremely high mobility of the proton and water molecules in $UO_2HPO_4.4H_2O$ is indicated by the ease of deuteriation of the compound[70]. Treatment of a specimen in an atmosphere of D_2O vapour for 24 h is sufficient for complete isotopic replacement.

Thus the monohydrogen orthophosphate has a polymeric structure containing uranyl phosphate layers; water occupies the space between the layers, through which the mobile proton moves freely.

Table 4. Vibrational wavenumbers (cm^{-1}) of U^{VI} and U^{IV} monohydrogen orthophosphates*[64].

$UO_2HPO_4.4H_2O$	$UO_2HPO_4.H_2O$	$U(HPO_4)_2.4H_2O$	Assignment

3300±20	3500±10	3200; 3400	ν(OH)

* The wavenumbers found in the Raman spectra are given in brackets.

On going to $UO_2HPO_4.H_2O$ there is an increase in the complexity of the infrared and Raman spectra; in the infrared spectra, the $\nu_3(F_2)$ band, as before, is split into two components (1055 cm^{-1} and 1120 cm^{-1}), which are displaced to larger wavenumbers by 65 cm^{-1} and 15 cm^{-1}. At the same time, the splitting $\Delta\nu_3$ decreases to 65 cm^{-1}. The $\nu_1(A_1)$ vibration is activated (990 cm^{-1}), and an additional $\nu_4(F_2)$ band appears at 500 cm^{-1}. An interesting feature is that the spectrum of the monohydrate contains bands at 1235 cm^{-1} and 2380 cm^{-1}, characteristic of the POH stretches and deformations of hydrogen orthophosphates. The ^1H NMR spectrum of $UO_2HPO_4.H_2O$ has the form typical of acid salts containing water of crystallisation and the proton of a hydrogen phosphate group. The molecules of water of crystallisation give a doublet of width 13.1 G. The calculated values of the second moment[76] and the distance between the protons[77] are 17.7 G^2 and 1.65 Å, typical of molecules of water of crystallisation. The central narrow component of width 1.3 G has a second moment of 2.2 G^2.

Thus the change from the tetra- to the monohydrate of uranyl monohydrogen orthophosphate leads to fixation of the mobile proton of the phosphate group and the formation of the acid salt, accompanied by a rearrangement of the structure[53].

Up to the present, relatively few solid compounds containing oxonium groups were known. Species of this kind with the general formula $H_{2n+1}O_n^+$ are extremely characteristic of solutions of strong acids[75,78-80]. In recent years, the improvement of physicochemical methods of study has made it possible to detect the dioxonium ion $H_5O_2^+$ in the hydrates of a number of complex acids: $H_3PWO_4.6H_2O$[81] and $H_2PtCl_6.nH_2O$[82]; $H_9O_4^+$ has been detected in $H_9O_4CF_3SO_3^+$[83] and $H_9O_4Cl.2H_2O$.[84]

The existence of the $H_3O_4^+$ group in uranyl monohydrogen orthophosphate distinguishes it from the series of acid phosphates with a fixed proton, and is responsible for its electrical conductivity. The presence of a proton gas, capable of moving along a line of hydrogen bonds, has been detected in studies of the electrical conductivity of various substances[85-90]. The conductivity, which is due to the migration of protons in the lattice, increases with increase in temperature. In fact, the electrical conductivity of a compressed disc of $UO_2HPO_4.4H_2O$ at a constant stabilised voltage of 3–6 V[70] begins to increase sharply at 72° by a factor of almost 10^6 compared with the original value (10^{-6} Ω^{-1} cm^{-1}), reaching a maximum of 0.2 Ω^{-1} cm^{-1} at 90°, after which it decreases equally sharply. A high proton conductivity in this phosphate was detected similarly by another group of workers[91] in the temperature range 20–60°. The anionic and electronic conductivity is negligibly small. The same authors[92] report that at 100 °C the proton conductivity of $UO_2HPO_4.4H_2O$ was 7×10^{-2} Ω^{-1} cm^{-1}, whereas the electronic conductivity is ~ 10^{-8} Ω^{-1} cm^{-1}. They discuss[92] the possibility of applying this phosphate in electrochemical devices, making use of such properties of the compound as the low solubility, corrosion resistance, ease of mechanical treatment, and ability to operate in the range 0–100°. According to their estimates[92], a cell having electrodes of CaH_2 and $TiFeH_2$ with uranyl monohydrogen phosphate as electrolyte will have an e.m.f. of 0.8 V and a theoretical specific energy of 294 W h kg^{-1}. The same authors[93,94] found by NMR that this compound in the temperature range 0–30° undergoes a phase transformation due to ordering of the hydrogen bonds in the structure; the diffusion of hydrogen at 20–70° has also been detected[95].

Comparison of data obtained by the present authors[53,64,70] with the data of Refs. 91–95 shows that the quantitative values of the electrical conductivity, the temperature range, and the explanation of the conductivity in terms of the migration of extremely mobile protons and water molecules for the most part agree; the views on the structure of the compound also coincide. The suggestion of the present authors that the substance has a layer structure involving a uranyl phosphate framework $(UO_2PO_4)_n^{n-}$ was confirmed by a calculation[96,97] for a fragment of the layer $[(UO_2)_nPO_4]^{5+}$ of symmetry D_{2d}, in which the heavy uranium atoms are practically at rest, and the kinematic interactions are weakly transmitted through them. The calculated vibrational wavenumbers show fairly good agreement with the experimental values for uranyl monohydrogen orthophosphate and double uranyl orthophosphates, and indicate that the calculation for the fragment of the layer model gives a sufficiently good qualitative description of the characteristic features of its structure. The conclusions about the structure of uranyl monohydrogen orthophosphate and double uranyl orthophosphates were confirmed by crystallographic data for $NH_4UO_2PO_4.3H_2O$,[98] the monohydrogen orthophosphate[99,100], and copper dioxophosphatouranate[101]. The structure of $UO_2HPO_4.4H_2O$ is made up of layers, containing UO_2^{2+} and PO_4^{3-} ions, and alternating two-dimensional networks containing water molecules. The U–O(PO_4) distance is 2.307 Å. In this compound there is a system of strong hydrogen bonds with O...O distances of 2.56–2.81 Å, which ensures proton migration and hence the electrical conductivity of the substance. When the proton is replaced by a metal or ammonium ion, the proton conductivity decreases sharply. The same result is achieved by removing part of the water, as for example in the monohydrogen orthophosphate monohydrate.

The structures of uranyl dihydrogen orthophosphate, normal uranyl orthophosphate, and uranium(IV) phosphates have not yet been determined. The spectra of these compounds have been analysed to determine their structural characteristics. On going from $UO_2(H_2PO_4)_2.3H_2O$ to $UO_2(H_2PO_4)_2.H_2O$ (the latter is stable at a water vapour pressure of 0.1 mmHg), the strength of the uranium–oxygen bond in the uranyl group increases (the ν_1 and ν_2 wavenumbers increase[102]). All the bands assigned to the $H_2PO_4^-$ vibrations are doublets (Table 5). It is suggested that the doublet structure of the bands is due to the existence of non-equivalent phosphate groups (see Table 5). A possible reason for the non-equivalence of the phosphate groups may be a difference in the influence of the hydrogen bonds of the water molecules on each $H_2PO_4^-$ group. In the monohydrate, where the influence of the water molecules is weaker, the splitting of the $H_2PO_4^-$ lines disappears.

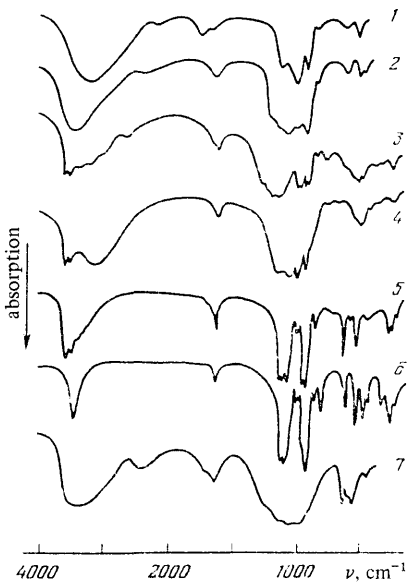
* The wavenumbers found in the Raman spectra are given in brackets.

The existence in $UO_2(H_2PO_4)_3.3H_2O$ of a system of strong hydrogen bonds and the participation of the phosphate anion in this system are indicated by the absorption in the ν(OH) region from 3600 cm^{-1} to 2600 cm^{-1}, the band of medium strength at 2550–2100 cm^{-1}, and the broad bands in the P–OH deformational region (1300–1100 cm^{-1}). The protons of the $H_2PO_4^-$ groups apparently form H-bonds with water molecules, giving bridged O...O structures[102-106]. Comparison of the spectra of dihydrogen orthophosphate specimens hydrated to different extents gives information on the state of the water in the compounds. The splitting of the $\delta(H_2O)$ band into two components at 1600 cm^{-1} and 1627 cm^{-1} in the spectrum of $UO_2(H_2PO_4)_2.3H_2O$, which increases with decrease in temperature, indicates that the water molecules in this compound are structurally non-equivalent. The spectrum of the monohydrate shows only one band at 1588 cm^{-1}, and the ν(OH) and δ(POH) bands tend to be narrower. At the same time, the broad range of absorption with a maximum at 2400 cm^{-1} disappears, and the two ν(OH) bands at 3572 cm^{-1} and 3530 cm^{-1} are preserved. The high values of ν(OH) and the low value of $\delta(H_2O)$ indicate that there is little distortion of the water molecule in the monohydrate under the influence of hydrogen bonds. At the same time, the difficulty of

removing the last H_2O molecule indicates that it is strongly bound in the structure, which is possible if it is coordinated to uranium. The infrared spectrum (Fig.1) shows bands due to the librational vibrations of water, which are sensitive to deuteriation and to decrease in temperature[102]. This separation of the protons was confirmed by ^1H NMR. The resonance lines of the water molecules were distinguished using the published atlas of crystalline hydrate spectra[107].



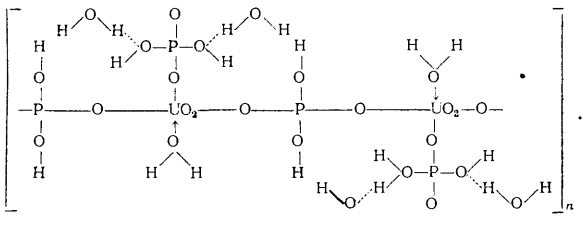


Figure 1. Infrared spectra of uranium orthophosphates: *1)* $UO_2HPO_4.4H_2O$;[64] *2)* $UO_2HPO_4.H_2O$;[64] *3)* $UO_2(H_2PO_4)_2.3H_2O$;[102] *4)* $UO_2(H_2PO_4)_2.H_2O$;[102] *5)* $(UO_2)_3(PO_4)_2.4H_2O$;[109] *6)* $(UO_2)_3(PO_4)_3.H_2O$;[109] *7)* $U(HPO_4)_2.4H_2O$.[58]

Like the monohydrogen orthophosphate, $UO_2(H_2PO_4)_2.3H_2O$ is a polymer in which one phosphate group binds the uranyl ions in a uranyl phosphate chain, while the other is terminal. One water molecule is coordinated directly to the uranium atom, and two others are joined by hydrogen bonds to $H_2PO_4^-$ groups:

The proposed scheme effectively explains the ease of hydrolysis of the dihydrogen orthophosphate with the removal of a terminal $H_2PO_4^-$ group under the influence of water and polar solvents, the reversible removal of two water molecules at low temperatures, and the decomposition of the compound when the last water molecule is removed. The coordination number of the uranyl group in this compound is probably four (the energy of the purely electronic transition is 20278 cm^{-1}[108]).

In the infrared spectrum of $(UO_2)_3(PO_4)_2.4H_2O$, the line corresponding to the $\nu_3(UO_2^{2+})$ vibrations is a doublet (Table 6)[109]. The totally symmetric $\nu_1(UO_2^{2+})$ stretch appears as a doublet. The observed splitting and activation of the $\nu_1(UO_2^{2+})$ band in the infrared spectrum indicate that the substance contains two types of uranyl group in environments with low symmetry. The nature of the absorption by the phosphate group indicates that it is extensively distorted, probably to C_{2v} symmetry. The $\nu_3(F_2)$ and $\nu_4(F_2)$ bands are split into three components[103]. The $\nu_1(PO_4^{3-})$ band is activated in the infrared spectrum. The spectra of the UO_2^{2+} and PO_4^{3-} ions of the hexahydrate are analogous to those for the tetrahydrate, although the bands are diffuse and broadened slightly. On the other hand, the spectrum of the PO_4^{3-} ion in the monohydrate (Table 6) has fewer bands, corresponding to an increase in the symmetry of this ion relative to the tetrahydrate.

* The wavenumbers found in the Raman spectra are given in brackets.

In normal uranyl orthophosphate, the PO_4^{3-} ions are probably coordinated to UO_2^{2+} as bridging bidentate anions to give uranyl phosphate layers.

The $\delta(H_2O)$ deformational wavenumbers for $(UO_2)_3(PO_4)_2.4H_2O$ indicate that the water molecules in the crystalline hydrates are non-equivalent, and the absorption at 460 cm^{-1} and 720 cm^{-1}, which is sensitive to decrease in temperature[110,111] and deuteriation ($K = 1.26$), corresponds to the librational vibrations of water.

It has been suggested[112] that the librational wavenumbers of water appear not only when H_2O is coordinated directly to the metal atom but also when a system of hydrogen bonds is formed. In the case of the tetrahydrate, however, and more particularly the monohydrate, for which the ν(OH) band has a half-width of only ~ 100 cm^{-1} with a maximum at 3450 cm^{-1}, the last effect is apparently slight. On the other hand, in the spectrum of the hexahydrate, the OH bands are broadened considerably (to 1300 cm^{-1}), apparently as a result of hydrogen bonding with excess water molecules. Analysis of the spectra indicates that in the uranyl phosphate

layer, one water molecule is coordinated to the uranyl ion, while the others are in the space between the layers.

On the whole, the spectrum of $U(HPO_4)_2.4H_2O$ shows diffuse bands due to PO_4^{3-} groups and water molecules[58] (see Table 4 and Fig.1). The ν(OH) range contains a very broad ($S_{1/2}$ = 500 cm^{-1}) band with a complex structure and maxima at 3400 cm^{-1} and 3200 cm^{-1}, against which it is possible to distinguish a band with a maximum at 2400 cm^{-1}. This band and the shoulder at 1265 cm^{-1} correspond to the P—OH stretches and deformations typical of acid phosphates[62,63].

6. Characteristic Features of the Thermal Decomposition

The thermal decomposition of the crystalline hydrates, which generally includes dehydration, depends on the state of the anion and the water molecules in the compound[5]. It was noted above that all the orthophosphates studied are three-dimensional polymers in which the PO_4^{3-} anion is coordinated to a uranium atom, and the water molecules either are mobile between the layers or complete the inner sphere of the complex. This is responsible for the great variety of forms of bonding of the water both to uranium and to the nearest groups by the formation of H-bonds of different types with the anions of neighbouring layers and with water molecules between the layers.

The dependence of the behaviour of uranyl orthophosphates when heated on these factors can be considered. The decomposition of uranyl monohydrogen orthophosphate is most complex, and shows a number of characteristic features.

1. The removal of water begins at relatively low temperatures, slightly above room temperature.
2. The dehydration of $UO_2HPO_4.4H_2O$ to the monohydrate involves a phase transformation.
3. On heating, the phosphate anion polymerises at 100° before all the water of crystallisation is removed. The quantity of polymeric forms increases with increase in temperature.
4. Up to ~ 6.5% free phosphoric acid is detected in the decomposition products.
5. Sublimation of phosphorus(V) oxide is observed at 500–600°.

The ease of removal of water is in good agreement with the assumption that the H_2O molecules lie between the layers, and with the increase in the mobility of the molecules with increase in temperature. At the same time, increase in temperature increases the probability of the movement of the protons through the system of hydrogen bonds, and in an electric field this movement becomes ordered. It may be noted that the temperature of the observed phase transformation coincides with the temperature range corresponding to the increase in the proton conductivity. A theory has been proposed[113,114] to explain the ordering of the motion of the protons in antiferroelectric orthophosphates and its relation to the phase transformation.

The increase in the mobility of the water molecules between the layers on heating may lead to the hydrolysis of the uranyl phosphate bonds and the removal of H_3PO_4 according to the schemes:

$$3UO_2HPO_4\cdot 4H_2O \rightarrow (UO_2)_3(PO_4)_2 + H_3PO_4 + 12H_2O$$

$$3UO_2HPO_4\cdot n\,H_2O \rightarrow (UO_2OH)_3PO_4 + 2H_3PO_4 + 3(n-1)\,H_2O\,. \qquad (1)$$

The concentration of free phosphoric acid reaches a maximum in the specimens heated to 150–200°. The appearance of H_3PO_4 during heating may create the impression that the increase in the electrical conductivity of the specimens is due to the electrolysis of H_3PO_4. The maximum on the electrical conductivity curve, however, does not coincide with the temperature range in which phosphoric acid is formed[70], and the conductivity in this range is low.

The formation of polyphosphates during the thermal decomposition of $UO_2HPO_4.4H_2O$ is probably the result of the superposition of a number of processes—the condensation of acid phosphate groups

$$2UO_2HPO_4\cdot n\,H_2O \rightarrow (UO_2)_2P_2O_7 + (2n+1)\,H_2O$$

and the decomposition of phosphoric acid with the subsequent reaction of pyrophosphoric acid with the components of the solid phase:

$$2H_3PO_4 \rightarrow H_4P_2O_7 + H_2O$$
$$2(UO_2)_3(PO_4)_2 + H_4P_2O_7 \rightarrow 3(UO_2)_2P_2O_7 + 2H_2O$$
$$2(UO_2OH)_3PO_4 + 2H_4P_2O_7 \rightarrow 3(UO_2)_2P_2O_7 + 7H_2O$$
$$5(UO_2)_3(PO_4)_2 + 4H_4P_2O_7 \rightarrow 3(UO_2)_5(P_2O_{10})_2 + 8H_2O \text{ etc.}$$

The reaction of H_3PO_4 with uranyl phosphates may explain the decrease in its concentration in the substance at 200–500°. Beginning at 550°, small quantities of phosphorus(V) oxide sublime into the gas phase[115].

Table 7. Stages in the removal of water from uranium orthophosphates under equilibrium conditions, and the thermodynamic characteristics of the process[116,54].

Compound	Dehydration temperature range, °C	Number of moles of H_2O	ΔH, kcal $mole^{-1}$	$\Delta S°$, e.u.
$UO_2HPO_4.4H_2O$	50—80	2.0	12.3±0.6	44.6±0.4
$UO_2HPO_4.4H_2O$	100—115	0.5	13.5±0.8	45.6±0.6

$U(HPO_4)_2.4H_2O$	150—170	1.0	11.8	10.0
$U(HPO_4)_2.4H_2O$	180—205	0.5	38.6	33.8
$U(HPO_4)_2.4H_2O$	205—260	0.5	—	—

It was noted above that the data on the stepwise character of the removal of water and the temperature range of the dehydration given by different authors do not agree. This may be due to differences in the conditions of the experiments. To exclude the influence of such factors as the size and shape of the crystals, the rate of heating, etc., we studied[116] the thermal decomposition of the compounds under equilibrium conditions using a quartz membrane null manometer[117]. Table 7 gives data on the stepwise character of the dehydration under equilibrium conditions; it was found that it is different from that observed on heating in a stream of dry air. Throughout the entire range of temperatures studied, the anionic composition of the solid phase was restricted to ortho- and pyrophosphates (the latter was detected from 90°), whereas in the decomposition of the substance in a dry atmosphere, the heating products contained not less than six phosphate forms. A phosphorus-containing substance in concentrations of 10^{-2}–10^{-4} M was also detected in the gas phase. Increase in the water vapour pressure in the system increases the thermal stability of the substance slightly. Analysis of the infrared spectra of specimens kept under equilibrium conditions at 200° and 400° showed that the products contained uranyl hydroxo-complexes[110], whose appearance may be due to the reaction described by scheme (1). The value of $\Delta H \cong 14$ kcal $mole^{-1}$ obtained agrees with the ease of removal of water from the compound being studied, and the high value of $\Delta S°$ (45 e.u.) is apparently related to the high entropy of sublimation of water ($\Delta S°$ = 35.6 e.u.), and also to the rearrangement of the crystal

structure of the substance during the decomposition. Thus these data do not agree with the statement[119] that the atmosphere has no influence on the extent of the decomposition of the phosphate anion in bivalent metal orthophosphates.

Ammonium dioxophosphatouranate $NH_4UO_2PO_4.3H_2O$, which is isostructural with the monohydrogen phosphate, loses three water molecules in a single stage when heated, but the removal of ammonia, like that of the last water molecule from $UO_2HPO_4.4H_2O$, takes place over a wide temperature range (280–800°) and is accompanied by polymerisation of the phosphate anion[56]. The product obtained after heating was found to contain a water-soluble phosphate compound containing no uranium, and consisting of ammonium phosphate, capable of dissociating and volatilising[119]. At low heating rates, this compound dissociates, and at high heating rates it volatilises. The product of the thermal decomposition of these phosphates is a compound with the overall composition $U_2O_3P_2O_7$,[54,56] whose formation is accompanied by the liberation of oxygen and the reduction of uranium.

The thermal decomposition of the dihydrogen orthophosphate $UO_2(H_2PO_4)_2.3H_2O$, which was studied in detail by Japanese workers[120], is also complex. Since the intermediate decomposition products are metaphosphates, the authors[120] were interested in their structure. A definite relationship exists between the structure of the metaphosphates and the magnitude of the charge and size of the cation[121]; phosphates with a metal ion of medium size are cyclic, and those with very small and very large metal ions are linear. It was shown[120] that the removal of two water molecules at 120° is not accompanied by the polymerisation of the phosphate anion. Up to 300° the products are pyro-, tri-, and tetrapolyphosphates, which at a temperature above 350° are converted into linear metaphosphates according to the scheme·

$$(UO_2)_n H_2P_{2n}O_{6n+1} \rightarrow [UO_2(PO_3)_2]_n + H_2O \ .$$

In the range 900–1000°, reduction of uranium takes place, and the composition of the substance becomes simpler. The final decomposition product is uranium(IV) pyrophosphate:

$$[UO_2(PO_3)_2]_n \rightarrow nUP_2O_7 + n/2O_2 \ .$$

The anionic composition and structure of $(UO_2)_3(PO_4)_2.4H_2O$ remain unchanged on thermal decomposition up to 950°. The loss of the last water molecule begins above 330°.[54] At 950–1000°, the orthophosphate is dehydrated completely, with the simultaneous liberation of oxygen and the formation of a mixture of uranium(IV) phosphate and U_3O_8, and not a phase with the composition $U_3O_8P_2O_7$.[39] Although the heating products obtained in the range 400–800° contain small quantities of water, their spectra are practically the same as those of the monohydrate. The stepwise character of the removal of water under thermodynamically equilibrium conditions is the same as in air (see Table 7). The low values of the entropy of dehydration indicate that the changes in the structure of the substance during the thermal decomposition are slight. The oxygen pressure over anhydrous $(UO_2)_3.(PO_4)_2$ on heating to temperatures above 800° has been measured[122].

The dehydration of uranium(IV) monohydrogen orthophosphate $U(HPO_4)_2 \cdot 4H_2O$ takes place in accordance with classical ideas to give pyrophosphate according to the scheme:

$$U(HPO_4)_2 \cdot 4H_2O \rightarrow U(HPO_4)_2 + 4H_2O$$
$$U(HPO_4)_2 \rightarrow UP_2O_7 + H_2O \ .$$

UP_2O_7 crystallises at ~ 760°.

Shchegrov[118] reviewed published data on the regular features of the mechanism of the dehydration of bivalent metal orthophosphates on the basis of the state of the water molecules present, in particular the strength of the hydrogen bonds with the phosphate anion. The dehydration of both acidic and normal orthophosphates takes place in three stages[118].

The first stage takes place at relatively low temperatures, and is accompanied by the removal of water molecules forming relatively weak hydrogen bonds with the anion, with energies up to 7–8 kcal mole^{-1}:

$$M_3(OH_2)_x(PO_4)_2(m-x)H_2O \rightarrow M_3(OH_2)_x(PO_4)_2 + (m-x)H_2O$$
$$[M(OH_2)_x HPO_4](m-x)H_2O \rightarrow [M(OH_2)_x HPO_4] + (m-x)H_2O \ .$$

The second stage, the removal of more firmly bound water (with hydrogen bond energies of 9–11 kcal mole^{-1}), is accompanied by extensive structural transformations such as the formation of a mixture of higher phosphates, hydroxides, or oxides of the metal:

$$n/2M_3(OH_2)_x(PO_4)_2 \rightarrow M_{(n+2)/2}P_nO_{3n+1} + (n-1)M(OH)_2 + \frac{nx-2n+2}{2}H_2O$$
$$n[M(OH_2)_xHPO_4] \rightarrow M_{(n+2)/2}P_nO_{3n+1} + \frac{n-2}{2}MO + \frac{n(2x+1)}{2}H_2O \ .$$

The third stage gives an intermediate dehydration product with a simpler composition, as a result of the following reactions:

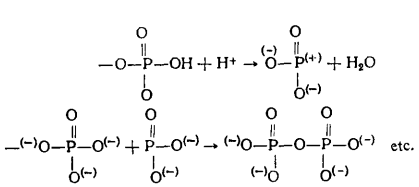
$$M_{(n+2)/2}P_nO_{3n+1} + (n-1)MO \rightarrow \frac{n}{2}M_3(PO_4)_2$$
$$M_{(n+2)/2}P_nO_{3n+1} + \frac{n-2}{2}MO \rightarrow \frac{n}{2}M_2P_2O_7 \ .$$

The data in Refs.118 and 123–127 show some lack of agreement. Analysis of the infrared spectra of the dehydration products shows that the specimen first loses the water joined by "strong hydrogen bonds" (ν(OH) = 3030–3060 cm^{-1})[123–125], whose energy was estimated as 35–40 kJ mole^{-1}. At the same time, the high-wavenumber vibrations of the water molecules (above 3400 cm^{-1}, bond energies 10–15 kJ mole^{-1}) are preserved in the spectrum, while the OH stretching bands show an overall decrease in width. These bands generally remain in the spectrum up to fairly high temperatures.

In the discussion of the spectra in Refs.126 and 127, no account was taken of the possibility of the direct coordination of the phosphate group to the metal. Ideas about the aquocomplexes of a number of isostructural sulphates and perchlorates of bivalent metals (Co, Ni, Fe, Zn, Ca, Mg)[128,129], in which the water molecules are in the inner coordination sphere, and the anion is in the outer sphere and forms H-bonds with the water molecule, were applied to the phosphates. X-ray diffraction data on the phosphates of Ca^{2+}, Co^{2+}, Fe^{2+}, Zn^{2+}, Mg^{2+}, Al^{3+}, etc.[130–137] have shown that they are three-dimensional polymers, in which the polyhedron around the metal atoms is formed by the oxygen atoms of phosphate groups. The water molecules in hydrates with low water contents can act as bridges between metal atoms[131] or be coordinated to the metal or situated in the space between the layers[138,139], being held in the crystal lattice by hydrogen bonds. X-ray diffraction data indicate that the strength of the bonding of the water on dehydration is determined by the structure of the phosphate. The coordinated water molecules are naturally held much more strongly, as confirmed by the measured M–O(H_2O) bond lengths, which are equal to 2.0–2.2 Å and are comparable with the M–O(PO_4) distance. The formation of H-bonds with the outer-sphere anion will increase the force constant of the M ← OH_2 bond.

When extremely strong symmetrical H-bonds O...O with length 2.4–2.6 Å, which are formed extremely rarely in crystals, are produced, ν(OH) may reach 3000 cm^{-1} or less. When estimating the energy of hydrogen bonds from the lowering of the ν(OH) vibrational wavenumbers, however, care must be taken, since it is necessary to make allowance for a number of factors which displace the ν(OH) wavenumber in the same direction as hydrogen bonding. On coordination,

the displacement of ν(OH) to lower wavenumbers may reach 600 cm^{-1}, and it is complex in character and does not always depend on the strength of the bond formed with the metal. The displacement is also determined by the symmetry of the molecule, the perturbing influence of the field of the central atom, the nature of the hybridisation of the orbitals, Fermi resonance, etc.[140-143] The nature of the bonds formed by water is best deduced from the librational wavenumbers[141-143]; the wavenumbers of the rocking and wagging vibrations increase with increase in the strength of the M ← OH_2 bond.



It is clear from the foregoing that without a knowledge of the structure of the compound, the estimation of the perturbing influence of the anion on the water molecules from the displacement of the ν(OH) wavenumbers is inaccurate. The situation is complicated by the fact that even in the anhydrous acidic compounds[132,138,144,145], the proton of the phosphate group is involved in a system of H-bonds with neighbouring layers, and in the case of the crystalline hydrates, the number of possible hydrogen bonds increases sharply.

Returning to the uranium phosphates, it can be seen that the dehydration of uranyl monohydrogen orthophosphate, which contains mobile water between the layers, involves the production of up to six forms of polyphosphate and free phosphoric acid, whose formation in the decomposition of bivalent metal phosphates has been related[118,123-127] to the existence of strong hydrogen bonds between the coordinated water molecules and the outer-sphere phosphate anion.

It can be seen from the case of $UO_2HPO_4.4H_2O$ that it is probably premature to reject the possibility of hydrolysis to explain the thermal decomposition of phosphates, particularly in view of the fact that many phosphates contain mobile water between the layers. On the other hand, in the decomposition of the normal orthophosphate monohydrate, which contains coordinated water (ν(OH) = 3450 cm^{-1}), the H_2O molecules are removed gradually up to a temperature of 900°, and polymeric forms of phosphate were not detected in the dehydration products. On the other hand, uranium(IV) monohydrogen orthophosphate, which gives extremely broad ν(OH) bands with a maximum at 3200 cm^{-1}, indicating strong hydrogen bonding, decomposes in accordance with classical ideas to uranium pyrophosphate.

Thus the ideas developed in Refs.5, 118, and 123–127 do not make possible a sufficiently reliable explanation of the mechanism of the dehydration of uranyl and uranium orthophosphates. A preferable concept was developed by the authors of Refs.146–149, who regard all crystalline hydrogen phosphates as proton semiconductors, which when heated above a definite temperature give free protons, capable of moving easily through interstices in the crystal lattice. The concentration of this "proton gas" increases with increase in temperature; the probability of its reaction with the phosphate tetrahedra also increases.

The condensation takes place by a series of successive processes involving ionisation of anionic sites:

The proton transfer is most effective when the compound contains a system of hydrogen bonds, and the degree of transfer depends on the crystal structure of the compound. With the formation of hydrogen orthophosphates, an increase in the strength of the P–OH bond and a decrease in the strength of the PO–H bond compared with the HPO_4^{2-} anion are assumed. The formula $[...(M-O)_3-P=O]^-H^+$ has been proposed to describe the structure of group IV metal phosphates[150].

III. CONDENSED URANIUM PHOSPHATES

A review of uranium phosphates would be incomplete without an examination of polymeric phosphates with different degrees of condensation. Uranium pyrophosphates in solution were studied in Refs.151–155, where it was shown that the reaction of uranyl nitrate with sodium pyrophosphate gives cationic complexes $[(UO_2)_nP_2O_7]^{2(n-1)}$, where n = 3–5. The composition of the pyrophosphates depends on the medium. The insoluble complex $[Na_4(UO_2)_8(P_2O_7)_5]$ and the soluble complexes $[Na_2UO_2P_2O_7]$, $Na_6UO_2(P_2O_7)_2$,[151] and $[UO_2H_q(P_2O_7)_x]^{(4x-q-2)-}$ (x = 1,2) were detected. At pH 0.83–3.00, $[(UO_2)_5H_2P_2O_7]^{8+}$ is formed[153]. Uranyl pyrophosphates including heavy metal cations (Ag^+, Cd^{2+}, Zn^{2+}, Co^{2+}, Ni^{2+}) have been prepared[155]. The possible formation of the uranyl hydroxide pyrophosphate $(RNH_3)_3UO_2OHP_2O_7$ in the extraction of uranium(IV) from pyrophosphate solution by alkylamines has been suggested[156].

The $UO_2(NO_3)_2$–$Na_4P_2O_7$–H_2O system has been studied[157], and the following salts isolated: the soluble $Na_6UO_2(P_2O_7)_2.6H_2O$ and the insoluble $Na_2UO_2P_2O_7.3H_2O$, $Na_2UO_2P_2O_7.2H_2O$, $Na_2(UO_2)_3(P_2O_7)_2.5H_2O$, and $(UO_2)_2P_2O_7.4H_2O$. Secondary processes gradually take place in the system, but their nature was not established[157].

The $Na_4P_2O_7$–$UO_2(NO_3)_2$–H_2O system was studied by the present authors by measuring the electrical conductivity, pH, and refractive index of isomolar series at concentrations of 0.001–0.2 M[158]. The existence in solution of complexes with ratios $P_2O_7^{4-}$:UO_2^{2+} of 2:1, 1:1, 1:2, and 1:6 was detected (some of these complexes were reported earlier[151,157]). To isolate the solid compounds, they were synthesised by mixing solutions to give the above component ratios. The pyrophosphates $Na_6UO_2(P_2O_7)_2.3H_2O$, $Na_2UO_2P_2O_7.5H_2O$ and $(UO_2)_2P_2O_7.8H_2O$ were obtained. The first of these is readily soluble in water, and it was salted-out with acetone or ether and dried in a desiccator over phosphorus(V) oxide. The pyrophosphate with ratio 1:6 could not be obtained[158]. When solutions to give this ratio were mixed, the precipitate, which formed 24 h after the solutions were mixed, contained up to 30% of the ortho-form. When the solutions were kept for a long time, the specific conductivity and refraction curves showed a displacement of some of the maxima, and in an excess of the uranyl ion (ratio > 1:2), changes were also observed visually; the external appearance and volume of the precipitates altered. To determine the reasons for these changes, the pyrophosphates were kept in equilibrium with the solution and then analysed by chromatography. After one month, the 1:1 and 1:2 compounds contained appreciable quantities of orthophosphate (~ 14 and 27), and at a ratio of 1:6 the system contained no pyrophosphate, and the precipitate consisted of $(UO_2)_3(PO_4)_2.4H_2O$.

Thus uranyl pyrophosphates in solution undergo appreciable degradation, which increases with increase in the uranium concentration. Thus the changes detected[157] in the system result from the decomposition of the polyphosphate anion. It was important to determine whether analogous degradation of the anion takes place in the solid phase. The chromatographic data showed that one month after the formation of the 2:1, 1:1, and 1:2 compounds, the first contained practically no ortho-form, and the others ~ 10% and 25% PO_4^{3-} respectively.

The $Na_4P_2O_7$–$UO_2(NO_3)_2$–H_2O system was also studied by other workers[159], who isolated the 1:1 and 1:2 complexes. The preparation of the 2:3 compound $Na_2(UO_2)_3(P_2O_7)_2.14H_2O$ has been reported[158]. The individuality of the last compound is doubtful, since its composition is extremely sensitive to slight changes in the $P_2O_7^{4-}$:UO_2^{2+} ratio in the solution[158]. The infrared spectrum and heating curves of the product[159] are practically the same as those of the 1:1 compound. The authors[159], in spite of the reported[158] possibility of the degradation of uranyl pyrophosphates, studied the equilibrium in the system over a prolonged period. It will be shown below that with increase in the length of the polyphosphate chain, the ability of the uranyl phosphates to undergo degradation increases. The composition and structure of the compounds crystallising from melts of the $(UO_2)_2(P_2O_7)$–$Na_4P_2O_7$ system have been studied[160].

In the $Na_5P_3O_{10}$–$UO_2(NO_3)_2$–H_2O system, compounds with $P_3O_{10}^{5-}$: UO_2^{2+} ratios of 2:1, 1:1, 1:3, 3:5, 1:2, and 2:5 exist in solution[161]; some of these compounds were reported earlier[162–166]. The ranges of stability of the crystalline hydrates of uranyl tripolyphosphates were determined by the present authors, and the following solid compounds isolated[161]: $Na_3UO_2P_3O_{10}.6H_2O$, $Na_4(UO_2)_3(P_3O_{10})_2.14H_2O$, $Na_5(UO_2)_5.(P_3O_{10})_3.22H_2O$, $Na(UO_2)_2P_3O_{10}.9H_2O$, and $(UO_2)_5(P_3O_{10})_2.21H_2O$.

The 1:1 and 2:5 compounds are obtained even with slight variation in the ratios of these components, but the 2:3, 3:5, and 1:2 complexes have these compositions in the solid state only with the appropriate stoichiometry in the solution.

The characteristics of the vibrational spectra of uranyl tripolyphosphates have been discussed[167]. On going from the 1:1 to the 2:5 compound, the $\nu_{as}(=PO_2)$ stretching wavenumbers tend to decrease from 1240 cm^{-1} to 1210 cm^{-1}, and $\nu_{as}(PO_3)$ from 1165 cm^{-1} to 1155 cm^{-1}. This can apparently be related to an increase in the degree of polymerisation of uranyl tripolyphosphates. A gradual increase in the strength of the binding of the water molecules in the complexes is observed in the same order (1:1 < 2:3 < 3:5 < 1:2 < 2:5). This can be seen from the thermal analysis data: water is removed at ~ 300° from the 1:1 compound, 500° from the 2:3 and 3:5 compounds, 700° from the 1:2 compound, and only at 800° from the 1:5 compound. The melting points of the dehydration products increase in the same order: the 1:1, 2:5, and 3:5 complexes melt in the range 800–850°; the 1:2 compound at 1150°, and the 2:5 compound at 1200°. On the other hand, the tendency of uranium to be reduced decreases: reduction takes place at 900° for the 1:1 complex, and at 700° for the 1:2 and 2:5 complexes. The final product of the thermal decomposition of uranyl polyphosphates at 1000° is a mixture of linear phosphates.

When considering the thermal stability of uranyl phosphates, mention must be made of the final decomposition products. The possibility of determining uranium as phosphates has been discussed many times. Different forms to be weighed have been proposed by different authors: $U(PO_3)_4$,[168] $U_2O_3P_2O_7$,[169–171,29] and $U_2O_5P_2O_5$.[172] In the description of the thermal stability of uranium orthophosphates, it was shown that the final decomposition products of the phosphates have different overall compositions. The decomposition products of the polyphosphates also have a different composition. The final products often contain a mixture of phosphates with different anionic compositions; the identification of the products is also complicated by the reduction of uranium on heating. Care must therefore be taken in the analytical determination of uranium by the published methods[29,169,171], and it should be remembered that the overall composition of the products formed on heating depends on the composition of the original specimen.

The tripolyphosphates, like uranyl pyrophosphates, are unstable when left to stand; Fig.2 illustrates their degradation at 0° and 25°. It can be seen from Fig.2 that the tendency to undergo degradation decreases with decrease in temperature. Unlike the pyrophosphates, for which the degree of degradation increases with increase in the uranium concentration, the degree of degradation of the tripolyphosphates shows a complex dependence on composition. In the series of compounds with the 1:1, 2:3, and 3:5 compositions, the degradation of the anion increases (the $P_3O_{10}^{5-}$ concentration after 100 d at 25° was 55, 25, and 5% respectively), whereas the 1:2 and 2:5 complexes after the same time interval contained 15% and 35% $P_3O_{10}^{5-}$.[173] In the 2:3 and 3:5 compounds there is probably considerable deformation of the phosphate anion. Thus the tendency of uranyl polyphosphates to undergo degradation increases with increase in the length of the phosphate chain, and depends on the structure of the phosphate. More complex linear polyphosphates should probably be even less stable.

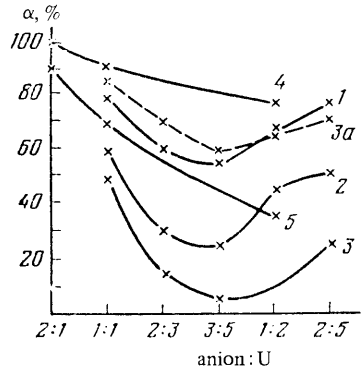


Figure 2. Dependence of the degree of degradation of uranyl pyro- and tripolyphosphates on the time for which they have been kept: *1, 2, 3*) tripolyphosphates at 25 °C after 10, 30, and 100 d respectively; *3a*) tripolyphosphates at 0 °C after 100 d; *4, 5*) pyrophosphates after 30 d; α is the concentration of the original phosphate[158,161].

In the discussion of the degradation of phosphate anions, it should be noted that there are practically no published data on the decomposition of solid polyphosphates. The dependence of the degradation of polyphosphates in solution on the pH of the medium and temperature has been studied[174,176]. It was shown only recently[177,178] that like uranyl phosphates, the tripolyphosphates of Co^{2+}, Ni^{2+}, and Cu^{2+} undergo degradation in the solid phase, the extent of the decomposition being greater for the copper phosphate.

Uranyl metaphosphates are much more stable than the polyphosphates. Japanese workers[179] have shown that uranyl tetrametaphosphate is more stable than the trimetaphosphate with respect to hydrolysis in the presence of UO_2^{2+} ions. α- and β-$U(PO_3)_4$ have been obtained and identified by X-ray diffraction[180].

The study of condensed uranyl and uranium phosphates was extended by Soviet workers[181–185]. The crystalline condensed phosphates formed in the UO_2–P_2O_5–H_2O and UO_2–P_2O_5–M_2O–H_2O systems (M = alkali metal), which contain

molten polyphosphoric acids, were synthesised and studied. The conditions of formation and crystallisation of the phosphates $UO_2(PO_3)_2$, $UO_2H(PO_3)_3$, and $(UO_2)_2P_6O_{17}$ were determined[181]. The synthesis of the hydrogen phosphate stimulated the search for analogous compounds with alkali metal ions, of the type $MUO_2(PO_3)_3$, where M = Na, K, Rb, or Cs; their optimum crystallisation temperature is 320°.[181]

$UO_2H(PO_3)_3$ is made up of spiral polyphosphate chains $[H_2P_6O_{18}]^{4-}$ of six PO_4^{3-} tetrahedra, extending along the (100) direction, and joined by uranyl ions to form a three-dimensional framework[183].

The behaviour in a melt of the uranyl ion with the cations Sr, Ba, and Pb, and oxocations MO_2^{2+}, has been compared[181]. Uranyl cations and the cations of these metals form ultraphosphates $M^{II}{}_2P_6O_{17}$.

The possibility of obtaining the metaphosphate $U(PO_3)_4$ by the reaction of metallic uranium or $UO_2(NO_3)_2.6H_2O$ with a melt of 87% H_3PO_4 in the presence of $NH_4H_2PO_4$ (which accelerates the reduction of UO_2^{2+} to U^{4+}) has been studied[184,185]. $U(PO_3)_4$ crystallises in two forms. The compound $U(PO_3)_4$(I) has a structure analogous to the zirconium phosphate structure. It consists of a framework of $[UO_8]$ eight-apex polyhedra and chains of PO_4 tetrahedra cross-linked into double spirals. The structural analysis of metaphosphates makes it possible to regard all uranyl phosphates as polymers with a uranyl phosphate framework in which the water molecules and other metal ions are situated in the space between the layers. In a number of phosphates, the water molecules are coordinated directly to the uranium atom.

Uranyl phosphites $UO_2HPO_3.3H_2O$,[186] $M_2UO_2(HPO_3)_2$ (M = Na, K, NH_4),[187] and the products of the reaction with amides[188] are also polymeric. The uranium(IV) phosphites $U(HPO_3)_2.2H_2O$ and $U(H_2PO_3)_4$[189] have also been obtained.

The reduction of $UO_2(PO_3)_2$ and vitreous $UO_3.1.5P_2O_5$ by hydrogen has been studied[190]. It is suggested that the reduction takes place according to the scheme:

$$UO_2(PO_3)_2 \xrightarrow{450-600^\circ} \rightrightarrows P_2O_7\ \text{(cubic)} \rightarrow UP_2O_7\ \text{(orthorhombic)} \rightarrow (UO_2)_2P_2O_7 \rightarrow U_8O_{13}.$$

Cubic UP_2O_7 is stable up to 1000°. In $NaPO_3$–NaCl melts at 700–900° in the range rich in sodium metaphosphate, favourable conditions are created for the rapid solution of the sparingly soluble oxide UO_2.[191] The mechanism of the reaction in the system, and the form of the phosphate obtained, were not studied, however[191].

---o0o---

The material examined deals with the synthesis of uranyl and uranium phosphates, the problems of studying their behaviour in solution, the stability of the crystalline hydrates, and the stability of the phosphate anion with increase in the length of the phosphate chain. Study of the thermal decomposition has shown that the behaviour of the compounds in these processes is determined by their structure and the mode of binding of the phosphate anion and the water molecules. When uranium phosphates contain mobile water molecules and protons, the decomposition processes become more complex: polymerisation of the phosphate anion, liberation of H_3PO_4, etc.

The study of uranium phosphates is opening up new possibilities for their further use in electrochemical devices, for dissolving sparingly soluble oxides, and also to solve the problems of improving the technology of the extraction of uranium from phosphate raw material, which is now acquiring increasing importance as rich uranium ores become exhausted. In the production of phosphoric acid by extraction, methods have been developed which make it possible to extract up to 10% of the total uranium produced[192–199].

Kinetics and Mechanism of the Dissolution and Oxidation of Semiconductors

S.M.Repinskii

A generalised kinetic approach to the description of the dissolution of semiconductors (including the thermal oxidation of silicon and germanium) is based on a statistical thermodynamic analysis of the adsorption steps, and on an analysis of the structure of the activated complex and of the effects of solvation of the intermediate and the final products (calculated from model descriptions). 66 references.

I. INTRODUCTION

Academician Ioffe once wrote: "The most important property of semiconductors, which determines their behaviour and their suitability for various applications, is the nature of their chemical bond"[1]. The interaction between nearest neighbours has been used as a basis for classifying electronic, optical, and kinetic processes in semiconductors as well as in various vitreous solids[2,3]. This justifies the present attempt to analyse data on the kinetics of chemical dissolution reactions and of oxidation processes on semiconductor surfaces, aimed at identifying the main features of the elementary steps which play an important role in the transfer of an atom from the semiconductor to the adjacent gaseous or condensed phase as a result of chemical interaction[4-8]. We shall show that in spite of differences in the detailed chemistry of these phenomena the elementary acts which control the dissolution and oxidation processes are basically similar.

Once the basic characteristics of the elementary steps are known, a kinetic model of the overall multi-step process can be constructed, allowing for the special features of the reacting system: for example, a model for analysing the kinetics of semiconductor oxidation processes. A large amount of experimental information on the properties of the silicon–silica interface is now available. However, since these studies describe the system *a posteriori*, they do not allow the processes taking place at the semiconductor–dielectric interface during the oxidation to be reconstructed unambiguously. The approach suggested here offers entirely new possibilities for studying and controlling the properties of this interface.

II. DEFINITION AND CLASSIFICATION OF DISSOLUTION REACTIONS

In general, the term dissolution reaction describes a process at a phase boundary which results in the transfer of atoms or structural units from a crystal (or other solid) to the surrounding medium as a consequence of their chemical interaction with the active components of the neighbouring phase[9]. The chemical interaction can be treated in as much detail as in the molecular theory of solutions[10-12]. The dissolution reactions can be described as solvating, oxidising, or oxidising–solvating. The solvating type includes the reactions which cause the dissolution of ionic crystals in polar solvents, and also the dissolution of solids in melts. All other dissolution processes are either oxidising–solvating or oxidising.

Dissolution reactions can be classified (according to the type of phases in contact) as dissolution into a gas, a liquid, or a solid phase. Of course, reactions leading to dissolution into a gas phase are an example of oxidative dissolution. Reactions leading to dissolution into a condensed phase are the most complex type of oxidative–solvating interaction.

III. KINETIC MODEL

Like all heterogeneous reactions, the dissolution reaction is the result of a succession of elementary steps: adsorption of the active reactant, chemical conversion in the adsorption layer, and desorption of the product (with a corresponding reorganisation of the element of volume of the condensed phase in the interfacial region)[13-15]. This sequence of elementary acts can be described by the series of steps

$$A_2^{(II)} \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} A_2^{(s)} \qquad (1)$$

$$A_2^{(s)} \underset{k_{-1}'}{\overset{k_1'}{\rightleftarrows}} 2A^{(s)} \qquad (1')$$

$$A^{(s)} + U^{(I)} \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} UA^{(s)} \qquad (2)$$

$$UA^{(s)} \underset{k_{-3}}{\overset{k_3}{\rightleftarrows}} UA^{(II)} \qquad (3)$$

Eqns.(1) and (1') describe the adsorption on the crystal surface (phase I) of the molecule A_2 in the surrounding phase II. In general, adsorption is a two-step process in which k_1 is the rate constant for the adsorption of the intermediate molecular form and k_1' is the rate constant for the dissociative adsorption step. In most cases the adsorption process is accompanied by a structural rearrangement of the near-surface region of the crystal. Eqn.(2) defines the step (chemical reaction in the adsorption layer) in which the

adsorbed particle $A^{(s)}$ reacts with an atom or with a structural unit of the crystal ($U^{(I)}$) to form an adsorbed particle of the reaction product $UA^{(s)}$. The last step corresponds to desorption of this particle and formation of the final reaction product in the near-surface region of phase II: $UA^{(II)}$.

The kinetic analysis of this sequence of steps is not difficult. We shall confine our discussion to reactions in systems far from thermodynamic equilibrium and ignore the reversibility of step (2), i.e. we shall put $k_{-2} \cong 0$. This condition cannot apply at the boundary between a crystal and its melt, or to the dissolution of a semiconductor in the gas phase at high temperature, when crystal growth and crystal dissolution processes take place at comparable rates.

In our model the rate of the dissolution process (w_2) can be written

$$w_2 = k_2 \frac{k_1}{k_{-1}} [A_2^{(II)}] / \left(1 + \frac{k_1}{k_{-1}} [A_2^{(II)}] + \frac{k_2}{k_{-1}}\right) . \quad (4)$$

Two important special cases can be defined. In the first, the adsorption rate constant for the irreversible chemisorption of the reactant A_2 is much smaller than the rate constant of reaction (2): $k_2 > k_1 \gg k_1$, and therefore

$$w_2 = k_2 \alpha [A_2^{(II)}] / (1 + \alpha [A_2^{(II)}]) , \quad (5)$$

where $\alpha = k_1/k_2$. In the second case the adsorption step is reversible, i.e. $k_{-1} \gg k_2$, and

$$w_2 = k_2 a [A_2^{(II)}] / (1 + a [A_2^{(II)}]) , \quad (6)$$

where $a = k_1/k_{-1}$.

The equations describing these two cases are formally identical, but the physical significance of the parameters is entirely different in the two cases. The case described by Eqn.(5) is typical of oxidative dissolution only. On the other hand Eqn.(6) corresponds to kinetics of the Langmuir type, and it applies both to oxidative and to oxidative–solvating dissolution.

These two possible alternatives of our kinetic model of the dissolution process lead to the following conclusions. In the region of low concentrations of the reactant A_2 the reaction is always of the first order with respect to the active molecules. However, in the first variant [Eqn.(5)] the reaction rate is determined by the rate of the adsorption step. We should stress that the experimental value of the activation energy corresponds to the activation energy for adsorption, and the pre-exponential factor is $C_T = k_{01}$. The parameter k_{01} can be calculated from model considerations of the adsorption complex[13–15]. In the second variant [Eqn.(6)] the activation energy found experimentally in the region of first-order kinetics is $E_{exper} = H_2^{\neq} - \Delta H_{ads}$ (where $H_2^{\neq}$ is the activation energy of step (2), and ΔH_{ads} is the heat of adsorption), and the pre-exponential factor is $C_T = a_0 k_{02}$. Usually $k_{02} = n_S \nu$, where n_S is the density of surface atoms (or structural units), and ν is the frequency of their thermal vibrations. Statistical mechanical calculations gave values of a_0 in the range of 10^{-14}–10^{-13} for the immobile adsorption state and 10^{-8}–10^{-4} Torr^{-1} for mobile adsorption.

At high concentrations of the reactant A_2 the reaction is kinetically of zero order. In both variants the experimental activation energy corresponds to the parameter $H_2^{\neq}$, and the pre-exponential factor is usually $C_T = n_S \nu$. By analysing the experimental kinetic and thermodynamic data for the oxidative dissolution of semiconductors we conclude that the main exothermic effect of the reaction is contributed by the chemisorptive interaction between the active molecule and the crystal surface. Often the heat of chemisorption is greater than 20 kcal mole^{-1}, and the energy released in the adsorption interaction step makes possible the rearrangement of the short-range order region surrounding the given surface atom. Under these conditions the kinetics of the dissolution reaction are no longer affected by the crystallographic orientation, as has been demonstrated for the interaction of germanium with H_2S, S_2, and Br_2,[13–15] with O_2,[16] and for the interaction of silicon with O_2.[17]

When the heat of adsorption is a few kcal mole^{-1}, as in the interaction of silicon and germanium with their tetra-halogen derivatives[15,18], the dissolution usually takes place in the region of low surface coverage and is kinetically of the first order with respect to the reactant. This usually implies a dependence of the heat of adsorption, and therefore also of the activation energy of the dissolution reaction, on the orientation of the crystal.

IV. SPECIAL FEATURES OF SEMICONDUCTOR DISSOLUTION REACTIONS IN A CONDENSED MEDIUM

Adsorption processes associated with dissolution reactions have a number of special features. If the heat of dissolution of the A_2 active molecules in the condensed phase is $\Delta H_{diss}^{(II)}$, their heat of adsorption on the semiconductor surface is

$$\Delta H_{ads}^{K} = \Delta H_{ads} - \Delta H_{diss}^{(II)} . \quad (7)$$

The special case of $\Delta H_{ads} = \Delta H_{diss}$ can occur. In this case there is no surface excess of component A_2, and the reaction takes place by simple collisions between the A_2 particles and the surface. There is an analogous case in the kinetics of catalytic reactions (the Eley–Rideal mechanism). This type of dissolution reaction was originally proposed by Myuller[19]. We conclude that in oxidative–solvating dissolution reactions the contribution from adsorption interactions to the observed activation energy is small (or even zero) as compared with gas-phase reactions.

The coefficient a_0^K which appears in the expression for the pre-exponential factor can be calculated by a model approach[20,21]. The simplest involves the assumption that the molecules of the active component A_2 occupy holes of linear dimension d in the condensed phase, and that when these molecules are transferred to a cell immediately adjacent to the crystal surface they lose one translational degree of freedom and become adsorbed according to Eqn.(1). In this case

$$a_0^K = h/(2\pi MRT)^{1/2} d , \quad (8)$$

where h and R are Planck's and Boltzmann's constant (the gas constant here Ed. of Translation), and M is the molecular weight of the A_2 particle. A typical value of a_0^K is 1×10^{-2} cm^3 mole^{-1}.

Allowance for the adsorption of solvent molecules (as well as that of the A_2 molecules) is often needed when the dissolution medium is highly polar[8,22]. This means that the reaction rate is proportional to the product of the surface coverages by reactant molecules (θ_{A_2}) and by molecules of the polar solvent (θ_L):

$$w_2 = k_2 \theta_{A_2} \theta_L . \quad (9)$$

V. ATOMIC AND ELECTRON–ION SUBSYSTEMS IN THE DISSOLUTION PROCESS

The dissolution of a semiconductor is usually assumed to occur by two processes taking place in parallel (either independent, or conjugated): the delocalised interaction of the solid with the oxidiser and solvating agent particles (electrochemical mechanism) and the localised interaction of the

oxidiser with an active surface complex (chemical mechanism)[23–26]. We have shown[4,6,8] that in most cases the kinetics of the dissolution process are determined by the local aspects of the interaction between the oxidiser particles and the active surface complex. Though a strict calculation of the exchange currents for the electron–ion and atom–ion subsystems of the semiconductor has not yet been attempted, a qualitative comparison of semiconductors and metals can be based on experimental data.

The exchange currents for the electron–ion reactions Fe^{3+}/Fe^{2+} and $Fe(CN)_6^{3-}/Fe(CN)_6^{4-}$ on a metallic electrode are known[26] to be 5×10^{-3} and 10 A cm^{-2} respectively. From the relationship between the exchange currents i_0^M and i_0^S for a metallic and semiconductor electrode (which are determined by the width of the forbidden energy gap E_g [27])

$$i_0^S = i_0^M \exp(-E_g/4RT) \qquad (10)$$

we find that for a typical semiconductor with a forbidden gap 0.75 eV wide the exchange currents of these electron–ion reactions are 10^{-6} and 10^{-2} A cm^{-2} respectively. Our study[28] of the temperature dependence of the anodic dissolution of germanium gave an exchange current of 10^{-10} A cm^{-2} (at 25 °C) for the exchange current of the atom–ion subsystem.

These numerical results confirm the conclusion that equilibrium in the electron–ion subsystem is established easily and rapidly at the semiconductor–electrolyte interface. In this sense the atom–ion subsystem is the slow system[29]. Thus we must examine the effects arising from two subsystems (electron–ion and atom–ion) in order to describe the dissolution of semiconductors in polar media. We have also shown[23] that the step in which the oxidiser particles interact with the crystal can be assumed to have reached equilibrium (including the injection of positive holes into the semiconductor as a result of electron transfer between the crystal and the oxidiser). It follows that the potential difference at the semiconductor–electrolyte interface ($\Delta\phi$) is determined by the constants of the adsorption equilibrium steps (1) and (1′).

If γ is the fraction of the potential drop $\Delta\phi$ corresponding to the Helmholtz layer, the activation energy of reaction (2) depends on the potential in the normal way[24]. The fraction of the potential $(1 - \gamma)$, associated with the space charge layer, affects the exchange current of the atom–ion subsystem (see Ref. 24). The establishment of thermodynamic equilibrium at the adsorption interaction step assists the electron transfer processes between the bands (valence, and conduction) of the semiconductor and the Red–Ox system of the solution (as was first pointed out by Gerischer[25]).

VI. STRUCTURE OF THE ACTIVATED COMPLEX

The structure and the characteristics of the activated complex can be determined strictly by calculating the profile of the potential surface for the system of interacting atoms. Recent advances in computational methods of quantum chemistry have made these calculations possible for some of the simpler systems. However, for the reactions being discussed here the calculations cannot be strict, but though the analysis is only qualitative it leads to some definite conclusions.

The special properties of the potential energy curves are identified by comparing the thermodynamic and the kinetic characteristics. The total enthalpy change of the reaction

$$\tfrac{1}{2}A_2 + U = UA(g) \qquad (11)$$

is

$$\Delta H = \tfrac{1}{2}(\Delta H_1 + \Delta H_{1'}) + \Delta H_2 + \Delta H_3 , \qquad (12)$$

where ΔH_1, $\Delta H_{1'}$, ΔH_2, and ΔH_3 are the enthalpies of steps (1), (1′), (2), and (3) respectively.

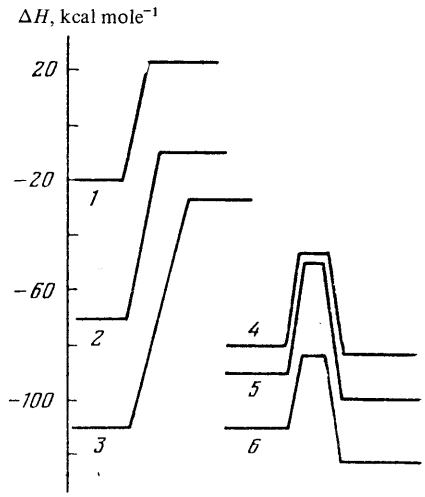
For exothermic reactions we have $\Delta H < 0$. It follows from published data[6,9,13,16,20] that for dissolution reactions giving rise to bivalent germanium and silicon products we can write

$$|\Delta H_2 + \Delta H_3| \simeq H_2^{\neq} , \qquad (13)$$

whereas for reactions in which quadrivalent compounds are formed

$$|\Delta H_2 + \Delta H_3| < H_2^{\neq} . \qquad (14)$$

From these expressions we note that reactions in which bivalent compounds are formed are barrierless, whereas reactions in which quadrivalent compounds are formed have an energy barrier (see Fig. 1). A barrierless reaction path indicates a smooth change in the structure of the activated complex from the state corresponding to the potential energy minimum to that of the final product. The presence of a barrier leads to the formation of a special type of complex which rearranges itself into the final product. Often the life-time of this complex is greater than 10^{-12} s, and in this case the formation of an intermediate product becomes possible.



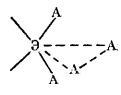


Figure 1. Examples of barrierless reactions [U + $1/2A_2$ = UA(g); U = Ge (*1, 2*) or Si (*3*), $A_2 = S_2$ (*1*) or O_2 (*2, 3*)] and of barrier reactions [U + $2X_2$ = UX_4(g); U = Ge (*4, 6*) or Si (*5*), $X_2 = Br_2$ (*4, 5*) or Cl_2 (*6*)].

We have previously studied[6] the nature of the activated complex for the formation of GeS by the interaction of Ge with H_2S and S, and we have shown that it has the Ge_2GeS structure, in which the germanium–sulphur bond is multiple but the two germanium–germanium bonds are weakened simultaneously as the GeS particle moves away from the surface. The displacement on activation amounts to 1.5–2.0 Å.

Dissolution reactions involving the formation of quadrivalent products take place by a barrier mechanism, and Eqn. (14) applies to these reactions. This conclusion was confirmed for the interaction of germanium and silicon with Cl_2 and Br_2.[15] In these reactions the activated complex has the structure

in which the A atoms are located at the corners of a distorted tetrahedron and the displacement of the semiconductor atom U on activation corresponds to the distortion of the bonds between the semiconductor atom and its nearest neighbours, and is therefore assisted by the insertion of the U atom into the centre of the tetrahedron.

The barrier mechanism is typical of dissolution reactions involving polar solvents. In these cases the donor–acceptor interaction of the adsorbed polar molecules of the solvent assists the formation of the tetrahedrally coordinated complex.

The kinetic characteristics of semiconductor gas-phase dissolution reactions are the simplest and the most accurately calculable. These can be treated as model reactions, and their kinetic parameters can often be used to establish the characteristics of reactions in which the semiconductor is dissolved into a liquid.

In the case of an inert solvent (which does not interact with the semiconductor) the activation energy of the dissolution reaction can be calculated from the linearity relationship

$$H_{\text{к}}^{\neq} = H_{\text{g}}^{\neq} - \alpha\Delta H_{solv} , \qquad (15)$$

where $H_{\text{K}}^{\neq}$ and $H_{\text{g}}^{\neq}$ are the activation energies of the reaction in the condensed and in the gas phase respectively, ΔH_{solv} is the enthalpy of solvation of the reaction product, and α is a fractional coefficient determined by the shapes of the potential surfaces. If the reaction product is chosen as the inert solvent the heat of solvation is equal to the heat of evaporation of the solvent. An example of this type of reaction is the interaction between germanium and a solution of bromine in $GeBr_4$.[20,21] In this case the activation energy of the reaction between germanium and bromine in a condensed phase is 25 kcal mole^{-1}, i.e. it is lower than the activation energy for the same reaction in the gas phase (33 kcal mole^{-1}) by an amount equal to the heat of evaporation of $GeBr_4$ (9 kcal mole^{-1}). It follows that $\alpha = 1$, and that the intermediate complex (in the case of an activated reaction) is relatively long-lived.

The value $\alpha = 1$ is typical of barrierless reactions[23], but since in this case the activation energy is high we cannot observe this behaviour experimentally in low-boiling liquids. However, suitable conditions may be met in the thermal oxidation of semiconductors, which we shall discuss below.

Clearly, in order to interpret the dissolution of semiconductors in polar liquids we need to know the composition of the reaction products and their heat of solvation. In many systems of great practical importance these characteristics are not known. In the absence of satisfactory methods of numerical estimation we must rely on expressions for the dependence of the kinetic characteristics of a reaction on the composition and properties of the solvent. This approach is discussed in detail in Ref.8.

VII. INITIAL STAGES OF OXIDATION

We shall use the considerations outlined above to discuss the special features of the thermal oxidation of semiconductors. At first sight the kinetics and mechanism of the reaction of silicon (say) with bromine and with oxygen have very little in common, since the former produces the volatile $SiBr_4$ whereas the latter produces a layer of SiO_2 whose thickness is determined by the rate at which oxygen can diffuse through it. We should immediately point out that when discussing the kinetics and mechanism of reactions at a phase boundary, i.e. of thermal oxidation processes, we are concerned with changes in instantaneous reaction rates, which can be determined experimentally by extrapolating to zero time the differential with respect to time of the thickness of the initial oxide layer. In this sense it is preferable to rely on experimental data obtained at moderately high temperatures or for relatively thin oxide layers.

The first step in our discussion is to examine the adsorption processes taking place during the initial stages of oxidation, and to establish the criteria which govern the transition from dissolution of the semiconductor in the gas phase (etching) to dissolution into an oxide phase (oxidation). We shall consider the steady-state reaction at constant temperature T and oxidiser pressure p in the gas phase. Using the symbol k_1 for the rate constant of the adsorption of the oxidiser on the atomically clean semiconductor surface we can express the rate of adsorption as

$$w_{\text{ads}} = k_1 p(1-\theta) .$$

The coverage of the surface (θ) by particles of oxidiser is given by the sum $\theta_1 + \theta_2$, where the first term defines the fractional monolayer coverage of the surface by irreversibly chemisorbed oxidiser, while the second term describes the surface coverage by oxidiser species in the second and higher adsorption layers. In the latter case the adsorption is treated as reversible, and is characterised by the equilibrium constant a and by the relatively low heat of adsorption q_2. Under these conditions

$$\theta_2/\theta_1 = ap/(1+ap) . \qquad (16)$$

The adsorption processes are accompanied by the transfer of semiconductor atoms to the gas phase with a rate constant $k_{2\text{g}}$ and to the oxide phase with a rate constant $k_{2\text{K}}$. The condition for the transition from dissolution into the gas phase to the formation of an oxide layer is the equality of the rates w_1 and w_2, i.e.

$$k_{2\text{g}}\theta_1 = k_{2\text{к}}\theta_2 , \qquad (17)$$

corresponding to

$$k_{2\text{g}}/k_{2\text{к}} = ap_{\text{кр}}/(1+ap_{\text{кр}}) . \qquad (18)$$

We shall assume that for a barrierless surface reaction the activation energy of the reaction with rate constant $k_{2\text{K}}$ is lower by ΔH_{solv} than the activation energy of the reaction with rate constant $k_{2\text{g}}$ [Eqn.(15)]. Thus, since

$$\exp(\Delta H_{solv}/RT) \ll 1,$$

we have

$$p_{\text{кр}} = a_{02}^{-1}\exp\left(\frac{\Delta H_{solv} - q_2}{RT}\right) . \qquad (19)$$

It follows from this expression that the condition $p < p_{\text{Kp}}$ corresponds to the formation of a gaseous product (i.e. to etching of the semiconductor), whereas the condition $p > p_{\text{Kp}}$ corresponds to oxidation with formation of a layer of oxide phase. Evidently, by plotting $\lg p$ against $1/T$ we obtain a straight line which divides the pressure–temperature space into two regions corresponding to etching and to oxidation respectively. The slope of this straight line is determined by the quantity ($\Delta H_{\text{solv}} - q_2$). The parameter q_2 can be identified with the heat of dissolution of the oxidiser in the oxide phase. In many systems (for example, in the SiO_2 system) this parameter is of the order of 1 kcal mole^{-1},[7] and therefore it lies within the uncertainty limits of ΔH_{solv}, which thus plays the main role in determining the condition (19). The coefficient a_{02} can be estimated by model calculations, and is typically in the range 10^{-3}–10^{-4} Torr^{-1}.[14,15] Some values of ΔH_{solv} are calculated below, and used (see Table) to compare calculation with experiment for the oxidation of silicon[30,31] and the sulphidation of germanium[14]. Calculations by Eqn.(19) agree in order of magnitude with experimental data on the sulphidation of germanium at 461 °C. For the oxidation of silicon the limiting oxygen pressure (above which an oxide layer begins to be formed) is 1×10^{-2}

Torr at 1100 °C, as compared with an experimental value[31] of 4×10^{-2}–1×10^{-1} Torr. For higher oxidation temperatures the calculated values are an order of magnitude lower than the experimental values. However, we should note that the conditions used in those experiments[30,31] may have produced rate limitation by diffusion of the reactants in the gas phase.

Thermodynamic and kinetic characteristics of germanium and silicon oxidation reactions (kcal mole^{-1}).

VIII. KINETIC CHARACTERISTICS OF REACTIONS AT THE SEMICONDUCTOR–OXIDE PHASE BOUNDARY

A large volume of experimental information on the thermal oxidation of silicon is now available. The following results are especially relevant to our discussion.

1. Beyond a certain thickness, the oxidation of silicon is controlled by the rate of diffusion of oxygen to the semiconductor–oxide interface. It has been shown that the oxygen diffuses as undissociated particles: O_2 molecules or O_2^- molecular ions[7,32–35]. The reaction rate is usually proportional to the oxygen pressure.

2. The presence of SiO_x structural units at the semiconductor–dielectric interface, where $x < 2$, has been confirmed by electron spectroscopy methods. At the Si–SiO_2 interface the thickness of the intermediate layer is 2–10 Å, but unusual properties are observed up to oxide thicknesses of 100–150 Å.[36–44]

The thermal oxidation reaction of germanium has been studied in detail for the germanium–sulphur system[14]. It was shown that the diffusion of sulphur through a layer of germanium disulphide up to 1 μm thick does not limit the rate of sulphidation. The intermediate layer is 100–200 Å thick and its thickness depends on the total thickness of the sulphide layer.

3. The layer of silicon dioxide is in a glassy state whose structure is described by two levels of ordering: short-range order, determined by the presence of tetrahedral $SiO_{4/2}$ structure units, and the ordering associated with various arrangements of the initial structure units to give ring and spiral structures which form microscopic pores and extensive channels along which the oxygen species can diffuse[45–48].

These observations allow us to describe the kinetic model of the thermal oxidation reaction of silicon at the semiconductor–dielectric interface as follows. The region close to the interface (Fig. 2) includes a layer of oxide (to the right of the geometric boundary) containing randomly distributed microscopic holes which are arbitrarily shown as spheres. Some of these holes are occupied by oxidised (A_2) molecules whose state can be defined as free gas-phase particles in a volume of linear dimension d. The transition of an A_2 particle from an occupied to an empty hole and back is described by the rate constants k_1 and k_{-1}. A special situation arises when the hole is directly adjacent to the geometric boundary. An A_2 particle entering such a hole can undergo a non-activated interaction with an atom of the semiconductor at the crystal surface (U), and the rate constant of the step leading to the formation of the intermediate compound $\geq$U=A is k_2. We shall assume that in this step the characteristics of the chemical interaction of the oxidiser particle with the atom from the crystal are the same for dissolution into the gas and for the formation of an oxide phase. The process is completed by the incorporation of the intermediate compound UA into the network of structure units of the oxide, characterised by the rate constants k_3 and k_{-3}. The energetics of this step (ΔH_{solv}) define the solvation of the UA species.

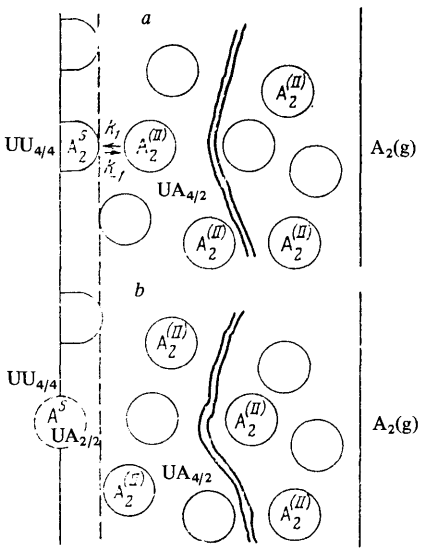

Figure 2. Schematic model of the thermal oxidation of a semiconductor U by interaction with A_2 to give a layer of $UA_{4/2}$: (*a*) adsorption of A_2 with rate constant k_1, (*b*) formation of the intermediate oxidation product $UA_2/_2$ with rate constant k_2. Microscopic holes in the oxide layer are shown. The concentration of $A_2^{(II)}$ is constant throughout the thickness of the layer. The broken line indicates the intermediate (translational) layer at the U–UA_2 boundary.

The sequence of steps involved in the oxidation of silicon by oxygen can be described as follows[49–56]. The initial step is the chemisorption of oxygen molecules with formation of an adsorbed intermediate on a surface centre, which we assume to be a doubly coordinated silicon atom, $\geq$Si, corresponding (strictly speaking) to a (100) orientation of the crystal:

$$\geq Si + O_2 \rightarrow \geq Si \cdot O_2 \text{ (chemisor.)}$$

The second step leads to an oxidative form of adsorption:

$$\geq Si \cdot O_2 \text{ (chemisor.)} \rightarrow \geq Si{=}O + O \text{ (ads.)}$$

This results in the dissociation of an O_2 molecule in the adsorption layer, one of the oxygen atoms becoming incorporated in the surface centre by a double bond. The other oxygen atom is held by an adsorption bond whose form is not clearly understood. We should stress that in the case of the reaction at the silicon–silica interface the probability of finding two adjacent surface centres (each capable of forming an $\geq$Si=O structure) is very low. In this case the second oxygen atom probably forms a metastable adsorption bond with atoms of the glass network: for example, giving an

Si–O–O–Si peroxide group. The last step limits the rate of the overall process and controls the removal of silicon atoms from the crystal and their incorporation into the network of silicon dioxide:

$$\rangle \mathrm{Si{=}O} \rightarrow \mathrm{SiO}_{2/2} \ . \qquad (20)$$

The oxidation process is completed by the formation of an $SiO_4/_2$ structure unit:

$$\mathrm{SiO}_{2/2} + \mathrm{O\,(ads.)} \rightarrow \mathrm{SiO}_{4/2} \ . \qquad (21)$$

Thus our model is generally consistent with the sequence of steps (1)–(3) proposed above, and the general kinetic equation for the rate of the thermal oxidation process can be written in the form of Eqn.(4). Since the solubility of A_2 particles in the oxide is usually low, i.e. $(k_1/k_{-1})[A_2] \ll 1$, and in most cases $[A_2] = \kappa p_{A_2}$ (where κ is the Henry coefficient and p_{A_2} is the partial pressure of A_2 particles in the gas), we can write

$$w_2 = k_2 k_1 \kappa p_{A_2}/(k_2 + k_{-1}) \ . \qquad (22)$$

There are two important special cases. At relatively low temperatures, when $k_2 \ll k_{-1}$, Eqn.(22) simplifies to

$$w_2 = k_2 k_1 \kappa p_{A_2}/k_{-1} \ . \qquad (23)$$

On the other hand at high temperatures ($k_2 \gg k_{-1}$) we have

$$w_2 = k_1 \kappa p_{A_2} \ . \qquad (24)$$

These two cases correspond to rate limitation at the semiconductor–oxide interface [Eqn.(23)] and to slow supply of A_2 particles to the interface [Eqn.(24)] respectively. In the latter case p_{A_2} is the equilibrium pressure, determined by the concentration of oxidiser dissolved in the layer adjacent to the semiconductor–oxide interface.

IX. COMPARISON WITH EXPERIMENT

The main characteristics of the dissolution of O_2 in silicon dioxide have been discussed by various workers[24,57–59]. The heat of dissolution is found to be ~0.7 kcal mole^{-1}, and the Henry coefficient is $\kappa = 0.0017$ at 900 °C. It has also been shown[34,35,58] that the rates of oxidation of silicon (in the parabolic regime) and of penetration of O_2 through the SiO_2 are almost identical, so that in our symbols the rate constant can be expressed as

$$k_1, \mathrm{cm^2\ s^{-1}} = 2.8 \cdot 10^{-4} \exp\,(-27.6/RT) \ . \qquad (25)$$

In Eqn.(23) the ratio k_1/k_{-1} is the constant for the adsorption equilibrium

$$a^{\kappa} = \frac{k_1^0}{k_{-1}^0} \exp(q_2/RT).$$

We shall assume that the heat of adsorption of O_2 at the $Si–SiO_2$ interface is equal to the heat of adsorption of oxygen for coverages greater than a monolayer.

Then, using Eqn.(8) with $d = 4$ Å, we can calculate the pre-exponential factor C_T of Eqn.(23):

$$C_T = \frac{kT}{h} n_s a_{O\kappa} \ . \qquad (26)$$

In this expression k is Boltzmann's constant h is Planck's constant, T is the absolute temperature, n_s is the concentration of active sites on the silicon surface, corresponding to the average density of holes at the geometric boundary which are filled with oxygen molecules, and $a_{OK} \cong 10^{-2}$ cm^3 mole^{-1}. The solubility of O_2 in silicon dioxide is typically[34,36,37] 5×10^{16} cm^{-3}, or 1.5×10^{11} cm^{-2}, so that we obtain $C_T = 9 \times 10^{21}$ atoms cm^{-2} s^{-1} from Eqns.(23) and (26). This value is close to that obtained from van der Meulen's results[60] (7.6×10^{22} atoms cm^{-2} s^{-1}).

The activation energy for the case described by Eqn.(23) can be calculated by the expression

$$H_{2\kappa}^{\neq} = H_{2g}^{\neq} - \Delta H_{solv} - q_2 \ , \qquad (27)$$

where $H_{2g}^{\neq}$ is the activation energy for the formation of the gas-phase molecule (in this case SiO).

In contrast to the dissolution of semiconductors in electrolyte solutions or in molecular liquids, in the case of thermal oxidation the use of the solvation energy concept requires some clarification. By definition, the solvation energy is the energy evolved when a particle is transferred from a vacuum to the stated medium. If the dissolution product is chemically identical to the medium this quantity is equivalent to the heat of evaporation or sublimation. In many polar or molecular solutions the molecular relaxation time of the medium is so short that the activated complex (or intermediate compound) produced during the dissolution reaction can be assumed to be fully solvated, and the activation energy of the reaction can be calculated by using Eqn.(15). However, in the thermal oxidation of semiconductors the rate of structural relaxation is comparable to the rate of chemical reaction at the phase boundary, which formally implies that the intermediate product of the reaction is only partially solvated. This aspect of the reaction is accounted for by the scheme suggested above for the oxidation of silicon.

Whereas the silicon atoms in the bulk of the oxide have a four-fold coordination, the intermediate compound formed during the rate-limiting step has only two-fold coordination. This is a feature of all the thermal oxidation reaction of semiconductors. Since the nearest neighbour approximation is very accurate in covalently bonded systems, the solvation energy of the intermediates in these reactions can be calculated. It is easy to show that the parameter of interest (ΔH_{solv}) is given by

$$\Delta H_{solv} = H_{U=O} - 2H_{U-O}, \qquad (28)$$

where $H_{U=O}$ is the energy of the double bond in the U=O molecule (for example, SiO), and H_{U-O} is the energy of the U–O single bond (for example, Si–O). By using data for the germanium–sulphur[3,61], germanium–oxygen[3,61], and silicon–oxygen[34] systems we obtained the ΔH_{solv} values given in the Table. We note that the solvation energies are highest for the silicon–oxygen system. The qualitative conclusion from this observation is that in the silicon–oxygen system the semiconductor atoms can be most effectively incorporated into the network of the glassy dielectric layer. By combining these results with experimental values of the activation energy for the dissolution of semiconductors in the appropriate gases[14,16,17,62] we can calculate [by Eqn.(27)] the activation energies for the thermal oxidation ($H_2^{\neq}$) of the semiconductors, which are also given in the Table.

For the germanium–sulphur system comparison with experiment is possible by using the results of Ref.14. The comparison shows that the contribution from the entropy of activation is often important in interfacial reactions, and cannot be ignored. As we have shown[14], the entropic contribution to the activation of the surface complex includes cooperative effects in the layer of sulphide adjacent to the crystal. It is difficult to allow for these effects with adequate precision, but it can be shown that the free energy of activation of the sulphidation reaction corresponds (to within ±8 kcal mole^{-1}) to the activation energy for the dissolution of germanium in sulphur vapour. Since ΔH_{solv} for this system is 7 kcal mole^{-1}, the conclusion is confirmed.

For the germanium–oxygen system the tabulated value is a first estimate of the activation energy of the oxidation process, determined by the reaction at the phase boundary.

For the thermal oxidation of silicon the activation energy of the initial stages was found[60] to be 53.7 kcal mole^{-1}, and an activation energy of 60 kcal mole^{-1} was reported[63] for the region 750–900 °C. These experiments were carried out under conditions favouring rate limitation by the reaction at the interface. The published values of the activation energy are not inconsistent with our estimate of 52 kcal mole^{-1}.

The solvation of the reaction product can be discussed by using a model of the reactive centre consisting of one structure unit of the crystal and one structure unit of the dielectric. This model is obviously valid at temperatures below the glass transition temperature T_g. Above T_g the kinetic processes associated with the switching of valence bonds are strongly hindered, and the activation volume often includes several dozen structural units[64]. As a result, heats of solvation calculated by Eqn.(28) can be expected to be inaccurate.

However, at temperatures above T_g the reactions may take place not through the formation of the intermediate complex $UO_{2/2}$ but directly by the breaking of a U–U bond in the activated complex $U_{2/4}UO$, giving a $UO_{4/2}$ structure unit. This means that the heat of solvation increases almost two-fold, and the activation energy of the reaction at the phase boundary is correspondingly reduced. This effect may explain the decrease in the activation energy of the oxidation from 60 kcal mole^{-1} (at 750–950 °C) to 26.8 kcal mole^{-1} (above 950 °C).[63] Unfortunately the glass transition temperature is not always accurately known. For quartz glass $T_g \cong$ 1157 °C,[34] but there are reasons to believe that very thin layers may soften at a lower temperature. We should re-state the need to allow for the entropic contribution to the activation of the surface complex when the oxidation reaction takes place under conditions compatible with viscous flow of the glassy oxide[9,13,14].

---o0o---

Our analysis of experimental data on the kinetics of the dissolution and of the thermal oxidation of semiconductors has shown that these two reactions have the same elementary step whose nature is determined by the activated displacement of a surface atom. This allows us to calculate the kinetic characteristics of the process at the semiconductor–oxide interface during thermal oxidation if the characteristics of the dissolution of the semiconductor into the gas phase and of the solvation of the intermediate by the oxide layer are known. In covalent systems the heats of solvation can be calculated by the two-fold coordination model of the semiconductor atom in the nearest neighbour approximation. The structure-chemical theory of reaction kinetics on a semiconductor surface and of relaxation processes in glass oxides offers a unified approach to the semiconductor oxidation reactions. As a result, an atomic–molecular theory of semiconductor–dielectric systems can be developed and used to synthesise materials having prescribed properties.

Reactions of Hydroperoxides with Amines and Aminoalcohols in Aqueous Solutions in the Presence and Absence of Metal Ions

S.K.Grigoryan

The intermolecular interactions in hydroperoxide-amine and hydroperoxide-amine-M^{2+} systems in aqueous media are examined. The formation of binary complexes between the system components is demonstrated; the amine complexes of metals $(MA)^{2+}$ show the highest activity in the decomposition of hydroperoxides. The fundamental kinetic characteristics of the decomposition reactions of hydroperoxides with amines in an aqueous medium in the presence and absence of metal ions are reduced from the data obtained and reaction mechanisms are proposed.
The bibliography includes 57 references.

I. INTRODUCTION

The study of the mechanism of the decomposition of hydroperoxides (ROOH) is of both theoretical and applied importance. They are intermediates in oxidation reactions in living organism and also in the autoxidation of low- and high-molecular weight organic substances. Hydroperoxy-compounds have found major practical applications as oxidising agents for various organic compounds and in the organic synthesis of oxygen, sulphur, phosphorus, and nitrogen compounds.

Nitrogen-containing organic compounds, particularly amines, aminoalcohols, aminoacids, etc. (present in the living organism as component parts of proteins and enzymes), form complexes with "metals of life" such as Co^{n+} (n = 2, 3), Cu^{n+} (n = 1, 2), Fe^{n+} (n = 2, 3), Mo^{n+} (n = 5, 6), Mn^{n+} (n = 2, 3, 4), Na^+, K^+, Zn^{2+}, Mg^{2+}, Ca^{2+}, etc. Some of them induce the catalytic decomposition of hydroperoxides in aqueous solutions analogous to that observed in enzyme catalysis.

The oxidation of high-molecular-weight compounds (polymers, rubbers, etc.) is an undesirable phenomenon which leads to their degradation and ageing. (Oxidation with atmospheric oxygen results in the formation on the hydrocarbon chains of the polymer of hydroperoxy-groups OOH, whose radical decomposition actually induces the degradation and hence also the ageing of polymers.) The elimination of or the prevention of the formation of the ROOH groups in macromolecules can be achieved by employing certain aminoalcohols and amine complexes as stabilisers.

This review deals with the kinetics and mechanisms of the reactions of cumenyl or t-butyl hydroperoxides with amines (A) in the presence and absence of M^{2+} ions in aqueous solutions. The studies were undertaken to elucidate the mechanism of the decomposition of hydroperoxides in aqueous media, to select amino-compounds and their complexes for reactions with specified pathways and products, and to select the necessary systems consisting of amines and M^{2+} complexes to be used as stabilisers in adhesive latexes and rubbers based on polychloroprene. In addition, the results obtained in studies on ROOH–A and ROOH–A–M^{2+} systems made it possible to explain the positive influence of Cu^{2+}, Co^{2+}, and monoethanolamine on the organisms of animals and man.

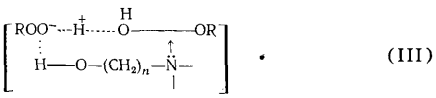
The kinetics of the formation and decomposition of ROOH in the absence and presence of variable-valence metal ions in organic solvents have been studied[1–7]. This review deals with investigations in aqueous media. All vital processes occur in water and nitrogen-containing compounds and hydroperoxides play an important role in them[8].

II. INTERMOLECULAR INTERACTIONS IN HYDROPEROXIDE–AMINE AND HYDROPEROXIDE–AMINE–M^{2+} SYSTEMS IN AQUEOUS MEDIA

The H_2O–ROOH–A–M^{2+} system is complex and several processes and reactions can occur simultaneously in it. In order to elucidate the character and mechanisms of the possible individual stages, studies were therefore made of complex formation and the binary interactions between the system components.

1. Complexes between ROOH and A

De La Mare et al.[9] showed in an earlier study that the interaction of hydroperoxides with amines in solution in the latter results in the formation of a hydrogen-bonded complex;



$$[ROO{-}H \leftarrow \ldots : \underset{|}{N}{-}] \quad . \qquad (I)$$

It has been shown[10,11] that the interaction of a hydroperoxide with amines in aqueous media involves conjugation between the electrons at the nitrogen atom and the oxygen bond with formation of a complex having a different structure:

$$\left[\begin{array}{c} \\ -\underset{|}{N}- \\ \vdots \\ RO\text{———}OH \end{array}\right] . \qquad (II)$$

The formation of complex (II) in aqueous media had been postulated earlier on the basis of kinetic data[12]. The authors of that investigation[12] also suggested that complex (III) between the ROOH dimer and an aminoalcohol molecule is

formed, in addition to complex (II), in aqueous solutions in the presence of aminoalcohols:

(III)

Subsequently this was also demonstrated by infrared spectroscopy[13].

It has been shown by NMR that complexes are formed in organic solvents (benzene, acetone, ethanol, etc.). The chemical shifts of the OOH group in t-butyl (TBHP), cumenyl (CHP), and t-pentyl hydroperoxides on formation of complexes with proton-accepting compounds (ethers and amines) have been investigated[14,15]. Depending on the concentration of, for example, triethylamine (TEA), there are three types of associated species (i.e. hydrogen-bonded complexes between TEA and TBHP) with a 1 : 1 composition; the hydroperoxide–hydroperoxide complex of the type ROOH....OOR predominates at low amine concentrations, while at high amine concentrations a complex resembling (II) is the dominant species. According to Yablonskii and co-workers[14,15], the O–O bond of the hydroperoxide in the complexes with amines is weakened more than in associated species with other proton acceptors and for this reason ROOH in saturated hydrocarbons (at 130–140 °C) and in water (up to 90 °C) are thermally stable[12,16], while in the presence of amines in aqueous solutions they decompose already at 30–40 °C.[12] Since the O–O bond of the hydroperoxide in complex (II) is weakened, the reaction is of first order with respect to ROOH.[12]

The formation of complexes between CHP and TEA has been investigated by proton magnetic resonance (^{1}H NMR) in aqueous solution at 34 °C.[17] It was found that the complex has the 1 : 1 composition and that the equilibrium

(1)

exists. The complex formation constant (K_p = 0.18 litre mol^{-1} at 34 °C) was calculated graphically[18] using the equation

$$\Delta/[A]_0 + K_p\Delta = K_p\Delta_0 \qquad (2)$$

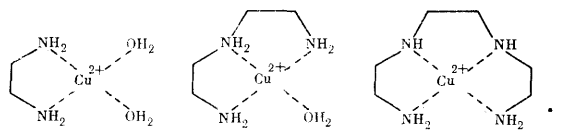
where Δ_0 is a standard quantity which represents the difference between the chemical shifts of the OOH group in the complex and in the ROOH–cyclohexane system (CHP was diluted with an inert solvent—cyclohexane), Δ is the difference between the chemical shifts of the CHP–TEA system in cyclohexane and of the CHP–cyclohexane system and is a measure of the reaction between OH and  alone, and $[A]_0$ is the initial amine concentration; we have $[A]_0 \gg [ROOH]$.

2. Complex Formation Reactions between A and M^{n+}

The thermodynamically stable ammine and amine complexes of copper and cobalt have the composition $(MA_4)^{2+}$.[19] Kinetic studies have shown that the decomposition of the hydroperoxide in the presence of M^{n+} complexes of amines obeys a first-order equation with respect to the amine[20,21]. Spectroscopic measurements (infrared spectroscopy and NMR) also indicate the formation of complexes in aqueous media between amino-compounds and metal ions[19,22]. It follows from the data of Grigoryan and co-workers[21,23] that 1 : 1, 1 : 2, and 1 : 3 complexes are formed together with the complexes $(MA_4)^{2+}$ in aqueous solutions of monoethanolamine, TEA, morpholine, etc. in the presence of Cu^{2+} and Co^{2+}.

The formation of complexes between ligands and M^{2+} was demonstrated by ^{1}H NMR [24,25] on the basis of the paramagnetic shifts of the M^{2+} signals in the presence of different ligands. The NMR spectra of the coordinated ligands not only yield information about the delocalisation of spin density over the bond system of the ligand but also make it possible to determine the equilibrium (complex formation) constant, the heat of complex formation, and other parameters[26].

The concentration dependence of the ^{1}H NMR spectra of TEA (taken in excess) in the presence of Ni^{2+} in aqueous solutions has been investigated[23]. The magnitude and signs of the spin density of the protons in the TEA molecules as well as the constant for the complex formation reaction between TEA and Ni^{2+} were determined from the shifts of the signals; the complex has the 1 : 1 composition. A downfield shift of the signals of the protons in the methylene and methyl groups of TEA was observed in the test solutions, for $[TEA]_0$ = 0.05–0.35 M and $[Ni^{2+}]_0 = 5 \times 10^{-3}$ M, the shift of the methylene proton signals being greater than the shift of the methyl proton signal. At the same time the multiplet signals of these groups are broadened and distorted, which indicates the existence in the solutions of labile paramagnetic complexes[27]. The signals for the CH_2 and CH_3 group are displaced downfield, which means that positive spin density is located on the protons of these groups following the formation of complexes. The dependence of the shift of the NMR lines on the ligand concentration is described by the formula[28,29]



$$-\mu/\delta = 1/\alpha aK + S/\alpha a\,, \qquad (3)$$

where μ is the molar concentration of the paramagnetic substance (in this case Ni^{2+}), δ the paramagnetic shift (p.p.m.) equal to the difference between the chemical shifts in the presence and absence of paramagnetic species (Ni^{2+}), S the molar concentration of TEA with $[TEA]_0 \gg [Ni^{2+}]_0$, K the complex formation constant, a the hyperfine coupling (HFC) constant (G) at 304 K, and α = 72.8). The HFC constants for the methylene and methyl protons of TEA and the complex formation constants were determined from the graphical analysis of the linear dependence of μ/δ on $[TEA]_0$ and $a^H_{CH_2}$ = +0.02 G, $a^H_{CH_3}$ = +0.008 G, and $K = 1.32 \times 10^2$ litre mol^{-1} (34 °C) were obtained.

The mechanism of the transfer of spin density to the atomic orbitals of the TEA molecule is as follows. For chelate Ni^{2+} complexes of amines, the unpaired electron is delocalised as a result of the formation of a σ-bond. The unshared electron pair of the nitrogen atom and the d_{z^2} orbital of the Ni^{2+} ion are involved in the formation of the Ni^{2+}–TEA σ-bond. In this case the spin density at the nitrogen atom is positive.

On comparing the complex formation constants obtained for Ni^{2+} ($K = 1.32 \times 10^2$) with the constants for the analogous Co^{2+} ($K = 2.6 \times 10^4$) and Cu^{2+} ($K = 6.1 \times 10^{15}$) complexes[30,31], we may note that the Ni.TEA complex is less stable. It is noteworthy that, in contrast to the analogous Cu^{2+}, Co^{2+}, and Mn^{2+} complexes, the above complex does not exhibit catalytic activity in the CHP and TBHP decomposition reactions in an aqueous medium[21]. The presence of free orbitals in the chelate complex apparently also plays an important role under these conditions. Thus it has been found that the manifestation of a catalytic activity by chelate Cu^{2+} complexes of diamines requires that the complexes contain two coordination-unsaturated bonds. The chelate Cu^{2+} complexes in which all the orbitals are occupied are inactive in the ROOH or HOOH decomposition reactions[32]. This is evident from a

comparison of the chelate copper(II) complexes of the following diamines: ethylenediamine, diethylenediamine, and triethylenediamine; they are illustrated schematically below:

The activity in the ROOH or HOOH decomposition reactions decreases in the sequence ethylendiamine (en) ≫ diethylenediamine (dien) > triethylenediamine (trien), i.e. the complex in which the central atom is not fully blocked by the ligand proved to be the most active; complexes with tetradentate ligands show almost no catalytic activity.

3. The Formation of Complexes between ROOH and M^{n+}

The formation of an intermediate complex between the hydroperoxide and the metal ions in organic media has been established[33–36]. The formation of complexes between metal ions (Ni^{2+}, Mn^{2+}, etc.) and TBHP in CCl_4 and CH_2Cl_2 has been demonstrated by NMR.[29] The intermolecular interactions between ROOH and M^{n+} in aqueous solutions were first investigated by Markaryan et al.[37] At very high water concentrations it becomes almost impossible to demonstrate the occurrence of the interaction of ROOH with Mn^{2+}, since the signals of the hydroperoxide and water protons merge; the complex formation in the CHP–Co^{2+} system was therefore investigated at low water concentrations. The results made it possible to estimate quantitatively the degree of intermolecular interaction between the ROOH and M^{n+} in aqueous solutions. The concentration dependence of the shift of the signal due to the protons of the CHP molecule in aqueous solutions in the presence of an excess of the hydroperoxide (>97, 98, 98.5, and 99%) was investigated. The constant for the complex formation between CHP and Co^{2+} was determined by Eqn.(3) from the shift; it proved to be $K = 0.158$ litre mol^{-1} at 34 °C.

One must note that the interaction of the individual components (ROOH and A) with water (as the medium) was also investigated by ^1H NMR. After the addition of water to CHP, the signal of the OOH group of the hydroperoxide is slowly displaced downfield as a result of the formation of the hydrogen bond between ROOH and H_2O.[37] The calculated rate constants for proton exchange and the proton lifetime in the complex [ROOH...H_2O] formed are $K = 8.5 \times 10^{-1}$ s^{-1} and $\tau = 1.2 \times 10^{-2}$ s. The formation of associated species comprising water and the TBHP dimer under ambient conditions had been demonstrated previously by infrared spectroscopy[13]. It was also established[38,39] that associated species involving the amine and water are formed in aqueous solutions of amines via both hydrophobic and hydrophilic interactions.

Thus intermolecular interactions occur in aqueous ROOH + A + M^{n+} systems with formation of binary associated species and complexes differing in their stability. Under standard conditions, these intermediate compounds are stable (some of them exhibit a catalytic activity in the ROOH decomposition reaction). Among the binary complexes indicated, the highest activity is shown in the decomposition of cumenyl and t-butyl hydroperoxides in an aqueous medium by the complexes of the amine with the metal ions $(MA)^{n+}$; this is indicated not only by the formation constants but also by kinetic data obtained in the study of the decomposition of hydroperoxides under the influence of these complexes[17,20,21].

III. KINETICS OF THE REACTIONS OF HYDROPEROXIDES WITH AMINES AND AMINOALCOHOLS IN THE ABSENCE AND PRESENCE OF M^{2+}

1. Kinetics of the Decomposition of ROOH in the Presence of the Amine and M^{2+}

The complex formation constants for the components of binary systems are listed below[30,31]:

System	CHP-TEA	CHP-Co^{2+}	TEA-Ni^{2+}	MEA-Cu^{2+}
K_p, litre mol^{-1}	1.6	0.16	132	26 000

Their comparison shows that the complex $(MA)^{2+}$ should be the most active[17,23]. For example, the ratios $K_{A+M^{2+}}/K_{A+ROOH}$ and $K_{A+M^{2+}}/K_{ROOH+M^{2+}}$ are approximately 10^2–10^6. Indeed the kinetic data obtained confirm that the hydroperoxides in the H_2O–ROOH–A–M^{2+} systems decompose mainly catalytically[20,21] as a result of the effect of the complex $(MA)^{2+}$ (although two other reactions can also occur simultaneously with the above reaction), the rate of the reaction catalysed by the complex $(MA)^{2+}$ being several times that in the absence of the complex[20,21].

The data permit the following conclusions concerning the decomposition of ROOH in the presence of amines and metal ions.

1. In the presence of monoethanolamine, pyridine, and some of its derivatives at temperatures up to 80 °C hydroperoxides hardly decompose in aqueous media[40–42]. Nor do the ROOH decompose at an appreciable rate in the presence of only the cations Cu^{2+}, Co^{2+}, Mn^{2+}, Ni^{2+}, Zn^{2+}, etc.) (up to 90 °C).[12,42,44]

2. The rate of decomposition of hydroperoxides in the presence of aminoalcohols and M^{n+} for $[A]_0 = [ROOH]_0$ in aqueous solutions is expressed by the general equation[40–44]

$$w_{tot} = -\frac{d[ROOH]}{dt} = w_1 + w_2 + w_3 = k_1[A]_0[ROOH]_0 + k_2[ROOH]_0^2 + k_3[M^{2+}]^n[A]_0[ROOH]_0 , \quad (4)$$

where w_1 is the initial rate of reaction directly between ROOH and the aminoalcohol, w_2 the initial rate of decomposition of the CHP dimer catalysed by the aminoalcohol, w_3 the initial rate of the catalytic reaction catalysed by the complex $(MA)^{2+}$, and n is the order of the reaction with respect to M^{2+}, which is between zero and 1.[21] The kinetics of the reaction of ROOH with aminoalcohols have been studied in the range 40–80 °C.[12] In the presence of aminoalcohols the amount of CHP in the system decreases as a result of the occurrence of two independent simultaneous reactions, both being of second order; although the aminoalcohol is involved in one of them, it is not consumed as a reactant: ROOH is consumed to a greater extent in the reactions with aminoalcohols than the aminoalcohol[12,42].

The excess consumption of the hydroperoxide is due to the occurrence of two simultaneous reactions, one of which takes place directly between the hydroperoxide and the aminoalcohol and the other involves the decomposition of the hydroperoxide by the aminoalcohol[12]. It has been established[40] that the first reaction, whose rate is w_1, takes place between ROOH and A molecules, while the second, whose rate is w_2, is the aminoalcohol-catalysed reaction between the $ROOH^-$ and $ROOH_2^+$ species, i.e. involves the formation of the cumenyl hydroperoxide dimer. Both reactions have a non-radical mechanism[40], although one cannot rule out a

slight "radical contribution" (3–5%) to the decomposition of the hydroperoxide in the presence of amines in aqueous solutions[52], despite the fact that this hydroperoxide decomposition pathway is difficult to demonstrate by a kinetic method. The catalytic activity of aminoalcohols (except monoethanolamine) can be explained by the presence of two groups in their molecules—proton donating (the hydroxy-group) and proton accepting (the nitrogen atom), which may entail the formation of complex (III).[12,40] Indeed in the presence of amines and without an alcoholic group hydroperoxides are not decomposed catalytically and only the direct reaction between ROOH and A takes place[41,45]. Table 1 shows that an increase in the number of hydroxy-groups and their removal from the nitrogen atom in the aminoalcohol molecule as well as the presence of hydrogen atoms at the nitrogen atom in the same molecule decrease the overall rate of decomposition of the hydroperoxide[12,40]: under these conditions, the formation of the intermediate active complexes (II) and (III) is hindered.

The replacement of the hydrogen atom in the alcoholic group by the methyl group deprives the amine of catalytic activity in the CHP decomposition reaction. It is thereby confirmed that the catalytic action of the aminoalcohol in the process under consideration involves the migration of the proton in the intermediate active complex (III).[12,41]

The presence of two idential proton-accepting centres (for example, in hydrazine $H_2\ddot{N}-\ddot{N}H_2$) does not lead to the catalytic decomposition of ROOH; the presence of pyridine or triethylamine together with ethanolamine in equimolar proportions or separately does not induce the catalytic decomposition of CHP.[12,41] The catalytic decomposition of the hydroperoxide requires the joint presence in the same molecule of two opposed active centres[12,40,41].

At 30° and 35 °C and for $[CHP]_0 = [TEA]_0$, the consumption of the aminoalcohol is not observed, whereas more than 10% of the initial amount of the hydroperoxide is consumed. i.e. only the catalytic decomposition of ROOH takes place[12]. In addition it has been shown kinetically that a little less than 10% of the consumption of the hydroperoxide is due to its decomposition purely via the catalytic pathway (the overall ratio of the consumptions of ROOH and A is 1.12 : 1). A similar equimolar amount of oxygen evolved was determined in the overall ROOH decomposition reaction in the presence of triethanolamine under the same conditions[12,40].

Table 1 presents kinetic data for the reaction of CHP with amines in an aqueous medium at 80 °C [k_1 and k_2 are the rate constants for the first and second reactions catalysed by the aminoalcohol (litre mol^{-1} min^{-1}); $k = k_1 + k_2$; for amines without alcoholic groups, $k_2 = 0$]. For comparison, Table 1 also lists the activation energies E (kcal mol^{-1}) and pre-exponential factors A (litre mol^{-1} min^{-1}) for the first and second reactions.

Thus, in the presence of only aminoalcohols such as diethanolamine, triethanolamine, diethylaminoethanol, diethylaminopentanol, diethylbutanolamine, diethyl-2,3-dimethylaminopropanol, β-piperidinylethanolamine, etc. (except monoethanolamine), the rate of reaction is expressed by the following equation[21,40]:

$$w_{tot} = w_1 + w_2 = k_1[A]_0[ROOH]_0 + k_2[ROOH]_0^2 \qquad (5)$$

if $[A]_0 = [ROOH]_0$. If has been shown[40] that w_1 and w_2 are comparable in magnitude; for example, $w_1/w_2 = k_1/k_2 = 1.67$ for the reaction of CHP with triethanolamine at 80 °C.

It has been established by ^1H NMR [14,15,17] that at high amine concentrations a complex of type (II) predominates and there is therefore virtually no catalytic decomposition

Table 1. Kinetic parameters of the reactions of CHP with amines (in water at 80 °C).

**At 70 °C.

of the hydroperoxide under the influence of the aminoalcohol when $[A]_0 \gg [ROOH]_0$. For example, $w_1/w_2 = 15$ for the reaction of CHP with triethanolamine, i.e. the rate of the catalysed reaction may be neglected compared with w_1.[40] We therefore obtain from Eqn.(5)

$$w_{tot} = k_1[A]_0[ROOH]_0 . \quad (6)$$

In the presence of amines without alcoholic groups [triethylamine, diethylamine, morpholine, piperidine, methyl β-piperidinylethyl ether, octylmorpholine, hydrazine, etc. [except pyridine and its derivatives)] the rate of consumption of ROOH (in the absence of M^{2+}) is expressed by an equation[40,41,45] analogous to Eqn.(6):

$$w_{tot} = w_1 = k_1[A]_0[ROOH]_0 . \quad (7)$$

In the presence of M^{2+} for equal initial reactant concentrations, i.e. with $[A]_0 = [ROOH]_0$ it is necessary to use Eqn.(4) instead of Eqn.(5) whereupon the following expression is obtained:

$$w_{tot} = w_1 + w_3 = k_1[A]_0[ROOH]_0 + k_3[M^{2+}]^n[A]_0[ROOH]_0 . \quad (8)$$

The same expression is obtained from Eqn.(4) when $[A]_0 \gg [ROOH]_0$; as above, one can assume in this case that $w_2 \to 0$, since

$$w_2 \ll w_1 \text{ and } w_2 \ll w_3 .$$

When $[A]_0 \gg [ROOH]_0$ and in the case of monoethanolamine or pyridine for any amine concentration, only one reaction catalysed by the complex $(MA)^{2+}$ takes place, its rate being expressed by the equation

$$w_{tot} = w_3 = k_3[M^{2+}]^n[A]_0[ROOH]_0 = k_{cat}[ROOH]_0 , \quad (9)$$

where $k_3[M^{2+}]^n[A]_0 = k_{cat}$ (k_{cat} is a constant for given concentrations of M^{2+} and A).

Transformation of Eqn.(8) yields

$$w_{tot} = k_{non\text{-}cat}[ROOH]_0 + k_{cat}[ROOH]_0 = (k_{non\text{-}cat} + k_{cat})[ROOH]_0 = k_{eff}[ROOH]_0 , \quad (10)$$

where $k_{non\text{-}cat} = k_1[A]_0$. The constant k_{eff} is determined from Eqn.(10).

Table 2. Temperature variation of the rate constants for the decomposition of CHP and TBHP in the presence of the monoethanolamine–Cu^{2+} complex.

t, °C	$10^2 k_{CHP}$, min^{-1}	$10^2 k_{TBHP}$, min^{-1}
60	0.35	0.06
65	0.80	0.12
70	1.34	0.23
75	2.73	0.54
80	4.95	0.90

Note. The initial concentrations of monoethanolamine and ROOH were 0.05 M: $[CuSO_4]_0 = 10^{-3}$ M.

The rate constants for the decomposition of the hydroperoxide by the amine complex $(MA)^{2+}$ are calculated in this way. Next, taking into account the fact that $k_{non\text{-}cat}$ is known[40], k_{cat} is determined:

$$k_{cat} = k_{eff} - k_{non\text{-}cat} . \quad (11)$$

For monoethanolamine or pyridine, k_{cat} is determined from Eqn.(9). One must note that, in contrast to the direct interaction of ROOH with the aminoalcohol and the decomposition of the hydroperoxide dimer by the aminoalcohol[40,41], the catalytic ROOH decomposition reactions under the influence of the complex $(MA)^{2+}$ have a radical-chain mechanism, although the chains are very short[21]. In certain cases the radical character of the reaction is hardly noticed, as in the decomposition of CHP and TBHP in the presence of the 1 : 1 Co^{2+} or Cu^{2+} complex of monoethanolamine.

It is noteworthy that the rate of decomposition of CHP in the presence of the 1 : 1 Cu^{2+}–monoethanolamine complex exceeds severalfold the rate of decomposition of TBHP (Table 2).

Comparison of the temperature variations of the rates of decomposition of the above hydroperoxides readily shows that the rate of decomposition of CHP increases appreciably in the presence of the phenyl group in the hydroperoxide molecule (being a weaker electron donor than the methyl group, the phenyl group diminishes the electron density in the O–O bond and thereby facilitates the decomposition of the CHP compared with TBHP). The mechanism of the catalytic decomposition is apparently independent of the type of hydroperoxide, since the activation energies are almost identical:

$$k_{CHP}\,(min^{-1}) = 8.13 \cdot 10^{17} \cdot \exp[(31\,000 \pm 500)/RT] \cdot$$
$$k_{TBHP}\,(min^{-1}) = 1.62 \cdot 10^{17} \cdot \exp[(31\,500 \pm 500)/RT] \cdot \quad (12)$$

Like metal ions, amines are catalysts of the decomposition of ROOH in aqueous solutions; it has been shown by the kinetic and chromatographic methods[21] that, in the course of the decomposition of ROOH, the amine is not consumed and after the complete decomposition of ROOH the amount of amine remains unchanged.

The rate of consumption of the hydroperoxide in the presence of Cu^{2+} is higher than in the presence of Co^{2+} or Mn^{2+}, which can be explained by the stability of the amine complexes whose criterion is the oxidation potential of the metal; there is a correlation between the normal oxidation potential of the cation and the rate of decomposition of the hydroperoxide: the rate of decomposition of ROOH increases in parallel with the increase of the normal oxidation potentials of M^{2+}.[21]

One must note that there are also other factors which influence the stability of metal ion complexes (the presence of unfilled orbitals in the complex, the charge and size of the ion, the nature or basicity of the ligand, and others[32]).

2. The Amine Complexes of Metal Ions as Models of Enzymes in the Decomposition Reactions of Cumenyl and t-Butyl Hydroperoxides in an Aqueous Medium

The hypothesis of the formation of an intermediate active complex of the type $[ROOH...(MA)^{2+}]$ has been used to account for the kinetics of the homogeneous catalytic reactions of cumenyl and t-butyl hydroperoxides in the presence of an amine and M^{2+} in an aqueous medium[42].

As mentioned above, in the presence of amines or aminoalcohols and M^{2+} ions, the decomposition of the hydroperoxide catalysed by the M^{2+} complexes of the aminoalcohol may be accompanied by the simultaneous occurrence of other reactions. The complex catalyst (E), consisting of M^{2+} and A, can be regarded as the simplest analogue of an enzyme inducing the decomposition of hydroperoxides[42].

It is known[19] that the thermodynamically stable ammine or amine complexes of copper or cobalt have the composition $(MA_4)^{2+}$. Studies have shown[21] that the decomposition of ROOH obeys a first-order kinetic equation with respect to A, indicating that the amine complex of the bivalent metal involved in the chemical reaction has the composition $(MA)^{2+}$.

The formation of the given intermediate complex between the amine complex (E) and the hydroperoxide can be represented by the equation

$$E + n\text{ROOH} \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} [E \cdots n\text{ROOH}] \quad . \qquad (13)$$

Reaction (13) is reversible and, since $k_{-1} \gg k_1$, the equilibrium is established faster than the decomposition of the intermediate active complex[17,46]. All amines and aminoalcohols have the capacity to form such complexes in aqueous solutions[17,42], but MEA in the presence of Cu^{2+} or Co^{2+} constitutes a purely model system, because in the joint presence of the above reactants the catalytic process is not accompanied by other simultaneous reactions.

The equilibrium constant is given by

$$K = \frac{k_1}{k_{-1}} = \frac{[E \cdots n\text{ROOH}]}{[\text{ROOH}]^n [E]} \quad . \qquad (14)$$

If $[E]_0$ is the initial overall concentration of the bound and free catalyst, then the following relation is valid:

$$[E] = [E]_0 = [E \cdots n\text{ROOH}] \quad . \qquad (15)$$

On substituting Eqn.(15) in Eqn.(14), we obtain

$$K = \frac{[E \cdots n\text{ROOH}]}{[\text{ROOH}]^n ([E]_0 - [E \cdots n\text{ROOH}])} \quad ,$$

whence the concentration of the intermediate complex is given by the expression

$$[E \cdots n\text{ROOH}] = \frac{K [\text{ROOH}]^n [E]_0}{1 + K [\text{ROOH}]^n} \quad . \qquad (16)$$

The final reaction products are obtained as a result of the decomposition of this complex[21,46]:

$$[E \cdots n\text{ROOH}] \xrightarrow{k_{\text{decomp}}} (MA)^{2+} + \text{final products.} \qquad (17)$$

If the overall rate of decomposition of the initial hydroperoxide or the rate of formation of the reaction products are determined by the rate of reaction (17), one can write

$$w = d[\text{ROOH}]/dt = k_{\text{decomp}} [E \cdots n\text{ROOH}] . \qquad (18)$$

From Eqns.(16) and (18), we obtain an expression for w:

$$w = \frac{k_{\text{decomp}} K [\text{ROOH}]^n [E]_0}{1 + K [\text{ROOH}]^n} \quad . \qquad (19)$$

The initial concentration of the complex catalyst $[E]_0$ cannot be greater than the concentration of the metal ions (Cu^{2+}, Co^{2+}, Mn^{2+}, etc.). Consequently $[E]_0$ in Eqn.(19) can be expressed in terms of the initial concentration of the metal ion bearing in mind that the stability constants of the complexes $(MA)^{2+}$ are much greater than unity[17,30,31]. An equation of the Michaelis–Menten type is then obtained in the following form:

$$w = \frac{k_{\text{decomp}} K [\text{ROOH}]^n [M^{2+}]_0}{(1 + K [\text{ROOH}]^n)} \quad . \qquad (20)$$

After rearranging Eqn.(20) and taking into account the fact that, according to kinetic data[42] the order of the reaction with respect to the hydroperoxide is $n = 1$, we obtain

$$\frac{1}{w} = \frac{1}{k_{\text{decomp}} [M^{2+}]_0} + \frac{1}{k_{\text{decomp}} K [\text{ROOH}] [M^{2+}]_0} \quad . \qquad (21)$$

Eqn.(21) was used for the graphical evaluation of K and k_{decomp} (Table 3) from plots of 1/w against 1/[ROOH] (Lineweaver and Burk[47]) for the intermediate active complexes in the reactions of CHP with the Cu^{2+} or Co^{2+} complexes of monethanolamine, diethanolamine, triethanolamine, TEA, morpholine, etc.[42]

It has been shown that there are correlations between k_{decomp} and K_{form}—the formation constant of the complexes $(MA)^{2+}$ between A and M^{2+}, and also between the stability constant K_{st} and $\lg k_{\text{decomp}}$. The results demonstrate the validity of the selected model of the process for the test systems. Thus the M^{2+} complexes of amines and aminoalcohols $(MA)^{2+}$ in aqueous solutions behave as simple analogues of enzymes of the catalase type in the CHP and TBHP decomposition reactions. One must point out that these complex catalysts (particularly the complexes of monoethanolamine and pyridine) are also not consumed in the reactions and, behaving as models of enzymes, induce the continuous decomposition of ROOH.[42]

Table 3. The constants K and k_{decomp} for intermediate complexes of the type [E...ROOH] in the reactions of CHP with $(MA)^{2+}$.

	A	K, litre mol^{-1}	k_{decomp}, min^{-1}
TEA	(60°)	5.4	3.7
Morpholine	(80°)	3.5	58.8
Morpholine*	(80°)	6.0	6.7
Monoethanolamine	(78°)	3.7	18.2
Diethanolamine	(80°)	4.7	62.5
Triethanolamine	(60°)	2.5	66.7
Triethanolamine*	(80°)	2.2	4.0

*M = Co; in the remaining cases M = Cu.

3. The Effect of Monoethanolamine and Its Bivalent Copper and Cobalt Complexes on the Living Organism

It is known that the oxidation of organic substances (proteins, fats, carbohydrates, alcohols, etc.) in the living organism is regulated by various enzymes. The final stable products (H_2O, CO_2, N_2, etc.) of such oxidation are obtained mainly as a result of the decomposition of the intermediate nitrogen-containing and hydroperoxy-compounds. Enzymes containing in many instances the ions of "metals of life" (Cu^{2+}, Co^{2+}, Mn^{2+}, etc.) control the mechanism and rate of decomposition of these hydroperoxides by virtue of the specificity of their action[32].

Numerous investigations have shown[6,56] that, apart from certain biometals (for example, Cu^{2+} and Co^{2+}), monoethanolamine plays a definite biochemical role in the living organism. It has been established that the introduction of the above substances in microamounts separately or jointly into the living organism (both healthy and diseased) enhances its biochemical activity. For example, the growth and development of birds, calves, and plants are accelerated and a number of human diseases are cured (sugar diabetes, diseases of the liver, kidneys, heart etc.). The experimental data obtained indicate an appreciable intensification of the metabolism of substances, particularly when monoethanolamine is introduced together with Cu^{2+}. Monoethanolamine is also an active stimulant enhancing the egg laying capacity in chickens, etc.[8]

The use of monoethanolamine in the treatment of the chronic renal failure in man has a positive influence on functional parameters of the operation of kidneys such as diuresis, the secretion of urine, etc. Monoethanolamine is non-toxic in small doses and, on being introduced into the organism, sharply enhances its protective responses. Monethanolamine is capable of inhibiting the development of

cardiac hypertrophy without influencing the contracting function of the heart at the same time. It has been shown that the aminoalcohol does not stimulate the absorption of O_2 when glutamate is used as the respiratory substrate[8].

One should note that hitherto there has been no explanation in the literature of the wide variety of the positive effects of monoethanolamine (colamine) and its Cu^{2+} and Co^{2+} complexes on living organisms.

It follows from a number of studies[40–45,52–54] that, in aqueous solutions at temperatures starting from 30–40 °C, CHP and TBHP decompose at a moderate rate in the presence of amines and aminoalcohols. However, in the presence of monoethanolamine or M^{2+} alone[21,42,44] at temperatures up to 90 °C hydroperoxides hardly decompose, while in the joint presence of the above substances with $M^{2+} = Cu^{2+}$, Co^{2+}, Mn^{2+}, etc. CHP and TBHP are decomposed catalytically mainly via a non-radical mechanism. As already mentioned, the M^{2+} complexes of monoethanolamine of the type $(MA)^{2+}$ are "non-consumable" catalysts in the decomposition of ROOH under conditions where hydroperoxides are continuously added to the reaction system, i.e. the effect of the complexes $(MA)^{2+}$ can be identified with enzyme catalysis (naturally in a model form).

On the basis of the data obtained, we shall attempt to explain the role of monoethanolamine and its Cu^{2+} and Co^{2+} complexes in the living organism. The accumulation of hydroperoxides (or peroxides) in the living organism is an undesirable phenomenon, since their decomposition via a radical mechanism results in the formation of extremely active free radicals, which can decompose cells and can induce chemical changes in enzymes, proteins, etc.[57] Hydroperoxides thereby initiate definite biochemical modifying processes, which lead to functional damage in the organism.

To prevent such action of hydroperoxides, one must stimulate their decomposition, preferably in a continuous manner and via a non-radical mechanism[57]. This role is apparently played by monoethanolamine and its Cu^{2+} and Co^{2+} complexes, which catalyse the non-radical decomposition of hydroperoxides. "Biometals", in particular Cu^{2+} and Co^{2+}, are present in microamounts in the living organism and, when monoethanolamine is introduced (providing the amount of colamine in the organism is small), the above scattered ions are "collected" by monoethanolamine in the form of complexes.

Thus it is extremely likely that monoethanolamine, jointly with certain variable-valence metal cations (including Cu^{2+} and Co^{2+}), regulates the required level of hydroperoxides in the organism.

IV. THE MECHANISM OF THE REACTIONS OF HYDROPEROXIDES WITH AMINES AND AMINOALCOHOLS IN THE PRESENCE AND ABSENCE OF M^{2+}

In order to elucidate the mechanism of the reactions of ROOH and A and of ROOH, A, and M^{2+} in aqueous media, the final stable reaction products were identified, in addition to studies of the intermolecular interactions between the components of the reacting systems (determination of the compositions of the intermediate complexes) and the study of the kinetics.

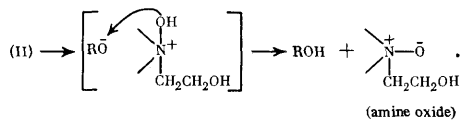
Amines and aminoalcohols exhibit interesting properties in reactions with hydroperoxides (in the absence and presence of M^{n+}): (a) they react with hydroperoxides in both aqueous[40–42] and organic solvents with a high dielectric constant, for example, in amides[40–42,48,49]; (b) they are effective complex-forming agents (ligands) for metal cations, for example, Cu^{2+}, Co^{2+}, Mn^{2+}, Ni^{2+}, etc. The complexes $(MA)^{2+}$ induce the decomposition of hydroperoxides in an aqueous phase via a mechanism which sometimes resembles homogeneous enzyme catalysis[20,21,42,44]; (c) the products of the reactions of amines with hydroperoxides are in many instances of practical interest[40–42]; (d) certain aminoalcohols and their chelate complexes with bivalent copper, cobalt, etc. ions are stabilisers and hardening agents respectively for polychloroprene and butadiene-acrylonitrile (with an epoxy-resin) adhesives [50,51].

The nature of the products of reactions of ROOH, A, and M^{2+} depends on the nature of the amines and hydroperoxides, on the presence of M^{2+}, and also on the solvent[21,40–42,52]. In aqueous media the oxidation of amines by hydroperoxides (in the absence of M^{2+}) leads to the formation of an aminoaldehyde in 89.3% yield (in the case of CHP) [12] and the amine oxide (in the case of TBHP).[52] It has been shown by infrared spectroscopy and elemental analysis that the corresponding alcohols are then obtained from the hydroperoxides—phenylisopropyl alcohol (yield 97.6%) and t-butyl alcohol[21,23,54].

The simultaneous catalytic decomposition of the CHP dimer by the aminoalcohol (diethanolamine, triethanolamine, etc. except monoethanolamine) in aqueous media results in the formation of phenylisopropyl alcohol and oxygen in 9.6% yield[40,54].

As mentioned above, in the presence of variable-valence metal cations (Cu^{2+}, Co^{2+}, Mn^{2+}, etc.) the reactions between ROOH and amines are accompanied also by the catalytic decomposition of ROOH by the amine complexes $(MA)^{2+}$.[21,42,44] The latter reaction predominates—its rate is several times greater than the rates of the other two reactions. Identification of the final stable products of the reaction of ROOH, A, and M^{2+} in water by infrared spectroscopy, ^1H NMR, chromatography, polarography, volumetric measurements, and elemental analysis showed that the final products are phenylisopropyl alcohol (for CHP) or t-butyl alcohol (for TBHP) and oxygen (the yield of all the products was 99.6%).[54] In the presence of diethanolamine, triethanolamine, and other aminoalcohols involving the simultaneous occurrence of the above reactions (direct interaction between CHP and A and the decomposition of the cumenyl hydroperoxides dimer catalysed by the aminoalcohol molecule)[40], an aminoaldehyde is obtained apart from the corresponding alcohol and oxygen. The aminoaldehyde was determined polarographically by elemental analysis and by other methods[54]. In the presence of monoethanolamine and pyridine only one reaction catalysed by the metal–amine complex takes place and for this reason the aminoaldehyde was not detected among the products of the reactions of these amines. However, the polarograms obtained for the reaction between ROOH and an aminoalcohol in the absence and presence of M^{2+} show that the aldehyde is formed only via the first, direct reaction between ROOH and the aminoalcohol. These data agree with the earlier kinetic results[40–42].

On the basis of the data presented, we put forward mechanisms for the reactions investigated which are presented below [the charges of the species shown in the various schemes (RO_2^-, RO_3^-, etc.) reflect the tendency towards a redistribution of electron density].

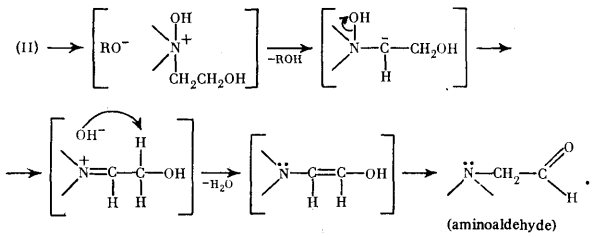


1. The First Reaction—Direct Interaction between ROOH and Aminoalcohols (except Monoethanolamine)

As an example, we shall consider the reaction of CHP with triethanolamine. As stated at the beginning of the review, the first step in the reactions of hydroperoxides with amines in water involves the formation of complex (II):

$$\mathrm{ROOH} + :\mathrm{N}- \rightleftarrows \text{(II)} \quad (22)$$

The mechanism of the decomposition of complex (II) to the products depends on the nature of R for given amine and solvent.

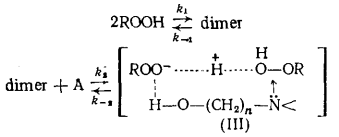


(a) R = $(CH_3)_3C$. The t-butyl group is electron repelling:

(23)

CH_3

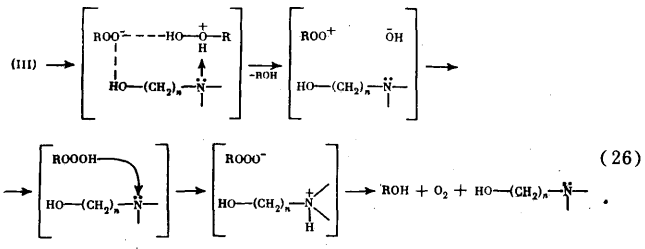
(b) R = $C_6H_5-C-CH_3$. By virtue of the presence of the phenyl substituent, the phenylisopropyl group has distinct electron repelling properties and the mechanism can be represented in this instance in the following manner:



(23a)

2. Second Reaction—Decomposition of the Hydroperoxide Dimer Catalysed by the Aminoalcohol (except Monoethanolamine)

The rate of this reaction is described by an equation of type (4):[40]



$$w_2 = k_{cat}[ROOH]^2, \qquad (24)$$

where $k_{cat} = k_2[A]$. The involvement of the cumenyl hydroperoxide dimer in the catalytic decomposition of CHP by the aminoalcohol has been established on the basis of this equation and kinetic data[12,40-42]:

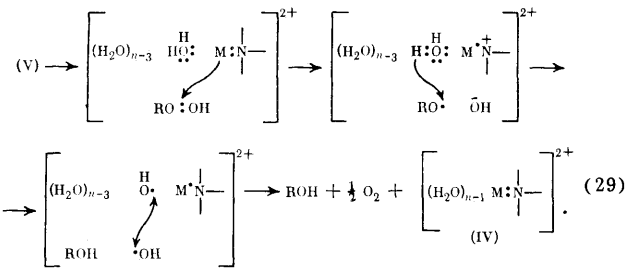
(25)

It has been established[55] that alkali catalyses the decomposition of CHP in aqueous solution, the rate of decomposition being a maximum for $[ROOH]/[ROO^-] = 1$. In the intermediate complex (III) this ratio in fact obtains; the ROO^- group is an electron donor, while the O–O bond is an electron acceptor. Taking this into account, the following transformations within the complex, leading to the formation of the final stable products, have been postulated:

(26)

3. Third Reaction—Decomposition of Hydroperoxides Catalysed by the M^{2+}–Amine Complex

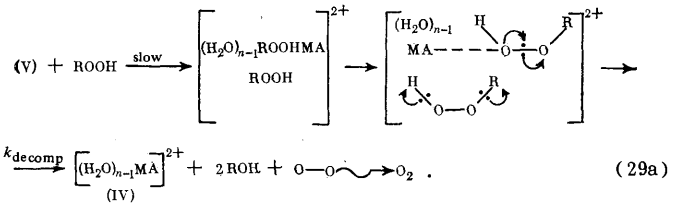
According to the present author[42], the cationic complex $(MA)^{2+}$ is catalytically active in the ROOH–A–M^{2+} reaction system. It is known[19] that amine complexes having the composition $[MA_n]^{2+}$, where $n = 4$ or 6, are thermodynamically active. In particular, when $M^{2+} = Cu^{2+}$, Co^{2+}, etc., $n = 4$ and the complex has the structure $[MA_4]^{2+}$.



The following equilibria obtain in aqueous solutions[19]:

$$[MA_n]^{2+} \xrightleftharpoons{H_2O} [H_2OMA_{n-1}]^{2+} \xrightleftharpoons{H_2O} \cdots \xrightleftharpoons{H_2O} \underset{(IV)}{[(H_2O)_{n-1}MA]^{2+}}. \qquad (27)$$

However, the aquo-complex (IV) is catalytically active[21]. The reaction of complex (IV) with CHP and TBHP can be represented as follows:



$$[(H_2O)_{n-1}MA]^{2+} + ROOH \xrightleftharpoons{fast} H_2O + \underset{(V)}{\left[(H_2O)_{n-3}H_2OMA\begin{matrix}\\ROOH\end{matrix}\right]^{2+}}. \qquad (28)$$

The transfer of one or two electrons from the aminoalcohol molecule to the hydroperoxide actually occurs in complex (V) via the catalyst cation:

(29)

The mechanism of the formation of the final products (the corresponding alcohols and oxygen) can be represented by another scheme[32] if it is assumed that the rate-limiting stage is the interaction of complex (V) with ROOH:

(29a)

Eqn.(9) shows that the order of the reaction with respect to M^{2+} is unity[44]. However, in many cases the order of the decomposition reaction of hydroperoxides catalysed by the complex $(MA)^{2+}$ is less than unity with respect to M^{2+}.[21] This can be explained by the equilibrium

$$(IV) + [MA]^{2+} \rightleftarrows \underset{(VI)}{[(H_2O)_{n-2}MA]^{2+}} + [(H_2OMA_{n-1}]^{2+}. \qquad (30)$$

According to a study by the present author[42], when $n \geq 2$, the complexes, including complex (VI), are inactive in the decomposition of hydroperoxides in an aqueous medium. Thus only complex (IV) is a catalytically active amine complex in the decomposition of ROOH in aqueous media.

---

† $[(H_2O)MA]^{2+}$? (Ed.of Translation).

The Splitting of the Silicon-Carbon Bond by Compounds of Platinum and Palladium

I.S.Akhrem, N.M.Chistovalova, and M.E.Vol'pin

Reactions involving the splitting of an Si-C bond under the influence of platinum and palladium complexes have been examined, and the mechanisms of these reactions discussed. It has been shown possible to use reactions involving the splitting of the Si-C bond in organic synthesis.
The bibliography contains 101 references.

I. INTRODUCTION

The extensive application of organosilicon compounds in various branches of industry has stimulated the search for new methods of synthesis. The considerable progress in this direction in the last 20–30 years has been related to the use of metal-complex catalysts, in particular compounds of platinum and its analogues, which are the most active catalysts for a wide range of reactions in the synthesis of organosilicon compounds. Among these reactions, a process of the greatest importance is hydrosilylation, which is a general method for the synthesis of organosilicon compounds of different classes. Heterogeneous systems containing platinum and palladium were first proposed as hydrosilylation catalysts in 1953.[1] The use of these catalysts made it possible to carry out the reaction between hydrosilanes and unsaturated compounds with functional groups; this had not been possible before, since the hydrosilylation methods used required high temperatures or the presence of radical initiators. Somewhat later, the use of hydrogen chloroplatinate as a highly effective hydrosilylation catalyst was proposed[2]. In 25 years, the range of catalysts has extended considerably, but even now, H_2PtCl_6 is most frequently used for the hydrosilylation of alkenes and alkynes. Alkene complexes of Pt^{II}, phosphine complexes of Pt^0 and Pd^0, complexes of platinum with silyl ligands and with polymeric ligands, and many others are also widely used[3]. Hydrosilylation can now be applied to practically all unsaturated compounds: simple alkenes and alkenes with functional groups, dienes, alkynes, and carbonyl compounds. Recently, this reaction has been used not only for the synthesis of organosilicon monomers and oligomers, but also for the conversion of linear and branched organosilicon polymers into polymers with a reticular structure. It is also acquiring importance for the synthesis of polycarbo-organosiloxanes[3]. In a number of cases, hydrosilylation is used industrially[4].

As well as the addition of hydrosilanes to unsaturated compounds, reactions involving the replacement of hydrogen on a silicon atom by other groups in the presence of platinum metal complexes are also of preparative importance. These reactions are used to obtain silanols, alkoxy- and aryloxysilanes, silyl ethers, siloxamines, silicon halides, etc.[5–11]

The reactions of hydrosilanes (and also metal-silyl derivatives of silicon) with platinum and palladium complexes form the basis of methods for synthesising complexes of these metals with silyl ligands[12–18]. The interest in platinum metal complexes containing group IVb elements is largely due to the promise of their practical application as catalysts.

Like silicon hydrides, compounds with a silicon–halogen bond can undergo oxidative addition to coordinatively unsaturated transition metal complexes, again giving silyl derivatives of the transition metals[17]. An interesting feature is that the splitting of a carbon–halogen bond under the influence of Pt^0 compounds can also take place in the coordination sphere of the metal, converting silyl complexes into silylene compounds[19].

In recent years, in addition to reactions accompanied by the splitting of Si–H bonds, reactions involving the splitting of Si–Si bonds have been used successfully in organosilicon synthesis. The disproportionation of disilanes to polysilanes in the presence of *trans*-$(Et_3P)_2PtCl_2$ was first detected in 1970.[20] A development of this work was the extensive use of the splitting of Si–Si bonds in disilanes, catalysed by triphenylphosphine complexes of platinum and palladium, "double silylation", to introduce two organosilicon groups into alkenes, 1,3-dienes, alkynes[21–25], and allenes[24].

The ability of Pd^0 complexes to catalyse the disproportionation of disilanes[26] has also been used to convert relatively easily accessible disilanes into monosilanes with functional groups by a reaction involving the combination of disilanes with halogen derivatives[27–29].

The transformations of organosilicon compounds under the influence of platinum and palladium complexes, examined above, include the splitting of both polar bonds Si–M and Si–Cl and non-polar bonds Si–H and Si–Si, and are used chiefly for the synthesis of organosilicon compounds. The last known review in this field is that of Curtis and Epstein[30].

In the last ten years, the activation and splitting of the even more inert Si–C bonds have been increasingly studied. Studies in this direction are opening up new possibilities for the use of organosilicon compounds in organic synthesis and as components of catalytic systems.

The urgency of this task is determined by the following features. Organic derivatives of silicon, unlike organometallic compounds, are stable to oxygen and moisture, do not ignite in air, and are generally non-toxic. On the other hand, organosilicon compounds are fairly readily accessible, and many of them are produced on the industrial scale. Thus the use of organosilicon compounds of the organometallic derivative type in organic synthesis or as components of catalytic systems is a promising field.

II. THE SPLITTING OF SILICON–CARBON BONDS IN ORGANOSILICON COMPOUNDS CONTAINING AN ACTIVATED Si–C BOND

1. The Removal of Unsaturated Groups from a Silicon Atom

The bonds formed by silicon with α,β-unsaturated compounds are more reactive than a silicon–alkyl bond. This is due to the increase in the polarity of the silicon–carbon bond when an alkyl group is replaced by an unsaturated group[31], and also to the instability of the products of the addition of electrophilic reagents to multiple bonds as a consequence of β-decomposition[32]. These bonds can be split by protonic and aprotic acids, halogens, and nucleophiles[32–35]. An important feature, however, is that vinyl-, allyl-, and alkynylsilanes readily undergo reactions which are not accompanied by the rupture of silicon–carbon bonds: hydrogenation, the addition of halogens and hydrogen halides, etc. The vinyl group is not removed from the silicon atom when unsaturated silanes are polymerised in the presence of peroxides, protonic and aprotic acids, and also Ziegler–Natta systems[31].

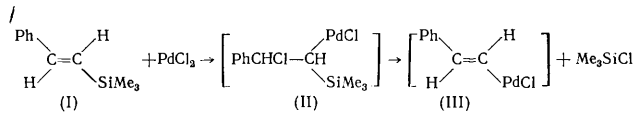
Studies of the transformations of unsaturated silanes, catalysed by Pt and Pd complexes, were begun more than ten years ago[36]. It has now been shown that a wide range of platinum and palladium complexes bring about the removal of unsaturated groups from the silicon atom. π-Complex formation is the first stage in these reactions, and in a number of cases the corresponding π-complexes of the unsaturated silanes have been isolated as stable products. Allyl-[37–38], vinyl-,[38,39] and ethynylsilanes[36,40] are split by platinum and palladium complexes at the bonds between silicon and the unsaturated groups. For example, allylsilanes react very rapidly with palladium chloride and acetate in proton-containing solvents, forming a π-allyl complex of palladium and organic splitting products[37]†:

$$Me_3SiCH_2CH{=}CH_2 + Li_2PdCl_4 \xrightarrow{MeOH,H_2O} \rightarrow (\pi\text{-}C_3H_5PdCl)_2 + Me_3SiOMe + (Me_3Si)_2O + C_3H_6 + HCl$$
$$32\%\ (81\%) \qquad 75\%\ (188\%) \qquad 25\%\ (63\%) \qquad 56\%\ (140\%)$$

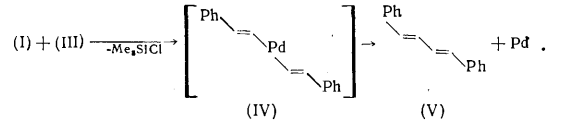
The mechanism proposed by the authors includes the initial exchange of groups between the Si and Pd atoms with the formation of a chlorosilane and a σ-allyl and then a π-allyl complex of palladium:

$$R_3SiCH_2CH{=}CH_2 + PdCl_2 \rightarrow R_3SiCl + [CH_2{=}CHCH_2PdCl]$$
$$[CH_2{=}CHCH_2PdCl] \rightarrow (\pi\text{-}C_3H_5PdCl)_2 \rightarrow \text{products}$$
$$R_3SiCl + R'OH \rightarrow R_3SiOR' + HCl$$
$$R_3SiCH_2CH{=}CH_2 + HCl \rightarrow R_3SiCl + CH_3CH{=}CH_2 .$$

The overall reaction is not catalytic with respect to the palladium salt[37], but formally, the catalytic yield of splitting products, calculated relative to Li_2PdCl_4, is due to the splitting, taking place in parallel, of the allylsilanes under the influence of HCl, formed by the alcoholysis or hydrolysis of the chlorosilane.

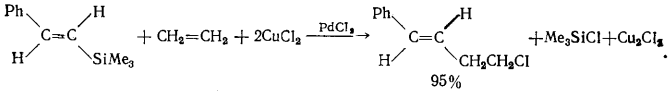


The benzonitrile complex of palladium $(PhCN)_2PdCl_2$ reacts with trimethylallylsilane, forming bis(η³-allyl)-μ-dichlorodipalladium and trimethylchlorosilane[38]:



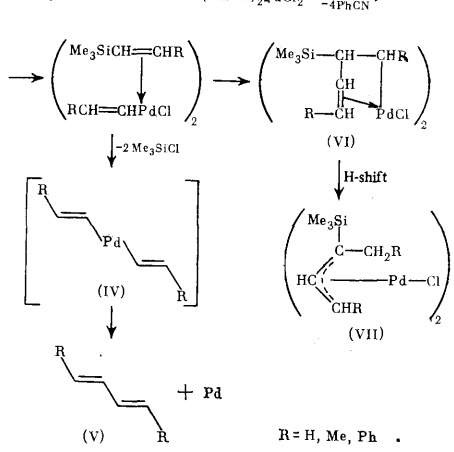
$$2\,Me_3SiCH_2CH{=}CH_2 + 2(PhCN)_2PdCl_2 \xrightarrow[-4\,PhCN]{} \left(HC(CH_2)(CH_2)\text{—}Pd\text{—}Cl\right)_2 + 2\,Me_3SiCl .$$

The reaction is quantitative in 3 d at 20°.



† The yields are given relative to the original silane, and in brackets relative to Li_2PdCl_4.

Interesting transformations take place with vinylsilanes under the influence of palladium chloride. In the presence of palladium chloride at room temperature, oxidative combination of β-trimethylsilylstyrene (I) takes place with the formation of *trans*, *trans*-1,4-diphenyl-1,3-butadiene (V).[39] In the presence of copper(II) chloride, the reaction is catalytic. The authors postulate the intermediate formation of organic derivatives of palladium (II)–(IV):



In the presence of an alkene and an excess of copper(II) chloride, chloroethylation products are formed, by analogy with Heck's chloroethylation reactions[41]:

The reaction of vinylsilanes with the benzonitrile complex of palladium in benzene shows an interesting feature: in addition to the products of oxidative combination, it gives a new π-allyl complex of palladium (VII) in 26% yield[38]:

According to the scheme proposed by the authors, the reaction giving divinylpalladium (IV) competes with the insertion of the alkene at the Pd–C bond, which gives an unstable compound (VI). The final π-allyl complex of palladium (VII) is formed as a result of the stabilisation of compound (VI) by a hydrogen shift.

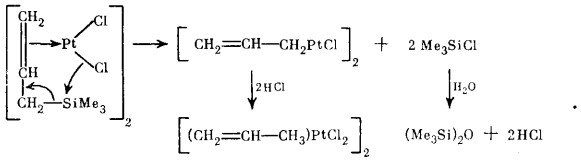
Zeise's salt $K[PtCl_3(C_2H_4)]$ catalyses the removal of vinyl and allyl groups from a silicon atom in boiling absolute ethanol[36]. For the reaction of trimethylvinylsilane with Zeise's salt[42] it was proved that π-bonding is the first stage in the splitting of unsaturated silanes. In acetone, a π-complex containing trimethylvinylsilane has been isolated quantitatively and characterised:

$$Me_3SiCH{=}CH_2 + K[PtCl_3(C_2H_4)] \rightarrow K[PtCl_3(Me_3SiCH{=}CH_2)] + C_2H_4 .$$

In moist acetone this compound undergoes splitting of the Si-vinyl bond to give Zeise's salt and hexamethyldisiloxane:

$$K[PtCl_3(Me_3SiCH{=}CH_2)] + \frac{1}{2}H_2O \rightarrow K[PtCl_3(C_2H_4)] + \frac{1}{2}(Me_3Si)_2O .$$

The formation of π-complexes of vinyl- and ethynylsilanes have also been observed when unsaturated silanes are treated with other Pt^0 and Pt^{II} compounds such as $Pt(C_2H_4)_2(PR_3)$,[43] $(Ph_3P)_2Pt(C_2H_4)$,[40,44] and $PtCl_2(C_2H_4)Py$.[45] A comparison of vinylsilane complexes of Pt^0 and Pt^{II} [44] showed that the Pt^0 complexes are more stable to splitting.



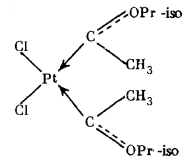
In 1976, French chemists[45] made a detailed study of the reactions of unsaturated silanes with the general formula $Me_3Si(CH_2)_nCH=CH_2$ ($n = 0, 1, 2$) with the dimeric platinum complex $Pt_2Cl_4(C_2H_4)_2$. As in most of the reactions described above, the first stage in this case is ligand exchange to give a new Pt^{II} complex containing an unsaturated silane as ligand. The activated silicon–carbon bond is then split. Thus in the reaction of $Me_3SiCH_2CH=CH_2$ with $Pt_2Cl_4(C_2H_4)_2$ in the presence of water at 20° (molar ratio silane : platinum complex : water = 2 : 1 : 1), the silane is converted quantitatively into hexamethyldisiloxane and propene:

$$2Me_3SiCH_2CH{=}CH_2 + H_2O \xrightarrow{[Pt]} 2CH_3CH{=}CH_2 + Me_3SiOSiMe_3 .$$

The reaction of allylsilane with $Pt_2Cl_4(C_2H_4)_2$ takes place catalytically at 20° in 10 d (molar ratio silane : complex : water = 20 : 1 : 10). For all the silanes studied, in the stoichiometric reaction with the dimeric platinum complex, a rapid equilibrium is first established, with the formation of the π-complex. At $n = 2$, the crystalline complex of the silane with $PtCl_2$ was isolated:

$$2\,Me_3Si(CH_2)_nCH{=}CH_2 + Pt_2Cl_4(C_2H_4)_2 \rightleftarrows \left[\begin{array}{l} CH_2 \\ \| \\ CH \\ | \\ (CH_2)_nSiMe_3 \end{array}\!\!\rightarrow PtCl_2\right]_2 + 2C_2H_4 .$$

The splitting of the vinyl- and allylsilanes by the dimeric platinum complex is attributed[45] to the decomposition of an intermediate π-complex in which the platinum atom creates a positive charge in the β-position relative to silicon.

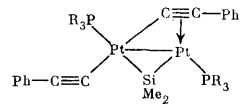


This explains the observed stability of the complex with butenylsilane $Me_3Si(CH_2)_2CH=CH_2$, in which a positive centre is created in the γ- and δ-positions relative to the silicon atom. In the proposed scheme, Pt^{II} acts as a π-acid. An interesting feature is that in the splitting of silanes, Pt^{II} has been found to be a stronger acid than protonic acids such as CF_3COOH and HCl. The phosphine complex $Pt_2Cl_4(Ph_3P)_2$ is also active in reactions with $Me_3Si(CH_2)_nCH=CH_2$. Its reaction with allylsilane in aqueous $CDCl_3$ at 20° leads to slow splitting of the silane to give hexamethyldisiloxane (90% after 60 h).[45] Pt^{II} complexes can also split Si–C_{sp} bonds[36]. Thus the reaction of $Pt_2Cl_4(C_2H_4)_2$ with $PhC{\equiv}CSiMe_3$ in dry benzene at 20° in an atmosphere of nitrogen gives a deeply coloured complex containing platinum; its infrared spectrum shows a band corresponding to the frequency of the ethyne group $\nu = 2070$–$2110\ cm^{-1}$:

$$2PhC{\equiv}CSiMe_3 + Pt_2Cl_4(C_2H_4)_2 \xrightarrow{60°} 2Me_3SiCl + 2C_2H_4 + 2PhC{\equiv}CPtCl .$$

In boiling alcohol, the ethynyl group is removed from the silicon atom under the influence of catalytic quantities of the complexes $Pt_2Cl_4(C_2H_4)_2$ or $K[PtCl_3(C_2H_4)]$. Under these conditions, allylsilanes are split even more easily[36].

The reactions of ethynylsilanes with platinum complexes are sometimes unusual, and do not reduce to a simple scheme including π-complex formation with the subsequent elimination of unsaturated compounds. An example[46,47] is the interesting transformation of trimethylethynylsilane under the influence of H_2PtCl_6 in isopropyl alcohol at 20° into an alkoxycarbene complex of Pt^{II}, whose structure was established by X-ray diffraction:



The reaction is accompanied by rupture of the Si–C bond. The resulting complex is a good catalyst for the hydrosilylation of alkynyl compounds.

The reaction of $Me_2Si(C{\equiv}CPh)_2$ with the platinum(0) complex $[Pt(C_2H_4)_2(PR_3)]$ is also extremely unusual[40]. In this case, both phenylethynyl groups are removed from the silicon atom to give a diplatinum complex containing all the fragments of the organosilicon molecule:

$$Me_2Si(C{\equiv}CPh)_2 + 2Pt(C_2H_4)_2(PR_3) \rightarrow [Pt_2(Me_2Si)(C{\equiv}CPh)_2(PR_3)_2] + 4C_2H_4 .$$
$$R = C_6H_{11}$$

X-Ray diffraction showed that the platinum atoms in this complex are not equivalent; one of them (formally Pt^{IV}) is joined by σ-bonds to the dimethylsilyl and two phenylethynyl groups, and the other platinum atom (formally Pt^{II}) is joined by a σ-bond to the dimethylsilyl groups and by a π-bond to one of the phenylethynyl groups:

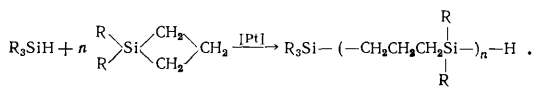
This reaction is of interest as the first rigorously proved example of the oxidative addition of an Si–C bond to a transition metal atom.

2. The Rupture of Silicon–Carbon Bonds in Strained Cyclic Silanes and Disilanes

Platinum and its derivatives Pt/C, H_2PtCl_6, and $(C_2H_4)_2$. Pt_2Cl_4 catalyse the splitting on of an Si–C bond in strained organosilicon heterocyclic compounds such as sila- and 1,3-disilacyclobutanes to give telomerisation and polymerisation products[48–50]. Thus silacyclobutanes are converted into polymers by heating with catalytic quantities of Pt/C or H_2PtCl_6 at 50–100° [49]:

$$nR^1R^2Si\begin{array}{l}CH_2\\CH_2\end{array}CHR^3 \xrightarrow{[Pt]} -(-R^1R^2SiCH_2CHR^3CH_2-)_n- .$$

The dimeric ethlene complex $(C_2H_4PtCl_2)_2$ is effective in this reaction even at room temperature[50]. Disilacyclobutanes in the presence of platinum catalysts are polymerised at 100 to 150°:

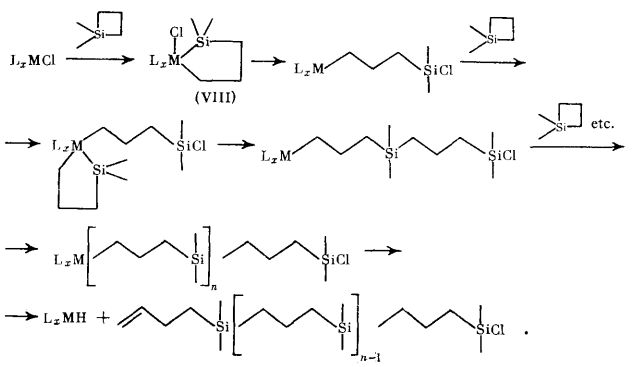


$$nMe_2Si\begin{array}{l}CH_2\\CH_2\end{array}SiMe_2 \xrightarrow[150°]{[Pt]} -(-Me_2SiCH_2-)_n- .$$

In the absence of catalysts, polymerisation does not take place at this temperature.

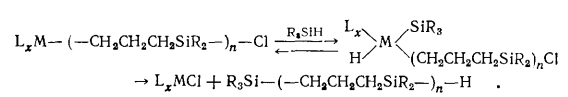
With 1,1-dimethyl-1-silacyclopentane, polymerisation on platinum does not take place up to 200°, and the silacyclohexanes $CH_2-(CH_2)_4-SiH_2$ and $CH_2(CH_2)_4-SiMeH$ are not split under the influence of platinum and palladium catalysts at

500°.[51] Thus the driving force of the splitting of Si–C bonds in sila- and disilacyclobutanes is the strain in the four-membered ring.



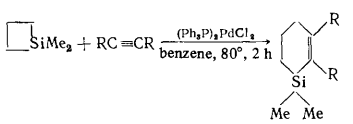
In the presence of platinum catalysts, silacyclobutanes and disilacyclobutanes react with hydrosilanes at 50–100° to give telomers:

$n = 1, 2$



This reaction can be regarded as an example of alkyl-hydrogen ligand exchange at a silicon atom under comparatively mild conditions. Without the catalyst, it takes place at a higher temperature.

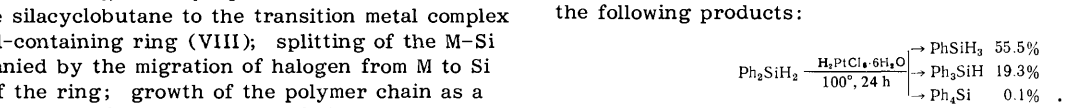
The role of the transition metal in the homogeneous catalytic polymerisation of strained organosilicon heterocyclic compounds has been studied[50]. A mechanism including the following successive stages was proposed: the oxidative addition of the silacyclobutane to the transition metal complex to give a metal-containing ring (VIII); splitting of the M–Si bond, accompanied by the migration of halogen from M to Si and opening of the ring; growth of the polymer chain as a result of the insertion of a new molecule of silacyclobutane at the M–C bond; and chain termination by the ejection of a hydrogen atom from the β-position relative to the metal:



(VIII)

The formation of telomeric products can be explained similarly.

Interesting reactions involving the cyclo-addition of silacyclobutanes to alkynes in the presence of palladium catalysts have also been described[52].

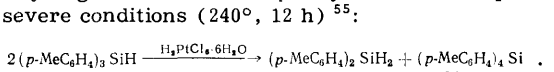


R=COOMe .

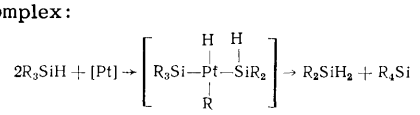
Pd^{II} and Pd^{0} complexes are effective in these reactions: $PdCl_2(PhCN)_2$, L_4Pd, L_2Pd(alkene), and metallic Pd. The authors suggest that the driving force of these reactions is again the strain in the silacyclobutane ring, since silacyclopentanes and other non-strained silacyclanes do not react with alkynes.

3. Rupture of Silicon–Carbon Bonds in Hydrosilanes

Hydrosilanes can disproportionate when heated or under the influence of Lewis acids. The ease of the disproportionation of hydrosilanes compared with tetra-alkyl(aryl)-silanes is due to the ease of formation of five- and six-co-ordinate complexes of silicon in the case of the hydrosilanes, since for these the geometric and electronic factors are more favourable than for tetraorganosilanes. In five- and six-co-ordinate complexes of silicon, the rupture of Si–H and Si–C bonds is facilitated. The tendency for these complexes to be formed increases with increase in the number of hydride hydrogen atoms in the molecule and with increase in the acceptor power of the groups joined to silicon.



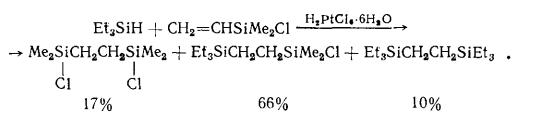
The disproportionation of diphenylsilane in the absence of catalysts is observed at 160°. Lewis acids ($AlCl_3$, $ZnCl_2$) catalyse these transformations under milder conditions[53]. Platinum derivatives also catalyse the disproportionation of hydrosilanes[53]. Thus in the presence of catalytic quantities of H_2PtCl_6 at 100°, diphenylsilane disproportionates to give the following products:



PtO_2 and metallic platinum are also effective in this reaction.

$PhSiH_2Cl$ begins to disproportionate under the influence of H_2PtCl_6 even at room temperature, $PhSiHCl_2$ at 50°, and Ph_2.SiHCl at 200°.[54] K_2PtCl_4 and K_2PtCl_6 also show catalytic activity in these reactions.

The disproportionation of tri-*p*-tolylsilane in the presence of H_2PtCl_6 to give di- and tetra-*p*-tolylsilanes takes place under severe conditions (240°, 12 h)[55]:



Disproportionation is not observed under these conditions in the absence of H_2PtCl_6. In the authors' opinion, the reaction mechanism includes the rupture of the Si–H and Si–tolyl bonds with retention of these fragments in the sphere of the platinum complex:

The authors cited[54,55] consider that the hydrosilane not only reduces Pt^{IV} to Pt^{II} but also takes part in the formation of the active complex. The formation of the various products is thermodynamically determined.

Several reactions have been described, in which the hydrosilylation of unsaturated compounds, in addition to the main processes, involves parallel processes with splitting of an Si–C bond. Thus the reaction of Et_3SiH with $CH_2=CHSiMe_2$.Cl in the presence of H_2PtCl_6 [55] gives a mixture of products:

The formation of side products can be explained if it is assumed that vinyl-hydrogen exchange takes place at the silicon atom:

In the reaction of $(Me_3SiO)_2SiMeH$ with hex-2-ene in the presence of $H_2PtCl_6.6H_2O$ at 140°, in addition to the "normal" hydrosilylation product $(Me_3SiO)_2SiMeC_6H_{13}$, the side products $(Me_3SiO)_3SiH$, $Me_3SiOSiMe_2C_6H_{13}$, and $Me_3SiOSiMe_2H$ were detected[56]. To explain the formation of the latter, it must be assumed that intermolecular exchange of Me_3SiO and Me groups takes place at the silicon atom:

$$2(Me_3SiO)_2SiMeH \xrightarrow[140°]{[Pt]} Me_3SiOSiMe_2H + (Me_3SiO)_3SiH$$
$$\downarrow \text{hex-2-ene}$$
$$Me_3SiOSiMe_2C_6H_{13}$$

In the extensive literature devoted to hydrosilylation reactions, however, very little mention is made of the anomalous products obtained by the splitting of Si–C bonds.

III. THE SPLITTING OF SILICON–ALKYL AND SILICON–ARYL BONDS BY Pt AND Pd COMPOUNDS

A silicon–carbon bond not containing activating groups is fairly inert in homolytic and heterolytic reactions. The reactivity of the silicon–alkyl bond resembles most closely that of the carbon–carbon bond in alkanes. In homolytic reactions in tetra-alkylsilanes, as a rule, the carbon–hydrogen bond, and not the silicon–alkyl bond, is broken preferentially[33,51,57]. Tetra-alkylsilanes also have a high thermal stability. Tetramethylsilane decomposes at 700°, and methyldibutylsilane only at 1000°.[57] Substituted alkylsilanes, in particular β-halogenoalkylsilanes, are much less stable to heat[51].

The silicon–carbon bond is more sensitive to electrophilic and nucleophilic reagents than the carbon–carbon bond. This is due to the slight polarity of the Si–C bond and the ability of the silicon atom to increase its co-ordination number, facilitating attack by a base at this atom. Nevertheless, in these reactions also, the silicon–alkyl bond is chemically fairly inert. Thus under ordinary conditions, tetra-alkylsilanes are not affected by alkali metals, organometallic compounds, metal hydrides, and alkalis and acids of medium strength[35,51].

The chemical inertness of the Si–Alk and Si–Ar bonds is greater than that of the vinyl, allyl, ethynyl, and other activated Si–C bonds examined in section II. The problem of the metal-complex activation of Si–Alk and Si–Ar bonds therefore appears most difficult.

1. Transformations of Silanes Under the Influence of Pt^{IV} and Pd^{II} Complexes

The splitting of an Si–Alk bond was first detected[58] by the action of Pt and Pd derivatives on hexamethyldisiloxane. When hexamethyldisiloxane is heated in the presence of 0.01 to 1% of a catalyst, octamethyltrisiloxane is formed:

$$Me_3SiOSiMe_3 \xrightarrow{\text{catalyst}} Me_3SiOSiMe_2OSiMe_3 .$$

Methane is detected in the gas phase.

Under the same conditions in the absence of a catalyst, octamethyltrisiloxane and methane are not formed from the disiloxane. The reaction takes place both in solvents (alcohol, benzene) and without a solvent, and takes place to a slight extent even at 100°. The yield of octamethyltrisiloxane after 10 h at 200° is 10–20%, calculated relative to the original hexamethyldisiloxane. Catalytic activity in this reaction is shown by a fairly wide range of platinum and palladium compounds: $H_2PtCl_6.6H_2O$, $(Ph_3P)_4Pt$, $(Ph_3P)_3Pt$, $PdCl_2$, Pt/C, etc.

Subsequently, the possibility of splitting the Si–C bond under the influence of platinum and palladium complexes in organosilicon compounds not containing functional groups—tetra-alkyl- and trimethylarylsilanes—was studied[59–67]. The transformations of the following silanes were examined: Me_4Si, Me_3SiEt, Me_3SiPr, Me_3SiBu, $Me_3SiC_6H_4X$ (X = H, *p*-Me, *p*-MeO, *p*-Cl, *m*-Me, *m*-MeO, *m*-Cl). Chloro-complexes of platinum and palladium in different oxidation states $PtCl_4$, $H_2PtCl_6.6H_2O$, Na_2PtCl_6, $PtCl_2$, K_2PtCl_4, $(Ph_3P)_2PtCl_2$, $(Py)_2PtCl_2$, $(Ph_3P)_2Pt_2Cl_4$, *trans*-$[Pt(CO)Cl(Ph_3P)_2][ClO_4]$, $Pt_2Cl_4(C_2H_4)_2$, $PdCl_2$, $LiPdCl_3$, Li_2PdCl_4, and $(PhCN)_2PdCl_2$, metallic Pt and Pd, and triphenylphosphine complexes of Pt^0 and Pd^0, $(Ph_3P)_4Pt$ and $(Ph_3P)_4Pd$, were studied. It was found[59–63] that the silicon–carbon bond can be split unexpectedly easily by platinum(IV) and palladium(II) chlorides: $PtCl_4$, H_2PtCl_6, $PdCl_2$, $LiPdCl_3$, Li_2PdCl_4, and $(PhCN)_2PdCl_2$. Compounds of these metals in lower oxidation states ($PtCl_2$, K_2PtCl_4, $(Ph_3P)_2PtCl_2$, $(Ph_3P)_4Pt$, $(Ph_3P)_4Pd$, Pt/C, Pt black) have a low activity or are completely inactive.

Under the influence of $PtCl_4$ or $PdCl_2$ in organic solvents containing a small quantity of water, tetraorganosilanes are split to give the hydrocarbon and the hexa-alkyldisiloxane as main products:

$$2Me_3SiR + H_2O \xrightarrow[60–120°]{MX_n} 2RH + Me_3SiOSiMe_3$$
$$MX_n = PtCl_4, H_2PtCl_6, PdCl_2, LiPdCl_3, Li_2PdCl_4, (PhCN)_2PdCl_2 .$$

Organic chlorides and products of radical decomposition are formed in parallel to a slight extent in a number of cases.

The disiloxane formed is also demethylated under the influence of these complexes. For example, in the reaction of Me_4Si with $PtCl_4.3H_2O$ in benzene at 80°, octamethyltrisiloxane is formed in addition to methane and hexamethyldisiloxane.

Special experiments showed that HCl does not catalyse these reactions, that is in this case metal-complex activation, and not acid activation, of the Si–C bonds take place. The reactions take place under mild conditions, and the degree of conversion reaches 90%.

The role of the solvent is different in the reactions of silanes with Pd^{II} and Pt^{IV} chlorides. With the palladium complexes, silanes react readily in the most varied solvents (alcohols, THF, DMF, MeCN, benzene). In the reactions of silanes with $PtCl_4$, on the other hand, the nature of the solvent is more significant. Thus in the reaction of Me_3SiBu with $PtCl_4.3H_2O$, the degree of conversion of the silane is 80% in $CHCl_3$, 50% in benzene, and 14% in DMF, and the reaction does not take place in EtOH and Et_2O.[62] The passivating influence of donor solvents was attributed to their ability to form stable coordinatively saturated solvates with the metal salt.

An interesting feature is that the splitting of silanes is highly selective: in trimethylarylsilanes the aryl group is removed exclusively, and in mixed trimethylalkylsilanes practically only the methyl group is removed. The authors discuss the possible mechanism of this reaction, and suggest that the splitting of the Si–C bond by platinum and palladium chlorides takes place as an exchange reaction, giving the trialkylchlorosilane and an unstable organic derivative of the transition metal[62]:

$$Me_3SiR + MCl_n \rightarrow Me_3SiCl + [RMCl_{n-1}]$$
$$Me_3SiCl + \frac{1}{2}H_2O \rightarrow \frac{1}{2}Me_3SiOSiMe_3 + HCl .$$

The intermediate organic derivative of the transition metal can decompose further by two routes: it can undergo protolysis with the formation of the hydrocarbon and the regeneration of the metal chloride, or it can give organic chlorides

and the products of radical decomposition#:

$$[RMCl_{n-1}] + HCl \rightarrow RH + MCl_n$$
$$[RMCl_{n-1}] \rightarrow \begin{cases} \rightarrow RCl + MCl_{n-2} \\ \rightarrow R^{\cdot} + MCl_{n-1} \end{cases}$$

The reactions of Me_4Si with $PtCl_4$ in benzene or of Me_3SiPh with Li_2PdCl_4 in DMF in the presence of alcohols labelled with deuterium (ROD) give the hydrocarbons MeD and PhD respectively, containing a high percentage of deuterium (up to 80% of the theoretical yield). Thus in the presence of a source of protons, the principal direction of the decomposition of the intermediate organometallic compound is its protolysis, leading to the regeneration of the original transition metal complex. This route opens up the possibility of carrying out a catalytic reaction. In fact, in the presence of small quantities of added alcohol or water, the reactions of silanes with Pt and Pd chlorides take place catalytically[62]. A high activity is shown by H_2PtCl_6 in acetonitrile (Table 1) and by palladium(II) chloride in DMF (Table 2).

Table 1. Catalytic reactions of tetraorganosilanes with platinum compounds[62].

Silane	Catalyst	t, °C	τ, h	α	Solvent	A
Me_4Si	$H_2PtCl_6 \cdot 6H_2O$	150	10	100	MeCN *	14
Me_3SiEt	$PtCl_4 \cdot 3H_2O$	80	20	20	$PhNO_2$ *	12
Me_3SiPr	$PtCl_4 \cdot 3H_2O$	80	20	20	C_6H_6	4,4
Me_3SiBu	$PtCl_4 \cdot 3H_2O$	80	20	20	C_6H_6	6
Me_3SiBu	$PtCl_4 \cdot 3H_2O$	80	20	20	C_6H_6	17
Me_3SiBu	$H_2PtCl_6 \cdot 6H_2O$	120	20	1000	MeCN	20
Me_3SiPh	$H_2PtCl_6 \cdot 6H_2O$	150	20	1000	MeCN	130
Me_3SiPh	Pt/C	100	50	30	EtOH	32

Symbols. Here and in later Tables: τ is the reaction time, α the molar ratio Me_3SiR : catalyst, and A the degree of conversion of the silane, moles per mole of catalyst.

* [EtOH] = 0.5 M.

Although the presence of small quantities of water or alcohol is a necessary condition for catalysis, large quantities of these reagents inhibit the reactions.

The reactions of silanes with Pd^{II} can be converted into catalytic reactions by another method, by oxidising the precipitated metal by external oxidising agents ($CuCl_2$, p-benzoquinone), but the stability of the system is low: the degree of conversion of the silane does not exceed 7 moles per mole of Li_2PdCl_4 (see Table 2).

The behaviour of platinum and palladium compounds towards the silicon–carbon bond differs significantly from that of other transition metals, in particular the metals of the 3*d* series in their principal oxidation states[58–63]. The latter activate chiefly the splitting of arylsilanes, whereas Pt and Pd compounds split both Si–Ar and Si–Alk bonds[61].

For the reactions of silanes with $PtCl_4$, it is apparently necessary to take account of the possibility of the equilibrium $RPtCl_3 + PtCl_2 \rightleftharpoons RPtCl + PtCl_4$, although at a high temperature it is displaced to the left[68].

The kinetics and mechanism of the splitting of the silicon–aryl bond in Me_3SiAr, catalysed by Li_2PdCl_4 in DMF in the presence of 0.7% H_2O, have been studied[63]. At 80–100°, the reactions take place exclusively with the splitting of the Si–Ar bond to give hexamethyldisiloxane and the corresponding aromatic hydrocarbon:

$$2Me_3SiC_6H_4X + H_2O \xrightarrow{Li_2PdCl_4} Me_3SiOSiMe_3 + 2C_6H_5X$$
X = H, *p*-Me, *p*-Cl, *p*-MeO, *m*-Me, *m*-Cl, *m*-MeO .

The rates of the reactions of trimethylarylsilanes (except Ar = *p*-$MeOC_6H_4$) with Li_2PdCl_4 are described by an equation of first order with respect to the silane; the order of the reaction with respect to Li_2PdCl_4 in all cases was 0.5:

$$w = k\,[Me_3SiAr]\,[Li_2PdCl_4]^{0.5} .$$

The catalyst for the reaction is not the original complex, but the complex of $LiPdCl_3$ with DMF, formed by solvolysis[69]:

$$PdCl_4^{2-} + L \rightleftarrows PdCl_3(L)^- + Cl^-$$
L = DMF .

A characteristic feature of this reaction is that its rate is not sensitive to the nature of the substituent in the aromatic ring.

Table 2. Catalytic reactions of silanes with Pd^{II} compounds at 100°.[62]

Silane	Catalytic system	τ, h	α	Solvent	A
Me_4Si	Li_2PdCl_4	50	200:1	DMF*	150
Me_3SiPh	Li_2PdCl_4	50	1000:1	DMF	200
Me_3SiBu	Li_2PdCl_4	10	10:1	EtOH	2
Me_3SiBu	Pd(II)—$FeCl_3$—LiCl	10	10:1:10:10	EtOH	2
Me_3SiBu	Pd(II)—$C_6H_4O_2$—LiCl	10	10:1:10:10	EtOH	3.5
Me_3SiBu	Pd(II)—$CuCl_2$—LiCl	40	10:1:10:10	THF	1.3
Me_3SiBu	Pd(II)—$CuCl_2$—LiCl	10	10:1:10:10	EtOH	4.4
Me_3SiBu	Pd(II)—$CuCl_2$—LiCl	20	10:1:10:10	EtOH	7

* $[H_2O] = 0.4$ M.

Table 3. Influence of substituents in the splitting of Si–Ar bonds in $Me_3SiC_6H_4X$ under the influence of Li_2PdCl_4 in DMF at 100° (k'_{rel}) and under the influence of acids (k''_{rel}).

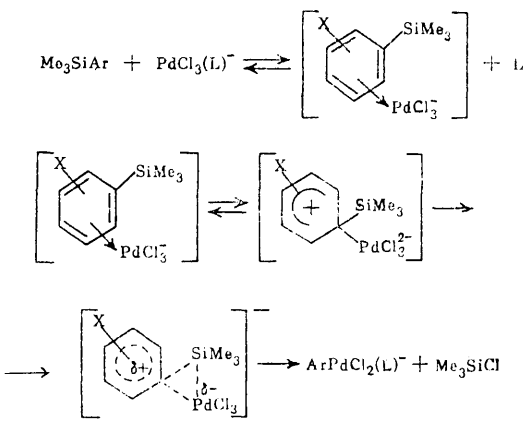


* Figures in brackets for the reaction with $FeCl_3$ in MeCN.[71]

** Ratios of the average reaction rates after 2 h taken.

Table 3 gives the relative rates of the splitting of trimethylarylsilanes under the influence of Li_2PdCl_4 in DMF and under the influence of electrophilic reagents. It can be seen from Table 3 that the position and nature of the substituents

have very little influence on the rate of splitting of the silanes under the influence of Li_2PdCl_4: silanes of the *meta*-series react at practically identical rates, irrespective of the nature of the substituent (*m*-Me, *m*-Cl, *m*-MeO). Substituents in the *para*-position, both electron donors (*p*-Me) and electron acceptors (*p*-Cl), increase the reaction rate slightly relative to non-substituted phenylsilanes. On the other hand, the rate of the acid splitting of the Si–Ar bond is extremely sensitive to the nature of the substituent, and the values of ρ in this case reach −5. An even greater influence of the substituents is observed in the reaction of trimethylarylsilanes with $FeCl_3$.

The following scheme was proposed for the splitting of Si–Ar bonds under the influence of Li_2PdCl_4 in aqueous DMF [69]:

$$2\,Me_3SiCl + H_2O \longrightarrow Me_3SiOSiMe_3 + 2\,HCl$$

$$ArPdCl_2(L)^- + HCl \longrightarrow ArH + PdCl_3(L)^-$$

L = DMF .

According to this scheme, the reaction involves the formation of a cyclic intermediate state with a low polarity. This suggestion agrees with the levelling of the influence of substituents, the low value of the enthalpy of activation (20.1 kcal mole^{-1}), the fairly high negative orientational entropy of activation (−27.2 e.u.), and the fact that the reaction rate is independent of the ionic strength of the solution, observed for the reaction of Me_3SiPh with Li_2PdCl_4 in DMF at 80–100°.

The authors suggest that the specific character of the action of the Pd^{II} complex on the Si–Ar bond is due to its biphilic character, that is its ability not only to accept electrons from the carbon atom but also to take part in a co-ordinative interaction with the silicon atom, as a result of which palladium simultaneously activates both atoms of the Si–C bond. Special calculations for geometric models of the corresponding σ-complexes showed that the Pd–Si distance in them is 3.20 Å, which is much less than the sum of the van der Waals radii of Pd and Si, equal to 4.25 Å. Thus the calculation of the model is consistent with the suggestion that there is a co-ordinative Pd–Si interaction[69].

The subsequent stages of the reaction involve the formation of an aryl palladium complex, which undergoes protolytic decomposition to give the final products and regenerate the catalyst. The intermediate formation of the σ-organic derivative of palladium is confirmed by the methylation and phenylation of alkenes by organosilicon compounds[59,60]. Thus in the presence of $PdCl_2$, the hydrogen at the double bond in styrene and cyclohexene is replaced by the methyl or phenyl group of an organosilicon compound:

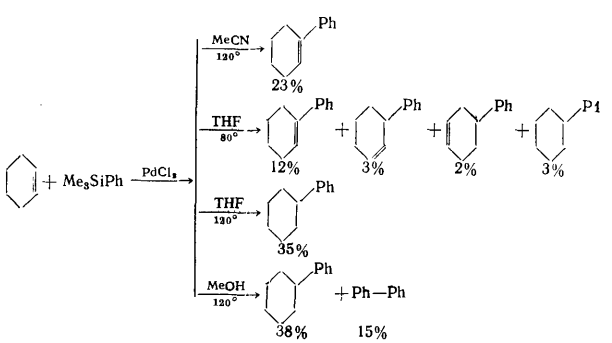
$$R_3SiR' + PdCl_2 \rightarrow R_3SiCl + [R'PdCl]$$

$$[R'PdCl] + \underset{H}{\overset{}{\rangle}}C{=}C\langle \rightarrow \underset{R'}{\overset{}{\rangle}}C{=}C\langle + HCl + Pd$$

R′=Me, Ph .

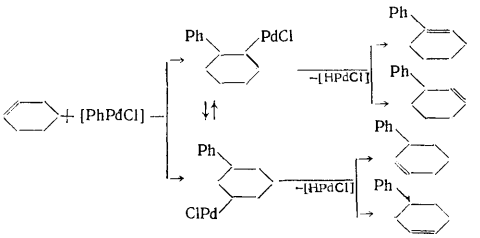
The reactions take place very slowly even at room temperature, and at 100° and above, the yields of the products may be fairly high. Thus styrene can be methylated by tetraorganosilanes (Me_4Si, Me_3SiEt), silazane, and siloxanes. The methylating power of organosilicon compounds changes in approximately the same sense as the ease of splitting of the Si–C bond by electrophilic reagents:

$$Me_4Si\,(66\%),\ Me_3SiEt\,(66\%) > Me_3SiNHSiMe_3\,(52\%) > > Me_3SiOSiMe_3\,(34\%) > Me_3SiCH_2Cl\,(32\%) > > (Me_2SiO)_3\,(3\%) > Me_3SiCl\,(0\%)\ .$$



The chief product is that formed by the replacement of the β-hydrogen of styrene. The phenyl group in Me_3SiPh is removed more readily than the methyl group. It is also more readily transferred to the alkene. Examples of the phenylation of alkenes under the influence of Me_3SiPh are given in Table 4.

Table 4. Phenylation of alkenes under the influence of Me_3SiPh*. [60]



Alkene	Palladium compound	Solvent	*t*, °C	τ, h	Product	Yield, % calculated relative to the silane
Styrene	Li_2PdCl_4	THF	20	100	*trans*-stilbene	20**
Styrene	Li_2PdCl_4	THF	60	6	*trans*-stilbene	17
Styrene	Li_2PdCl_4	MeOH	60	6	*trans*-stilbene	20
Styrene	Li_2PdCl_4	THF	120	10	*trans*-stilbene	94
Styrene	$LiPdCl_3$	MeCN	120	10	*trans*-stilbene	65***
Styrene	Li_2PdCl_4	MeOH	120	10	*trans*-stilbene	47
Cyclohexene	Li_2PdCl_4	THF	120	10	phenylcyclohexane	35
Cyclohexene	$LiPdCl_3$	MeCN	120	10	1-phenylcyclohexene	23
Cyclohexene	Li_2PdCl_4	MeOH	120	10	phenylcyclohexane	38
					biphenyl	15

* Molar ratio $[Me_3SiPh] : [alkene] : [Pd^{II}] = 1 : 2 : 1$.
** + 5% β-methylstyrene.
*** + 8% β-methylstyrene.

Cyclohexane is phenylated less readily than styrene. The formation of 1-phenylcyclohexene, the "normal" product of the phenylation of cyclohexene, as the only product is observed only in acetonitrile. The reactions in THF and MeOH are complicated by side reactions—isomerisation, hydrogenation, and disproportionation:

Thus the reaction of Me_3SiPh with cyclohexene in the presence of Li_2PdCl_4 in the THF at 80°, in addition to the main product, 1-phenylcyclohexene, also gives 3- and 4-phenylcyclohexenes and phenylcyclohexane. The formation of the isomeric phenylcyclohexenes is attributed[60] to the isomerisation of the intermediate phenylcyclohexylpalladium chloride, since 1-phenylcyclohexenes do not isomerise under the reaction conditions:

At 120° in THF, the only product of the reaction of Me_3SiPh with cyclohexene is phenylcyclohexane. Under the same conditions in methanol, a mixture of phenylcyclohexane and biphenyl is formed. The formation of the latter is attributed to the disproportionation of 1-phenylcyclohexene under these conditions by a reaction of the irreversible Zelinskii catalysis type[60].

The above reactions involving the transfer of organic compounds to alkenes in the presence of Pd^{II} compounds are analogous to the familiar Heck reactions[41,72-76]. In the Heck reactions, organic derivatives of Hg, Sn, and Pb are used as alkylating and arylating agents.

The possibility of using organosilicon compounds in these reactions is of preparative interest, particularly for the methylation of alkenes, since organosilicon compounds are non-toxic and stable to air and moisture.

2. The Splitting of Silanes Under the Influence of Pt^{II} Compounds

Dimeric alkene complexes of Pt^{II} are active in the splitting of tetra-alkylsilanes[64-66].

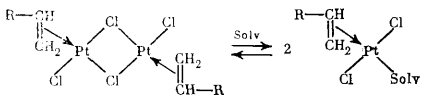
The reactions of the silanes Me_3SiR (R = Ph, Me) with $Pt_2Cl_4(alkene)_2$ complexes take place even at room temperature. In $CHCl_3$ in the absence of water, the reaction gives Me_3SiCl and the corresponding σ-organic derivative of Pt^{II}, identified by ^1H NMR:

$$Me_3SiR + Pt_2Cl_4(C_2H_4)_2 \rightarrow Pt_2Cl_3(C_2H_4)_2R + Me_3SiCl .$$

In an excess of Me_3SiR, the reaction may proceed further:

$$Me_3SiR + Pt_2Cl_3(C_2H_4)_2R \rightarrow Pt_2Cl_2(C_2H_4)_2R_2 + Me_3SiCl .$$

The rate of the removal of different groups from the Si atom in Me_3SiR under the influence of $Pt_2Cl_4(C_2H_4)_2$ at 20° in $CHCl_3$ changes in the following order:

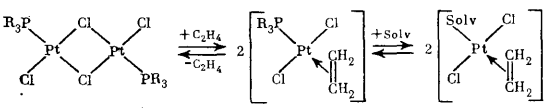


$$CH_2{=}CH > CH_2{=}CH{-}CH_2 > Ph \gg Me .$$

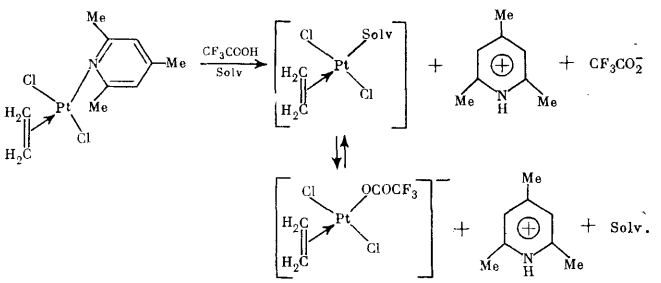
In the presence of water, the process becomes catalytic with respect to the Pt^{II} complex. As in reactions catalysed by Pd^{II} and Pt^{IV} complexes, the catalyst is regenerated by the protolytic splitting of the σ-organic derivative of the metal:

$$2Me_3SiCl + H_2O \rightarrow Me_3SiOSiMe_3 + 2HCl$$
$$[Pt_2Cl_3(C_2H_4)_2R_2] + 2HCl \rightarrow [Pt_2Cl_4(C_2H_4)_2] + 2RH .$$

In the reaction with Me_3SiPh, a wide range of monomeric *cis*- and *trans*-complexes of Pt^{II} containing phosphines, pyridines, biallyl, thiols, and ethene as ligands have been studied. All were inactive under the conditions studied (20°, 24 h). Among the dimeric complexes $Pt_2Cl_4L_2$, the collidine and phosphine complexes are also inert.



The high activity of dimeric alkene complexes of Pt^{II} in reactions with silanes was attributed[66] to the ease of formation of the intermediate coordinatively unsaturated Pt^{II} complex obtained by the dissociation of $Pt_2Cl_4(alkene)_2$:



Solv = solvent .

In agreement with this, the rate of the splitting of silanes under the influence of the complexes $Pt_2Cl_4(C_2H_4)_2$ depends significantly on the solvent. Thus after 20 h, Ph is removed from Me_3SiPh to the extent of 100% in $CHCl_3$, 60% in benzene, 10% in acetone, and 2% in MeOH.[66] Thus solvents which form stable solvates decrease the coordinative unsaturation of the intermediate monomeric complex $PtCl_2(C_2H_4)$, and hinder the reaction.

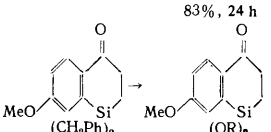
The suggestion that an active three-coordinate Pt^{II} complex is formed agrees with the fact that the phosphine complexes $Pt_2Cl_4L_2$ [L = PPh_3 and $P(n\text{-}Bu)_3$], which are inert in reactions with silanes, react with them in the presence of ethene. The replacement of ethene by argon stops the reaction, and saturation again with ethene renews it. These facts are explained by ligand exchange in the presence of ethene.

Similarly, the ethene complex of Pt^{II} with the collidine ligand, *trans*-$PtCl_2(C_2H_4)(Me_3C_5H_2N)$, which is inactive in reactions with silanes, reacts with them in the presence of CF_3COOH at room temperature[64]. It has been proved that in the presence of CF_3COOH, protonation and removal of the collidine ligand take place to give the complex $PtCl_2(C_2H_4)$.

The unique activity of the complex $[PtCl_2(C_2H_4)Solv]$ is attributed to the increased electrophilic character of Pt^{II} in the presence of the π-acceptor, and the coordinative unsaturation of this complex.

The nature of the ethene ligand in the dimeric complex $Pt_2Cl_4(alkene)_2$ also influences its activity with respect to the Si-C bond. With increase in the size of the group R at the co-ordinated multiple bond, the rate of the splitting of silanes decreases in the order: ethene > styrene > propene > pentene > 3,3'-dimethyl-1-butene. This is attributed to the decrease in the accessibility of the metal with increase in the volume of the group R.

Low activity in the reaction with Me_3SiPh is also shown by the dimeric complex $Pt_2Cl_4(S\text{-}Bu_2\text{-}n)_2$, which has bridging ligands and can be converted into the three-coordinate complex $PtCl_2(S\text{-}Bu_2\text{-}n)$.



In the authors' opinion, Pt^{II} complexes can bring about either electrophilic splitting of the Si–C bond or oxidative addition of the silanes at the Si–C bond with the subsequent reductive elimination of R_3SiCl.[65]

3. The Splitting of the Si–C Bond by Metallic Pt and Pd

Metallic palladium in the presence of hydrogen is able to split the Si–CH_2Ph bond[77]. Thus various benzyl- and dibenzylsilanes in the presence of the catalytic complexes Pd/C in alcohol in an atmosphere of hydrogen are converted into alkoxysilanes and toluene. The reactions take place slowly at room temperature:

$$PhMe_2SiCH_2Ph \rightarrow PhMe_2SiOMe \quad (67\%,\ 24\ h)$$

$$m\text{-}MeOC_6H_4Si(Et)(CH_2Ph)_2 \rightarrow m\text{-}MeOC_6H_4Si(OEt)_2Et \quad (83\%,\ 24\ h)$$

54% (R = Me)
55% (R = Et)

$$C_6H_{11}Me_2SiCH_2Ph \rightarrow C_6H_{11}Me_2SiOMe \quad (10\%,\ 9\ d)$$

The method can be used to synthesise alkoxysilanes difficult to prepare, for example dialkoxysilatetralins. Electron-donor groups in the benzene ring facilitate the reaction, and acceptor groups (CF_3) hinder it. This feature led the authors to the conclusion that complex formation by the benzyl π-system with metallic Pd is the limiting stage of the process. The activated Si-benzyl bond is then split by alcohol (by an S_NSi mechanism) to give the alkoxysilane and benzylpalladium hydride, after which the latter is reduced by hydrogen to toluene and Pd^0. Platinum is inactive in this reaction. It has been shown, however, that the Si–Ph bond in Me_3SiPh is split very slowly under the influence of Pt/C in ethanol at 100°. The degree of conversion of the silane after 50 h corresponds to 32 moles per g-atom of platinum[62].

The triphenylphosphine complexes L_4Pt and L_4Pd are inert with respect to silanes on prolonged heating in benzene at 150°.[62] The apparent explanation is that the metal atom in these complexes is completely shielded, and is inaccessible to attack. The dissociation of L_4M gives the complexes L_3M and L_2M, in which the metal is still fairly well shielded by the molecules L and is still not readily accessible to attack by the silicon atom, which in turn is shielded by four organic groups[78].

4. Electrochemical splitting of the Si–C Bond.

Tetra-alkyl- and trialkylarylsilanes are oxidised at a Pt anode at 2.63 V in the presence of the fluoride anion in absolute MeCN.[79] The reaction is accompanied by the formation of fluorosilanes and the elimination of the most stable radical:

$$R_3SiR' \xrightarrow[H_3F_4^-,\ MeCN]{Pt,\ 2.63\ V} R_3SiF + R'^{\cdot} \quad (50\text{–}80\%)$$

R′ = Me, Et, CH_2Ph .

Silanes are not oxidised in the absence of the fluoride anion. In the authors' opinion, this reaction takes place by a mechanism involving one-electron oxidation with the nucleophilic co-operation of the fluoride anion. The transfer of the electron from Si takes place in step with the attack by F^- at the Si atom.

The proposed mechanism is confirmed by the selectivity of the splitting of the Si–C bonds and the nature of the products formed. Thus in the anodic oxidation of Me_3SiPh and $Me_3SiC_6H_4F$, the methyl group is eliminated exclusively, whereas in the case of trimethylbenzyl- and triethylbenzylsilanes, only the benzyl group is eliminated. The anodic oxidation of Me_3SiEt is accompanied by the preferential replacement of the ethyl group. Thus the ease of the removal of the radicals decreases in the order: $PhCH_2$ > Et > Me. The resulting radical then dimerises, or removes hydrogen from the solvent ($Me^{\cdot}$), or undergoes further anodic oxidation to the cation ($Et^{\cdot}$, $PhCH_2^{\cdot}$).

It is of interest to compare the selectivity of the splitting of the Si–C bond under the influence of Pd^{II} and Pt^{IV} on the one hand and in electrochemical splitting at a platinum anode on the other. In the first case, in trimethylarylsilanes, the aryl group is removed exclusively, whereas in the mixed trimethylethyl-, trimethylpropyl-, and trimethylbutylsilanes, practically only the methyl group is removed. Unlike the Ph and Me groups, the benzyl group is not removed from the Si atom under the influence of the complex $Pt_2(C_2H_4)_2Cl_4$. The opposite relationships are observed for the electrochemical oxidation of silanes.

5. The Reactions of Siloxanes with Platinum and Palladium Complexes

Of particular interest is the splitting of the silicon–oxygen bond in siloxanes, which would open up the possibility of using the readily accessible siloxanes in organic synthesis. On the other hand, the selectivity of the replacement of organic groups in siloxanes by polar groups provides a method for the directed modification of siloxanes in the absence of aggressive media.

The siloxane bond is fairly strong, and is split only by strong acidic and basic reagents[80]. There are several published examples, indicating the stability of siloxanes to the action of Pt and Pd complexes. Thus the reactions of substituted acetylenes with dihydrodisiloxanes in the presence of the Speier catalyst or Pt/C at 110° in toluene gives five-membered organocyclosiloxanes[81], that is, the reaction takes place without rupture of the SiOSi unit:

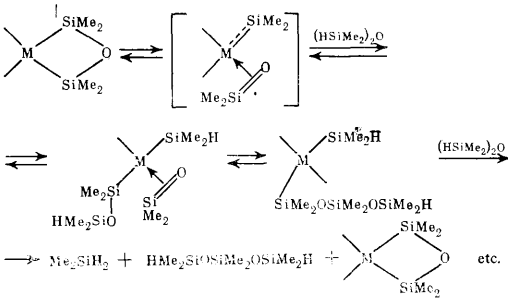
$$XC{\equiv}CX' + HR'RSiOSiRR'H \xrightarrow{catalyst} R'RSi\begin{matrix}O\\ \diagdown\ \diagup\\ XHC{-}CHX'\end{matrix}SiRR' \quad (50\text{–}70\%)$$

X = H, Ph; X′ = Ph;
R = R′ = Me; R = Me, R′ = Et .

When hexamethyldisiloxane is heated for a prolonged period with trichlorosilane at 150° in the presence of $H_2PtCl_6.6H_2O$, $PtCl_2$, or $Pt_2Cl_4(C_2H_4)_2$, selective exchange takes place between the methyl group and chlorine, and the siloxane bond is not affected[82]:

$$Me_3SiOSiMe_3 + HSiCl_3 \xrightarrow[150°,\ 24\ h]{catalyst} ClMe_2SiOSiMe_2Cl + HClSiMe_2 .$$

When 1,1,3,3-tetramethyldisiloxane is boiled with $L_2Pt(C_2H_4)$ in benzene, a disila-ring containing the metal is obtained[83]:



$$(HMe_2Si)_2O + L_2Pt(C_2H_4) \xrightarrow[C_6H_6]{20\text{–}80°} L_2Pt\begin{matrix}Me_2\\ Si\\ \diagup\ \ \diagdown\\ Si\\ Me_2\end{matrix}O + C_2H_4 + H_2$$

L = Ph_3P .

In this case, selective splitting of the Si–H bonds is observed, and rupture of the siloxane bond is not observed. The palladium, iridium, and rhodium analogues of these complexes were subsequently obtained[84]. Metal-containing rings of the type $L_2M(Me_2SiOSiMe_2)$ even at room temperature catalyse the disproportionation of 1,1,3,3-tetramethyldisiloxane to give dimethylsilane and higher siloxane oligomers:

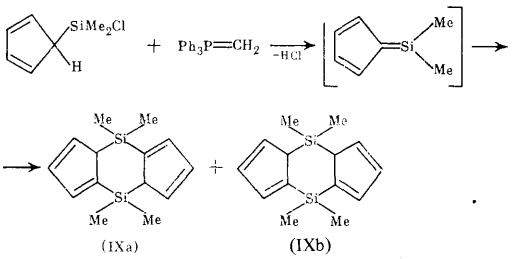
$$n\,(HSiMe_2)_2O \xrightarrow{\text{catalyst}} Me_2SiH\,(OSiMe_2)_n\,OSiMe_2H + n\,Me_2SiH_2$$
$$M = Ir,\ Rh,\ Pt,\ Pd.$$

The platinum and palladium metal-containing rings are poor catalysts for these reactions, but the iridium and rhodium complexes show a high activity[84]. The authors suggest that the disproportionation of the disiloxane involves the participation of intermediate complexes of dimethylsilylene and dimethylsilanone, co-ordinated to the transition metal atom:

The dimeric ethene complex of platinum $Pt_2Cl_4(C_2H_4)_2$ in the presence of water brings about the slow hydrolysis of hexamethyldisiloxane at room temperature to give polysiloxanes[64]. The composition of the products was not determined.

It was noted above that the hydrosilylation of hex-2-ene under the influence of $(Me_3SiO)_2SiMeH$ at 140° in the presence of H_2PtCl_6 is complicated by a side process, which is also accompanied by the splitting of the siloxane bond[56]. The platinum and palladium compounds $PdCl_2$, $PtCl_4$, $H_2PtCl_6.6H_2O$, $(Ph_3P)_2PtCl_2$, $(Ph_3P)_4Pt$, and $(Ph_3P)_4Pd$, and also metallic Pt and Pd at 80–100°, activate both the Si–C bond and the Si–O bond in hexamethyldisiloxane. Linear and cyclic siloxanes are formed. The chief product is octamethyltrisiloxane, the yield of which corresponds to 10 moles per mole of catalyst[58, 60,61]. In the reaction of hexamethyldisiloxane with $PdCl_2$ (molar ratio 2:1, 150°, 10 h, in the absence of a solvent), methane, methyl chloride, and ethane are formed in the molar ratio 70:10:1 together with chlorine derivatives and higher linear and cyclic siloxanes[85].

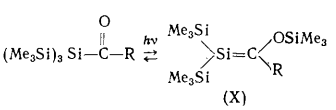
In solvents (aqueous THF, MeCN, and MeOH), hexamethyldisiloxane reacts with Pd^{II} salts at 120° to give octamethyltrisiloxane, decamethyltetrasiloxane, and hexamethylcyclotrisiloxane. In the presence of $CuCl_2$, this reaction becomes catalytic. Thus 1 mole of Li_2PdCl_4 at 120° after 10 h converts approximately 5 moles of disiloxane. Metallic Pt and Pd are also active in the splitting, and the reaction with Pt/C takes place even at 80°. The products are methane and $Me_3SiOSiMe_2OSiMe_3$. The degree of conversion of the disiloxane after 10 h amounts to 10 mole per g-atom of Pt.[85]



Unlike metallic platinum and palladium, the triphenylphosphine complexes of these metals, $(PPh_3)_4Pt$ and $(Ph_3P)_4Pd$, do not react with hexamethyldisiloxane in benzene even at 150°. The reaction with these complexes was observed only at 200°, that is under conditions in which decomposition of the complex to the metal is possible[85]. A significant feature is that the formation of cyclic siloxanes from hexamethyldisiloxane under the influence of platinum and palladium compounds or the corresponding metals is observed not only in aqueous solvents, but also under anhydrous conditions and in the initial stages of the reaction.

To explain the formation of cyclic dimethyldisiloxanes under anhydrous conditions, the authors assumed the intermediate formation of silacetone $Me_2Si=O$, stabilised by complex formation with a transition metal compound. Its polymerisation gives cyclic siloxanes, and insertion into linear and cyclic siloxanes at the Si–O bond gives higher linear and cyclic oligomers:

$$Me_3SiOSiMe_2OSiMe_3 + ML_n \rightleftarrows Me_3SiOSiMe_3 + Me_2SiO\cdot ML_n$$
$$Me_2SiO\cdot ML_n \xrightarrow{\text{polymerisation}} (Me_2SiO)_n$$
$$Me_2SiO\cdot ML_n \xrightarrow{Me_3Si(OSiMe_2)_n\,Me} Me_3Si\,(OSiMe_2)_{n+1}\,Me$$
$$Me_2SiO\cdot ML_n \xrightarrow{(Me_2SiO)_n} (Me_2SiO)_{n+1}.$$



Until recently, it was considered that compounds containing a silicon atom forming multiple bonds did not exist. The formation of unstable organosilicon compounds with a double $(p-p)_\pi$-bond at the silicon atom is now well established. Thus the formation of short-lived silicon analogues of the unsaturated compounds $R_2Si=CH_2$,[86–90] $R_2Si=O$,[87,91] $R_2Si=SiR_2$,[92,93] $R_2Si=NR$,[94] and $R_2Si=S$[95] has now been proved.

Recently, several groups of research workers have attempted to synthesise stable silaethylenes. Thus with the idea of stabilising structures of the type C=E by delocalisation of the π-bond and an increase in the steric hindrance at the C and E atoms, attempts have been made[96] to synthesise silafulvenes, which, according to quantum-mechanical calculations[97], should be the most stable systems. The reaction of $C_5H_5SiMe_2Cl$ with triphenylmethylenephosphorane, however, instead of the expected silafulvene, gave a mixture of its dimers (IXa) and (IXb) with sp^3 hybridisation of the silicon atoms. The authors consider that the intermediate products of this reaction—silafulvenes—are too reactive, and are converted exceptionally readily into the thermodynamically stable dimers:

(IXa) (IXb)

Silaethylenes (X), relatively stable at room temperature in argon, were first obtained by the photolysis of acylpolysilanes[88]:

R=CMe$_3$, CEt$_3$, 1-adamantyl, etc.

With R = 1-adamantyl, a solid compound stable in argon, and characterised from its infrared, Raman, NMR (^1H, ^{13}C, ^{29}Si), and mass spectra, was isolated. Its structure (X) was confirmed by X-ray diffraction. Attempts to stabilise the intermediate unstable species of the silaethylene $R_2Si=CH_2$[98] and sila-allyl $R_2Si=CH=CH_2$[99–101] type by co-ordination to complexes of transition metals (Fe, Mo, W) has as yet, unfortunately, been unsuccessful.

Thus the new branch of metal-complex catalysis in organosilicon chemistry has arisen and developed successfully in the last ten years.

In this period it has been found that platinum and palladium complexes are effective catalysts for the splitting of Si–C bonds in vinyl-, allyl-, and ethynylsilanes, strained

sila- and disilacyclobutanes, silyl hydrides, and alkyl- and arylsilanes. These studies are being carried out with a view to investigating the mechanism of the activation of Si–C bonds by Pt and Pd complexes, and also using the splitting of these bonds in synthesis.

The removal of unsaturated groups from the Si atom is preceded by complex formation at the multiple bond. The driving force of the splitting of the Si–C bonds in cyclosilanes is their strain. In the splitting of Si–C bonds by Pd complexes, a significant feature is the ability of the Pd atom both to accept an electron pair from the carbon of the Si–C bond and to take part in a co-ordinative interaction with the silicon atom.

The splitting of Si–C bonds opens up new possibilities for the use of organosilicon compounds in synthesis: for the vinylation, methylation, phenylation, and chloroethylation of alkenes, the polymerisation of sila- and disilacyclobutanes, the preparation of organosilicon compounds not readily obtained, by the direct replacement of organic group on Si, the synthesis of platinum and palladium complexes containing organic and organosilicon groups on the metal, etc. The splitting of Si–C bonds in siloxanes is opening up new possibilities for the modification and oligomerisation of siloxanes.

The Synthesis and Properties of Aliphatic Fluoronitroso-compounds

I.L.Knunyants, Yu.A.Sizov, and O.V.Ukharov

The methods of synthesis and properties of aliphatic fluoronitroso-compounds are described systematically and the mechanisms of their reactions are discussed. A section is devoted to a survey of the properties and applications of copolymers of fluoronitroso-compounds.
The bibliography includes 304 references.

CONTENTS

I. Introduction 554
II. The synthesis of aliphatic fluoronitroso-compounds 554
III. The properties of aliphatic fluoronitroso-compounds 557
IV. The properties and applications of copolymers of fluoronitroso-compounds 569

I. INTRODUCTION

Compared with their non-fluorinated analogues, fluoronitroso-compounds are more electrophilic and the dissociation energy of their C–N bond is low, which led to the discovery of new reactions of both theoretical and practical importance—in particular the ready copolymerisation of fluoronitrosoalkanes with fluoro-olefins which leads to the formation of fluoronitroso-rubbers with unique properties.

This review includes data up to 1981 inclusive.

II. THE SYNTHESIS OF ALIPHATIC FLUORONITROSO-COMPOUNDS

The first representative of perfluoronitrosoalkanes, namely trifluoronitrosomethane, was obtained accidentally in 1936. Ruff and Giese[1] obtained trifluoronitrosomethane in a low yield by treating silver cyanide, containing an admixture of silver nitrate, with elemental fluorine. Interest in substances of this class was not renewed until the beginning of the 1950s when the chemistry of organofluorine substances began to develop vigorously. A series of general and special methods of synthesis, which have rendered available many aliphatic fluoronitroso-compounds, were also developed at that time.

1. Radical Reactions with Participation of Nitric Oxide

The first method of synthesis of trifluoronitrosomethane from trifluoroiodomethane and nitric oxide was proposed by Haszeldine[2]. Subsequently, this method was extended to a series of homologues of trifluoronitrosomethane[3–5]. It is based on the photochemical reaction of perfluoroalkyl iodides with nitric oxide in the presence of mercury as the acceptor of the evolved iodine:

$$R_F{-}I \xrightarrow{h\nu} \dot{R}_F + \dot{I}, \quad \dot{R}_F \xrightarrow{\dot{N}O} R_F{-}NO ,$$
$$2\dot{I} \xrightarrow{Hg} HgI_2 .$$

It is of interest that, when higher perfluoroalkyl iodides are used in this method in the absence of mercury, nitroso-compounds with a shorter fluorocarbon chain are formed in addition to the corresponding fluoronitroso-compounds[6,7]:

$$CF_3CF_2\dot{C}F_2 \xrightarrow{\dot{N}O} CF_3CF_2CF_2{-}NO; \quad 2NO \xrightarrow{h\nu} NO_2 + {}^1/_2\,N_2$$
$$CF_3CF_2\dot{C}F_2 \xrightarrow{NO_2} CF_3CF_2CF_2{-}ONO \xrightarrow[\dot{N}O]{h\nu} CF_3CF_2CF_2{-}\dot{O} \xrightarrow{O=CF_2}$$
$$\longrightarrow CF_3\dot{C}F_2 \xrightarrow{NO_2} CF_3CF_2{-}ONO \xrightarrow[\dot{N}O]{h\nu} CF_3CF_2{-}\dot{O} \xrightarrow{O=CF_2} \dot{C}F_3 .$$
$$\downarrow \dot{N}O \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad \downarrow \dot{N}O$$
$$CF_3CF_2{-}NO \qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad CF_3{-}NO$$

The purpose of mercury therefore consists not only in binding the iodine evolved but also in binding nitrogen dioxide, which appears on disproportionation of nitric oxide[7]. The yields of fluoronitrosoalkanes synthesised by this method are fairly high but the degree of conversion is low. It has also been shown that this reaction can occur on thermal initiation[8] but with a low yield.

Perfluoroalkyl bromides can also be introduced into this reaction[9]. Unsaturated fluoronitroso-compounds have likewise been obtained in this way[10,11]:

$$\begin{matrix} CF_2{=}CF{-}I \\ \\ CF_2{=}CX{-}CF_2{-}I \end{matrix} + NO \xrightarrow[Hg]{h\nu} \begin{matrix} CF_2{=}CF{-}NO \\ (9\%) \\ CF_2{=}CX{-}CF_2{-}NO \ ; \\ X{=}F\,(24.5\%);\ X{=}H\,(34\%) . \end{matrix}$$

Fluorodinitrosoalkanes can be synthesised by the radical reaction of fluoro-olefins with nitric oxides[303,304]:

$$CF_2{=}\underset{\displaystyle X}{\underset{|}{CF}} + 2NO \xrightarrow{\Delta,h\nu} ON{-}CF_2{-}\underset{\displaystyle X}{\underset{|}{CF}}{-}NO ;$$
$$X{=}F,\ Cl,\ CF_3 .$$

Several other methods, based on a different procedure for the generation of fluoroalkyl radicals and nitric oxide, were proposed later[12–16]:

$$CF_3COOH + Cl{-}NO\ (or\ BrNO) \xrightarrow[\text{gas phase}]{h\nu} CF_3{-}NO ;$$
$$CF_3{-}CF_3\ (or\ CF_3Cl) + NO \xrightarrow[12\ MH_2]{\text{chemical plasma}} CF_3{-}NO ;$$
$$(CF_3)_2C{=}O + 2NO \xrightarrow{h\nu} 2CF_3{-}NO ;$$
$$CF_3{-}H + Cl{-}NO \xrightarrow{h\nu,\Delta} CF_3{-}NO .$$

However, the need to work in the gas phase in a closed space in apparatus transparent to ultraviolet light lowers the value of this method for the synthesis of fluoronitroso-compounds in large amounts.

2. Decarboxylation of Perfluoroacyl Nitrites

Yet another method of synthesis of fluoronitrosoalkanes, based on the thermochemical and photochemical decarboxylation of perfluoroacyl nitrites, was proposed at the beginning

of the 1950s:

$$R_F—C—O—NO \xrightarrow[-CO_2]{\Delta(h\nu)} R_F—NO \ .$$

Several methods have been put forward for the thermal decomposition of perfluoroacyl nitrites. Direct heating[5,17–22] or contact with a high-boiling inert solvent[23–25] have been proposed to reduce the risk of explosion in the process.

A version of the decarboxylation of perfluoroacyl nitrites is their photochemical decomposition[26–30]. In certain cases perfluoroacyl nitrites decompose at the instant of formation[31]:

$$(CF_3)_3C—\overset{O}{\overset{\|}{C}}—F + Na—ONO \xrightarrow[-NaF]{} (CF_3)_3C—\overset{O}{\overset{\|}{C}}—ONO \xrightarrow[-CO_2]{} (CF_3)_3C—NO \ .$$

3. The Addition of Nitrosyl Fluoride to Fluoro-olefins

A method of synthesis of perfluoronitroso-compounds by the addition of nitrosyl fluoride to fluoro-olefins was developed in the 1960s. It was shown that, on passing from tetrafluoroethylene derivatives to higher fluoro-olefins, the mechanism of the addition of nitrosyl fluoride undergoes inversion[32]. Nitrosyl fluoride readily adds to tetrafluoroethylene via an electrophilic mechanism in the presence of boron trifluoride[32,33]:

$$F—NO + BF_3 \rightarrow BF_4^- + NO^+ \ ;$$

$$CF_2=CFX \xrightarrow{NO^+} \overset{+}{C}F_2—CFX—NO \xrightarrow[-BF_3]{BF_4^-} CF_3—CFX—NO \ ;$$

X=F, Cl .

When X = F, the nitroso-compound cannot be isolated, since it immediately gives rise to an oxazetidine on reaction with a second tetrafluoroethylene molecule:

$$CF_2=CF_2 + F—NO \xrightarrow{BF_3} CF_3—CF_2—N=O \xrightarrow{CF_2=CF_2} CF_3—CF_2—\underset{\displaystyle CF_2—CF_2}{\overset{\displaystyle |}{\overset{\displaystyle |}{N—O}}} \ .$$

Fluoronitrosyl compounds are formed via the same mechanism from alkyl perfluorovinyl ethers and nitrosyl fluoride[33–35]:

$$RO—CX=CF_2 \xrightarrow{NO^+} RO—\overset{+}{C}X—CF_2—NO \xrightarrow{F^-} RO—CXF—CF_2—NO \ ;$$

X=F, Cl, R_F .

Nitrosyl fluorides add to higher fluoro-olefins via a nucleophilic mechanism in the presence of fluoride ions[32,36,37]:

$$CF_3—\underset{\displaystyle X}{\overset{\displaystyle |}{C}}=CF_2 \xrightarrow{F^-} CF_3—\overset{-}{\underset{\displaystyle X}{\overset{\displaystyle |}{C}}}—CF_3 \xrightarrow[-F^-]{F—NO} (CF_3)_2C—\underset{\displaystyle X}{\overset{\displaystyle |}{N}}—O \ ;$$

X=F, CF_3 .

The possibility of a radical interaction of nitrosyl fluoride with tetrafluoroethylene to form difluorocarbene when the reaction is initiated by ultraviolet radiation has been postulated[40]:

$$F—NO + CF_2=CF_2 \xrightarrow{u.v.} \underset{(I)}{} \underset{\displaystyle CF_2}{\overset{\displaystyle CF_2—CF_2}{}} + \underset{(II)}{CF_3—\underset{\displaystyle CF_2—CF_2}{\overset{\displaystyle |}{\overset{\displaystyle |}{N—O}}}} + \underset{(III)}{CF_3—CF_2—\underset{\displaystyle CF_2—CF_2}{\overset{\displaystyle |}{\overset{\displaystyle |}{N—O}}}} \ ;$$

$$CF_2=CF_2 \xrightarrow{u.v.} 2\ddot{C}F_2 \ ;$$

$$\ddot{C}F_2 + F—NO \xrightarrow{u.v.} \dot{C}F_3 + \dot{N}O \longrightarrow CF_3—NO \xrightarrow{CF_2=CF_2} \Big\rfloor \rightarrow CF_3—\underset{\displaystyle CF_2—CF_2}{\overset{\displaystyle |}{\overset{\displaystyle |}{N—O}}} \ ;$$

$$CF_2=CF_2 + F—NO \xrightarrow{u.v.} F—\underset{\displaystyle CF_2—CF_2}{\overset{\displaystyle |}{\overset{\displaystyle |}{N—O}}} \xrightarrow{\ddot{C}F_2} \dot{C}F_3 + \dot{N}—\underset{\displaystyle CF_2—CF_2}{\overset{\displaystyle |}{\overset{\displaystyle |}{O—}}} \Big\rfloor$$

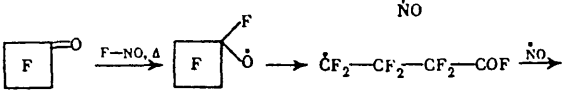
(III)

$$CF_2=CF_2 + \ddot{C}F_2 \rightarrow \underset{\displaystyle CF_2}{\overset{\displaystyle CF_2—CF_2}{}} \ .$$

(II)

The following facts have been adduced in support of the mechanism. In the absence of ultraviolet radiation, only compound (IV) is formed:

$$CF_2=CF_2 + F—NO \rightarrow CF_3—CF_2—NO \xrightarrow{CF_2=CF_2} CF_3—CF_2—\underset{\displaystyle CF_2—CF_2}{\overset{\displaystyle |}{\overset{\displaystyle |}{N—O}}} \ .$$



(IV)

When a mixture of compound (I), (II), and (IV) is irradiated, compound (III) is produced in a low yield.

There have been a number of other studies[36,37,41] in which it was shown that nitrosyl fluoride adds to fluoro-olefins also in the absence of a catalyst but at temperatures above 100 °C, which lowers the yield of fluoronitroalkanes due to side reactions.

Nitrosyl fluoride adds not only to fluoro-olefins but also to other compounds with a double bond[42,43]:

$$CF_2=C(CF_3)—COF \xrightarrow{F—NO} CF_3—\underset{\displaystyle NO}{\overset{\displaystyle |}{C}}(CF_3)—COF$$

$$\xrightarrow{F—NO,\ \Delta}$$

$$\rightarrow \dot{C}F_2—CF_2—CF_2—COF \xrightarrow{\dot{N}O} \rightarrow ON—CF_2—CF_2—CF_2—COF \ .$$

4. The Addition of Nitrosyl Chloride to Fluoro-Olefins

The first attempt to add nitrosyl chloride to fluoro-olefins[44–46] led only to the formation of nitroso-compounds. However, subsequently, using Lewis acids as catalysts, it was possible to obtain chlorofluoronitroso-compounds in both liquid[47] (without irradiation) and gaseous[48–50] (with and without irradiation) phases:

$$\left.\begin{array}{l} CF_2=CF_2 + Cl—NO \xrightarrow[\text{liq. phase}]{AlCl_3} \\ CF_2=CF_2 + Cl—NO \xrightarrow[\text{gas phase}]{h\nu, FeCl_3} \end{array}\right\rfloor \rightarrow Cl—CF_2—CF_2—NO \xleftarrow[\text{gas phase}]{FeCl_3} NO + CF_2=CF_2 \ ;$$

$$FeCl_3 + NO \rightleftarrows FeCl_3NO \xrightarrow{NO} FeCl_2NO + Cl—NO \xrightarrow{FeCl_3} FeCl_4NO \xrightarrow{2NO} \rightarrow FeCl_2NO + 2Cl—NO$$

$$CF_3—S—CF=CF_2 + Cl—NO \xrightarrow[\text{gas phase}]{h\nu} CF_3—S—\underset{\displaystyle NO}{\overset{\displaystyle |}{C}}F—CF_2Cl \ .$$

Nitrosyl chloride adds smoothly to fluoro-olefins in the presence of potassium fluoride[39,77]:

$$X—CF=C(CF_3)_2 \xrightarrow[-KCl]{KF,\ Cl—NO} X—CF_2—C(CF_3)_2—NO \ ;$$

X=F, C_2F_5 .

Fluoronitrosoalkanes can be obtained by the reaction of nitrosyl chloride with organofluorine derivatives of mercury[51] and also with 1-hydro-1-fluorosulphonyltetrafluoroethane[76]:

$$(CF_3—CXY)_2Hg + Cl—NO \xrightarrow{-HgCl_2} 2CF_3—CXY—NO \ ;$$

$$\begin{matrix} FSO_2 \\ CF_3 \end{matrix}\!\!>\!CFH \xrightarrow[-H^+]{\text{pyridine}} \begin{matrix} FSO_2 \\ CF_3 \end{matrix}\!\!>\!\overset{-}{C}F \xrightarrow[-Cl^-]{Cl—NO} \begin{matrix} FSO_2 \\ CF_3 \end{matrix}\!\!>\!CF—NO \ .$$

5. The Interaction of Nitrogen Oxides with Fluoro-olefins

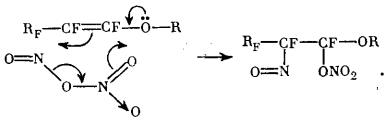
It has been observed[52,53] that tetrafluoroethylene readily combines with nitrogen dioxide. Apart from a dinitroalkane and a nitronitrite, a small amount of a nitronitrosoalkane is formed under these conditions[53]:

$$CF_2=CF_2 + N_2O_4 \rightarrow O_2N—CF_2CF_2—NO_2 + O_2N—CF_2CF_2—ONO + O_2N—CF_2CF_2—NO \ .$$

When nitric oxide is used, the yield of the nitronitrosoalkane is higher[54–58]. As a consequence of its low reactivity, pure nitric oxide does not react with fluoro-olefins in the

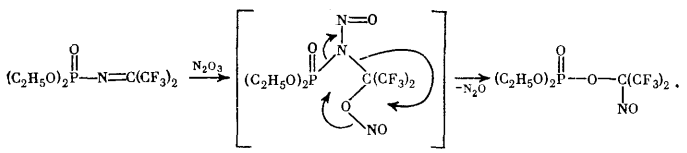
dark[59]. However, on irradiation nitric oxide disproportionates with formation of nitrogen dioxide and trioxide, which initiate the subsequent radical processes.

The addition of nitric oxide to fluoro-olefins can be initiated also by adding chlorine, bromine[55], and oxygen[57]. When nitrogen oxides interact with fluoro-olefins, the NO_2 radical, which initiates the process, attacks specifically the least sterically hindered difluoromethylene group[60-66]. Whereas the interaction of perfluoropropene with nitrogen oxides[56,60,65,66] results in the formation of a small amount of a dinitroalkane in addition to the nitronitrosoalkane and the nitronitrite, in the case of perfluoroisobutene a dinitroalkane is not formed[62,63]:



$$CF_3-CF=CF_2 \xrightarrow{N_2O_4} CF_3-\underset{NO}{CF}-CF_2-NO_2 + CF_3-\underset{ONO}{CF}-CF_2-NO_2 + CF_3-\underset{NO_2}{CF}-CF_2-NO_2 ;$$

$$(CF_3)_2C=CF_2 \xrightarrow{N_2O_4} (CF_3)_2\underset{ONO}{C}-CF_2-NO_2 + (CF_3)_2\underset{ONO}{C}-CF_2-ONO .$$



The interaction of perfluoroisobutene with nitrogen tetroxide in the presence of potassium fluoride leads to the formation of perfluoronitroso-t-butane alone[32,38]:

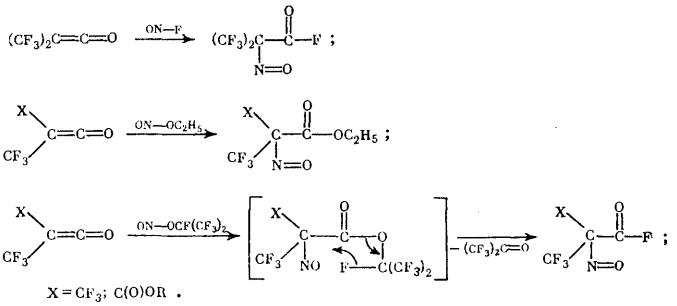
$$(CF_3)_2C=CF_2 \xrightarrow{F^-} (CF_3)_3C^- \xrightarrow{N_2O_4} (CF_3)_3C-N=O + NO_3^- .$$

Nitrogen dioxide adds to alkyl perfluorovinyl ethers[67] with formation of fluoronitrosonitrates:

Fluoronitrosoalkanes can also be formed by the reaction of phosphorylated imines with nitrogen trioxide[68]:

6. The Synthesis of Fluoronitro-compounds from Fluorine-containing Oximes

After the development of methods of synthesis of fluorooximes, fluoronitrosoalkanes were obtained by the Pilotti reaction[69,70]:

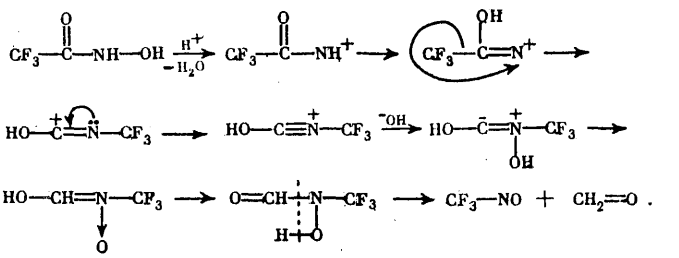


$$R_F-CF=N-OH \xrightarrow{Cl_2} \left[R_F-\underset{Cl}{CF}-\underset{Cl}{N}-OH\right] \xrightarrow{-HCl} R_F-CFCl-NO .$$

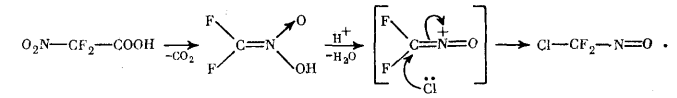
Perfluoro-2-nitrosopropane has been obtained by oxidising hexafluoroacetone oxime in anhydrous hydrogen fluoride[71]:

$$(CF_3)_2C=N-OH \xrightarrow[-H_2O]{Cr_2O_3,\ HF} (CF_3)_2CF-NO .$$

7. The Addition of Nitrosyl Fluoride and Alkyl Nitrites to Ketens

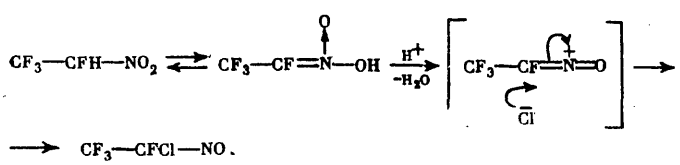


Derivatives of carboxylic fluoro-α-nitrosoacids can be obtained by the addition of nitrosyl fluoride and alkyl nitrites to ketens[72-75]:

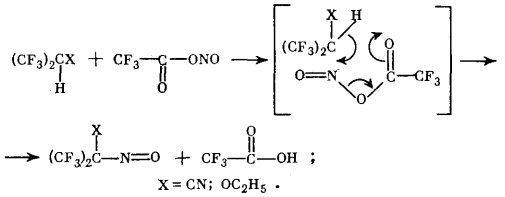


X = CF_3; C(O)OR .

8. Other Methods of Synthesis of Fluoronitroso-compounds



When trifluoroacetohydroxamic acid was heated *in vacuo*, trifluoronitrosomethane was obtained[79]. The following reaction mechanism is possible:

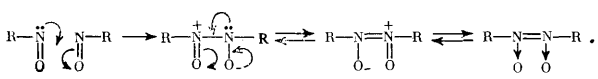


Difluoronitroacetic acid is converted into chlorodifluoronitrosomethane via several stages in a hydrochloric acid medium[80]:

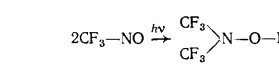
When tetrafluoro-α-hydronitroethane was allowed to react with hydrogen chloride, the corresponding nitroso-compound was obtained[81]:

Derivatives of hexafluoro-2-nitrosoisobutyric acid can be obtained by the substitution of the hydrogen atom in the corresponding C–H acid by the nitroso-group on treatment with trifluoroacetyl nitrite[78]:

X = CN; OC_2H_5 .



Trifluoroacetyl nitrite can also be used to synthesise fluoronitrosoalkanes from fluoro-olefins[78]:

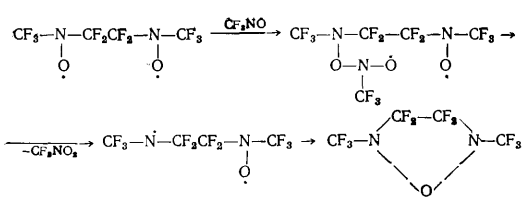


III. THE PROPERTIES OF ALIPHATIC FLUORONITROSO-COMPOUNDS

1. Characteristic Features of the Chemical Properties of Fluoronitrosoalkanes

A tendency towards dimerisation is a characteristic feature of non-fluorinated aliphatic nitroso-compounds[82,83] and most of them can exist in a monomeric form only in the melt, in solution, or in the gas phase[84]:

As a consequence of the decrease of the basicity of the nitrogen atom in fluoronitroso-compounds, the latter do not dimerise and they all exist exclusively in the monomeric form[84]. However, fluoronitrosoalkanes are also capable of forming dimers on irradiation but with a different structure[85]:

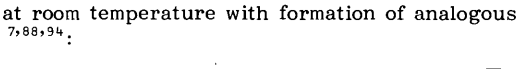


The inductive effect of the perfluoroalkyl group increases the electrophilicity of fluoronitrosoalkanes and decreases the C–N bond strength. Compared with their non-fluorinated analogues, fluoronitroso-compounds are therefore more readily reduced, are oxidised with greater difficulty, and typically undergo reactions with nucleophiles and reactions involving the dissociation of the C–N bond. In cycloaddition reactions fluoronitroso-compounds behave as active dienophiles.

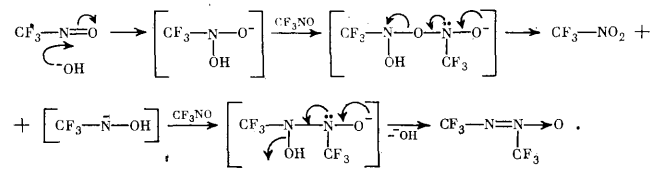
2. Oxidation of Fluoronitroso-compounds

Trifluoronitrosomethane is a strong electrophile and is resistant to the action of oxidants (HNO_3, $HMnO_4$, $H_2Cr_2O_7$, and Hal_2).[86,87] The oxidation of perfluoronitrosoalkanes at 65–130 °C with hydrogen peroxide[5,7,88] and higher metal oxides[4,45] has been described. In the presence of Hopcalite trifluoronitrosomethane is oxidised only at 150–200 °C;[86] nitroxy-radicals are also capable of oxidising trifluoronitrosomethane[89,139]:

The most convenient method involves oxidation by liquid nitrogen tetroxide. Secondary fluoronitroso-compounds are then oxidised preferentially to nitro-compounds[76,90–92].

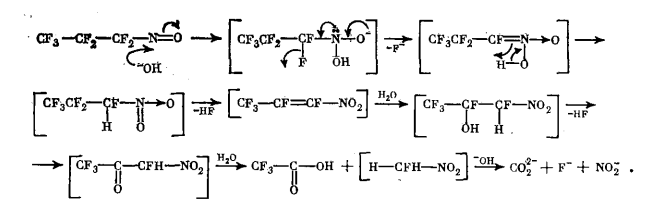


Tertiary fluoronitroso-compounds are oxidised by nitrogen tetroxide and other oxidants only to nitrites[38,39,42,62,90,93]:

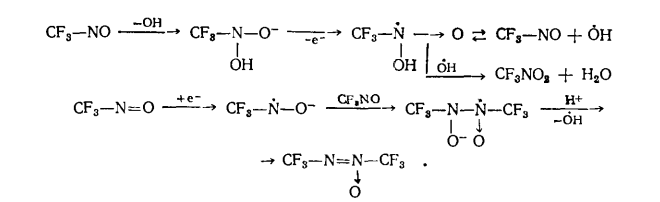


The formation of nitrites can be explained by the ready radical dissociation of the C–N bond in tertiary fluoronitroso-compounds.

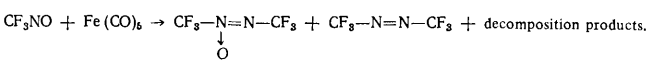
3. Disproportionation of Fluoronitroso-compounds



Fluoronitrosoalkanes, including trifluoronitrosomethane, undergo oxidative-reductive disproportionation over activated charcoal (at 100 °C) to perfluoronitroalkanes and perfluoroazoxyalkanes[7,88,94]:

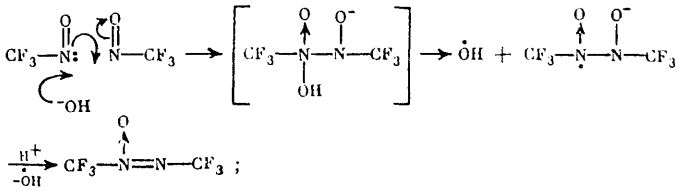


In aqueous alkalis trifluoronitrosomethane disproportionates at room temperature with formation of analogous products[7,88,94]:



Higher homologues then decompose with formation of carboxylic acids[7,86,87]:

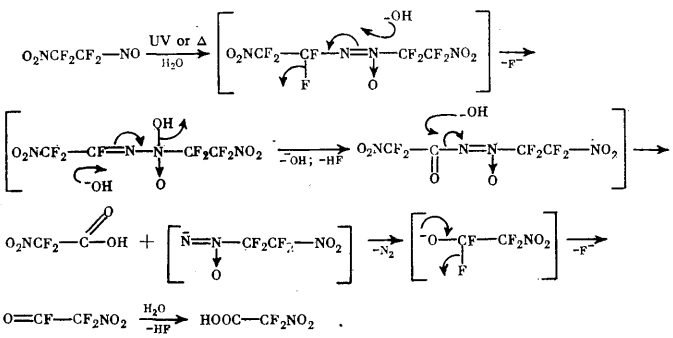
The radical-ion mechanism has also been proposed for the alkaline disproportionation of trifluoronitrosomethane[95] on the basis of EPR data:



Hexafluoroazoxymethane is also formed when trifluoronitrosomethane reacts with iron pentacarbonyl[96]:

The preferential formation (90%) of hexafluoroazoxymethane in the presence of reducing agents (sodium hypophosphite—$NaHPO_3$) and the preferential formation (90%) of trifluoronitromethane in the presence of oxidising agents (sodium hypochlorite—NaOCl) [86] can be explained by means of a mechanism based on the hypothesis that charge-transfer

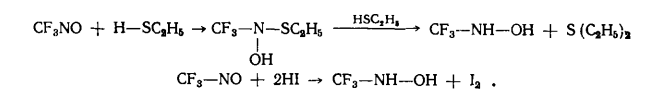
complexes are formed[97]:



According to the authors, the reducing agent ($NaHPO_3$) binds hydroxy-radicals and prevents the formation of trifluoronitromethane, while the oxidising agent NaOCl generates hydroxy-radicals and promotes the preferential formation of trifluoronitromethane:

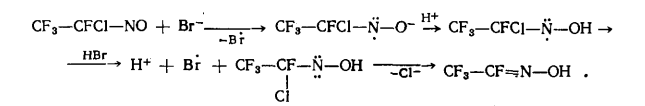
$$NaHPO_3 + 2\dot{O}H \rightarrow Na_2HPO_4 + H_2O \ ;$$
$$NaOCl + H_2O \rightarrow NaCl + 2\dot{O}H \ .$$

Tetrafluoro-2-nitro-1-nitrosoethane[98] hydrolyses to difluoronitroacetic acid in the presence of alkali:

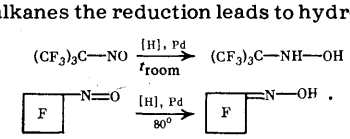


It is believed[98] that difluoronitroacetic acid is also formed in an aqueous medium on ultraviolet irradiation or on heating, via the intermediate formation of an azoxy-compound:

4. Reduction of Fluoronitroso-compounds



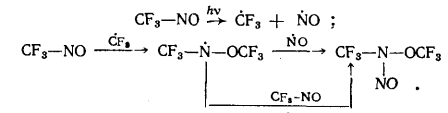
Trifluoronitrosomethane is reduced by ethanethiol and hydrogen iodide[86] to trifluorohydroxylamine, which is stable in the form of the etherate:



On reduction to hydroxylamine, α-chloroperfluoronitrosoalkanes[55,59] split off hydrogen halide with formation of the fluorides of perfluorohydroxamic acids:

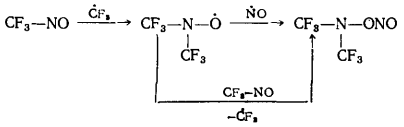
Fluoronitrosoalkanes can be reduced also by other methods—by treating a solution of a nitrosoalkane and phenol in ether with bromine and by catalytic hydrogenation. In the former case the reducing agent is the bromide ion formed when bromine interacts with phenol[99]:

In the catalytic hydrogenation of secondary and tertiary fluoronitrosoalkanes the reduction leads to hydroxylamines[92,100]:



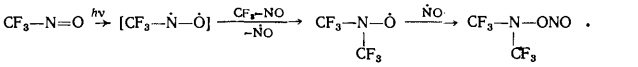
The attempts to reduce perfluoronitroso-t-butane to perfluoro-t-butylamine by hydrogenation over Raney nickel led only to the formation of perfluoromonohydro-t-butane—the product of the hydrogenolysis of the initial nitroso-compound. This finding confirms yet again the low energy of the C–N bond in tertiary fluoronitroso-compounds.

Perfluoro-t-butylhydroxylamine has been obtained in the form of the etherate by treating perfluoronitroso-t-butane with tin dichloride[101].



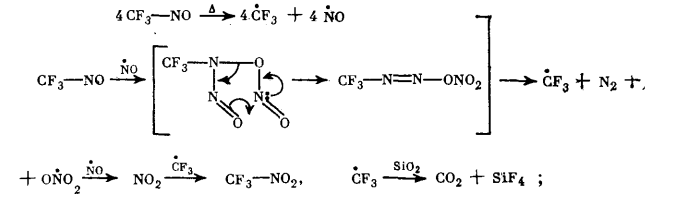
5. Pyrolysis and Photolysis of Fluoronitroso-compounds

The pyrolysis and photolysis of fluoronitroso-compounds proceed with dissociation of the C–N bond whose strength in trifluoronitrosomethane corresponds to 31–50 kcal mole^{-1} [102–106].



It has been suggested that in the photolysis of trifluoronitrosomethane the trifluoromethyl radical attacks the oxygen atom of the molecule of the nitroso-compound with [subsequent] formation of an *N*-nitroso-compound whose structure proved to be erroneous[107]:

A mechanism involving the attack of the nitrogen atom by the trifluoromethyl radical with formation of an *N*-nitrite, whose structure was demonstrated, was proposed later[108–109]:



Masson[103] suggested that another primary step is also possible, in which the trifluoronitrosomethane molecule passes to an excited triplet state:

Since *N*,*N*-difluoro(trifluoromethyl)amine (CF_3NF_2) was not found among the products obtained on irradiation of trifluoronitrosomethane in the presence of tetrafluorohydrazine (N_2F_4), it was also concluded that there is no primary photodissociation of the C–N bond[110].

Thermal decomposition of trifluoronitrosomethane results in the formation of only trifluoronitromethane and low-molecular-weight decomposition products[111]. The following mechanism has been proposed to explain this:

or overall:

$$4CF_3{-}NO \xrightarrow{\Delta} 2CF_3{-}NO_2 + N_2 + 2\dot{C}F_3 \text{ (in the form of } CO_2 + SiF_4) .$$

Apart from trifluoronitromethane, tris(trifluoromethyl)-hydroxylamine and a polymeric product $(-CF_2{-}NF-)_n$ were isolated from the products of the pyrolysis of trifluoro-nitrosomethane at 250–300 °C:[112]

$$CF_3{-}NO \xrightarrow{250-300^\circ} \begin{cases} \longrightarrow \dot{N}O + \dot{C}F_3 \xrightarrow{CF_3NO} CF_3{-}\underset{CF_3}{N}{-}\dot{O} \xrightarrow{\dot{C}F_3} CF_3{-}\underset{CF_3}{N}{-}OCF_3 \\ \xrightarrow{CF_3NO} CF_3{-}NO_2 + [CF_3{-}\ddot{N}] \rightarrow CF_2{=}NF \rightarrow (-CF_2{-}NF-)_n . \end{cases}$$

On pyrolysis, higher homologues of trifluoronitrosomethane give rise to fluoroazomethines together with nitroalkanes[41,55,112,113]. Two mechanisms have been proposed to account for this finding[41,112]:

$$\text{a) } R_F{-}CF_2{-}NO \xrightarrow{\Delta} R_F\dot{C}F_2 + \dot{N}O ;$$

$$R_FCF_2{-}NO \xrightarrow{R_F\dot{C}F_2} R_FCF_2{-}\underset{\dot{O}}{N}{-}CF_2R_F \rightarrow R_F{-}CF{=}N{-}CF_2R_F +$$

$$+ \dot{O}F \xrightarrow{R_F\dot{C}F_2NO} R_FCF_2{-}NO_2 + \dot{F} \xrightarrow{R_F\dot{C}F_2} R_F{-}CF_3 ;$$

$$\text{(b) } (CF_3)_2CF{-}NO \xrightarrow{\Delta} (CF_3)_2\dot{C}F + \dot{N}O$$

$$(CF_3)_2CF{-}NO \xrightarrow{(CF_3)_2\dot{C}F} (CF_3)_2CF{-}\underset{\dot{O}}{N}{-}CF(CF_3)_2 \xrightarrow{\dot{N}O} (CF_3)_2CF{-}\underset{ONO}{N}{-}CF(CF_3)_2 \rightarrow$$

$$\rightarrow (CF_3)_2CF{-}\dot{N}{-}CF(CF_3)_2 + \dot{O}NO \rightleftarrows \dot{N}O_2$$

$$\xrightarrow[-RF]{\downarrow \dot{R}} (CF_3)_2C{=}N{-}CF(CF_3)_2 \qquad \xrightarrow{\downarrow (CF_3)_2\dot{C}F} (CF_3)_2CF{-}ONO \qquad \xrightarrow{\downarrow (CF_3)_2\dot{C}F} (CF_3)_2CF{-}NO_2$$

$$(CF_3)_2C{=}\dot{O} + F{-}NO ;$$

$\dot{R}$ = iso-$\dot{C}_3F_7$, $\dot{N}O$, $\dot{N}O_2$.

The first mechanism[112] gives rise to major doubts. It was shown later that trifluoronitrosomethane can produce on pyrolysis not only fluoroazomethines, like its higher homologues, but also hexafluoroazomethane[114]:

$$2CF_3{-}NO \longrightarrow CF_3{-}\underset{CF_3}{N}{-}ONO \longrightarrow CF_3{-}N{=}CF_2 + F{-}NO_2$$

$$\xrightarrow{SiO_2} NO_2 + SiF_4;$$

$$2CF_3{-}NO \longrightarrow \begin{matrix} CF_3{-}N{-}\dot{O} \\ | \\ CF_3{-}N{-}\dot{O} \end{matrix} \xrightarrow{2CF_3NO} \begin{matrix} CF_3 \\ | \\ CF_3{-}N{-}O{-}N{-}\dot{O} \\ | \\ CF_3{-}N{-}O{-}N{-}\dot{O} \\ | \\ CF_3 \end{matrix} \longrightarrow$$

$$\longrightarrow CF_3{-}N{=}N{-}CF_3 + 2CF_3NO_2;$$

$$CF_3{-}NO \xrightarrow{2NO} \begin{matrix} CF_3{-}N{-}O \\ | \quad | \\ N \quad N \\ \| \quad \| \\ O \quad O \end{matrix} \longrightarrow CF_3{-}N{=}N{-}ONO_2$$

$$\xrightarrow[-\dot{O}NO_2]{} CF_3{-}N{=}\dot{N} \xrightarrow{\dot{C}F_3} CF_3N{=}NCF_3.$$

On the basis of these data, it was concluded that trifluoro-nitrosomethane can be pyrolysed via the "diazonium nitrate",[111] via the dimer $(CF_3)_2N{-}ONO$,[108] and via the Andreades mechanism[41]. On thermal decomposition of α-chlorofluoronitroso-compounds[48,115], the products of the substitution of the nitroso-group by a chlorine atom were isolated together with nitroso-compounds:

$$ClCF_2{-}CFCl{-}NO \xrightarrow{\Delta} ClCF_2{-}\dot{C}FCl + \dot{N}O ;$$

$$ClCF_2{-}CFCl{-}NO \xrightarrow{\dot{N}O} ClCF_2{-}CFCl{-}NO_2 + {}^1/_2 N_2 ;$$

$$ClCF_2{-}\underset{Cl}{CF}{-}NO \xrightarrow{ClCF_2{-}\dot{C}FCl} [ClCF_2{-}\dot{C}F{-}NO] + ClCF_2{-}CFCl_2 .$$

A study has been published recently[116] in which the compositions of the pyrolysis and photolysis products of perfluoronitrosopropane were compared. Photolysis results in a more complex mixture of decomposition products:

$$C_3F_7{-}NO \xrightarrow[24\ h]{80^\circ} \underset{(72\%)}{C_3F_7{-}N{=}CF{-}C_2F_5} + \underset{(11\%)}{C_3F_7{-}NO_2} + \underset{(7\%)}{(C_3F_7)_2N{-}OC_3F_7} ;$$

$$C_3F_7{-}NO \xrightarrow[18\ h]{u.v.} \left.\begin{matrix} (C_3F_7)_2N{-}ONO \\ (C_3F_7)_2N{-}NO_2 \end{matrix}\right\} (30\%) + \begin{matrix} (C_3F_7)_2N{-}OC_3F_7 \\ (<30\%) \\ (C_3F_7)_2N{-}C_3F_7 \\ (<30\%) \\ (C_3F_7)_2N{-}N(C_3F_7)_2 \\ (<30\%) \end{matrix} .$$

In the catalytic fluorination of trifluoronitrosomethane[117] there is also a possibility of radical decomposition processes:

$$CF_3{-}NO \xrightarrow{F_2} CF_3{-}\underset{CF_3}{N}{-}OCF_3 + CF_3{-}\underset{F}{N}{-}OCF_3 .$$

An increase of the decomposition temperature of trifluoro-nitrosomethane from 30° to 170 °C in the presence of silver difluoride and of silver difluoride with a simultaneous supply of fluorine increases the yield of tris(trifluoromethyl)-hydroxylamine from 0 to 15% in the former case and reduces the yield from 55 to 7% in the latter case[118]:

$$CF_3{-}NO \xrightarrow{AgF_2} (CF_3)_2N{-}OCF_3 \xleftarrow[F_2]{AgF_2} CF_3{-}NO .$$

6. Interaction of Fluoronitroso-compounds with Radicals

(a) Interaction with Nitric Oxide

Trifluoronitrosomethane reacts with liquid nitric oxide[111] even at −100 °C with formation of trifluoronitromethane, *N*-bis(trifluoromethyl)ammonium nitrite, and nitrogen. In the gas phase the same products are formed much more slowly. A mechanism has been proposed with the intermediate formation of "diazonium nitrate":[111]

$$CF_3{-}NO \xrightarrow{2NO} \left[CF_3{-}\underset{N}{\overset{O}{N}} \longrightarrow CF_3{-}N{=}N{-}ONO_2 \right] \longrightarrow$$

$$\longrightarrow \dot{C}F_3 + N_2 + \dot{O}NO_2 \xrightarrow{\dot{N}O} 2\dot{N}O_2;$$

$$\dot{C}F_3 + \dot{N}O_2 \longrightarrow CF_3{-}NO_2;$$

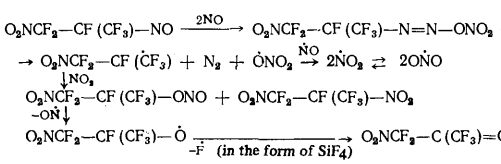
$$CF_3{-}NO \xrightarrow{\dot{C}F_3} (CF_3)_2N{-}\dot{O} \xrightarrow{\dot{N}O} (CF_3)_2N{-}ONO;$$

or overall:

$$3CF_3NO + 3NO \rightarrow CF_3NO_2 + (CF_3)_2N{-}ONO + NO_2 + N_2.$$

Later it was possible to detect the intermediate adduct of two nitric oxide molecules with a trifluoronitrosomethane molecule[119]:

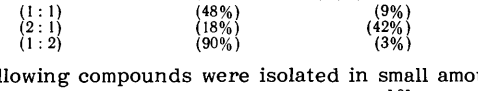
$$CF_3{-}NO + 2NO \xrightarrow{-100^\circ} CF_3{-}\underset{N}{\overset{O}{N}} \xrightarrow{-50^\circ} \dot{C}F_3 + N_2 + \dot{O}NO_2 ;$$



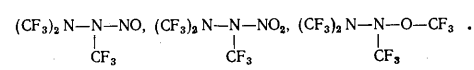
$$CF_3{-}NO + 2NO \xrightarrow{-100^\circ} CF_3{-}\underset{N}{\overset{O}{N}} \xrightarrow[CH_3ONa]{} CF_3{-}\underset{N}{N}{-}ONa + CH_3O{-}NO$$

$$CF_3{-}\underset{N}{\overset{O}{N}} \xrightarrow{2HN(C_2H_5)_2} CF_3{-}\underset{N}{N}{-}OH \cdot HN(C_2H_5)_2 + ON{-}N(C_2H_5)_2 .$$

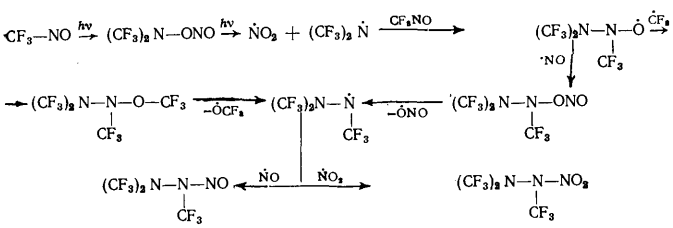
Ginsburg et al.[119] claim reasonably that nitric oxide cannot attack trifluoronitrosomethane via a radical mechanism, since radical species were not detected by EPR at temperatures corresponding to the formation of the colourless adduct. A different pathway leading to the formation of this adduct was therefore proposed—via a complex of the trifluoronitrosomethane molecule with two nitric oxide molecules, which is stabilised as a result of electron transfer within the complex without the liberation of free radicals:



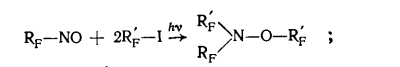
Apart from the dinitro-compound, an α-nitroketone is formed on interaction of 1-nitro-2-nitrosoperfluoropropane with nitric oxide[65]:



(b) Interaction with Fluoroalkyl and Other Radicals

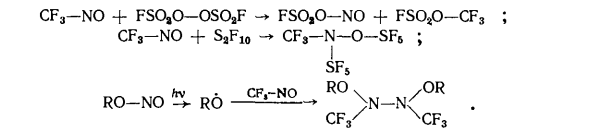


When trifluoronitrosomethane reacted with the trifluoromethyl radical, generated photochemically from trifluoroiodomethane[120,121], *N*-bis(trifluoromethyl)ammonium nitrite and tris(trifluoromethyl)hydroxylamine were obtained. The ratio of the initial reactants does not influence the ratio of the reaction products:



The following compounds were isolated in small amounts from the mixture of products of this reaction[121]:

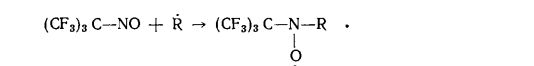
In order to explain their formation, the mechanism



was put forward. Analogous reactions lead to both homogeneous and mixed hydroxylamines[113,122]:

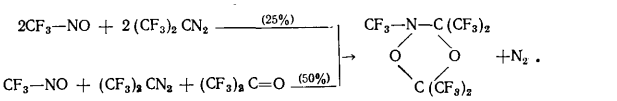
A number of studies have been devoted to the interaction of trifluoronitrosomethane with the trifluoromethyl radical, generated in different ways—by the pyrolysis of trifluoroacetyl nitrite[123], by the photolysis of hexafluoroazomethane[124], and by the photolysis of hexafluoroacetone[15].

Trifluoronitrosomethane reacts also with other substances which are readily converted into radicals[125–127]:

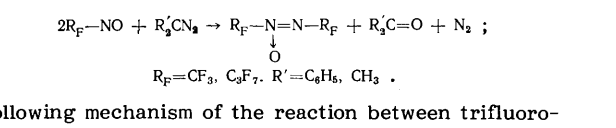


(c) Fluoronitroso-compounds as Radical-trapping Agents

On interaction with radicals, certain fluoronitrosoalkanes form relatively long-lived nitroxy-radicals which can be detected by EPR:[128,129]

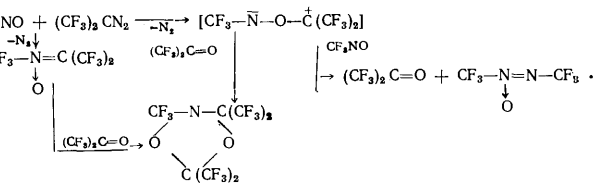


By virtue of this property, perfluoronitroso-t-butane has found applications[129–132] as a spin-trapping agent for long-lived radicals:

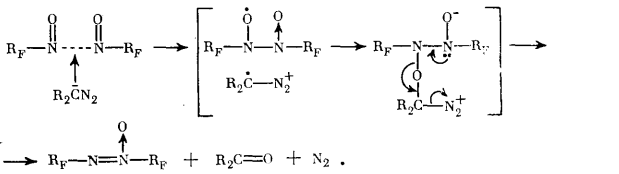


(d) Interaction With Carbenes

On interaction with bis(trifluoromethyl)azomethane, trifluoronitrosomethane gives rise to a cyclic product[133]:



The authors suggested that hexafluoroacetone is formed as an intermediate, because the yield of the dioxazolidine increases by a factor of two when hexafluoroacetone is added to a mixture of trifluoronitrosomethane and bis(trifluoromethyl)diazomethane.



Later, other workers[134] confirmed this hypothesis also by the observation that the interaction of trifluoronitrosomethane with diphenyl- and dimethyl-diazomethanes results in the formation of a dialkyl ketone:

The following mechanism of the reaction between trifluoronitrosomethane and bis(trifluoromethyl)diazomethane has been suggested:

The authors believe that, when other diazoalkanes [Ph_2CN_2, $(CH_3)_2CN_2$] are used in this reaction, a nitrone is not formed and suggest a mechanism with charge transfer (at low temperatures in the condensed phase):

Mixed fluoroazoxyalkanes were obtained in the same study[134]:

$$CF_3{-}NO + C_3H_7{-}NO + R_2CN_2 \rightarrow CF_3{-}\underset{\downarrow}{N}{=}N{-}C_3F_7 + CF_3{-}\underset{\downarrow}{N}{=}N{-}C_3F_7 \ .$$
$$O \qquad\qquad O$$

On reaction with diphenyldiazomethane, perfluoronitroso-t-butane gives rise to oxaziridine[135], while other fluoronitroso-alkanes react with diazoalkanes to form copolymers[136,137]:

$$(CF_3)_3C{-}N{=}O + Ph_2CN_2 \rightarrow (CF_3)_3C{-}\underset{\diagdown\ \diagup}{N}\!\!-\!\!O + N_2 \ ;$$
$$CPh_2$$
$$R_F{-}NO + X{-}CHN_2 \rightarrow (-\underset{R_F}{\underset{|}{N}}{-}O{-}\underset{X}{\underset{|}{CH}}{-})_n + N_2 \ ;$$
$$R_F{=}CF_3,\ C_3F_7;\ X{=}H,\ CF_3 \ .$$

Methylisonitrile deoxygenates trifluoronitrosomethane with formation of a carbodi-imide[138]:

$$CF_3{-}NO + \ddot{C}{=}N{-}CH_3 \xrightarrow[-O{=}C{=}N{-}CH_3]{} [CF_3{-}\ddot{N}] \xrightarrow{\ddot{C}{=}N{-}CH_3} CF_3{-}N{=}C{=}N{-}CH_3 \ .$$

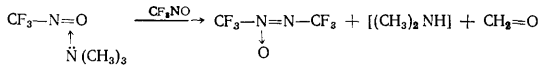
(e) Substitution of the Nitroso-Group

Substitution of the nitroso-group by a halogen. The low energy of the C–N bond in fluoronitroso-compounds promotes easy substitution of the nitroso-group. This was first observed[115] in the thermal decomposition of 1,2-dichlorotrifluoronitrosoethane (see above). The nitroso-group is readily substituted on interaction of secondary and tertiary fluoronitrosoalkanes with halogens[76,140]:

$$\begin{matrix} CF_3 \\ FSO_2 \end{matrix}\!\!>\!CF{-}NO \xrightarrow{Br_2} \begin{matrix} CF_3 \\ FSO_2 \end{matrix}\!\!>\!CF{-}Br + BrNO \ ;$$
$$(CF_3)_3C{-}NO \xrightarrow{X_2} (CF_3)_3C{-}X + X{-}NO \ ;$$
$$X{=}Cl,\ Br,\ I \ .$$

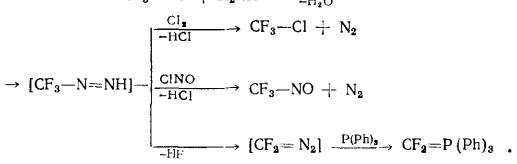
It is of interest that the substitution of the nitroso-group in 2-chloro-trifluoro-1-nitro-2-nitrosoethane[140] occurs only on treatment with chlorine, while treatment with bromine and iodine results in the formation of a dichloro-compound, which is a disproportionation product of the initial nitrosoalkane:

$$O_2N{-}CF_2{-}CFCl{-}NO \xrightarrow{Cl_2} O_2N{-}CF_2{-}CFCl_2 + Cl{-}NO \ .$$



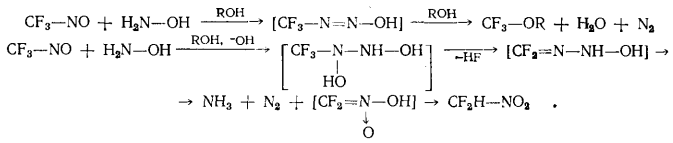
The formal substitution of the nitroso-group by a hydrogen atom takes place on hydrolysis and alcoholysis of alkyl hexafluoro-2-nitrosobutyrates[74,141] and (hexafluoroisopropyl-2-nitroso)diethyl phosphate[68] and on interaction of perfluoronitroso-t-butane with *N,N*-dimethylaniline, aniline, or ethanol[140]:

$$\begin{matrix} X \\ CF_3 \end{matrix}\!\!>\!\underset{\underset{N=O}{|}}{C}{-}C(O)OR \xrightarrow{H_2O(C_2H_5OH)} \begin{matrix} X \\ CF_3 \end{matrix}\!\!>\!\underset{\underset{H}{|}}{C}{-}C(O)OR \ ;$$
$$X{=}CF_3;\ C(O)OR$$
$$(C_2H_5O)_2P{-}O{-}\underset{\underset{N=O}{|}}{C}(CF_3)_2 \xrightarrow{H_2O(C_2H_5OH)} (C_2H_5O)_2P{-}O{-}\underset{\underset{H}{|}}{C}(CF_3)_2 \ ;$$
$$(CF_3)_3C{-}N{=}O{-}\begin{cases} H{-}\langle\!\rangle{-}NX_2 \rightarrow O{=}N{-}\langle\!\rangle{-}NX_2 \\ H{-}OC_2H_5 \rightarrow O{=}N{-}OC_2H_5 \end{cases} + (CF_3)_3C{-}H \ ;$$
$$X{=}H;\ CH_3.$$

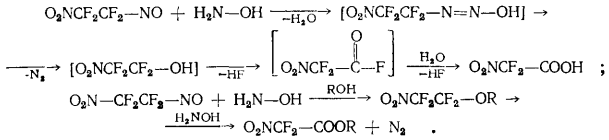


Interaction with tetrafluorohydrazine. On interaction with tetrafluorohydrazine, the nitroso-group is substituted only in tertiary fluoronitroso-compounds[142–144], in which the dissociation energy of the C–N bond is lowest:

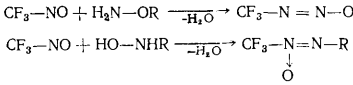
$$\begin{matrix} CF_3 \\ CF_3{-}C{-}NO \\ R \end{matrix} \xrightarrow{N_2F_4} \begin{matrix} CF_3 \\ CF_3{-}C{-}NF_2 \\ R \end{matrix} + \begin{matrix} CF_3 \\ CF_3{-}C{-}N{=}NF \\ R \end{matrix}\!\!\!



results in the formation of hexafluoroazoxymethane:

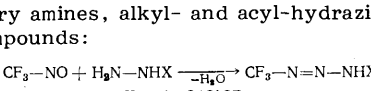


The reaction of trifluoronitrosomethane with ammonia[150] leads to an unstable azo-compound, whose formation has been demonstrated by chemical transformations:

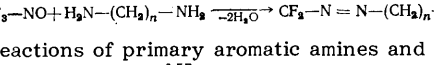


The interaction of trifluoronitrosomethane with hydroxylamine in an alcoholic medium leads to the formation of alkyl trifluoromethyl ether, while the product in an alcoholic alkaline medium is difluoronitromethane[150]:

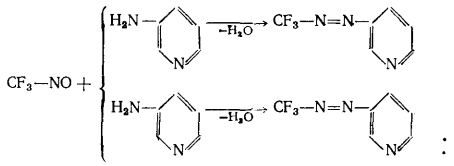
Tetrafluoro-1-nitro-2-nitrosoethane is decomposed by hydroxylamine to difluoronitroacetic acid[153], while in an alcoholic medium the alkyl ester of the acid is formed:



The reactions of trifluoronitrosomethane with *O*-alkylhydroxylamines[150] result in the formation of azo-compounds, while the reactions with *N*-alkylhydroxylamines[154] yield azoxy-compounds:

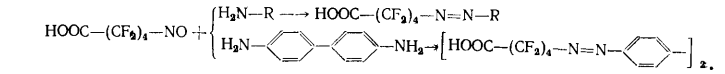


Hydrazine reacts with trifluoronitrosomethane[150,155] to form an unstable azo-compound, which decomposes under the influence of chlorine to trifluoromethyl azide:

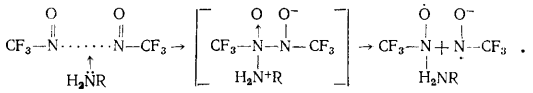


Like primary amines, alkyl- and acyl-hydrazines form aminoazo-compounds:

Trifluoronitrosomethane reacts with diamines[156] to form bisazo-compounds;

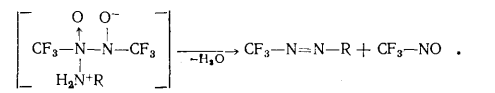


The reactions of primary aromatic amines and diamines with trifluoronitrosomethane[157] also yield azo- and bisazo-compounds respectively. 2-Aminopyridine and 3-aminopyridine[158] react with trifluoronitrosomethane to give azo-derivatives, while 4-aminopyridine does not react with trifluoronitrosomethane:

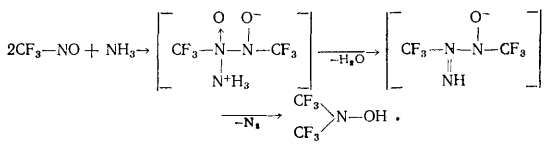


Electron-accepting groups in the α-position with respect to the amino-group [$(H_2N)_2C{=}O$, H_2NCOOH] lower the nucleophilicity of such amines and prevent their reaction with trifluoronitrosomethane[159].

Electron-accepting groups in the β-position with respect to the amino-group ($H_2N{-}CR^1R^2{-}COOR$) do not prevent the formation of the azo-compound[160,161]. *p*-Aminobenzoic acid also enters into this reaction[162].

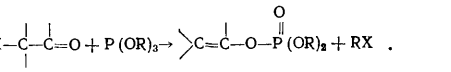


Carboxylic α,ω-fluoronitrosoacids[163] react with amines and diamines to form azo- and bisazo-compounds respectively:

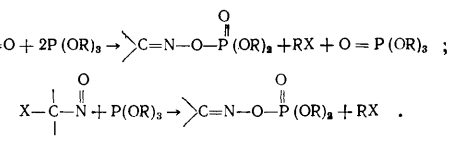


Radical-ions, formed via a charge-transfer complex, have been detected by EPR in the interaction of trifluoronitrosomethane with amines at low temperatures[164,165]:

On this basis, the following mechanism of the interaction of amines with trifluoronitrosomethane has been proposed[165]:

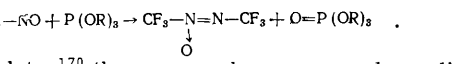


The suggested mechanism for the reaction of trifluoronitrosomethane with ammonia is

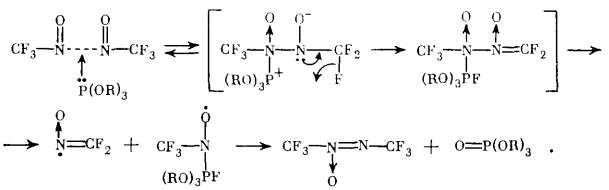


(b) Interaction with Phosphorous Acid Esters and Phospholans

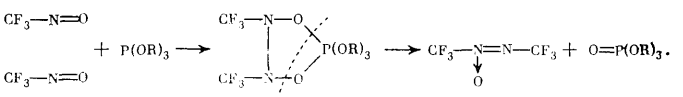
The analogy between the nitroso-group and the carbonyl group is manifested strikingly also in the reactions of nitrosoalkanes with phosphorus acid esters. The Perkow reaction between α-halogenocarbonyl compounds and trialkyl phosphites is widely known[166–168]:



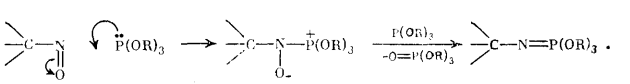
Allen[169] showed that geminal halogenonitro- and halogenonitroso-alkanes react analogously, forming the phosphates of



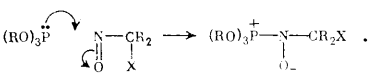
the corresponding oximes:



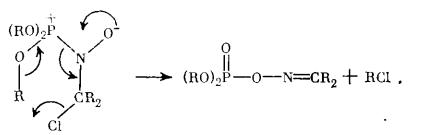
The first fluoronitroso-compound investigated in the reaction with phosphites was trifluoronitrosomethane[86]:



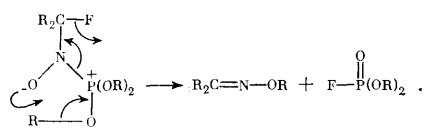
Several years later[170] the same workers proposed a radical-ion mechanism for this reaction on the basis of an EPR study:



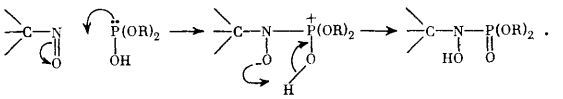
By analogy with hexafluoroacetone[171], the possibility of another version has been suggested[144]:



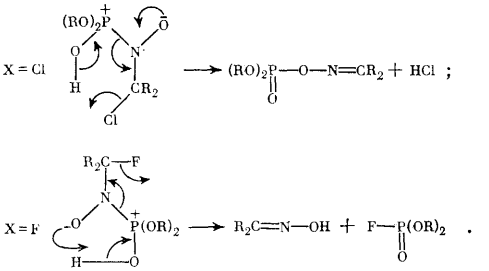
A number of general features have been established in studies of the interaction of fluoronitroso-compounds with phosphite esters[172-174]. The first step in the reaction is attack by the phosphorus atom on the nitrogen atom. Neutral phosphites react with tertiary fluoronitrosoalkanes to form phosphazo-compounds:



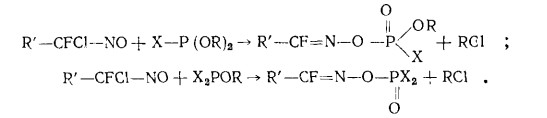
The interaction of fluoro-α-halogenonitrosoalkanes involves the intermediate formation of the *O*-anion of a hydroxylamine, whose subsequent fate depends on the nature of the halogen X:



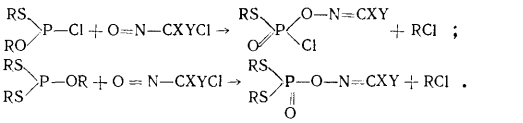
When X = Cl, the alkyl chloride is split off with formation of the products of the Allen reaction:



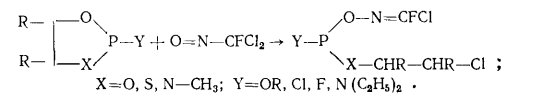
When X = F, the fluoro-oxime group acquires "pseudo-halogen" properties as a result of the high strength of the P–F bond and is split off with the alkyl group:



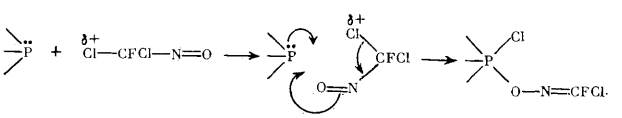
Trifluoronitrosomethane and perfluoronitroso-t-butane react with acid phosphites to form phosphorylated hydroxylamines (similarly to compounds with a carbonyl group[175,176]):



The interaction of fluoro-α-halogenonitrosoalkanes with acid phosphites results in the formation of the *O*-anion of a hydroxylamine, which splits off hydrogen chloride in the presence of a chlorine in the α-position and an oxime in the presence of a fluorine atom:

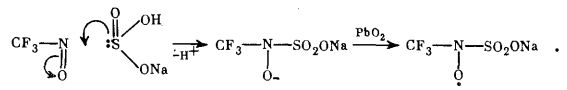


Similar reactions have been achieved with various α-chloronitrosoalkanes and halogenoalkyl phosphites[177]. In this case the products of the Allen reaction are also formed:

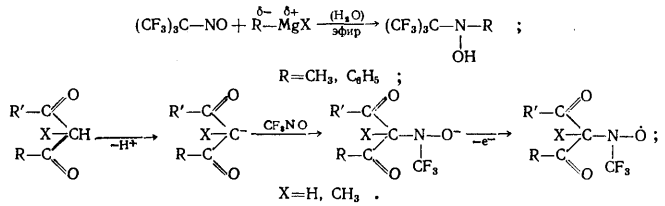


It has likewise been established that, when the alkyl halide is split off in the Allen reaction, the alkyl group is abstracted only from the alkoxy-group and not the thioalkoxy-group:

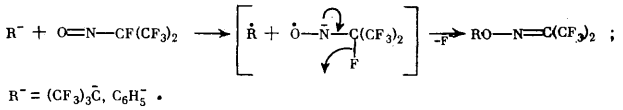
In subsequent studies[178-181] it was shown that phospholans containing at least one oxygen atom at the phosphorus atom can also enter into the Allen reaction with α-chlorofluoronitroso-compounds:



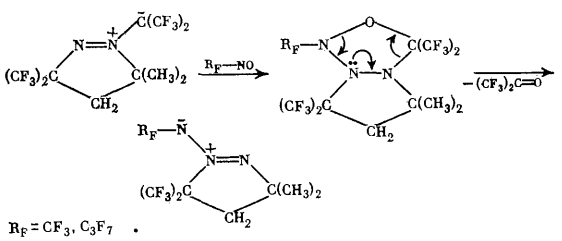
Having surveyed the available experimental data, Maleikin et al.[182] proposed a mechanism for the Allen reaction which we believe to be unlikely; it involves initial attack by the unshared electron pair of the phosphorus atom on the positively polarised chlorine atom (cf. Dyatkin et al.[174]):



(c) Interaction with Other Nucleophiles

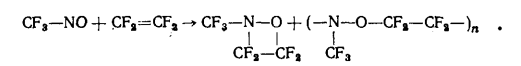


Like carbonyl compounds[183], trifluoronitrosomethane combines with sodium bisulphite[184]:



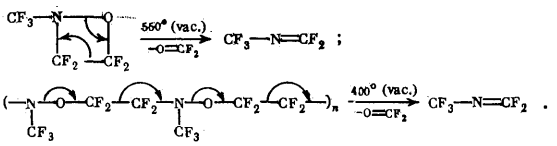
When nitrosoperfluoroalkanes were allowed to react with Grignard reagents[185] and α-diketones[186], the products of the attack by the carbanion on the nitrogen atom of the nitroso-compound were obtained:

It has been reported[187] that carbanions can attack also the oxygen atom in 2-nitrosoperfluoropropane:



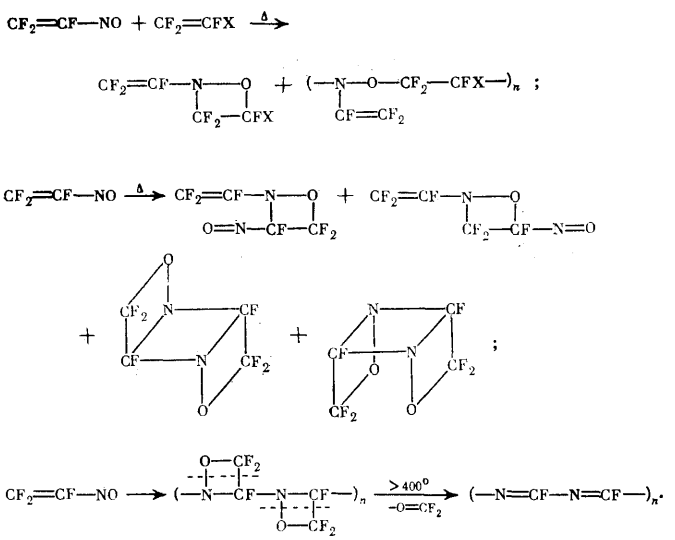
It may be that such interaction also takes places with other carbanions[188]:

8. Reactions with Unsaturated Compounds



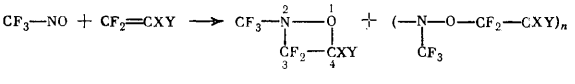
(a) Interaction with Fluoro-olefins

The development of the chemistry of fluoronitroso-compounds is perhaps most closely related to the discovery of the reaction of fluoronitrosoalkanes with fluoro-olefins from whose products copolymers with unique properties were isolated. The interaction of trifluoronitrosomethane with tetrafluoroethylene was first investigated by Barr and Haszeldine[189] in 1955:

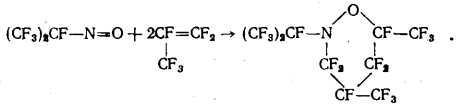


Later it was established that other fluoronitroso-compounds ($O_2NCF_2CF_2NO$,[54,190] C_2F_5NO, and $ClCF_2NO$ [46]) and fluoro-olefins ($CF_2=CFH$,[191-193] $CF_2=CFCL$,[193] $CF_2=CF-CFCl-CF_2CL$,[194] and $CF_2=CF-COF$ [195]) react analogously.

The ability of the copolymers and the oxazetidines formed simultaneously to produce on pyrolysis fluoroazomethines (in particular perfluoro-2-azapropane), with unusual chemical properties and high reactivity, whose chemistry is still being investigated, constitutes a very important property:

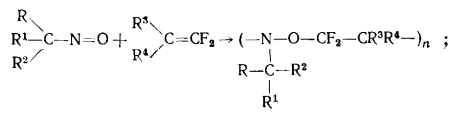


Trifluoronitrosoethylene has very interesting properties, which are a combination of those of a nitrosoalkane and a fluoro-olefin[10,196,197]. This fluoronitrosoalkene reacts with both fluoro-olefins and with itself, forming oxazetidines, polymers, and bicyclic compounds:



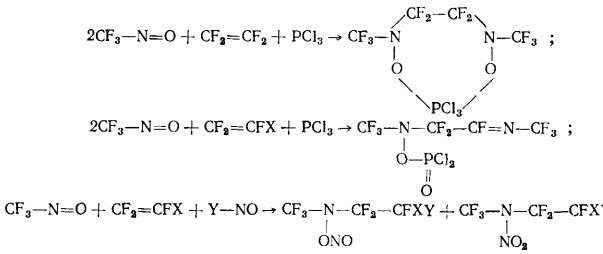
The interactions of fluoronitrosoalkanes with fluoro-olefins have a number of characteristic features.

1. At room temperature and below, a copolymer is formed preferentially, while on raising the temperature to 100 °C, the main product becomes an oxazetidine[46,54,58,189,191,194,196].

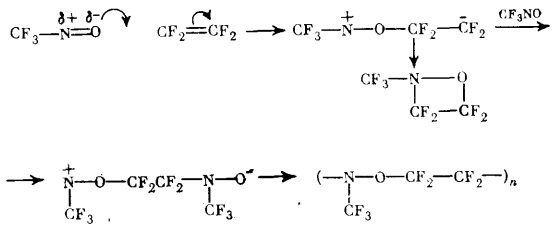


2. The interaction of fluoronitroso-compounds with asymmetric fluoro-olefins involves different modes of addition[111]. When an oxazetidine is formed, the difluoromethylene group of the olefin adds to the nitrogen atom, while on formation of a copolymer it adds to the oxygen atom:

3. Steric factors exert a significant influence on the formation of the oxazetidine[41,111]. The branching of the alkyl group of the fluoronitrosoalkane hinders the formation of the oxazetidine to a lesser extent than the branching in the fluoro-olefin. If only one of the reactants in the interaction of a fluoronitrosoalkane with a fluoro-olefin is branched in the fluorocarbon chain, an oxazetidine with a substituent predominantly in the 4-position is formed[41,65,111]. If both reactants are branched, an oxazetidine is not formed. Only in one instance has it been possible to obtain a cyclic product in the reaction of a branched fluoronitrosoalkane with a substituted fluoroethylene[198]:

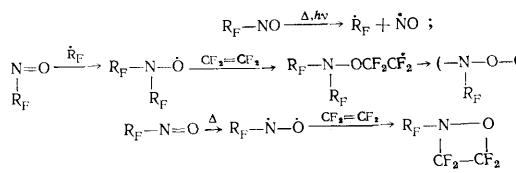


It is of interest that non-fluorinated nitroso-t-alkanes give rise to copolymers with both unsubstituted and substituted fluoro-olefins[199,200]:



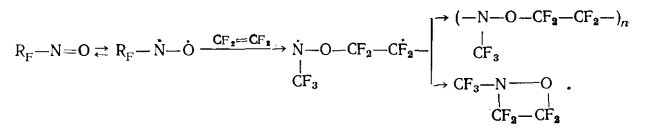
R, R^1, R^2 = alkyl, aryl, cycloalkyl; R^3, R^4 = F, Cl, H .

The introduction of hydrogen atoms into the tetrafluoroethylene molecule diminishes the reactivity with respect to trifluoronitrosomethane and prevents the formation of an oxazetidine[192].

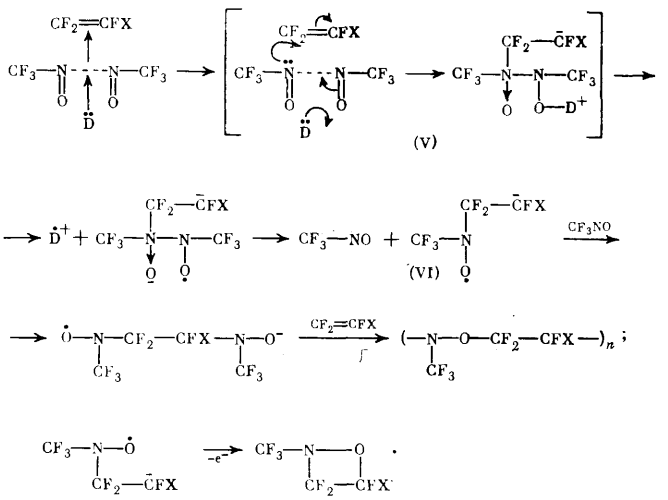


When trifluoronitrosomethane reacts with tetrafluoroethylene in the presence of phosphorus trichloride, cyclic and linear derivatives of phosphoric acid are formed, while in the presence of nitrosyl chloride or nitrogen trioxide the products are *N*-nitrites and *N*-nitro-compounds[22,201-203]:

A unanimous view on the mechanism of the reactions of fluoronitrosoalkanes with fluoro-olefins has not yet been established. An ionic mechanism was proposed initially[189]



Later the same workers replaced it by a radical mechanism[7]:



The following facts have been adduced in favour of the radical mechanism. Irradiation of the reaction mass with ultraviolet light or addition of t-butyl peroxide doubles the polymer : oxazetidine ratio. The addition of hydroquinone lowers by a factor of 2 the rate of reaction and diminishes by a factor of 8 the polymer: oxazetidine ratio.

Crawford and co-workers[193-204] also reject the ionic mechanism on the grounds that the copolymerisation takes place in an aqueous medium in the presence of classical deactivators of carbanions such as CO_2, BF_3 etherate, and $TlCl_4$ and that the presence of radical chain-transfer agents diminishes the molecular weight of the copolymer. However, they claim that the radical process is not initiated with homolytic dissociation of the C–N bond but takes place with formation of radicals arising on interaction of the fluoro-olefin with the fluoronitrosoalkane, which passes to the triplet state at the copolymerisation temperature:

The study of mixtures of trifluoronitrosomethane with various fluoro-olefins[205-207] by EPR led to the detection of paramagnetic species, which were assumed to be of the radical-ion type. Having failed to detect biradical species, whose existence had been predicted by Haszeldine and Crawford (see above), Ginsburg et al.[206] rejected the radical mechanism and proposed a radical-ion mechanism according to which a molecule of trifluoronitrosomethane, enriched by an electron donor (the OH^- species present in solution, metal ions, or the nuclophilic solvent), attacks the positively polarised difluoromethylene group of the fluoro-olefin with formation of a radical-ion, which enters into further reactions:

It was established by low-temperature thermography[207] that the formation of associated species (V) on reaction with the electron-donating medium occurs at temperatures between -130 ° and -80 °C with evolution of heat. The radical-ions (VI) are produced at higher temperatures. An electron-donating medium promotes the appearance of paramagnetic species at lower temperatures than in perfluorinated solvents or in the absence of solvents.

The size of the substituent in the fluoro-olefin does not influence significantly the ease of the above reactions. Nor is there a clear-cut correlation between the inductive influence of the substituent and the temperature at which the radical-ion is formed[207].

A detailed study of the kinetics of the copolymerisation of trifluoronitrosomethane and tetrafluoroethylene[208] again confirmed the hypothesis of the radical mechanism of the copolymerisation reaction. It was shown that the rate of formation of the copolymer obeys the equation

$$\partial [C]/\partial t = K_1 [CF_3{-}NO]^{3/2} [CF_2 = CF_2] \ .$$

This equation is also valid for the gas phase and for a homogeneous solution in fluorocarbon solvents at temperatures between -36° and -80 °C with different ratios of the initial reactants. On the basis of this equation, the possibility of a 1 : 1 complex of the monomers is rejected, since the rate of

formation of the copolymer would then have been proportional to $[CF_3NO]^{1/2}$, and the following mechanism is proposed:

$$3CF_3{-}NO \rightarrow \dot{R}^1 + \dot{R}^2$$
$$\dot{R}^1 + CF_2{=}CF_2 \rightarrow R^1{-}CF_2\dot{C}F_2,\ \dot{R}^2 + CF_2{=}CF_2 \rightarrow R^2{-}CF_2\dot{C}F_2\ ;$$

for chain initiation,

$$R{-}CF_2\dot{C}F_2 + \underset{\underset{CF_3}{|}}{N}{=}O \rightarrow R{-}CF_2CF_2{-}\underset{\underset{CF_3}{|}}{N}{-}\dot{O} \xrightarrow{CF_2=CF_2} R{-}CF_2CF_2{-}\underset{\underset{CF_3}{|}}{N}{-}O{-}CF_2\dot{C}F_2\ .$$

for chain propagation, and

$$2\,(R^1{-}\underset{\underset{CF_3}{|}}{N}{-}\dot{O}) \rightarrow \text{copolymer}$$

for chain termination. This mechanism requires a steady-state concentration of the radicals proportional to $[CF_3NO]^{3/2}$, which agrees with experiment. It has been suggested that the chain propagation proceeds via the interaction of $R^1{-}\underset{\underset{CF_3}{|}}{N}{-}\dot{O}$ with tetrafluoroethylene. The presence of this radical has been confirmed rigorously by EPR. The radical $R^1{-}\underset{\underset{CF_3}{|}}{N}{-}O{-}CF_2{-}\dot{C}F_2$ evidently reacts very rapidly with trifluoronitrosomethane, since it has not been detected in the EPR spectra even in a mixture of trifluoronitrosomethane with an excess of tetrafluoroethylene. The radical-ions mentioned above[207] were not detected in the above study and chain propagation via an ionic mechanism is thought to be unlikely.

In the proposed mechanism[208] the structures of the radicals $\dot{R}^1$ and $\dot{R}^2$ were not established but their concentration is proportional to $[CF_3NO]^{3/2}$, which clearly confirms the three-step initiation mechanism. The rate of formation of these radicals depends greatly on the nature of the solvent, which does not agree with earlier ideas concerning the initiation of the process in the homolysis of the C–N bond in trifluoronitrosomethane. It is also emphasised that the usual radical process initiators do not accelerate the copolymerisation in this instance. However, it has been established that the bis(trifluoromethyl)nitroxy-radical initiates specifically the copolymerisation of trifluoronitrosomethane and tetrafluoroethylene.

Kinetic studies[208,209] of the formation of oxazetidine showed that the rate of its formation obeys the equation

$$\partial[O]/\partial t = K_2[CF_3NO][CF_2{=}CF_2]\ .$$

The authors concluded that this is not a radical-chain process, since the kinetic data are consistent with a four-centre transition state but do not enable one to distinguish between a concerted mechanism and an ionic transition state.

A version of radical initiation was proposed[210] on the basis of the electronic spectra of copolymers of trifluoronitrosomethane and fluoro-olefins and the results of calculations by the INDO SCFMO method. It involves thermal excitation of the trifluoronitrosomethane molecule to the triplet state with subsequent addition of a fluoro-olefin molecule to the nitrogen or oxygen atom:

$$CF_3{-}N{=}O \xrightarrow{\Delta} CF_2{-}\dot{N}{-}\dot{O}\ ;$$

$$CF_3{-}\dot{N}{-}\dot{O} + CF_2{=}CF_2 \begin{cases} \rightarrow \dot{N}{-}O{-}CF_2{-}\dot{C}F_3 \quad (A) \\ \qquad\quad | \\ \qquad\quad CF_3 \\ \rightarrow \dot{O}{-}\underset{\underset{CF_3}{|}}{N}{-}CF_2{-}\dot{C}F_2 \quad (B) \end{cases};$$

$$CF_3{-}N{=}O + \begin{cases} \dot{N}{-}O{-}CF_2{-}\dot{C}F_2 \xrightarrow{CF_2=NO} \dot{N}{-}O{-}CF_2CF_2O{-}\underset{\underset{CF_3}{|}}{N} \quad (C) \\ \quad | \\ \quad CF_3 \quad (A) \\ \qquad\qquad \rightarrow \dot{N}{-}O{-}CF_2CF_2{-}\underset{\underset{CF_3}{|}}{N}{-}O \quad (D) \\ \dot{O}{-}\underset{\underset{CF_3}{|}}{N}{-}CF_2{-}\dot{C}F_2 \xrightarrow{CF_2=NO} \dot{O}{-}\underset{\underset{CF_3}{|}}{N}{-}CF_2CF_2{-}\underset{\underset{CF_3}{|}}{N}{-}\dot{O} \quad (E)\ . \\ \quad | \\ \quad CF_3 \quad (B) \end{cases}$$

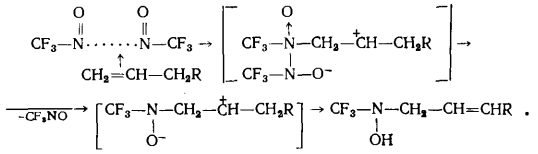
The excitation energy of the trifluoronitrosomethane was estimated as 28 kcal mol^{-1}, which is sufficient for the operation of the proposed mechanism. A regularity was observed in the spectra of the copolymers $(-\underset{\underset{CF_3}{|}}{N}{-}O{-}CF_2{-}CFX)_n$, indicating that, apart from the radical D (which is the main one), there is a possibility of the formation also of other radicals (C and E).

Simultaneously with the studies of Crabtree and co-workers[208,209] and Clark et al.[210], a report was published in 1972 [211] concerning the interaction of trifluoronitrosomethane with fluoro-olefins in a condensed phase in the presence of halogens and sulphur dichloride as copolymerisation initiators:

$$CF_3{-}NO + CF_2{=}CFR \xrightarrow{XX'} X{-}CF_2{-}CFR{-}(-\underset{\underset{CF_3}{|}}{N}{-}O{-}CF_2{-}CFR-)_n{-}X'\ ;$$
$$XX' = Cl_2,\ Br_2,\ I_2,\ SCl_2\ .$$

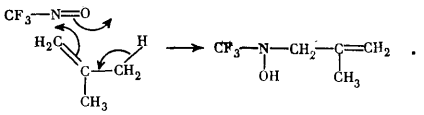
A radical mechanism has been proposed for this reaction. On the basis of the analysis of the EPR spectra, it is claimed that the reaction is initiated by the trifluoromethyl radical arising from a charge-transfer complex in which the halogen molecule functions as the donor.

However, the authors[211] claim that this is a special case and that in general the copolymerisation of trifluoronitrosomethane with fluoro-olefins takes place via an ionic and not a radical mechanism and the latter is possible only under special conditions (for example, in the presence of halogens). Thus the problem of the mechanism of the interaction of fluoronitrosoalkanes with fluoro-olefins has still not been ultimately resolved at the present time but one should note that the evidence for radical copolymerisation is fairly convincing.

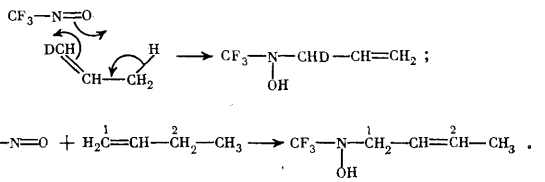


(b) Interaction with Perfluoro-olefins

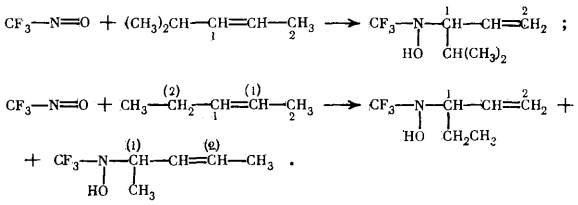
Between 1962 and 1974, experimental data were accumulated on the interaction of trifluoronitrosomethane with various alkenes[138,205,212–214]. It was found that non-fluorinated olefins have only partially the same properties as their fluorinated analogues in relation to fluoronitrosoalkanes. Among all the alkenes investigated, only styrene[138], vinyl acetate[205], and methyl acrylate[214] react with trifluoronitrosomethane to form oxazetidines, while only ethylene[192] forms a copolymer by reaction with trifluoronitrosomethane with a yield of 75% in 22 months at 20 °C.



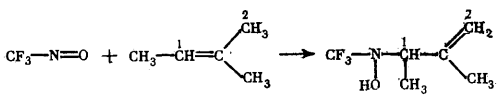
All other olefins form alkenyltrifluoromethylhydroxylamines on reaction with trifluoronitrosomethane:



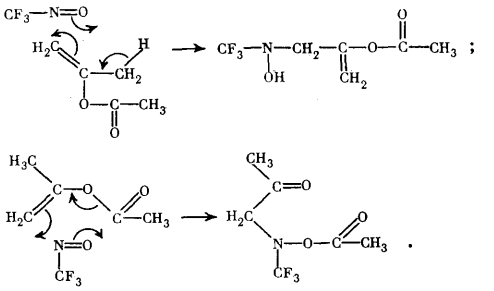
A mechanism postulating the intermediate formation of donor–acceptor charge-transfer complexes was proposed for these reactions[215]:



Haszeldine and co-workers[212] proposed a mechanism for the interaction of trifluoronitrosomethane with isobutene involving nucleophilic attack by a carbon atom in the unsaturated bond on the nitrogen atom of the fluoronitrosoalkane:

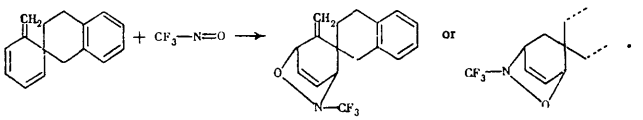


Subsequently they developed this mechanism in greater detail. It was shown in relation to 20 alkenes that in these reactions the C(1) carbon atom attacks the nitrogen atom of trifluoronitrosomethane and that hydrogen is transferred from C(2) to the oxygen atom[216]†:

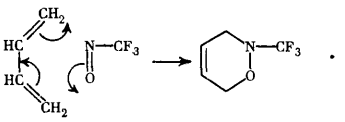


Allyl hydrogen is transferred from the least substituted carbon atom:

The least substituted carbon atom in the unsaturated bond attacks the nitrogen atom:

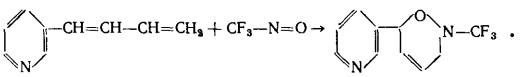


Attack on the nitrogen atom of trifluoronitrosomethane by the methylene group of isopropenyl acetate leads to the formation of two products:

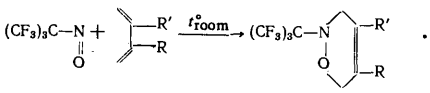


(c) Interaction with Dienes

Trifluoronitrosomethane is one of the most reactive dienophiles in Diels–Alder reactions[217]. This was first observed when the [2 + 4] cyclic adduct of trifluoronitrosomethane with spiro-di-*o*-xylylene was obtained[218]:

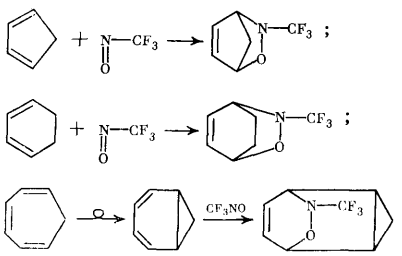


Later it was shown[219] that a copolymer is also formed under these conditions.

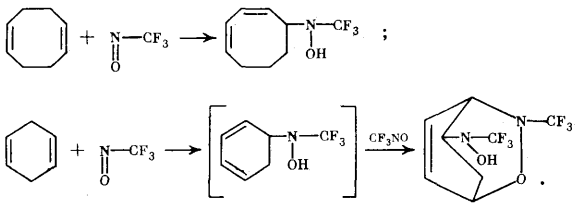


Trifluoronitrosomethane readily reacts with butadiene at −78 °C and an oxazine is formed in 97% yield:

A similar reaction takes place also with β-butadienylpyridine[220]:

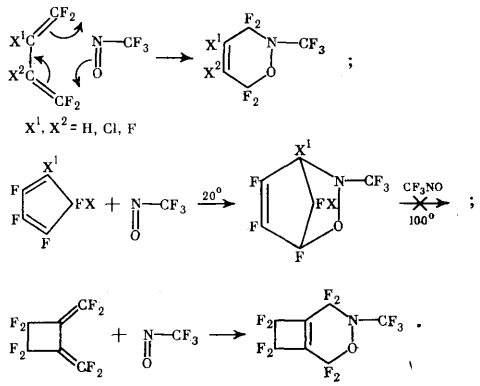


On the other hand, nitroso-t-butane does not react with dienes at all, while its perfluoro-analogue forms oxazines on reaction with butadiene and its derivatives[185] at room temperature:



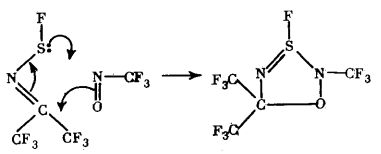
Apart from the oxazine, a copolymer is also formed in this reaction[221]. The ratio of the cyclic product to the copolymer increases as the reaction temperature is reduced, while in the interaction of fluoronitroso-compounds with fluoro-olefins the opposite behaviour is observed (see above).

† The numeral 1 designates the carbon atom attacking the nitrogen atom. The numeral 2 designates the carbon atom from which the hydrogen atom migrates.



Cyclic conjugated dienes also enter into the Diels–Alder reaction with trifluoronitrosomethane[216,222]:

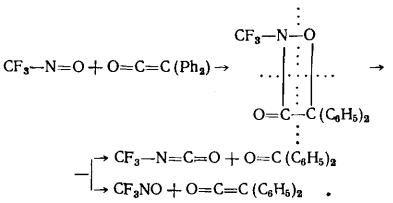
Non-conjugated cyclic dienes form hydroxylamines on reaction with trifluoronitrosomethane[216] as a result of the attack of the carbon atoms of the double bond on the nitrogen atom and the migration of the allyl hydrogen atom to the oxygen atom:



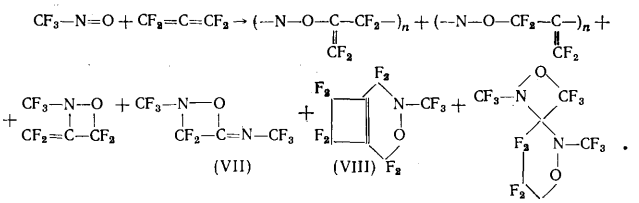
Trifluoronitrosomethane is capable of functioning as the dienophile also in relation to conjugated fluorine-containing aliphatic[194,223,224] and cyclic dienes[225–288]:

Hexafluorobutadiene reacts with various fluoronitroso-compounds more slowly than butadiene[221]. The reaction with trifluoronitrosomethane is slower by a factor of 40 and that with tetrafluoro-1-nitro-2-nitrosoethane by a factor of 600.

A radical-ion mechanism of the interaction of trifluoronitrosomethane with polyfluorinated and non-fluorinated dienes has been put forward on the basis of EPR spectra[222] (analogously to the mechanism described above).

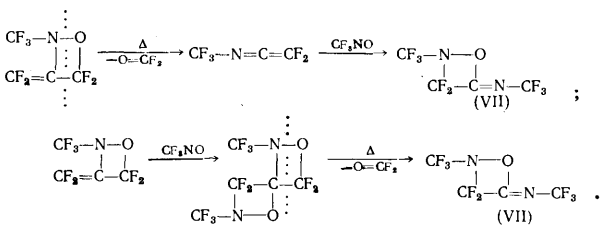


An unusual [2 + 3] cycloaddition takes place on interaction of trifluoronitrosomethane with hexafluoroacetone fluorosulphenylimine[229]:

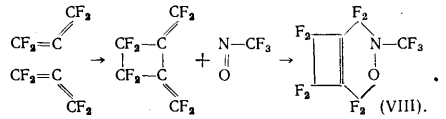


(d) Interaction with Cumulenes

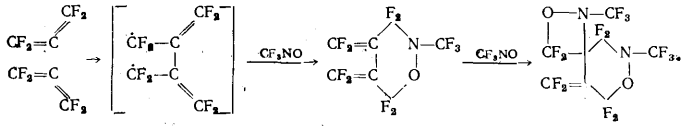
The interaction of fluoronitroso-compounds with cumulenes has been investigated only in relation to trifluoronitrosomethane. Like other unsaturated compounds, cumulenes are capable of forming oxazetidines and polymers on reaction with trifluoronitrosomethane.



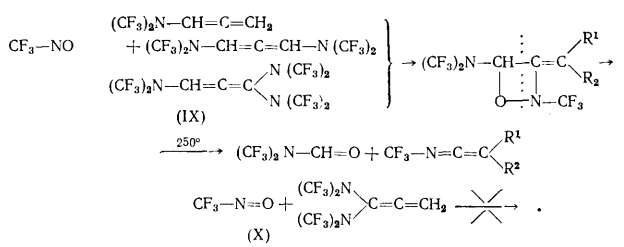
Diphenyl ketone reacts with trifluoronitrosomethane to form an oxazetidine, which can be pyrolysed via two pathways[138]:



Tetrafluoroallene reacts with trifluoronitrosomethane to form a complex mixture of substances[230], from which polymers, oxazetidines, oxazines, and spiro-compounds were isolated:

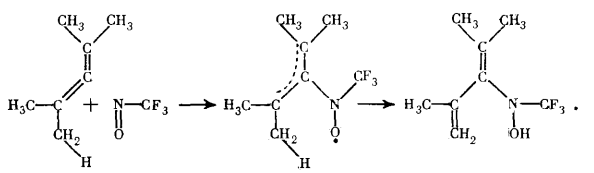


The formation of compound (VII) is explained by the following mechanisms:

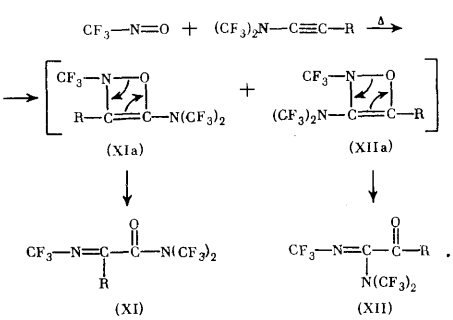


Compound (VIII) is formed from the tetrafluoroallene dimer as described by Banks et al.[228]:

The following mechanism has been postulated to account for the formation of spiro-compounds:



N,N-Bis(trifluoromethyl)aminoallenes react with trifluoronitrosomethane to form only oxazetidines[231,232] whose pyrolysis yields bis(trifluoromethyl)formamide and cumulated



For reasons which are obscure[232], compound (X) does not enter into this reaction, while its close structural analogue (IX) reacts with trifluoronitrosomethane to form an oxazetidine.

Tetramethylallene forms the corresponding hydroxylamine on interaction with trifluoronitrosomethane[233]. The authors suggest the possibility of a mechanism involving a biradical:

(e) Interaction with Acetylenes

The reaction of fluoronitroso-compounds with acetylenes has been studied in only one instance[234]. The formation of the products of the reaction of trifluoronitrosomethane with bis(trifluoromethyl)aminoacetylenes has been explained by the intermediate formation of oxazetidines:

When R = H, Br, or CF_3, the main product is compound (XI), evidently as a consequence of the preferential formation of the less sterically hindered oxazetidine (IXa), whereas for R = $N(CF_3)_2$ only one reaction product is naturally obtained.

IV. THE PROPERTIES AND APPLICATIONS OF COPOLYMERS OF FLUORONITROSO-COMPOUNDS

Data on the copolymers of fluoronitrosoalkanes with fluoro-olefins first appeared in 1955.[189,235] The copolymers immediately attracted much attention having shown a series of interesting and useful properties—resistance to concentrated sulphuric acid, 50% potassium hydroxide solution, and hot aqueous alkali[189], thermal stability in air up to 200 °C, and retention of elasticity at −30 °C.[236]

Further studies yielded a large number of copolymers of fluoronitrosoalkanes with various unsaturated compounds. Whereas the number of studies on the chemical properties of fluoronitrosoalkanes has decreased appreciably in recent years, in the field of copolymers of fluoronitro-compounds publications have continued to appear up to the present time in which further new properties and applications of these substances are described.

Several reviews have been devoted in recent years to the synthesis and properties of the copolymers of fluoronitroso-alkanes[237–242].

All the copolymers of fluoronitrosoalkanes can be divided by convention into three large groups.

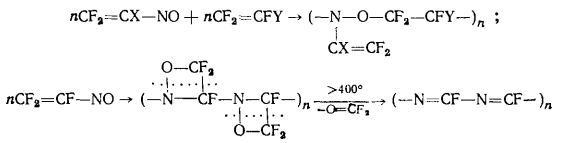
1. The copolymers of fluoronitrosomethane and tetrafluoro-ethylene.
2. The copolymers of other fluoronitrosoalkanes and various fluoro-olefins.
3. Ternary copolymers.

1. The Copolymers of Trifluoronitrosomethane and Tetra-fluoroethylene

It was noted above that the preferential formation of the copolymer relative to the oxazetidine in the interaction of trifluoronitrosomethane with tetrafluoroethylene takes place at 0 °C and below. Depending on the copolymerisation conditions, a liquid[189,235] or solid[236,243] copolymer can be obtained. Usually efforts are made to obtain rubber-like copolymers with a molecular weight in excess of 10^6.

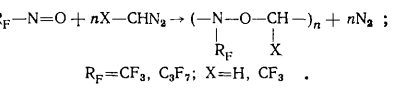
The copolymers of trifluoronitrosomethane with tetrafluoro-ethylene $(-N(CF_3)-O-CF_2-CF_2-)_n$ are highly resistant to chemical reagents and ozone-induced and natural ageing, are frost resistant (the glass point of the copolymer with a molecular weight in excess of 10^6 is −51 °C), and their properties remain unchanged for a long time at 200 °C. The vulcanisates are resistant to aromatic and aliphatic hydrocarbons, alcohols, ethers, aldehydes, ketones, and concentrated acids, do not ignite, and when placed in a flame evolve pyrolysis products which quench the flame[244,245]. Such copolymers do not ignite even in pure oxygen[241]. They are soluble only in halogenoalkanes, cyclic perfluoro-ethers, and perfluorotri-butylamine. In the presence of strong bases, for example, triethylamine, the copolymer readily decomposes[242]. Difluoro-phosgene and perfluoro-2-azapropene are formed on radiolysis and thermal and photochemical decomposition of the copolymer[246].

The inadequate thermal and radiation stability limit the applications of these copolymers. The usual vulcanising agents, employed for hydrocarbon elastomers[241], are unsuitable for them. However, it has been observed that triethylenetetramine and hexamethylenediamine form a network structure in cured rubbers based on raw nitroso-rubbers[247,248].



Fillers are used to improve the strength of the copolymers. The most effective is finely ground silica (in the case of amine vulcanisation)[241].

Vulcanisation and addition of various fillers[244,247,249–252] resulted in elastic and thermoplastic copolymers virtually without residual deformation, which are useful as protective coatings and articles[249,253], lubricants[254], and protective low-temperature coatings resistant to highly corrosive oxidants, for example, ClF_3.[250,251]



2. The Copolymers of Other Fluoronitrosoalkanes and Different Fluoro-olefins

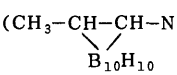
Thermostable[255,256] and elastic[257] copolymers, which can be used as lubricants and protective coatings for metals[258], have been obtained by the copolymerisation of various perfluoronitrosoalkanes with fluoroethylenes.

Among fluorovinyl nitroso-compounds[259,260], elastic and thermostable polymers have been synthesised by copolymerisation and homopolymerisation:

Copolymers with satisfactory thermal and corrosion stabilities, which can be used as films, protective coatings, gaskets, and washers, have been synthesised from trifluoronitrosomethane and diazoalkanes[136,137]:

The study of the thermal stabilities of raw fluoronitrosorubbers *in vacuo* and in oxygen[261] established that the perfluoro-copolymers are more stable in oxygen.

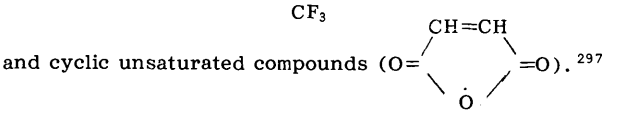
The vulcanisation of certain raw fluoronitroso-rubbers improves their resistance to solvents and halogen-containing oxidants[262].



The introduction of various functional groups into the copolymer chain also promotes the appearance of useful properties in the copolymers and improves their capacity for vulcanisation. Both olefins with functions groups [CH_2–C(–CH_3)–$COOCH_3$, CH_2=CH–CN, and CH_2=CH–C_6H_5;[263] CF_2=CF–SO_2F;[264] CF_2=C=CXY;[265,266] CH_2=CH–CH=CH_2;[267] CF_2=CF$(CF_2)_n$–COONa;[268] CF_2=CF–OR [269]] and fluoronitrosoalkanes [O=N–CF_2–COF;[270] O=N–CF_2–$COOCH_3$;[271] O=N–$(CF_2)_n$–COOH [272]] are used in the copolymerisation reaction.

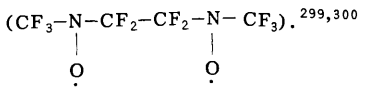
Such copolymers have satifactory thermal and chemical stabilities and can be used as lubricants, waxes, and elastomers[265–268]. Copolymers with improved resistance to oxidants have been obtained[270,271]. Some of them can be used as cation-exchange membranes in the electrolysis of alkali metal halides[272].

3. Ternary Copolymers



Yet another effective and widely used method for the introduction of functional groups into the polymer chain of raw nitroso-rubbers involves the use in the copolymerisation, apart from the fluoronitrosoalkane and the fluoro-olefin, of a third monomer having an alkenyl or nitroso-group at one end of the molecule and the required functional group at the other. Such copolymers are referred to as ternary polymers or terpolymers.

The most common "third" monomers are nitroso-compounds with functional groups, which consist of carboxylic perfluoronitrosoacids [O=N–$(CF_2)_n$–COOH],[273–282] methyl esters of carboxylic fluoronitrosoacids [O=N–$(CFX)_n$–$COOCH_3$],[283,284] aromatic fluoronitroso-compounds[285–288], aromatic non-fluorinated nitroso-compounds[289], nitrosoethers (O=N–CF_2–CFCl–O–C_2H_5),[290] and 1-methyl-2-nitrosocarbaborane



[291]

The following olefins with functional groups have been used: acrylic acid[292,293], unsaturated carboxylic fluoroacids and their esters, metal salts, amides, and nitriles [CF_2=CF–$(CF_2)_n$–A, where A = COOH, COOR, COOM, $CONH_2$, or CN),[294] unsaturated polyether carboxylic fluoroacids and their nitriles, fluorides, esters, metal salts, and dialkylamides [CF_2=CF–O–CF_2–(CFX–O–$CF_2)_m$–$(CFX)_n$–$(CF_2$–O–$CFX)_l$–A, where A = COOH, CN, COF, COOR, COOM, or $CONR_2$],[295] unsaturated fluoroethers with a sulphonyl fluoride group (CF_2=CF–CF_2–CF(–CF_3)–O–CF_2–CF_2–SO_2F),[296]

Such polymers can be vulcanised with metal oxides, metal salts of organic and organofluorine acids (chromium trifluoroacetate), epoxy-compounds[241], poly(butadiene)di-isocyanate [O=C=N–$(CH_2$–CH=CH–$CH_2)_n$–N=C=O] [298] and perfluoro-2,5-diazahexane-2,5-dioxy-biradical

[299,300]

The ternary copolymers of fluoronitrosoalkanes have perhaps the widest range of useful properties among all the copolymers of fluoronitroso-compounds. The unique property of the nitroso-polymers—incombustibility in pure oxygen—has led to their wide-scale employment in the Apollo spaceship[241].

The ternary copolymers have the following properties.

1. Satisfactory chemical and thermal stability[279,287,290,297] and suitability for use as lubricants, washers, and gaskets.
2. High elasticity and tensile strength[273,284–286,288]. Some of them have a relative elongation ranging from 150 to 950% with retention of a high tensile strength[280,281].
3. Thermoplasticity and capacity for being moulded[275,278]. At the same time they are resistant to oxidants such as nitrogen tetroxide[278].
4. The ability to "remember" their initial shape and to recover it on heating[276].
5. A modulus of hardness of 5–200 km cm^{-2} (they are used for the coating of artificial dentures)[301].
6. Elasticity and resistance to the components of rocket fuels (N_2H_4, N_2O_4, ClO_3F, N_2F_4, and ClF_3). They are therefore used in rocket engineering as shutters in the exhaust chambers for the retention of the rocket fuel and oxidant[240,274,277,285,302].
7. Properties permitting their use as binders for rocket fuels and explosives[281,292,293].
8. Properties permitting their employment as cation-exchange membranes in the electrolysis of alkali metal halides[295,296].

However, in planning the applications of such copolymers, one must bear in mind that they evolve toxic gases on decomposition—difluorophosgene, perfluoro-2-azapropene[241], and other fluoroazamethines.

2-Oxazolidinones

V.A.Pankratov, Ts.M.Frenkel', and A.M.Fainleib

The synthesis and properties of 2-oxazolidinones and polymers containing 2-oxazolidinone rings are examined. Attention is concentrated on studies devoted to reactions in which the initial monomers are readily available substances produced on a large scale-epoxides and isocyanates. The mechanisms of the formation reactions of oxazolidinones, the catalytic systems employed, and the possible side processes are discussed. The properties and applications of polymers with 2-oxazolidinone rings in the chain are described.
The bibliography includes 218 references.

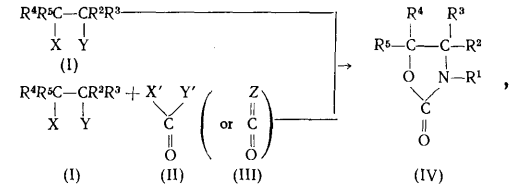
I. INTRODUCTION

2-Oxazolidinones occupy a special place among heterocyclic compounds in modern organic chemistry. They are widely used in medicine as drugs and pharmaceutical preparations, as intermediates in the paint and varnish industry, as lubricants, and in many other branches of the national economy. In recent years there has been a considerable development of the synthesis of polymers containing 2-oxazolidinone rings, which are used to prepare adhesives, foams, coatings, fibres, and electrically insulating and other materials, which as a rule have effective physicomechanical properties and high thermal stability and heat resistance.

Numerous methods of synthesis of 2-oxazolidinones have been described in the literature. The most promising method, which is of industrial importance, involves the reaction of epoxides with isocyanates[1]. Numerous studies devoted to this reaction and its employment for the synthesis of a large number of polyoxazolidinones with a wide variety of structures have been published.

There are virtually no Russian and foreign reviews dealing with the present state of the chemistry of 2-oxazolidinones. The present review deals with the available data on the methods of synthesis of 2-oxazolidinones, attention being concentrated on studies of the reactions of epoxides with isocyanates having different structures; the physical and chemical properties of 2-oxazolidinones are discussed. A considerable proportion of the review is devoted to a detailed consideration of the synthesis, reaction mechanisms, properties, and applications of poly-2-oxazolidinones—one of the most important fields of practical application of heterocyclic compounds of this type.



II. THE SYNTHESIS OF 2-OXAZOLIDINONES

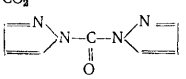
The numerous methods of synthesis of 2-oxazolidinones known at the present time can be arranged systematically as follows: (1) cyclisation of β-difunctional compounds in the presence or absence of a cyclising agent; (2) reactions involving the conversion of various (other than epoxides) heterocyclic compounds into 2-oxazolidinones; (3) reactions of epoxides with various compounds.

The reactions are examined below in the same sequence, those of epoxides with isocyanates being dealt with in greater detail, since they are the most promising from the standpoint of practical application.

1. Cyclisation of β-Difunctional Compounds

The reactions involving the synthesis of 2-oxazolidinones from β-difunctional compounds, described in the literature, can be represented schematically in a general form as follows:

where X, Y, X′, and Y′ are functional groups, which are listed in the Table. Hydrogen atoms and aromatic, aliphatic, and alicyclic ligands can be used as substituents R^1, R^2, R^3, R^4, and R^5; R^1 forms part of one of the functional groups of the β-difunctional compound (I).



In order to carry out the ring closure reaction, the initial β-difunctional compound (I) is treated with a cyclising agent (II) or (III), which interacts with one of the functional groups of compound (I); this is followed by ring closure with participation of the second functional group. Compound (I) can be cyclised also without adding a cyclising agent, either thermally or under the conditions of acid or base catalysis. The Table presents different versions of the synthesis of 2-oxazolidinones by this method.

The synthesis of 2-oxazolidinone derivatives by the cyclisation of β-hydroxyalkanesulphonic acids (I, X = OH, Y = SO_3H),[40] 1,2-dihalogeno-derivatives (I, X = Y = Hal),[41] β-aminochloroformates (I, X = OCOCl, Y = NH_2),[42] β-hydroxyalkylsemicarbazides [I, X = OH, Y = $N(NH_2)CONH_2$],[43] and nitrenes (I, X = OCO$\ddot{N}$, Y = H) [44] have also been mentioned in the literature.

2. Reactions Involving the Conversion of Various (Other than Epoxides) Heterocyclic Compounds into 2-Oxazolidinones (IV)

Methods of synthesis of 2-oxazolidinones from a series of heterocyclic compounds (mainly three- and five-membered) by their reaction with isocyanates, amines, substituted ureas, carbon dioxide, and other compounds have been described in the literature. In this section we shall consider these reactions with the exception of the conversion of epoxide rings into 2-oxazolidinones.

The synthesis of 2-oxazolidinones (IV) from β-difunctional compounds (I) and cyclising agents (II) or (III).

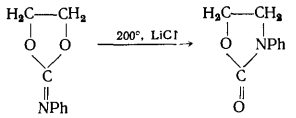
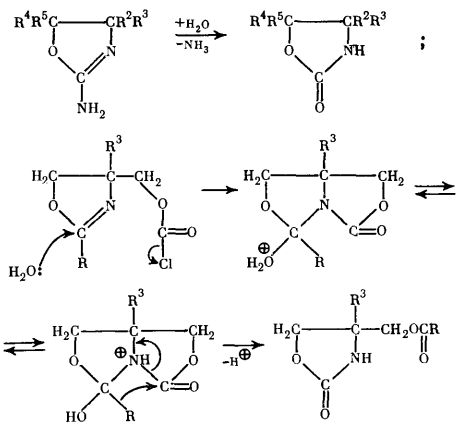
(a) The Synthesis of 2-Oxazolidinones from 2-Dioxolans



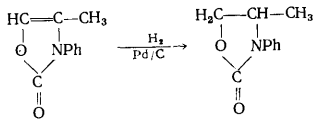
The synthesis of 2-oxazolidinones by the reaction of 2-dioxolans (cyclic carbonates) with isocyanates has been described. Tertiary amines[45], lithium, zinc, and tin chlorides, potassium and sodium carbonates, and sodium hydroxide[46] have been used as catalysts of this reaction. It has been suggested[45] that a molecular complex of the isocyanate and the carbonate is formed as an intermediate, which has been isolated and proved to have a distinct melting point. On heating, this complex decomposed with evolution of carbon dioxide and formation of 2-oxazolidinone. When the reaction of 2-dioxolans with isocyanates was carried out at elevated temperatures, the formation of the complex was not observed.

Substituted 2-oxazolidinones have been obtained by the reaction of cyclic carbonates with formamide[47].

Gulbins and Hamann[48] synthesised 2-oxazolidinones by the reaction of 2-dioxolans with aromatic amines using lithium chloride or alkali (NaOH, KOH) as the catalyst:

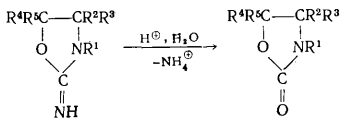


The preparation of oxazolidinones by the reaction of cyclic carbonates with diacylureas[49] and with ammonium carbonate and potassium cyanide[50] and also by the rearrangement of 2-amino-1,3-dioxolans under the influence of lithium chloride[51]:



(b) The Synthesis of 2-Oxazolidinones from Oxazolines, Oxazolinones, and Imino-oxazolidinones

2-Oxazolidinones have been obtained by the hydrolysis of 2-amino- and 2-alkyl-2-oxazolines in accordance with the scheme[52,53]



The syntheses of 2-oxazolidinones by the rearrangement of 2-alkoxy-2-oxazolines in inert solvents in the presence of catalytic amounts of alkyl halides have been described in patents[54,55].

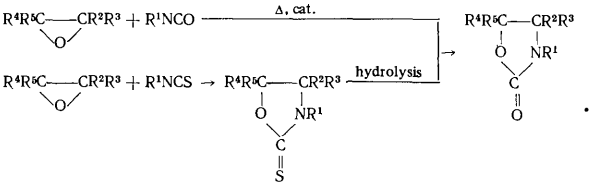
The reaction involving the reduction of oxazolinones by hydrogen at atmospheric pressure and room temperature in the presence of a palladium catalyst[56], i.e.

and the hydrolysis of 2-imino-oxazolidones[57], i.e.

belong to methods of synthesis of 2-oxazolidinones without the cleavage of the initial ring.

(c) The Synthesis of 2-Oxazolidinones by the Cleavage of Nitrogen-Containing Heterocycles

The preparation of 4-methyl-2-oxazolidinones by the reaction of propyleneimine with carbon dioxide has been described; polypropyleneimine and polyurethane are formed as side products[58].

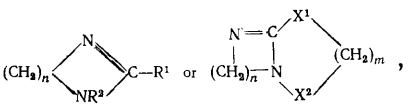


Ikeda and Soga[59] obtained 2-oxazolidinone by the reaction of aziridines having the general formula $\overline{CH_2-CHR^2-NR^1}$ with carbon dioxide; the reaction proceeds in the presence of Lewis acids ($ZnCl_2$, $AlCl_3$) at 60 °C in the course of 50 h.

3. The Reactions of Epoxides with Various Compounds

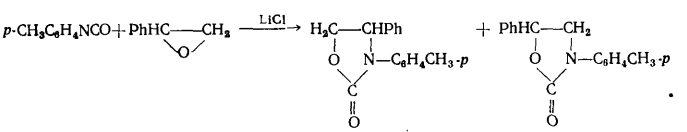
As mentioned above, one of the most important and promising methods of synthesis of 2-oxazolidinones involves the reactions of epoxides with various compounds (particularly isocyanates), since the initial reactants are in this instance substances produced industrially on a large scale.

(a) The Reactions of Epoxides with Isocyanates and Isothiocyanates



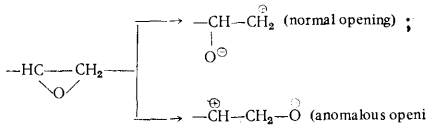
Numerous studies[1,60-77] devoted to the synthesis of 2-oxazolidinones by the reactions of epoxides with organic isocyanates and isothiocyanates have been published. However, there is as yet no unanimous view in the literature concerning either the reaction products or the reaction mechanism. The formation of 2-oxazolidinones can be represented schematically in a general form as follows:

(1)

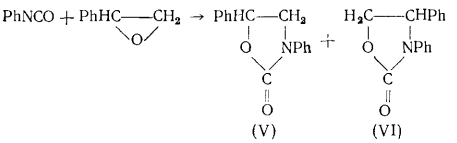


The reaction takes place at elevated temperatures in solvents such as dimethylformamide (DMF), acetonitrile, dioxan[1], and benzene[60] or in the absence of solvents[61], in the presence or absence of catalysts. Secondary[62] and tertiary[63] amines, quaternary ammonium halides[61,64], carboxylate anions[65], zinc, iron[60], and lithium[66] chlorides, the lithium bromide–tributylphosphine oxide complex (or hexamethylphosphoramide),[67] the complexes of aluminium, zinc, and iron halides with ethers, amines, amides, sulphoxides, and phosphines[68], organic derivatives of zinc [R_2Zn and $Zn(OCOR)_2$] and aluminium (AlR_3), with R = alkyl,[69] and Group IIA and IIIA metal alkoxides and phenoxides[70] are used as catalysts. A method of synthesis of oxazolidinones by the reaction of isocyanates with epoxides in the presence of catalysts comprising phosphonium compounds of the type $[R(R^1)(R^2)(R^3)P]^+X^-$, where R^1, R^2 = C_{1-25} alkyl or substituted alkyl, R^3 = alkyl, substituted alkyl, aryl, or substituted aryl, and X = anion of an inorganic or lower aliphatic carboxylic acid [for example, $(n\text{-}C_4H_9)_4PBr$] and with primary and secondary alcohols as cocatalysts has been proposed in a patent[71].

Cyclic amidines having the general formula



where R^1, R^2 = H, pentyl, or C_{1-8}, X^1, X^2 = alkylene, n = 2–6, and m = 2–11, and their salts have been suggested as catalysts in the synthesis of oxazolidinones[72].

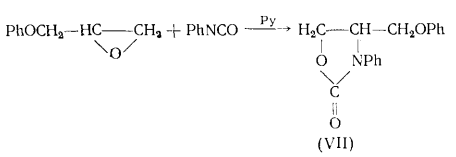


The interaction of isocyanates and epoxides has been investigated[65] in the presence of LiCl as the catalyst. It was found that the reaction results in the formation of a mixture of 3,5- and 3,4-substituted 2-oxazolidinones in proportions of 4 : 1 (by weight):

The formation of two isomers in this reaction is explained by the fact that various ways of opening the epoxide ring are possible:

The formation of a mixture of isomers in the reaction of phenyl isocyanate with 2-phenyloxiran (styrene oxide) has been mentioned[73]:

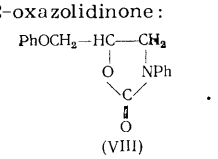
(2)



(V) (VI)

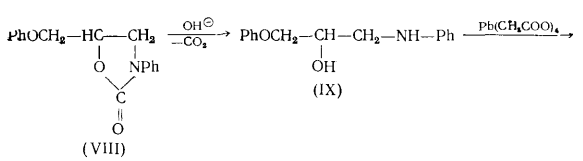
It has been established[74] that the reaction of 2-phenyloxiran with phenyl isocyanate in the presence of $AlCl_3$ as the catalyst leads to the formation of a mixture of 3,5-diphenyl-2-oxazolidinone (V) and 3,4-diphenyl-2-oxazolidinone (VI) in proportions of 2:1 [see reaction (2)]. The reaction apparently proceeds preferentially via the formation of the intermediate complex

When $Ca(OC_2H_5)_2$ was used as the catalyst, the formation of only the 3,5-isomer was noted. The authors[74] separated the isomers by fractional crystallisation. They also described[74] the synthesis of various bisoxazolidinones.



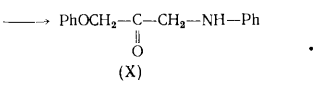
The reaction of glycidyl phenyl ether with phenyl isocyanate in the presence of pyridine (Py) has been investigated[63]:

(3)



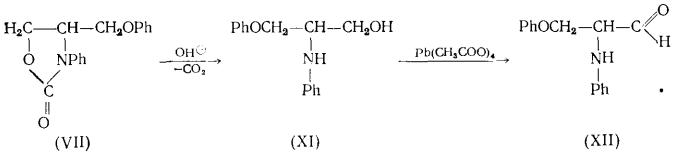
(VII)

The authors[63] concluded that the reaction results in the formation of 4-phenoxymethyl-3-phenyl-2-oxazolidinone (VII), while other workers[60,75] noted that, when the process is carried out under anomalous conditions, the product is 5-phenoxymethyl-3-phenyl-2-oxazolidinone:



(VIII)

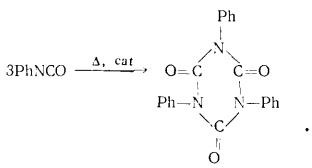
Braun and Weinert[10] also described the synthesis of 5-phenoxymethyl-3-phenyl-2-oxazolidinone (VIII) by reaction (3) in a high yield. Pyridine as well as metal alkoxides and chlorides and $(CH_3)_4Ni$ were used as the catalysts. In order to demonstrate the structure of the resulting 2-oxazolidinone, the authors[10] hydrolysed it. Evidently the hydrolysis of 5-phenoxymethyl-3-phenyl-2-oxazolidinone (VIII) should result in the formation of the secondary alcohol 1-phenoxy-3-phenylamino-2-propanol (IX), which yields the corresponding ketone (X) on oxidation with lead tetra-acetate:



(VIII) (IX)

(X)

The hydrolysis of 4-phenoxymethyl-3-phenyl-2-oxazolidinone results in the formation of the primary alcohol 3-phenoxy-2-phenylamino-1-propanol (XI), which can be oxidised to the aldehyde (XII) by lead tetra-acetate:



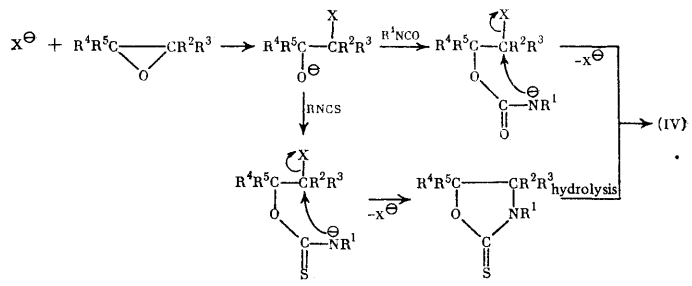
(VII) (XI) (XII)

The infrared spectra of the products of hydrolysis and subsequent oxidation confirmed that the reaction of glycidyl phenyl ether with phenyl isocyanate in the presence of all the catalysts tested (see above) leads to the formation of 5-phenoxymethyl-3-phenyl-2-oxazolidinone (VIII).

Thus inspection of the literature data permits the conclusion that the views of different workers concerning the isomeric products of the reaction of epoxides with isocyanates are extremely contradictory. As a rule the mode of opening of the epoxide ring and hence the formation of a particular isomeric 2-oxazolidinone depend on the catalyst employed and on the nature of the substituent in the epoxide.

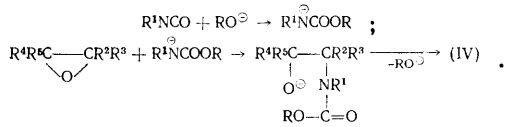
Sandler et al.[61] investigated the relative contributions of the two competing reactions involving the formation of the oxazolidinone [see Scheme (3)] and the cyclotrimerisation of phenyl isocyanate:

(4)

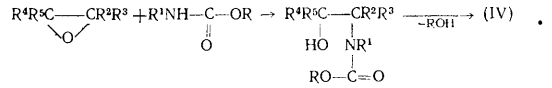


The reaction was carried out in the presence of $(CH_3)_4Ni$ as the catalyst in DMF. The authors[51] showed that oxazolidinone formation reactions take place preferentially in accordance with Eqn.(3) at 140–160 °C, while at 56 °C triphenyl isocyanurate is formed in accordance with reaction (4).

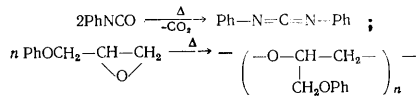
The reaction of epoxides with isocyanates has been carried out in a number of investigations[51,66] in DMF. However, according to Weiner[76], aryl isocyanates react with DMF at an elevated temperature to form formamidines:



However, Sandler[61] did not point out the possibility of this side reaction. In order to eliminate it, Herweh et al.[66] added the isocyanate to a solution, heated under a reflux condenser, of the epoxide and the catalyst [$(CH_3)_4Ni$ or LiCl] in DMF. However, in the present author's view, this cannot prevent the reaction of the isocyanate with DMF.

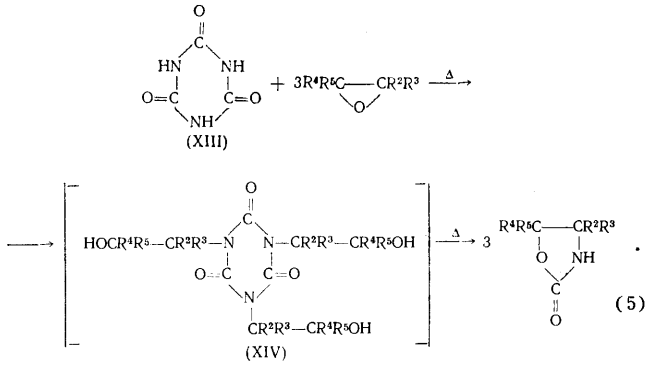


The nature of the catalyst influences the mechanism of the reaction of epoxides with isocyanates. Thus it has been suggested[1] that in the presence of metal halides the epoxide adds directly to the isocyanate (or isothiocyanate) with formation of an activated complex via the reaction



It has been established[77] that, in the presence of alkaline earth metal alkoxides, there is no reaction between the epoxide and the alkoxide and also between the epoxide and the isocyanate. It has therefore been suggested that the oxazolidinone is formed via a stage involving the interaction of the isocyanate with the alkoxide anion followed by the condensation of the urethane anion and the liberation of the alkoxide anion in accordance with the reaction

It has been shown[75] that the formation of oxazolidinones in the presence of quaternary ammonium salts takes place only in the presence of small amounts of an alcohol. Hence, it is believed[75] that oxazolidinones are formed via the condensation of the urethane with the epoxide with liberation of an alcohol and the closure of the oxazolidinone ring. According to the authors[75], the quaternary ammonium salts play the role of compounds which enhance the nucleophilic properties of the urethane nitrogen. The reaction proceeds as follows:

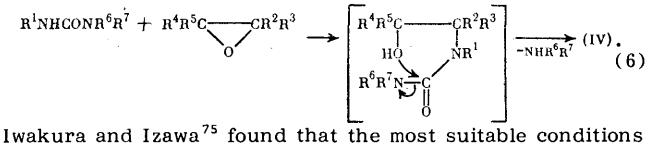


One should note that the reaction of epoxides with isocyanates in the absence of catalysts and solvents has been mentioned in the literature. Thus 5-phenoxymethyl-3-phenyl-2-oxazolidinone has been obtained[61] by heating a mixture of equivalent amounts of phenyl isocyanate and glycidyl phenyl ether at 210 °C for 15 h. Evidently in the absence of a catalyst of the oxazolidinone formation reaction, side reactions occur in the given system, namely the cyclotrimerisation of phenyl isocyanate [see reaction (4)] and also the conversion of phenyl isocyanate into a carbodiimide and linear polymerisation of glycidyl phenyl ether:

(b) The Reaction of Epoxides with Isocyanurates

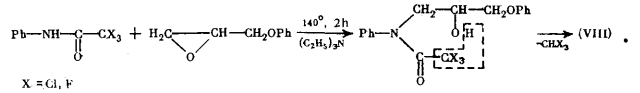
Since one of the main side processes in the reaction of epoxides with isocyanates involves the formation of isocyanurates, studies on the interaction of the latter with epoxides are of undoubted interest. Thus it has been found in a number of investigations[78–80] that, on treatment with epoxides, the stable isocyanurate ring decomposes with formation of a 2-oxazolidinone.

The reaction of epoxyethane and other epoxides with isocyanuric acid (XIII) has been investigated[78–79]. It has been shown[79] that the reaction proceeds as follows:



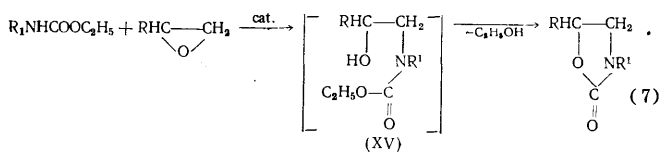
It was carried out in DMF or dimethylacetamide at 100 °C and atmospheric pressure. Pyrolysis of the tris(hydroxyalkyl) isocyanurate (XIV) *in vacuo* at 200 °C or on heating in DMF (150–155 °C) leads to the corresponding 2-oxazolidinone [reaction (5)].

Korshak et al.[80] investigated the reaction of glycidyl phenyl ether and triphenyl isocyanurate in molar proportions of 3:1 (at 230 °C for 10 h) and showed that the only product is 5-phenoxymethyl-3-phenyl-2-oxazolidinone.



(c) The Reactions of Epoxides with Ureas, Amides, and Urethanes

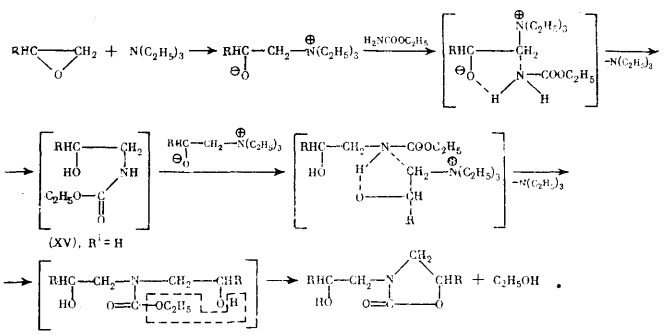
Apart from their reactions with isocyanates, isothiocyanates, and isocyanurates, epoxides are capable of cleaving the urea, amide, and urethane linkages with formation of 2-oxazolidinones. Thus the reaction of epoxides with urea derivatives to give 2-oxazolidinones has been reported[75–81]:



Iwakura and Izawa[75] found that the most suitable conditions for the reactions of di- and tri-substituted ureas with epoxycompounds [see reaction (6)] are a temperature of 90 °C, the absence of a solvent, and the presence of the $(C_2H_5)_3N$ catalyst. A two- or threefold excess of the epoxide is also necessary, since the primary or secondary amines formed rapidly react with epoxides. It is noteworthy that *N*-aryl-*N*,*N*'-disubstituted ureas give rise to oxazolidinones, while *N*-alkyl-*N*,*N*'-disubstituted ureas do not form such compounds.

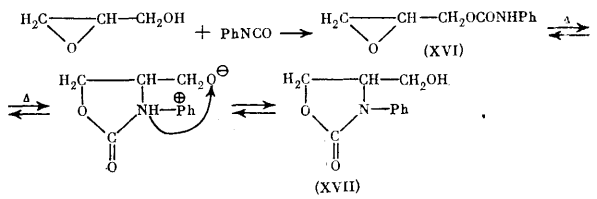
The same investigators[82,83] studied the interaction of epoxides with acid amides. In particular they studied the reaction of acetanilide and its derivatives with glycidyl phenyl ether and showed that 2-oxazolidinones are formed only from trifluoro- and trichloro-acetanilides, which indicates the necessity for the presence of strong electron-accepting substituents in the acetanilide molecules for the cyclisation to occur:

Urethanes react with epoxides to form oxazolidinones in the presence of nucleophilic catalysts such as KOH,[6] tertiary amines, and quaternary ammonium salts[75]:



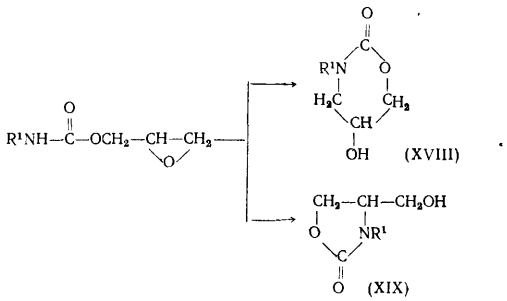
(7)

It has been observed[97] that without a catalyst reaction (7) between a urethane and an epoxide does not take place. When the mixture of the initial components is heated from 0° to 200 °C, only the homopolymerisation of the epoxide is observed. In the presence of $(C_2H_5)_3N$ at 25 °C the reaction takes place quantitatively in 2 h. At 140 °C the reaction terminates after 2–3 min (side reactions were not observed).



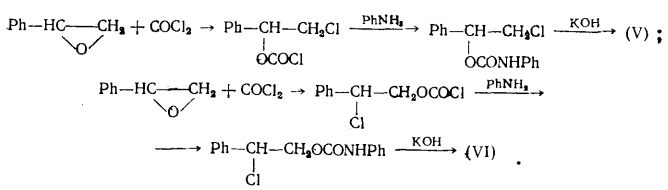
The authors[75] showed that in the presence of solvents (ethanol, benzene, toluene, chloroform and DMF) the reaction occurs at a higher rate than in bulk. *N*-Arylurethanes and *N,N'*-difunctional arylurethanes form oxalidinones on interaction with epoxides, while *N*-alkylurethanes do not undergo the oxazolidinone formation reaction with epoxides (like *N*-alkylureas—see above). According to the mechanism proposed[75], the catalyst is involved in the opening of the epoxide ring and reacts with the epoxide to form an intermediate complex, which then interacts with the urethane; this entails the formation of *N*-(β-hydroxyethyl)urethane (XV), which cyclises with elimination of an alcohol and the formation of a 2-oxazolidinone (IV).

The kinetics of the reaction of an epoxide with *N*-unsubstituted ethylurethane in the presence of $(C_2H_5)_3N$ as the catalyst have been investigated[84]. The mechanism proposed[84] is similar to that described above[75], but the authors[84] believe that the *N*-(β-hydroxyethyl)urethane (XV, R' = H) formed reacts with yet another molecule of the adduct of the epoxide and triethylamine which results in the formation of a hydroxy-2-oxazolidinone:

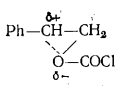


(d) Intramolecular Cyclisation of Glycidyl Esters of *N*-substituted Carbamic Acids

The glycidyl esters of *N*-substituted carbamic acids undergo intramolecular cyclisation on heating with formation of 2-oxazolidinone derivatives. Thus the reaction of phenyl isocyanates with glycidol results in the formation of glycidyl *N*-phenylcarbamate (XVI), which is converted on heating into 4-hydroxymethyl-3-phenyl-2-oxazolidinone (XVII):[85]



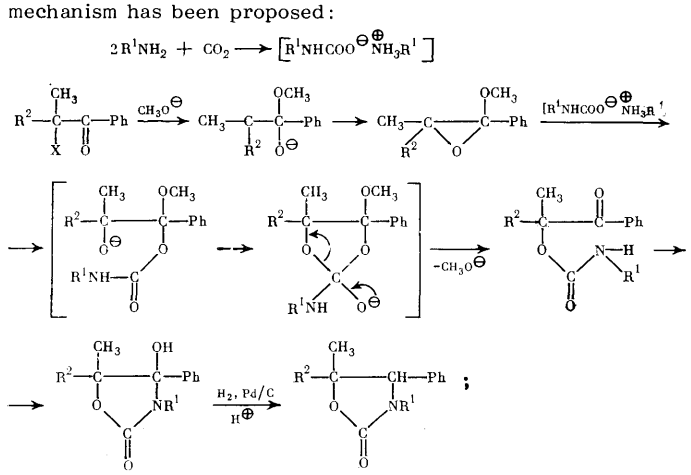
^{1}H NMR spectra[74,85] confirm the location of the hydroxymethyl group in compound (XVII) at the carbon atom adjoining the nitrogen atom of the oxazolidinone ring. However, hitherto there has been no definite view concerning the structure of the cyclisation products. Thus the formation of the six-membered 2-oxazinone ring (XVIII) has been postulated[86], while according to other data[85] the five-membered 2-oxazolidinone ring (XIX) is produced:



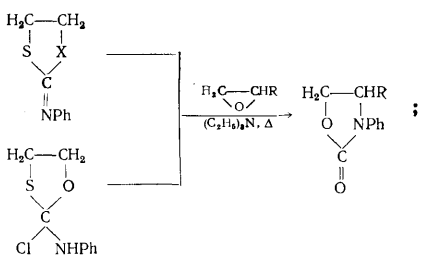
Sorokin and co-workers investigated in a series of studies in recent years[87–92] the intramolecular cyclisation of glycidylurethanes and demonstrated the formation of a five-membered structure (XIX). They showed[87–92] that in proton-donating solvents the reaction takes place at lower temperatures (100 to 140 °C) than in neutral solvents (170–200 °C). Tertiary amines are active cyclisation catalysts. The equality of the molecular weights of the resulting product and of the initial glycidylurethane, the absence of epoxy-groups, and the appearance of hydroxy-groups in an amount corresponding to the cyclisation product indicates the absence of side reactions and the quantitative interaction of the epoxide and urethane groups to form the cyclic compound (XVIII) or (XIX). In order to demonstrate the structure, a study was made[92] of the ^{1}H NMR spectra of the reaction product and it was shown that the signals of the protons in the epoxide and urethane groups are absent and that the signal due to the OH group with δ = 5.2 p.p.m. appears. Its triplet form shows that the hydroxy-group is primary and not secondary and that anomalous opening of the epoxide ring therefore takes place (see above) and the cyclisation product is the five-membered 2-oxazolidinone ring (XIX).

(e) The Interaction of Epoxides with Other Compounds

Irwin and Wheeler[73] investigated the successive interaction of 2-phenyloxiran with phosgene, aniline, and KOH. Two reaction pathways are possible; the products are 3,5-diphenyl-2-oxazolidinone and 3,4-diphenyl-2-oxazolidinone respectively:



The authors[73] concluded that the oxazolidinone is formed via an intermediate complex:



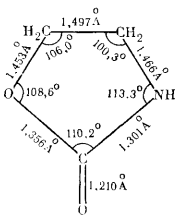
The ^1H NMR spectra confirmed that 3,5-diphenyl-2-oxazolidinone is the main reaction product.

The reactions of 2-methoxyoxirans and of α-halogeno-derivatives of acylphenones with carbon dioxide in aliphatic amines in methanol have been studied[36] and the following reaction mechanism has been proposed:

X = Br, Cl; R^1 = alkyl ; R^2 = CH_3, H .

A series of syntheses of 2-oxazolidinones from epoxides and five-membered heterocycles containing oxygen and sulphur in various combinations have been achieved[93]:

X=O, S; R=H, CH_3, CH_2Cl .



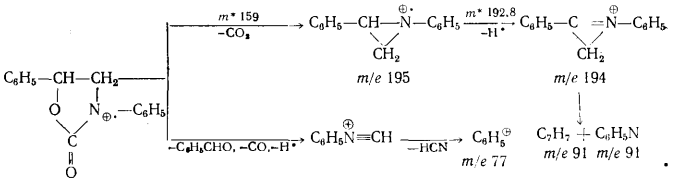
Substituted oxazolidinones have been synthesised[94] by the reaction of epoxides with compounds of the type p-RC_6H_4N = CCl_2 in the presence of $ZnCl_2$ or $SnCl_2$ as catalysts.

III. THE PROPERTIES OF 2-OXAZOLIDINONES

1. The Physical Properties of 2-Oxazolidinones

2-Oxazolidinones are stable heterocyclic compounds whose melting points are in most cases in the range 100–200 °C;[95,96] they are soluble in water and form neutral solutions.

The polymorphism and the mechanochemistry of 5-phenoxymethyl-2-oxazolidinone have been investigated[97] and it has been observed that the oxazolidinone exhibits dimorphism, existing in two independent forms or their mixture.



The crystal structure of 2-oxazolidinone

The crystal structure of 2-oxazolidinone has been described[98]. It has a monoclinic three-dimensional crystal lattice with the unit cell dimensions a = 7.313 Å, b = 5.672 Å, c = 9.970 Å, and β = 110.78° (measured at 24 °C). The bond lengths and the angles in the ring are shown in the Figure above.

The infrared spectra of 2-oxazolidinones have been investigated in a number of studies[99–102]. The carbonyl absorption of 2-oxazolidinones is observed in the range 1740–1810 cm^{-1} (usually at 1740–1760 cm^{-1}). 2-Oxazolidinones with an unsubstituted hydrogen atom at the nitrogen atom show an absorption by the N–H group in the range 3200–3500 cm^{-1}.[100]

Several detailed studies on the NMR of 2-oxazolidinones have been made[66,103].

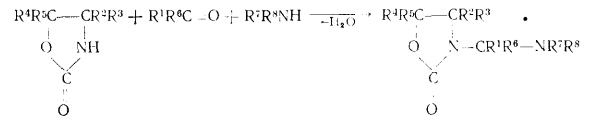
Disubstituted mono- and bis-2-oxazolidinones have been investigated mass-spectrometrically[73,104] and it has been shown that the decomposition of 5-alkyl-, 4-alkyl-, 5-aryl-, and 4-aryl-3-phenyl-2-oxazolidinones takes place as follows: (1) with evolution of CO_2 on β-decomposition; (2) with evolution of CO and the formation of the corresponding aldehyde on α-decomposition. The intense *m/e* 194 peak in the mass spectrum of 5-aryl(or alkyl)-3-phenyl-2-oxazolidinone, characterising the decomposition with evolution of Cl_2, is almost completely absent from the spectrum of 4-aryl(or alkyl)-3-phenyl-2-oxazolidinone, a characteristic feature of which is the cleavage reaction with evolution of CO and the formation of the corresponding aldehyde. For example, the decomposition of 3,5-diphenyl-2-oxazolidinone under the influence of β-irradiation proceeds in accordance with the following scheme:

The dipole moments of 2-oxazolidinones have been published[105] and it has been concluded that the dipolar structure makes a contribution of approximately 21% to the experimental dipole moment (5.04 ± 0.005 D).

Lebedev and Yakshimets[106] investigated the magnetic susceptibility of 2-oxazolidinone and established that the substance is diamagnetic.

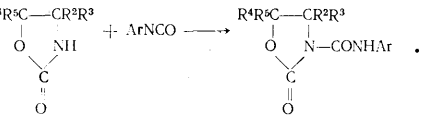
Volumetric titration with silver nitrate, spectrophotometry[107,108], calorimetry[107,109], reaction with indole[110], chromatography[107], and methods based on the formation of a phenylhydrazone[111] have been suggested as methods whereby 2-oxazolidinones can be characterised.

2. The Chemical Properties of 2-Oxazolidinones



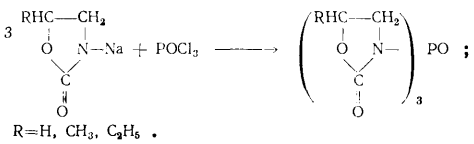
A number of studies have been made on the chemical properties of 2-oxazolidinones. The reactions of 2-oxazolidinones can be divided into the following groups: (a) reactions involving substitution at the ring atoms; (b) ring opening reactions; (c) other reactions involving the ring; (d) reactions of the substituents.

Only the first three groups of reactions, which characterise directly the chemical properties of the oxazolidinone ring, are discussed below.



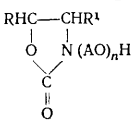
(a) Reactions involving Substitution at the Atoms of the 2-Oxazolidinone Ring

The hydrogen atom linked to the nitrogen atom of the oxazolidinone ring can be substituted by various groups using the following procedures: by reaction with carbonyl compounds, aryl isocyanates, and phosphorus compounds, by alkylation, acylation, carbamoylation, nitration, and amination, by reaction with nitrous acid, etc.

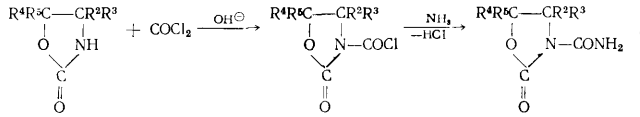


2-Oxazolidinones react with carbonyl compounds in the presence of secondary amines[112]. In the absence of an amine, a second oxazolidinone molecule behaves as an amine (R″R‴NH = $OCOCH_2CH_2NH$). The reaction proceeds as follows:

2-Oxazolidinone-3-carbanilides can be obtained by the reaction of substituted 2-oxazolidinones with aryl isocyanates in the presence of pyridine or triethylamine[113]:



Sodio-derivatives of 2-oxazolidinones react with phosphoryl chloride in DMF in a stream of nitrogen[114]:



Alkylation is usually carried out in the presence of K_2CO_3, NaOH, CH_3ONa, NaH, and other bases[115]. Organic halides[115,116], olefins[117], and ethers together with benzoic acid and mercury acetate[117] have been proposed as alkylating agents.

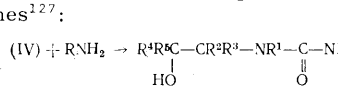
The synthesis of a compound having the general formula

(R, R^1 = H, alkyl, or phenyl; AO = C_2–C_5 alkylene oxide group; n = 1–25) by treating 1 mole of 2-oxazolidinone with n moles of an alkylene oxide in the presence of 0.1–10% of a strong basic catalyst (alkali metal hydroxide, sodium salt of 2-oxazolidinone, or a quaternary base) at 90–180 °C and a pressure of 2–10 atm for 2–4 h has been described in a patent[118].

The nitrogen atom has been acylated in alkaline and acid media[119] and carbamoylation has been carried out by treating 2-oxazolidinone with phosgene in an alkaline medium followed by reaction with ammonia[120]:

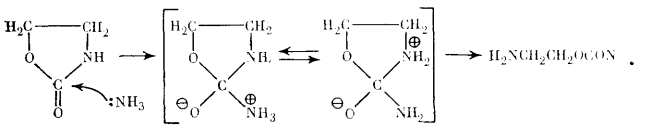
The substitution of the hydrogen atom at the nitrogen atom of the oxazolidinone ring by the NO group has been achieved by the reaction of 2-oxazolidinone with HNO_2 or NOCl.[121]

The nitration of 2-oxazolidinone has been performed by treatment with a mixture of nitric and sulphuric acids or nitric acid and acetic anhydride[122]. The nitro-group can be reduced to the amino-group electrolytically, by hydrogenation in the presence of platinum oxide in an acid medium, or by reaction with zinc and hydrochloric acid[121].



(b) Reactions involving the Opening of the 2-Oxazolidinone Ring

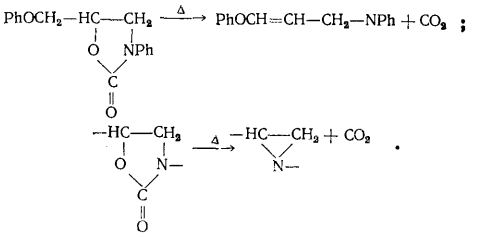
Alkaline hydrolysis of 2-oxazolidinones leads to β-aminoalcohols. It takes place in aqueous[57,116,123] and alcoholic[124] media and in dioxan[125]. It is usually employed to demonstrate the structure and stereochemistry of oxazolidinones[27,37,124,125]. The catalytic conversion of 2-oxazolidinone into the corresponding aminoalcohols by heating the initial compound at 105–200 °C in the presence of bases such as NaOH, KOH, Na_2CO_3, K_2CO_3, and $NaHCO_3$ has been achieved[126]. The reaction takes place in accordance with the following scheme:



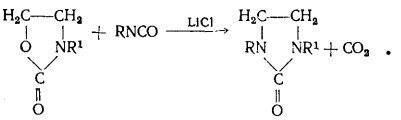
β-Aminoalcohols are also formed on reduction of 2-oxazolidinones with lithium tetrahydroaluminate[27].

N,*N*′-Disubstituted ureas are the main products of the reaction of 2-oxazolidinones with equimolar amounts of primary aliphatic amines[127]:

2-Oxazolidinone reacts with aqueous ammonia to form β-aminoethyl carbamate[128]:

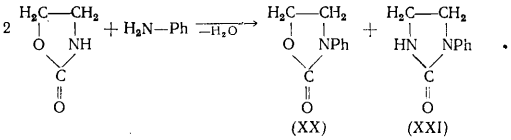


The reaction of 2-oxazolidinones with hydrazine leads to semicarbazides[129]:

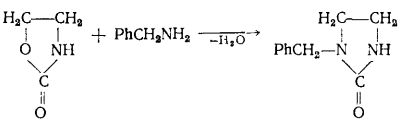


Acid hydrolysis (with concentrated or diluted hydrochloric acid) leads to the formation of the hydrochlorides of β-aminoalcohols[130], while the reaction of 2-oxazolidinone with anhydrous hydrogen chloride results in the formation of β-chloroamine hydrochloride[131].

The thermal stability, the kinetics of the initial stage of the thermal decomposition, and the main decomposition products of 2-oxazolidinones have been investigated[132–134]. It has been shown[133] that heating of 2-oxazolidinones in the absence of air and water is accompanied by autocatalytic decomposition with evolution of CO_2 as the main gaseous reaction product. It was noted that 2-oxazolidinones with alicyclic substituents at the ring nitrogen atom have a higher thermal stability than 2-oxazolidinones with aromatic substituents. Comparison[134] of the thermal stabilities of isocyanurates, oxazolidinones, and carbamates showed that compounds of these classes can be arranged in the following sequence in terms of their thermal stabilities: carbamates < oxazolidinones < isocyanurates. The thermal decomposition of 5-phenoxymethyl-3-phenyl-2-oxazolidinone results in the formation of PhOH, $PhNH_2$, H_2, CH_4, CO, CO_2, C_2H_4, C_2H_6, C_3H_6 + C_3H_8, and a C_4 fraction. The formation of the possible intermediate thermolysis products is illustrated schematically below:



(c) Other Reactions involving the 2-Oxazolidinone Ring



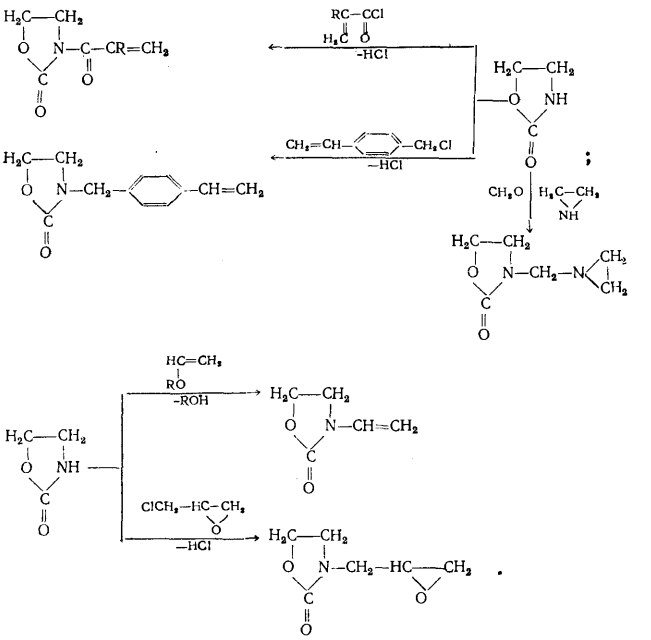
The reaction of *N*-substituted 2-oxazolidinones with organic isocyanates in the presence of lithium chloride leads to *N*,*N*'-disubstituted 2-imidazolidinones[135]:

It has been noted[136] that the reaction of 2-oxazolidinone with aniline results in the formation of water, 3-phenyl-2-oxazolidinone (XX), and 1-phenyl-2-imidazolidinone (XXI):

The synthesis of 1-benzyl-2-imidazolidinone from 2-oxazolidinone and benzylamine has been described[137]:

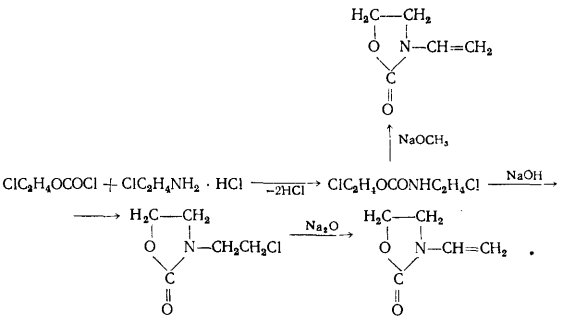
IV. THE SYNTHESIS, PROPERTIES, AND APPLICATIONS OF POLYMERS CONTAINING 2-OXAZOLIDINONE RINGS

One of the most important practical applications of 2-oxazolidinones involves the synthesis of polymers containing 2-oxazolidinone rings; recently these polymers have found applications in the preparation of thermostable and heat-resistant foams, coatings, adhesives, fibres, and electrically insulating materials with effective physicomechanical properties.



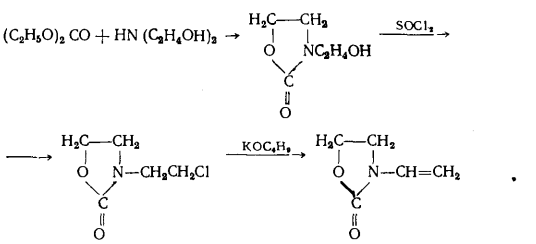
There are virtually no reviews in the Soviet and foreign literature on polymers with oxazolidinone ring. In this section of the present review we shall therefore examine the available information about the synthesis, reaction mechanisms, properties, and applications of polymers in this practically important class.

Numerous methods of synthesis of polymers whose structure incorporates 2-oxazolidinone rings have been described. It is possible to distinguish two fundamentally different types of synthesis of polyoxazolidinones: the first involves the synthesis of the polymers from monomers containing complete 2-oxazolidinone rings in their structure, while in the second the 2-oxazolidinone rings are formed in the course of the synthesis of the polymer. In the former case the products are polymers whose 2-oxazolidinone rings are in a side chain while in the latter case they are in the main chain. They will be examined below in the same order.



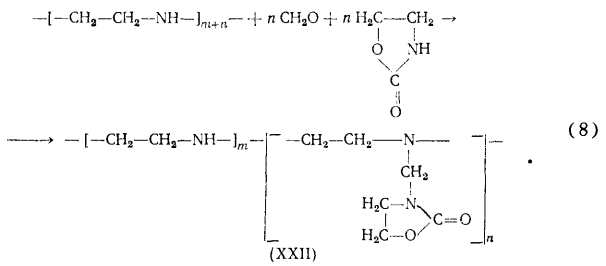
1. Polymers Containing 2-Oxazolidinone Rings in a Side Chain

Polyoxazolidinones based on monomers incorporating complete 2-oxazolidinone rings can be obtained in several ways and contain these rings in a side chain and at the ends of the macromolecules.



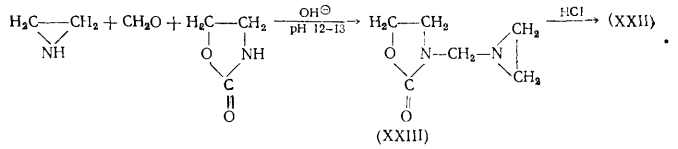
The initial monomers for the synthesis of polyoxazolidinones with side or terminal 2-oxazolidinone rings are obtained by substituting the hydrogen at the nitrogen atom of the oxazolidinone ring by groups capable of polymerisation. A series of syntheses of such monomers are shown schematically below:

The following method of synthesis of *N*-vinyl-2-oxazolidinone has been proposed[138]:



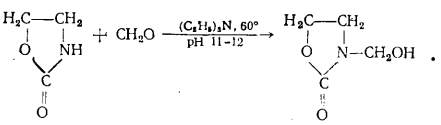
Drechsel[139] obtained *N*-vinyl-2-oxazolidinone by the following procedure:

N-Vinyl-2-oxazolidinones[33,140-142], *N*-isopropenyl-2-oxazolidinones[143], *N*-allyl-2-oxazolidinones[144], 5-methylene-2-oxazolidinones[31], and other 2-oxazolidinones containing unsaturated bonds enter into radical homopolymerisation and copolymerisation reactions with various vinyl and other monomers, such as *N*-vinyl-2-pyrrolidinone[145], *N*,*N*',*N*''-triphenyl-*B*,*B*',*B*''-trivinylborazole[146], maleic anhydride[147], isocyanates[148], acrylonitrile, ethyl acrylate, styrene, methyl methacrylate, vinyl acetate, vinylidene chloride, acrylamide, vinyl chloride, decyl methacrylate[141,142,149,150], monovinyl ethers of glycols having the general formula $HO(C_nH_{2n}O)_x$. $.CH=CH_2$, where $n = 2-4$ and $x = 1-3$,[151] and phthalic anhydride[152]. α,α-Azobisisobutyronitrile is usually employed as the polymerisation catalyst. The polymers and copolymers based on monomeric unsaturated 2-oxazolidinones dissolve in *m*-cresol and acetic, formic and dilute hydrochloric acids, but are insoluble in solvents such as ethanol, acetone, and dioxan. They have fairly high softening temperatures (up to 300° and above) and effective physicomechanical properties, which makes it possible to employ them in various branches of engineering (see below).



A series of polyethyleneimines containing 2-oxazolidinone rings in the side chains have been synthesised[112] in several ways. The reaction of 2-oxazolidinone with formaldehyde and polyethyleneimine at room temperature in solvents such as water, DMF, and a dioxan–water mixture proceeds in accordance with the following scheme:

(8)



(XXII)

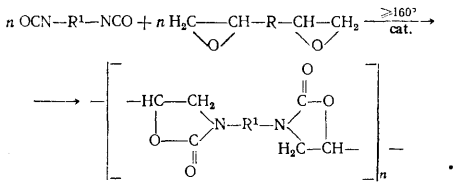
The polymer (XXII) has also been synthesised[112] by the polymerisation of *N*-(1-azirinomethyl)-2-oxazolidinone (XXIII), which had been obtained in its turn from aziridine, formaldehyde, and 2-oxazolidinone:

(XXIII)

In addition, a polymer of type (XXII) had been obtained[112] by the reaction of polyethyleneimine with *N*-hydroxymethyl-2-oxazolidinone in an aqueous medium at room temperature. *N*-Hydroxymethyl-2-oxazolidinone was synthesised from 2-oxazolidinone and formaldehyde by the reaction

The polyethyleneimines described are capable of adsorbing polar substances from aqueous solutions. In an alkaline medium these polymers form complexes with phenol and with toluene-*p*-sulphonic acid; the infrared spectra of the complexes indicate the presence of a hydrogen bond between the CO group of the 2-oxazolidinone ring of the polymer and the hydrogen atom of the phenol or toluene-*p*-sulphonic acid[112].

2. Polymers Containing 2-Oxazolidinone Rings in the Main Chain



There are literature data on the synthesis and properties of linear, branched, and cross-linked poly-2-oxazolidinones and also polymers containing in their structure other rings and functional groups in addition to the 2-oxazolidinone groups. Studies on the synthesis and properties of linear poly-2-oxazolidinones with 2-oxazolidinone rings in the main chain, hydroxy-2-oxazolidinones, and cross-linked oxazolidinone-isocyanurate polymers are examined below.

(a) Linear Poly-2-oxazolidinones

As mentioned above, one of the most important methods of synthesis of mono- and poly-2-oxazolidinones involves the reaction of epoxides with isocyanates, since these starting materials are readily available industrial products.

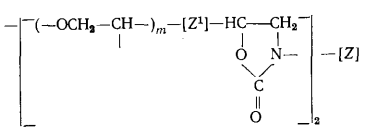
Gromakov et al.[153] investigated the reaction of epoxy-resins with di-isocyanates by differential thermal analysis (DTA). The formation of poly-2-oxazolidinones has been observed in the absence of catalysts at temperatures in the range 160 to 250 °C. The same workers[154] investigated by infrared spectroscopy and DTA the reactivities of various epoxy-resins and di-isocyanates. The reactivities of the epoxy-resins increased in the sequence diglycidyl ether of bisphenol A < triglycidyl isocyanurate < diglycidylaniline. The reactivities of the di-isocyanates increase in the sequence 3,3'-dimethyl-4,4'-diphenylmethylene di-isocyanate < 4,4'-diphenylmethylene di-isocyanate < 2,4(2,6)-tolylene di-isocyanate.

High-molecular-weight linear poly-2-oxazolidinones have been synthesised[77] by the slow addition of a di-isocyanate to a solution of a diepoxide and a catalyst (lithium n-butoxide in butanol) in *o*-dichlorobenzene in accordance with the following reaction:

Effective catalysts for the synthesis of elastomeric poly-2-oxazolidinones have been sought in one of the latest studies on the synthesis of linear poly-2-oxazolidinones[155]. The initial di-isocyanate used was polyoxytetramethylene glycol with terminal isocyanate groups and the diepoxide was the diglycidyl ether of bisphenol A. The polymerisation was carried out in bulk. Insoluble catalysts (LiF, $MgCl_2$) proved to be relatively ineffective; the most effective catalysts were the complexes of LiBr, LiCl, LiI, $MgCl_2$ with hexamethylphosphoramide. With increase of temperature from 80° to 150 °C, the yield of the polymer increased by 20%, the reaction occurring over a period of 1 h at 150 °C. The optimum ratio of the initial epoxy-groups and NCO groups is 45 : 55. Hexamethylphosphoramide is a chelating agent, forming coordinate bonds with metal chlorides. In this connection the influence of the coordination number *m* on the polymerisation was discovered and it was shown that $m = 2$ to 4 is preferred. The authors investigated the physicomechanical properties (Young's modulus, tensile strength, relative elongation, tearing energy, the relaxation of stress, and creep) of elastomers containing oxazolidinone and urethane linkages in the main chain. From their results, it was concluded that, together with the high thermally insulating properties of polyester-urethanes and polyoxazolidinones, the polyoxazolidinone has a higher yield point (T_{yield} is 235 to

245 °C for the polyoxazolidinone and 200–220 °C for polyester-urethane) and retains its strength much more effectively after ageing at 170 °C. However, the polyoxazolidinone has a lower strength at a high temperature, while the tearing energy, the relaxation of stress, and creep are virtually at the same level as in polyester-urethane.

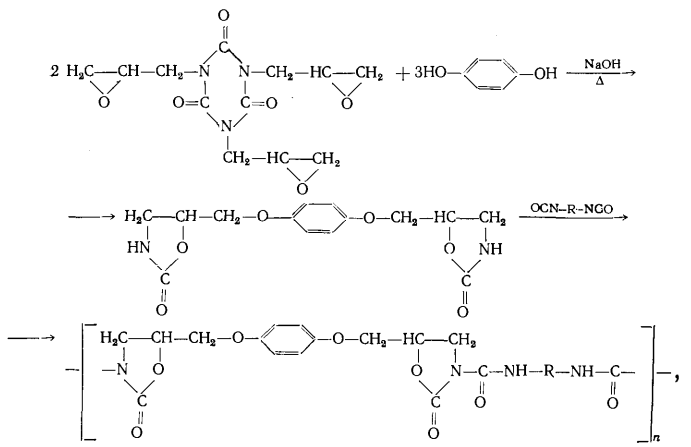
Chelate complexes, namely the Mg, Li, Al, Ba, Ca, Ti, V, Cr, Mn, Fe, Co, Ni, Cu, Zn, Hg, Pb, Sn, Be, Mo, and Zr complexes of β-diketones, dimethylglyoxime, salicylaldehyde, α-nitroso-β-naphthol, benzoylacetone, anthranilic acid, etc. have also been proposed in a patent[156] as catalysts of the reaction of polyisocyanates with polyepoxides leading to the formation of oxazolidinones [polyoxazolidinones?]. Complexes of Lewis acids (Al, Zn, and Fe halides) with Lewis bases such as thioesters, amines, (*N*-alkyl)lactams, amides, etc. have been put forward[157–159] as catalysts for the synthesis of polyoxazolidinones.



Quaternary ammonium salts of the type $(CH_3)_4NI$, $(C_2H_5)_4NI$, $(CH_3)_4NBr$, and $(C_2H_5)_4NBr$ are very widely used as catalysts of the oxazolidinone formation reaction[160–162].

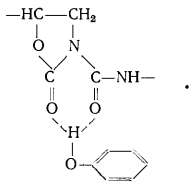
Linear poly-2-oxazolidinones have been synthesised in DMF in the presence of $(CH_3)_4NI$ at 140–160 °C.[61,64,163]. The possibility of the occurrence of a side reaction of DMF with isocyanates, described by Weiner[76], was not discussed in the above investigations, although it undoubtedly occurs in the given instance.

Herweh and Whitmore[164] synthesised poly-2-oxazolidinones by the 1,3-cycloaddition of diglycidyl ethers and di-isocyanates in the presence of a catalyst (lithium chloride), also in DMF. The reaction was carried out with refluxing in DMF for 12 h. It was found that at 150 °C the side reaction of isocyanates with DMF [76] takes place together with the formation of oxazolidinones. It was noted[164] that the poly-2-oxazolidinones obtained from aromatic di-isocyanates have a lower degree of crystallinity than the polymers obtained from aliphatic di-isocyanates. The authors[164] believe that the amorphous structure of the poly-2-oxazolidinones is due to the irregular structure of the polymer chain and the presence in the latter of isomeric 2-oxazolidinone rings.

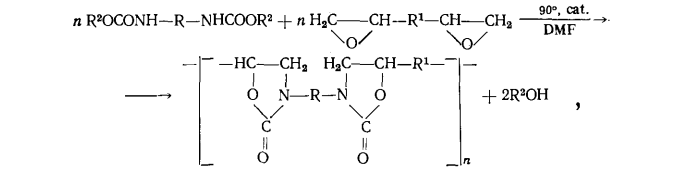


ε-Caprolactam[165], organic compounds of zinc and aluminium[69], cyclic amidines[72], a wide variety of phosphonium compounds[71,166–169], salts of the type BF_3–$C_2H_5NH_2$,[170] tri(ethylaminophenyl) borate[171], and metal compounds containing halogens and the CO_3^{2-}, NO_2^-, ClO_4^-, CN^-, and SCN^- groups with and without neutral ligands[172] have also been proposed as catalysts for the synthesis of poly-2-oxazolidinones.

Novolak epoxy-resins modified by oxazolidinone and having the general formula

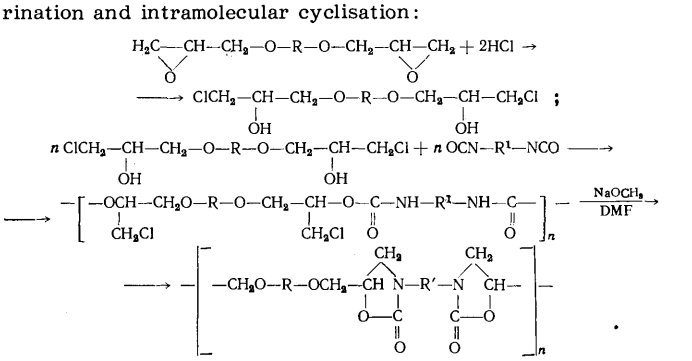


where Z is the organic polyisocyanate residue, Z^1 the epoxy-compound residue, m = 1.5–5.0, have been synthesised[173] by the reaction of polyisocyanates with epoxy-compounds. These polymers are suitable for the preparation of adhesives which are stable under the conditions of high humidity.



Poly-2-oxazolidinone has been obtained[174] by the reaction of di-isocyanates with bisoxazolidinones in *N*-methylpyrrolidinone at 48 °C in the presence of triethylenediamine. The bisoxazolidinone was obtained by refluxing tris(2,3-epoxypropyl) isocyanurate with hydroquinone in DMF in the presence of NaOH:

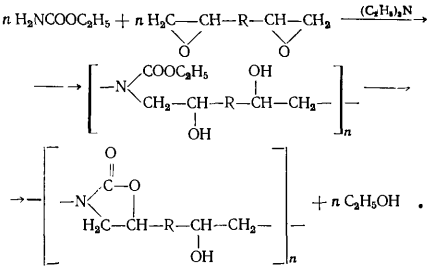
where R = alkyl or aryl. The polymers obtained are soluble in *N*-methylpyrrolidinone and *m*-cresol and less so in DMF. The intrinsic viscosities are 0.16–0.64 dl g^{-1} depending on the nature of the di-isocyanate. The presence of the 2-oxazolidinone rings in the polymer is responsible for their ability to form complexes with phenol:



One of the common methods of synthesising poly-2-oxazolidinones involves the reaction of diepoxy-compounds with difunctional urethanes[7,163,175]:

where R = aryl.

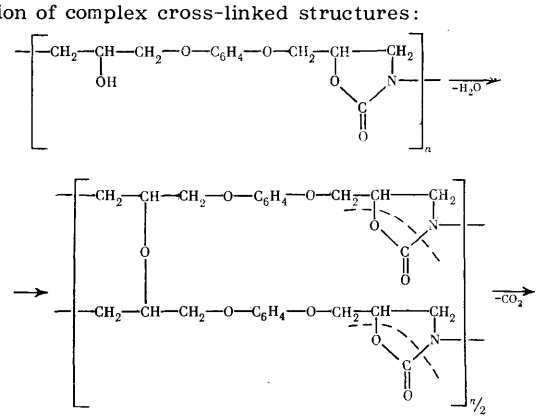
It has been shown[175] that the solubilities and melting points of polymers are determined mainly by the structure of the initial diurethane.



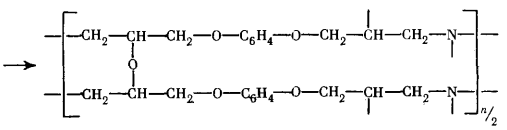
Polyoxazolidinones have been synthesised[176] by the reaction of bischlorohydrins with isocyanates followed by dehydrochlorination and intramolecular cyclisation:

The rate of ring closure depends on the nature of the *N*-substituted polyurethanes. The polyurethanes synthesised from di(4-isocyantophenyl)methane reacts in several

minutes: those obtained from 2,4-tolylene di-isocyanate react more slowly owing to steric hindrance (due to the *o*-methyl group); the cyclisation of the polyurethanes based on tetramethylene di-isocyanate is slower still. The polyoxazolidinones[176] are soluble in DMF and *m*-cresol but are insoluble in acetone, methanol, n-hexane, tetrahydrofuran, dioxan, toluene, and formic acid. The initial polyurethanes with CH_2Cl groups[176] are amorphous substances, while the polyoxazolidinones obtained from them and aromatic di-isocyanates are partly crystalline, and those obtained using aliphatic isocyanates are highly crystalline.



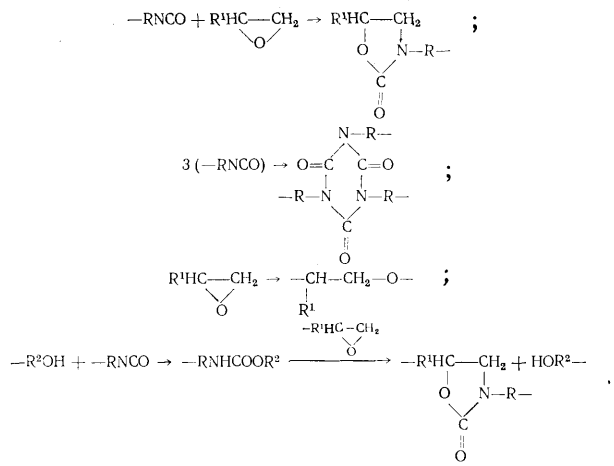
The reaction of ethylurethane with various diepoxy-compounds yielded[177–181] a new class of polymers—linear hydroxylated polyoxazolidinones:



The diglycidyl ethers of hydroquinone, resorcinol, and di(hydroxyphenyl)propane, as well as epoxide oligomers have been used as the diepoxy-component.

The hydroxylated polyoxazolidinones are soluble in the cold in DMF, *m*-cresol, and sulphuric acid. Compared with the usual polyurethanes and hydroxylated *N*-arylpolyurethanes, these polymers have a higher thermal stability, decomposing 260–300 °C above their softening temperatures. The products obtained from the *trans*-forms of the diglycidyl ethers of bisphenols are more resistant to thermal decomposition than the products based on the corresponding *cis*-forms.

The hydroxylated polyoxazolidinones readily react with mono- and di-isocyanates. On oxidation, they give rise to carbonyl compounds, which indicates the presence of secondary hydroxy-groups in their structure. The reactivity of the secondary hydroxy-groups is much higher than that of the second hydroxy-group in isopropyl alcohol, which has been explained[180] by the presence of the oxazolidinone ring nitrogen atom in the β-position relative to them. The hydroxy-groups form intramolecular hydrogen bonds with this atom. The mechanism of the pyrolysis of polymers of this kind has been established by the DTA method in combination with dynamic and isothermal thermogravimetric data[181,182]. It has been observed that the thermal degradation of the oxazolidinone ring is preceded by intermolecular dehydration, which is followed by the decarboxylation of the rings with formation of complex cross-linked structures:

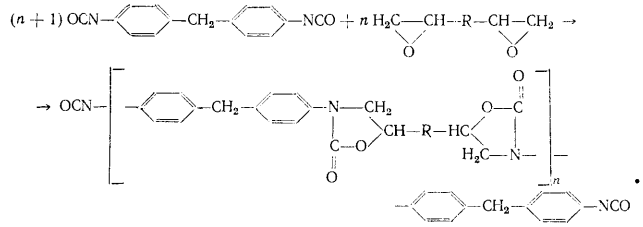


The enhanced reactivity of the hydroxy-groups, the regularity of their arrangement along the polymer chain, and the presence of the thermally stable oxazolidinone rings makes these low-molecular-weight polymers likely to be useful as hardening agents for polyurethane resins[179]. These potential hardening agents can ensure a specified distance between the cross links, which should promote in its turn the reproducibility of properties of the final materials and should improve many mechanical properties. The effectiveness of linear hydroxylated polyoxazolidinones in the hardening of macrodi-isocyanates has been demonstrated[180]. This entails the formation of insoluble and non-swelling very strong polyurethane film materials with good mechanical properties and a higher thermal stability than the polyurethanes hardened by polyols and polyamines.

(b) Cross-Linked Polymers with 2-Oxazolidinone Rings

Several methods of synthesis of cross-linked polymers containing 2-oxazolidinone rings have been described in the Soviet and foreign literature. These are mainly polymers incorporating isocyanurate rings together with 2-oxazolidinone rings.

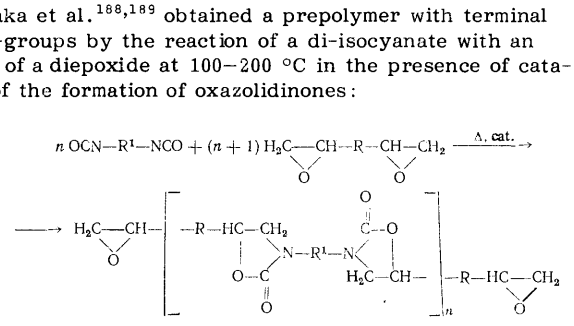
As already mentioned, the interaction of isocyanates with epoxides involves, apart from the formation of 2-oxazolidinone rings, the competing cyclotrimerisation reaction of the NCO groups. The interaction of epoxide oligomers with di-isocyanates has been investigated[183]. It has been shown that, in the presence of an excess of a di-isocyanate at 160–165 °C, the formation of oxazolidinones is accompanied by the cyclotrimerisation of the isocyanate groups, the homopolymerisation of the epoxy-groups, the reaction of the isocyanates with the compound containing hydroxy-groups, and the reaction between the urethane and the epoxide:



In the synthesis of foam plastics by a single-stage method using an excess of di-isocyanate[60,184] the polymerisation reaction takes place in several minutes and there is virtually no homopolymerisation of the epoxy-groups. The main competing reactions are then cyclotrimerisation and the formation of a urethane.

When tertiary amines are used as catalysts, the epoxide oligomer greatly enhances the catalytic effect in the polycyclotrimerisation of the isocyanate, accelerating thereby this

reaction. The occurrence of competing reactions precludes in this instance the possibility of regulating the distance between the cross links. The considerable brittleness and strain of the foam plastics can be explained by the presence of a large number of isocyanurate rings. The single-stage process takes place[60,184] in the presence of catalysts of the formation of oxazolidinone and cyclotrimerisation, for example, *N,N',N''*-tri[3-(dimethylamino)propyl]hexahydro-*sym*-triazine and the aluminium chloride–hexamethylphosphoramide complex.

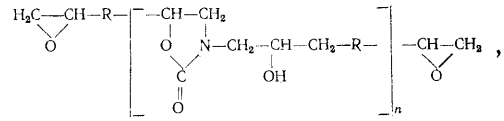


The application of the prepolymer (two-stage) method makes it possible to avoid to a large extent the above difficulties, because cycloaddition (the formation of the oxazolidinone ring) and polytrimerisation (the formation of the polyisocyanurate) take place separately.

Thus the synthesis of an oxazolidinone prepolymer with terminal isocyanate groups has been described[60,185–187]; the synthesis was carried out by the reaction of a diepoxide with an excess of a di-isocyanate at 100–150 °C in the presence of a Friedel–Crafts catalyst ($AlCl_3$, $FeCl_3$, and $ZnCl_2$) for 0.5 to 5 h:

In the second stage the prepolymer is hardened by the polycyclotrimerisation of the terminal isocyanate groups in the presence of catalysts: 2,4,6-tris(dimethylaminomethyl)phenol[185,186] and 2,4,6-tris(dimethylaminoethyl)phenol[60]. However, from our point of view it is doubtful if it is possible to separate clearly and carry out in succession the two reactions—the formation of oxazolidinones and polycyclotrimerisation.

Tanaka et al.[188,189] obtained a prepolymer with terminal epoxy-groups by the reaction of a di-isocyanate with an excess of a diepoxide at 100–200 °C in the presence of catalysts of the formation of oxazolidinones:



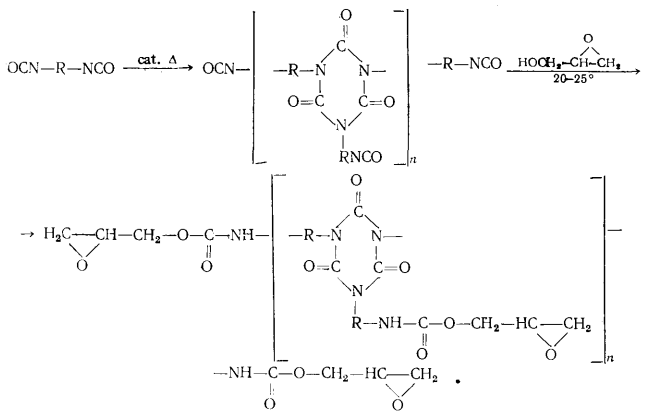
In the second stage an excess of the di-isocyanate was added to the oxazolidinone prepolymer with terminal epoxy-groups and three-dimensional polymers were obtained in the presence of catalysts of the formation of oxazolidinones and polycyclotrimerisation.

Polyisocyanates based on diphenylmethylene di-isocyanate, a mixture of 2,4- and 2,6-tolylene di-isocyanates, and hexamethylene di-isocyanate are usually employed in the synthesis of oxazolidinone-containing polyisocyanurate foam plastics. Among epoxides, applications have been found for epoxide polymers based on 2,2-di(hydroxyphenyl)propane (for example Epon-828 with an epoxide equivalent of 189) and others[60]. Potassium and magnesium ethoxides, aluminium isopropoxide, and iron(III) chloride have been used as catalysts of the formation of oxazolidinones[60].

It has been established[60] that the reaction between unpurified di-isocyanates and the Epon-828 epoxy-resin at 130 °C takes place without the addition of a catalyst. A considerable increase in the viscosity of the reaction medium was observed in the course of the reaction and oxazolidinone rings were formed. However, when purified di-isocyanates were used, a visible increase of viscosity was not observed. The authors[60] explained this by the presence in the unpurified di-isocyanates of admixtures of iron chloride (0.01 wt.%) which catalysed the cycloaddition reaction with formation of oxazolidinone rings.

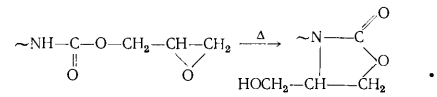
A method of synthesis of oxazolidinone-containing epoxide oligomers from polyglycidyl ethers of polyols and isocyanuric acid in the presence of catalysts (tertiary amines, quaternary ammonium salts, alkali metal halides and alkoxides, the phosphonium compounds) at 130–180 °C has been described[190]. The reaction takes place with decomposition of the isocyanurate rings and the formation of oxazolidinone rings. The products are oligomers having the general formula

where R is a bivalent residue of the polyglycidyl ether of the polyol and $n = 1–10$. Such oligomers have been synthesised both in bulk and in solvents (DMF, nitrobenzene, *o*-dichlorobenzene, and dioxan). The corresponding derivatives of phenols, bisphenols, Novolak resins, polyoxyalkylene glycols, and aliphatic polyols can be used as the polyglycidyl ethers.



A patent[191] describes the synthesis of thermoreactive resins by the reaction of a polyisocyanate, containing in its structure isocyanurate rings, with a polyepoxide compound, the reaction involving the free isocyanate groups. The resins were hardened at 200–300 °C without a catalyst or at 100 to 185° in the presence of a hardening agent of the amine type.

Oxazolidinone-isocyanurate foam plastics are not very brittle and their combustibility is insignificant. In a study of the influence of the content of the epoxide oligomer in the prepolymer on the physicomechanical properties of oxazolidine-containing foam plastics, it was shown[60,185,186] that an increase of the concentration of the epoxide greatly increases the weight loss in fire tube tests. The content of the epoxide oligomer influences the smoke density particularly when the weight ratio of the epoxide to the isocyanate is greater than 0.1–0.2. An appreciable decrease of the brittleness of the foam plastics is observed when the epoxide : isocyanate weight ratio is approximately 0.05. A further increase of the content of the epoxide entails an insignificant increase of the brittleness[60]. The epoxide : isocyanate ratio (by weight) of 0.05–0.1 may be regarded as optimal.



The thermal stability of the foam plastics has been investigated by thermogravimetric analysis (TGA). It was shown[60] that the onset of weight loss is observed at 100 °C and amounts to approximately 30% by 400°. In air, oxazolidinone-isocyanurate foam plastics are more stable than in an atmosphere of nitrogen; in both cases their thermal stability is higher than that of polyurethane foam plastics, evidently owing to the greater stability of the isocyanurate and oxazolidinone rings. It has also been noted[186] that, in contrast to the polyurethane foam plastics and the unmodified polyisocyanurate foam plastics, the mechanical properties of oxazolidinone-isocyanurates are fully isotropic in all directions.

A new method of synthesis of epoxyisocyanurate oligomers has been proposed[92,192–195]. In the presence of polycyclotrimerisation catalysts the initial di-isocyanates were converted into oligoisocyanurates containing isocyanate groups;

then at room temperature the terminal isocyanate groups were made to react with hydroxylated epoxides, for example, with glycidol:

It was shown[192-195] that the hardening of the resulting epoxyisocyanurate oligomers in the presence of hardening agents (acid anhydrides) is accompanied by competing cross-linking reactions involving the epoxy-groups and intramolecular cyclisation with formation of oxazolidinone rings:

However, in the above reports no mention is made of the possibility of the reaction of epoxide rings with isocyanurate rings accompanied by the decomposition of the latter, which has been described in a number of communications[78-80,190].

Hardened epoxyisocyanurates containing 2-oxazolidinone rings have been found to have good physicomechanical properties, to be chemically stable, and to exhibit an effective adhesion in varnish coatings[194]. The temperature of the 10% weight loss by hardened epoxyisocyanurates reached 290 to 300 °C.[88] The ratio of the oxazolidinone rings and cross-links and hence also the physicomechanical and thermal properties can be regulated by the amount of hardening agent and by varying the hardening conditions[88].

3. Applications of Poly-2-Oxazolidinones

Polymers containing oxazolidinone rings are widely used in various branches of modern technology. Their thermal stability and heat resistance are high compared with epoxide materials and polyurethanes and they are more elastic and have more effective physicomechanical properties than polyisocyanurates. By virtue of this set of properties, poly-2-oxazolidinones are used successfully as coatings, varnishes[68,69,156,168,189,190,192,194,196-200], electrically insulating materials[156,188,189,198,201], and binders for various composite materials[156,168,169,190,198,202], in rubber compositions[203], and as adhesives[85,163,168,189,190,197,199], foam plastics[60,68,157-160,184-187,196,204-206], fibres, films[174], corrosion inhibitors[33], etc.[140,144,145,198].

After the manuscript had been sent to the editors, a series of studies on oxazolidinones were published.

Gramain and Remuson[207] described the photochemical oxidation of 2-oxazolidinone which takes place on irradiation by the light of a high-pressure mercury lamp in the presence of O_2 and a 0.1 M solution of Ph_2CO in t-butyl alcohol with formation of oxazolidine-2,4-dione. The study of Itskovich et al.[208] was devoted to the intramolecular cyclisation of diepoxycarbamates with formation of oxazolidinone rings. Kadurina et al.[209] showed that the reactivity of diepoxides in reactions with di-isocyanates decreases in the following sequence: aliphatic diepoxides > aromatic diepoxides > alicyclic diepoxides, the epoxide ring of the alicyclic group altogether failing to react with NCO groups in the absence of a catalyst. According to the authors, steric factors and the lower mobility of the epoxide oligomers with cyclic groups determine their reactivity.

The study of Shukurov et al.[210] was devoted to the synthesis of copolymers of aromatic di-isocyanates and epoxy-resins with high impact strength, hardness, and heat resistance. Sorokin et al.[211] suggest that substituted ureas be used as hardening agents for epoxide oligomers; 2-oxazolidinone rings are then formed in the hardened polymer. Two studies[212,213] were devoted to the synthesis and viscoelastic properties of thermoreactive oxazolidinone-isocyanurate resins. Several patents[214-216] report the synthesis of oxazolidinone-containing polymers. Numata and Kinjo[217] demonstrated the possibility of synthesising oxazolidinone-isocyanurate resins modified by raw rubber. A patent[218] describes the synthesis of 2-oxazolidinone derivatives by the cyclocondensation of substituted β-aminoalcohols with CO_2.

The Present State of Quantum-chemical Calculations of the Intermolecular Interaction of Polyatomic Molecules

V.A.Zubkov, B.I.Kolegov, and T.M.Birshtein

In the present review, the results of quantum-chemical calculations of the energy of the interaction of polyatomic molecules are discussed for the case of dimers. The main theoretical approaches used in the calculation of intermolecular interaction, the self-consistent field method (supermolecule approximation) and perturbation theory, are analysed briefly. The range of applicability and the advantages and disadvantages of these main approaches are evaluated. The results of non-empirical calculations of the interaction of molecules forming dimers of different kinds: with the participation of hydrogen bonds, donor-acceptor complexes, and others, are examined. The accuracy of non-empirical calculations and the influence of the basis set used are discussed, and recommendations for improving the non-empirical data are given. The possibility of constructing analytical potentials (including atom-atom potentials), which can be used to study many-particle systems, from the results of non-empirical calculations is analysed. In addition to non-empirical calculations, the possibilities provided by semi-empirical methods of calculating the intermolecular interaction of polyatomic molecules both in the self-consistent field approximation and using perturbation theory are also examined. The bibliography contains 202 references.

I. INTRODUCTION

Intermolecular interactions (IMI) play an important role in many physical and chemical phenomena. The existence of liquid and solid phases, the effects of the self-organisation of biological molecules and more complex structures, solution and adsorption processes, etc. are determined by IMI.

One of the main tasks in the theoretical study of IMI is the study of the potential energy surface for the interaction of two molecules—a dimer. The total intermolecular potential can be obtained from the experimental data only in rare cases, so that extensive use has been made of theoretical approaches to the estimation of IMI using the most varied approximations and methods, from empirical atom-atom potentials to non-empirical (*ab initio*) quantum-chemical calculations. The most reliable data are obtained from precision non-empirical calculations, in which the wavefunctions are constructed using a sufficiently broad set of basis functions (extended basis) and, in addition, account is taken of electron correlation. These calculations are extremely laborious, and up to the present it has been possible to use them to study only the interaction of atoms and various small molecules. To analyse

the IMI of polyatomic molecules, it is necessary to carry out less rigorous non-empirical calculations using restricted basis sets. For complex molecules, however, even these calculations are extremely laborious, and often present an insoluble computational problem, and it is then necessary to resort to the semi-empirical methods of quantum chemistry; the results of non-empirical calculations for model molecules with a small number of atoms can be used to estimate the reliability of semi-empirical methods.

Data on the potential energy surface of the dimer make it possible to proceed to the study of a system of many molecules and to study the structure and properties of liquids and solids. A natural step on going from the dimer to a system consisting of a large number of molecules is the construction of analytical pair potentials of the atom-atom type, carried out on the basis of information on the potential energy surface, obtained non-empirically. The analytical potentials found in this way are used to calculate various characteristics of polyatomic systems; in a number of cases, the Monte Carlo method is used.

Considerable experience of non-empirical calculations of IMI has now accumulated, calculations have been carried out for a large number of dimers with different types of bonding, and definite ideas exist on the most effective methods of calculation and their accuracy and ranges of application. In the present review, the results of non-empirical calculations of IMI, different methods of constructing analytical IMI potentials on the basis of *ab initio* calculations, and the results of IMI calculations obtained by various semi-empirical quantum-chemical methods are discussed. The review deals chiefly with the results of calculations on polyatomic molecules; the large number of papers dealing with the interaction of atoms and diatomic molecules of the type $H...H^+$, $H...H$, $H_2...H_2$, He...He etc. are not examined in the present work.

II. NON-EMPIRICAL METHODS FOR CALCULATING INTERMOLECULAR INTERACTIONS

There are two main approaches to the calculation of the energy of IMI. One is based on the variation principle. This principle is applied in a system consisting of several molecules, which is regarded as a single quantum system—a supermolecule. The energy of the interaction is calculated as the difference between the energy of the ground state of the supermolecule and the total energy of the corresponding isolated molecules. Since the most widespread method for estimating the energy and constructing the wavefunctions of molecules is the method of molecular orbitals (MO), which are determined from the solution of the Hartree–Fock–Roothaan equations, often called self-consistent field (SCF) equations, this approach will subsequently be called the SCF approximation or the supermolecule approximation. In the second approach, the energy of the interaction of the molecules is determined using perturbation theory, whose application requires a knowledge of the wavefunctions and energies of not only the ground states but also the excited states of the isolated molecules.

1. The Method of Molecular Orbitals and the Basis Sets Used in Non-empirical Calculations

Molecular orbitals are usually constructed as linear combinations of atomic orbitals (LCAO) and are determined from the solution of the SCF equations. The principles of SCF theory have been described in detail in many monographs (see, for example, Refs.1–4), so that only those points necessary for the subsequent discussion will be considered here.

The wavefunction of the system is represented in the form of a Slater determinant, constructed from the MO with allowance for the spin properties of the system. This wavefunction with energy E^{SCF} is an approximate solution of the Schrödinger equation corresponding to the ground state. To obtain a better approximation to the solution of the Schrödinger equation, it is necessary to take account of electron correlation. Although the energy of electron correlation E^{cor} makes up only a small fraction of the total energy, allowance for this energy is nevertheless important in the examination of many properties of molecules, The value of E^{cor} is determined either by the method of configurational interaction (CI) or from perturbation theory.

The accuracy of non-empirical calculations of E^{SCF} and E^{cor} depends on the type and number of the basis AO used in the construction of the MO. If Slater orbitals (ϕ_{STO}) are used as AO, completely satisfactory results are obtained if each AO is represented by a linear combination of two ϕ_{STO} (double zeta basis, DZ). A basis set in which there is one ϕ_{STO} for each AO is called a minimum basis set.

In the Slater basis, however, it is difficult to calculate a number of integrals appearing in the SCF equations. In most cases, therefore, non-empirical calculations are carried out with Gaussian orbitals (ϕ_G). Since these functions decrease too rapidly with distance, to obtain results equivalent to those obtained with Slater orbitals, each of the functions ϕ_{STO} is represented in the form of a sum of several functions ϕ_G, leading to an increase in the number of SCF equations. Grouping of some of the functions ϕ_G (contraction) makes it possible to decrease the number of SCF equations. The most widely encountered basis sets, consisting of Gaussian functions, and the methods for contraction are described in Refs.5 and 6.

To find a wavefunction close to the Hartree–Fock limit, basis sets consisting of a large number of functions are required. At the present time, this procedure can be carried out only for small molecules. Calculations for polyatomic systems are usually carried out in restricted basis sets. In particular, extensive use is made of the minimum STO-3G basis set[7], in which there are three ϕ_G for one ϕ_{STO}. The basis set 4-31G,[8] in which the orbitals of the valence shells are divided into two groups, is close to the DZ Slater basis sets. There are also basis sets containing polarisation functions P, describing AO of the d and f type for atoms of the second period (for example, the basis sets 6-31G* and 6-31G**).[9] The selection of the optimum basis set represents one of the most important problems in non-empirical calculations.

2. The SCF Approximation

In SCF methods, the energy of intermolecular interaction is calculated using the equation

$$E_{int}^{SCF} = E_{AB}^{SCF} - E_A^{SCF} - E_B^{SCF} \quad (1)$$

where E_{AB}^{SCF}, E_A^{SCF}, and E_B^{SCF}, represent respectively the Hartree–Fock energies of the supermolecule AB and the isolated non-interacting molecules A and B. Eqn.(1) makes it possible to obtain only an approximate (Hartree–Fock) value of the energy of interaction, and for the further refinement of the energy of interaction it is necessary to take account of correlation corrections: $E_{int} = E_{int}^{SCF} + E_{cor}^{SCF}$. The correlation energy is made up of the intramolecular and intermolecular correlation energies. The most significant for

IMI is allowance for intermolecular correlation, which at large distances is equivalent to the dispersion energy E_{disp},[10] obtained in perturbation theory.

Calculations in the SCF approximation can be divided into three classes, depending on the nature of the basis set used.

1) Calculations in Hartree–Fock basis sets taking complete account of correlation. The accuracy of the results of these calculations is comparable with that of experiment, but the calculations can only be carried out for small systems. Calculations of this kind have been reviewed in Ref.11.

2) Calculations in DZ + P extended basis sets, and also in the basis sets DZ, 6-31G**, etc., are restricted to comparatively small systems, but their range of applicability is expanding rapidly.

3) The most widely encountered calculations are those in restricted basis sets (of the type 4-31 G) and particularly in minimum basis sets. As shown below, calculations in minimum basis sets can be applied to fairly complex systems.

In calculations in extended, restricted, and minimum basis sets, allowance for electron correlation usually reduces to the calculation of the dispersion energy.

The accuracy of calculations in restricted basis sets can be increased if the basis set superposition error (BSSE) is eliminated; this error arises because the basis set in the calculation of the supermolecule AB is broader than that in the calculation of the isolated molecules A and B. To eliminate this error, the calculation of E_A^{SCF} and E_B^{SCF} is carried out in the basis set used for the system AB (the counterpoise (CP) method[11,12].

For the analysis of the physical nature of IMI, it is of considerable interest to separate E_{int}^{SCF} into its components, although this separation is somewhat arbitrary. The principal components of E_{int}^{SCF} are the electrostatic energy ($E_{el\text{-}st}$), the exchange energy (E_{exch}), the induction (or polarisation) energy (E_{ind}), and the energy of delocalisation or charge transfer (E_{ct}), so that it is possible to write:

$$E_{int}^{SCF} = E_{el\text{-}st} + E_{exch} + E_{ind} + E_{ct} \qquad (2)$$

Effective methods exist[13–16] for separating E_{int}^{SCF} into its components. Usually, E_{ct} is determined as the difference $E_{int}^{SCF} - (E_{el\text{-}st} + E_{exch} + E_{ind})$. It is only in the improved scheme proposed in Ref.14 that E_{ct} is calculated directly, and an additional component is introduced, $E_{mix} = E_{int} - (E_{el\text{-}st} + E_{exch} + E_{ind} + E_{ct})$, in which account is taken of interactions of higher orders between different components.

The MO LCAO SCF approximation is now the principal method in non-empirical calculations of IMI for polyatomic molecules, since there exist well developed procedures for solving the Hartree–Fock–Roothaan equations. On the other hand, the procedure for calculating IMI using perturbation theory is still not fully developed (see below). Another advantage of the SCF method is the possibility of studying the interaction of molecules at short distances.

3. The Approximation of Perturbation Theory

In perturbation theory (PT), the Hamiltonian H_{AB} of the system AB is written as follows:

$$H_{AB} = H_A + H_B + V_{AB} = H_0 + V_{AB} \qquad (3)$$

where H_A and H_B are the energy operators of the isolated molecules A and B, V_{AB} the operator of the interaction, regarded as a perturbation, and $H_0 = H_A + H_B$. For large intermolecular distances (0.5–0.8 nm) it is possible to use as the basis functions of perturbation theory the products of the wavefunctions $A_i^0.B_j^0$ of the isolated molecules (i and j are the indices for the states). This method makes it possible to estimate the long-range components of E_{int} : $E_{el\text{-}st}$ in first-order perturbation theory, and E_{ind} and E_{disp} in second-order[11,17–19]. At distances close to the van der Waals minimum (0.3–0.4 nm), it is necessary to take account of exchange effects, and as functions of zeroth order it is necessary to take the antisymmetrised products $\mathscr{A}(A_i^0.B_j^0)$, which, however, unlike the products $A_i^0.B_j^0$ are not eigenfunctions of the Hamiltonian H_0. This leads to difficulties in the construction of the series of perturbation theory.

In the "symmetrical" approaches to this problem, the operator H_{AB} is divided more or less arbitrarily into $H^0 + V^{AB}$ [$H^0 \neq H_0$, $V^{AB} \neq V_{AB}$, compare with Eqn.(3)] in such a way that the antisymmetrised products $\mathscr{A}(A_i^0.B_j^0)$ are eigenfunctions of the operator H^0.[18,20,21] This makes it possible to take account of exchange effects using ordinary perturbation theory. The "non-symmetrical" formalism starts from the natural choice of H_0 and V_{AB} [Eqn.(3)], but in the expansion, forced antisymmetrisation of the wavefunction is carried out by means of the appropriate projection operators. Different "non-symmetrical" perturbation schemes differ from one another in the choice of projection operators and the method of applying them[22–27]. Although the two approaches in principle give equivalent results[18], the "non-symmetrical approaches" have been more widely used.

Different versions of perturbation theory have been used to carry out detailed studies of interaction in the simplest systems (H...H, He...He). The results obtained, in particular the ratio of the contributions of second and third orders, make it possible to state[18,26,28] that in the attraction region the interaction between molecules with closed shells can be explained by restricting the treatment to terms of second order, that is by representing approximately the IMI energy in the form:

$$E_{int}^{PT} = \Delta E^{(1)} + \Delta E^{(2)} \qquad (4)$$

where $\Delta E^{(1)} = E_{el\text{-}st} + E_{exch}$ is the first order contribution, $\Delta E^{(2)} = E_{ind} + E_{disp} + E_{exch}^{(2)}$ the second order contribution, and E_{exch} the second order exchange energy, taking account of the exchange corrections to E_{ind} and E_{disp}. This conclusion is confirmed by calculations for more complex systems[29,30].

The different versions of perturbation theory generally differ only in the expressions for $E_{exch}^{(2)}$.

Precise calculations of the interaction H...H and He...He have shown[18] that the contribution of $E_{exch}^{(2)}$ represents a few percent of E_{int}^{PT}. This contribution has not been estimated for more complex systems, but a precise calculation for the dimer $(H_2O)_2$ showed[30] that satisfactory values of E_{int}^{PT} are obtained without taking account of E_{exch}. It may be assumed that the part played by $E_{exch}^{(2)}$ is also small in the case of the interaction of polyatomic molecules. A rigorous analysis of E_{ind} [28] showed that in the range of non-negligible overlap, allowance for induction interaction requires the introduction of significant ionic terms into the wavefunction. This means that for the correct calculation of E_{ind}^{PT} it is necessary to use as basis functions the wavefunctions of excited states, which contain ionic terms, that is states with charge transfer.

Thus in the calculation of the interaction energy from perturbation theory in extended basis sets which make it possible to take account of ionic states, it is possible to restrict the treatment to the contributions $E_{el\text{-}st}$, E_{exch}, E_{ind}, and E_{disp}. If however the basis set of the excited states is restricted and does not contain ionic terms, it is necessary

to take direct account of the contribution of E_{ct}. This quantity is used in explicit form in the perturbation theory developed by Murrell and co-workers[31], and also in the "symmetrical" theory[20].

The possibilities provided by perturbation theory and the SCF method can now be compared. Unlike E_{int}^{SCF}, the quantity E_{int}^{PT} contains E_{disp} directly. For the other components, for exact (correlated) wavefunctions, the calculation of the electrostatic and exchange energies from perturbation theory and in the SCF approximation leads to identical results. The differences for the Hartree–Fock limit are also negligible. In the calculation in a basis set containing ionic terms, E_{ind}^{PT} corresponds to the sum of E_{ind}^{SCF} and E_{ct}^{SCF} from Eqn.(2) (it must be borne in mind that E_{ind}^{SCF} and E_{ct}^{SCF} also contain added terms from higher order contributions). In the calculation in restricted basis sets without ionic states, E_{ind}^{PT} is compared only with E_{ind}^{SCF},[29] but in this case it is necessary to estimate E_{ct}^{PT}, for example according to Ref. 31. It is suggested[18] that $E_{exch}^{(2)}$ corresponds to a certain fraction of E_{ct}^{SCF}.

There are grounds for assuming that the SCF method and perturbation theory give equivalent results[29,30,32], particularly in calculations in extended basis sets[30]. The methods of perturbation theory have as yet been little tested for polyatomic molecules, and at present, the great majority of non-empirical calculations of IMI for complex molecules are carried out by the SCF method.

The questions dealt with in this section are examined in more detail in monographs[11,17]† and reviews[18,19]. The most complete analysis of "unsymmetrical" perturbation theory is given in Refs. 19, 26, and 27.

III. NON-EMPIRICAL CALCULATIONS FOR DIMERS OF DIFFERENT CHEMICAL CHARACTER

The IMI calculations discussed in this section were carried out chiefly in restricted basis sets. As indicated above, this means that the data obtained in the calculations on the equilibrium geometry and energy of interaction may differ slightly from the experimental results.

1. Hydrogen Bonding

Systems with a hydrogen bond have been studied in detail, both theoretically and experimentally (see published monographs[33–35] and reviews[36,37]). The interest in these systems is due to the fact that they include such materials as water and biopolymers. From the theoretical viewpoint, it is of interest to determine why the hydrogen bond is generally stronger than other types of IMI, and has a definite direction in space.

The water dimer can be considered first. Non-empirical calculations have been carried out for this dimer, which have made it possible to determine the three-dimensional structure and bond energy of the dimer and to distinguish the most important factors determining the stability of the dimer. Calculations for the dimer $(H_2O)_2$ have been carried out in different approximations as far as the use of Hartree–Fock basis sets with allowance for correlation. All non-empirical calculations, irrespective of the choice of basis set, indicate that the most favourable of the three possible structures—linear, crossed, and cyclic (Fig. 1)—is the linear structure with a distance between the oxygen atoms R_{O-O} close to 0.3 nm. This result agrees with the experimental data[38], according to which $R_{O-O} = 0.298$ nm and $\theta = 60°$. The magnitude of the energy of interaction depends on the method of calculation. The results of a detailed calculation for the dimer $(H_2O)_2$ by the SCF method and perturbation theory in a basis set close to the Hartree–Fock set are given in Ref. 30. The calculation using perturbation theory gave the components E_{el-st}, E_{exch}, E_{ind}, and E_{disp}. Since the basis functions used to calculate E_{ind} contained functions of the charge transfer type, E_{ind} in Ref. 30 in fact took account of the contribution of E_{ct}. It is natural to compare the sum $E'_{PT} = E_{el-st} + E_{exch} + E_{ind}$ with the quantity E_{int}^{SCF} calculated in the same basis set. It was found (Table 1) that for distances greater than 0.275 nm, E_{int}^{SCF} is reproduced with a good accuracy by the quantity E'_{PT}. The distance $R_{O-O} = 0.3$ nm corresponds to the minimum values of E_{int}^{SCF} and E'_{PT}: $E_{int}^{SCF} = -16.2$ kJ mole^{-1}, $E'_{PT} = -16.1$ kJ mole^{-1}. According to Ref. 39, the Hartree–Fock limit for E_{int}^{SCF} is 16.3 ± 1.1 kJ mole^{-1}. The fact that the minimum values of E_{int}^{SCF} and E'_{PT} coincide provides evidence that the two approaches to the calculation of IMI, based on SCF theory and on perturbation theory, are equivalent. The discrepancies between E_{int}^{SCF} and E'_{PT} at short distances is attributed to the presence in E_{int}^{SCF} of corrections of higher orders, and various other characteristics of the SCF method[29]. When allowance is made for E_{disp} from perturbation theory (see Table 1), the value of R_{equil} is found to be 0.286 nm, and $E_{int} = E_{int}^{SCF} + E_{disp} = -24.3$ kJ mole^{-1}.[30] The data from Ref. 40, obtained for the dimer $(H_2O)_2$ in an extended basis set with allowance for correlation by CI methods are: $E_{int}^{SCF} = -18.1$ kJ mole^{-1}, $E_{int}^{cor} = -3.6$ kJ mole^{-1}, and $E_{int} = -21.7$ kJ mole^{-1}.

From experimental data it is known that the bond energy in the water dimer lies in the range -16 kJ mole^{-1} to -28 kJ mole^{-1}[11,38,41]. The calculation gives satisfactory values for the bond energies, but the scatter in the experimental data makes it impossible to determine which is the best method for taking account of the correlation correction to E_{int}^{SCF}.

The results of calculations carried out for a linear dimer using perturbation theory in a basis set close to the Hartree–Fock set[30] and by the SCF method in different restricted basis sets with separation of E_{int}^{SCF} into its components[42] are compared in Table 2. The data in Table 2 make it possible to follow the influence of the basis set on the results and to analyse the nature of the bond in the dimer $(H_2O)_2$. It follows from Table 2 that the greatest contribution to the bond energy is made by the electrostatic interaction, and the contributions of E_{ct} and E_{ind} are less significant [$E_{disp} = -6.4$ kJ mole^{-1} (Table 1) is also not decisive]. In the STO-3G basis set, the contribution of E_{el-st} is lowered, and the role of E_{ct} is increased. The calculation in the basis set 4-31G leads to an increase in the bond energy in $(H_2O)_2$ as a result of an excessive value of the electrostatic attraction. More balanced data

† See also I.G.Kaplan, "Vvedenie v Teoriyu Mezhmolekulyarnykh Vzaimodeistvii" (Introduction to the Theory of Intermolecular Interactions), Izd.Nauka, Moscow, 1982.

are obtained in the basis set 6-31G**, which contains polarisation functions, but in this case also the role of E_{ct} is increased. It should be noted that the minimum basis set[43], optimised for calculating IMI, in the case of the linear dimer of water gives $E_{int}^{SCF} = -18.6$ kJ mole^{-1} for $R_{O-O} = 0.3$ nm, which is close to the results of the calculation in the Hartree–Fock basis set[39]. The influence of the basis set on the calculated values of E_{int}^{SCF} will be considered below.

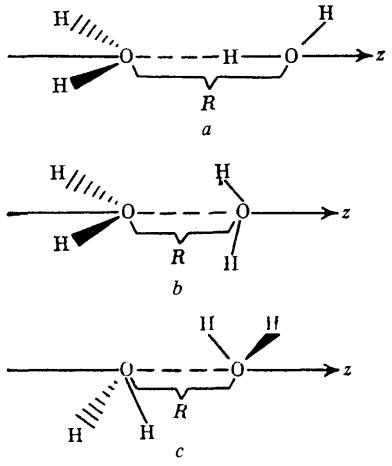

Figure 1. Linear (*a*), crossed (*b*), and cyclic (*c*) configurations of the water dimer[42].

Table 1. Energy characteristics of the IMI, found by the SCF method and from perturbation theory (PT) for the dimer $(H_2O)_2$.

R_{O-O}, nm	E_{PT}	E_{int}^{SCF}	E_{disp}	$E_{int}^{SCF} + E_{disp}$
0.212	54.8	144.9	—60.5	84.4
0.233	13.6	44.9	—35.2	9.7
0.254	—5.3	3.8	—20.5	—16.7
0.275	—13.4	—11.6	—11.9	—23.5
0.300	—16.1	—16.2	—6.4	—22.6
0.370	—12.0	—12.4	—1.3	—13.7
0.476	—4.8	—4.8	—0.2	—5.0

Other examples of small molecules with a hydrogen bond have been examined in a large number of studies. Some of the results obtained in the SCF approximation for different basis sets are given in Table 3 (the data in Table 3 were taken from Ref.43, which gives references to the original papers). The values of E_{int}^{SCF} obtained for $(H_2O)_2$ and $(HF)_2$ in Hartree–Fock basis sets are the most reliable. The bond energies for the systems $HOH...NH_3$ and $H_2O...HNH_2$, calculated in extended basis sets, are slightly too high[43] (absolute values). It may also be noted that a number of calculations carried out without eliminating the superposition error in other basis sets (for example in the standard minimum STO-3G and (7*s*3*p*), denoted OLD in Ref.43, in the minimum basis set NEW, obtained in Ref.43 by optimising the basis set OLD for the calculation of IMI, in the basis set of intermediate type 4-31G, and in the basis set 6-31G*, containing polarisation functions) lead to values of E_{int}^{SCF} which are higher than those obtained using an extended basis set. Elimination of the superposition error by the counterpoise method in the case of calculations carried out in the basis sets OLD and NEW gives results close to those obtained with Hartree–Fock and extended basis sets. Unfortunately, a correct comparison of the values of E_{int}^{SCF} found from the calculation with the experimental data is difficult. Firstly, the experimental data are not always available, and their accuracy is low. Secondly, a meaningful comparison of E_{int}^{SCF} with experiment requires at least an approximate estimate of E_{disp}. Table 3 gives the values of E_{disp} calculated in Ref.43 using an equation of the London type in terms of bond polarisability. Although these values of E_{disp} are too low[44], they nevertheless make up an appreciable part of the total energy of interaction. Allowance for dispersion corrections improves the agreement between the experimental data and the calculated bond energies, obtained by the SCF method in extended Hartree–Fock basis sets and also in the basis sets OLD and NEW. It may be noted that different dimers with a hydrogen bond were also examined in Ref.42 in the basis set 4-31G and without additional allowance for dispersion corrections. The most characteristic properties of hydrogen bonds, which make them unique, were discussed in this paper. The authors[42] studied different dimers, in which the proton donors were HF, H_2O, NH_3, and CH_4, and the proton acceptors HF, H_2O, and NH_3. It was shown that the bond energy E_{int}^{SCF} varies over a fairly wide range from −68.2 kJ mole^{-1} for the complex $H_3N...HF$ to −42.0 kJ mole^{-1} for the complex $H_3N...HF$ to −4.6 kJ mole^{-1} for the $H_2O...H_4C$ system. An analysis of the components of the energy E_{int}^{SCF} found using the published scheme[14] led to the following conclusions about the nature of the hydrogen bond [for the dimer $(H_2O)_2$ see Table 2].

Table 2. Components of the energy of the IMI in the linear dimer $(H_2O)_2$ with $R_{O-O} = 0.3$ nm, obtained in different approximations[30,42].

Components of the energy, kJ mole^{-1}	Perturbation theory[a]	SCF method[b]

[b]$R_{O-O} = 0.298$ nm, $\theta = 60°$. According to Ref.42, the results change little with change in θ.

[c]$\Delta E = E''_{PT}$ in perturbation theory[30] and $\Delta E = E_{int}^{SCF}$ in the calculation by the SCF method.

[d]E_{ind} from perturbation theory contains E_{ct} (see text of the present review and Ref.30).

[e]See discussion of Eqn.(2).

1) All the hydrogen bonds are electrostatic in character, that is the stabilisation is determined chiefly by the electrostatic contribution.

2) The relative part played by E_{ct} is slight in strongly bonded dimers, but increases in weakly bonded dimers.

3) The length and degree of departure from linearity of a hydrogen bond Y–H...X are determined by the ratio of E_{exch} and E_{disp}.

Table 3. Energies E_{int}^{SCF}, kJ mole^{-1}, calculated in different basis sets for the equilibrium configurations of various dimers with a hydrogen bond[43].

Both the calculated and the experimental data indicate that the absolute magnitude of the energy of a normal hydrogen bond does not exceed 60–70 kJ mole^{-1} (ionic hydrogen bonds $NH_3...H^+$ or $FH...F^-$, where the bond energies reach hundreds of kJ mole^{-1}, are not considered here). Comparison of the hydrogen-bonded dimers with the lithium complexes $(LiF)_2$ and $(LiH)_2$ [42] and the strong electron donor–acceptor (EDA) complexes $H_3N...BH_3$ and $BH_3...OC$,[45] in which the bond energy reaches between −150 kJ mole^{-1} and −300 kJ mole^{-1}, makes it possible to estimate the position of dimers with a hydrogen bond in the general series of strongly bonded complexes. The authors[42] consider that the unique character of the hydrogen bond is determined by the fact that in it the proton donor has a short strong bond Y–H of medium polarity. Since the bond has medium polarity, the energy of electrostatic attraction is insufficiently large, and therefore does not compensate the contribution of E_{exch}, which increases rapidly as the atoms H and X approach one another. Since the atoms Y and X are insufficiently far apart, and the bond Y–H is short and its stretching is difficult, the interaction of the atoms Y and X also makes a significant contribution to the exchange energy. In the strong EDA complexes and in the lithium complexes, the strong electrostatic interaction compensates the exchange repulsion, and the atoms of different molecules approach one another to distances less that 0.2 nm [$R_{N...B} = 0.175$ nm in $H_3N...BH_3$, and $R_{Li...F} = 0.180$ nm in $(LiF)_2$]. In the lithium complexes, the bond in the monomer is easily stretched, and this leads to greater possibilities for bond formation in the complex. Thus in $(LiF)_2$ and $(LiH)_2$, the cyclic structure, and not the linear structure, is more favourable. The stretching of the strong bond Y–H, however, requires too great an expenditure of energy. Thus in accordance with published work[42,46], the normal hydrogen bond is characterised by a definite (linear) direction and intermediate energy values.

Various other polyatomic systems with a hydrogen bond can now be considered. A cycle of studies by Pullman and co-workers[47–61] (see also references therein) was devoted to a study of hydrogen bonding involving biological molecules, in particular their mono- and polyhydration. The calculations were carried out in the SCF approximation in restricted basis sets and without additional allowance for E_{disp}. The energy of interaction E_{int}^{SCF} was analysed by the scheme of Ref.15, which is simpler than the schemes of Refs.13 and 14. The contributions E_{el-st}, E_{exch}, and $E_{ind}+E_{ct}$ were separated. The electrostatic energy in some cases was approximated by the energy of interaction of the point multipole moments of the molecules, and this simplifies considerably the estimation of this contribution. Pullman and co-workers have studied in detail the hydration of amides[53,54,57], nucleotide bases[47], urea and thiourea[58,59], and the carboxylate anion[60]; they showed that the characteristic features of the hydration are determined by the magnitude of the contribution E_{el-st}, since E_{exch} and $E_{ind}+E_{ct}$ approximately compensate one another. A more detailed review of this work can be found in Ref.61.

Many authors have studied hydrogen bonding in formamide oligomers[62–66], which provides a model of the interaction in polypeptides and proteins. The most interesting results were obtained for the description of the interaction of amide groups in different configurations, which are characteristic of polypeptides; mention must also be made of the study of cooperative effects[65]. It was recently shown[66] that the attraction of amide groups is stronger in an α-spiral than in a 3_{10} spiral, and cooperative effects were detected on going from the dimer to the trimer.

Table 4. Components of the energy of IMI in the dimers $(HCONH_2)_2$ and $(HCOOH)_2$, calculated in different basis sets (from data in Refs.67 and 68).

Components of the energy, kJ mole^{-1}	$(HCONH_2)_2$	$(HCOOH)_2$		
	STO–3G[a]	STO-3G[a]	minimum basis set	DZ[b]
E_{el-st}	−45.7	−60.0	−94.4[c]	−103.6[c]
E_{exch}	46.5	96.0	89.7	142.9
E_{ind}	−3.2	−3.5	−16.7	−27.5
E_{ct}	−61.2	−97.9	−46.2	−43.1
E_{disp}	—	—	−31.8[d]	−28.0[d]
E_{int}	−63.6	−65.5	−99.6	−59.4

[a]From Ref.67, for $R_{O-O} = 2.73$ Å.

[b]From Ref.68, for $R_{O-O} = 2.7$ Å in minimum and DZ basis sets.

[c]Corrected with allowance for the ratio μ_{calc}/μ_{expt}, where μ is the dipole moment.

[d]Non-empirical calculation using perturbation theory.

The SCF method has been used[67] to study hydrogen bonding in the dimers $(HCOOH)_2$, $(HCONH_2)_2$, and $[B(OH)_3]_2$ in an STO-3G basis set without additional allowance for E_{disp}

(Table 4). The value found for E_{int}^{SCF} (STO-3G) for $(HCOOH)_2$ is close to the experimental value, and amounts to between -60.8 kJ mole^{-1} and -73.3 kJ mole^{-1}.[67,68]. It follows from Table 4 that in the basis set STO-3G, the bond energy in the dimers $(HCONH_2)_2$ and $(HCOOH)_2$ is determined chiefly by the contributions $E_{el\text{-}st}$ and E_{ct}. In the STO-3G basis set, however, the contribution E_{ct} is too large. This follows from a comparison of the components of E_{int}^{SCF} in the dimer $(HCOOH)_2$, obtained in the basis set STO-3G [67] and in the DZ basis set[68] (see Table 4). According to Ref.68, the greatest contribution to the bond energy in $(HCOOH)_2$ is made by $E_{el\text{-}st}$. In the case of the DZ basis set, to obtain results close to the experimental data, it is necessary to take additional account of the dispersion contributions E_{disp}. It may also be noted that the data obtained in Ref.68 were used in Ref.69 to construct model potentials (see R.p. 1073). Calculations carried out in an STO-3G basis set gave satisfactory values for the enthalpies of formation of the dimers of a number of alcohols [70], and were also found to be suitable for the study of the intramolecular hydrogen bond in 7-norbornenol[71]. Mention must also be made of the extensive series of studies by Del Bene (see Refs.72 and 73 and references therein), devoted to the examination of hydrogen bonds in various systems. Lack of space makes it impossible to give a detailed description of the results of recent calculations[74–77] for systems containing a hydrogen bond, such as nitric acid and ammonia, pyrrole and acetonitrile, formaldehyde and hydrogen sulphide, and the sulphide anion and water.

In Ref.78, the $HO^-...H_2O$ system was studied, and data were obtained on the influence of the solvent on the relative acidity of water and methanol.

In most of the work discussed, the MO LCAO SCF approximation was used. Perturbation theory was used in Refs.30, 79, and 80. The last two papers also discuss calculations carried out by the self-consistent field method for the systems $(H_2CO)_2$, $(H_2O)_2$, and $(HF)_2$ in different approximations. Symmetrical perturbation theory[20] has been used successfully [32] to calculate the bond energy in the systems $H_2CO...OH^-$ and $H_2CO...NH_3$.

2. Electronic Donor–Acceptor Complexes

From Mulliken's model for EDA complexes[81] it followed that in these systems an important part is played by charge transfer; in particular, it was suggested that the structure of a complex is determined by the interaction between the occupied MO of the donor and the unoccupied MO of the acceptor. Semi-empirical calculations for EDA complexes[82,83] showed, however, that E_{ct} does not make the decisive contribution to the interaction energy, and the electrostatic interaction is generally more significant. Non-empirical calculations for EDA complexes have begun to appear only comparatively recently. It has been shown[84,85] that in a minimum basis set and the DZ basis, the equilibrium geometries in the complexes formed by H_3N and $(CH_3)_3N$ with F_2, Cl_2, FCl, ClF, SO_2, and O_3 are approximately the same, but higher values are obtained for the bond energy in the DZ basis set. These calculations showed that the bond energy of the complexes of H_3N with F_2, Cl_2, FCl, and SO_2 is greater than the bond energy of the corresponding complexes of trimethylamine. In contrast to the complexes $H_3N...F_2$ and $H_3N...Cl_2$, in the case of the complexes $H_3N...FCl$ and $H_3N...ClF$ the results depend markedly on the choice of basis set. From qualitative considerations, a high bond energy is expected for the complex $H_3N...ClF$, since in the ClF molecule the Cl atom is positively charged, and the N atom in the NH_3 molecule is negatively charged. According to the results of the calculation carried out in the DZ basis set, the bond energy in the complex $H_3N...ClF$ is -32.2 kJ mole^{-1}, and the complex $H_3N...FCl$ is unstable, whereas according to the calculation in the minimum basis set, the complex $H_3N...FCl$ is more favourable. The reason for this lack of agreement between the results of the calculation in different basis sets is apparently that in the minimum basis set it is not possible to estimate correctly the direction of the dipole moment in the ClF molecule.

A systematic study of EDA complexes has been carried out [45,46,86,87]. The calculations were carried out chiefly in the basis set 4-31G. For some of the complexes examined, perturbation theory was used to estimate the value of E_{disp}.

Table 5. Energy characteristics of IMI, kJ mole^{-1}, for the optimised intermolecular distances (R_{equil}), and the classification of the EDA complexes (calculation in the basis set 4-31G).

	Type of complex	R_{equil}	$E_{el\text{-}st}$	E_{exch}	E_{ind}	E_{ct}	E_{mix}	E_{int}^{SCF}	E_{disp}	$E_{int}^{SCF}+E_{disp}$	Classification	Refs.

[a] The value of E_{disp} was calculated non-empirically using perturbation theory.

[b] STO-3G basis set.

[c] The value of E_{disp} was calculated in terms of bond polarisability.

[d] $E_{ct}+E_{mix}$.

Breakdown of the energy E_{int}^{SCF} into its components made it possible to determine the interactions responsible for bond formation in the complexes. All the complexes examined were classified according to the values of the bond energy as strong (s.) with E_{int} in hundreds of kJ mole^{-1}, intermediate (int.) with E_{int} in tens of kJ mole^{-1}, or weak (w.) with E_{int} in units of kJ mole^{-1}, and according to the nature of the bond as electrostatic (el-st), induction (ind), and charge-transfer (ct).

The calculated characteristics of some of the complexes examined in these studies are given in Table 5. The data in Table 5 show that the EDA complexes are not charge-transfer complexes. The influence of charge-transfer is different for different EDA complexes and does not correlate with the strength of the complexes. Thus the suggestion[81] that EDA complexes are always charge-transfer complexes was not confirmed in the non-empirical calculations. Significant contributions from E_{ct} were found for the $n\sigma^*$– and $\sigma\sigma^{**}$–complexes formed by polar molecules (H_3N, BF_3, OC, BH_3). These complexes are characterised by strong electrostatic interaction and short equilibrium distances. With decrease in the polarity of the molecules, the complexes become weaker ($H_2CO...F_2$). It may be noted that the values of the energy E_{int}^{SCF} calculated in the 4-31G basis set are found to be too high, since, for example, in the strong complexes $R_3N...BF_3$ and $R_3N...BH_3$ ($R = CH_3$, C_2H_5), which have similar bond character, the experimentally determined values of the bond energy lie in the range from −110 kJ mole^{-1} to −150 kJ mole^{-1}.[88]

Complexes involving molecules containing π-electrons are of considerable interest. For a complex of the type $n\pi^*$ [for example $(CN)_2CO...H_2O$], the most favourable configuration was found to be that in which the water molecule is situated above the plane of the $(CN)_2CO$ molecule[86] (Fig.2). Calculations were carried out in this configuration for the water...tetracyanoethylene (TCE) $n\pi^*$-complex. In these configurations, the stabilisation of the complexes is determined by $E_{el\text{-}st}$.

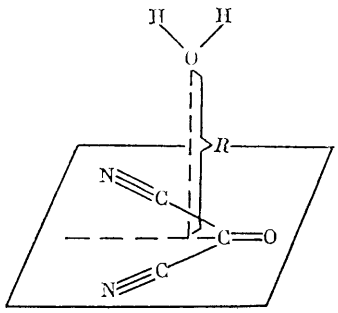

Figure 2. Configuration of the dimer $H_2O...(CN)_2CO$.[86]

The equilibrium distances (0.27–0.30 nm) are greater in the $n\pi^*$-complexes than in the strong $n\sigma^*$-complexes, so that the contributions of E_{ct} and E_{ind} are small. The role of dispersion energy in these systems is slight. It may be noted that the choice of the basis set has a significant influence on the calculated values of the bond energy. For example, in the STO-3G basis set the energy E_{int}^{SCF} of the complex $(CN)_2CO...H_2O$ is −16.3 kJ mole^{-1},[86,87] whereas in the 4-31G basis set it is −38.8 kJ mole^{-1}.[87] The value $E_{int}^{SCF} = -38.9$ kJ mole^{-1} is too high, as is typical of calculations in the 4-31G basis set. The experimental value of the bond energy in the similar system $(CN)_2CO...$diethyl ether is −18.4 kJ mole^{-1}.[86]

For the $\pi\pi^*$-complex $(CN)_2COC_6H_6$ in Ref.87 a "stacking" configuration was chosen, in which the distance between the planes of the molecules and the position of the centre of the benzene ring relative to the C=O axis were optimised (in an STO-3G basis set). A calculation in the 4-31G basis set was carried out for the equilibrium configuration obtained, with $R_{equil} = 0.36$ nm.

The differences in the values of E_{int}^{SCF} for the two basis sets (see Table 5) are due to the characteristic features of the electron distributions obtained in the different basis sets, since these influence the values of $E_{el\text{-}st}$ and E_{ind}. The experimental bond energies for these systems are between −20 kJ mole^{-1} and −25 kJ mole^{-1},[87] which appear to agree only with the results of the calculation in the 4-31G basis set: $E_{int}(4\text{-}31G) = E_{int}^{SCF}(4\text{-}31G) + E_{disp}(4\text{-}31G) = -28.5$ kJ mole^{-1}. It should be noted, however, that the value $E_{disp}(STO\text{-}3G) = -3.7$ kJ mole^{-1}, calculated in the STO-3G basis set using perturbation theory, is clearly too low. The calculation of E_{disp} in terms of the bond polarisability for the dimer $(CN)_2CO...C_6H_6$ being discussed gives the value −13.1 kJ mole^{-1} for $R = 0.36$ nm.[89] Kolos[89] points out that if the more realistic values of E_{disp} calculated in terms of the bond polarisability are added to the values of $E_{int}^{SCF}(STO\text{-}3G)$ from Ref.87, then R_{equil} becomes 0.31 nm, and the bond energy −20.4 kJ mole^{-1} (see Table 5). It may therefore be assumed that the bonding in the dimer involves both dispersion interactions and electrostatic interactions, and the estimate of their contributions to the bond energy depends on the basis set (the value of $E_{el\text{-}st}$ is smaller for the STO-3G basis set, and larger for the 4-31G basis set).

In conclusion, mention may be made of a paper[90] describing a study of charge transfer in the glyoxal-water, $(H_2O)_2$, and $H_2O...Li^+$ systems by different methods (supermolecule, perturbation theory, etc.).

3. Dimers With Other Types of Bond

There have been comparatively few studies of weakly polar or non-polar van der Waals systems, whose stabilisation is determined chiefly by dispersion interactions. Here, mention must be made of detailed studies[91–94] of the potential energy surface for the dimers $(N_2)_2$ and $(C_2H_4)_2$. A significant feature of these studies is that they examined a large number of possible configurations of the dimers and obtained fairly complete information on the potential energy surface.

The authors[91–94] used perturbation theory, and represented the bond energy E_{int} as the sum of $E_{el\text{-}st}$, E_{exch}, E_{ind}, and E_{disp}. The calculations were carried out in DZ and DZ+P basis sets. It was found that in the systems studied, the attraction involves chiefly dispersion interaction; the absolute magnitude of the electrostatic components is several times smaller than that of E_{disp}. The conclusion that E_{disp} plays a decisive role in the stabilisation of dimers containing non-polar systems was also reached by other workers, who calculated the energies of IMI in the dimers $Ar...H_2O$, $Ar...HCl$, $Ar...HF$,[95] and $CH_4...CH_4$.[44] In Ref.44, the results of calculations of E_{int}^{SCF} carried out in different basis sets were given (E_{disp} was estimated in terms of the bond

polarisability), and it was concluded that it is appropriate to use the previously mentioned minimum basis set[43] for IMI calculations. At the same time, as shown by other authors[91,94], although the attraction is determined by E_{disp}, the structure of the equilibrium van der Waals dimers depends to a significant extent on the energy of exchange repulsion E_{exch}. The configurations of the most stable dimers correspond to the lowest exchange repulsion, and in these configurations the attraction (E_{disp}) may not be a maximum. For example, for the dimer $(N_2)_2$ the most stable structure corresponds to the crossed (cross-shaped) arrangement of the molecules[93,94], although the dispersion energy is a maximum in the energetically less favourable linear configuration, in which the exchange repulsion is large. For a distance R between the centres in $(N_2)_2$ equal to 0.4 nm, for the crossed configuration, $E_{exch} = 0.25$ kJ mole^{-1} and $E_{disp} = -1.35$ kJ mole^{-1}, and for the linear configuration $E_{exch} > 3$ kJ mole^{-1} and $E_{disp} = -2.7$ kJ mole^{-1}. The absolute minimum on the potential energy surface corresponds to the crossed structure with values $E_{int} = -1.5$ kJ mole^{-1} and $R = 0.35$ nm.

For the dimer $(C_2H_4)_2$, two structures with low values of E_{exch} were found to be most favourable[92,94]: the staggered parallel configuration and the screw configuration (bond energies -5.01 kJ mole^{-1} and -5.05 kJ mole^{-1} respectively), although the value of E_{disp} is a maximum for the linear arrangement of the molecules, and the value of $E_{el\text{-}st}$ is a maximum for the T-shaped structure. Thus in each case the equilibrium structure of the van der Waals dimer is determined by a fine balance between the forces of repulsion and dispersion attraction, and its determination requires a detailed non-empirical calculation.

These results cast doubt on the reliability of the prediction of the structure of van der Waals dimers on the basis of simple considerations[96,97]. The use of such characteristics of the individual molecules as the dipole and quadrupole moments and polarisability tensors makes it possible to characterise only the long-range contributions of E_{disp} and $E_{el\text{-}st}$, which have been shown to be non-decisive. It has also been suggested that information on the structure of the free dimer can be obtained from the packing of the molecules in the crystal, since the relative arrangement of the nearest neighbours in the crystal should correspond to structures with a low value of the energy of exchange repulsion. The most stable structure of the free dimer, however, may differ from the relative orientation of the nearest neighbours in the crystal. Of the two most favourable structures of the dimer $(C_2H_4)_2$, only one (the screw structure) resembles the packing of the C_2H_4 molecules in the crystal; the staggered parallel structure of $(C_2H_4)_2$, like the crossed configuration of the dimer $(N_2)_2$, differs considerably from the packing of the molecules in the crystal.

Another important result from these studies[92-94] is the conclusion that for the dimers being discussed, there are a large number of structures in which the bond energy amounts to more than 80% of the maximum value. This distinguishes van der Waals dimers from systems with a hydrogen bond and from donor-acceptor complexes, for which there are only a few energetically favourable configurations of the dimers.

Model calculations of the energy of interaction in biological systems are of considerable interest. The study of the interaction of hydroxytryptamines (HT) with the imidazole (IMD) cation has been described in a series of papers[98-100]. The calculation for a system consisting of these fairly large molecules was carried out in a minimum basis set in the "stacking" configuration. Analysis of the components of E_{int}^{SCF} showed that the principal contribution to the stabilisation of the complex is made by electrostatic interaction. The same conclusion was reached in a calculation in a 4-31G basis set with partial allowance for correlation in the interaction of fragments providing models of HT and IMD.[99]

The interactions in the imidazole–methanethiol system, the imidazole–methanethiol–formaldehyde system, and the imidazole–methanethiol–formaldehyde system in the electric field created by the charges on the atoms of an α-spiral which provided a model of the active centre of the enzyme papaine have been studied[101] in minimum and extended basis sets. It was shown that the electrostatic field created by the spiral is responsible for the formation of an ion pair $RS^-...ImH^+$ from the basic residues Cys 25 and His 159. The anomalous values of pK for these residues were also explained[101]. The authors[101] concluded that the α-spirals are important parts of enzymes and play an important role in the catalytic process. An analogous problem and similar substances were studied in Ref.102, where STO-3G and 4-31G basis sets were used to study the interaction in systems containing imidazole, methanol, formic acid, and methanethiol, which provided models of the active centres of serine and cysteine proteases. The number of papers devoted to the non-empirical calculation of the interaction of large molecules is still small, however; the calculation of the interaction of such large molecules as tetracyanoquinodimethane $(CN)_2CC_6H_4C(CN)_2$ and tetrathiofulvene $H_2C_2S_2C_2S_2C_2H_2$ [103] as yet represents the exception.

The thermodynamic stability of dimers at finite temperatures is determined not only by the enthalpy of the system, but also by its entropy. Particular attention was paid to the calculation of the entropy in Refs.104–107. In particular, mention must be made of results[104] which showed that even in polar systems, the role of the entropy term is significant, and in non-polar systems the entropy determines the behaviour of the dimer (see Ref.105). The role of entropy was discussed in Ref.106, devoted to a study of the nature of the stationary points of the potential energy surface for the dimer $(HCl)_2$, and in Ref.107 in a study of the interaction of water with chloroform, fluoroform, and cyclopropane.

IV. NON-EMPIRICAL ANALYTICAL POTENTIALS

The theoretical analysis of IMI for complex many-particle systems is carried out chiefly using simple potentials. The results of non-empirical IMI calculations have recently begun to be used to obtain analytical potentials. An extensive cycle of studies has been carried out by Clementi and co-workers[108-132]. The structure and thermodynamic properties of solutions of ions and biological molecules have been studied. The overall calculation procedure was broken down into three stages.

1. Non-empirical calculations were first carried out for a large number (up to several hundred) different configurations of the corresponding dimer, to obtain sufficiently complete information on the potential energy surface for the system.

2. A set of pair potentials was then chosen in the form of functions of a definite type, depending on the parameters. The parameters were selected to give the best reproduction of the potential surface obtained in the non-empirical calculation.

3. Finally, the analytical potentials obtained in the previous stage were used to calculate the thermodynamic and structural characteristics of the system being studied. Usually, at this stage, the Monte Carlo method was used for the calculation.

The procedure described above was used to study the structure and properties of liquid water[108]. An extended basis set was chosen for the calculation on the $(H_2O)_2$ dimer, and 216 different configurations were calculated in the SCF

approximation. The results of the calculation were approximated by a fairly complex analytical expression consisting of the sum of pair contributions[108].

A calculation by the Monte Carlo method of the radial distribution functions in water and their characteristics gave results close to the experimental data. Particularly good agreement with experiment was obtained using analytical potentials[108] approximating the potential surface of the $(H_2O)_2$ system found with allowance for correlation by the CI method. This result clearly demonstrates the possibilities provided by quantum-chemical methods for estimating various characteristics of many-particle systems.

To investigate the relative role of regular structures in the overall structure of water, the analytical potentials obtained were used to study small regular and non-regular clusters of the form $(H_2O)_n$ ($n = 3$–8). It was found that for the trimer, the most favourable structure is a cyclic structure with symmetry close to C_{3v}; for $n = 4$ and 5, the cyclic structures are energetically most favourable, and for $n = 6$, 7, or 8 there are a large number of non-regular configurations with similar energies. These results, and the fact that the bond energy corresponding to one molecule increases with increase in the number of molecules in the cluster, led the authors[108] to the conclusion that the energy properties of water apparently cannot be described by modelling the liquid phase as an ideal mixture of small regular clusters.

By studying dimers of the type formed by water with the ions Li^+, K^+, F^-, Cl^-, Na^+, etc.[109–112], and also the interaction of water molecules or ions with fragments of proteins and nucleic acids (aminoacids in different forms[113–115], the polypeptide core[116], nucleotide bases[114,117], and phosphate groups[118,119]), Clementi and co-workers created a library of model potentials based chiefly on the results of non-empirical calculations in a minimum basis set. These potentials, and the Monte Carlo method, were used to study a large number of systems. In particular, solutions of ions[120,121] and ion pairs[122,123] in water were examined. Particular attention was paid to the investigation of the structure of water close to nucleotide bases[124], DNA fragments[125,126], aminoacids[127, 128], and various enzymes[129–131]. A detailed analysis of the results of this important cycle of studies is beyond the scope of the present review; they can be found in a recently published monograph by Clementi[132]. It is appropriate, however, to deal with various methodological features of these calculations[108,115].

In the construction of the analytical potentials, Clementi and co-workers took account of the fact that the same atoms in molecules may be present in different valence states (for example, the states of the oxygen atom are different in the OH group, in the C=O bond of the COOH group, and in the C=O group, where the C atom is in an aromatic ring). For most systems (except water), the potentials were chosen in the form of a Lennard-Jones potential with allowance for electrostatic corrections. The reliability of the analytical potentials was estimated from the accuracy of the non-empirical calculations.

In the opinion of the authors of Ref.44, however, the values of the energy E_{int}^{SCF} are determined more accurately in minimum basis sets optimised for the calculation of intermolecular interaction (see for example Ref.43), with elimination of the superposition error by the counterpoise method, than in standard basis sets of the DZ+P type. It is recommended[44, 89] that allowance for correlation be made using perturbation theory, by expressing E_{disp} in terms of bond polarisability, and this has been confirmed by recent results[44].

An analogous series of studies was carried out by Jorgensen and co-workers[133–138]. The calculation procedure was identical to that described above. Systems with hydrogen bonds $(HF)_2$, $(H_2O)_2$, $(CH_3OH)_2$, etc. were studied, and the potentials were taken in the form (12-6-3-1) or (12-6-1). The calculation for the dimer $(HF)_2$ [133,134] was carried out in the 6-31G basis set for 250 points on the potential surface. The model potentials obtained were used to calculate the properties of liquid hydrogen fluoride. The calculations carried out in the 6-31G basis set, however, give a value for the energy of attraction which is too large, so that the calculated heat of volatilisation obtained was too high. Better agreement with experiment was obtained in a calculation for the dimer $(HF)_2$ in the minimum basis set STO-3G. Similarly, in the case of water[136], the results of calculations in the STO-3G basis set also show fairly good agreement with the experimental data. Jorgensen, like Clementi, recommends the use of a minimum basis set in calculations for polar systems, and also that allowance be made for dispersion interactions when non-polar groups are present.

The pair potentials (in the Lennard-Jones form) used in these studies should not be confused with the generally adopted atom–atom potentials, which are capable of reflecting more or less realistically the interaction of individual atoms. Fig.3 gives curves[132] describing the interaction of the oxygen of a water molecule with a nitrogen atom in different fragments of biological molecules. It can be seen that for a nitrogen atom in glycine or asparagine, there is no region of attraction at all. For nitrogen in guanine or 4-hydroxypyridine, however, the potential curves show minima corresponding to equilibrium distances of ~0.30–0.31 nm. The potentials obtained by Clementi and co-workers (Fig.3) and by Jorgensen and co-workers apparently must be regarded only as an analytical approximation to the results of the calculations, making it possible to go from quantities characterising individual molecules to macroscopic quantities, and the physical significance of individual curves cannot be discussed.

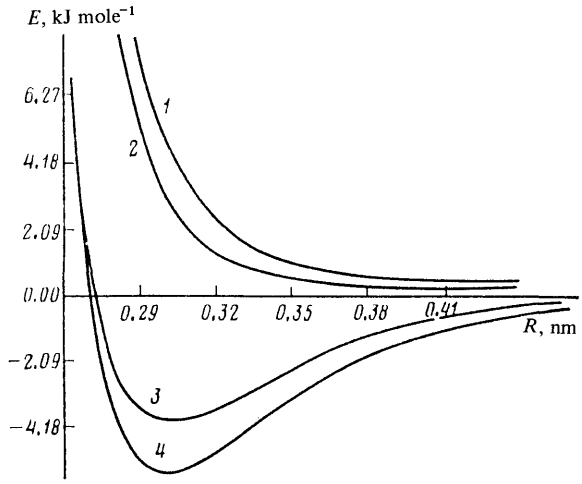

Figure 3. Potentials of the interaction between the oxygen atom of water and a nitrogen atom in different fragments of biological molecules (*1*—glycine, *2*—asparagine, *3*—guanine, *4*—hydroxypyridine).[132]

In another approach, the breakdown of the energy E_{int}^{SCF} into its components is used to construct analytical potentials on the basis of non-empirical calculations. In this case, the

individual components of E_{int}^{SCF} are approximated, and this method makes it possible to reduce the number of configurations whose energy must be calculated non-empirically. Moreover, the pair potentials found in this way acquire a definite physical significance (they can be regarded as non-empirical atom–atom potentials). This method has been used to carry out calculations for crystals of carboxylic acids[68,69]. In Ref.69, the model potentials for the atoms i and j were sought in the form

$$\varphi_{ij} = q_i q_j r_{ij}^{-1} + B^{XY} \exp(-C^{XY} r_{ij}) + A_{XY} r_{ij}^{-6} - D^{XY} \exp(-F r_{ij}) \quad (5)$$

where r_{ij} is the distance between the atoms i and j; q_i and q_j the effective charges on the atoms i and j; and X and Y denote the chemical elements corresponding to the atoms i and j (X, Y = C, O, H).

The individual terms in the right-hand side of Eqn.(5) were compared[69] with the corresponding components of the energy E_{int}^{SCF}, determined in Ref.13, and also with E_{disp} calculated using perturbation theory. The first term in Eqn. (5) was used to approximate the contribution of E_{mult}, where E_{mult} is the part of E_{el-st} which is independent of penetration effects[69]; the second term was used to approximate $E_{ex} + E_{el-st} - E_{mult}$; the third term is compared with the part of $E_{ind} + E_{disp}$ proportional to R^{-6}; and the last term takes account of E_{ct} and the corrections to $E_{ind} + E_{disp}$. The constants A, B, C, D, and F were determined from the results of non-empirical calculations for 12 configurations of $(HCOOH)_2$ and 16 configurations of the dimer $H_2CO...CH_3OP$, which is only one tenth of the number of dimer configurations studied by Clementi and Jorgensen.

The analytical potentials obtained in this way were used[69] to carry out calculations for the dimers of formic and acetic acids and crystals of formic acid and α- and β-acetic acids. The structures found for the dimers and crystals of the carboxylic acids are close to the experimental structures. Unfortunately, the calculation of the energies gives an error of 20–30 kJ mole^{-1} (~30%).

As noted in Ref.69, the errors arising in a calculation of this kind are of different character: for example, they may be associated with the use of restricted basis sets and non-correlated wavefunctions. In addition, errors arise when the analytical potential is fitted to the energy values obtained non-empirically. In Refs.139 and 140, the values of the dispersion energy found in Refs.141 and 142 by a non-empirical method in a DZ basis set for dimers consisting of azabenzenes were approximated as $E_{disp} = \sum_{i \in A} \sum_{j \in B} A_{ij}^{XY} r_{ij}^{-6}$, where r_{ij} is the distance between the atom i of the molecule A and the atom j of the molecule B, and A_{ij}^{XY} represents the parameters of the atom–atom interactions (X, Y = C, N, H). An interesting feature is that the values of these parameters were found to be very close to the empirical atom–atom parameters given by Williams[143]. An attempt to reproduce the non-empirical values of the electrostatic interaction between the azabenzenes in the form of the sum of atom–atom interactions was less successful.

Non-empirical atom–atom potentials have been constructed [92,93] for the dimers $(N_2)_2$ and $(C_2H_4)_2$. Atom–atom potentials have been used[93] to calculate the potential energy surface of the dimer $(N_2)_2$ and various characteristics of the α and β crystalline forms of molecular nitrogen. Analytical atom–atom potentials have been used to carry out a calculation for the ethylene crystal[92].

Non-empirical pair potentials have also been constructed for the complexes formed by water with ammonia[144] and ethanol[145].

V. ACCURACY OF NON-EMPIRICAL CALCULATIONS OF INTERMOLECULAR INTERACTION

Analysis of the above results makes it possible to reach various conclusions about the accuracy of non-empirical calculations. The best agreement with experiment is given by calculations with Hartree–Fock basis sets with complete allowance for correlation (see the calculations of the structural characteristics of water[108]). These calculations, which are close to the exact solution of the Schrödinger equation, can be regarded as standard. These calculations are not readily accessible, however, and it is necessary to know what can be expected from less precise calculations. Here it must be borne in mind that the value of non-empirical IMI calculations lies in their giving not only the quantitative characteristics of IMI but also data on the nature of the bonding in dimers. In addition, the relative values of IMI characteristics may often be useful. The calculation of the correlation energy can be considered first. In the many-configuration approximation, account is taken of both intermolecular and intramolecular correlation. These calculations are much more complex than the calculation of E_{int}^{SCF}, from both the computational and theoretical viewpoints. This is related to the fact that there are serious difficulties in the optimum choice of the excited configurations included in the CI. The treatment is therefore usually restricted to taking account of intermolecular correlation, and E_{disp} is calculated from perturbation theory. To obtain satisfactory values of E_{disp}, it is necessary to use DZ + P basis sets with diffuse polarisation functions P (Ref. 142 and p.60 of Ref.11). DZ basis sets apparently underestimate the value of E_{disp} only slightly, since published data[142] indicate that the DZ and DZ + P basis sets give similar values for E_{disp}.

Calculations carried out in intermediate basis sets, for example in the basis set with split valence 4-31G give values of E_{disp} which are 1.5–2 times smaller than the actual values[87], and minimum basis sets are not suitable for calculating E_{disp}. Kolos and Clementi[44,89] recommend that in these cases E_{disp} should be estimated in terms of the bond polarisability, although the values of E_{disp} obtained are slightly too low[44]. The dispersion energy makes up an appreciable proportion of the bond energy (in the case of van der Waals dimers its role is decisive), but intramolecular correlation may decrease this contribution slightly. For example, the correlation corrections for $(H_2O)_2$ for $R_{O-O} = 0.3$ nm in extended basis sets are −6.4 kJ mole^{-1} (perturbation theory[30]) and −3.6 kJ mole^{-1} (CI [40]). As yet, however, little is known about the influence of intramolecular correlation on E_{int},[146, 18], and this question will not be discussed further in the present review. The correct calculation of the energies E_{el-st} and E_{exch} requires wavefunctions which provide a sufficiently good description of the multipole moments of the molecules. These requirements are satisfied by the wavefunctions found in DZ + P basis sets with polarisation functions P localised close to the nuclei. The correct calculation of E_{ind} requires a DZ + P basis set with diffuse P functions, in which the polarisabilities of the molecules are effectively reproduced. From what has been said above about the basis sets required for the correct calculation of E_{disp}, it is to be expected that non-empirical IMI calculations in DZ + P basis sets with two types of polarisation function should give reliable results. Calculations of this kind are not very practicable for complex systems.

Calculations with DZ basis sets without polarisation functions or with polarisation functions of one type (basis sets 6-31G and 6-31G**, and also the basis sets DZ and DZ + P, described in Refs.92–94) are more readily accessible. The use of these basis sets for the small systems $(H_2O)_2$,[42]

$(HF)_2$,[147] $(N_2)_2$,[93] and $(C_2H_4)_2$ [92,142] has been fairly effective (see Tables 2 and 3). The calculations already mentioned for the crystal of ethylene[92] and molecular nitrogen[93] also indicate that the calculation of E_{int}^{SCF} and E_{disp} in DZ basis sets is reliable from the quantitative viewpoint.

Of the intermediate basis sets, the basis set 4-31G is used most frequently. The energies E_{int}^{SCF} calculated in the 4-31G basis set are apparently more than double the exact values (see the data for $(H_2O)_2$ in Table 2 and the results of the calculation for the dimer $H_3N...BH_3$ in Table 3). The error of the calculation of IMI in the 4-31G basis set is to a large extent related to the overestimation of the electrostatic interaction. Calculations in the 4-31G basis set, however, apparently give sufficiently reliable information on the nature of the bonding in dimers (Tables 2 and 5).

The most widely encountered calculations in minimum basis sets are those for the dimers of polar molecules, particularly dimers with a hydrogen bond. It has been found that in many cases[135-138], E_{int}^{SCF} shows good agreement with the experimental value of the bond energy. This is explained, firstly, by the relatively small contribution of E_{disp} to the energy of the interaction, and, secondly, to the mutual compensation of errors: the energy of repulsion E_{exch} and the electrostatic attraction are underestimated, and the contribution of E_{ct} is overestimated[42]. If however the dimers contain polar and non-polar molecules (for example $(CN)_2CO...C_6H_6$), E_{disp} must be taken into account to obtain the experimental values of the bond energies (see Ref.87 and also Table 5 and R.p.1069). No Hartree-Fock calculations have been carried out for systems of this kind, so that an exact estimate of the accuracy of the calculations in the minimum basis sets is impossible. The STO-3G basis set is apparently unsuitable for calculations for the dimers of non-polar molecules (for example the calculation for $(C_2H_4)_2$ in Ref.91).

The quantitative results obtained in calculations with minimum basis sets must be approached with care, but many other conclusions reached in these calculations (the nature of the stabilising forces, the most favourable structure of the dimer) for the case of polar molecules are also obtained in calculations in broader basis sets.

Kolos, Clementi, and co-workers[43,44] have now pointed out methods for improving considerably calculations in minimum basis sets, based firstly on the elimination of the superposition error and secondly on the use of minimum basis sets specially optimised for the calculation of IMI. This makes it possible to obtain in minimum basis sets results close to those obtained by calculations in extended basis sets not only for polar molecules (Table 3) but also for non-polar systems $[(CH_4)_2]$,[44] if E_{disp} is estimated in terms of bond polarisability.

Thus comparatively reliable results are obtained in calculations in DZ basis sets. It is difficult to reach a final conclusion about the accuracy of calculations in restricted basis sets, but several conclusions can be reached, for example that E_{int}^{SCF} is overestimated in the basis set 4-31G and that satisfactory results are obtained by calculating the interaction of small polar molecules in the basis set STO-3G. It should be noted that authors[86,87,98-100] who have used these basis sets in calculations for large molecules paid particular attention to the qualitative conclusions. The available data indicate that different restricted basis sets give values of the energies E_{int}^{SCF} and their components which differ from one another by a factor of more than two, and it is to be expected that these discrepancies increase with increase in the size of the systems. Thus the absolute and relative differences in the values of the components of E_{int}^{SCF}, calculated in the basis sets STO-3G and 4-31G for the dimers $(CN)_2CO...H_2O$ and $(CN)_2CO...C_6H_6$, increase with increase in the size of the molecules (Table 5), but at the same time the conclusions about the nature of the bond are independent of the basis set.

VI. SEMI-EMPIRICAL IMI CALCULATIONS

Semi-empirical IMI calculations retain their importance in those cases where non-empirical calculations cannot be carried out, for example for a system containing a large number of atoms. Like *ab initio* calculations, semi-empirical calculations are carried out in the supermolecule approximation and using perturbation theory. Supermolecule calculations are most frequently carried out using CNDO, INDO, etc. methods, which are based on neglect of differential overlap (NDO) and use SCF equations. In these calculations, no account is taken of dispersion energy. Unfortunately, the results of most supermolecule calculations carried out in the NDO approximation have proved to be unsatisfactory, and the observed discrepancies when compared with experimental data are not systematic.

Some typical results of IMI calculations in the NDO approximation can be considered. The CNDO/2 method gives a value of the energy of attraction for π-conjugated systems which is much too high. Thus for the $\pi\pi$-complex $C_6H_6...TCE$ in the "stacking" configuration this method gives the values $E_{int} \approx -520$ kJ mole^{-1} and $R_{equil} = 0.175$ nm,[148] whereas experiment gives E_{int} from -7.9 kJ mole^{-1} to -18.1 kJ mole^{-1} and $R_{equil} = 0.33-0.35$ nm.[149] On the other hand, for the dimer $(C_2H_4)_2$ the CNDO/2 calculation gives practically no minimum[150]. For dimers with a hydrogen bond this method often gives satisfactory values of E_{int} and R_{equil}.[151] A calculation by the MINDO/2 method showed that the $\pi\pi$-complex $C_6H_6...TCE$ should not be stable; satisfactory results were obtained for the $n\pi$-complex $NH_3...I_2$, but for the $\pi\sigma$-complex $C_6H_6...I_2$ the energy of attraction was too large[152]. The MINDO/2 and MINDO/3 methods are not suitable for the description of the hydrogen bond[153].

One of the main reasons for the inadequate results of supermolecule calculations in the NDO approximation is the unsatisfactory estimation of exchange terms. In the supermolecule calculation by the CNDO/2 method, account is taken of only the repulsion arising as a result of electrostatic interaction, parameterised in such a way that it leads to repulsion at short distances[154]. Thus for the complex $H_2CO...H_2O$, according to CNDO/2 estimates[13], the energy $E_{int} = -26.3$ kJ mole^{-1}, and from the breakdown of E_{int} into its components according to the scheme in Ref.13 it was found that $E_{el-st} = 20.1$ kJ mole^{-1}, $E_{ind} + E_{ct} = -46.4$ kJ mole^{-1}, and $E_{exch} = 0$. A non-empirical calculation[13] for the same system in the same configuration gives $E_{int} = -14.2$ kJ mole^{-1}, and the contribution of the electrostatic interaction is $E_{el-st} = -19.2$ kJ mole^{-1}; the other values are $E_{ct} + E_{ind} = -23$ kJ mole^{-1} and $E_{exch} = 28$ kJ mole^{-1}. These data show that the values of the individual contributions for E_{int}, obtained from non-empirical calculations, do not agree at all with one another; in particular, the values of E_{el-st} have opposite signs, and E_{exch} in the semi-empirical calculation is equal to zero. The breakdown of the balance between the components of E_{int} in the NDO approximation also leads to the random discrepancies in the results mentioned above. To improve the results, the CNDO/2 parametrisation is modified by changing the values of the intermolecular resonance integrals β. Decrease in β (absolute magnitude) makes it possible to obtain more realistic values of E_{int} for $\pi\pi$-complexes by the CNDO/2 method[155]; at the same time, increase in the value of β led to satisfactory results in a calculation for crystals of small molecules (C_2H_4, N_2, C_2H_2, etc.) by CNDO/2 and INDO methods[150].

In view of these fundamentally unsatisfactory features of the calculations in the NDO approximation, it must be concluded that the use of NDO methods to calculate the quantitative characteristics of supermolecules is not effective. Calculations of this kind may be useful, however, when dimers of similar chemical structure are being compared, and it is sufficient to know only the relative characteristics of the IMI in these dimers. For example, they have been used to determine the preferred configuration of approaching molecules in replacement or addition reactions[156,157] and to compare the qualitative characteristics of complexes with similar structures[158].

Calculation by the extended Hückel method (EHM) usually gives unsatisfactory results. This is related to the fact that in the EHM, account is taken of only the IMI components that depend on the overlap integrals, which at distances equal to or shorter than the van der Waals radius lead to repulsion. In Ref.159, the results of a calculation for the complex $(N_2)_2$ by the EHM were supplemented by calculating the dispersion energy, and in this approximation, good agreement with experiment was obtained for various characteristics of a molecular crystal of N_2. This approach has not been extended further, however. It may also be noted for excimers and exciplexes[160,161].

It is possible to avoid the extensive breakdown of the balance between the components of E_{int}, characteristic of semi-empirical IMI calculations in the supermolecule approximation, if the semi-empirical IMI calculation is carried out using perturbation theory. In the first semi-empirical calculations by purturbation theory, devoted to EDA complexes[82,83,162,163,164], it was assumed that the IMI energy can be represented in the form $E_{int} = E_{exch} + E_{ct} + E_{el\text{-}st} + E_{ind} + E_{disp}$ (that is the results of the theory of Murrell and coworkers[31] were used). Murrell's theory forms the basis of the semi-empirical calculations of IMI using perturbation theory, carried out at the present time. It is possible to distinguish two approaches to the estimation of the components of E_{int}. Studies in which the various components of E_{int} are calculated using the wavefunctions of the isolated molecules, obtained by some single method (usually the CNDO/2 method), can be considered first. In Ref. 154, all the integrals appearing in the expression of the theory[31] were calculated approximately. The differential overlap between AO relating to the same molecule was neglected, and account was taken of the overlap between the AO of different molecules. In Ref.165, to estimate the intermolecular integrals containing differential overlap, the Mulliken approximation was used at the AO level, but in Ref.166 this approximation was applied to the MO. This technique reduces considerably the number of two-electron and one-electron integrals, and simplifies the structure of the expressions under the integral sign. The other integrals are estimated using the approximations characteristic of the CNDO/1 and CNDO/2 methods.

A detailed analysis of possible versions of the approximations was carried out in Ref.154, where it was shown that the application of the Mulliken approximation to the MO gives better results than its application to the AO. In the latter case, the calculated energy E_{exch} is too large. (In Ref.154 it is pointed out that to obtain correct results for the $CH_2...CH_2$ system and for various other systems, the value of E_{exch} must be decreased by a factor of 10 relative to the data in Ref.165!) Ref.154 gives an optimum set of approximations, denoted PE-1 by the present authors. The application of PE-1 to the dimers $(H_2O)_2$ and $C_6H_6...(CN)_2CO$ gives results close to those of non-empirical calculations carried out in an STO-3G basis set (Table 6).

An approximate calculation of all the integrals required for the application of Murrell's theory was also carried out in Ref. 167, where complexes of nucleotide bases with hydrogen bonds were examined. In Refs. 168–170, devoted to an analysis of the interaction of molecules containing silicon, the wavefunctions of the isolated molecules, obtained by the CNDO/2 method, were used for the semi-empirical calculation of all the integrals appearing in "symmetrical" perturbation theory[20]. In the works cited above[154,165–170], the wavefunctions of the isolated molecules were calculated by the CNDO/2 method, after which perturbation theory was used. Perturbation theory is used in a slightly different form in the PCILO method[171,172]. Analysis of IMI by the PCILO method in the CNDO/2 parametrisation gives much better results[173,174] than supermolecule calculations by the CNDO/2 method.

Table 6. Energy characteristics of the IMI, kJ mole^{-1}, for the dimer $C_6H_6...(CN)_2CO$, obtained by different methods.

[a] E_{disp} calculated using perturbation theory in a basis set of wavefunctions.

[b] E_{disp} calculated in terms of bond polarisability.

In many calculations, the components of E_{int} are estimated using different approximations, corresponding to the physical nature of the individual contributions. In these calculations, the representation of the components of E_{int} as the sum of terms characterising the interactions between the separate fragments of the molecules (atoms or groups of atoms) is widely used. This approach is based on the possibility of representing the density matrix of the molecule as the sum of local charge densities. In the case of the long-range components $E_{el\text{-}st}$, E_{disp}, and E_{ind}, the potential for the interaction between the local charge distributions can be represented as a multipole series, and it is possible to obtain, for these components, multipole many-centre expansions, which reduce to simplified equations. In particular, the value of $E_{el\text{-}st}$ is usually estimated in terms of the energy of the interaction of atomic multipoles (up to quadrupoles), and in the calculation of E_{disp}, the treatment is restricted to dipole-dipole terms, and E_{disp} is expressed in terms of the bond polarisability tensor and the effective ionisation potentials. The energy E_{ind} is expressed in terms of the bond polarisability and the atomic multipole moments. In the calculation of $E_{el\text{-}st}$ and E_{ind}, the atomic moments are calculated by a semi-empirical method, suitable for these purposes (CNDO/2 or EHM),[175] and the bond polarisability values for the calculation of E_{ind} and E_{disp} are taken from experiment.

An analysis of various simplified expressions for the long-range components is given in various reviews[18,176,177] and other works[178,179].

Simplified equations are also used to calculate E_{exch}. Murrell and co-workers[31] showed that the energy E_{exch} of two one-electron atoms can be approximated successfully by the expression CS^2/R, where S is the overlap integral of the corresponding atomic orbitals. For a polyatomic system, an expression of more general form is used: $\sum_a \sum_b C_{ab}S_{ab}^2/R_{ab}$, where a and b are the atomic orbtials of the interacting molecules. The constants C_{ab} are chosen from a comparison with non-empirical calculations[18,180,181]. Different versions of simplified equations for E_{exch} were discussed in Ref.18.

There are no equations expressing the contribution of E_{ct} to the energy E_{int} as the sum of the interactions between local electron density distributions. This term, therefore, is often not included in calculations using simplified equations [181]; alternatively, it is estimated as $|kS_{mn}*|^2/h\nu_{mn}*$,[83] where $h\nu_{mn}*$ is the energy of the charge-transfer transition, $S_{mn}*$ is the overlap integral of the corresponding MO, and the coefficient k depends on the chemical structure of the interacting molecules[83].

Calculations using simplified equations (or hybrid calculations, as they are sometimes called) have been carried out for different systems. In particular, it has been shown[83,162] that the stability of the EDA complexes C_6H_6...TCE, p-xylene...TCE, and C_6H_6...Hal is determined chiefly by the magnitude of the contributions $E_{el\text{-}st}$ and E_{disp}. These conclusions about the forces bonding the complexes agree with the results of non-empirical calculations (Ref.46, see Tables 5 and 6).

Mention must also be made of a study[162] in which good agreement was obtained between experimental data and the calculated bond energies in complexes of tetracyanoethylene with substituted benzenes. Many studies have been made of the influence of the long-range interactions $E_{el\text{-}st}$, E_{ind}, and E_{disp} between nucleotide bases on the stability of the secondary structure of nucleic acids[179,182]. The long-range components were calculated for two cases, for a hydrogen bond between the nucleotide bases and for their "stacking" configuration. In Ref.183, bond energies for the van der Waals dimers $(N_2)_2$, $(C_2H_4)_2$, and $(C_6H_6)_2$, showing good agreement with the experimental values, were obtained, but the conclusions reached by the authors[183] about the structure of the equilibrium dimers $(N_2)_2$ and $(C_2H_4)_2$ differed from the results of non-empirical calculations[92-94]. This is quite natural, since the non-empirical calculation revealed a large number of structures with energies close to that of the energetically most favourable structure, and the semi-empirical calculation cannot take account of all the fine differences between dimers with similar energies.

In Ref.180 it was shown that the crystal lattice energy of benzene is determined chiefly by two contributions: E_{disp} and E_{exch}. Calibration of the parameters in simplified equations for E_{exch}, E_{disp}, and E_{ind} made it possible[181] to obtain for the dimers of the cations Na^+, K^+, and NH_4^+ with H_2O results equivalent to the results of non-empirical calculations. The use of these parameters made possible a successful description of the interaction of ions with more complex molecules. Various other applications of calculations using simplified schemes have been described[18].

In addition to semi-empirical calculations in which account is taken of all the integrals appearing in the expression for the energy E_{int}, and calculations using simplified equations, there are calculations combining these two approaches. The complex $C_6H_6Cl_2$ has been studied[184]. The contributions E_{ind} and E_{disp} were calculated using simplified equations, and in the estimation of the values of E_{exch} and $E_{el\text{-}st}$, account was taken of all the integrals appearing in the corresponding equations from Ref.31, as was done in Ref.165. As in Ref.165, the value of E_{exch} was found to be much too large. In calculations for the systems $(C_6H_6)_2$, C_6H_6...TCE, naphthalene-TCE,[185] and (pyromellitimide)$_2$,[186] the contributions $E_{el\text{-}st}$, E_{ind}, and E_{disp} were calculated using the simplified equations proposed in Refs.176 and 179, and E_{exch} and E_{ct} were calculated using the MO found by the EHM. These MO in the one-electron approximation were used to calculate the values of the contributions E_{exch} and E_{ct} in accordance with Murrell's theory[31] (this calculation scheme is denoted PE-2). The approach used in Ref.187 to analyse EDA complexes of the $\pi\pi$ type has been justified. The interaction of the π-electrons was taken into account in explicit form, and the interaction of the σ-electron cores was estimated in terms of the atom–atom potentials; the agreement with experiment was satisfactory.

In the analysis of the results of semi-empirical IMI calculations using perturbation theory, it should be noted that a successful choice of approximations makes it possible to obtain useful information on the nature of IMI; the calculated bond enegies and equilibrium distances are often close to the experimental values, and the conclusions about the nature of the forces stabilising the dimers agree with the results of non-empirical calculations.

Table 7. Dependence of E_{int} on the distance R_{O-O} for the dimer $(H_2CO)_2$ in kJ mole^{-1} (data from Ref.189).

R_{O-O}, nm	S configuration[a]		P configuration[a]

0.35	—3.0	—2.7	—1.3	—1.0
0.37	—3.4	—3.0	—	—

[a]For configuration notation see Fig.4.

Table 6 compares the results of calculations for the dimer C_6H_6...$(CN)_2CO$ with allowance for all the integrals (PE-1 approximation[154]) and calculations using the PE-2 hybrid scheme with the results of non-empirical calculations. Although the semi-empirical methods used differ considerably from one another, they give results close to those obtained non-empirically (an exception is the dispersion energy, for which the value obtained in the calculation in a minimum basis set is much too low, irrespective of whether the calculation is non-empirical or semi-empirical).

Calibration of the parameters in semi-empirical schemes to bring their results closer to the results of non-empirical calculations or to experimental data can make it possible to obtain values which are satisfactory from the quantitative viewpoint, and in this case, semi-empirical schemes can be used in the same way as non-empirical pair potentials. Calculations using simplified equations are more suitable for these purposes, since unlike calculations with allowance for all the integrals, these calculations contain parameters convenient for calibration. An example of this approach is provided by the above-mentioned work[181] in which semi-empirical

methods were used to examine the interaction of cations with water molecules and various other molecules. Table 7 gives the results of a calculation[189] for the dimer $(H_2CO)_2$ for the case of antiparallel and perpendicular configurations (Fig.4) in a non-empirical version in Kolos' basis set and by a semi-empirical method using the PE-2 scheme, in which some of the parameters were calibrated from the results of non-empirical calculations. The semi-empirical scheme not only reproduces the difference in the IMI energies in different configurations but also gives results showing quantitative agreement with the results of a non-empirical calculation.

---oOo---

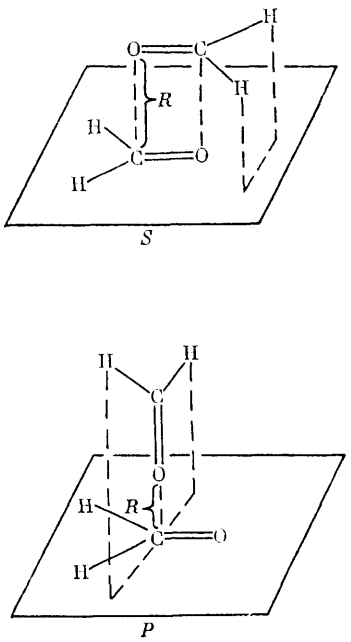

Figure 4. Parallel (*S*) and perpendicular (*P*) configurations of the formaldehyde dimer[189].

Thus the information that can be obtained from IMI calculations depends to a marked extent on the size of the system. If the interacting molecules are small (water, ethylene, etc.) and it is practicable to carry out non-empirical calculations in basis sets of the DZ type, it is possible to obtain satisfactory quantitative results both for a dimer and for many-particle systems.

Non-empirical calculations in restricted and minimum basis sets, which can be carried out for more complex systems, give valuable qualitative results, but their quantitative reliability is low, and appreciable departures from the Hartree–Fock or experimental bond energies (several tens percent) are possible.

Semi-empirical calculations undoubtedly retain their importance in those cases where non-empirical calculations are impossible even in minimum basis sets. Semi-empirical calculations often give results close to the experimental data; with appropriate parameterisation they can be used to obtain results equivalent to *ab initio* data.

The present state of quantum-chemical IMI calculations gives grounds for assuming that IMI calculations will develop in two directions: increase in the accuracy of non-empirical calculations, associated with the development of computational technique, and the creation of flexible semi-empirical schemes making it possible to reproduce experimental and non-empirical data.

While the present review was being prepared for publication, two monographs[190,191] devoted to the analysis of IMI were published. It also seems useful to mention some other recent studies. The influence of the basis set error (BSSE) on the properties of interacting molecules has been examined [192], the breakdown of E_{int}^{SCF} into its components has been analysed[193], and it has been shown[194] for the case of $(HF)_2$ that exchange interactions of second order decrease E_{disp} by 10%. Exchange repulsion has been analysed[195,196]; in particular, SCF calculations of the interaction between valence-non-bonded atoms have been used to obtain simple atom-atom potentials for E_{exch}.[195]

It has been shown non-empirically in a 4-31G basis set[197] that chloroform can bring about the rupture of peptide bonds, and this possibly explains its anaesthetising action. An additive semi-empirical scheme[181] has been used[198,199] to analyse the interaction of biologically active molecules with ions. A semi-empirical IMI calculation scheme which uses an expansion with respect to inverse powers of the intermolecular distance has been proposed[200]. Super-molecule *ab initio* calculations and semi-empirical calculations using perturbation theory have been compared for the case of the hydrogen bond and ion pairs[201]. Various present-day theoretical and experimental problems relating to IMI have been examined in a collection of IMI papers[202].

The Mechanism of the Decomposition of Organometallic Compounds of Transition Metals and the Role of Intermediate Species in Catalysis

B.A.Dolgoplosk

The three pathways leading to the decomposition of organometallic compounds of transition metals (Mo, W, Ta, Re, Pt, Pd, Rh, Cr, Nd, Y, and Nb) at the instant of formation are examined. α-Decomposition accompanied by the formation of carbene and carbyne species is of decisive importance for methyl, benzyl, trimethylsilylmethyl, and neophyl derivatives. The decomposition proceeds without superposition of radical stages. The mechanism of the chain metathesis of olefins and cycloolefins under the influence of carbene complexes of transition metals is considered. Ideas concerning the chemical nature of the elementary steps in the hydrogenolysis and isomerisation of the carbon skeleton and the dehydrogenation and hydrogenation of hydrocarbons are put forward on the basis of the hypothesis that the primary step in the oxidative addition of hydrocarbons to zerovalent metals involves the formation of organometallic compounds.
The bibliography includes 108 references.

I. INTRODUCTION

Fairly numerous investigations have been carried out on the decomposition of organometallic compounds of transition metals. In early studies of Kondyrev and Fomin[1], published in 1915, it was shown that the products of the decomposition of the organometallic compounds formed on interaction of alkylmagnesium halides with transition metal halides are saturated and unsaturated hydrocarbons corresponding to the alkyl groups of the initial compounds RMgX. These reactions were subsequently studied in greater detail in numerous investigations by Kharasch and many other workers (see, for example, Refs. 2–10).

The decomposition of alkyl derivatives as a rule results in the formation of the corresponding hydrocarbons R + H and R − H (alkane and alkene) and a certain amount of recombination products (R − R). If R = benzyl, phenyl, neopentyl, or other groups without an H atom in the β-position relative to the C–M bond, then the main decomposition product is R − R. When methyl-lithium interacts with halides of a number of metals, the main products are methane and ethane depending on the nature of the metals[5]:

$$CH_3Li \xrightarrow[\text{Ti, Zr, Mn, Cr, La}]{} \text{mainly } CH_4,\quad \xrightarrow[\text{Au, Fe, Ni}]{} \text{mixture of } CH_4 \text{ and } C_2H_6,\quad \xrightarrow[\text{Ag, Cu}]{} \text{mainly } C_2H_6. \qquad (1)$$

The mechanisms of these reactions are considered mainly on the basis of the hypothesis of free-radical stages. The idea of intermediate radical stages in the decomposition are still used by many investigators to account for the mechanism of the formation of the final reaction products, although there is no direct experimental evidence for this. In particular, the "trapping" of these intermediate decomposition products by styrene may be due to the addition to the latter of an organometallic compound of a transition metal. The present author and his co-workers[11–13] were the first to show experimentally that, in the presence of free-radical acceptors, for example, α-methylstyrene, the composition of the products of the reactions of C_2H_5MgBr and C_2H_5Li with $NiCl_2$, $CoCl_2$, and $TiCl_4$ remains unchanged. The reactions involving $NiCl_2$ and $CoCl_2$ lead to the formation of equimolar amounts of ethane and ethylene; in the reaction with $TiCl_4$, a large proportion of ethylene disappears owing to polymerisation. The absence of radical stages has also been noted in the reactions involving the oxidative addition of ethyl bromide to zerovalent cobalt and nickel[14]. The very fact of the formation of equimolar amounts of ethane and ethylene indicates a non-radical nature of the process, since ethyl free radicals readily abstract a hydrogen atom from the solvent. It has been shown that free radical reactions proceed smoothly in those cases where the reduction of M^{n+1} to M^n in the organometallic compound takes place very readily, for example, with conversion of the stable cobalt(III) or manganese(III) complexes into unstable ionic forms[15]:

$$(acac)_3Co + CH_3COOH \rightarrow (CH_3COO)_2Co + CH_3^{\cdot} + CO_2,$$
$$(acac)_3Mn + CH_3COOH \rightarrow (CH_3COO)_2Mn + CH_3^{\cdot} + CO_2. \qquad (2)$$

Homolytic decomposition at the C–M bond, accompanied by the formation of free radicals, is known for compounds characterised by a low energy of this bond. However, in most cases the energies of the carbon–transition metal bond are 30–60 kcal mol^{-1} [16] and the instability of the above compounds at the instant of formation requires a special explanation. Apart from the decomposition pathways leading to the β-disproportionation (R − H and R + H) and recombination (R–R) products, which have been studied in detail, in many cases α-decomposition, accompanied by the formation of carbene and carbyne complexes of transition metals, is the dominant process.

The formation of the carbene complexes of tantalum in the decomposition of $[(CH_3)_3CCH_2]_5Ta$ and $(C_6H_5CH_2)_5Ta$ has been demonstrated[17,18]. The reaction products were respectively $[(CH_3)_3CCH_2]_3Ta{=}CHC(CH_3)_3$ and $(C_6H_5CH_2)_3Ta{=}CHC_6H_5$. The formation of three and more ethane molecules in the decomposition of tetramethyltitanium has been demonstrated[19]. The α-disproportionation of methyl groups, accompanied by the formation of methane, has been demonstrated in relation to the decomposition of $(CD_3)_4Ti$.[20]

Interest in a more detailed study of the α-disproportionation reactions was aroused by the development of ideas concerning the carbene and carbyne nature of the active centres in the metathetical reactions of olefinic and acetylenic hydrocarbons. The stabilisation of carbenes by transition metals tends to drive the reaction towards the formation of carbene species. The carbene stabilisation effect can be illustrated by the work of Fischer[21], who demonstrated the possibility of synthesising stable carbene complexes of transition metals. As a rule, one or two heteroatoms (O, S, and N) are attached to the carbene carbon atom, while different stabilising ligands are attached to the transition metal.

The free carbenes, formed, for example, in the decomposition of diazo-compounds, are extremely reactive and are incapable of causing the development of selective reactions, while the stable Fischer carbene complexes have a low reactivity. The carbene and carbyne complexes arising in the decomposition of organometallic compounds of transition metals at the instant of their formation and occupying an intermediate position between the above species as regards chemical reactivity are of special interest.

Below we present the experimental results of studies in our laboratory of the contributions of the α-decomposition reactions for compounds of different transition metals.

II. THE MECHANISM OF THE DECOMPOSITION OF ORGANOMETALLIC COMPOUNDS OF TRANSITION METALS AT THE INSTANT OF FORMATION. THE RELATIVE CONTRIBUTIONS OF REACTIONS INVOLVING THE α-DISPROPORTIONATION AND RECOMBINATION OF GROUPS

Organometallic compounds of lithium or magnesium containing groups incapable of β-decomposition [CH_3, $C_6H_5CH_2$, $(CH_3)_3SiCH_2$, $C_6H_5C(CH_3)_2CH_2$] have been used as alkylating agents in the reactions with metal halides. The metals investigated (Pt, Pd, Cr, Rh, Mo, Re, W, Ta, Nb, Co) have found extensive applications in the catalytic reactions of hydrocarbons. In recent years some of them (Mo, W, Re, and Ta) in combination with alkylating agents have begun to be used to initiate the chain metathetical reactions of olefins and cyclo-olefins.

Table 1. The composition of the gaseous products of the reaction of CD_3Li with MCl_n.

MCl_n	CD_3Li/MCl_n	Yield, % of CD_3Li			Balance of CD_3 groups, %	$2CD_4+CD_3-CD_4^*$
		CD_4	CD_3-CD_3	$CD_2=CD_2$		
$MoCl_5$	1	60	4.2	3.8	68	124.2
$MoCl_5$	3	70	1.1	0.8	71.9	141.1
WCl_6	1	11	66	0.8	77.8	88
WCl_6	2	20	46	1.5	67.5	86
WCl_6	4	40	35	0.8	75.8	115

*The overall balance of the groups based on Eqn.(3) is presented.

(a) The reaction of CD_3Li with $MoCl_5$ and WCl_6.[22,23] The reaction was carried out in solution in dibutyl ether at 20 °C for 30 min. The yields of the reaction products are given in Table 1.. The products do not contain hydrogen atoms, which indicates the absence of free-radical stages. The main product is CD_4, which is formed solely as a result of the α-disproportionation reaction:

$$(CD_3)_2MX_n \rightarrow CD_4 + CD_2 : MX_n \qquad (3)$$

However, the yield of CD_4, particularly in the reaction involving $MoCl_5$, is much higher than would follow from Eqn. (3), which is confirmed by the overall balance of CD_3 groups. These results can be explained solely by the intensification of the α-decomposition reactions as far as the formation of carbyne and carbide species:

$$\begin{aligned}(CD_3)_3MX_m &\rightarrow 2CD_4 + CD \vdots MX_m\ ,\\ (CD_3)_4MX_y &\rightarrow 3CD_4 + \text{carbides.}\end{aligned} \qquad (4)$$

CD_2H_2, CDH_3, and CH_4 were isolated in proportions of 4 : 3 : 2 in the decomposition of the resulting precipitate with water, which confirms the formation of species of this kind. It is noteworthy that only a few methylene species are evolved in the form of ethylene or remain bound to molybdenum and tungsten. The carbyne formed is apparently mainly consumed in the reaction with the solvent or with other system components. This phenomenon is also characteristic of the other reactions derived below.

(b) The reactions of $(CH_3)_3SiCH_2Li$ and $(CH_3)_3GeCH_2Li$ with various metal chlorides[24–29]. The reaction was carried out in benzene at 20 °C. When tungsten, molybdenum, tantalum, rhenium, and niobium chlorides were used, the process began in solution, while in the case of cobalt, rhodium, platinum, and palladium chlorides the system was heterogeneous. In this case the metal chloride was taken in a tenfold excess relative to the organolithium compound, which ensured the complete consumption of the latter. The interaction of the organolithium compound with the metal halide can proceed via the following main pathways:

$$(CH_3)_3SiCH_2Li + MCl_n \begin{cases} \longrightarrow (CH_3)_3SiCH_2CH_2Si(CH_3)_3\ , & (5a)\\ \longrightarrow (CH_3)_4Si + (CH_3)_3SiCH : MCl_{n-2}\ , & (5b)\\ \longrightarrow (CH_3)_3SiCl + CH_2 : MCl_{n-2}\ . & (5c) \end{cases}$$

The possibility of the occurrence of radical stages is excluded from consideration, since it has been shown[24] that, when the reaction is carried out in perdeuterobenzene, analogous products without deuterium atoms are formed. When the reactions were carried out in trideuterotoluene ($C_6H_5CD_3$), the tetramethylsilane formed also did not contain deuterium. Pathway (5a) is characteristic of the usual decomposition leading to the formation of a recombination product. Pathways (5b) and (5c) lead to the formation of trimethylsilyl and methylene–carbene complexes respectively.

Table 2 presents the experimental results. The overall balance of trimethylsilylmethyl groups was set up on the basis of twice the amount of tetramethylsilane [in conformity with Eqn.(5b) and the number of groups detected in the form of $(CH_3)_3SiCl$ and $(CH_3)_3SiCH_2CH_2Si(CH_3)_3$]. The main pathway in the decomposition of trimethylgermylmethyl and trimethylsilylmethyl derivatives of tungsten, formed for the ratio $RLi/WCl_6 = 0.5–1.0$, is pathway (5c), leading to the formation of methylene species. In the case of tantalum, niobium, and rhodium compounds, the α-disproportionation reaction [pathway (5b)] predominates. The contribution of this reaction is fairly large for platinum and palladium compounds and even for $CoCl_2$, although the main reaction product in these cases is the recombination product R–R. The formation of appreciable amounts of $(CH_3)_3SiCl$ in the reaction of $(CH_3)_3SiCH_2Li$ with $PtCl_4$ is noteworthy.

The results obtained show that the formation of carbene species in the decomposition of organometallic compounds is characteristic also of platinum group metals and not only of transition metals involved in metathetical reactions.

(c) Reactions of benzyl derivatives of magnesium and lithium with MX_n.[30–34] The composition of the products of the interaction of benzylmagnesium chloride in diethyl ether with various metal halides was investigated. Control experiments in perdeuterodiethyl ether showed that, in the reaction with $PdCl_2$, the amount of $C_6H_5CH_2D$ formed does not exceed 5% of the overall amount of toluene produced. Apparently the formation of $C_6H_5CH_2D$ is due to the metallation of diethyl ether by organometallic palladium compounds. When the reaction of benzylmagnesium chloride with $MoCl_5$ is carried out in perdeuterodiethyl ether, $C_6H_5CH_2D$ is not formed.

Table 2. The composition of the products of the interaction of $(CH_3)_3ZCH_2Li$ with MCl_n.

MCl_n	RLi/MCl_n	Yield, % of theoretical			Overall group balance, %	Refs.
		$(CH_3)_4Z$	$(CH_3)_3ZCl$	$(CH_3)_3ZCH_2-CH_2Z(CH_3)_3$		
		Z = Ge				
WCl_6	0.5	11.2	55.4	—	—	[25, 26]

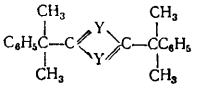
WCl_6	2.0	11.2	34.5	—	—	[25, 26]
		Z = Si				
WCl_6	1.0	17.0	31.5	24—26	90.5	[24, 26]
WCl_6	2.0	23.5	23.5	24—26	95.5	[24, 26]
$MoCl_5$	2.0	31.0	10.0	14	86	[27]
$TaCl_5$	0.5	43.0	10.0	traces	96	[27]
$TaCl_5$	1.0	35.0	12.0	11	93	[27]
$ReCl_6$	0.5	7.6	9.5	81	105.7	[29]
$ReCl_5$	1.0	20.0	5.4	55	100.4	[29]
$NbCl_5$	1.0	40.0	6.0	18	104	[29]
$CoCl_2$	0.1	20.0	traces	61	101	[29]
$RhCl_3$	0.1	43.0	traces	16	102	[28]
$PtCl_4$	0.1	16.0	8.0	55	95	—
$PdCl_2$	0.1	17.0	2.0	55	91	[28]

The interaction of $C_6H_5CH_2MgCl$ with metal halides can proceed via the following principal pathways:



$$C_6H_5CH_2MgCl + MX_n \begin{cases} \longrightarrow C_6H_5CH_2CH_2C_6H_5\,, & (6a) \\ \longrightarrow C_6H_5CH_3 + C_6H_5CH : MX_{n-2} \rightarrow C_6H_5HC{=}CHC_6H_5\,, & (6b) \\ \longrightarrow 2C_6H_5CH_3 + C_6H_5C : MX_{n-3} \rightarrow C_6H_5C{\equiv}CC_6H_5\,. & (6c) \end{cases}$$

The carbene and carbyne fragments can be partly disposed of in the form of stilbene and toluene. The data in Table 3 show that in the reactions of organomagnesium compounds the main product is toluene, in the formation of which 40 to 70% of the benzyl groups of the organometallic compound are consumed. In the reaction with $PtCl_4$ a considerable amount (9–10%) of stilbene is formed.

Particular mention should be made of the fact that in the reactions with $NdCl_3$ and YCl_3 a stable organometallic compound soluble in hydrocarbons is formed in a yield exceeding 90%, to which the following dimeric structure has been attributed:

$$(C_6H_5CH_2)_3Nd\,(Y) \rightarrow 1.8\,C_6H_5CH_3 + 0.5\,C_6H_5C\begin{matrix}\diagup\!\!\diagup Nd\,(Y)\\ \diagdown\!\!\diagdown Nd\,(Y)\end{matrix}CC_6H_5 + \\ + 0.2\,(C_6H_5HC{=}CHC_6H_5 + C_6H_5C{\equiv}CC_6H_5)\,. \qquad (7)$$

In these compounds one fragment of the benzyl group corresponds to each Nd or Y atom. When they are treated with D_2O, $C_6H_5CD_3$ is formed quantitatively. In the reaction with neophenyl-lithium the compound

is formed quantitatively and its hydrolysis yields two t-butylbenzene molecules. In terms of their thermal stability, the complexes produced are analogous to the Fischer carbene complexes.

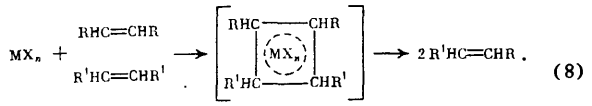
	A = $C_6H_5C(CH_3)_2CH_2Li$		
YCl_3	3	100	0

When the reaction of $(CH_3)_3SiCH_2Li$ with $NdCl_3$ was carried out in bromine, stable products were obtained[35] to which the structure

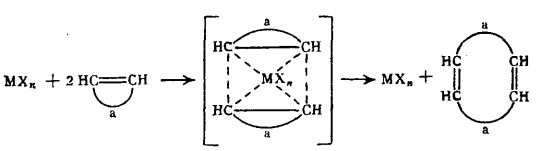
$$(CH_3)_3SiHC{=}Nd{-}CHSi(CH_3)_3\,.\\ \quad\quad\quad\



was attributed. When this compound is decomposed with deuterated water, $(CH_3)_3SiCHD_2$ is produced quantitatively.

Particular mention should be made of the considerable contribution of the α-decomposition reaction in the presence of platinum, palladium, and chromium, which are widely used in the catalysis of the reactions of hydrocarbons. Table 4 summarises data characterising the contribution of the α-decomposition reactions leading to carbene species and the contribution of the group recombination reactions (the formation of R–R). It lists the minimum and maximum yields of products obtained for different proportions of organolithium (organomagnesium) compounds and transition metal chlorides.

Thus the α-disproportionation of groups leading to the formation of carbene and carbyne species is in many instances the main pathway in the decomposition of the organometallic compounds of transition metals when the latter do not have hydrogen atoms at the β-carbon atom. As mentioned above, the carbene and carbyne species formed apparently disappear mainly as a result of the reaction with the solvent and only a small proportion are detected as recombination products ($D_2C{=}CD_2$, $C_6H_5HC{=}CHC_6H_5$, and $C_6H_5C{\equiv}CC_6H_5$) and bound as complexes with the transition metal. It will be shown below that the decomposition of the alkyl derivatives of certain transition metals can involve some α-decomposition as well as the main β-decomposition reaction.

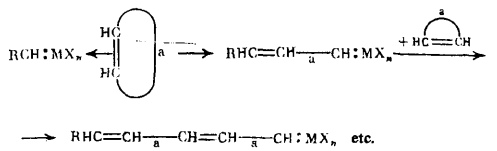


III. THE CHAIN METATHETICAL PROCESS UNDER THE INFLUENCE OF CARBENE COMPLEXES OF TRANSITION METALS

The metathesis of olefins under the influence of molybdenum and tungsten compounds on alumina was first observed by Banks and Bailey[36]. Subsequently systems based on molybdenum, tungsten, and rhenium compounds in combination with organometallic compounds of aluminium, tin, etc. were used widely for these reactions. In their composition, they resemble the Ziegler systems used for the polymerisation of olefins and dienes. The metathetical reactions of olefins in homogeneous systems proceed at the usual temperatures at a very high rate without heat changes. The mechanism proposed initially for this unusual reaction provided for a stepwise process via intermediate stages with formation of quasi-cyclobutane rings having four equivalent carbon atoms[37]:

(8)

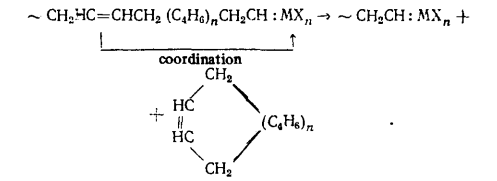
Simultaneously and independently Natta and co-workers[38,39] developed their research into the opening of cyclo-olefins under the influence of the same catalytic systems. They showed that the metathesis catalysts initiate the polymerisation of cyclo-olefins at the usual temperatures with formation of polymers in which the double bonds are retained quantitatively. The hypothesis of the intermediate formation of a quasi-cyclobutane ring was used[40] to explain the mechanism of the opening of cyclo-olefins:



(9)

Calderon et al.[41] were the first to demonstrate that the metathesis of olefins proceeds via a C=C bond dissociation reaction:

$$CD_3DC{=}CDCD_3 + CH_3HC{=}CHCH_3 \rightarrow 2\,CD_3DC{=}CHCH_3\,. \qquad (10)$$

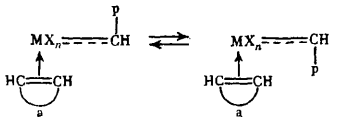


It has been shown in studies[42,43] of the composition of products of the decomposition of the ozonides of a copolymer of a ^{14}C-labelled cyclopentene with cyclo-octene that the polymerisation of cyclo-olefins also takes place with dissociation of the double bonds.

The present author and his co-workers[44–46] showed for the first time that the polymerisation of various cyclo-olefins under the influence of metathesis catalysts results in the formation of high-molecular-weight products at low conversions, oligomers being absent, which constituted direct confirmation of the chain mechanism of the process. The polymerisation of cyclo-olefins initiated by diazo-compounds, which decompose under the influence of WCl_n, was the first experimental evidence for the carbene nature of the active centres[47,48]. The following mechanism of chain propagation under the influence of carbene complexes of transition metals was proposed:

(11)

The polymerisation process consists of consecutive stages in which the monomer is coordinated to the active centre (the carbene complex of the transition metal) and is incorporated in the chain with regeneration of the active centre. The formation of high-molecular-weight products indicated a small number of effective active centres and their comparatively long lifetime. It was shown that unsaturated polymers are readily destructured in solution via the same mechanism with formation of a set of cyclic oligomeric molecules[49–53]:



(12)

Thus, high-molecular-weight polybutadiene (molecular weight 200 000) is converted into cyclic oligomers with a number-average molecular weight of 1600 in solution (concentration of raw rubber 8–10%) under the influence of metathesis catalysts after 15 min at room temperature. In the R_2AlCl–$MoCl_3(OCOC_{17}H_{35})_2$ system the oligomers formed retain the *cis*-configuration of the units[53], while in the R_2AlCl–WCl_6 system the ratio of the *cis*- and *trans*-units in the oligomers corresponds approximately to equilibrium. The initial stage of the polymerisation of cyclo-olefins involves the formation of a polymer with a narrow molecular-weight distribution (MWD),[54] which corresponds to a process via a live chain mechanism. The contribution of intramolecular reactions [Eqn.(12)] increases with the degree of polymerisation, which leads to a gradual widening of the MWD.

The $(CH_2{=}CHCH_2)_4Si$–WCl_6 system has been used for the polymerisation of cyclopentene. At −30 °C it gives rise to a polymer containing 98% of *cis*-units, while at +30 °C the product is a polypentenamer with a predominant (~80%) *trans*-configuration of the units[55]. The formation of units with the *cis*- and *trans*-configurations in metathetical reactions is

apparently associated with the rotation of the carbene about the C=M bond:

(13)

where p is the polymer chain.

The energy of rotation of carbenes in the complex $(C_6H_5CH_2)_3Ta{=}X$, where X represents carbene species, has been estimated[56] as 15–22 kcal mol^{-1}. For metathesis catalysts, it is apparently significantly lower and depends on the nature of the transition metal and the ligands surrounding it. The hypothesis of the possibility of such an isomerisation mechanism was first put forward by Ivin et al.[57]

As in other radical anionic chain processes, the metathetical reaction is inhibited by impurities leading to the formation of more stable carbene complexes than those of the growing chain. It has been shown[58–60] that ethyl vinyl ether, butyl vinyl sulphide, and trimethylvinylsilane fully inhibit the cyclopentene ring opening reaction even when present in an amount corresponding to two moles per mole of tungsten:

$$\begin{gathered}
\mathrm{pHC:MX_n + H_2C{=}CHSi(CH_3)_3 \xrightarrow{(a)} pHC{=}CH_2 +} \\
\mathrm{+ (CH_3)_3SiHC:MX_n \xrightarrow{(b)} p'HC:MX_n\ ,} \\
\mathrm{pHC:MX_n + H_2C{=}CHOR \xrightarrow{(a)} pHC{=}CH_2 +} \\
\mathrm{+ ROHC:MX_n \xrightarrow{(b)} p'HC:MX_n\ ;} \\
\mathrm{pHC:MX_n + H_2C{=}CHSR \xrightarrow{(a)} pHC{=}CH_2 + RSHC:MX_n \xrightarrow{(b)} p'HC:MX_n\ .}
\end{gathered} \tag{14}$$

The reaction is inhibited in stages (14b) involving the transition from the relatively stable complex to the more reactive complex formed after the incorporation of the monomer.

It has been shown[51] that in the cometathesis of α-olefins the reaction proceeds preferentially towards the exchange of methylene fragments [degenerate metathesis—reaction (15a)]:

$$\mathrm{R'HC{=}CH_2 + RHC{=}CD_2} \begin{cases} \longrightarrow \mathrm{RHC{=}CH_2 + R'HC{=}CD_2}\ ; & (15a) \\ \longrightarrow \mathrm{R'HC{=}CHR + H_2C{=}CD_2}\ . & (15b) \end{cases}$$

The rate of reaction (15a) is higher by a factor of 10^2–10^3 than that of reaction (15b). The mechanism of this phenomenon was examined and confirmed by the present author and his co-workers[62]. Reaction (15b) can proceed via intermediate stages involving the formation of secondary and primary carbene complexes differing in reactivity:

$$\underline{\mathrm{R'HC:MX_n}} \underset{\mathrm{R'HC:MX_n}}{\overset{\mathrm{H_2C:MX_n}}{\rightleftarrows}} \underline{\mathrm{RHC:MX_n}} \underset{\mathrm{RHC:MX_n}}{\overset{\mathrm{H_2C:MX_n}}{\rightleftarrows}} \underline{\mathrm{R'HC:MX_n}}\ \text{etc.} \tag{16}$$

Under the conditions of the chain process, even small differences between the reactivities of the primary and secondary carbenes cause a marked retardation of the reaction. Reaction (15a) proceeds via a stage in which secondary carbene complexes with identical reactivities are formed:

$$\mathrm{R'HC:MX_n \longrightarrow RHC:MX_n \longrightarrow R'HC:MX_n \longrightarrow RHC:MX_n}\ \text{etc.} \tag{17}$$

Therefore its rate is much higher than that of reaction (15b).

This mechanism has been confirmed experimentally by the results obtained in the cometathesis of β-butene with α-pentene in equimolar amounts under the influence of the R_2AlCl–WCl_6 system at 20 °C. The following reactions can take place in the initial stage:

$$\mathrm{C_3H_7HC{=}CH_2 + CH_3HC{=}CHCH_3 \rightarrow C_3H_7HC{=}CHCH_3 + CH_3HC{=}CH_2}\ ; \tag{18a}$$

$$\mathrm{2\,C_3H_7HC{=}CH_2 \rightarrow C_3H_7HC{=}CHC_3H_7 + H_2C{=}CH_2}\ . \tag{18b}$$

Reaction (18a) should proceed via consecutive stages involving the formation of the carbene complexes $CH_3CH_2.CH_2HC:MX_n$ and $CH_3HC:MX_n$, while reaction (18b), accompanied by the formation of ethylene, proceeds via stages in which $C_3H_7CH:MX_n$ and $CH_2:MX_n$ are formed. It has been established experimentally that the initial reaction product is only propene and not ethylene.

In the first section of this review, pathways leading to the formation of carbene species in the decomposition of organometallic compounds of transition metals capable of β-disproportionation were considered. In metathesis systems alkyl derivatives of aluminium (tin) are used in which there is a possibility of the α- and β-disproportionation of groups. It appeared important to explain the relatively small contribution in the above systems of α-decomposition reactions leading to the formation of carbene active centres. For this purpose, a study was made of the composition of the products formed in the reaction of $(C_2H_5)_2AlCl$ with $MoCl_3(OCOC_{17}H_{35})_2$ and of $C_2H_5AlCl_2$ with $WCl_4(OR)_2$ in the presence of trimethylvinylsilane[58,63]:

$$\mathrm{C_2H_5Mo\,(W)\,X_n} \begin{cases} \longrightarrow \mathrm{C_2H_4 + C_2H_6}\ ; & (19a) \\ \longrightarrow \mathrm{C_2H_6 + CH_3HC{:}\,Mo\,(W)\,X_n}\ . & (19b) \end{cases}$$

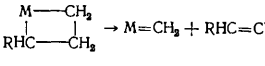
In the presence of trimethylvinylsilane, the reaction leading to the formation of the more stable trimethylsilylcarbene species and propene should take place:

$$\mathrm{CH_3HC:MX_n + H_2C{=}CHSi(CH_3)_3 \rightarrow (CH_3)_3SiHC:MX_n + C_3H_6}\ . \tag{20}$$

It has been shown that 3(10)% of propene relative to molybdenum (tungsten) is formed in the reaction. Hence it follows that reaction (19b) plays an appreciable role in the systems considered.

It was noted above that the $(H_2C{=}CHCH_2)_4Si + WCl_6$ system is used for the polymerisation of cyclopentene at −30 °C. It has been shown[64] that the reaction of $H_2C{=}CHCH_2SI(CH_3)_3$ with WCl_6 at room temperature in the absence of the monomer is rapidly completed by the formation of propene in an amount significantly exceeding that permitted by the equation

$$\mathrm{(H_2C{=}CHCH_2)_2WX_n \rightarrow C_3H_6 + H_2C{=}CHCH{:}\,WX_n}\ . \tag{21}$$



Hence it follows that the reaction of WCl_6 with $H_2C{=}CHCH_2.Si(CH_3)_3$ as well as CD_3Li is more far reaching and involves the formation of the carbyne species $H_2C{=}CHC{\vdots}WX_m$.

A series of studies describing the reactions involving the redistribution of acetylenic hydrocarbons under the influence of carbyne complexes of transition metals have been published recently[65,66]. It has been shown[67] that in the metathesis of acetylenic hydrocarbons under the influence of $(CH_3)_3CC{\equiv}W[OC(CH_3)_3]_3$ the equilibrium composition of product is attained after only 2 min at room temperature:

$$\mathrm{2R'C{\equiv}CR \rightleftarrows RC{\equiv}CR + R'C{\equiv}CR'}\ , \tag{22}$$

where R and R′ = C_2H_5 or C_3H_7.

The metathetical reaction is initiated by the metal–cyclobutane complexes, which form carbene active centres on dissociation[68]:

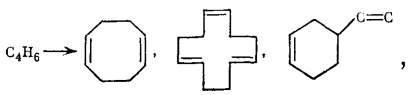
(23)

This served as a basis for the hypothesis that metal–cyclobutane intermediates are involved in the chain metathetical process, which is hardly justified, since metal–cyclobutane

complexes are relatively stable and chain propagation in metathetical reactions proceeds at enormous rates.

The unusual metathetical reactions of olefinic and acetylenic hydrocarbons have attracted the attention of investigators to a new class of active centres arising in the chemical reactions—the carbene and carbyne complexes of transition metals. In many instances they are apparently intermediates in the catalytic reactions of hydrocarbons.

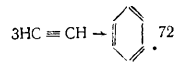
IV. THE MECHANISMS OF THE ELEMENTARY STEPS IN THE CATALYTIC REACTIONS OF HYDROCARBONS UNDER THE INFLUENCE OF TRANSITION METAL COMPOUNDS



It is well known that many catalytic reactions of hydrocarbons proceed at low temperatures via stages involving organometallic compounds. Apart from the polymerisation of olefins, dienes, and their derivatives, one may quote instances of many other reactions in which the formation of organometallic intermediates has been established. For example, the dimerisation (linear oligomerisation) proceeds via consecutive stages involving the formation of HMX and the corresponding organometallic compound[69,70]:

$$HNiX + H_2C{=}CH_2 \rightleftarrows CH_3CH_2NiX \xrightarrow{C_2H_4} CH_3CH_2CH_2CH_2NiX \rightarrow C_2H_5HC{=}CH_2 + HNiX \quad (24a)$$

$$HNiX + H_2C{=}CH \rightleftarrows \underset{\displaystyle C_6H_5}{CH_2CHNiX} \xrightarrow{H_2C=CH-C_6H_5} \quad (24b)$$



$$CH_3\underset{\displaystyle C_6H_5}{CH}CH_2-\underset{\displaystyle C_6H_5}{CH}NiX \rightarrow CH_3\underset{\displaystyle C_6H_5}{CH}-\underset{\displaystyle C_6H_5}{CH}=CH + HNiX \ .$$

Other reactions, in particular the cyclic oligomerisation of olefins, dienes, and acetylenic compounds under the influence of reduced transition metal (Ni, Co, Ti, etc.) compounds (the formation of vinylcyclohexene, cyclo-octadiene, cyclododecadiene, aromatic derivatives of acetylenic compounds, etc.), proceed cooperatively at a transition metal atom, sometimes without explicit stages with formation of organometallic σ-compounds,

(25a)

linear dimers and trimers being produced[71]:

(25b)

The same applies to the dienylation reactions occurring under the influence of reduced cobalt, palladium, rhodium, etc. compounds (see, for example, Müller et al.[73]):

$$H_2C{=}CHCH{=}CH_2 + \underset{\displaystyle COOR}{H_2C{=}CH} \rightarrow H_2C{=}CHCH{-}\underset{\displaystyle COOR}{CHCH_2CH_2} \ ; \quad (26a)$$

$$H_2C{=}CHCH{=}CH_2 + C_2H_4 \rightarrow CH_3CH{=}CHCH_2CH{=}CH_2 \ ; \quad (26b)$$

$$2H_2C{=}CHCH{=}CH_2 \xrightarrow{Pd} H_2C{=}CHCH-\underset{\displaystyle CH_3}{CH}{=}CHCH{=}CH_2 \ . \quad (26c)$$

All the above reactions take place with migration of a hydrogen atom.

The oxo synthesis under the influence of cobalt and rhodium compounds is also related to reactions proceeding via stages with formation of organometallic compounds[74,75]:

$$HCo(CO)_3 + C_2H_4 \rightarrow CH_3CH_2Co(CO)_3 \xrightarrow{CO} CH_3CH_2COCo(CO)_3 \rightarrow$$

$$\xrightarrow{H_2} CH_3CH_2C\overset{H}{\underset{O}{\diagdown\!\!\diagup}} + HCo(CO)_3 \ . \quad (27)$$

Many other catalytic reactions of hydrocarbons under the influence of transition metals at elevated temperatures should proceed, according to their character, via stages involving the formation of organometallic compounds. This applies to the dehydrogenation, hydrogenation, skeletal isomerisation, and hydrogenolysis of hydrocarbons.

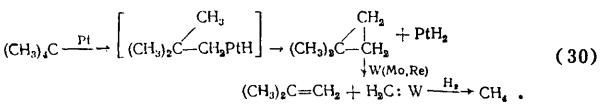
The pathways in the chemical reactions involved in heterogeneous catalysis are usually represented by pathway mechanisms which are convenient for the kinetic description of the process but in many instances fail to elucidate the chemical significance of the elementary steps. The study of the mechanisms of the reactions of organometallic compounds in model systems can apparently yield additional information about the chemical nature of the individual stages of the reaction. On the basis of experimental data on the decomposition pathways of organometallic compounds of transition metals, it is possible to consider the chemical nature of the hydrogenolysis and isomerisation of the carbon skeleton via stages involving the formation of carbene species and cyclopropane derivatives respectively.

1. Hydrogenolysis and Skeletal Isomerisation of Hydrocarbons

The mechanisms of hydrogenolysis usually employed involve the adsorption of adjacent carbon atoms on adjacent metal atoms with dissociation of the C–H bond. It is assumed that the dissociation of the C–C bonds requires that the hydrocarbon groups linked to the metal must undergo further dehydrogenation up to the complete elimination of hydrogen from the carbon atoms[76–78] in $-CH_2C-C$ (with the ruptured bonds to M M) fragments are then hydrogenated. The hydrogenolysis belongs to the type of catalytic reactions which are believed to require the simultaneous involvement of a complex *ensemble* of active centres in the reaction. Furthermore the metathetical reaction of olefins indicates the possibility of its occurrence in the presence of hydrogen at one of the metal atoms:

$$RHC{=}MX_n + H_2 \rightarrow RCH_3 + MX_n \ (\text{or } H_2MX_n) \quad (28)$$

As studies on metathetical reactions have developed, it has become clear that almost all transition metals can take part in them. The catalysts of metathesis are usually believed to be only those metals (Mo, W, Re, Ta) in the presence of which the reaction proceeds with a long chain. For the metals indicated, the chain length reaches 10^6–10^7. Although the formation of carbene species is characteristic of almost all other transition metals, the metathetical reactions in their presence do not occur or develop with a short chain.



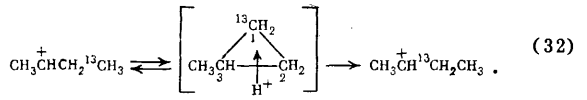
Free carbons in solution combine at the instant of formation with a hydrogen molecule[79]. It has been shown[80] that hydrogen adds at 49 °C to the stable carbene complex $(CO)_5W{=}C(C_6H_5)_2$. A similar reaction in the presence of deuterium should lead to the appearance of two deuterium atoms at a single carbon atom in the initial stage.

The activating effect of small amounts of reduced tungsten, rhenium, and molybdenum compounds in the hydrogenolysis of ethane and neopentane in the presence of a platinum catalyst[81,82] may be caused, as mentioned in our communications[83,84], by their activity in metathetical reactions. The fact that the first stage in the hydrogenolysis of paraffins involves the formation of C=C bonds is also correlated with this fact:

$$RCH_2CH_2R \underset{(a')}{\overset{Pt\ (a)}{\rightleftarrows}} H_2 + RHC{=}CHR \xrightarrow{(b)} \begin{cases} \xrightarrow{W\ \text{etc.}} RHC{=}W \\ \xrightarrow{Pt} RHC{=}Pt \end{cases} \xrightarrow{H_2} RCH_3 \ . \quad (29)$$

In the absence of tungsten, molybdenum, and rhenium compounds, the excess hydrogen retards the hydrogenolysis by shifting the equilibrium towards the starting material [reaction (29a')]. The decrease of the inhibiting effect of

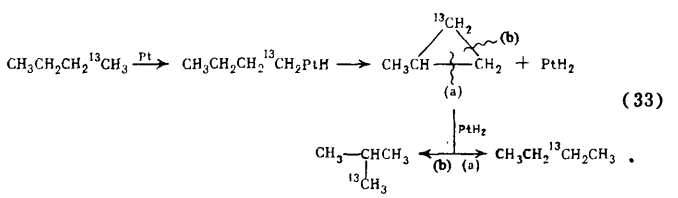
hydrogen in the presence of the above metals is associated with the fact that the latter are more effective in metathetical reactions than platinum. The accelerating effect of tungsten and other metals active in metathetical reactions on the hydrogenolysis of neopentane under the influence of platinum agrees with the extremely effective decomposition of cyclopropane groups by metathetical catalysts:



(30)

Numerous studies have been devoted to the skeletal isomerisation of hydrocarbons under the influence of cationic systems. It has been shown[85] that n-[1-^{13}C]butane isomerises rapidly to n-[2-^{13}C]butane under the influence of solutions of superacids (HF + SbF_5):

$$CH_3CH_2CH_2^{13}CH_3 \rightleftarrows CH_3CH_2^{13}CH_2CH_3 . \qquad (31)$$



The rate of migration of the ^{13}C atom in n-butane is approximately equal to the rate of isomerisation of n-pentane to isopentane in the presence of the same catalyst. It has been suggested[85] that protonated cyclopropane, which can be formed from a classical carbonium ion, is an intermediate:

(32)

The addition of H^+ to the carbon atom (1) with dissociation of the C(1)–C(3) bond leads to the reformation of the initial cation; the addition of H^+ to the C(2) atom with dissociation of the C(2)–C(3) bond leads to the formation of a carbon skeleton with migration of ^{13}C to a neighbouring position; on the other hand, the addition of H^+ to the C(1) atom with dissociation of the C(1)–C(2) bond results in the formation of an iso-skeleton with the ^{13}C atom in the methyl group. These ideas were used to explain the mechanism of the rapid skeletal isomerisation of n-pentane to isopentane under the influence of cationic systems[86]. The nature of the intermediate state, consisting of protonated cyclopropanes, has been examined[87–89].

Cyclopropane derivatives can be formed also in the α-decomposition of the organometallic compound. This apparently determines the possibility of skeletal isomerisation also in the presence of non-acid catalysts. It has been established[90] that n-[1-^{13}C]butane is converted on platinum films into isobutane (containing the label only in the methyl group) and n-[2-^{13}C]butane, the isobutane/n-[2-^{13}C]butane ratio remaining constant in the course of the reaction. Hence it follows that the above product should arise from a single intermediate. Thus the above migration of the ^{13}C atom on acid catalysts is also possible on metallic catalysts without cationic components. Such reactions can proceed via stages involving the formation of an organometallic compound with subsequent formation of the cyclopropane ring:

(33)

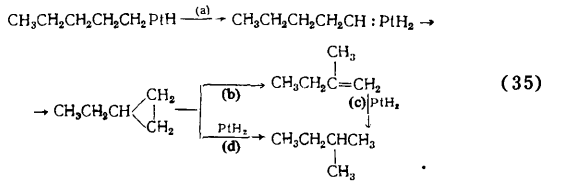
The usual reactions (decomposition of diazo-compounds etc.) leading to carbene species in solution are as a rule accompanied by the formation of cyclopropane derivatives and olefins (iso-olefins), which arise also as a result of the decomposition of the cyclopropane derivatives formed as the primary products. The ratio of the cyclopropane derivatives and olefins depends in the first place on the structure of the carbene and to a certain extent on the method of its synthesis. According to the data quoted by Kirmse[91], the yields of cyclopropane derivatives are as follows for different carbenes (expressed in percentages of the theoretical yield): 80–96% for $(CH_3)_3CCH$:, 25–51% for $(CH_3)_2CHCH$:, 41% for $C_2H_5CH(CH)_3CH$:, and 43–65% for $(CH_3)_3C-C(CH_3)$:.

So far there are no data on the specific character of the reactions of carbene complexes of transition metals, but one may expect that the ability to form cyclopropane derivatives will also be manifested in such cases. The formation of cyclopropane and its derivatives in metathetical reactions has been noted in a number of studies[36,63,92]. Diphenylcarbenepentacarbonyltungsten reacts with ethyl vinyl ether to form the cyclopropane derivative

in 65% yield[93].

The reactions described above presuppose the primary formation of an organometallic compound via the oxidative addition of hydrocarbons to active zerovalent metals. The possibility of such reactions is considered below. The reaction involving the isomerisation of n-pentane to isopentane, which is the starting material for the synthesis of isoprene, has been studied in a number of investigations. In order to account for the mechanism of this process in the presence of a platinum/alumina catalyst, the following pathway mechanism has been proposed[94]:

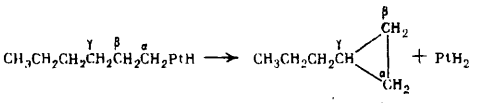
$$n\text{-}C_5H_{12} + 2Z_1 \rightarrow C_5H_{11}Z_1 + HZ_1 ; \qquad (34a)$$



$$C_5H_{11}Z_1 + Z_2 \rightarrow C_5H_{11}Z_2 ; \qquad (34b)$$

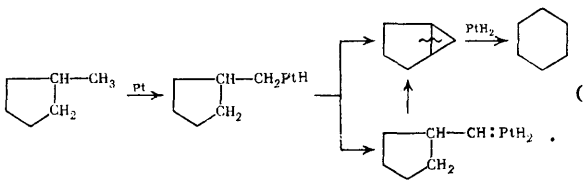
$$C_5H_{11}Z_2 \xrightarrow{H_2} \text{iso-}C_5H_{12} . \qquad (34c)$$

The mechanism presupposes the presence of two types of active centres on the catalyst (Z_1 and Z_2). A group of the type of an organometallic compound arises in reaction (34a), while in reaction (34b) the group [C_5H_{11}] is transferred to the active centre Z_2 on which the isomerisation step takes place with participation of hydrogen. The chemical significance of this stage of the reaction as well as the role of hydrogen in it remain obscure. In the absence of a considerable excess of hydrogen (5–10 moles per mole of pentane) the catalyst becomes covered in coke and is rapidly deactivated. In the discussion the chemical nature of the dehydrogenation reactions of hydrocarbons, arguments are adduced below in favour of the initial occurrence of the oxidative addition of hydrocarbons to the metal. For the reactions considered, the primary step may lead to organometallic compounds of two types:



The main pathway in the decomposition of the compounds indicated (β-disproportionation) leads to pentene with a normal carbon skeleton, while α-decomposition, accompanied by the formation of carbene species can lead to the isomerisation of the carbon skeleton:

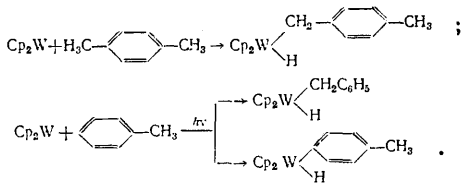
(35)



One cannot rule out the possibility of the formation of cyclopropane derivatives as a result of a γ-elimination reaction, as noted by Davidson et al.[16]

(36)

On the basis of the mechanism proposed, the saturation of the catalyst with coke can be accounted for by the formation of an extremely reactive analogue of isobutene, namely $CH_3CH_2C(CH_3)=CH_2$. Hydrogen converts it into isopentane, which prevents the saturation of the catalyst with coke.



The mechanism of the reversible isomerisation of methylcyclopentane to cyclohexane in the presence of a platinum catalyst can be treated analogously. In the given instance the reaction also requires a considerable excess of hydrogen:

(37)

2. Dehydrogenation of Hydrocarbons

The reaction involving oxidative addition to reduced forms of metals is nowadays well known. The addition of alkenyl halides to nickel carbonyl has been used[95] to obtain the corresponding π-allyl complexes. Alkyl and alkenyl halides readily add to arene complexes of zerovalent vanadium[96] with formation of primary organometallic derivatives. Green has shown[97] that *p*-xylene adds to biscyclopentadienyltungsten even at 60 °C, while toluene reacts with the latter at the usual temperature under the influence of light in accordance with the equation

(38)

The oxidative addition of triphenylphosphine to zerovalent metals (Pd, Ir, Rh, Pt) has been described[98–100]:

$$Ph_3P + Pd^0 \rightarrow Ph_2P{-}Pd{-}Ph \ . \qquad (39)$$

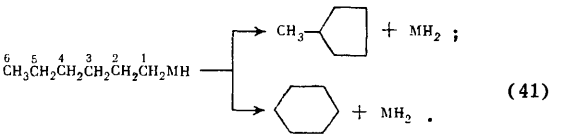
Since the least coordination saturated metal atoms, located on the crystal faces and in the defects, participate preferentially in the dehydrogenation reactions of hydrocarbons, it may be expected that at high temperatures the primary step is oxidative addition accompanied by the formation of an organometallic compound, since decomposition leads to the dehydrogenation products:

$$CH_3CH_2CH_2CH_3 + M^0 \rightarrow CH_3CH_2CH_2CH_2MH \rightleftarrows CH_3CH_2CH{=}CH_2 + MH_2 \ ; \qquad (40a)$$

$$C_6H_5CH_2CH_3 + M^0 \rightarrow C_6H_5\underset{\displaystyle MH}{\underset{|}{C}}HCH_3 \rightleftarrows C_6H_5CH{=}CH_2 + MH_2 \ ; \qquad (40b)$$

$$CH_3CH_2CH_2CH{=}CHR + M^0 \rightarrow CH_3CH_2\underset{\displaystyle MH}{\underset{|}{C}}HCH{=}CHR \rightleftarrows$$

$$\rightleftarrows CH_3CH{=}CHCH{=}CHR + MH_2 \ . \qquad (40c)$$



The oxidative addition of butane [reaction (40a)] takes place most readily with participation of the methyl group, since this entails the formation of a more stable primary organometallic compound and the dehydrogenation step involves the usual decomposition pathway of alkyl derivatives (β-decomposition). The finding that the primary product of the dehydrogenation of butane is α-butene, which isomerises further to β-butenes, is consistent with the above considerations. In the case of paraffins containing a large number of CH_2 groups, the fraction of such groups participating in the oxidative addition step increases, which leads to the primary formation of inner double bonds.

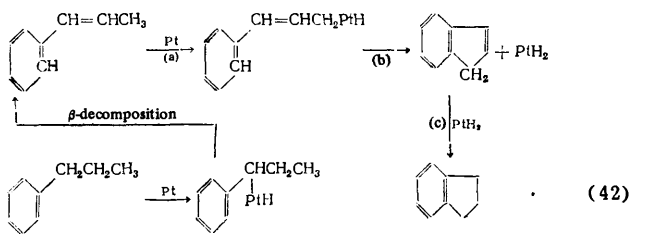
The reaction of benzene derivatives [reaction (40b)] takes place with participation of the α-methylene group, since this results in the formation of a more stable compound in which the C–M bond is conjugated with the benzene ring. This fact is correlated with the finding that the α-methylene group at the benzene ring is the first to undergo deuterium exchange under dehydrogenation conditions (deuterium adds to the C–M bond).

In unsaturated hydrocarbons the α-methylene group at the double bond is most reactive, which leads to the π-allyl coordination of the olefin to the transition metal in the primary step. As a consequence of the migration of the double bonds in the allyl system, all the hydrogen atoms are involved in deuterium exchange.

In all the examples presented the dehydrogenation mechanism reflects the main pathway in the decomposition of alkyl and a number of aryl derivatives of organometallic compounds of transition metals—β-decomposition. The mechanism of the dehydrogenation of hydrocarbons at a single metal atom as a result of β-decomposition operates most explicitly in the thoroughly investigated dimerisation (oligomerisation) reactions of ethylene, styrene, and other olefins[69,70]. The decomposition of organolithium and organoaluminium compounds at comparatively low temperatures with formation of olefins and metal hydrides proceeds analogously.

The possible decomposition pathways become more complex with increase in the length of the carbon skeleton. The mechanism under discussion for hydrocarbons becomes just as probable for the reaction at the C–H bond of the fifth or sixth carbon atom, starting from C_5 (and particularly C_6) hydrocarbons:

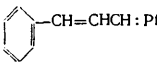
(41)



The abstraction of a hydrogen atom from C(5) and C(6) does not entail steric hindrance, while the abstraction of hydrogen atoms from C(3) and C(4) is accompanied by the formation of strained three- and four-membered rings. The contribution of α-decomposition, leading to carbene complexes, is extremely small for alkyl derivatives. One cannot rule out the possibility that the mechanism described reflects the mechanism of the dehydrocyclisation of hexane to methylcyclopentane.

The α-decomposition of organometallic compounds becomes possible in those cases where the reaction leads to the formation of a relatively stable carbene complex, for example, in the dehydrogenation of alkyl ethers, dialkyl sulphides, tetramethylsilane, etc.

It was shown above that the carbene pathway leading to the decomposition of organometallic compounds of platinum, palladium, and many other metals predominates when these have no β-hydrogen atoms. Such a decomposition pathway



is apparently rate-determining in the dehydrogenation of toluene, tetramethylsilane, neopentane, etc. when the removal of hydrogen from the system is ensured. The oxidative addition of toluene to a zerovalent metal should lead to the formation of bibenzyl.

The main initial products of the reactions of n-propylbenzene and ω-methylstyrene in the presence of Pt/Al_2O_3 at 450–500 °C are indene and indan, while the formation of other products (the hydrogenolysis and isomerisation products) is associated with the reactions of intermediates[101]. The CH_3 group in ω-methylstyrene and the α-methylene group in n-propylbenzene should be extremely reactive in oxidative addition to platinum. It is therefore possible to consider a reaction mechanism involving oxidative addition stages, which leads to one intermediate:

(42)

Reaction (42) can proceed via ω-elimination or via a stage in which a carbene species is formed:

3. Hydrogenation of Olefins

The addition of olefinic and diene hydrocarbons to a hydrogen-transition metal bond is known to occur in many instances. Nickel, cobalt, and chromium hydrides in ether combine with butadiene to form π-allyl complexes, which dissolve[102]:

$$\begin{aligned} NiH_2 &\xrightarrow{C_4H_6} (\pi\text{-}C_4H_7)_2Ni \ ; \\ CoH_n &\xrightarrow{C_4H_6} (\pi\text{-}C_4H_7)_3Co \ ; \\ CrH_3 &\xrightarrow{C_4H_6} (\pi\text{-}C_4H_7)_3Cr \ . \end{aligned} \qquad (43)$$

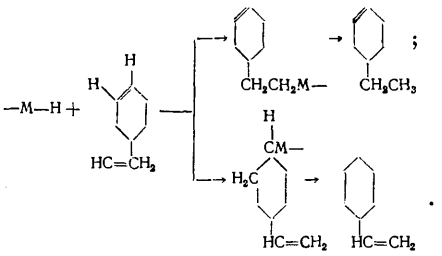
As mentioned above, the dimerisation reactions of ethylene and styrene proceed via a stage in which the olefin adds to HNiX. In the polymerisation of dienes and olefins under the influence of Ziegler–Natta systems containing titanium, cobalt, nickel, and other metal halides as well as organoaluminium compounds, hydrogen is used as the chain transferring agent:

$$pCH_2MX + H_2 \rightarrow pCH_3 + HMX \xrightarrow{\text{olefin}} RMX \ . \qquad (44)$$

Thus there are sufficient grounds to assume that the first stage in the hydrogenation reaction is the addition of the olefin to the M–H bond with formation of an organometallic derivative. This is consistent with the concept of the semihydrogenated state adopted in catalysis. On the basis of the available data for the reaction pathways of organometallic compounds of transition metals, the hydrogenation mechanism can be represented as follows in relation to metal dihydrides:

$$H{-}M{-}H + 2H_2C{=}CHR \rightarrow RCH_2CH_2MCH_2CH_2R \rightarrow$$

$$\begin{cases} \xrightarrow{2H_2} 2RCH_2CH_3 + H{-}M{-}H \ ; & (45a) \\ \rightarrow RHC{=}CH_2 + RCH_2CH_3 \ ; & (45b) \\ \rightarrow RCH_2CH_3 + RCH_2CH : M \xrightarrow{D_2} RCH_2CHD_2 \ ; & (45c) \\ \rightarrow RCH_2CH_2CH_2CH_2R \ . & (45d) \end{cases}$$



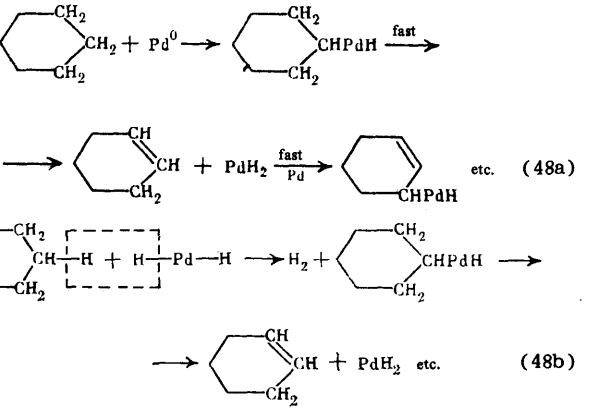
Reaction (45a) leads to the hydrogenation of both olefinic molecules. Reaction (45b), which proceeds via the β-decomposition mechanism, regenerates one olefinic molecule. The contribution of reaction (45c) can increase on formation of relatively more stable carbenes and can be estimated from the number of molecules containing two deuterium atoms at a single carbon atom at low conversions.

The semihydrogenated state in the case of styrene, 1,1-diphenylethylene, or compounds of the type of alkyl vinyl ethers and acrylonitrile corresponds to an addition product in which the C–M bond is conjugated with the benzene ring or other groups:

$$\begin{aligned} &{-}M{-}H + C_6H_5HC{=}CH_2 \rightarrow {-}M{-}\underset{C_6H_5}{CHCH_3} \ ; \\ &{-}M{-}H + (C_6H_5)_2C{=}CH_2 \rightarrow {-}M{-}\underset{(C_6H_5)}{C}{-}CH_3 \ ; \\ &{-}M{-}H + H_2C{=}CHOR \rightarrow {-}M{-}\underset{OR}{CHCH_3} \ ; \\ &{-}M{-}H + H_2C{=}\underset{CN}{CH} \rightarrow {-}M{-}\underset{CN}{CH}{-}CH_3 \ . \end{aligned} \qquad (46)$$

This mode of addition of styrene to HNiX has been demonstrated[70].

It has been shown that, in the hydrogenation of vinylcyclohexene derivatives over platinum and nickel, the vinyl group is hydrogenated faster than the double bond in the cyclohexene ring[103]:

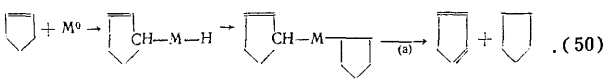


(47a)

(47b)

Pathway (47a) leads to the formation of a more stable primary organometallic compound than pathway (47b). For the same reason, the hydrogenation of α-olefins is always faster than that of olefins with inner double bonds.

The accelerating effect of a small amount of hydrogen on the dehydrogenation of cyclohexane in the presence of a palladium catalyst has been noted[104]. These somewhat unexpected results can be explained by considering two reaction pathways via stages involving the formation of organometallic compounds:



If reaction (48b) is faster than (48a), then the activating effect of hydrogen can apparently be explained by the formation of the hydride PdH_2, which accelerates the stage in which the organometallic compound is formed.

The autohydrogenation phenomenon, observed in the reactions of ethylene, butadiene, and cyclopentene over nickel, palladium, and iron[105–108] can be explained solely in terms of organometallic intermediates:

$$H_2C{=}CH_2 + M^0 \rightarrow H_2C{=}CH{-}M{-}H \xrightarrow[(a)]{C_2H_4} H_2C{=}CH{-}M{-}CH_2CH_3 \rightarrow \rightarrow HC{\equiv}CH + CH_3CH_3 \ . \quad (49)$$

Analogous subsequent reactions of acetylene lead to the formation of carbide species:

. (50)

The above equations presuppose the consecutive occurrence of the reaction via stages involving oxidative addition to the zerovalent metal (M^0), the addition of the olefin to the M–H bond, and the β-decomposition of the organometallic compound. Numerous examples of deuterium exchange involving olefins and dienes, observed in hydrogenation with deuterium[108], are consistent with the above ideas:

$$H_2C{=}CH_2 + D{-}M{-}D \rightarrow CH_2D{-}CH_2MCH_2CH_2D \xrightarrow[\beta\text{-decomposition}]{} HDC{=}CH_2 + CH_3CH_2D \ . \quad (51)$$

Reactions (49) and (50) lead to analogous products of single-stage exchange in olefins and dienes if deuterium adds to the C–M bond in stages (a).

---o0o---

Thus studies of the composition of the decomposition products of methyl, benzyl, trimethylsilylmethyl, and certain other derivatives of transition metals (Mo, W, Re, Ta, Pt, Pd, Cr, Rh, Nd, Y, Nb) established that the main pathway leading to the decomposition of the above organometallic compounds at the instant of their formation is α-decomposition accompanied by the formation of carbene and carbyne species. The absence of radical stages in the decomposition of the above compounds has been demonstrated.

The metathetical reactions of olefins and the ring opening reactions of cyclo-olefins proceed via a chain mechanism under the influence of carbene complexes of transition metals. The mechanisms of the elementary stages of the process, namely initiation, chain propagation, and chain transfer, have been examined. It has been established that the above reactions obey the usual rules characteristic of chain processes.

Analysis of experimental data for the reaction pathways of organometallic compounds of transition metals led to hypotheses concerning the chemical nature of the elementary steps in the catalytic reactions of hydrocarbons at a single metal atom. It has been suggested that the hydrogenolysis of the carbon skeleton proceeds via consecutive stages involving dehydrogenation (the formation of C=C bonds), the formation of carbene complexes, and addition of hydrogen to the latter.

The skeletal isomerisation reactions proceed via a stage in which cyclopropane groups are formed. The mechanism of the dehydrogenation reaction includes a stage involving the oxidative addition of the hydrocarbon to a zerovalent metal followed by the β-decomposition of the organometallic compound.

A two-stage mechanism, providing for the addition of the olefin to the M–H bond and of hydrogen to the C–M bond, has been proposed for the hydrogenation reactions. The above considerations explain the mechanism of the autohydration reactions. The above considerations explain the mechanism of the autohydrogenation of olefins and dienes and the mechanism of the deuterium exchange involving such compounds.

The Mechanism of the C_5- and C_6-Dehydrocyclisation and Skeletal Isomerisation Reactions of Hydrocarbons in the Presence of Metal-Containing catalysts

O.V.Bragin and S.A.Krasavin

A systematic account is given of data on the most important reactions of hydrocarbons in the presence of metal-containing catalysts. The modern ideas concerning the mechanisms of the isomerisation and C_5- and C_6-dehydrocyclisation of alkanes are described. The role of hydrogen in these reactions in the presence of metal-containing and in the first place platinum catalysts is analysed. The influence of the structure of metallic catalysts on the mechanisms of the dehydrocyclisation of skeletal isomerisation reactions of alkanes is examined.
The bibliography includes 170 references.

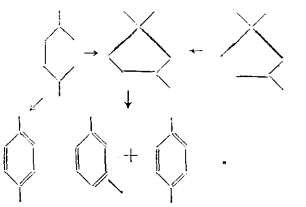
I. INTRODUCTION

The dehydrocyclisation and isomerisation of hydrocarbons are some of the most important processes in organic and petrochemical synthesis. More than half of the aromatic hydrocarbons are obtained nowadays from petroleum raw materials with the aid of dehydrocyclisation (DHC), dehydrogenation, and dehydroisomerisation reactions. It is therefore natural that these processes have been investigated most vigorously during the last decade.

The DHC reactions are divided into two types—C_5- and C_6-DHC. This classification is based on the different natures of the hydrocarbons formed, the considerable differences between the mechanisms of the reactions, and finally, in many instances, the differences between the catalysts employed. C_5-DHC results in the formation of cyclopentane hydrocarbons or a new five-membered ring in condensed systems; C_6-DHC leads to the formation of aromatic (mono- or poly-nuclear) hydrocarbons.



It is noteworthy that both types of DHC, in the presence of both metallic and oxide catalysts, were discovered in the Soviet Union[1-4]. The work of D.A.Kazanskii and his co-workers has made a particularly large contribution to the investigation of DHC reactions. These and certain subsequent researches into C_5- and C_6-DHC were described in monographs and reviews[5-11]. However, the problems of the interrelation between the C_5- and C_6-DHC reactions of alkanes, the specific details of the mechanisms of both types of cyclisation, the skeletal isomerisation reactions of alkanes and the hydrogenolysis of cyclopentanes, which are closely related to the above processes, and finally the involvement and role of hydrogen in these reactions merit special consideration.

II. CATALYTIC REACTIONS OF ALKANES AND CYCLOPENTANES IN THE PRESENCE OF PLATINUM CATALYSTS

C_6-Dehydrocyclisation of Alkanes

In the majority of studies in the presence of various metallic and in the first place platinum catalysts the C_5- and C_6-DHC reactions were investigated jointly because their conditions are very similar. In the first studies on reforming[9] the possibility of the intermediate formation of cyclopentane in the aromatisation of n-pentane was pointed out, because the catalytic reaction mixture contained a certain amount of alkylcyclopentanes.

Subsequently, this aromatisation pathway received a rigorous experimental confirmation, particularly as a result of the study of the reactions of 2,5-dimethylhexane, 2,2,4-trimethylpentane, and 1,1,3-trimethylcyclopentane in the presence of various platinum catalysts:

It was found that, in the presence of monofunctional platinum catalysts, 2,2,4-trimethylpentane as well as 1,1,3-trimethylcyclopentane give rise to approximately equal amounts of *m*- and *p*-xylenes[12-15], i.e. the aromatisation proceeds via

the intermediate formation of a C_5 ring. It has been suggested[15] that the rate-limiting stage in C_6-DHC involves the expansion of the five-membered ring. On the other hand, the main product of the aromatisation of 2,5-dimethylhexane is *p*-xylene, which shows that the C_5- and C_6-DHC reactions take place simultaneously and independently. Thus the pathway followed in the aromatisation proceeds depends significantly on the structure of the initial alkane.

The possibility of the direct 1,6-ring closure in the presence of Pt/C and various Pt/Al_2O_3 catalysts has been discussed[5,14,16-19]. This conclusion is based on the reactions of 2,2- and 3,3-dimethylhexanes[17,20], which partially cyclise to *gem*-dimethylcyclohexane and the latter is in its turn dehydrogenated under the experimental conditions with formation of aromatic hydrocarbons. An analogous alkane aromatisation pathway was discussed by Ivan'kovich et al.[21] The results of the study of the C_6-dehydrocyclisation of n-[1-^{14}C]- and n-[4-^{14}C]-heptanes have been analysed in detail[16].

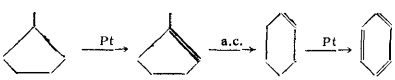
On the other hand, Paal and Tetenyi[22-24] concluded that n-hexane undergoes successive dehydrogenation to a triene in the presence of nickel and platinum catalysts with subsequent cyclisation and aromatisation. This reaction mechanism and the absence of intermediate cyclohexane and cyclohexene in the reaction chain were confirmed by the same workers by introducing the ^{14}C label. Kazanskii and co-workers[25-28] reached an analogous conclusion concerning the n-alkane aromatisation pathways in the presence of Pt, Pt/Al_2O_3, and Pt/C catalysts.

Thus it can be assumed that the aromatisation of n-alkanes proceeds via intermediate dehydrogenation stages. At the same time, alkanes with a quaternary carbon atom cannot be dehydrogenated quite so readily under the reaction conditions and their aromatisation proceeds at least partially via the direct "cyclohexane" mechanism.

Analysis of data on aromatic C_7-hydrocarbons in the presence of Pt/Al_2O_3 [29,30] demonstrated yet another possibility for the formation of aromatic hydrocarbons from alkanes—namely as a result of the primary formation of a C_7 ring and its subsequent contraction. This is indicated by the formation of small amounts of cycloheptane from ethylcyclopentane and by the position of the ^{14}C label in the [1-^{14}C]heptane aromatisation products.

Under real conditions of catalysis, the aromatisation of alkanes in the presence of metal-containing catalysts apparently proceeds via all the mechanisms indicated above. One of these may predominate to a significant extent depending on the structure of the initial hydrocarbon, the reaction conditions (the temperature and the carrier gas), the chemical composition of the catalyst, etc. Thus it has been stated that, with decrease of the acidity of the platinum/alumina catalyst[32-35] and with increase of temperature[36], the contribution of the C_5-dehydrocyclisation to the aromatisation process diminishes. In the presence of the Pt/Al_2O_3 catalysts the dehydroisomerisation reaction plays an appreciably greater role in aromatisation than in the presence of the palladium catalyst[9].

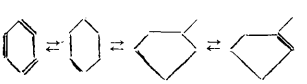
The C_6-DHC of n-hexane in the presence of platinum deposited on "non-acid" Al_2O_3 has been investigated[14]. The authors suggested that the reaction proceeds via two pathways: (a) via consecutive mechanism involving the dehydrogenation and subsequent cyclisation of a triene and (b) via the direct aromatisation of n-hexane. The important role of hydrogen in the reaction and the undoubted dependence of the aromatisation mechanism on the hydrogen pressure in the reaction mixture were noted.



The results of studies of the aromatisation of n-heptane in the presence of Pt/Al_2O_3 catalysts by the thermal desorption and kinetic methods are of undoubted interest[37-39]. The temperature ranges of the desorption process and the number of active centres were determined. It was suggested that at least two types of platinum active centres are present on the surface of the Pt/Al_2O_3 catalyst. According to the authors[37-39], the C_6-DHC reaction takes place predominantly on one of them with formation of toluene, while the second type of centres are characterised by a greater activity in relation to the dissociation of the C–C bond and lead to the formation of benzene from toluene. The authors suggest that one of the two types of catalytically active centres is associated with the existence of crystalline platinum and the other with platinum complexes; the latter may also consist of cluster formations whose composition includes aluminium ions and OH groups as well. Overall, the results presented are in good agreement with the consecutive aromatisation mechanism. The authors[37-39] point out the possibility that the reaction rate is limited by the stage involving the desorption of the superdehydrogenated forms of aromatic compounds (with participation of hydrogen) on centres of one of the types. On centres of the other type the reaction rate is limited by the dehydrogenation stage[39].

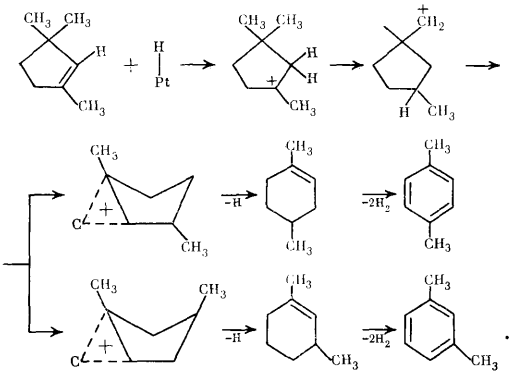
As shown above, one of the pathways leading to the formation of aromatic hydrocarbons from alkanes is dehydroisomerisation of the intermediate alkylcyclopentanes.

Dehydroisomerisation of Cyclopentanes



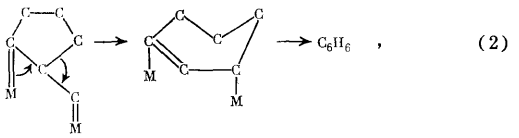
It has been shown by the kinetic isotope method[40] that, in the presence of Pt/C at 310 °C in a stream of helium, benzene is not formed from n-hexane via methylcyclopentane. The methylcyclopentane dehydroisomerisation reaction is suppressed under these conditions. Under other conditions (550 °C, p_{H_2} = 2.25 atm), it was established by the same method[25] that approximately 20% of benzene is formed from hexane via methylcyclopentane in the presence of the platinum/alumina catalyst, the rate of formation of benzene from methylcyclopentadiene being significantly higher than the rate of its formation from methylcyclopentane and methylcyclopentenes. On this basis, it is suggested that the C_6 ring is formed after the dehydrogenation of the cyclopentane hydrocarbon to methylcyclopentadiene.

In studies where the bifunctional character of dehydroisomerisation catalysts is emphasised, the occurrence of a process with participation of the acid centres (a.c.) of the carrier[34,35], for example via a carbonium ion mechanism[41-43], has been postulated:



It has also been suggested that the dehydroisomerisation reaction proceeds at an active centre formed by a platinum atom or crystal and the adjoining acid centre[42].

The application of the kinetic isotope method made it possible to demonstrate that the dehydroisomerisation of methylcyclopentane in the presence of the Pt/Al_2O_3 and Pd/Al_2O_3 catalysts under reforming conditions (480 °C, p_{H_2} = 20 atm) can take place also without the intermediate formation of a cyclene[44]:

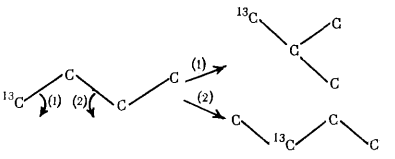


However, it is not clear which factor (hydrogen pressure, the acidity of the carrier, etc.) is involved in the discrepancy between the results of two studies by Isagulyants and co-workers[25,44].

The study of the dehydroisomerisation reaction in the presence of platinum/alumina catalysts with a suppressed acid function and also in the presence of a platinum film or platinum deposited on a relatively inert carrier (activated charcoal) demonstrated the possibility that the reaction takes place only at metallic centres. According to Lesger[15] the dehydroisomerisation mechanism consists in the formation of electron-deficient cyclopentyl rings on electron transfer from the semihydrogenated alkylcyclopentene to the platinum atom (functioning as a weak Lewis acid) accompanied by the 1,4-hydrogen shift or a series of 1,2-hydrogen shifts with subsequent ring expansion via a bicyclic intermediate:

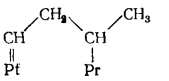
(1)

It is emphasised[15] that the acid centres of the carrier of an industrial platinum/alumina catalyst may be more active in the isomerisation reaction than the platinum centres. According to the authors[8,15] the above mechanism (1) is preferable to the mechanism



(2)

proposed by Muller and co-workers[13,45], according to which the preliminary abstraction of four hydrogen atoms is required. We may note that the proposed dehydroisomerisation mechanisms have overall features in common with the alkane isomerisation reaction.

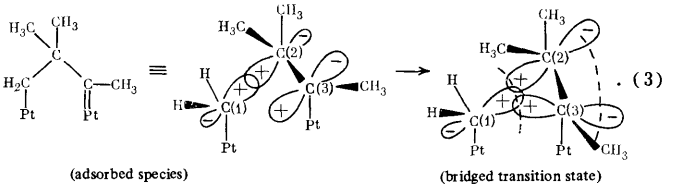


Isomerisation of Alkanes

The C_5-dehydrocyclisation and skeletal isomerisation reactions of alkanes as well as the hydrogenolysis and dehydroisomerisation of cyclopentanes in the presence of monofunctional catalysts are closely related and under certain conditions can occur simultaneously via parallel-consecutive mechanisms. Two main mechanisms of the isomerisation of alkanes in the presence of monofunctional platinum catalysts are distinguished at the present time[5,6]: the bond shift mechanism and the C_5-cyclic mechanism. However, despite the large number of studies carried out, there is as yet no unanimous view concerning the detailed reaction mechanism.

The bond shift mechanism was proposed to account for the characteristic features of the isomerisation of n-butane, isobutane, neopentane, and neohexane in the presence of sputtered platinum films[46,47].

Here (1) and (2) denote the possible directions of the bond shifts on formation of the corresponding product. Since isobutane and neopentane reacted at the same rates and with the same activation energies and the formation of a 1,2-diadsorbed or π-bonded intermediate cannot be postulated for neopentane, it has been suggested that the isomerisation proceeds via 1,3-adsorbed intermediate forms:

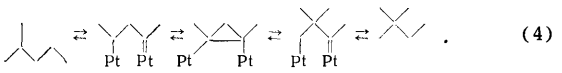


This structure of the adsorbed species is consistent also with data for the deuterolysis of 1,1-dimethylcyclopropane[13].

The study of the isomerisation reaction on oriented platinum films showed[47] that isobutane isomerises on the (111) face of a platinum single crystal more effectively than on the other faces, while for n-butane there are no great differences between the activities of different faces. This was explained by the possibility of the formation of a triadsorbed intermediate for isobutane on the platinum (111) face:

It is noteworthy that the isomerisation of neopentane is a structure-sensitive reaction[48]. Changes in the selectivity of the neopentane isomerisation as a function of the preliminary treatment of the catalyst and the degree of dispersion of the metal were explained on the basis of the characteristic features of the changes in the concentrations of triplets of platinum atoms and the corners and edges in polycrystalline platinum with increase in the size of crystallites. The possibility of three-point adsorption of neopentane on the platinum(111) face and the stepped platinum faces and the impossibility of such adsorption on the (110) and (100) faces were demonstrated with the aid of simple geometrical considerations.

The bond shift mechanism has been examined[49] from the standpoint of the molecular orbital method. The rearrangement of neohexane to 2-methylpentane can be represented as follows (henceforth referred to as Anderson's mechanism):

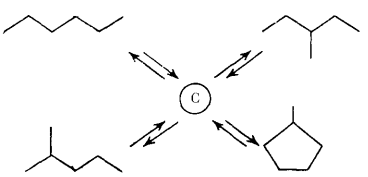


(adsorbed species) (bridged transition state)

(3)

It has been suggested that the electrons of the pπ orbital of the C(3) atom are partly displaced towards the metal, so that a structure intermediate between a carbonium ion and a radical is produced. Calculation of the energy of the bridge bond makes it possible to arrange alkanes in the sequence $n\text{-}C_4H_{10} < iso\text{-}C_4H_{10} < neo\text{-}C_5H_{12}$, which had been established previously[47] for the relative reactivities of these hydrocarbons in the presence of platinum. It has been noted[49] that,

whereas the sp^3 hybridisation of the C(2) atom does not prevent the isomerisation of neopentane, the sp^2 hybridisation of the C(3) atom [see mechanism (3)] to which the migrating group is transferred, rules out the possibility of the formation of neopentane from isopentane, which has been observed experimentally[47]. However, small but not negligible amounts of neohexane are formed from methylpentanes in the presence of platinum. It has been suggested[13] that in this case the isomerisation proceeds via the mechanism



(4)

We may point out that the proportions of the products of the hydrogenolysis of methylcyclopropane observed experimentally[50] differ significantly from those of the butane isomerisation products[47]. The above mechanism can therefore be considered as one of the possible mechanisms of the isomerisation reaction only if it is assumed that the adsorbed cyclopropane is a transition state but not an intermediate in the reaction.

Thus the two bond shift isomerisation mechanisms examined differ mainly by the structure of the transition state. In both cases, firstly, the metal atom must be sufficiently electronegative and, secondly, the surface metal atoms must be capable of undergoing a rapid change in their valence in the rearrangement. The characteristic features of the catalytic action of iridium and platinum, which are the only Group VIII metals capable of catalysing the isomerisation of neopentane, have been treated from these standpoints[51]. For a long time it was impossible to observe the isomerisation of neopentane in the presence of palladium[47,51], although isobutane undergoes a rearrangement on palladium. It has only recently been reported[52] that neopentane can isomerise on an oriented palladium (111) film under the conditions of a high H_2/hydrocarbon ratio.

Isopentanes, n-hexane, and their homologues isomerise more readily than neopentane and neohexane in the presence of monofunctional platinum catalysts. Methylcyclopentane is then always formed, its concentration passing through a maximum with increase of the degree of conversion. It has been shown that methylcyclopentane and isomeric hexanes give identical initial proportions of the products (C_6 alkanes) on contact with the Pt/Al_2O_3 catalyst whose acidic function has been suppressed[45,53]. Analogous proportions of products are characteristic also of reactions in the presence of platinum deposited on activated charcoal and pumice and on platinum films, but they differ significantly from the proportions of the products obtained in the presence of explicitly bifunctional catalysts. On the basis of these findings, it has been suggested that there is a single transition complex in the isomerisation of hexanes and hydrogenolysis of methylcyclopentane in the presence of monofunctional platinum catalysts (the C_5-ring mechanism); the reactions of hydrocarbons are then represented schematically in the following manner[45]:

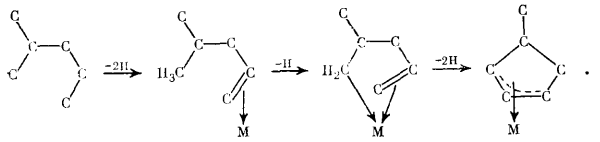
Here © represents a set of hydrocarbon interconversion products, some of which must have a cyclic structure, and the intermediates in the dehydrocyclisation reaction of alkanes are the same as in the hydrogenolysis of methylcyclopentane[54]. Thus the isomerisation and C_5 dehydrocyclisation reactions of alkanes, on the one hand, and the hydrogenolysis reactions of alkylcyclopentanes, on the other, are interrelated, which must be taken into account in explaining the structure of the interconversion products ©. We may note that the possibility of the isomerisation of alkanes as a result of the hydrogenolysis of an intermediate C_5-cyclic hydrocarbon was pointed out by Liberman et al.[55]

Hydrogenolysis of Cyclopentane

The hydrogenolysis of cyclopentane and its homologues has been most thoroughly investigated among this group of reactions. Detailed information about this process can be found in a number of communications[7,56-58]. Here we shall briefly discuss only the principal characteristic features and the proposed mechanisms of this reaction. The hydrogenolysis of cyclopentane hydrocarbons takes place successfully in the presence of platinum, rhodium, iridium, and osmium catalysts[59]. In the presence of platinum catalysts the hydrogenolysis slows down with increase of the number of substituents in the five-membered ring[58]. Data on the selectivity of the hydrogenolysis of substituted cyclopentanes via different pathways are of greatest importance. The selectivity depends on a number of factors: the size, number, and location of the substituents in the C_5 ring[58,60], the partial pressure and surface concentration of hydrogen†,[59,61] and the degree of dispersion of the metal[62-64].

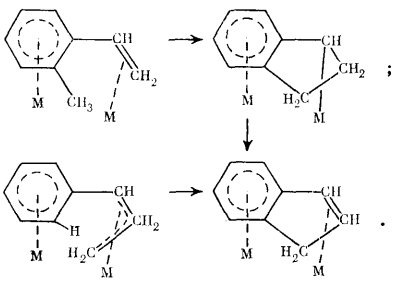
Thus an increase of the partial pressure of hydrogen from 10 to 50 atm decreases the 2-methylpentane/n-hexane ratio in the hydrogenolysis of methylcyclopentane in the presence of different platinum catalysts[61]. It is of interest to note that at 50 atm in the presence of the 0.3% Pt/Al_2O_3 catalyst the tertiary-secondary C–C bonds are exclusively ruptured in the five-membered ring. It has been suggested[61-65] that the pathway followed in the hydrogenolysis of the C_5 ring is determined by the structure of the monoadsorbed complex, which depends on the relative contributions of two factors: the distribution of electron density in the alkylcyclopentane molecule and the electrophilicity (electron-donating properties) of the transition metal atoms in the catalyst, which is influenced by the hydrogen pressure. The influence of the hydrogen pressure on the pathway in the cyclisation of n-octane, namely an increase of the yield of 1,2-ethylmethylcyclopentane relative to propylcyclopentane with increase of hydrogen pressure, has been treated from the same standpoint[66]. However, the role of the carrier in the hydrogenolysis of alkylcyclopentanes remains obscure. The preferential dissociation of the tertiary-secondary C–C bonds in the C_5 ring can be logically explained on the assumption[67,68] that the hydrogenolysis of alkylcyclopentanes takes place preferentially at the acid centres of the 0.3% Pt/Al_2O_3 catalyst at a hydrogen pressure of 50 atm.

In his study of the influence of the platinum concentration in platinum/alumina catalysts on the hydrogenolysis of methylcyclobutane and methylcyclopentane, Gault[63] concluded that there are at least two hydrogenolysis mechanisms: the selective mechanism in which only the bonds between the secondary carbon atoms in the ring are ruptured and the non-selective mechanism leading to the equally probable dissociation of all the ring C–C bonds. The first mechanism is characteristic of the reaction on platinum films at low temperatures and in the presence of the 10% Pt/Al_2O_3 catalyst. The second



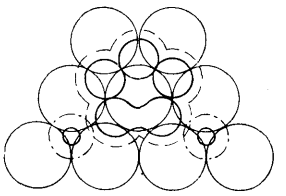
†See also C.Corolleur, F.G.Gault, and L.Beránek, React. Kinet.Catal.Letters, 1976, 5, 459.

mechanism operates on platinum films at high temperatures and in the presence of the 0.2% Pt/Al_2O_3 catalyst; in this case the proportions of the products are independent of the degree of conversion[62]. It has been suggested that the hydrogenolysis via the non-selective mechanism proceeds via the intermediate formation of α, β, γ-triadsorbed (π-bonded) species, while the reaction via the selective mechanism proceeds via α, α, β, β-tetra-adsorbed species. In the former case the plane of the ring is parallel and in the latter case perpendicular to the surface of the metal. The principal features of the selectivity of the hydrogenolysis of various cyclic hydrocarbons can be logically explained from the above standpoints. For example, an increase of the partial pressure of hydrogen should suppress the formation of the tetra-adsorbed species, i.e. should diminish the contribution of the selective mechanism to the hydrogenolysis of cyclopentanes, which is in fact observed experimentally.



We may note that by no means all experimental data can be described in terms of the selective and non-selective mechanisms (or their linear combination). Maire et al.[62] were therefore forced to introduce the concept of the partially selective mechanism of hydrogenolysis, but it proved difficult to put forward any postulates concerning the character of the intermediate species. The results of a study[69] in which it was shown that the partially selective mechanism can be observed in those cases where the acid centres of the catalyst exhibit an appreciable activity in the hydrogenolysis of cyclopentanes are of interest in this connection. We may note that the interpretation of the results for the hydrogenolysis of alkylcyclopentanes must be treated with caution, since the monofunctional character of the catalysts employed has been no means always reliably demonstrated.

The C_5-Dehydrocyclisation of Alkanes



Data on the hydrogenolysis of alkylcyclopentanes in the presence of platinum catalysts suggested the following mechanism of the C_5-dehydrocyclisation of alkanes[45]:

An analogous mechanism has been proposed previously[70] for the C_5-dehydrocyclisation of alkylbenzenes in the presence of the Pt/Al_2O_3 and Pt/SiO_2 catalysts:

Other views concerning the structure of the transition state in the C_5-dehydrocyclisation of alkanes and the hydrogenolysis of cyclopentanes in the presence of Pt/C have been developed[54,59,71]. The hydrogenolysis of cyclopentane to pentane in the presence of this catalyst is known to proceed without the formation of side products at 200–290 °C. Neither n-pentane[71,72] nor cyclohexane[73] undergoes hydrogenolysis at these temperatures. These facts cannot be interpreted from the standpoint of the strain in the cyclopentane molecule[74] or the differences between the energies of the C–H and C–C bonds in these hydrocarbons[75]; however, they can be rationally accounted for within the framework of this sextet-doublet mechanism of the hydrogenolysis of cyclopentane hydrocarbons in the presence of the Pt/C catalyst, according to which[54,71] the carbon atoms of the five-membered rings are located in the interstices of the platinum (111) lattice on adsorption of the hydrocarbon. The geometrical requirements are such that one of the bonds in the ring is then extended, dissociating in the presence of adsorbed hydrogen. According to Liberman[54], the structure of the transition state can be represented schematically as follows:

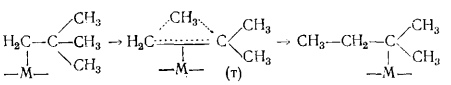
where the large circles represent platinum atoms, the medium circles represent carbon atoms, and the small circles represent hydrogen atoms; the dashed lines denote the van der Waals volumes of the carbon and hydrogen atoms.

In conformity with the principle of microscopic reversibility, the C_5-dehydrocyclisation reaction of alkanes should proceed via the same transition state. According to this mechanism, an increase of the surface concentration of hydrogen should entail a decrease of the probability of the disposition of the substituents in the interstices of the platinum lattice following the adsorption of the cyclopentane hydrocarbon (which facilites the attack by hydrogen on the C–C bond adjoining the substituent), i.e. entails a decrease of the selectivity of the hydrogenolysis[59,76,77]. The increase of the fraction of 1,2-dimethylcyclopentane compared with ethylcyclopentane in the products of the C_5-dehydrocyclisation of n-heptane on passing from a flow to a pulsed system can be explained analogously[78]; here it is suggested that the lowest surface concentration of hydrogen is attained under the conditions of the flow system.

In the presence of rhodium, iridium, and osmium catalysts the hydrogenolysis takes place equally successfully for both cyclopentanes and for cyclohexanes and alkanes, which, together with certain other facts, led Bragin et al.[59] to the conclusion that the reaction proceeds via a doublet mechanism.

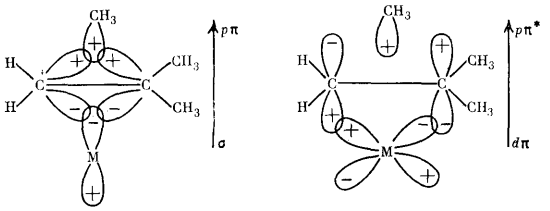
We may note that, although the models of the sextet-doublet and doublet mechanisms differ significantly in detail from the concepts of the selective and non-selective mechanisms of the hydrogenolysis of cyclopentanes, they also have certain features in common. In particular, in the hydrogenolysis via the non-selective mechanism[62] and the sextet-doublet mechanism, it is assumed that the ring of the molecule is arranged parallel to the surface of the metal. On the other hand, the question of the nature of the adsorption of the reacting molecule remains open within the framework of the sextet-doublet mechanism[54,71], although the authors have in fact indicated the possibility of physical adsorption.

Among other Group VIII metals, palladium[79,80], iridium[81,82], rhodium[83,84] and its alloys[85,86] exhibit a catalytic activity in the C_5-dehydrocyclisation of alkanes and their isomerisation via the C_5-ring mechanism.



The characteristics and mechanisms of the isomerisation and cyclisation of aromatic alkyl-substituted hydrocarbons in the presence of platinum catalysts have been described in detail in recently published reviews[8,87].

III. THE MECHANISMS OF THE ISOMERISATION AND C_5-DEHYDROCYCLISATION REACTIONS OF ALKANES AND THE HYDROGENOLYSIS OF CYCLOPENTANES



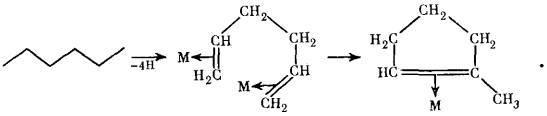
One of the fruitful methods for the investigation of reaction mechanisms involves the study of the reactions of model hydrocarbons (the term "model hydrocarbons" is treated here in a broad sense). With their aid, the investigator can make a choice between several alternative reaction mechanisms or can estimate the contributions of different mechanisms to the overall process. Hydrocarbons with a characteristic feature in the structure of the carbon skeleton, for example, the position of the substituents and the presence of a quaternary carbon atom or an isotope label, can be used as models. In most cases the difficulty of the synthesis of such hydrocarbons is compensated by the ease of the interpretation of the experimental data and the possibility of observing detailed features in the course of the reactions.

Thus the application of neopentane as a model hydrocarbon made it possible to introduce the concept of 1,3-diadsorption in isomerisation via the bond shift mechanism (the Anderson mechanism). Rooney and co-workers[88-90] demonstrated the ease of isomerisation on platinum (at 160–300 °C) and palladium (at 200–300 °C) of a series of polycyclic hydrocarbons for which the formation of 1,3-diadsorbed intermediate species is impossible or difficult. For example, the adsorption of the adamantane dimer during isomerisation then proceeds with elimination of only one hydrogen atom. This is also indicated by data for the D_2 exchange with this hydrocarbon.

In order to account for the characteristics of the isomerisation of polycyclic hydrocarbons, the following mechanism (henceforth referred to as the Rooney mechanism), considered for simplicity in relation to neopentane, has been suggested[90,91]:

In the transition state (T), the occupied $p\pi$ orbital of the hydrocarbon species overlaps with the σ orbital of the metal. Simultaneously the $d\pi$ orbital of the metal overlaps with the unoccupied antibonding $p\pi$ orbital of the hydrocarbon fragment:

The electron-deficient character of the $p\pi$ orbital explains some similarity of this mechanism with the carbonium ion mechanism of isomerisation. The character of the bonding in the transition state (T) resembles that in metal–olefin complexes. In conformity with this finding, platinum, which forms stronger metal–olefin bonds, is a better catalyst of isomerisation via the bond shift mechanism than palladium. Similarly, the greater selectivity of the (111) face of platinum compared with the other faces in isomerisation[53] cannot be explained by the more effective adsorption of the hydrocarbon on this face; the true explanation is that the (111) face has no affinity for the formation of a strong bond between the hydrocarbon and the surface, which is necessary for hydrogenolysis[6]. We may note that the transition state (T) cannot be common to the isomerisation and hydrogenolysis reactions of alkanes[91], in contrast to the Anderson mechanism according to which identical intermediate species are formed in these two reactions. We may draw attention to the similarity of the Rooney mechanism to the mechanism of the dehydroisomerisation of alkylcyclopentanes on platinum discussed above [see mechanism (1)].

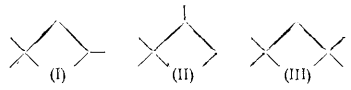


The isomerisation of neopentane on a platinum film in the presence of D_2 involves the formation of an appreciable amount of monodeuterated isopentane[92], which confirms, according to the authors, the formation of intermediate adsorbed alkyl species in the isomerisation reaction.

It was stated earlier that intermediate species of the type

may play an important role in the C_5-dehydrocyclisation and skeletal isomerisation of alkanes. This possibility is also confirmed by the results of the study of the C_5-dehydrocyclisation from the standpoint of the characteristics of electrocyclic reactions[93].

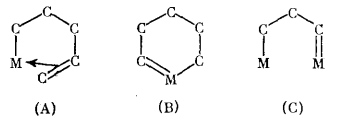
Comparative study of the reactions of a series of hexenes, hexadienes, hexa-1,3,5-triene, and n-hexane in a stream of hydrogen and helium on the Pt/Al_2O_3 catalyst[26] and in a mixture of these gases (20% H_2) on platinum black[24] showed that the yields of five-membered cyclic hydrocarbons are a maximum in the case of the initial hexa-1,5-diene. The amount of methylcyclopent-1-ene formed under these conditions increases with decrease of the dehydrogenating activity of the catalyst. The following cyclisation mechanism has been proposed on the basis of the facts presented above[94]:



However, one should bear in mind that, together with processes involving the formation of a five-membered ring, other reactions proceed vigorously: skeletal isomerisation, double bond shift, aromatisation, dehydrogenation processes, and hydrocracking. Thus small changes in the yields of five-membered carbocyclic products may be associated, depending on the nature of the initial hydrocarbon, with a change in the contribution of different reactions to the overall process, particularly when the closure of the five-membered ring is the rate-limiting stage.

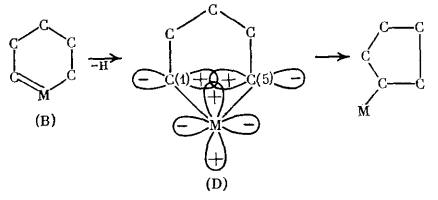
In order to investigate the role of olefins in the C_5-dehydrocyclisation reactions of alkanes, experiments were performed in which the alkane, alkene, and then again the alkane were passed over the Pt/C catalyst[27,95]. In the absence of a stream of H_2, different effects of the replacement of the initial hydrocarbon on the C_5- and C_6-dehydrocyclisations were demonstrated: in the latter case the introduction of an olefin into the reaction zone instead of the alkane increased the yield of the aromatic hydrocarbon, while the yield of alkylcyclopentanes fell. These facts indicate definite differences between C_5- and C_6-dehydrocyclisations; under the conditions investigated, the former proceeds in the presence of the Pt/C catalyst mainly via the direct pathway, bypassing the olefin-formation stage.

Under more severe conditions and in the presence of bifunctional catalysts[26,96-98], the reaction can also proceed differently, for example via two independent pathways: via the intermediate formation of olefins and via the direct closure of the five-membered ring. Quantitative data for these two pathways have been obtained by the kinetic isotope method[97,99];

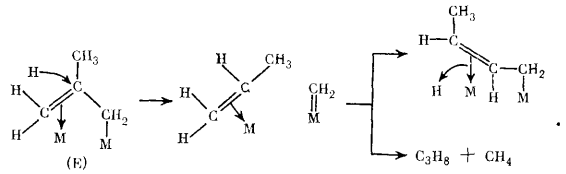


it was observed that the relative contributions of the two pathways vary with the experimental temperature and the nature of the catalyst. It is noteworthy that the rigorous application of the kinetic isotope method to the determination of the intermediates in the reaction is possible only in the presence of the adsorption–desorption equilibrium between the surface species and the corresponding compounds in the gas phase; however, this is not always achieved[25].

Another approach to the study of the possibility of the intermediate formation of π-adsorbed α-olefins in the C_5-DHC of alkanes has been used[100]: the reactions of 2,2,4-tri-methylpentane (I), 2,2,3-trimethylpentanes (II), and 2,2,4,4-tetramethylpentanes (III) on platinum and palladium films were investigated:

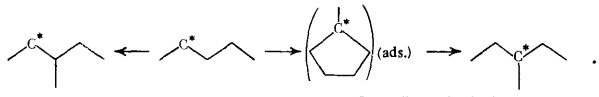


On platinum, the C_5-dehydrocyclisation of these hydrocarbons is the main process, the ratios of the rates of cyclisation of compounds (I), (II), and (III), being 1.2:1.2:1.0. In the presence of palladium, compound (II) cyclises at a rate higher by an order of magnitude than compound (I) and higher by two orders of magnitude than compound (III), the C_5-dehydrocyclisation of these hydrocarbons not being the main process. In an earlier study[111] similar results were obtained in the presence of the 20% Pt/C catalyst: under the same conditions, the yields of the cyclic products were 14% from compound (I) and 21% from compound (III). However, no conclusions about the reaction mechanism were reached[101].



The results of Muller and Gault[100] suggested that the cyclisation on platinum takes place via the intermediate formation of the species (B) but not (A), while on palladium the species (A) cyclise:

Cyclisation via the (B) stage can proceed as a result of simple *cis*-ligand inclusion; this results in the formation of adsorbed cyclopentane. An alternative pathway (possibly more favourable) involves the formation of the (D) state in which the 2*p* orbitals of the C(1) and C(5) atoms and the *d* orbital of the metal atom form an occupied bonding molecular orbital, two unoccupied non-bonding orbitals, and an antibonding orbital:



This mechanism of cyclisation on platinum [via the formation of the (B) or (D) state] is analogous to the mechanism of the skeletal isomerisation via bond shift with the intermediate formation of (C). Intermediates of type (C) do not account for the characteristics of the isomerisation on palladium. In the latter case the following mechanism of isomerisation and hydrogenolysis with participation of adsorbed hydrogen has been suggested[100]:

The necessity for the formation of an intermediate of type (E) explains the difficulty of isomerisation on palladium with participation of a quaternary atom. Thus the expansion of the ring of 1,1,3-trimethylcyclopentane on palladium proceeds via a tertiary carbon atom, while on platinum the expansion involves a quaternary carbon atom[13]. Neopentane readily isomerises on platinum, while on palladium the reaction does not occur under the usual conditions[47].

The use of mass spectrometry to determine the position of ^{13}C in labelled hydrocarbons[15] made it possible to use the latter to investigate the mechanisms of catalytic reactions. Thus in the case of the ^{13}C-labelled 2-methylpentane it is possible to distinguish the bond shift and C_5-cyclic isomerisation mechanisms:

The reactions of isomeric hexanes labelled with ^{13}C have been studied in the presence of the 0.2% Pt/Al_2O_3 [102] and 10% Pt/Al_2O_3 [103] catalysts and also on a platinum film [104] in a stream of hydrogen. The distribution of the label in the products shows that the isomerisation in the presence of the Pt/Al_2O_3 catalyst containing 0.2% Pt proceeds mainly via the C_5-cyclic mechanism; in the presence of Pt/Al_2O_3 with a 10% content of platinum and on a platinum film, the bond shift mechanism makes a significant contribution to the isomerisation process. It was found that in the adsorbed phase several consecutive rearrangements can occur in the molecule, their number being greater in the presence of the 10% Pt/Al_2O_3 catalyst and a platinum film than in the presence of the 0.2% Pt/Al_2O_3 catalyst. Not only the content (and the degree of dispersion) of the platinum in the catalyst, but apparently also the partial pressure of hydrogen influence the number of rearrangements in the adsorbed phase under these conditions, but the authors did not investigate the influence of this factor. Unfortunately, no data are quoted[102,103] concerning the hydrogen/hydrocarbon ratio; the conclusion that the ratio was small in the above studies[103,104] can be reached only on the basis of later investigations, for example, that of Garin and Gault[105].

The examples examined above demonstrate the great effectiveness of the study of the reactions of model hydrocarbons whose geometry permits a choice between the possible reaction mechanisms. However, the extension of certain conclusions to a wider range of starting materials always requires some caution, because one cannot rule out the possibility that the molecular geometry (for example, stereochemical limitations) actually prevents the occurrence of the reaction via an alternative pathway. When geometrical limitations are removed, such a pathway may become entirely possible. The application of labelled compounds, which permit the determination of the relative contributions of different reaction pathways without influencing the course of the reaction, is promising from this standpoint. In a number of instances the study of the position of the ^{13}C label in the reaction product makes it possible to determine the rate-limiting stage of the reaction.

IV. THE INFLUENCE OF HYDROGEN ON THE DEHYDROCYCLISATION AND ISOMERISATION REACTIONS OF ALKANES. KINETIC STUDIES

The role of hydrogen in the hydrogenolysis of alkylcyclopentanes and the dehydrocyclisation and skeletal isomerisation of alkanes was elucidated both in independent studies and within the framework of kinetic investigations. Whereas hydrogen is a direct participant in the first of the above reactions, in C_5-dehydrocyclisation and skeletal isomerisation it is involved as an astoichiometric component[106]. The study of the role of hydrogen in these reactions made it possible to discover certain additional details of their mechanisms.

A characteristic feature of the influence of hydrogen on the catalytic reactions of hydrocarbons in the presence of platinum catalysts is the presence of a maximum on the plot of the reaction rate (the yield of reaction products) against the partial pressure of hydrogen when p_{H_2} is varied within fairly broad limits. Such relations have been observed for the dehydrocyclisation and skeletal isomerisation of C_6-hydrocarbons on platinum black[107-112], in the presence of the Pt/C catalyst[113] and bifunctional Pt/Al_2O_3 and $Pt-Re/Al_2O_3-F$ catalysts[114] for the dehydroisomerisation of methylcyclopentane[41], the skeletal isomerisation of n-heptane[115] and certain C_4-C_6 alkanes[116-118], and for the dehydrocyclisation of n-heptane[119] in the presence of bifunctional platinum/alumina catalysts.

The position of the maximum depends in the general case on the experimental conditions: on the catalysts employed, on the type of reaction considered, on the structure of the initial hydrocarbon, on the experimental temperature, etc. As an example, we shall consider the results of our investigations[113,114,120] in which the influence of the concentration of hydrogen on the C_5-DHC and the skeletal isomerisation of alkanes and alkenes was studied on deposited platinum catalysts of different types—platinised charcoal and bifunctional platinum/alumina and platinum–rhenium/alumina catalysts. The positions of the maximum are different on plots of the yield of C_5-DHC products and the products of the skeletal isomerisation of alkanes against the partial pressure of hydrogen. In the case of C_5-DHC the coordinates of the maximum depend little on the reaction temperature and the structure of the initial alkane. The optimum H_2 concentration for the skeletal isomerisation of alkanes depends on their structure: for a more branched hydrocarbon, the maximum lies at higher H_2 concentrations. A decrease of temperature shifts the position of the maximum towards lower H_2 concentrations, which indicates the important role of the surface hydrogen in the skeletal isomerisation reaction (the concentration of such hydrogen increases with decrease of temperature). We may note the similarity of the relations obtained in the reactions of 3-methylpentane and 3-methylpent-2-ene in the presence of the Pt/C catalyst. This shows that the formation of methylcyclopentane from an alkane and alkene in the presence of H_2 apparently proceeds via similar intermediate stages.

We may note that the five-membered carbocyclic products derived from both alkanes and olefins and dienes are formed only in the presence of hydrogen[94,107,108]. In the presence of platinum black the skeletal isomerisation of alkanes in H_2 proceeds via both the C_5-cyclic mechanism and the bond shift mechanism. In the absence of hydrogen the isomerisation can take place only via the bond shift mechanism[109]; the C_6-DHC reaction of n-hexane on platinum black[107] and in the presence of the Pt/Al_2O_3 catalyst[79] takes place at an appreciable rate also in a stream of helium, in contrast to C_5-DHC. However, it has been stated[119] that under reforming conditions the rate of aromatisation of n-heptane on the Pt/Al_2O_3 catalyst is virtually zero in the absence of hydrogen.

Comparative study of the influence of the partial pressure of hydrogen on the C_5-cyclisation and skeletal isomerisation of 3-methylpentane and 3-methylpentenes on platinum black enabled Paal et al.[121] to postulate the operation of two different mechanisms of the formation of the C_5 ring. According to the authors[121], at a low hydrogen concentration the cyclisation proceeds via the intermediate formation of highly dehydrogenated species (for example, of the alkenyl type). At higher pressures, the cyclisation takes place via a "two-centre" mechanism involving the intermediate formation of semihydrogenated products, which are apparently "weakly" adsorbed on platinum centres, while the new C–C bond is formed as a result of the interaction of the terminal atoms of the carbon chain with other platinum centres. The operation of the "two-centre" mechanism of the C_5-dehydrocyclisation may be indicated by the following facts: the similarity of the nature of the reaction of 3-methylpentane and 3-methylpentenes under these conditions (there are no differences between the reactivities of *cis*- and *trans*-3-methylpent-2-enes), the proportionality of the rate of cyclisation and the hydrogenating activity of the catalyst[121], and data for the deactivation of platinum black under the influence of the hydrocarbon[122].

An attempt has been made[111] to describe the kinetics of the isomerisation of 3-methylpentane on platinum black in a static system. The kinetic equation obtained for the "two-centre" mechanism of isomerisation describes satisfactorily the character of the influence of hydrogen on the rate of reaction in qualitative terms, but the authors[111] did not provide a complete multistage scheme for the reaction and did not carry out a mathematical treatment of the experimental results.

The data examined show that hydrogen exerts a promoting or inhibiting influence on the reactions of hydrocarbons depending on the experimental conditions and the catalyst. This is associated with various functions performed by hydrogen on the surfaces of metallic catalysts. We may note the most important of these, which are discussed in the communications quoted above.

Vigorous dehydrogenation processes, leading to the formation of strongly adsorbed hydrocarbon fragments on the surface, take place at low H_2 pressures in the presence of platinum catalysts. By suppressing the above process, hydrogen increases the working area of the catalyst, which accelerates the reactions. On the other hand, hydrogen promotes the desorption displacement of the products of the reactions of hydrocarbons.

At fairly high partial pressures of hydrogen, the chemisorption of the hydrocarbon is suppressed as a consequence of the competitive character of the adsorption of hydrogen and the hydrocarbon. Hydrogen also prevents the dissociation of the initial hydrocarbon on the surface, which inhibits the reactions. Overall, when p_{H_2} is varied widely, the causes considered here lead to the appearance of maxima on the curve relating the yields of the reaction products to p_{H_2}.

One cannot rule out the possibility that, for different degrees of coverage of the catalyst surface with hydrogen, the rate-limiting state and the reaction mechanism can be different. Thus, according to our data[113], the skeletal isomerisation in the presence of the Pt/C catalyst proceeds via the C_5-cyclic mechanism over the entire range of hydrogen concentrations investigated. In the presence of bifunctional catalysts[114], the relative contributions of different mechanisms depend on the partial pressure of hydrogen and the acidity of the catalyst. At high partial pressures of

hydrogen the C_5-cyclic mechanism of isomerisation predominates and at comparatively low partial pressures another pathway, apparently involving the acid centres of the catalyst, makes a significant contribution.

The possibility of the involvement of hydrogen as an astoichiometric component in the reactions of hydrocarbons is of fundamental importance. Its role may not reduce solely to influencing the adsorption-desorption stages. It has been suggested[96,98] that hydrogen not only promotes the removal of the strongly adsorbed carbon-containing species but is also directly involved in the C_5-dehydrocyclisation reaction of alkanes itself. In our studies these views were further developed[113,114,120,123].

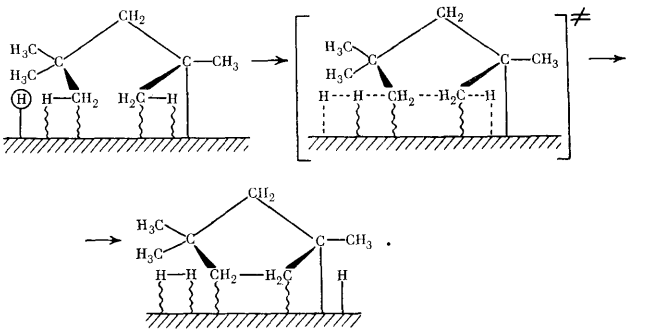
New data concerning the role of hydrogen in the C_5-DHC reaction of alkanes in the presence of the Pt/C catalyst have been obtained[120,123] in a study of the kinetics of the C_5-DHC of iso-octane. It was shown that, in the range of partial pressures of the reactants investigated, the C_5-DHC reaction is accelerated by hydrogen and inhibited by 1,1,3-trimethylcyclopentane. We put forward the following kinetic equation:

$$r = (kp_A - k'p_Bp_H)\Big/\left[\frac{p_A}{p_H^{0.5}} + A_1\frac{p_B}{p_H^{0.5}} + A_2p_H^{0.5} + A_3p_A\left(\frac{A_4}{p_H}\right)^{0.5(n+1)}\right],$$

where r is the rate of reaction, p_A, p_B, and p_H are the current partial pressures of iso-octane, 1,1,3-trimethylcyclopentane, and hydrogen respectively, and k, k', A_1, A_2, A_3, and n are constants whose physical significance is discussed by Krasavin et al.[123] Analysis of this equation using the numerical values of the constants indicated by Krasavin et al.[123] makes it possible to predict the appearance of a maximum on the curve relating the reaction rate to the partial pressure of hydrogen when p_{H_2} is varied widely. The position of the maximum depends on the stability of the surface carbon-containing compounds: with its increase, the maximum shifts towards higher values of p_{H_2}.

An important factor, observed by the present authors[120], is the occurrence of a kinetic isotope effect in the C_5-DHC reaction of iso-octane in the presence of a Pt/C catalyst when hydrogen is replaced by deuterium. The kinetic isotope effect $r_H/r_D = 2$ indicates the involvement of hydrogen in the slow stages of the C_5-DHC reaction. Under the same conditions, the rate of exchange of deuterium for hydrogen in iso-octane greatly exceeded the rate of the C_5-DHC reaction. This shows that the adsorption stage must apparently be regarded as rapid. The set of data obtained enabled us to describe the C_5-DHC reaction in terms of the following multistage scheme[123]:

(1) $H_2 + 2Z \rightarrow 2HZ$,



(2) $C_8H_{18} + HZ \rightarrow C_8H_{17}Z + HZ \rightarrow C_8H_{17}Z + H_2$,

(3) $C_8H_{17}Z + nHZ \rightarrow C_8H_{17-n}Z + nH_2 + nZ$,

(4) $C_8H_{17}Z + HZ \rightarrow$ (cyclo-C_8H_{15})$Z + HZ + H_2$,

(5) (cyclo-C_8H_{15})$Z + H_2 \rightarrow$ cyclo-$C_8H_{16} + HZ$.

Here Z denotes a site on the surface of platinum. Dissociative adsorption of the initial hydrocarbon when the latter interacts with surface hydrogen with simultaneous evolution of molecular hydrogen is postulated in stage (2). The $C_8H_{17}Z$ fragment formed can undergo further dissociation (stage 3). This pathway apparently does not lead to the formation of the C_5-DHC products under the conditions investigated, but stage (3) explains the multiple exchange of deuterium for hydrogen in the higher alkanes and certain characteristic features of the behaviour of the Pt/C catalyst at $p_{H_2} < 0.4$ atm. Stage (4) describes the cyclisation of the $C_8H_{17}Z$ fragment. The formation of the C_5 ring on the surface can be represented as follows:

Here the continuous lines denote the chemisorption linkages with the surface, the wavy lines indicate the topography of the disposition of the atoms at the surface, and the dashed lines represent the redistribution of bonds in the associative transition state.

Thus the hydrogen chemisorbed on the catalyst reacts with the $C_8H_{17}Z$ surface fragment to form a transition state in which the loosening of the H–C bond is accompanied by the simultaneous formation of a C–C bond in the hydrocarbon under the influence of the activated hydrogen species (the latter is enclosed in a circle). The surface cyclic compound formed reacts with molecular hydrogen in stage (5) of the mechanism under consideration to form the final reaction product and adsorbed hydrogen. According to the views developed here, adsorption and cyclisation takes place at different fairly close centres on the catalyst surface.

In the experimental temperature range (280–325 °C) stage (1) is rapid. Stages (2) and (3) can also be regarded as rapid, since the rate of isotope exchange between deuterium and the hydrocarbon is much higher than the rate of the C_5-DHC reaction. Stage (5) should likewise be regarded as rapid, since otherwise it would be impossible to explain the observed inhibition of the reaction by its product. It remains to assume that the slow stage in the above mechanism is stage (4), which agrees with the acceleration of the reaction when the hydrogen concentration is increased and with the presence of the kinetic isotope effect on replacement of H_2 by D_2.

Thus the results of the study of the influence of hydrogen on the C_5-DHC reaction of alkanes can be interpreted on the basis of the multistage scheme considered and the equation presented above. Other possible C_5-DHC mechanisms proposed in the literature are in poorer agreement with experimental data. However, we may note that, when the C_5-DHC reaction is carried out under other conditions (for example, in the presence of highly dispersed catalysts at higher temperatures or in the presence of a deficiency of hydrogen), the mechanism as a whole can change. On the basis of the above scheme, it is easy to set up a multistage scheme for the skeletal isomerisation of alkanes via the C_5-cyclic mechanism and to derive a kinetic equation which, as for the C_5-DHC reaction of alkanes, makes it possible to interpret the appearance of maxima on the curves relating the yields of skeletal isomers to the partial pressure of hydrogen.

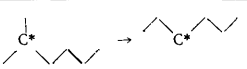
It was shown previously[124,125] that the activation energy for the C_5-DHC of alkanes on platinised charcoal is almost independent of the structure of the hydrocarbon and amounts to 83.7 kJ mol^{-1} (the data were obtained under the conditions

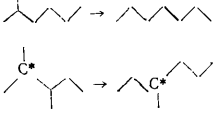
of a zero-order reaction). For alkylbenzenes, this quantity increases by 31.4 kJ mol^{-1}.

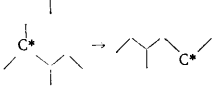
Negative formal reaction orders with respect to hydrogen as well as apparent activation energies have been found for the isomerisation of n-butane and isobutane on platinum black[126] (the activation energies are respectively 100 and 121 kJ mol^{-1}).

Few kinetic studies have been made on the isomerisation of alkanes; most of them[116–118,127–131] were carried out in the presence of industrial platinum/alumina bifunctional reforming catalysts. In the analysis of the kinetics, the slow stage is usually assumed to be that involving the isomerisation on the acid centres of the catalyst; the kinetic equations are characterised by negative or zero reaction orders with respect to hydrogen. Account has also been taken[128] of the influence of the poisoning of the catalyst by coke on the rate of isomerisation.

In a study of the isomerisation of pentane in the presence of a platinum/alumina catalyst by the flow-circulation method, the reverse kinetic isotope effect was observed[130,131] on replacement of hydrogen by deuterium. The rate of reaction was characterised by a positive order with respect to hydrogen, equal to 0.5, and the rate of exchange of deuterium in pentane under these conditions was higher than the rate of isomerisation. The above facts suggested that hydrogen is involved in the slow stage of the reaction—the isomerisation of the adsorbed fragment on the acid centres of the catalyst.





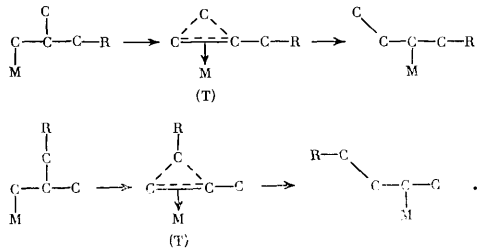


Interesting studies on the isomerisation reaction, particularly the C_5-DHC of alkanes in the presence of platinum/alumina catalysts under the conditions of monofunctional catalysis, have been carried out in recent years by Gault and co-workers[132]. We may note the fruitfulness of the approach by the authors, which combines kinetic studies with the employment of the method of labelled (^{13}C) molecules for reactions of the groups of C_5–C_7 alkanes in the presence of platinum catalysts with different degrees of dispersion. Since the change in the position of the ^{13}C label in the isomerisation products could always be predicted as a result of only one rearrangement (via the C_5-cyclic mechanism or the bond shift mechanism) of the adsorbed fragment on the surface, it was suggested that the rate-limiting stage is skeletal rearrangement on the catalyst surface, while the adsorption–desorption stages are fast. The Table presents the apparent activation energies and the formal reaction orders with respect to hydrogen according to the results of Garin and Gault[105]. For C_6 alkanes, it has only been stated that the orders of the isomerisation reaction with respect to hydrogen are negative[132].

According to the analysis by Sinfelt[133], a negative reaction order *b* with respect to hydrogen implies that the initial hydrocarbon is adsorbed dissociatively with abstraction of at least 2*b* hydrogen atoms. In order to account for the high negative orders of the pentane isomerisation reaction with respect to hydrogen (see Table), it is necessary to postulate extensive dehydrogenation of the initial hydrocarbon molecule, which appears unlikely under the conditions of an excess of hydrogen. On this basis, preference was given[105,134] to the so-called reaction mechanism in which the Frennet adsorption model[135,136] is used. The competative adsorption of hydrogen and the alkane on the same active centres of the catalyst is considered within the framework of this model, hydrogen occupying one such surface centre and the hydrocarbon a group (ensemble) of several centres.

It has been shown[105] that, in the dissociation of an alkane via the "bimolecular reaction" mechanism, the order of the reaction *b* with respect to hydrogen corresponds to the abstraction of only *b* hydrogen atoms; in addition, comparatively simple explanations have been found for the positive reaction order with respect to hydrogen in the isomerisation of C_7 alkanes and also for the characteristic features of the variation of the selectivity of the isomerisation reaction with the H_2 concentration in the system. Overall, the employment of the Frennet model for the interpretation of kinetic data appears to us extremely fruitful, but a quantitative test of the kinetic equations obtained on the basis of the "bimolecular reaction" is difficult because it requires the knowledge of the alkane adsorption isotherm in the presence of hydrogen, which is itself a fairly difficult experimental problem.

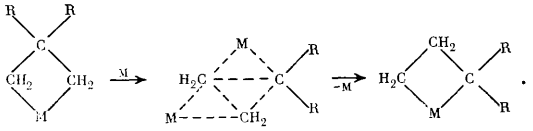
The activation energies (kJ mol^{-1}) and the kinetic orders with respect to hydrogen (*b*) of the isomerisation reactions of various C_5 and C_7 alkanes in the presence of a platinum/alumina catalyst (according to the data of Garin and Gault[105]).



No.	Reaction	E_a	*b*
1		297.3±6.3	−3.4
2		231.5±6.3	−1.8
3		244.3±6.3	−2.3
4		189.7	−1.9
5		188.4	−1.65

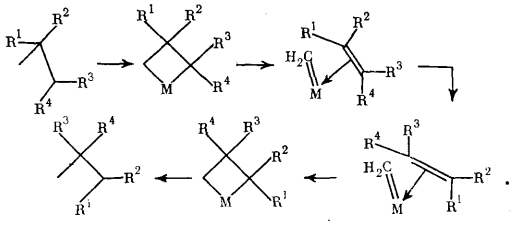
No.	Reaction	*b*
6		0.9±0.2
7		1.8±0.2
8		0.2±0.2
9		0.8±0.1
10		1.4±0.1
11		0.7±0.1

Note. The molecular skeleton and the position of the ^{13}C label are indicated. Reactions (1), (6), (9) and (10) have the C_5-cyclic mechanism, while others proceed via the bond shift mechanism.

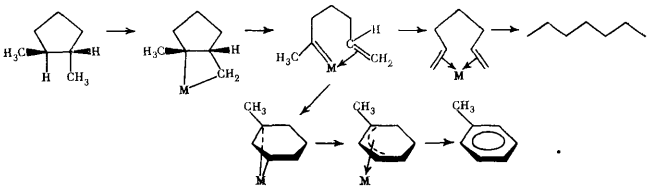


On the basis of kinetic data (see Table), it has been suggested[132] that isomerisation reactions involving the bond shift mechanism be divided into two groups: the "chain elongation" reaction (for example, the isomerisation of isopentane to pentane and conversely) and the "methyl shift" reaction. They have different activation energies and formal orders with respect to hydrogen and also exhibit variations,

characteristic of each group, of the relative rates of isomerisation via different pathways with the structure of the initial hydrocarbon for reactions of the homologues of C_5–C_7 alkanes (the so-called structural effect).[134,137,138]. It has been suggested that the mechanisms of these two isomerisation reactions are different. The characteristic features of the "chain elongation" reaction are best described by the Rooney mechanism:

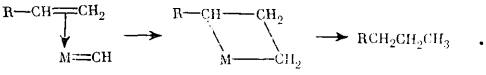


Thus, from an analysis of the stabilisation of the transition state (T), it proved possible[137] to explain the character of the variation of the relative contributions of the above reaction pathways in the isomerisation of alkanes with different alkyl substituents.



In order to account for the characteristic features of the "methyl (alkyl) shift" reaction, two new mechanisms were proposed, since the bond shift isomerisation mechanisms considered previously did not explain the entre set of data obtained[138,139]. In an earlier study[105] it was postulated that the isomerisation proceeds via the formation of intermediate methylcyclobutane species and a quasicyclopropane intermediate, arranged in a virtually flat position on the catalyst surface:

An alternative concept is in better agreement with the chemistry of coordination compounds and consists in the reversible dismutation of methylcyclobutane to a metallocarbene and a π-adsorbed olefin[138,139]:



A characteristic feature of this mechanism is that its occurrence requires the free rotation of the olefin about the bond with the metal. The introduction of bulky alkyl substituents hinders the rotation; this made it possible to explain the differences between the rates of isomerisation of different labelled [^{13}C] heptanes. It has been suggested that the cyclopentane ring can also undergo hydrogenolysis via an analogous mechanism[139]—one of the variants of the partly selective mechanism of hydrogenolysis:

This mechanism explained certain features of the hydrogenolysis of 1,2-dimethylcyclopentane and also the C_5- and C_6-DHC of labelled [^{13}C] heptanes[138,139].

Although the methylcyclobutane mechanism provides a satisfactory explanation of the fundamental features of the hydrogenolysis of alkanes, it was recently criticised from an unexpected direction. Clarke, Rooney, and co-workers[86,140] observed the conversion of alkanes into higher homologues on films of different metals (W, Pd, Pt, Rh, Ru, Nb, Mo) and obtained evidence for the following mechanism:

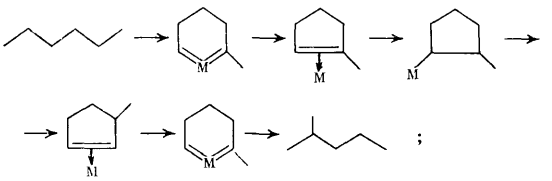
(it is the reverse of the mechanism of the hydrogenolysis of alkanes examined above). It was found that platinum is relatively inactive in the homologue generating reaction although it is one of the active metals in the isomerisation of hydrocarbons via the bond shift mechanism. On the other hand, tungsten is relatively inactive in isomerisation and is the most active among the metals investigated in the formation of higher homologues of alkanes. This shows that the mechanism of isomerisation via the reversible dismutation of a metallocarbene and an olefin is not important in the presence of platinum catalysts. It is believed[86,140] that the principal mechanism of the bond shift isomerisation in the presence of platinum is that of Rooney, i.e. the reaction proceeds via the formation of adsorbed species analogous to non-classical carbonium ions. A mechanism involving α,ε-diadsorbed species has also been proposed for C_5-DHC.

The mechanisms of the isomerisation of alkanes in the presence of other Group VIII metals have been investigated significantly less thoroughly than the mechanisms of reactions in the presence of platinum catalysts. In many instances the study of the characteristic features of the isomerisation suggested new isomerisation mechanisms. Thus a concerted mechanism via the formation of a quasi-cyclobutane intermediate (the 1–3-ethyl shift mechanism) has been postulated for the isomerisation of methylpentanes in the presence of the Ir/Al_2O_3 catalyst[141].

V. THE INFLUENCE OF THE STRUCTURE OF METALLIC CATALYSTS ON THE MECHANISMS OF THE DEHYDROCYCLISATION AND SKELETAL ISOMERISATION REACTIONS OF ALKANES

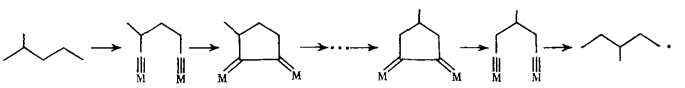
The structure of metallic catalysts (the concentration and degree of dispersion of the metal, the orientation of the crystal faces, and the nature of the carrier) influence significantly the character of the processes occurring. Thus in a series of studies[142–146] of the kinetics of various reactions in the presence of metal single crystals with simultaneous determination of the structure and composition of the surface by low energy electron diffraction and Auger spectroscopy, it was shown that the rates and selectivities of many reactions depend on the structure of the platinum single crystal face. For example, the stepped faces are the most active in the dehydrocyclisation of n-heptane to toluene. The important

role of the formation of a new phase (a carbon-containing layer) on the catalyst surface in the reaction was noted. The ordered carbon-containing layer formed on the stepped faces has little influence on the dehydrocyclisation of n-heptane. On smooth faces a disordered layer is formed, which is one of the causes of the rapid loss of activity by the catalyst[146].



The question of the dependence of the selectivity of the hydrogenolysis of methylcyclopentane and the isomerisation of hexanes on the degree of dispersion of the catalyst was discussed vigorously in earlier studies. Whereas the influence of the degree of dispersion of the deposited metal on the selectivity of these reactions has been demonstrated in a number of studies[45,62,147,148], the data of Dautzenberg and Platteeuw[14,149] indicate the independence of the selectivity of the reactions on the size of the platinum crystals (when the latter is varied in the range 15–80 Å). Without dwelling in detail on this controversy, we should like to draw attention to the conclusion[150] that the ratios of the numbers of different centres are determined by the size of the crystallites in the early stages of the reduction of the catalyst. This conclusion is confirmed by the fact that sintering of identically reduced catalysts does not alter the selectivity of the hydrogenolysis of methylcyclopentane with increase in the size of the platinum crystallites[103]. From this conclusion, certain differences between the results obtained by the two groups of investigators mentioned above can be explained by the significant difference between the reduction temperatures of the catalysts which they employed. On the whole, one may regard it as established that the non-selective C_5-cyclic mechanism of isomerisation and hydrogenolysis predominates in the presence of highly-dispersed platinum catalysts reduced under mild conditions. In the presence of a catalyst with a low degree of dispersion, the hydrogenolysis of the C_5 ring becomes selective and the isomerisation of alkanes takes place to a significant extent via the bond shift mechanism[102,103,151,152].

More detailed studies in the presence of a series of platinum/alumina catalysts with different degrees of dispersion showed[153–155] that the overall rates of isomerisation of hexanes and of the hydrogenolysis of methylcyclopentane are independent of the degree of dispersion, i.e. these reactions are structure-insensitive as regards rate, but are structure-sensitive as regards selectivity. The following features were discovered. In the reaction 2-methylpentane → 3-methylpentane the relative contributions of the C_5-cyclic and bond shift mechanisms remain constant over a fairly wide range of crystallite dimensions. However, the character of the hydrogenolysis of the C_5 ring varies continuously from selective to non-selective with decrease in the size of the crystallites.



As the size of the crystallites falls below 20 Å, sharp changes take place in the character of the reaction. In the presence of such catalysts, the selectivity of the isomerisation of neopentane with respect to its hydrogenolysis diminishes significantly[156]. The mechanism of the hydrogenolysis of the five-membered ring becomes fully non-selective[153–155]. On very small particles (less than 10 Å), the isomerisation of hexanes via the bond shift mechanism hardly occurs. Somewhat different data were obtained in a study[157] where the sensitivity of the isomerisation reaction of n-hexane to structure is attributed solely to particles with dimensions less than 20 Å, while on larger platinum crystallites the reaction is structure-insensitive.

The characteristic features of the influence of the size of crystallites on the mechanism of the hydrogenolysis of alkylcyclopentanes justified the following schemes for isomerisation via the C_5-cyclic mechanism with participation on metallocarbenes and metallodicarbynes as intermediates[132,155]:

(1) the non-selective mechanism

(2) the selective mechanism

The additional hypothesis that both mechanisms involve a common intermediate, namely an α-adsorbed olefin which is then converted into a metallocarbene or a metallodicarbyne, has been put forward[138]. Although this hypothesis explained the proportions of the products of the C_5-DHC of 3-methylhexane, it made it difficult to interpret data[100] showing the equality of the rates of cyclisation of 2,2,4-tri-, 2,2,2-tri-, and 2,2,4,4-tetra-methylpentanes in the presence of platinum.

We may note that neither the metallocarbene nor the metallodicarbyne mechanism of the hydrogenolysis of alkylcyclopentanes explains the hydrogenolysis of the quaternary-secondary C–C bonds in the cyclopentane ring. However, it has been shown recently[158] that the quaternary-secondary C–C bond in *gem*-dimethylcyclopentane can be cleaved in the presence of the Pt/C catalyst.

The operation of the selective mechanism of the hydrogenolysis of cyclopentanes (and hence of the isomerisation of alkanes) in accordance with the schemes examined above, requires a larger ensemble of platinum atoms than for the non-selective mechanism and the relative contributions of these two mechanisms must therefore be influenced by the geometrical factor. If it is supposed that only the edge atoms of the platinum crystallites promote the formation of reactive species, then the critical size of the crystallite required for the transition from one mechanism to another must be approximately 25 Å. This is the minimum dimension for a crystallite which has two neighbouring edge (but not corner) platinum atoms[132].

The decrease of the selectivity of the isomerisation of neopentane in the presence of highly dispersed catalysts is attributed analogously[156] to the transition from the many-centre bond shift mechanism (via the formation of 1,1,3-adsorbed species) to the one-centre isomerisation mechanism (the Rooney mechanism), which, however, is characterised by a lower rate.

It has been suggested that the relative contributions of the C_5-cyclic and bond shift isomerisation mechanisms depend primarily on electronic factors[155], which may be significant for crystallites whose size is less than 10–15 Å[159] (the second critical size of crystallites). Thus the two critical dimensions of crystallites in the reactions involving the isomerisation of alkanes and the hydrogenolysis of cyclopentanes are a consequence of the operation of geometrical and electronic factors[132].

Certain additional evidence for the influence of the electronic and geometrical factors on the isomerisation mechanism can be obtained from a comparison[132] of the catalytic effects of different metals with the same degrees of dispersion (particle size 80 Å). Thus the isomerisation in the presence of the Ir/Al_2O_3 catalyst takes place only via the selective C_5-cyclic mechanism[82], in the presence of the Pd/Al_2O_3 catalyst the reaction involves the non-selective C_5-cyclic mechanism with a small contribution by the bond shift mechanism[160], while in the presence of the Pt/Al_2O_3

catalyst the reaction proceeds mainly via the bond shift mechanism with participation of both C_5-cyclic isomerisation mechanisms. However, one should note that the comparison of the catalytic activities of the above catalysts cannot be regarded as sufficiently rigorous: the published data for the reaction mechanisms refer to different temperatures (the reaction temperature can influence the process selectivity).

Certain features of the structure sensitivity of the alkane isomerisation reaction suggested[154] the possibility of the migration of the reactive adsorbed species from the adsorption–desorption centres to the reaction centres and conversely. Thus the overall isomerisation mechanism includes the stages involving the adsorption of an alkane molecule from the gas phase on a crystal face of platinum with formation of a weakly adsorbed species, surface migration from the adsorption centre to the reaction centre located on the surface of the metallic particle, the formation of highly dehydrogenated species on the reacton centre, their skeletal rearrangement and subsequent rehydrogenation, and surface diffusion and desorption of the reaction products. Analysis of the relative rates of different stages in the above mechanisms as well as the number of active centres led to a classification of the reactions in terms of their structure sensitivity. However, within the framework of the above study[154], one cannot assume that the surface diffusion of carbon-containing species has been proved. On the other hand, in the presence of an excess of hydrogen the formation of highly dehydrogenated species of the type of metallocarbenes and metallodicarbynes appears unlikely. This confirms indirectly the results of a study[140] in which it was shown that platinum is relatively inactive in the formation of carbene species.

One must not fail to mention, at least briefly, yet another promising method for the elucidation of the mechanisms of catalytic reactions in the presence of platinum catalysts—by the study of the reactions of hydrocarbons in the presence of alloys of platinum with Group IB metals, for example, gold or copper (the latter are virtually inactive in the reactions considered). A change in the platinum concentration in the alloy can alter the size of the platinum ensembles and also their electronic properties. It is difficult to separate the geometrical and electronic factors (it is probably actually impossible to do this); however, in many studies only the influence of the geometrical factor has been considered as the alloy composition was varied.

The study of the reactions of hydrocarbons in the presence of deposited Pt–Au and Pt–Cu alloys[161–165] permitted the following conclusions. At a high platinum concentration in the alloy the reactions proceed mainly via many-centre mechanisms: the selective C_5-cyclic mechanism of isomerisation and C_5 ring closure and opening and the bond shift mechanism involving the intermediate formation of, for example, 1,1,3-adsorbed species. A decrease of the concentration of platinum in the alloy suppresses the many-centre isomerisation mechanisms as a consequence of which the reaction proceeds via the non-selective C_5-cyclic mechanism with a small contribution to the isomerisation by the one-centre bond shift mechanism (the Rooney mechanism). The nature of the reactions of hydrocarbons in the presence of alloys with a low platinum content is analogous to the characteristic features of the reactions in the presence of highly dispersed platinum catalysts. On highly dilute alloys (with a platinum concentration of several per cent), the isomerisation of alkanes proceeds only via the one-centre bond shift mechanism. Certain characteristics of the reactions in the presence of platinum alloys have been explained[165] by the influence of the nature of the carrier and heat treatment temperature on the degree of carbidisation of the alloy surface or on the topography of the surface. It has been suggested in all cases that the isomerisation via the many-centre mechanisms is faster than via the one-centre mechanisms.

In many instances there are discrepancies between the experimental data obtained by different groups of investigators[164,165]. The characteristic features of the catalytic activity of alloys probably require further study. The importance of the investigation of reactions on alloys is also confirmed by the fact that the possibility of the C_5-DHC of alkanes in the presence of rhodium catalysts was demonstrated for the first time precisely in the presence of rhodium–copper alloys[56]. A more detailed description of the characteristic features of the reactions in the presence of alloys would be outside the framework of the present review; some additional information can be found in other reviews[166–170].

* * *

Significant progress has been achieved in recent years in the understanding of the mechanisms of catalytic reactions of hydrocarbons on metals. These advances are associated with the application of model compounds in catalysis, in particular those labelled with ^{13}C and ^{14}C, in combination with careful kinetic investigations. An important contribution to the understanding of the mechanisms of the above reactions in the presence of metal-containing catalysts undoubtedly came from a series of studies involving the participation of hydrogen in these reactions (see Section IV). A series of investigations of the influence of the structure of metallic catalysts on the mechanisms of different reactions is of fundamental importance (Section V).

However, in most cases the available information about the transition state in the key stages of the reactions of hydrocarbons is clearly inadequate and the structure of the catalytic centres and the relative positions of the orbitals of the surface metal atoms and the orbitals of the reacting atoms of the adsorbed molecules have not been elucidated. An important problem in the study of mechanism involves the investigation of the effect arising when the surface of the metal is acted upon by the reactants and products of the reaction in the course of its occurrence.

Studies carried out with the aid of a set of new physical methods whereby one can obtain information about the geometry of the adsorbed molecular fragments and the structure of the most active sections of the surface of the metal and the elucidation of the nature of the cluster and ligand effects in monometallic and polymetallic systems are at present the most important trends in the establishment of the mechanisms of the action of metal-containing catalysts.

The Structure and Reactivity of Octadehydrocorrins and Corroles

T.A.Melent'eva

The review surveys the chemical properties of corroles, their metal complexes, and the metal complexes of octadehydrocorrins. The reactions of the metal complexes of octadehydrocorrins with electrophiles and nucleophiles, the interconversions of corrinoid compounds, the reactions involving the β,β-double bonds, and the acid-base properties and redox reactions of corrinoid compounds are considered. Problems of the structure of corroles, their metal complexes, and the metal complexes of octadehydrocorrins are discussed.
The bibliography includes 87 references.

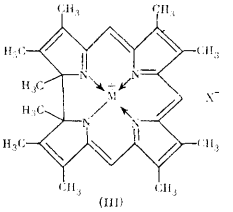
I. INTRODUCTION

Compounds containing the macrocyclic tetrapyrrole systems, which play an important role in biological processes, are presently arousing much interest. Such compounds include the metal complexes of porphyrins and corrins, which constitute the basis of many natural products involved in biocatalytic processes, for example haemin, chlorophyll, vitamin B_{12}, cytochrome *c*, and also the metal complexes of octadehydrocorrins.



Corroles (I), the nickel complexes of 1-methyloctadehydrocorrins (II), and the metal complexes of 1,19-disubstituted octadehydrocorrins (III) have the steric structure of corrins and the degree of unsaturation of porphyrins, so that the study of their chemical and physicochemical properties makes a significant contribution to the development of the chemistry of tetrapyrrole macrocyclic compounds.

(I)

(II)

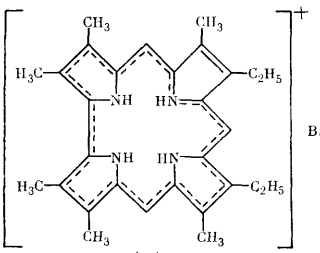
(III)

There are no reviews in the literature devoted directly to the chemical and physicochemical properties of octadehydrocorrins and corroles, but some problems have been considered in a review[1] and in a monograph[2] devoted to porphyrins. The present review deals with the available literature data on the chemical and physicochemical properties of corroles, their metal complexes, and the metal complexes of octadehydrocorrins.

II. THE STRUCTURE AND PHYSICAL PROPERTIES OF CORRINOIDS AND THEIR METAL COMPLEXES

1. Corroles

Corroles are crystalline red substances. They contain an aromatic 18π-electron cyclic system, indicated by the intense Soret band (~400 nm) in their absorption spectra, which contain in addition bands in the region of 540, 550, and 600 nm.[3] The mass spectrum of diethylhexamethylcorrole is very close to that of porphyrin and reflects the aromaticity and stability of corrole[4]. The aromatic properties of corroles are also indicated by their ^{1}H NMR spectra, in which the signals of the *meso*-protons are at 8.8–9.4 p.p.m. and those of the imino-protons are at ~–3.5 p.p.m.

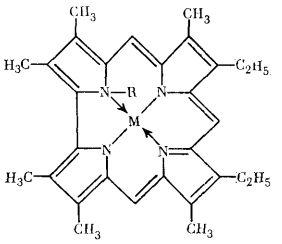


Quantum-chemical calculation of the distribution of π-electron density by the Pariser–Parr–Pople (PPP) method with the parameters of Nishimoto and Forster showed that the highest charge density is at the N atoms, while the π-electron density at the C atoms is enhanced in the 2-, 3-, and 10-positions[5].

The crystal and molecular structures of corrole[6], its hydrobromide (IV),[7] the copper complex of *N*-methylcorrole (Va),[8] the nickel complex of *N*-ethylcorrole (Vb),[9] the triphenylphosphinecobalt(III) complex of corrole (VI),[10] and the rhodium complexes of *N*-methylcorroles, (VII) and (VIII),[11] have not been determined.

8,12-Diethyl-2,3,7,13,17,18-hexamethylcorrole is not exactly planar[6]. Each of the four pyrrole rings is planar, the *A*, *B*, and *C* rings deviate from one another by only 1–3 degrees, while the *D* ring is inclined to the plane of the other rings at an angle of 8–10 degrees. The distances between the N atoms (2.89–2.53 Å) are shorter than in porphyrin (2.90 Å), but the length of three of these (2.89 to 2.66 Å) corresponds to the absence of strain. The N(21)–N(24) distance is 2.53 Å and the steric hindrance between these atoms affects the geometry of the *A* and *D* rings, in which the α,β-bonds are longer than the β,β-bonds. The three inner H atoms lie outside the plane of the macroring and are statistically distributed between the four N atoms[6].

However, quantum-chemical calculation by the PPP method of the bond length and the total π-electron energy of corrole for different dispositions of the inner H atoms shows that the fixation of these atoms in the 21-, 23-, and 24-positions is more probable[12]. The corrole model is asymmetric and has two forms [(+)- and (−)-] in the crystal, where the molecules are arranged in "parallel blocks"[6].



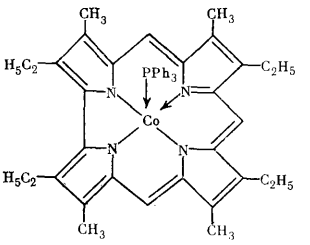
The bromine atom in corrole hydrobromide (IV) [7] is located above the centre of the corrole nucleus at the apex of a pyramid 2.58 Å high with a distorted square base made up of four N atoms. Three H atoms are involved in the formation of hydrogen bonds between the N and Br atoms.

(IV)

(a) R = CH_3, M = Cu

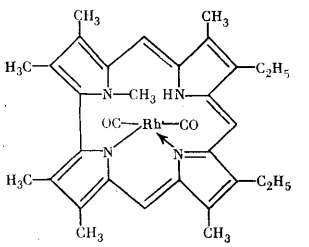
(b) R = C_2H_5, M = Ni

(V, a and b)



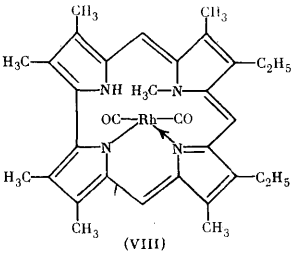
These bonds are non-linear and can bend. Two of them, involving the N(21) and N(23) atoms, are strong, the bond with the N(22) atom is weak, and the N(24)–H bond is directed towards the side away from the Br atom. The corrole system does not have a planar conformation.

The *B* and *D* rings are planar, while the *A* and *C* rings form a dihedral angle of 1–5 degrees along the line passing through the two α-carbon atoms. The N atoms of the *A* and *C* rings are inclined towards the Br atom, while the N atom of the *D* ring is inclined away from the Br atom. This is a result of two opposed effects—the opposite charges on the Br and N atoms and the overloading of the central part of the molecule by the N and H atoms. The *A* and *D* rings deviate in opposite directions, executing a twist around the C(1)–C(19) bond[7].



In the copper complex of N(21)-methylcorrole (Va) the *N*-alkylated *A* ring makes an angle of 23° relative to the molecular plane and the ring itself is bent along the line of the α-atoms by 10°, the β,β-bonds in this ring are longer than the α,β-bonds, and the N–CH_3 bond is longer than usual, its length amounting to 1.54 Å.[8]

In the nickel complex of N(21)-ethylcorrole (Vb) the *A* ring is also appreciably displaced from the molecular plane and the N atoms to which the C_2H_5 group is attached is to a large extent sp^3-hybridised[9].



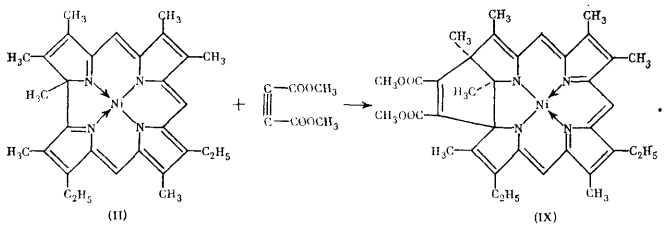
The triphenylphosphinecobalt(III) complex of corrole (VI) is formally a pentacoordinate square-pyramidal complex[10]. The corrole ligand is approximately planar, the N atoms projecting above the molecular plane by ~0.1 Å and the Co atom by 0.38 Å. The average Co–N distance (1.87 Å) is analogous to the corresponding distance in the cobalt complexes of corrins and is somewhat shorter than in porphyrins (1.98 Å). The molecules of complex (VI) have a distorted arrangement in the crystal[10].

(VI)

(VII)

(VIII)

An example of a non-planar complex is provided by the rhodium complexes of corrole (VII) and (VIII) [11] in which the N–CH_3 groups and the bis(dicarbonylrhodium) species are in the *trans*-positions. The pyrrole rings are approximately planar. The rings linked to rhodium are inclined towards it, while the other two rings are displaced in the oppsite direction. The average length of the Rh–N bond is 2.059 Å, being shorter than that of the similar bond in porphyrins (2.084 Å). The Rh...N distance in the *N*-methylated ring is greater by ~0.2 Å. The nitrogen atoms to which the CH_3 substituents are attached are sp^3-hybridised as in the *N*-alkylated copper[8] and nickel[9] complexes.



2. Metal Complexes of 1,19-Disubstituted Octadehydrocorrins

The metal complexes of 1,19-disubstituted octadehydrocorrins are high-melting crystalline substances with a violet or dark cherry-red colour. These are salts with a tetragonal-pyramidal structure where the tetradentate heterocyclic octadehydrocorrin system is the equatorial ligand, while the axial ligand (the anion) is at the apex of the pyramid. The cobalt(II) complexes of octadehydrocorrins are low-spin complexes with an unpaired electron in the d_{z^2} orbital of the cobalt atom oriented at right angles to the plane of the macroring[13,14]. The electronic spectra of the metal complexes of octadehydrocorrins contain three main absorption bands in the regions 280–300, 350–365, and 500–580 nm, but do not have a Soret band. The ^{1}H NMR spectra lead to the conclusion that the metal complexes of octadehydrocorrins occupy an intermediate position between those of the aromatic metal complexes of porphyrins and the non-aromatic corrin complexes. The signals of the *meso*-protons of the nickel complexes of octa-alkyl-1,19-dimethyloctadehydrocorrins are at ~7.5 p.p.m.[15], while the signals of the *meso*-protons of the nickel complexes of porphyrins are at ~11 p.p.m.[16] and those of the nickel complexes of corrins are at 5.9–6.4 p.p.m.[17]

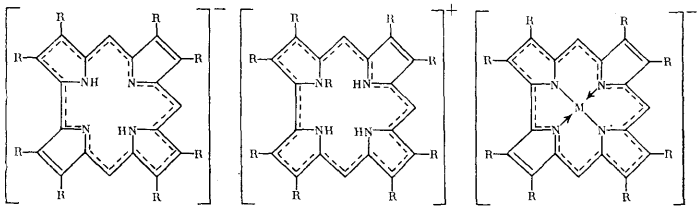
3. Nickel Complexes of 1-Alkyloctadehydrocorrins

1-Alkyloctadehydrocorrins are neutral metal complexes. Only the nickel(II) complexes are known. The signals of the *meso*-protons of these complexes are at 6.0–7.0 p.p.m.[18]

1-Alkyloctadehydrocorrins exhibit the properties of unsaturated compounds; they enter into the Diels–Alder reaction with dimethylacetylenedicarboxylate to form the adduct (IX):[2]

(II) (IX)

III. THE ACID–BASE PROPERTIES OF CORRINOIDS AND THEIR METAL COMPLEXES



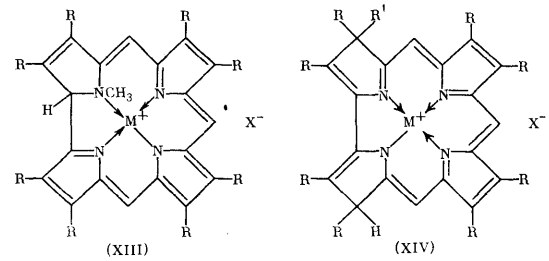
Tetrapyrrole macrocyclic compounds of all kinds react with both acids and bases.

1. The Acid–Base Properties of Corroles and Their Metal Complexes

On treatment with dilute alkali, corroles are converted into the stable aromatic anions (X).[3,19,20] The enhanced acidity of corrole may be explained by the steric hindrance between the imino-hydrogen atoms.

Corroles readily undergo monoprotonation[3,19,20] on treatment with dilute HBr in acetone; the crystalline monobromides formed are aromatic ambident cations (IV) whose charge is delocalised over the macroring[19]. On treatment with concentrated H_2SO_4, CF_3COOH,[3] or FSO_3H,[19,21] corrole is converted into a non-aromatic dication, from which the non-protonated corrole is reformed on treatment with alkali[19]. The ability of corrole to both give up a proton and to combine with one indicates the delocalisation of the free electron pair over all four nitrogen atoms.

N-Alkylcorroles are more basic than the initial corrole. Protonation of the N(21)- and N(22)-methylcorroles takes place when they are merely dissolved in acetic acid with formation of the aromatic monocations (XI).[22] In a 1 M solution of H_2SO_4 in acetic acid, *N*-methylcorroles are converted into dications whose spectra contain the Soret band, which rules out the breakdown of conjugation in the chromophore, but the site of addition of the second proton could not be established.



(X) (XI) (XII, a and b), (a) M = Ni; (b) M = Cu

With increasing H_2SO_4 concentration, a third proton adds to the *N*-methylcorrole, apparently at the C(5) atom[22]. The same substance is formed on dissolution of *N*-alkylcorroles in CF_3COOH.[19]

The nickel and copper complexes of corroles are relatively stable[3]. On treatment with alkalies, they are converted into the stable aromatic ambident anions (XII, a and b), whose electronic spectra contain the Soret band[20,23–25].

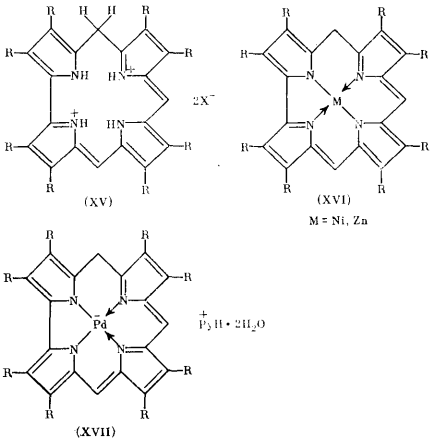
The nickel complexes of *N*-methylcorroles are protonated in the angular position on dissolution of CF_3COOH with formation of the non-aromatic compound (XIII) whose electronic spectrum is similar to that of the nickel complex of 1-methyloctadehydrocorrin[9,26]. The protonation of the palladium complexes of N(21)-alkylcorroles takes place analogously[27].

(XIII) (XIV)

M = Ni, Pd

Angular protonation of the nickel and palladium complexes of 3,3-dialkylcorroles, which causes the breakdown of the conjugation chain, is less favourable than the *N*-protonation[26–29] and on dissolution of the nickel complexes of 3,3-dialkylcorroles in CF_3COOH, the proton adds to the 17-position with formation of the complex (XIV).[26,29] The protonation of the palladium complexes of 3,3-dialkylcorroles takes place analogously[27,28].

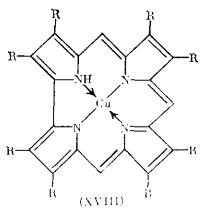
The pyridinium salt of the palladium complex of corrole is diprotonated in CF_3COOH in the 3- and 17-positions, which results in the formation of the complex (XIV), where R′ = H.[27]



Treatment of a solution of the square-planar cobalt(III) complex of corrole or any other pentacoordinate derivative with HBr in acetone leads to the formation of a green crystalline paramagnetic hydrobromide in which the protonation site has not been established[30]. When $HClO_4$ is added to a solution of Co-corrole in tetrahydrofuran (THF), the monoprotonated Co-corrole is formed, whose electronic spectrum resembles that of Ni-corrole[13]. The protonation of Co-corrole is reversible and the addition of pyridine results in the formation of the non-protonated pyridinecobalt(III) complex of corrole[30].

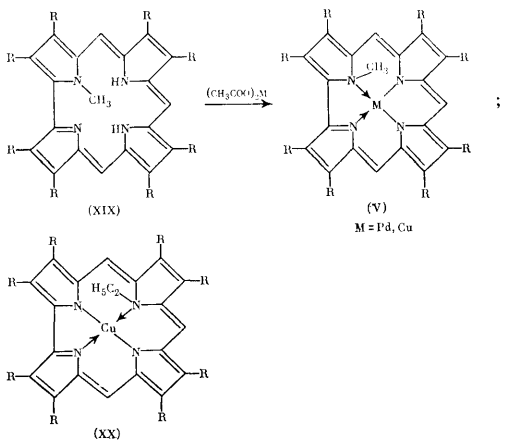
2. The Interaction of Corroles with Metals

The free bases of corroles readily react with metal cations to form metal complexes. Corrole is a tetradentate ligand, where three out of the four N atoms are linked to hydrogen atoms capable of being substituted. In the formation of metal complexes of corroles, all three, two, or one hydrogen atoms are substituted by the metal depending on the nature of the latter.



When corrole is treated with solutions of nickel, copper, zinc, and palladium salts[3,27] in the presence of bases, only two hydrogen atoms are substituted by the metal and the products are metal complexes of corroles derived from the non-aromatic base corresponding to the dication (XV),[3,9,26,27] the third hydrogen atom passing to one of the carbon atoms of the macroring and disrupting the aromatic conjugation system of corrole[21]. Its location at C(10) [27,31] or C(5) [21]

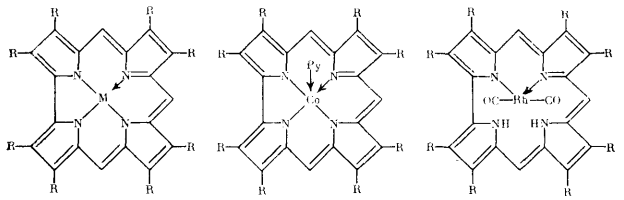
has not been finally established. Structure (XVI) is more probable. The palladium complex has been isolated as the dihydrate of the pyridinium salt (XVII), which is formed when corrole is treated with $(CH_3COO)_2Pd$ in pyridine[27].



(XV) (XVI) M = Ni, Zn (XVII)

The visible spectra of the copper complexes differ from those of the nickel and palladium complexes and are analogous to the spectra of the copper complexes of N(21)-methylcorroles, indicating at the same time the retention of the conjugated system of the macroring. Structure (XVIII), where the "extra" hydrogen is located at the N(21) atom, was therefore proposed for the copper complexes of corroles[21].

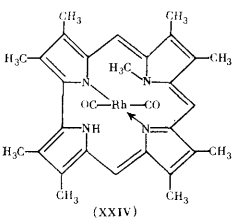
(XVIII)



N-Alkylcorroles readily react with metal salts. Treatment of N(21)-methylcorrole (XIX) with $(CH_3COO)_2Pd$ or $(CH_3COO)_2Cu$ yielded the palladium and copper complexes of N(21)-methylcorrole [compounds (V)].[21,27,28] The copper complex of N(22)-ethylcorrole (XX) was obtained analogously by the reaction of $(CH_3COO)_2Cu$ with N(22)-ethylcorrole[21,27,28]:

(XIX) (V) M = Pd, Cu (XX)

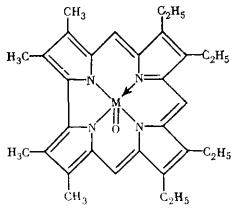
The reaction of zinc salts with *N*-alkylcorroles leads to the formation of unstable products[28], while nickel salts do not react with *N*-alkylcorroles[9,28]. The interaction of N(21)-alkylcorroles (XIX) with the perchlorate of the hexamethylnickel cyanide complex leads to the formation of the corresponding nickel complex (V, M = Ni).[9] The metal complexes of *N*-alkylcorroles are aromatic: the signals of their *meso*-protons in the ^1H NMR spectra are at 9.0–9.3 p.p.m.[9,27]



When an attempt is made to insert bivalent cobalt into N(21)-methylcorrole (XIX), the methyl group is split off and all three imino-protons are substituted by the metal with formation of the cobalt(III) complex of the *N*-unsubstituted corrole (XXI).[21,30] The complexes (XXI) are square-planar paramagnetic compounds. When corrole is treated with $(CH_3COO)_2Co$ in the presence of pyridine, purple prismatic crystals of the pentacoordinate pyridinecobalt(III) complex of corrole (VIa) are formed[30]; the latter readily splits off pyridine on treatment with hot methanol[3] and is converted into the planar tetracoordinate complex (XXI).[30] The pentacoordinate complexes (VI) are also formed in the presence of $(C_6H_5)_3P$ and p-$CH_3C_6H_4NC$.[30]

(XXI), (XXII), M = Co, Fe (VIa) (XXIII)

A crystalline paramagnetic iron(III) complex of corrole (XXII) has been synthesised by treating the corrole anion (X) with $FeCl_3$.[30]

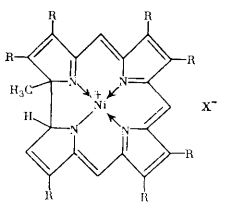


Rhodium complexes of corroles have been obtained quite recently[11,32,33]. The interaction of corrole with $RH_2(CO)_4Cl_2$ leads to the formation of the monorhodium complex of corrole (XXIII). The reaction of N(21)-methylcorrole (XIX) with $Rh_2(CO)_4 \cdot Cl_2$ in chloroform containing CH_3COONa leads to the formation of the complex (VII).[11]

(XXIV)

On interaction with an excess of $Rh_2(CO)_4Cl_2$ at room temperature, N(22)-methylcorrole gives rise to a mixture of the complex (VIII) and (XXIV), the complex (VIII) being converted into the complex (XXIV) on standing. The molybdenum and chromium complexes of corrole have been synthesised after the discovery of superconducting materials[34] in an attempt to obtain an electrical conductor in the form of metal complex species with a metal–metal bond stacked one on top of the other. When corrole was allowed to interact with $MoCl_5$ or $Mo(CO)_6$ at 170–180 °C in nitrogen, the complex (XXV) was obtained. It is a monomeric pentacoordinate oxomolybdenum complex with an axial disposition of the oxygen atom[35]. Its symmetry is close to that of a tetragonal pyramid. In the electronic spectrum there is a Soret band. The EPR spectra indicate a π-bonding interaction between the Mo and O atoms.

There is a considerable contribution of the π-interaction in the plane of the macroring between the Mo atom and the electron-donating N atom; the coordinate bonds have a high degree of covalence[34].



(XXV), (XXVI), M = Mo, Cr

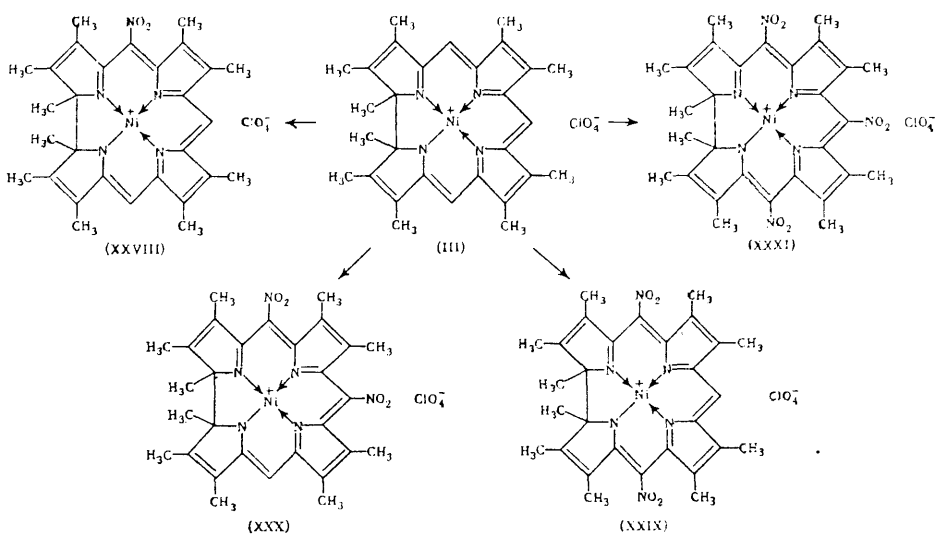
The oxochromium complex (XXVI) has been synthesised by treating corrole with $CrCl_2$ in dimethylformamide (DMF) in the presence of sodium acetate[36]. This is an N_4O-pentacoordinate complex with a symmetry close to that of a tetragonal pyramid[37]. The unpaired electron is in the $3d_{xy}$ orbital of chromium and there is a strong interaction between this orbital and the σ and/or π orbitals of the macroring[36].

3. Protonation of the Metal Complexes of Octadehydrocorrins

The nickel(II) complexes of 1-methyloctadehydrocorrins are effective electron donors and, on treatment with strong acids ($HClO_4$, CF_3COOH, FSO_3H), they are protonated in the 19-position with formation of salts of the nickel complexes of 1-methyloctadehydrocorrins (XXVII);[18,21,38–41] the corresponding perchlorate has been isolated in a crystalline form[39]. The protonation of 1-methyloctadehydrocorrins is reversible and treatment of the salts (XXVII) with alkali results in the reformation of the initial complexes of 1-methyloctadehydrocorrins.

(XXVII)

The metal complexes of 1,19-dimethyloctadehydrocorrins are capable of being protonated in a strongly acid medium[42]. When nickel and cobalt complexes of octadehydrocorrins are dissolved in concentrated sulphuric acid, a proton apparently adds to N(21) or N(24) with formation of an intramolecular hydrogen bond. In addition, the protonated form is probably a radical-cation, which is indicated by the intense absorption at 690 nm, characteristic of the free radicals of cyanonickel complexes of octadehydrocorrins[43]. The protonation of metal complexes of octadehydrocorrins is reversible and dilution of their sulphuric acid solutions with water leads to the reformation of the initial complexes[42].



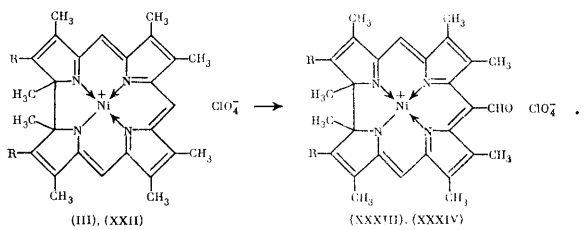
4. Deuterium Exchange

Corrinoid systems of all types are capable of deuterium exchange. Corroles exchange rapidly all three *meso*-hydrogen atoms for deuterium in CD_3COOD.[3] The exchange of all the *meso*-hydrogen atoms of 3,17-diethoxycarbonyl-8,12-diethyl-2,7,13,18-tetramethylcorrole in a mixture of CF_3COOD and $CDCl_3$ at room temperature takes place over a period shorter than 10 min.[19,44,45] The half-exchange period for the proton in the 10-position in the nickel complex of octa-alkyl-1-methyloctadehydrocorrins in CF_3COOD at 35 °C is 15 min, while that for the proton in the 5-position is 11–15 min.[40] In the presence of free β-positions in the octadehydrocorrin macroring, the β-proton exchanges for deuterium[29]. The nickel complex of hexa-alkyl-1,19-dimethyloctadehydrocorrin in CF_3COOD apparently exchanges the *meso*-hydrogen atoms as well as the β-hydrogen atoms.

IV. REACTIONS WITH ELECTROPHILES AND NUCLEOPHILES

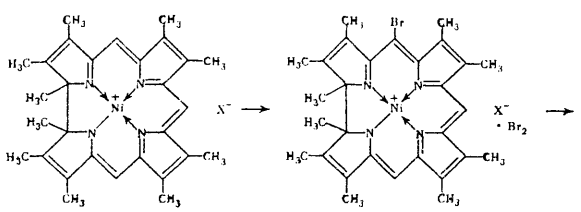
1. Electrophilic Substitution Reactions

In the metal complexes of octadehydrocorrins the equatorial ligand is the tetrapyrrole macroring containing an extensive system of conjugated C=C and C=N bonds. The presence of this system is responsible for the ability of these compounds to react with electrophiles.



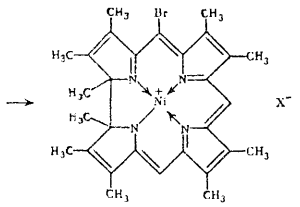
(XXVIII) (III) (XXXI)

(XXX) (XXIX)



The nickel complexes of octadehydrocorrins are readily nitrated. Treatment of the nickel complex of decamethyl-octadehydrocorrin (III) with fuming HNO_3 and urea at 0 °C yielded the perchlorate of the nickel complex of 5-nitro-octadehydrocorrin (XXVIII).[46] The 5-nitro-derivative is also formed on treatment of the nitrate of the nickel complex of 8,12-diethyl-1,2,3,7,13,17,18,19-octamethyloctadehydro-corrin with $Cu(NO_3)_2$ in acetic anhydride[43,47]. Treatment of the complex (III) with the 1 : 1 mixture of fuming HNO_3 and concentrated H_2SO_4 at 0 °C leads to the formation of a mixture of the perchlorates of the nickel complexes of the 5,10-dinitro derivative (XXIX) and the 5,15-dinitro derivative (XXX). Under more severe conditions, in the 1 : 1 mixture of HNO_3 and oleum, the nickel complex of 5,10,15-trinitro-octadehydrocorrin (XXXI) was isolated[46].

The nickel complexes of octadehydrocorrins readily undergo the Vilsmeier reaction, which takes place more readily with aromatic compounds having an enhanced activity with respect to electrophilic substitution. When the perchlorates of the nickel complexes of decamethyloctadehydrocorrin and octa-methyloctadehydrocorrin (XXXII) in boiling $CHCl_3$ are treated with $POCl_3$ and DMF, the nickel complexes of the corresponding 10-formyloctadehydrocorrins (XXXIII) and (XXXIV) are formed[48], their formyl groups readily forming bisulphite derivatives.

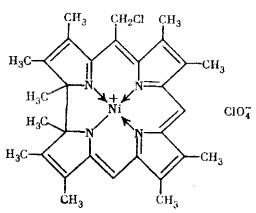


(III), (XXII) (XXXIII), (XXXIV)

Depending on the reaction conditions, the halogenation of the salts of the nickel complexes of octadehydrocorrins leads to the formation of mono- or di-halogeno-derivatives. When the perchlorate and nitrate of the nickel complex of deca-methyloctadehydrocorrin (III, a and b) are treated with bromine in acetic acid, the perchlorate and bromide of the nickel complexes of 5-bromo-octadehydrocorrin (XXXV, a and b) are formed[49], i.e. the substitution reaction is accompanied by the replacement of the NO_3^- anion by the Br^- anion. The two compounds (XXXV, a and b) contain two additional Br atoms, which are not substituents in the macro-ring and are readily removed on treatment with acids or bases with formation of the complexes (XXXVI, a and b):

(III, a and b)
X = ClO_4, NO_3

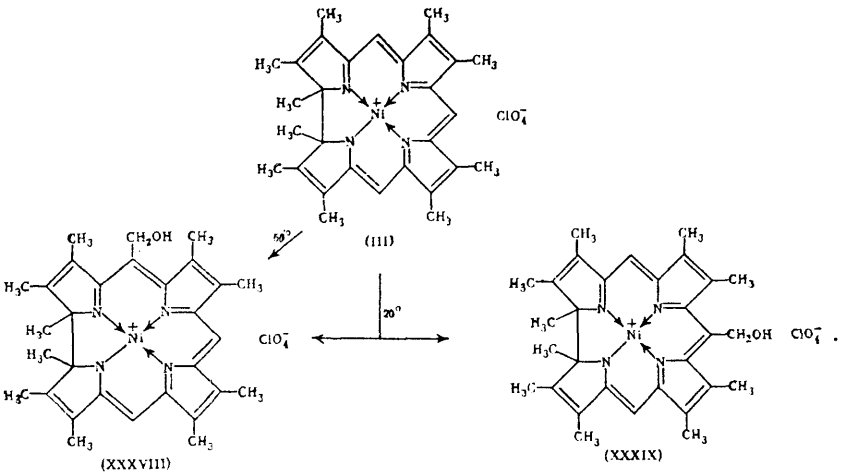
(XXXV, a and b)
X = ClO_4, Br



(XXXVI, a and b)

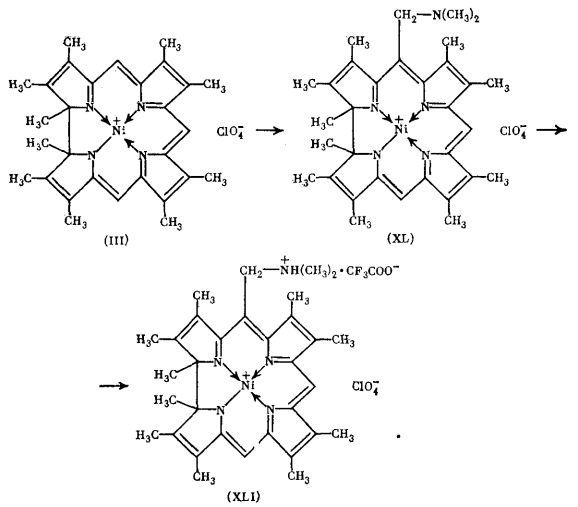
The bromination of the nickel complexes of octadehydro-corrins with bromine in $CHCl_3$ [49] or $C_2H_4Cl_2$ [43] yielded the nickel complexes of 5,10-dibromo-octadehydrocorrins; when hydroquinone was added, 5-bromo-octadehydrocorrin was isolated. The chlorination of the nickel complex of deca-alkyloctadehydrocorrin with chlorosuccinimide leads to the formation of the *meso*-dichloro-derivative[43]. Bromination with Br_2 in acetic acid is an electrophilic substitution reaction, while bromination with Br_2 in $CHCl_3$ and $C_2H_4Cl_2$ and chlorination with chlorosuccinimide takes place via a radical mechanism, i.e. electrophilic halogenation leads to the formation of 5-halogeno-derivatives, while radical halogenation results in the formation of 5,10-dihalogeno-derivatives.

The halogens in the *meso*-positions in octadehydrocorrins are readily substituted by hydrogen in the presence of traces of acid[43]. The debromination of the nickel complex of 5-bromo-octadehydrocorrin (XXXV) takes place when it is dissolved in nitromethane, apparently via the following reaction[49]:



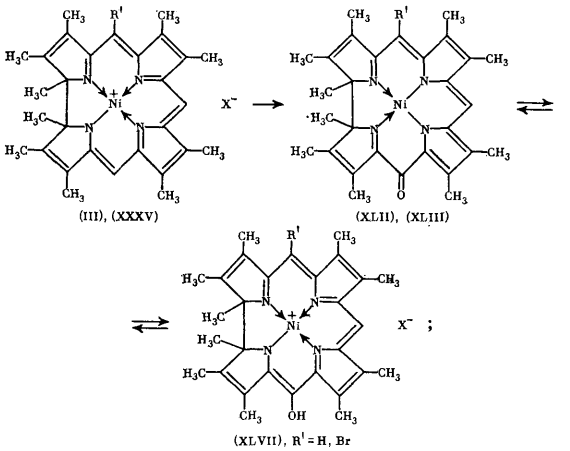
$$\text{C}{-}\text{Br} + CH_3NO_2 \rightarrow \text{C}{-}\text{H} + CH_2BrNO_2 \ .$$

The nickel complexes of octadehydrocorrins readily undergo the chloromethylation reaction, which consists in the direct substitution of hydrogen by the CH_2Cl group on treatment with paraformaldehyde and concentrated HCl in glacial acetic acid. The chloromethylation of the nickel complex of decamethyloctadehydrocorrin led to the isolation of the nickel complex of 5-chloromethyloctadehydrocorrin (XXXVII), i.e. the product of the introduction of one CH_2Cl group into the octadehydrocorrin macroring[50].

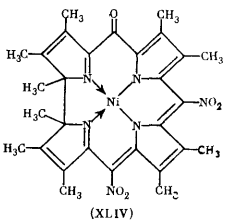


(XXXVII)

Treatment of the nickel complex of decamethyloctadehydro-corrin with paraformaldehyde in glacial acetic acid leads to the formation of the mono-*meso*-hydroxymethyl derivatives (XXXVIII) and (XXXIX).[50] The mode of reaction depends on temperature: the 5-hydroxymethyl derivative (XXXVIII) is formed at 50 °C, while at room temperature there are two products: 5-hydroxymethyloctadehydrocorrin (XXXVIII) and 10-hydroxymethyloctadehydrocorrin (XXXIX):



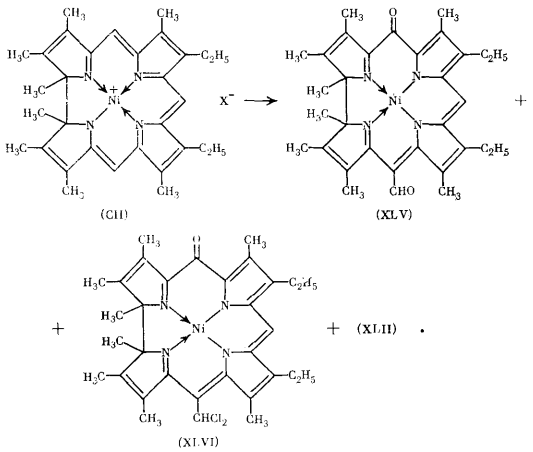
The reaction of the perchlorate of the nickel complex of decamethyloctadehydrocorrin with formaldehyde and dimethylamine in alcohol yielded the nickel complex of 5-dimethylaminomethyloctadehydrocorrin (XL), which is protonated in CF_3COOH and converted into the perchlorate of the nickel complex of decamethyloctadehydrocorrin (XLI) containing the $CH_2^+NH(CH_3)_2.CF_3COO^-$ substituent:[51]



2. Reactions with Nucleophiles

The positive charge in salts of the metal complexes of octadehydrocorrins is not fixed at the central metal atom but is delocalised over the octadehydrocorrin macroring[21]. The delocalisation has a major influence on the chemical behaviour of octadehydrocorrins. In particular, the cationic forms of the nickel complexes of octadehydrocorrins are very sensitive to attack by nucleophiles.

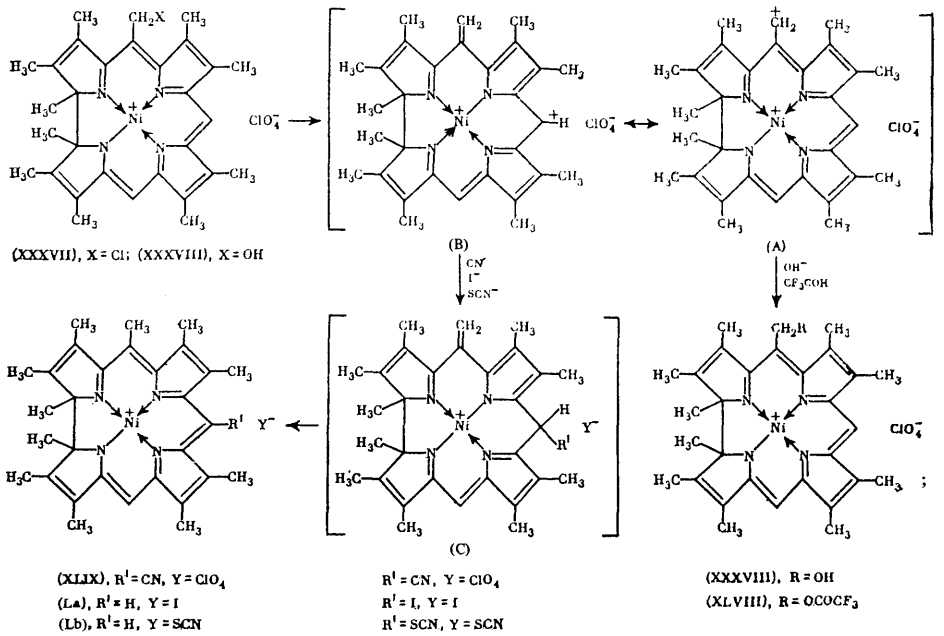
The salts of the nickel complexes of octadehydrocorrins are converted into neutral oxo-complexes on treatment with bases in air[21,43,49,52]. When the nickel complex of decaalkyloctadehydrocorrin, for example, compound (III), was treated with an aqueous solution of NaOH, an excess of $(C_2H_5)_3N$, or CH_3Li in moist THF,[43] the nickel complex of 5-oxo-octadehydrocorrin (XLII) was obtained.



The reaction of the nickel complex of 5-bromo-octadehydrocorrin (XXXV) with a 5% NaOH solution in 30% H_2O_2 leads to the nickel complex of 5-bromo-15-oxo-octadehydrocorrin (XLIII).[49]

Nitration of the nickel complex of decamethyloctadehydrocorrin with a mixture of fuming HNO_3 and glacial acetic acid at 0 °C yielded the nickel complex of 10,15-dinitro-5-oxo-octadehydrocorrin (XLIV),[49] while the addition of an aqueous NaOH solution to a chloroform solution of the nickel complex (CII) at room temperature led to the isolation, together with the nickel complex of 5-oxo-octadehydrocorrin (XLII), of the complexes of 15-formyl-5-oxo-octadehydrocorrin (XLV) and

15-dichloromethyl-5-oxo-octadehydrocorrin (XLVI):[43]

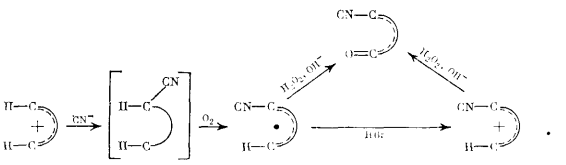


The conversion of the salts of the nickel complexes of octadehydrocorrins into neutral 5-oxo-derivatives probably proceeds as follows: initially the nucleophile adds on and the carbanion is formed, the latter being oxidised by atmospheric oxygen to the neutral nickel complex of oxo-octadehydrocorrin. The presence of electron-accepting substituents in octadehydrocorrin macrorings facilitates this reaction. In contrast to the nickel complexes, the cobalt complexes of octadehydrocorrins with electron-accepting substituents in the macroring are readily converted into cobalt(I) derivatives on treatment with bases. A whole series of oxo-complexes of substituted octadehydrocorrins, containing the $CHCl_2$, Br, CN, CHO, NO_2, and NH_2 groups in the *meso*-positions, have been obtained. The nitro-groups in the oxo-complexes are readily split off in an acid medium[43].

The oxo-group in the nickel complexes of octadehydrocorrins does not exhibit certain properties characteristic of this group. Thus, it has not been possible to convert the nickel complexes of oxo-octadehydrocorrins into the enolic forms[40]. However, when these compounds are dissolved in CF_3COOH, they are *O*-protonated with formation of hydroxy-forms, which could not be isolated. The hydroxy-complex (XLVII) is converted into the oxo-form on treatment with alkali[43,49].

The nickel complexes of octadehydrocorrins with the CH_2OH and CH_2Cl groups in the 5-position exhibit a dual reactivity in reactions with nucleophiles[51,53]. When the nickel complex of 5-chloromethyloctadehydrocorrin (XXXVII) was refluxed with a NaOH solution in alcohol, the nickel complex of 5-hydroxymethyloctadehydrocorrin (XXXVIII) was isolated and treatment with CF_3COOH resulted in the nickel complex of 5-trifluoroacetoxymethyloctadehydrocorrin (XLVIII). The reactions of the nickel complexes of 5-chloromethyloctadehydrocorrin and 5-hydroxymethyloctadehydrocorrin (XXXVIII) with KCN, KI, and KSCN proceed differently. When the nickel complexes of 5-hydroxymethyl- (XXXVIII) and 5-chloromethyl-octadehydrocorrins were treated with a solution of KCN in aqueous alcohol at room temperature, the nickel complex of 10-cyano-1,2,3,5,7,8,12,13,17,18,19-undecamethyloctadehydrocorrin (XLIX) was isolated in both cases, i.e. the reaction with the CN^- anion proceeds with transfer of the reaction centre. When the complexes (XXXVII) and (XXXVIII) were treated with KI or KSCN, the nickel complex of undecamethyloctadehydrocorrin (L, a and b) was isolated as the iodide or thiocyanate respectively[53]:

The following reaction mechanism has been proposed: the heterolysis of the C–X bond results in the formation of an ambident cation, whose stability is enhanced owing to the redistribution of electron density as a result of the delocalisation of the positive charge over the π-electron system of the macroring. The resonance structures of the carbonium ion (A) and (B) are possible. The addition of the nucleophile to the CH_2^+ group results in the formation of the CH_2X derivative and attack on the *meso*-carbon atom produces the intermediate compound (C), which is converted into a 10-substituted 5-methyloctadehydrocorrin after the migration of the proton from the *meso*-position to the methylene group. The *meso*-iodo- and *meso*-thiocyanato-derivatives readily lose



these substituents, being converted into undecamethyloctadehydrocorrin (L, a and b). The nature of the nucleophile determines the mode of reaction. This behaviour has been interpreted[51,53] on the basis of the principle of the hard and soft acids and bases (HSAB).[54,55] The CH_2^+ reaction centre formally corresponds to a hard acid, since there is a smaller possibility of the delocalisation of the charge on the primary carbon atom and, according to the HSAB principle, it should be coordinated preferentially to hard bases, i.e. OH^- and CF_3COO^-, while the reaction centre at the *meso*-carbon atom can be regarded as a soft acid which reacts preferentially with CN^-, I^-, and SCN^-.

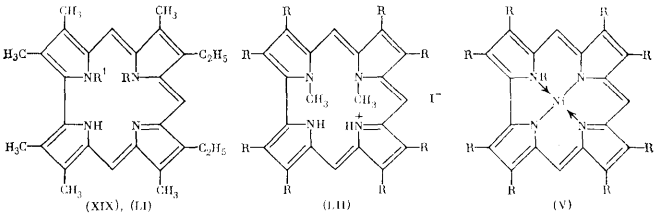
The cationic forms of the nickel complexes of octadehydrocorrins exchange anions in the course of the reactions of the perchlorates of the nickel complexes (XXXVII) and (XXXVIII) with KSCN and KI. When the complexes (L, a and b) are dissolved in CF_3COOH, I^- and SCN^- are replaced by the CF_3COO^- anion.

The oxidation of the nickel complexes of octadehydrocorrins to the oxo-complexes on treatment with nucleophiles is sometimes accompanied by a nucleophilic substitution reaction. Several instances of nucleophilic substitution without the oxidation of the macroring are also known. When the nickel complexes of 5,10-dibromo- and 5,10-dichloro-octadehydrocorrins are treated with CH_3Li in moist THF, the formation of the oxo-complexes is accompanied simultaneously by the nuclophilic exchange of the halogens for hydrogen, while on treatment with $LiCu(CH_3)_2$ the complexes are converted into 5,10-dimethyloctadehydrocorrins[38].

The interaction of the nickel complexes of *meso*-unsubstituted octadehydrocorrins with KCN in CH_3OH leads rapidly to the formation of three products: the neutral 15-cyano-5-oxo-octadehydrocorrin and the free radicals of 5-cyano- and 5,15-dicyano-octadehydrocorrins[56,57], whose unpaired electron is delocalised over the macroring. Treatment of the radical of 5-cyano-octadehydrocorrin with HBr yielded the bromide of the nickel complex of 5-cyano-octadehydrocorrin. The oxidation of this complex with an alkaline solution of hydrogen peroxide led to the formation of the nickel complex of 5-cyano-15-oxo-octadehydrocorrin:

Treatment of the radical of dicyano-octadehydrocorrin with $HClO_4$ converts it into the perchlorate of the nickel complex of dicyano-octadehydrocorrin. This salt can be readily converted into a radical when it is chromatographed on Al_2O_3. The introduction of the cyano-group and oxidation of the salt of the nickel complex of 5-cyano-octadehydrocorrin leads to the formation of a dicyano-octadehydrocorrin radical and then a salt of the nickel complex of 5,15-dicyano-octadehydrocorrin[56,67].

V. ALKYLATION OF CORRINOIDS AND THEIR METAL COMPLEXES



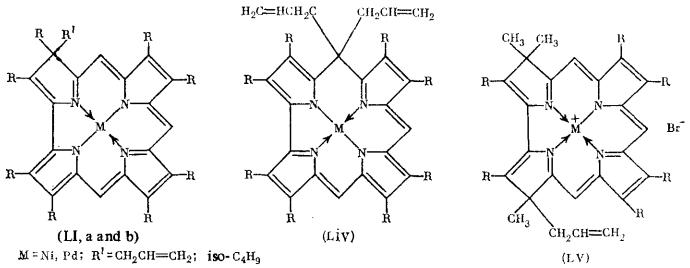
1. Alkylation of Corroles and Their Metal Complexes

Corrinoid macrocyclic compounds of all types undergo the alkylation reaction, but for each type of compound the reaction proceeds differently.

The alkylation of corroles and their metal complexes takes place at the nitrogen atoms. The reaction of the corrole anion, formed in the presence of K_2CO_3, with alkyl halides leads to the formation of a mixture of N(21)-alkylcorroles (XIX) and N(22)-alkylcorroles (LI), where R or R′ = CH_3, C_2H_5, $CH_2CH{=}CH_2$, or $(CH_3)_2C{=}CH_2$.[3,9,19,28] The N(21)-isomers are formed preferentially. In the absence of bases, alkylation does not occur. In the methylation of corrole having the $COOC_2H_5$ substituents in the 3- and 17-positions, the deactivating influence of these groups leads to the preferential formation of N(22)-methylcorrole[45].

(N(21)-Alkylcorroles are more stable than N(22)-alkylcorroles. Both isomers are aromatic and their electronic spectra contain the Soret band[28]. *N*-Alkylation increases the basicity of corroles, N(21)-methylcorroles being less basic than the N(22)-isomers: the relative acid dissociation constants of the monocations of N(21)- and N(22)-methylcorroles are 0.35 and 1.28 respectively[22].

The methylation of *N*-methylcorroles under severe conditions, for example treatment of N(21)- and N(22)-methylcorroles with CH_3I in sealed tubes (for 15 h at 100 °C) leads to the formation of N(21), N(22)-dimethylcorrole (LII), which was isolated as the iodide.



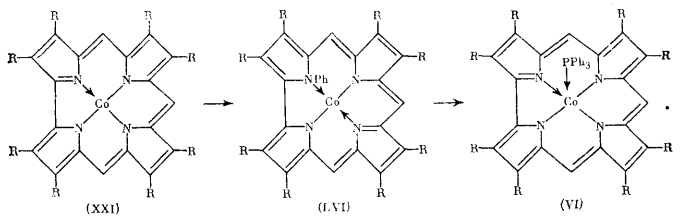
The *trans*-disposition of the *N*-alkyl groups in *N*,*N*-dialkylcorroles was demonstrated in a study of the optical rotation of a D-camphor-10-sulphonate salt[28]. The free base could not be obtained from the salt (LII). Under the same conditions, the *N*-unsubstituted corrole is also converted into *N*,*N*-dimethylcorrole and the *N*-monomethylcorrole was not isolated. Thus the rate of introduction of the second CH_3 group is higher than that of the first, i.e. *N*-alkylcorroles are more nucleophilic and basic than the *N*-unsubstituted corrole. The N(21), N(22)-dimethylcorrole salt (LII) is thermally unstable and on heating in boiling $C_6H_4Cl_2$ is converted into N(21)-methylcorrole[19]. The increased basicity of *N*,*N*-dialkyl-substituted macrocyclic compounds is a common property of corroles and porphyrins[58].

The acetylation of corroles takes place analogously to their alkylation[19]. When corrole is refluxed with acetic anhydride, N(21)-acetylcorrole is formed, its electronic spectra differing from the spectra of N(21)-alkylcorrole by the bathochromic shift of the absorption bands. The infrared spectrum of *N*-acetylcorrole has an absorption band at 1709 cm^{-1}, whose position indicates the absence of conjugation of the CO group with the chromophore of the macrocyclic compound. On an Al_2O_3 column or on treatment with NaOH, *N*-acetylcorrole is converted into *N*-unsubstituted corrole[19].

The nickel complexes of corrole anions also readily react with alkyl halides, which results in the formation of aromatic and diamagnetic N(21)-alkyl derivatives (V) whose additional alkyl group is shielded (τ = 12.6) and the molecule has no symmetry plane[9,23,26]. The reaction of the nickel complex of the corrole anion with $CH_2{=}CHCH_2Br$ leads to the formation of a mixture of the complexes of 3-alkyl-3-allylcorrole (LIII) and 5,5-diallylcorrole (LIV).[9,23,26] The nickel complex of 3-allyl-3-methylcorrole is apparently formed from the *N*-allyl

derivative via a [1,5]- or [3,3]-sigmatropic rearrangement. After the alkylation of the nickel complex with $(CH_3)_2C=CHCH_2Br$, triallylcorrole and *meso*-diallylcorrole (LIV) were isolated in addition to the 3-allyl derivative. The *meso*-derivative is not a product of the rearrangement of 3-allylcorrole, since the latter does not rearrange. The reaction of the nickel complex of corrole with isobutyl iodide leads to the formation of the 3-isobutyl derivative (LIIIb). This mode of reaction with $CH_2=CHCH_2Br$ and iso-C_4H_9I is probably due to steric factors[9].

(LI, a and b) (LIV) (LV)



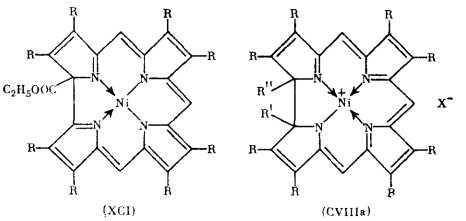
M = Ni, Pd; $R^1 = CH_2CH=CH_2$; iso-C_4H_9

The alkylation of the nickel complex of 3,3-dialkylcorrole (LIII) with $CH_2=CHCH_2Br$ or $C_6H_5CH_2Cl$ takes place in the 17-position with formation of the salt (LV).[9]

The methylation of the pyridinium salt of the palladium complex of corrole (XVII) with CH_3I in boiling acetone in the presence of NaOH results in the formation of N(21)-methylcorrole (V, M = Pd) and 3,3-dimethylcorrole (LIII). The alkylation of the palladium complex of 3,3-dialkylcorrole with $CH_2=CHCH_2Br$ yields the palladium complex of 3,3,17-trialkyl-17-allylcorrole (LV).[27]

The alkylation of the copper complexes of corroles leads to the formation of the N(21)-alkyl derivatives[9,27,28], which split off the *N*-alkyl group on heating in 1-chloronaphthalene[27].

Treatment of a solution of the cobalt(III) complex of corrole (XXI) in THF with C_6H_5MgBr or C_6H_5Li results in the formation of the green crystalline cobalt(II) complex of N(21)-phenylcorrole (LVI).[30] The *N*-*p*-tolyl derivative was obtained in the same way.



(XXI) (LVI) (VI)

Arylated Co-corroles are paramagnetic and non-planar. They are stable in the light both in the solid state and in solutions and do not form pentacoordinate cobalt(III) complexes of corroles on heating with pyridine or triphenylphosphine. The aryl group is split off at 130 °C and the resulting Co-corrole has been isolated in the form of the triphenylphosphine complex (VI). The attempts to obtain the N(21)-alkyl derivatives by alkylating Co(III)-corroles with alkylmagnesium bromide or alkyl-lithium were unsuccessful[30].

2. Alkylation of Metal Complexes of Octadehydrocorrins

The metal complexes of octadehydrocorrins also undergo the alkylation reaction. The alkylation of the nickel complexes of 1-methyloctadehydrocorrins by alkyl halides takes place in the 19-position with the formation of salts of the nickel complexes of 1,19-dialkyloctadehydrocorrins[18,21,38,40]. The CH_3, C_2H_5, n-C_3H_7, $CH_2=CHCH_2$, and $C_6H_5CH_2$ substituents have been introduced in this way into the 19-position[18]. Although the 19-position is not the usual reaction centre for electrophilic reactions, substituting in the 19-position in 1-methyloctadehydrocorrins causes the minimum interference with the conjugation of the system in the transition state. The alkylation of the nickel complexes of 1-ethoxycarbonyloctadehydrocorrins (XCI) also takes place in the angular position and leads to the formation of the nickel complexes of 19-alkyl-1-ethoxycarbonyloctadehydrocorrins (CVIIIa). The 19-methyl-,[59] alkyl-, and 19-(3,3-dimethylallyl)-derivatives[29] have been obtained in this way.

(XCI) (CVIIIa)

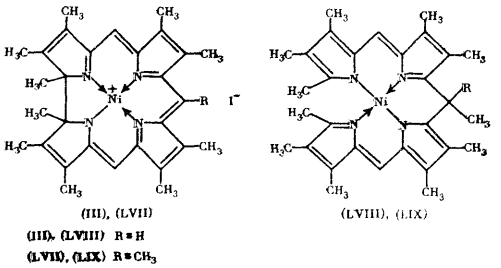
Since the cobalt complexes of 1-methyloctadehydrocorrins have not been isolated, their alkylation has been scarcely investigated. However, treatment of a solution of the cobalt complex of 1-methyloctadehydrocorrin with CH_3I in an inert gas atmosphere results in the formation of the 1,19-disubstituted derivative[2].

The methylation of the nickel complexes of 1,19-dimethyloctadehydrocorrins takes place in the *meso*-position but only to a slight extent. The methylation of the nickel complex of octa-alkyl-1,19-dimethyloctadehydrocorrin with CH_3I in the presence of $SnCl_4$ leads to the formation of the 5-methyl derivative in 6% yield [47].

Reductive methylation has been used to introduce the CH_3 group into the *meso*-position in the octadehydrocorrin macroring, which results in the formation of 10-methyloctadehydrocorrin (LVII).[60] The reductive methylation of salts of the nickel complexes of octadehydrocorrin (III) takes place as follows. On treatment with CH_3I in the presence of sodioanthracene in anhydrous THF in an inert gas atmosphere, the CH_3 group enters the 10-position with the simultaneous opening of the macroring and the formation of the nickel complex of undecamethylbiladiene (LVIII), the anthracene radical-anion functioning as an electron transferring agent in this reaction and participating in the formation of the anionic form $(III)^-$:

$$(III) + 2NaC_{14}H_{10} \rightarrow Na^+(III)^- + 2C_{14}H_{10} + NaI \ .$$

After the addition of CH_3I, the complex (LVIII) is formed:



$$Na^+(III)^- + CH_3I \rightarrow (LVIII) + NaI \ .$$

The oxidation of this complex leads to the formation of the cyclic system (LVII):

$$(LVIII) + I_2 \rightarrow (LVII) + 2HI \ .$$

Repeated reductive methylation of undecamethyloctadehydrocorrin (LVII) again leads to the addition of the CH_3 group in the 10-position and ring opening with formation of

the complex (LIX), which does not cyclise into the nickel complex of octadehydrocorrin even under severe conditions[60] as a consequence of the presence of two geminal CH_3 groups[15].

(III), (LVII)

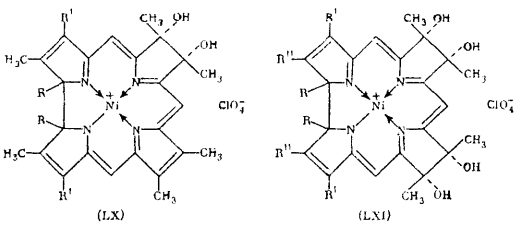
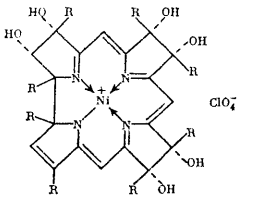
(LVII), (LIX) R = CH_3



(LVIII), (LIX)

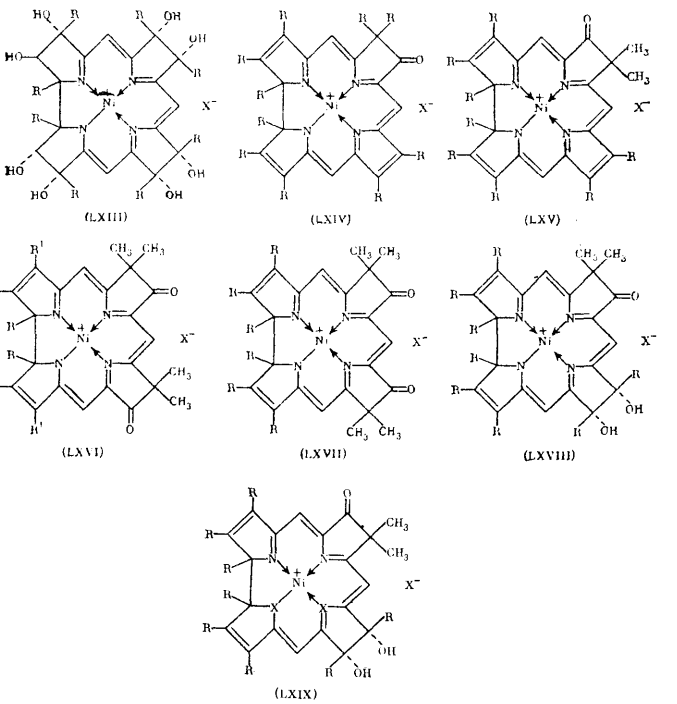
VI. REACTIONS INVOLVING THE β,β-DOUBLE BONDS

1. Hydroxylation of the Nickel Complexes of Octadehydrocorrins



The octadehydrocorrin macroring contains 10 double bonds, 6 of which are involved in a system of conjugated C=C and C=N bonds constituting the chromophore, which is characteristic of both octadehydrocorrin and corrins, while the four β,β-double bonds are cross-conjugated in relation to the chromophore and are characteristic only of octadehydrocorrins.

One of the few reactions involving the β,β-double bonds is hydroxylation of the metal complexes of octadehydrocorrin on treatment with OsO_4.[61-64] The hydroxylation of the nickel complexes of decamethyl- and 1,19-diethoxycarbonyl-octamethyl-octadehydrocorrins[62,65] as well as the nickel and cobalt complexes of octadehydrocorrins containing the $C_6H_5CH_2O$ substituents in the 3- and 17-positions[63] results in the formation of a mixture of the corresponding 7,8-dihydroxy-derivatives (LX) and 7,8,12,13-tetrahydroxy-derivatives (LXI), i.e. the *B* and *C* rings are involved in the reaction in the first place. The composition of the mixture of compounds (LX) and (LXI) depends on the amount of OsO_4.[62] The reaction of OsO_4 with the nickel complexes of octadehydrocorrins containing the residues of acetic and propionic acids in the *A* and *D* rings proceeds analogously[64]. After the hydroxylation of octadehydrocorrins with free 2- and 18-positions, 2,3,7,8,12,13-hexahydroxycorrin (LXII) and 2,3,7,8,12,13,17,18-tetrahydroxycorrin (LXIII) were isolated in addition to the 7,8-diols and 7,8,12,13-tetraols[61,62,65]. As a consequence of the *trans*-disposition of the 1,19-substituents and the *cis*-hydroxylation, which takes place on either side of the plane of the octadehydrocorrin molecule, a mixture of diastereoisomeric racemates is formed.



(LX)

(LXI)

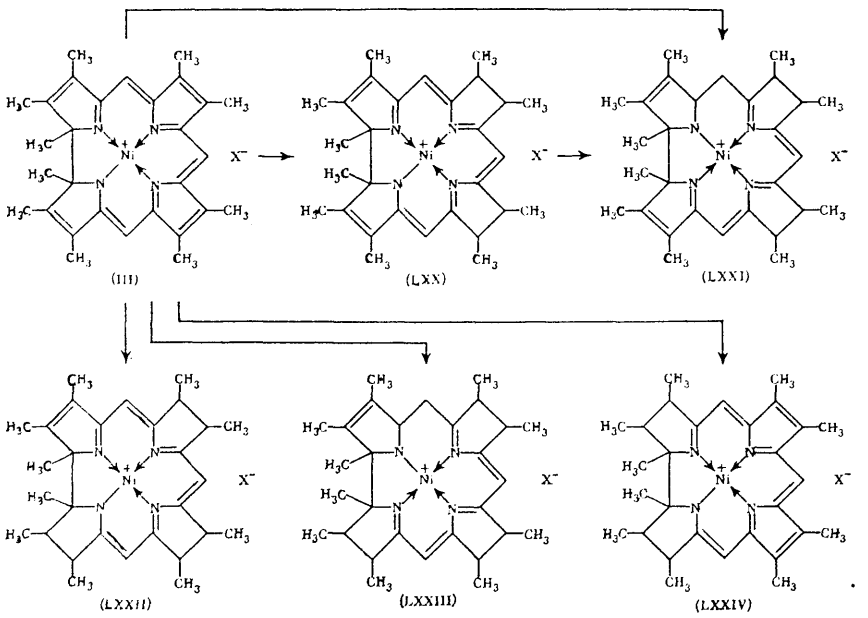
(LXII)

On treatment with H_2SO_4, the β-dihydroxy-derivatives of corrinoids undergo the pinacol rearrangement, which leads to the formation of ketones containing the *gem*-dimethyl group. The diol (LX) is converted into a mixture of the two monomers (LXIV) and (LXV), which could not be separated[64]. After the pinacol rearrangement of the tetraol (LXI), the two diketones (LXVI) and (LXVII) were isolated. Brief treatment of tetradehydrocorrin having OH groups in the *A* and *D* rings with H_2SO_4 led to the isolation of only the hydroxyketone (LXVI, R′ = OH), in which the OH groups of the *A* and *D* ring are retained[63]. Of the three possible products of the rearrangement of each tetraol (LXI), it was possible to isolate only the diketones (LXVI) and (LXVII):[64]

(LXIII)

(LXIV)

(LXV)

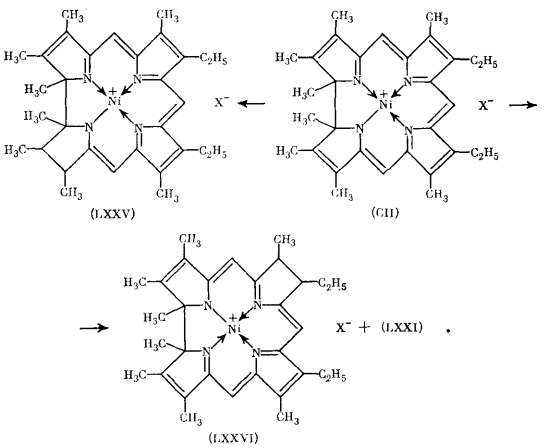


(LXVI)

(LXVII)

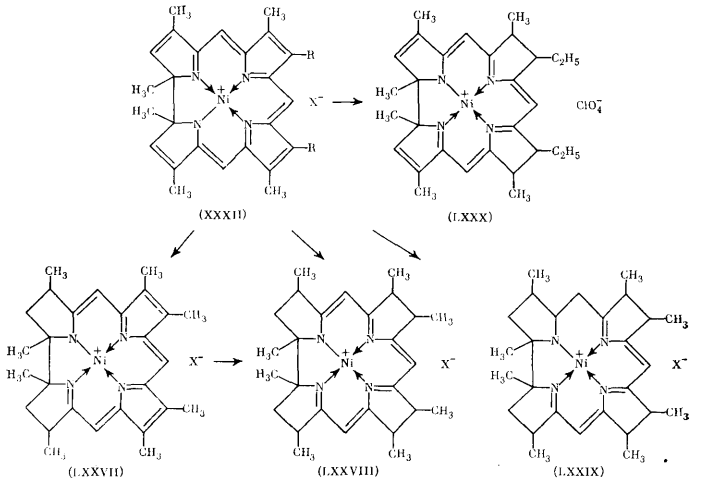
(LXVIII)

(LXIX)



The products of the pinacol rearrangement, namely the mono- and di-ketones, can again undergo the hydroxylation reaction. After treatment with OsO_4, the mixture of the monoketones (LXIV) and (LXV) is converted into a mixture of the dihydroxyketones (LXVIII) and (LXIX). The amount of the dihydroxyketone (LXVIII) is three times greater than that of the dihydroxyketone (LXIX), apparently because the two CH_3 groups in the 8-position hinder the hydroxylation of the *C* ring[65]. The structures of the dihydroxyketones were confirmed by the products of their pinacol rearrangement: compound (LXVIII) is converted into a mixture of the diketones (LXVI) and (LXVII), while compound (LXIX) gives rise to only the diketone (LXVI).[61,62,65]

2. Hydrogenation of the Metal Complexes of Octadehydrocorrins

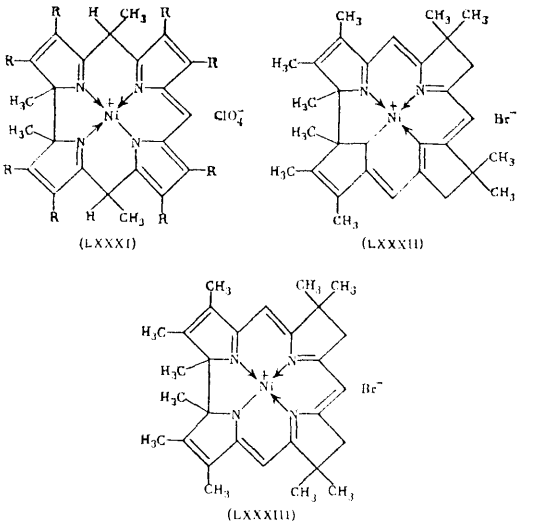


The second reaction involving the β,β-double bonds of the octadehydrocorrin macroring is hydrogenation, which leads under different conditions to a series of macrocylic compounds intermediate between corrins and octadehydrocorrins as regards degree of oxidation. The course of the hydrogenation reaction is greatly influenced by the β-substituents[66]. Hydrogenation of the metal complexes of octadehydrocorrins having alkyl groups in the 1-, 2-, 18-, and 19-positions involves in the first place the β,β-double bonds of the *B* and *C* rings. In the presence of Raney nickel at 100 °C and 100 atm, the nickel complex of decamethyloctadehydrocorrin is converted into the nickel complex of *AD*-tetradehydrocorrin(LXX),[66,67] which is also formed after reduction of the complex (III) in boiling acetic acid[67]. Further reduction of the *AD*-tetradehydrocorrin or the complex (III) over the 10% Pd/C catalyst (20 °C, 100 atm, 26 h) involves the addition of H_2 in the 4- and 5-positions of the macroring with formation of the complex (LXXI).[66] Vigorous hydrogenation of the complex (III) leads to the formation of *A*-hydrocorrin (LXXII) in which there is a β,β-double bond only in the *A* ring[67]. The most highly hydrogenated product is isocorrin (LXXIII), obtained on hydrogenation of the complex (III) over Raney nickel at 160 °C and 120 atm.[66]

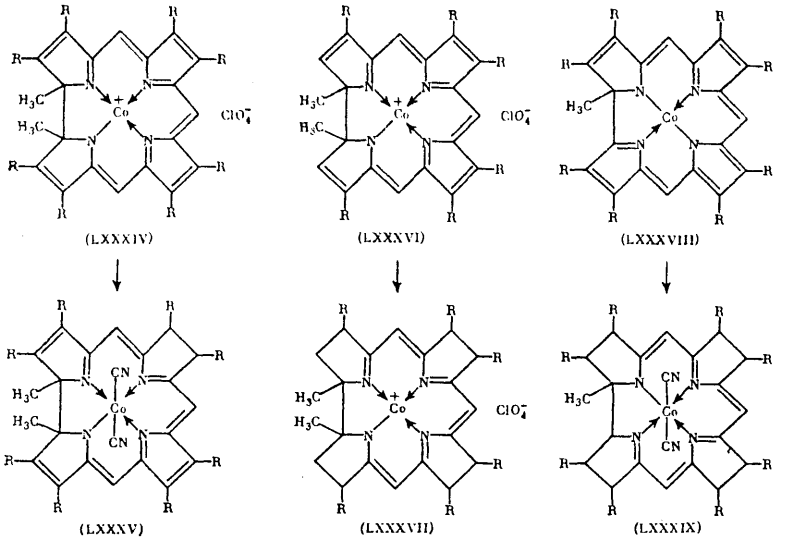
The selective hydrogenation of the *B* and *C* rings in β-substituted octadehydrocorrins is a consequence of the steric hindrance generated by the substituents in the 1-, 2-, 18-, and 19-positions. However, the hydrogenation of the complex (III) over the 10% Pd/C catalyst in acetic acid leads to the reduction of the β,β-double bonds of the *A* and *D* rings and the formation of *BC*-tetradehydrocorrin (LXXIV).[66] The replacement of the CH_3 substituents in the 8- and 12-positions by the more bulky C_2H_5 groups changes the mode of reaction: the hydrogenation of the nickel complex of 8,12-diethyloctamethyloctadehydrocorrin (CII) over Raney nickel at 160 °C and 120 atm results in the formation of the nickel complex of *ABC*-hexadehydrocorrin (LXXV).[66] The hydrogenation of the octadehydrocorrin (CII) over the 5% $Pd/BaSO_4$ catalyst (20 °C, 100 atm, 5 days) leads to the formation of a mixture of the hexadehydrocorrin (LXXVI) and the complex (LXXI).[66] After the hydrogenation of the octadehydrocorrin (CII) or *AD*-tetradehydrocorrin under severe conditions, the didehydrocorrin (LXXII) was isolated[66]:

In the hydrogenation of the nickel complexes of octadehydrocorrins unsubstituted in the 2- and 18-positions [compound (XXXII)] and in the 2-, 3-, 17-, and 18-positions, H_2 adds in the first place to the β,β-double bonds of the *A* and *D* rings: the hydrogenation of the complex (XXXII) (20 °C, 50 atm) leads to the formation of a mixture of *BC*-tetradehydrocorrin (LXXVII) and the corrin (LXXVIII), while under more severe conditions the corrin (LXXVIII) was isolated with an admixture of the 4,5-dihydrocorrin (LXXIX). A mixture of corrin and 4,5-dihydrocorrin was also obtained on hydrogenation of the *BC*-tetradehydrocorrin (LXXVII).[66] The hydrogenation of the complex (XXXII) at 100 °C leads to the formation of *AD*-tetradehydrocorrin (LXXX),[2] while hydrogenation over Raney nickel at 100 °C and 100 atm yielded corrins[67,68]. The hydrogenation of the

nickel complex of 1,7,8,12,13,19-hexamethyloctadehydrocorrin over Raney nickel (20 °C, 50 atm) leads to the formation of the nickel complex of *BC*-tetradehydrocorrin[66].



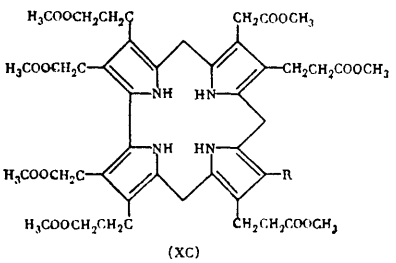
All the products of the hydrogenation of the nickel complexes of corrinoids containing 6 or 8 double bonds are capable of being dehydrogenated in the *B* and *C* rings in air and in the presence of basic catalysts[69]. The nickel complexes of corrins with unsubstituted 2-, and 18-positions[67,68] or 2-, 3-, 17-, and 18-positions[66,67] are converted into *BC*-tetradehydrocorrins, while the nickel complexes of *AD*-tetradehydrocorrins are converted into complexes of octadehydrocorrins[66,67]. The preferential dehydrogenation of the *B* and *C* rings is probably due to the steric hindrance in the region of the angular CH_3 groups or reflects the greatest acidity of the protons in the *B* and *C* rings compared with the acidity of those in the *A* and *D* rings.



In the hydrogenation over platinum of the nickel complex of β-alkyloctadehydrocorrin containing CH_3 groups in the 5- and 15-positions, one mole of H_2 adds on and an unstable amorphous orange product (LXXXI),[15] whose electronic spectrum resembles that of the nickel complex of dipyrrolylmethene, is formed.

The hydrogenation of the nickel complex of 7,8,12,13-tetrahydroxyoctadehydrocorrin (LXI, R′ = H) over the Pd/C catalyst leads to a corrin, while the hydrogenation under the same conditions of the tetraol containing the $C_6H_5CH_2O$ substituents in the 3- and 17-positions results only in the elimination of the $C_6H_5CH_2$ groups.[63]

The hydrogenation of the diketones (LXVI) and (LXVII) over Raney nickel at 150 °C and 10 atm involves the CO groups and leads to the tetradehydrocorrins (LXXXII) and (LXXXIII).[65]

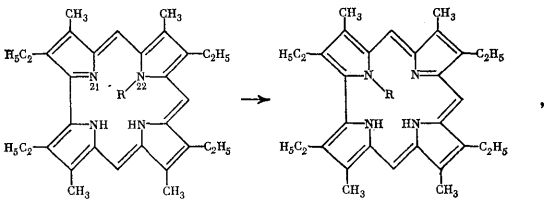


The hydrogenation of the cobalt complexes of octadehydrocorrin takes place analogously. The hydrogenation of the cobalt complex of octa-alkyl-1,19-dimethyloctadehydrocorrin (LXXIV) over Raney nickel at 100 °C and 100 atm results in the formation, after treatment with NaCN, of the dicyanocobalt complex of *AD*-tetradehydrocorrin (LXXXV),[15] which has also been obtained by the hydrogenation of the complex (LXXXIV) in methanol containing acetic acid over the 10% Pd/C catalyst at 80–82 °C and 85 atm.[70] The cobalt complexes of octadehydrocorrins (LXXXVI) with unsubstituted 2- and 18-position are converted into the corrins (LXXXVII) on hydrogenation at 175 °C and 100 atm,[38,68] while the

dicyanocobalt complex of corrin (LXXXIX), whose electronic spectrum is identical with that of cyanocobaltamin, was obtained in the form of an amorphous substance from the cobalt complex of 1-methyloctadehydrocorrin (LXXXVIII) under the same conditions after treating the hydrogenation product with CN^- ions[38].

When β-substituted octadehydrocorrins are hydrogenated, asymmetric carbon atoms are produced and the reaction products are mixtures of stereoisomers. The hydrogenation of the nickel complex of 1,19-dimethyloctadehydrocorrin (Raney nickel, 20 °C, and 25 atm or 160 °C and 100 atm), which has no β-substituents, led to another corrin complex[71,72]. The nickel complex of 1,19-dimethyloctadehydrocorrin is converted into crystalline corrin already at 20 °C and atmospheric H_2 pressure after 1 h.[72] The nickel complex of octadehydrocorrin acts itself as the catalyst of the hydrogenation proper: when a solution of the nickel complex of octadehydrocorrin is heated at 160 °C and 80–100 atm for 4 h without a catalyst, corrin is formed. The hydrogenation of the cobalt complex of 1,19-dimethyloctadehydrocorrin at 20 °C and 25 atm leads to a mixture of dicyanocobalt complexes of corrin and 4,5-dihydrocorrin after treatment of the product with CN^- ions; in the absence of treatment with cyanide ions, the perchlorate of the cobalt complex of corrin was isolated[72].

(XC)

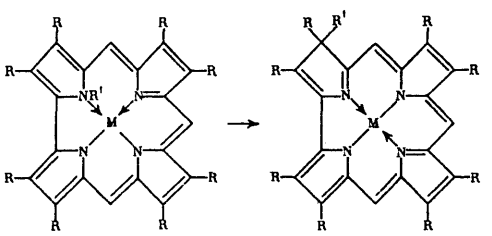


On hydrogenation over platinum, octa-alkylcorrole is converted into an unstable product, which is rapidly reoxidised in air to the initial corrole[3]. The hydrogenation of corroles containing the CH_3OOCCH_2 and $CH_3OOCCH_2CH_2$ groups in the β-positions over platinum oxide leads to colourless readily oxidisable crystalline corrologens (XC).[41]

VII. REARRANGEMENTS OF CORRINOIDS AND THEIR METAL COMPLEXES

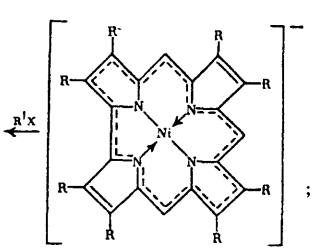
The metal complexes of 1-alkyl- and 1,19-dialkyl-octadehydrocorrins as well as the metal complexes and the free bases of *N*-alkylcorroles undergo thermal rearrangements.

1. The Rearrangements of Corroles and Their Metal Complexes



When *N*-alkylcorroles and their metal complexes are heated, the *N*-alkyl groups migrate to another N atom or to the 3-position in the macroring. N(22)-Methyl- and N(22)-allylcorroles (LI, a and b) are converted into N(21)-methyl and N(21)-allyl-corroles (XIX, a and b) on refluxing in toluene[19,21,28]. The thermal isomerisation of N(22)-allylcorrole in cumene[28] and the isomerisation of N(22)-3,3-dimethylallylcorrole (LIc) [19,28] showed that the migration proceeds via a free-radical mechanism.

(LI a–c) (XIX a–c)

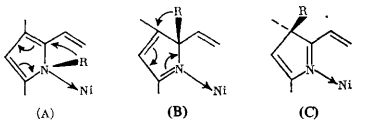


(a) R = CH_3; (b) R = $CH_2CH{=}CH_2$; (c) R = $CH_2CH{=}C(CH_3)_2$.

Heating of the nickel complexes of N(21)-alkylcorroles in chlorobenzene (130 °C, 90 min) leads to the formation of complexes of 3,3-dialkylcorroles (LIII).[9,21,23] The steric factor plays a major role in these reactions; migration of bulky alkyl substituents is the faster[23]. Thus N(21)-ethyl- and N(21)-propyl-corroles rearrange in boiling benzene, while the reaction of the Ni-corrole anion (XII) with $CH_2{=}CHCH_2Br$ or iso-C_4H_9I leads immediately to the nickel complex of the 3,3-disubstituted corrole[3,21,23]. The driving force of this arrangement is apparently the formation of a strong C–C σ-bond instead of the weak C–N σ-bond as well as the decrease of steric strain and the gain of the energy of stabilisation by the ligand field[21].

(V) (LIII)

M = Ni, Pd .

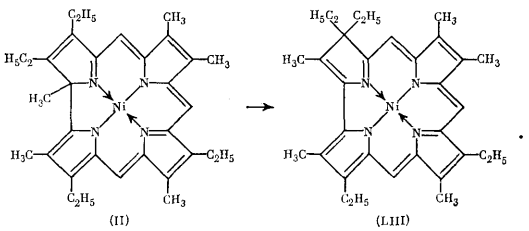


(XII)

The thermal arrangement of the metal complexes of *N*-alkylcorroles can proceed either via two [1,5]-sigmatropic shifts (A) → (B) → (C) or via the metal-[1,3]-sigmatropic shift (A) → (C). A choice between these two possibilities has not been made but preference has been given to the first possibility[9].

The rearrangement of the palladium complexes of N(21)-alkylcorroles takes place analogously; on heating in o-$C_6H_4Cl_2$, they are converted into complexes of 3,3-dialkylcorroles (LII).[27,28] The temperature of the rearrangements of the palladium complexes is higher than that of the nickel complexes probably as a consequence of the steric hindrance due to the large bulk of palladium.

The copper complexes of N(21)-ethylcorroles are converted into the complexes of *N*-unsubstituted corroles, while the complexes of N(22)-ethylcorroles are cleaved[28].

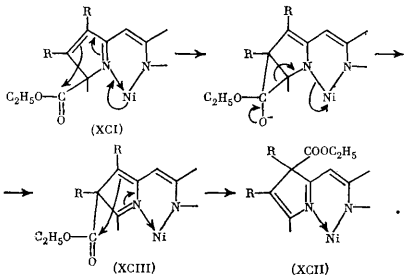


(A) (B) (C)

2. The Rearrangement of the Nickel Complexes of 1-Substituted Octadehydrocorrins

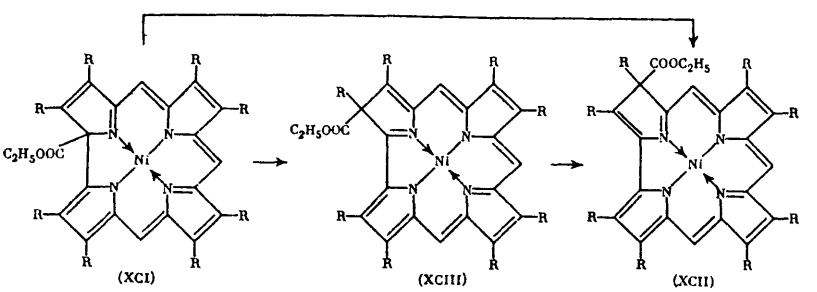
The thermal rearrangements of the metal complexes of 1-substituted and 1,19-disubstituted octadehydrocorrins take place with an alteration in the type of the tetrapyrrole macroring and the formation of more conjugated compounds.

On refluxing in o-$C_6H_4Cl_2$, the nickel(II) complexes of 1-methyloctadehydrocorrins are converted into the complexes of 3,3-dialkylcorroles (LIII).[18,21,29,56] The structure of the nickel complex of 2,2-dialkylcorrole was initially attributed to the thermal isomerisation product, since the nickel complex of 2-methylcorrole is formed in the case of 1-methyloctadehydrocorrin with an unsubstituted 2-position (XVI):[18,56]



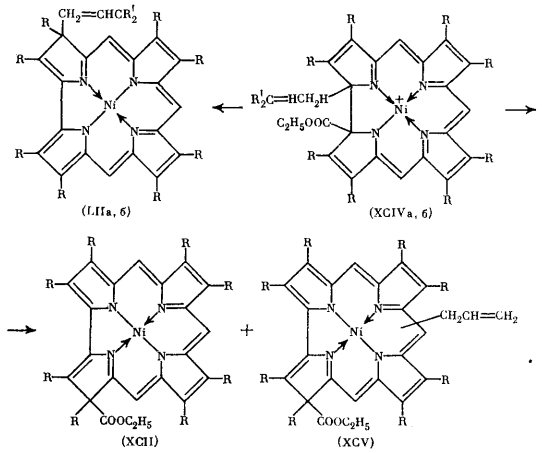
(II) (LIII)

However, it was found that the migration of the substituent from the 1-position takes place in two stages: initially to the 2-position with formation of 2,2-dialkylcorrole, which is followed by the shift of the substituent with the greater capacity for migration to the 3-position[21,29]. This sequence of reactions was demonstrated in the transformation of the nickel complex of 2,3,12,17-tetraethyl-1,7,8,13,18-pentamethyloctadehydrocorrin into the nickel complex of 3,3-diethylcorrole, whose formation is possible when 2-ethyl-2-methylcorrole is formed initially and then 3,3-diethylcorrole is produced as a consequence of the greater mobility of the ethyl group[29]. The migration of the angular CH_3 group from the 1-position to the 3-position can be regarded as a sigmatropic shift[73]. The capacity of substituents for migration varies in the sequence $CH_2{=}CHCH_2 > COOC_2H_5 > C_2H_5 > CH_3$.[21,29] The mechanism of the rearrangement of the nickel complexes of 1-substituted octadehydrocorrins was confirmed experimentally in the thermolysis of the nickel complex of 1-ethoxycarbonyloctadehydrocorrin (XCI), which is converted into the complex of 3-alkyl-3-ethoxycarbonylcorrole (XCII) on heating in boiling chlorobenzene, while on standing in the solid state (20 °C, 2 days) or in CH_2Cl_2 (12 h) in the dark it is converted into the complex (XCIII) containing the $COOC_2H_5$ group in the 2-position; the latter rearranges to the complex of 3,3-disubstituted corrole (XCII) on heating for 1 h in chlorobenzene[59].



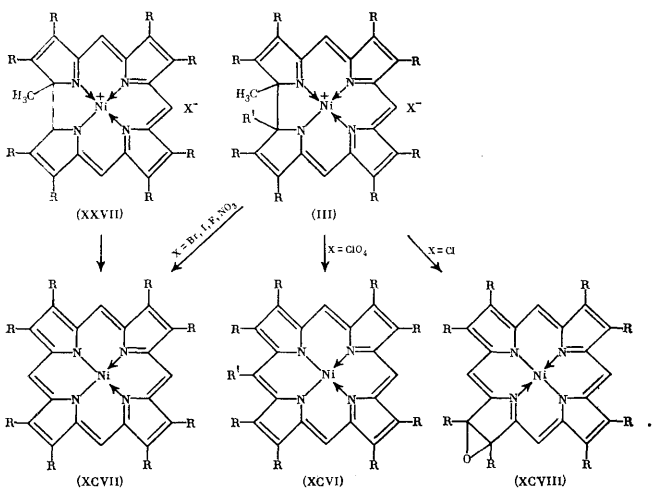
3. Rearrangements of the Metal Complexes of 1,19-Disubstituted Octadehydrocorrins

The metal complexes of 1,19-disubstituted octadehydrocorrins rearrange either into porphyrin complexes or into corrole complexes depending on the type of the angular substituents. The nickel complexes of 1,19-dialkyloctadehydrocorrins are converted into porphyrin complexes, while the nickel complexes of 1,19-diethoxycarbonyl- and 19-allyl-1-ethoxycarbonyl-octadehydrocorrins are converted into complexes of 3,3-disubstituted corroles. When the nickel complexes of octa-alkyl-1,19-diethoxycarbonyloctadehydrocorrins are heated in chlorobenzene, the complexes of 3-alkyl-3-ethoxycarbonylcorroles (XCII) are formed[20,56], the first stage involving the elimination of one angular $COOC_2H_5$ group and the formation of the nickel of 1-ethoxycarbonyloctadehydrocorrin (XCI), which was isolated when 1,19-diethoxycarbonyloctadehydrocorrin was treated cautiously with aqueous alkali. When the complex is heated in chlorobenzene, compound (XCII) is formed[29]. The migration of the ester group is either a [1,5]-sigmatropic shift analogous to the [1,5]-alkyl migration or the reaction mechanism involves the participation of the nickel atom and constitutes the sequence (XCI) → (XCIII) → (XCII).

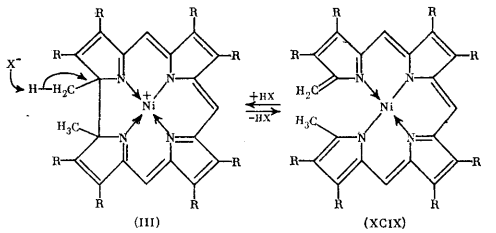


(XCI) (XCIII) (XCII)

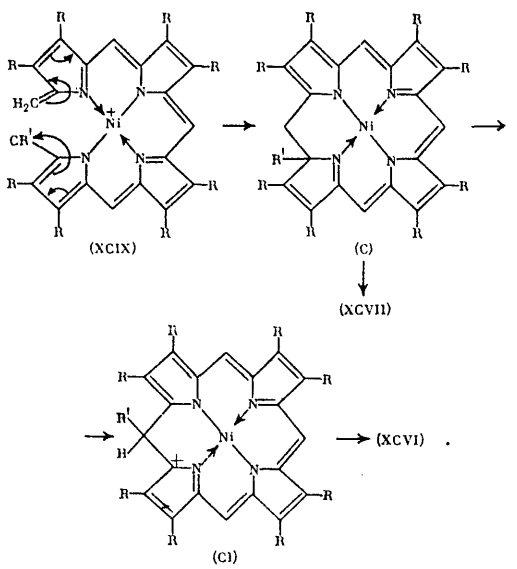
The rearrangement of the nickel complex of octa-alkyl-19-allyl-1-ethoxycarbonyloctadehydrocorrin (XCIVa, R′ = H) takes place analogously; on treatment with NaOH, this compound is converted into the complex of 3-alkyl-3-allylcorrole (LIIa, R′ = H).[29] The rearrangement of the nickel complex of 19-ethoxycarbonyl-1-dimethylallyloctadehydrocorrin (XCIVb, R′ = CH_3) leads to the formation of the nickel complex of 3-ethyl-3-dimethylallylcorrole (LIIb. R′ = CH_3), i.e. takes place without the inversion of the



(XCI) (XCIII) (XCII)



allyl substituent[42]. It is therefore probable that the allyl group migrates via two [1,5]-sigmatropic shifts C(1) → C(2) → C(3), as in the migration of the ester group. The thermal rearrangement of the nickel complex of 19-allyl-1-ethoxycarbonyloctadehydrocorrin (XCIVa) at 180 °C leads to the formation of a mixture of the complexes of 3-ethoxycarbonyl-3-methylcorrole (XCII) and the *meso*-allyl-3-ethoxycarbonylcorrole (XCV).[29]

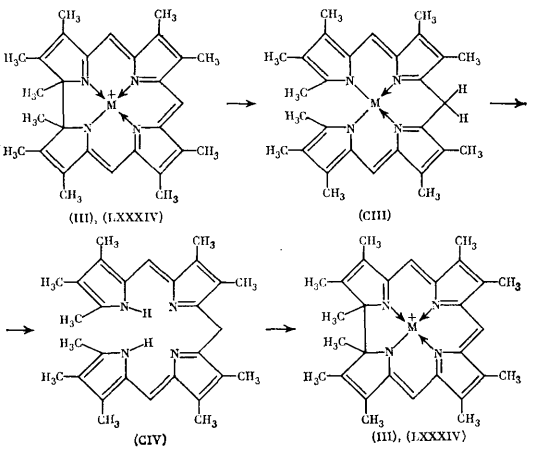


The thermal rearrangement of the salts of the nickel complexes of 1,19-dialkyloctadehydrocorrins take place with expansion of the macroring and consists in the conversion of octadehydrocorrins into porphyrins[21,24,43,74]. The pathway followed in this reaction depends on the nature of the anion: the perchlorates give rise to *meso*-alkylporphyrins (XCVI), while the iodides, bromides, fluorides, and nitrates produce the *meso*-unsubstituted porphyrins (XCVII); the third type of rearrangement is that of chlorides into 2,3-epoxy-5-methylchlorin (XCVIII).[43,74] The salts of the nickel complexes of 1-methyloctadehydrocorrins are converted into *meso*-unsubstituted porphyrins.

The first stage of the octadehydrocorrin–porphyrin rearrangement involves the elimination of a proton from one of the angular groups on attack by the anion, which acts as a base. This entails the dissociation of the C(1)–C(19) bond in the macroring of the type of the Hoffman elimination with formation of a neutral complex of bilatriene (XCIX).[24] The complex (XCIX), containing the benzylidene group instead of the methylene group, was isolated in the rearrangement of the bromide of the nickel complex of 19-benzyl-1-methyloctadehydrocorrin[74]. One of the angular groups, usually a methyl group, is a source of the fourth *meso*-carbon atom in the formation of the intermediate complex (C), which undergoes the following transformations: in the case of the I^-, Br^-, F^-, and NO_3^- anions, a second angular group is split off and the nickel complex of the *meso*-unsubstituted porphyrin is formed.

It has been shown that in the thermolysis of the iodide [of the nickel complex] of octa-alkyl-1,19-dimethyloctadehydrocorrin the angular CH_3 group is split off in the form of CH_3I, which suggests that the anion eliminates the angular group on nucleophilic attack[74]. In the case of the ClO_4^- anion, which is a weak nucleophile, the 19-alkyl group migrates and the *meso*-substituted porphyrin is formed. Since the ClO_4^- anion has oxidising properties, the rearrangement of the perchlorates apparently proceeds via the cationic form (CI), which is converted after oxidation into the porphyrin (XCVI).[74] In the thermolysis of the perchlorates of the nickel complexes of octadehydrocorrins containing the CH_3, C_2H_5, C_3H_7, C_4H_9, C_5H_{11}, $CH_2CH{=}CH_2$, and $COOC_2H_5$ groups in the 19-position, the substituents migrate without the isomerisation of the carbon skeleton with the exception of the allyl group, which is converted into the propenyl group[74]. Only the *meso*-alkylporphyrins are formed in the rearrangement of the perchlorates of the nickel complexes of 1,19-dialkyloctadehydrocorrins with unsubstituted 2- and 18-positions, i.e. there is no migration of the alkyl group to a neighbouring free β-position[74].

The thermolysis of the chlorides of the nickel complexes of 1,19-dimethyloctadehydrocorrins leads to the formation of complexes of 2,3-epoxy-5-methylchlorins (XCVIII) and *meso*-unsubstituted porphyrins, i.e. one angular CH_3 group migrates to the *meso*-position and the β,β-double bond of the neighbouring pyrrole ring is oxidised. Since the nickel complexes of porphyrins are insensitive to this type of oxidation by air, the substrate must be a non-aromatic product, for example, compound (XCIX) or the cyclic derivative (C).[43]



The presence of substituents in the *meso*-positions of 1,19-dialkyloctadehydrocorrins does not influence the rearrangement. For example, the iodides of the nickel complexes of octa-alkyl-5-cyano-1,19-dimethyloctadehydrocorrin and octa-alkyl-5,15-dicyano-1,19-dimethyloctadehydrocorrin are converted into the nickel complexes of the corresponding 5-cyano- and 5,15-dicyano-porphyrins on thermolysis[43].

The thermolysis of the cobalt complexes of octa-alkyl-1,19-dimethyloctadehydrocorrins leads to the formation of the corresponding cobalt complexes of porphyrins[75].

4. The Reductive Opening of the Macroring of the Metal Complexes of Octadehydrocorrins

The metal complexes of octadehydrocorrins are extremely stable. The cobalt and nickel atoms cannot be removed from these compounds without disrupting the macroring[75].

The interconversions of the nickel and cobalt complexes of the octadehydrocorrins (III) and (LXXXIV) have been achieved by treatment with reducing agents, which leads to the opening of the macroring between the C(1) and C(19) atoms with formation of the metal complexes of bilatrienes or the tautomeric biladienes, which are readily demetallated and can be recyclised to the metal complexes of octadehydrocorrins on treatment with $(CH_3COO)_2Ni$ or $(CH_3COO)_2Co$ in air.

The following mechanism for this migration has been proposed[79]: the metal complex of octadehydrocorrin, for example, the nickel complex (III), combines with two electrons under reductive conditions (in the presence of H_2S or $Na_2S_2O_4$) and is converted into a negatively charged complex, which, after the dissociation of the C(1)–C(19) bond, into the metal complex of 22,24-dihydrobilatriene and the latter is converted, after protonation at C(10), into a neutral complex of biladiene (CIII). On treatment with CF_3COOH, HCl, or even H_2S, the latter is demetallated and the resulting biladiene (CIV) can be reconverted into the metal complex of the octadehydrocorrin on treatment with nickel or cobalt acetate in the presence of atmospheric oxygen. The cobalt complexes of octadehydrocorrins are much more reactive than the corresponding nickel complexes; the opening of their rings takes place under very mild conditions (H_2S, room temperature)[76] and on treatment with HBr these compounds are converted into the monohydrobromides of bilatrienes-*abc*.[75]

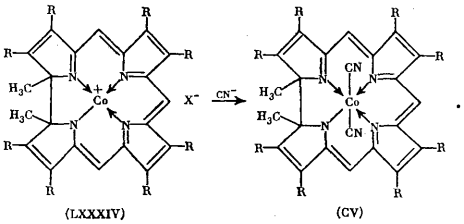
The C(1)–C(19) bond is ruptured also on hydrogenation of the nickel complex of 3,17-benzyloxyoctadehydrocorrin over the 10% Pd/C catalyst, the resulting metal complex of biladiene recyclising in air at 20 °C.[63]

The principle of the reductive ring opening has been used to obtain the cobalt complex of 7,8-dihydroxy-, 7,8,12,13-tetrahydroxy-, 8.13-dioxo-, and 8,12-dioxo-decamethyloctadehydrocorrins, which could not be obtained by another procedure[76,77].

The stability of the nickel complexes of the tetrapyrrole macrorings with respect to reducing agents increases on successive saturation of the β,β-double bonds in the *B* and *C* rings:

$$(LXXXIV) < (III) < (LX) < (LXVI) = (LXVII) < (LXI) \quad .$$

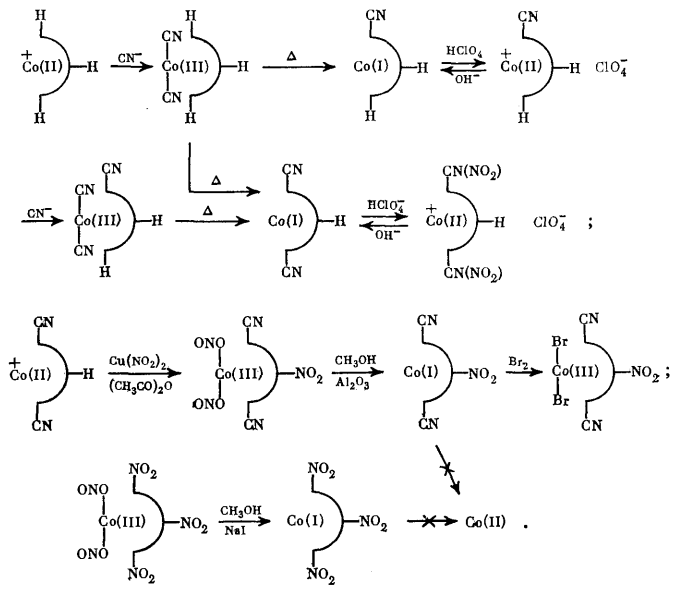
The cobalt complexes are so labile that substitution on the periphery of the macroring does not play an appreciable role.



VIII. THE CHANGE IN THE OXIDATION AND COORDINATION STATES OF THE METALS IN THE METAL COMPLEXES OF CORROLES AND OCTADEHYDROCORRINS

1. The Redox Reactions of Corrinoid Compounds

The oxidation-reduction properties of vitamin B_{12} and its derivatives have been the subject of lively interest, since the oxidation state of the cobalt atom of cobalamin changes in the enzymatic B_{12}-dependent reaction[78].



In recent years octadehydrocorrins have attracted attention as models of viatmin B_{12}. Ready interconversion of different oxidation states of cobalt takes place in the cobalt complexes of octadehydrocorrins (LXXXIV), in contrast to the stability of the bivalent nickel in the octadehydrocorrin complexes.

When the cobalt(II) complex of octa-alkyl-1,19-dimethyl-octadehydrocorrin is treated with a cyanide, the CN group does not enter the macroring. Instead a green diamagnetic dicyanide (CV) is formed, where two CN groups are located in the axial positions at the Co atom, which is oxidised to the tervalent state[15,63,75,79,80]. When cobalt(II) complexes of octadehydrocorrins are treated with $Cu(NO_3)_2$ in acetic anhydride, simultaneous nitration of the *meso*-positions of the macroring and the formation of a cobalt(III) complex with the ONO axial ligand take place; the *meso*-unsubstituted octadehydrocorrin is then converted into a mixture of 5,15(10)-dinitro- and 5,10,15-trinitro-octadehydrocorrins, while 5,15-dicyano-octadehydrocorrin is converted into 5,15-dicyano-10-nitro-octadehydrocorrin. On treatment with methanol, they are converted into salts of the cobalt(II) complexes of the corresponding octadehydrocorrins[75,79].

Cobalt(III) complexes of octadehydrocorrins can be obtained also from the cobalt(I) complexes. Treatment of the cobalt(I) complexes of 5,15-dicyano-10-nitro- and 5,10,15-trinitro-octadehydrocorrins with Br_2 leads to the formation of the dibromides of the cobalt(III) complexes of the corresponding octadehydrocorrins[75].

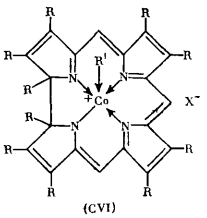
Cobalt(I) complexes of octadehydrocorrins are formed from both the cobalt(II) complexes[75] and from the cobalt(III) complexes[75,79]. When salts of the cobalt(II) complexes of monocyano- and dicyano-octadehydrocorrins were treated with alkali, neutral cobalt(I) complexes were obtained. This reaction is reversible; on treatment with $HClO_4$, the cobalt(I) complexes are converted into salts of the cobalt(II) complexes. The introduction of three electron-accepting substituents greatly stabilises the cobalt(I) complexes, which do not change on treatment with $HClO_4$. The thermolysis of the dicyanide of the cobalt(III) complex of the *meso*-unsubsituted octadehydrocorrin leads to the cobalt(I) complex of 5-cyano- and 5,15-dicyano-octadehydrocorrins, the latter being formed also on heating the dicyanide of the cobalt(III) complex of 5-cyano-octadehydrocorrin. The migration of the CN group from the Co atom to a C atom is probably an intermolecular process[75]. Treatment of the dinitrites of the cobalt(III) complexes of tri-*meso*-substituted octadehydrocorrins with NaI or Al_2O_3 in methanol also leads to the completion of the cobalt(I) complexes. The interconversions of the cobalt complexes of octadehydrocorrins can be represented schematically as follows:

The reduction of the cobalt(II) complexes of octadehydrocorrins on treatment with NaOH in aprotic solvents or with KOH in the form of a complex with a cyclic polyether also leads to the formation of cobalt(I) complexes, which are slowly reoxidised by atmospheric oxygen to the initial compounds[81]. It has been suggested[81] that an electron is transferred from the OH^- anion, which is unsolvated, to the cobalt(II) complex of octadehydrocorrin; in the reduction of the cobalt(II) complexes to the cobalt(I) complexes on treatment with $(C_2H_5)_3N$, the electron transfer from the amine to the cobalt(II) complex of octadehydrocorrin takes place via an outer-sphere mechanism. The reaction of the cobalt(II) complex of 1,19-diethoxycarbonyloctamethyloctadehydrocorrin (CVIIIb) with $NaBH_4$ in DMF also leads to a cobalt(I) complex[82]. The cobalt(I) complexes of octadehydrocorrins are stable, remaining unchanged in air for several hours. Their treatment with pyridine or triphenylphosphine does not alter the electronic spectrum[79]. Treatment of the cobalt(I) complexes with $FeCl_3$ or I_2 entails their instantaneous conversion into the cobalt(II) complexes[4,81].

The reduction of the nickel(II) and cobalt(II) complexes of octa-alkyl-1,19-diethoxycarbonyloctadehydrocorrins (CVIIIb) in THF has been studied with the aid of optical spectra and EPR.[14] The formation of one- and two-electron reduction products was observed in both cases. The product of the one-electron reduction of the nickel complex is a very stable free radical, formed on addition of one electron to the lowest unoccupied π orbital of the ligand. The first reduction potential of the initial cation in DMF (−0.30 V) indicates the stability of the radical and corresponds to one-electron reduction. The one-electron reduction of the cobalt(II) complex leads to the formation of a neutral cobalt(I) complex, i.e. in contrast to the nickel(II) complexes, the electron adds to the central metal ion, whose oxidation state changes. When reduced nickel and cobalt complexes of octadehydrocorrins are treated with oxidants (I_2, $FeCl_3$), the initial compounds are quantitatively regenerated[14].

Further reduction of the cobalt(I) complex of octadehydrocorrin and of the free radical of the nickel(II) complex also proceeds as a one-electron process, which leads in both cases to complexes of the bivalent metals with two additional electrons in the ligand π orbital. The oxidation of these substances in air results in the regeneration of approximately 90% of the products of the first reduction stage. Both nickel and cobalt complexes of octadehydrocorrins can be reduced further, but the compounds formed were not identified and the products of the preceding reduction stage cannot be regenerated on oxidation in air.

The reduction of the cobalt complexes of octadehydrocorrins constitutes a series in which the oxidation state of the central cobalt ion changes as follows: (II) → (I) → (II) with consecutive addition of one electron, and the final change from cobalt(I) to cobalt(II) must be a result of electron transfer from the cobalt(I) ion to the ligand together with competitive reduction of the ligand[14].



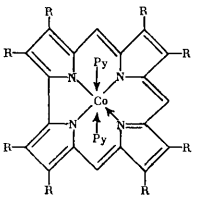
The electrolytic reduction of salts of the cobalt(II) complexes of 5,15-dicyano- and 5,15-dinitro-octadehydrocorrins at a platinum electrode leads to the formation of stable cobalt(I) complexes[73,79]. The reduction of the cobalt complexes of mono- and di-substituted octadehydrocorrins as well as unsubstituted octadehydrocorrins is a reversible one-electron process. The cobalt(I) complexes are stabilised with respect to oxidation in the presence of strong electron-accepting substituents in the macroring.

The reduction of the cobalt(III) complexes of corroles (XXI) with an Na film in THF *in vacuo* and also with $NaBH_4$ or $(C_4H_9)_4NOH$ in DMF leads to the formation of Co(II)-corrole anions (XII), which are reconverted in air into the initial cobalt(III) complexes of corroles[13,31]. The first reduction potential $E_{1/2} = -0.26$ eV. The enhancement of the electron-donating properties of the axial ligands hinders the reduction of the central cobalt ion[30]. When pyridine is added to solutions of the square-planar or pyramidal cobalt(III) complexes of corroles, $E_{1/2}$ becomes −0.54 eV in all cases as a consequence of the formation of the octahedral dipyridine complex[30]. According to other data[13], the potential of the reduction of Co(III)-corrole to the Co(II)-derivative is −0.34 eV in DMF and −0.47 eV in the presence of pyridine. All the redox processes are of the one-electron type and are

reversible[30], while the oxidation of the corrole bases is a quasi-reversible process[83].

2. The Coordination Properties of the Cobalt Atom in Complexes of Corrinoids

The central cobalt atom in the cobalt(II) complexes of octadehydrocorrins can be both tetracoordinate and pentacoordinate. The cobalt(II) complexes of octadehydrocorrins readily coordinate in the axial position one pyridine molecule[13] and also CH_3OH and DMF [13,14] with formation of pentacoordinate square-planar cobalt(II) complexes of octadehydrocorrin (CVI), [13,81] the unpaired electron being delocalised from the d_{z^2} orbital of the cobalt(II) atom over the coordinate bond between cobalt and the nitrogen atom of pyridine[13,82].



(CVI)

When pyridine and polyvinylpyridine are coordinated to the cobalt(II) complexes of 2,18-substituted octadehydrocorrin, the formation constants of the pentacoordinate complexes increase with enhancement of the electron-accepting properties of the β-substituents[84]. There is a linear relation between $\lg K$ for the coordination of pyridine and the σ_m constants of the β-substituents[84]. The constants of the coordination of substituted pyridines and aliphatic amines to the cobalt(II) complex of 8,12-diethyloctamethyloctadehydrocorrin have also been determined and correlations have been established between the coordination constants and the basicity of 4-substituted pyridines, on the one hand, and the coordination constants and the σ constants of the pyridine substituents, on the other[81]. The complexes of aliphatic amines and Co-octadehydrocorrins are less stable than the pyridine complexes. A mechanism has been proposed for the formation of these complexes, which consists in the amine giving up two electrons to the cobalt(II) complex in stages, the first electron being transferred to the cobalt atom via an outer-sphere mechanism and the resulting cobalt(I) complex and the electron-deficient amine combining to give a pentacoordinate cobalt(II) complex of octadehydrocorrin[81].

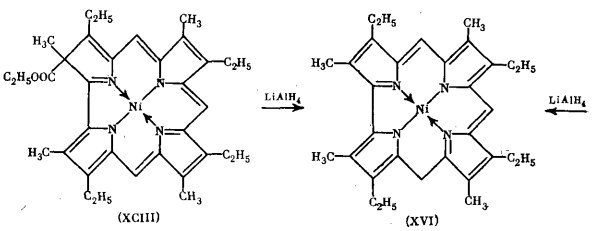
The coordination state of the cobalt(II) complexes of octadehydrocorrins depends on the nature of the anion[85]. The perchlorates and nitrates are tetracoordinate complexes, while the acetates and bromides are pentacoordinate. The nickel complexes of octadehydrocorrins are tetracoordinate in all the known cases and the nature of the anions does not affect this.

The cobalt(III) of corroles form both 1 : 1 and 1 : 2 adducts with pyridine and other amines[86]. The addition of an excess of pyridine to solutions of the square-planar or pyramidal complexes of corroles leads to the formation of the octahedral dipyridinecobalt(III) complexes of corroles (CVII), which are stable only in the presence of an excess of pyrine[30].

(CVII)

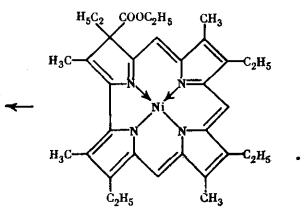
Correlations have been established between the formation constants of the penta- and hexa-coordinate cobalt(III) complexes of corroles and the basicity of the 4-substituted pyridines and between the constants of the coordination of 4-substituted pyridines to Co(III)-corroles and the σ constants of the pyridine substituents[86].

IX. REACTIONS OF SUBSTITUENTS IN THE CORRINOID MACRORINGS



The reactions of substituents in the octadehydrocorrin macroring have been little investigated. The reactions of substituents in the 1- and 19-positions have been studied in greatest detail, since their removal leads to the formation of other types of tetrapyrrole macrorings.

When the nickel and cobalt complexes of 1,19-diethoxy carbonyloctadehydrocorrins are treated with alkaline agents, the ester is hydrolysed and the resulting carboxylic acids are carboxylated, while treatment with a solution of $(C_4H_9)_4$. .NOH in methanol yielded complexes of the tetrabutylammonium salt of 1-carboxyoctadehydrocorrin[14]. Rapid treatment of the nickel complex of 1,19-diethoxycarbonyloctadehydrocorrin (CVIIIb, R′ = $COOC_2H_5$) with a solution of NaOH in water[29] or methanol[59] leads to the nickel complex of 1-ethoxycarbonyl octadehydrocorrin.



When the nickel complexes of 1-ethoxycarbonyl- and 1,19-diethoxycarbonyl-octadehydrocorrins (XCI) and (CVIIIb) are reduced with $LiAlH_4$, one ester group is eliminated and corrole and 1-ethoxycarbonyloctadehydrocorrin are formed respectively[59]. The nickel complex of 19-ethoxycarbonyl-1-methyloctadehydrocorrin (CVIIIa) is readily converted into the nickel complex of 1-methyloctadehydrocorrin on treatment with NaOH in methanol[29,40] or with sodium in alcohol[59].

The cobalt complexes are more reactive. When the cobalt complex of 1,19-diethoxycarbonyloctadehydrocorrin is treated with a solution of NaOH in methanol at 20 °C, the cobalt complex of corrole is formed[40].

Ester substituents at any saturated carbon atom are readily removed. When the nickel complexes of corroles, (XCII) and (XCIII), containing the $COOC_2H_5$ groups at C(3) and C(2) are reduced with $LiAlH_4$, they are both rapidly converted into the same corrole (XVI): [59]

(XCIII) (XVI)

(XCII)

The hydrogenation of the nickel complex of 3,17-dibenzyloxyoctamethyloctadehydrocorrin over the 10% Pd/C catalyst in alcohol at 20 °C leads to the formation of the nickel complexes of 17-benzyloxy-3-hydroxy- and 3,17-dihydroxyoctadehydrocorrins[63]. The oxidation of triphenylphosphinecobalt(III) complexes of octa-alkylcorroles with 2,3-dichloro-5,6-dicyano-1,4-benzoquinone results in the formation of 3,17-diformyl derivatives[30]. Thermolysis of the nitrate of the nickel complex of decamethyloctadehydrocorrin probably involves the transformation of the CH_3 group in the 3-position into the CN group via the mechanism $-CH_3 \rightarrow -CH{=}NOH \rightarrow -CN$; the nitrosation is caused by the nitrous vapours formed on decomposition of the NO_3^- anion[74]. An analogous reaction occurs in the thermolysis of the nitrate of the nickel complex of octa-alkyl-1,19-diethoxycarbonyloctadehydrocorrin[29,56].

The metal complexes of octadehydrocorrins with propionic acid residues in the β-positions readily undergo reactions characteristic of carboxylic acids. They are esterified on refluxing in methanol in the presence of $HClO_4$.[87] The esterification of the CH_2CH_2COOH groups in the 8- and 12-positions, which are less sterically shielded, proceeds more readily than the esterification of the same groups in the 2- and 18-positions. The reactions of metal complexes of octadehydrocorrins containing the CH_2CH_2COOH groups with epoxyethane leads to the corresponding esters which are the products of the addition of one epoxyethane molecule[87].

Thus the metal complexes of octadehydrocorrins have unusual chemical properties, whose study makes a considerable contribution to the chemistry of complex compounds and tetrapyrrole macrocyclic compounds.

Phosphorylation of Carbochain Polymers

A.P.Khardin, O.I.Tuzhikov, and S.N.Bondarenko

The methods for the chemical modification of carbochain polymers by various phosphorylating agents are examined. The possible ways of utilising macromolecular compounds with phosphorus-containing groups in the side chain are surveyed. The bibliography includes 186 references.

I. INTRODUCTION

The polymer analogue reactions of macromolecular compounds constitute one of the most important methods for the introduction of new functional groups into polymer side chains[1]. One of the most promising versions of this method involves the phosphorylation of carbochain polymers. The interest in this procedure can be readily accounted for because the introduction of a phosphorus atom into the side chains of the macromolecules of various polymers makes it possible not only to improve important properties of the initial high-molecular-weight compounds, such as fire resistance, hydrophilic properties, and thermal stability, but also (depending on the type of phosphorus-containing functional groups introduced) to obtain polymeric materials capable of ion exchange and sorption of transition metal ions from solutions and to synthesise polymers with oxidation-reduction properties and biological activity. Virtually all the macromolecular compounds modified by various phosphorylating agents are produced in large amounts and some of the products are manufactured on an industrial scale[2].

Extensive experimental data have now accumulated on the phosphorylation of carbochain polymers but there are no publications in the literature which survey adequately questions associated with this problem. The available monographs and review publications[3-11] only partially fill the gap in the systematic description and survey of data concerning this branch of the chemistry of macromolecular compounds and the chemistry of phosphorus.

II. OXIDATIVE CHLOROPHOSPHORYLATION OF CARBOCHAIN POLYMERS

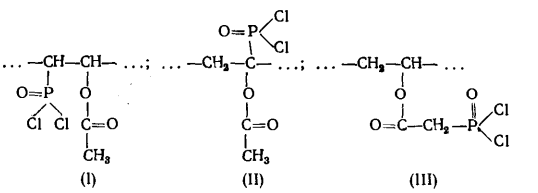
One of the effective methods of phosphorylating carbochain polymers involves their treatment by phosphorus halides and oxygen—the oxidative chlorophosphorylation of hydrocarbons. Phosphonyl chloride groups can then be introduced into the polyethylene side chain[12-17] in accordance with the mechanism[9-15]

$$\ldots -CH_2-CH_2-CH_2- \ldots + PCl_3 + {}^1/_2O_2 \rightarrow \ldots -CH_2CHCH_2- \ldots + HCl\ .$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad |$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad POCl_2$$

The reaction is carried out at 60–80 °C, whereupon polyethylene forms a solution in phosphorus trichloride. The rate of phosphorylation is determined by the rate of dissolution of oxygen in the mixture. When air is used instead of oxygen, the above reaction proceeds at a lower rate. The derivatives obtained contain up to 16% of phosphorus. With increase of the degree of phosphorylation, the crystallinity of the product diminishes relative to the initial polyethylene[12]. Under analogous conditions, the $POCl_2$ functional groups have also been introduced into the polypropylene macromolecule[18-20]:

$$\ldots -CH_2-\underset{CH_3}{CH}-CH_2-\underset{CH_3}{CH}- \ldots + PCl_3 + {}^1/_2O_2 \rightarrow \ldots -CH_2-\overset{CH_3}{\underset{POCl_2}{C}}-CH_2-\underset{CH_3}{CH}- \ldots + HCl\ .$$

It has been suggested that the phosphonyl chloride groups are linked mainly to a tertiary carbon atom in the polymer chain. With increase of the degree of phosphorylation, the hardness and rigidity of the polymer decrease. The phosphorus content reaches 7% in the final product.

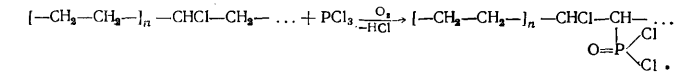


By treating the ethylene–propene copolymer with phosphorus trichloride and oxygen, Leonard et al.[21] and Weiss[22] obtained phosphorus-containing elastomers.

The heterogeneous oxidative chlorophosphorylation of polyethylene and ethylene–propene copolymers has also been investigated[23-29]. When thin films of polyethylene are treated with phosphorus trichloride vapour and oxygen, reactions of first order with respect to phosphorus trichloride and with 0.5 order with respect to oxygen take place. Phosphorylation takes place preferentially in the amorphous phase of the polymer.

Depending on the structure of the polyolefin chains, various reaction centres participate in the process. For branched polymers, such as high-pressure polyethylene and ethylene–propene copolymers, the main reaction centres are the hydrogen atoms at tertiary carbon atoms.

The phosphonyl chloride groups in polyolefins are highly reactive and undergo hydrolysis, alcoholysis and phenolysis and also interact with amines and metal salts. The hydrolysis of chlorophosphorylated polyolefins leads to the corresponding polymeric phosphonic acids[12].



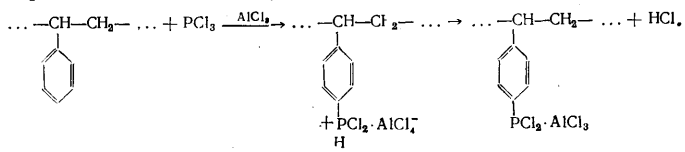
The oxidative chlorophosphorylation of poly(vinyl acetate), which resulted in the formation of copolymers containing units with different structures, has been investigated[30]:

(I) (II) (III)

It was suggested[30] that phosphorus enters mainly the polymer chain with formation of fragments (I) and (II).

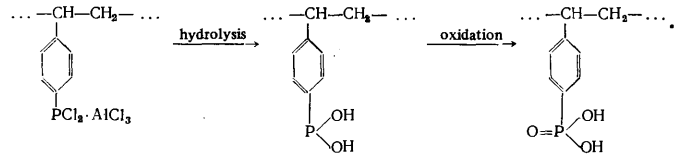
It has been shown[31-33] that an analogous reaction takes place also when chlorinated polyolefins are used. For chlorinated polyethylene, this can be represented schematically in the following manner:

The phosphorus content in chlorinated polyethylene and atactic polypropylene increases with decrease of the chlorine content in the initial polymers and reaches 7.8 and 11.4% respectively.



In a number of instances alkyl- and aryl-dichlorophosphines were used in the reaction instead of phosphorus trichloride[34-36]. This yielded polymers containing in the side chain groups characteristic of derivatives of dialkyl- or alkylaryl-phosphinic acids.

It is noteworthy that polyisobutylene, poly(methyl methacrylate), and polystyrene are degraded on phosphorylation, the final degradation product containing an insignificant amount of phosphorus[12]. A number of workers[37,38] believe that the oxidative phosphorylation can be classified as a process proceeding via a free-radical mechanism.

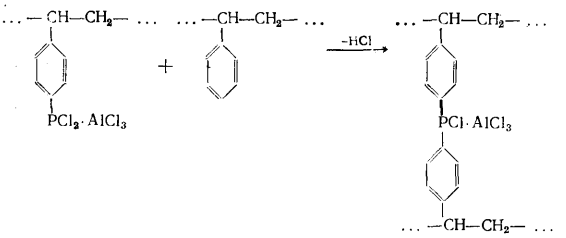


III. PHOSPHORYLATION VIA THE FRIEDEL–CRAFTS AND CLAY–KINNEAR–PERREN REACTIONS

A considerable proportion of the publications of the phosphorylation of carbochain polymers are associated with the employment of the Friedel–Crafts reaction. The phosphorylation of the copolymers of styrene with aromatic divinyl compounds has been studied in greatest detail[39-47]. Aluminium trichloride, titanium tetrachloride, tin tetrachloride, and zinc chloride have been recommended as catalysts. Aluminium trichloride has been used in most investigations, although it has been shown[48] that a more active catalyst, namely aluminium tribromide, would be more effective by increasing the degree of phosphorylation and reducing the reaction temperature.

The mechanism of the phosphorylation reaction can be represented schematically as follows:

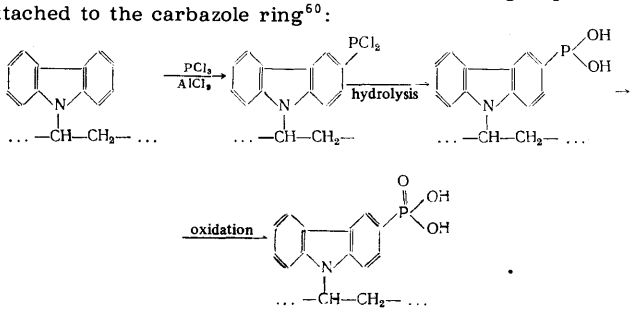
The complex of the dichloride of polystyrylphosphonic acid with aluminium trichloride can subsequently hydrolyse and undergo consecutive oxidation reactions:



Nitric acid, SO_2Cl_2, and $SO_2–Cl_2$ and $Cl_2–P_2O_5$ mixtures, as well as other reagents are used as oxidants.

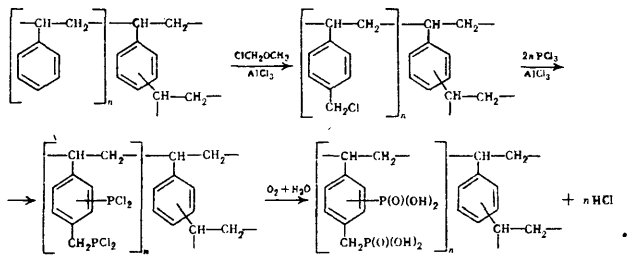
The interaction of cross-linked polystyrene with phosphorus trichloride followed by treatment of the resulting polystyrylphosphonic acid dichloride with a Grignard reagent led to the synthesis of monofunctional cation-exchange resins[50]. It has been stated that the substitution of two chlorine atoms in polystyrylphosphonic acid dichloride takes place stepwise as a result of steric hindrance. Under severe conditions, 85% of chlorine can be substituted to give the disubstituted derivative when ethylmagnesium bromide is used. Depending on the structure of the Grignard reagent, the degree of conversion decreases from 54 to 35% in the following sequence of substituents: $C_2H_5 > C_3H_7 > C_4H_9 > CH_3$.[51]

A detailed study of the influence of the reaction conditions on the degree of conversion of styrene–divinylbenzene copolymers[42] established that the latter depends on a series of parameters: the amount of aluminium trichloride and phosphorus trichloride, the reaction time, the degree of cross-linking of the copolymers, and their porosity.



It has been noted that the macromolecules are cross-linked under the reaction conditions[49]:

The study of the kinetics of the phosphorylation of styrene–divinylbenzene copolymers established[45] that the principal rate-limiting stage is diffusion of the phosphorylating agent through the film of liquid adjoining the surface of the grain. The diffusion of the phosphorylating agent within the copolymer grains as well as its concentration in the swollen copolymer can also have a definite influence on the rate of phosphorylation. The conclusion that the phosphorylation process has an external diffusion mechanism is consistent with data[47] according to which the phosphorylation front migrates from the surface to the centre of the grain and the degree of phosphorylation depends on the depth to which the phosphorylating agent penetrates into the copolymers. With increase of the degree of cross-linking of the copolymers, the rate of reaction falls, but, for copolymers with a macroporous structure, obtained in the presence of an inert solvent, the rate of reaction increases sharply[52,53].



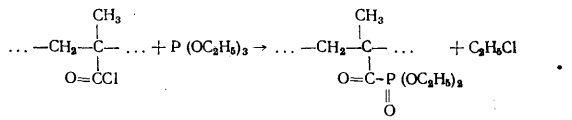
The phosphorylation of polystyrene grafted to polyethylene or polypropylene films has been achieved in a number of studies[54,55]. The phosphorylation was carried out at 40 to 65 °C by treatment with phosphorus trichloride in the presence of aluminium trichloride. On subsequent hydrolysis and oxidation with nitric acid, ion-exchange membranes with satisfactory electrochemical characteristics were obtained.

Modified copolymers with ion-exchange properties, a good mechanical strength, and an increased porosity and thermal stability have been obtained by the phosphorylation of macroporous ternary copolymers of styrene, divinylbenzene (1 to 20%), and acrylonitrile or ethyl, methyl, or butyl acrylate with phosphorus trichloride in the presence of aluminium trichloride[56-59]. The simultaneous treatment of poly-*N*-vinylcarbazole with phosphorus trichloride and aluminium trichloride yielded a product with the phosphonic acid group attached to the carbazole ring[60]:

The interaction was carried out in ethyl chloride with molar ratios polyvinylcarbazole : catalyst-phosphorylating agent of 1 : 2.5 : 10 in the temperature range 20–140 °C. Among phosphorylating agents, PCl_3 and PBr_3 proved to be the most effective and aluminium trichloride was the best catalyst. The degree of phosphorylation increased with temperature and reached a maximum (11.4% of phosphorus) at 76 °C (phosphorus trichloride) and 140 °C (phosphorus tribromide). The phosphorylated poly-*N*-vinylcarbazole has ion-exchange properties and does not dissolve in the usual organic solvents.

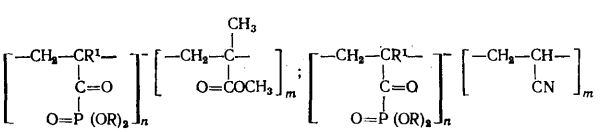
Polymers with phosphonic acid groups in the side chain have been obtained by treating chloromethylated vinyl derivative–aromatic compound copolymers with phosphorus trichloride in the presence of $AlCl_3$ in accordance with the scheme[61]

In this case substitution can take place via the Friedel–Crafts reaction in the benzene ring or via the Clay–Kinnear–Perren reaction in the chloromethyl group. Thus it has been suggested[62,63] that both reactions take place. Studies by Kinnear and Perren[64] showed that, when benzyl chloride interacts with PCl_3 and $AlCl_3$, phosphorylation takes place either in the chloromethyl group or in the aromatic ring, while simultaneous introduction of two phosphonic acid groups into the same benzene ring is unlikely.



The phosphorylation of the chloromethylated styrene–divinylbenzene copolymer gives rise to lower degrees of conversion, compared with the phosphorylation of the non-chloromethylated copolymer, which can be explained by the greater ability for swelling of the latter in phosphorus trichloride[33].

Phosphonic acid cation-exchange resins can be obtained by the chloromethylation of condensed aromatic petroleum processing products followed by their phosphorylation with phosphorus trichloride in the presence of Friedel–Crafts catalysts and oxidation[65]. In terms of their activity, the catalysts can be arranged in the sequence $SnCl_4 > FeCl_3 > AlBr_3 > AlCl_3 > ZnCl_2$. The maximum degree of phosphorylation is attained when the ratio of the chloromethylated asphaltide to PCl_3 or $SnCl_4$ is 1 : 10, at a temperature of 35 to 60 °C, and for a process time ranging from 1 to 2 h. By virtue of their structure, which resembles that of graphite, they withstand more effectively the effects of small and large doses of γ-radiation compared with phosphonic acid cation-exchange resins based on styrene–divinylbenzene copolymers.



Nitrogen- and phosphorus-containing polymers with ion-exchange properties have been synthesised by polymer analogue reactions of the copolymers of styrene with divinyl compounds[66]. The initial and chloromethylated macronetwork copolymers of styrene and divinyl compounds were phosphorylated with phosphorus trichloride in the presence of $AlCl_3$. The divinyl compounds employed were ethylene-, hexamethylene-, and decamethylene-dimethacrylamides, dimethacrylate esters of di(hydroxyphenyl)sulphone and di(hydroxyphenyl)sulphoxide, and the dimethacrylamides derived from *m*-phenylenediamine, di(aminophenyl)ether, di(aminophenyl)methane, and di(aminophenyl)sulphide. In the synthesis of nitrogen- and phosphorus-containing amphoteric ion-exchange resins, the unsubstituted CH_2Cl groups in the partially phosphorylated chloromethylated copolymer were aminated with various isomers of pyridinedicarboxylic acids and their nitriles in dimethylformamide at 100 °C.[67] The presence of amide, ester, sulphoxide, sulphide, pyridinecarboxylic acid, and nitrile groups promoted an increase of the selectivity of the ion-exchange resins in relation to the sorbed ions.

IV. PHOSPHORYLATION OF CARBOCHAIN POLYMERS WITH THE AID OF THE ARBUZOV REARRANGEMENT

In one of the first studies of the Arbuzov rearrangement of macromolecular compounds, poly(vinyl chloroacetate), poly-α-chloroacrylate, poly(vinyl chloride), and the polymeric acrylic and methacrylic acid chlorides were used as the polymeric matrices[68]. The reaction was carried out in solution in dioxane at 100–150 °C using polymeric methacrylic acid chloride; it took place in accordance with the mechanism

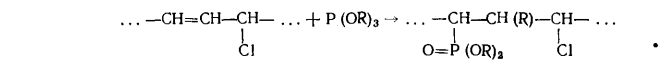
When the chlorine atom is linked directly to a carbon atom of the main chain of the macromolecule, the degree of phosphorylation is insignificant. Best results were obtained in the reaction of triethyl phosphite with poly(vinyl chloroacetate). The resulting polymers were elastic and hygroscopic, did not support combustion, were resistant to acids, and exhibited an effective adhesion to glass. Polymers with analogous properties have been obtained by the reaction of triethyl phosphite with the copolymers of acryloyl or methacryloyl chloride and methyl methacrylate or acrylonitrile[69]:

Phosphorus-containing vinyl copolymers have been synthesised by the reaction of phosphonate esters with halogenomethyl groups in the copolymer and subsequent hydrolysis of the ester groups. The product had ion-exchange properties[70]. A cation-exchange resin has also been obtained by treating halogenomethylated copolymers of mono- and polyfunctional compounds with triethyl or trimethyl phosphite[71].

In order to improve the stability and non-combustibility of vinyl chloride polymers and copolymers, it has been suggested that they be treated with trialkyl phosphites[72,73]. The introduction of phosphonoethyl groups into the side chain of the copolymer of vinyl chloride with acrylonitrile is accompanied by an increase of its thermal stability and resistance to acids and organic solvents with retention of its non-combustibility.

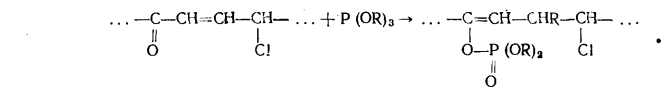
Phosphorus-containing polymers with improved technological properties and strength parameters have been obtained by the reaction of trimethyl phosphite with chlorosulphonated polyethylene[74].

Several studies have been devoted to the reaction of poly(vinyl chloride) with mixed alkyl(aryl)phosphites[75–77]. According to the authors of these investigations, the reaction is accompanied by the Arbuzov rearrangement, which entails the appearance of phosphorylated units in the initial polymer. In the course of modification at 200 °C, the dehydrochlorination of the polymer with formation of polyconjugated double bonds was observed together with the main

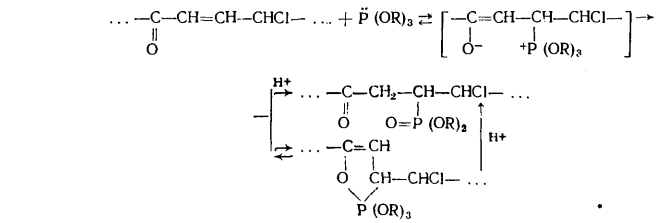


reaction. The specimens acquire a colour as a consequence of such modification.

The interaction of triethyl phosphite with poly(vinyl chloride) at 80–200 °C via the mechanism

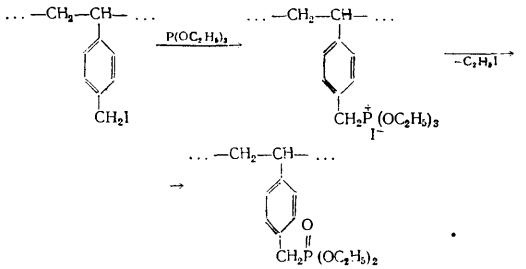


has been investigated[77]. The reaction was followed from the change in the chlorine and phosphorus contents in the final product. The polymers were amorphous powders soluble in organic solvents. At reaction temperatures up to 180 °C, there is no degradation of the polymer but on further increase of temperature a three-dimensional structure is formed.



A detailed study of the mechanism of the interaction of poly(vinyl chloride) with trialkyl phosphites showed[79] that the hypothesis that phosphorus-containing compounds add to the double bond in poly(vinyl chloride) [78] is incorrect:

Thus the interaction of tributyl phosphite with 4-chloropent-2-ene does not entail the reaction with inner β-chloroallyl groups. The main process is the dehydrochlorination of 4-chloropent-2-ene. If the hydrogen chloride evolved in this process is not bound, tributyl phosphite is dealkylated with formation of dibutylphosphorus acid[79]. Data on the ozonolysis of poly(vinyl chloride) subjected to a preliminary treatment with a phosphorus-containing compound[81] indicate the absence of unsaturated C=C bonds in the main polymer chain and therefore cast doubt on the probability of the reaction of trialkyl phosphites with the carbonyl–allyl groups of macromolecules via the Perkow mechanism to form unsaturated phosphites[80]:



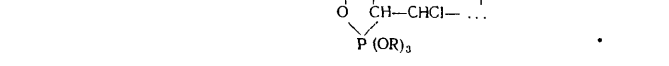
This effect may be attributed to the nucleophilic addition reaction in the presence of proton donors under the conditions of the stabilisation of poly(vinyl chloride) by organic phosphites involving attack by the latter on the β-carbon atom of the conjugated system of the carbonylallyl group followed by the protonation of the dipolar ion and the formation of a stable ketophosphonate[81]. Thus the reaction of organic phosphites with poly(vinyl chloride) under comparatively mild conditions leads to the quantitative opening of the inner unsaturated C=C bonds present in the polymer macromolecules with formation of single C–C bonds, which is due to the interaction of organic phosphites with the carbonylallyl groups of the polymer via the mechanism[82]

The occurrence of this interaction has been confirmed by the method of the competing reactions of trialkyl, alkyl, and aryl phosphites with a 1:1 mixture of methyl vinyl ketone (a model of the carbonylallyl group) and 4-chloropent-2-ene (a model of the β-chloroallyl group). Organic phosphites react selectively with methyl vinyl ketone, while 4-chloropent-2-ene is recovered unchanged from the reaction (apart from its dehydrochlorination products).[79]

Chloromethylated polystyrene and its copolymer with vinylidene chloride as well as poly(2,6-dimethyl-1,4-phenylene oxide), containing bromine in the side chain or in the benzene ring, are phosphorylated by triethyl phosphite (on refluxing in the presence of diethylmethanol) with formation of non-cross-linked polymers having phosphonate side groups[83]. The polyphosphonates are hygroscopic; the adsorbed water, whose amount increases with increase of the phosphorus content, influences the glass points of the polymers. The polyphosphonates can be combined with a large number of polymeric systems and may form "true" polymer alloys with acetylcellulose.

Iodomethylated derivatives of polystyrene are more readily phosphorylated by organic phosphites[84,85]:

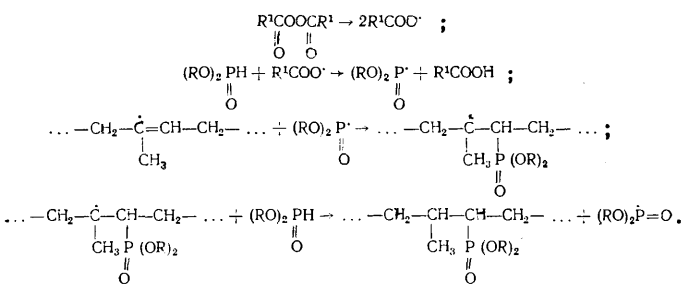
At a temperature above 70 °C, the Arbuzov rearrangement with participation of macromolecules is accompanied by the isomerisation of triethyl phosphite under the influence of the ethyl iodide evolved in the reaction. It has been shown[84] that the rate constants for the Arbuzov rearrangement of triethyl phosphite in the presence of iodomethylated polystyrene decrease in the course of the reaction and that the apparent activation energy has different values at high and low temperatures.



Products containing phosphonate groups in the side chain have been obtained by treating hydroxystyrene polymers with a phosphinate ester[86].

Dialkoxyphosphonomethylpolystyrenes have been obtained by the reaction of chloromethylpolystyrene with mixed alkyl phosphites having the general formula $(RO)_2POR^1$ (where $R = C_{3-7}$ alkyl and R^1 = methyl or ethyl) at 20–30 °C for 5–24 h and then at 170–190 °C for 10–20 h.[87]

Insoluble polymers containing polyalkylphosphonium groups in the side chain have been obtained by the reaction of PR_3 with diene, olefin, and alkylhalogeno-olefin polymers[88].

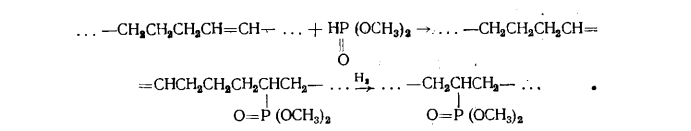


V. ADDITION OF PHOSPHORUS-CONTAINING COMPOUNDS WITH A MOBILE HYDROGEN ATOM TO UNSATURATED BONDS IN MACROMOLECULES

The addition of partially esterified phosphorus acids, initially investigated in relation to individual unsaturated compounds[89], was subsequently studied also in relation to polymers. The reaction was achieved for natural rubber by treatment of the latter with dialkyl phosphites[90] and somewhat later also for isoprene rubber[91]:

Investigation showed that, when various dialkyl phosphites are allowed to interact with natural rubber in the presence of benzoyl peroxide, it is possible to introduce up to 9–10% of phosphorus into the rubber, which corresponds to the addition of dialkyl phosphites to 60% of all the double bonds in the rubber. The vulcanised specimens obtained have reduced combustibility. With increase of the length of the

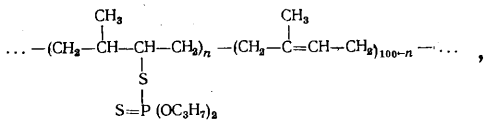
alkyl group in dialkylphosphorous acids, the content of the bound phosphorus in the polymer falls. A possible mechanism of such addition of dialkyl phosphites can be represented by the following scheme:



The polymers obtained do not dissolve in organic solvents and merely swell in them, which is apparently associated with the cross-linking resulting from the recombination of macroradicals.

The possibility of the addition of dialkyl phosphites to a dehydrochlorinated vinyl chloride–acrylonitrile copolymer has been demonstrated[92]. However, the phosphorus content in the final product was small (1.6 wt.%).

A method has been proposed for the synthesis of a phosphorus-containing polyallene by treating polyallene with dialkyl phosphites in the presence of organic peroxides as a result of irradiation with γ-rays at 20–140 °C.[93] The interaction of diorganophosphites with the product of the esterification of poly(vinyl alcohol) with the chloride of cinnamic acid has been investigated[94] and the influence of the nature of the initiator on the structure of the polymers obtained has been demonstrated. Structure formation was observed for peroxy-compounds, while in the presence of azobisisobutyronitrile the formation of a three-dimensional network was not observed. An increase of temperature to 120 °C increases the degree of phosphorylation but the final product ceases to be soluble. The introduction of phosphono-groups plasticises the initial polymer, reduces the softening temperature by 40–65 °C, increases the intrinsic viscosity, and imparts self-extinguishing properties to the polymer.

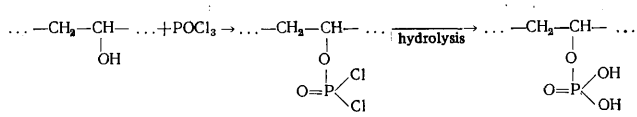


Phosphorylated derivatives of polycyclopentene containing 5–10 mole % of dimethylphosphonate groups have been obtained by the addition (initiated by peroxy-compounds) of dimethyl phosphite to the double bonds of polycyclopentene containing 82% of *trans*-double bonds, 17% of *cis*-double bonds, and 1% of vinyl side groups at 85–90 °C in solution in toluene with subsequent hydrogenation of the residual unsaturated bonds by toluene-*p*-sulphohydrazide at 145 °C:[95]

Dehydrated poly(vinyl alcohol) fibre containing 32–90% of double bonds is phosphorylated by dialkyl phosphites via the addition of the latter to the double bonds[96].

Phosphorylated raw rubbers for technical rubber articles have been obtained by the interaction of unsaturated raw rubbers in the form of aqueous latexes, stabilised by hydroxyethylated alkylphenols or higher alcohols, with dialkyl phosphites at 80–90 °C in the presence of radical initiators[97].

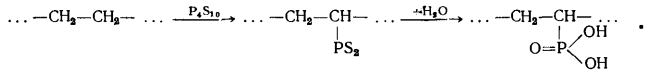
The reaction of *cis*-1,4-polyisopropene with di-isopropylphosphorodithioic acid in the presence of a catalyst led to the synthesis of a phosphorus-containing polymer having the structure[98]



where $n = 5–63$. The polymer contains 0.7–6.9 wt.% of phosphorus and 0.9–16.6 wt.% of sulphur. The addition of certain other esters of dialkylphosphorodithioic acids to unsaturated elastomers has been carried out under analogous conditions[99,100]. The reaction takes place readily in the presence of benzoyl peroxide or isopropylphenyl hydroperoxide. The products contain 0.3–8 wt.% of phosphorus and 0.5–20% of sulphur and are readily soluble in organic solvents.

Phosphorus acids have been used in some investigations[101–104] as phosphorylating agents for carbochain polymers. Thus a phosphorus-containing polyallene has been obtained by treating polyallene with hypophosphorous acid in the presence of radical initiators in an inert gas atmosphere[103]. The final product contains 11 wt.% of phosphorus and is of interest for the formation of fire-resistant polymeric materials. Hypophosphorus acid proved to be the best phosphorylating agent in the hydrophosphorylation of polymers containing allyl groups in the side chain[101]. Polymers containing from 4 to 11% of phosphorus and having self-extinguishing properties have been obtained by this reaction.

VI. OTHER METHODS

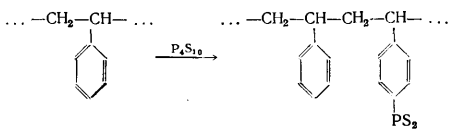


Phosphoryl chloride is an effective phosphorylating agent for hydroxyl-containing polymers. Phosphorylated derivatives of poly(vinyl alcohol) have been obtained by reaction with $POCl_3$.[105–107] After phosphorylation, the polymer loses its solubility in water and the phosphorus content in the final product reaches 14.7%. The potentiometric titration curve for the hydrolysed product has the form characteristic of dibasic acids. The reaction proceeds via the mechanism

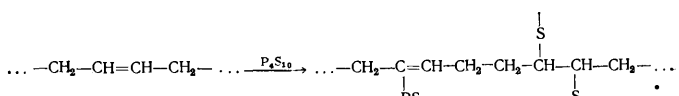
The degree of conversion of the poly(vinyl alcohol) units in the phosphorylation reaction reaches 30–35%, which corresponds to one phosphoric acid group for each three hydroxy-groups in the polymer.

A series of ion-exchange materials have been synthesised by treating with phosphoryl chloride the fibres, fabrics, and films obtained from poly(vinyl alcohol).[108–110] It has been shown that an analogous reaction can also be achieved for other hydroxyl-containing polymers, for example, polyhydroxystyrene[111] and polydimethylethynylmethanol[112]. Phosphorus-containing poly(vinyl alcohol) has also been obtained by the reaction of poly(vinyl alcohol) with phosphoric acid in the presence of *N*-methylpyrrolidinone[113]. The phosphorylation of macromolecular compounds with phosphorus sulphide has been investigated in relation to polyethylene, polypropylene, polystyrene, polyacrylonitrile, and synthetic rubbers.

Polyethylene is phosphorylated in solution in chlorobenzene at temperatures in excess of 100 °C under a normal or excess pressure. The main reaction and subsequent hydrolysis of the PS_2 groups proceed via the mechanism[114]

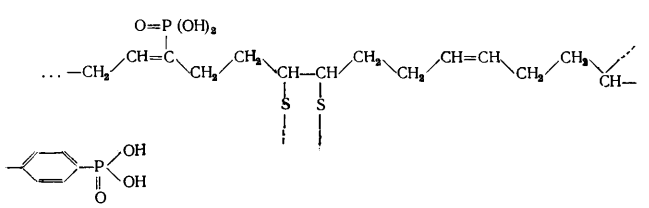


Depending on the reaction conditions and the reactant ratio, the phosphorus content in the product can vary from 3 to 10%.

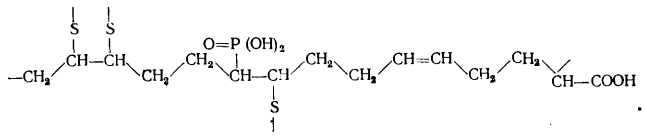


Polypropylene has been phosphorylated at normal and enhanced pressures and temperatures from 132° to 200 °C in an autoclave. The phosphorus content in the product did not exceed 1%. The low reactivity of polypropylene has been explained by the shielding of the tertiary carbon atoms by methylene groups[114]. The phosphorylated polypropylene contains up to 1% of sulphur, which corresponds to one sulphur atom for 75 elementary units of the polymer.

In the phosphorylation of polyacrylonitrile with phosphorus sulphide, it was possible to introduce only 0.5% of phosphorus into the polymer. As for polypropylene, despite the enhanced reactivity of the tertiary carbon atom, access to the latter is sterically hindered. Phosphorylation under more severe conditions makes it possible to increase the phosphorus content to 7.3%. When an attempt was made to hydrolyse the PS_2 groups in the phosphorylated polyacrylonitrile, the hydrolysis of the nitrile groups to carboxy-groups was noted at the same time.

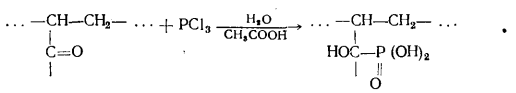


A study has also been made of the phosphorylation of polystyrene. This resulted in products in which a phosphorus atom is present in each second, fourth, or tenth elementary unit of the polymer depending on the conditions. The PS_2 groups enter preferentially into the *para*-position in the benzene ring[10]:



The phosphorylation of various raw rubbers has also been studied[115]. The phosphorylation of butadiene rubber proceeds via the mechanism

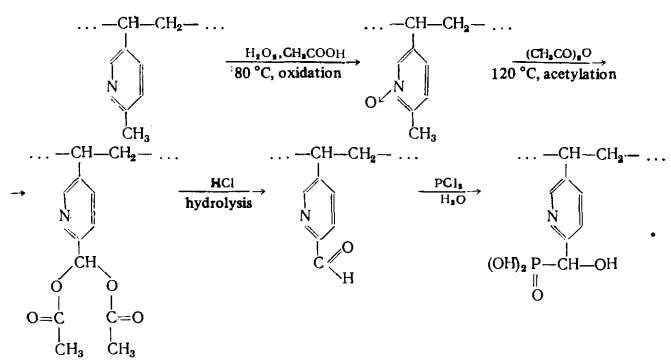
When the SKS-30 rubber was phosphorylated in solution in chlorobenzene at 132 °C, it was shown by infrared spectroscopy that the reaction involves both the carbon atoms of the main macromolecular chain and the phenyl substituent. The final product contains 11.5% of phosphorus and 22.7% of sulphur and has the structure



The phosphorylation of butadiene-nitrile rubbers proceeds with greater difficulty than that of butadiene–styrene rubbers. After hydrolysis, the products have the structure

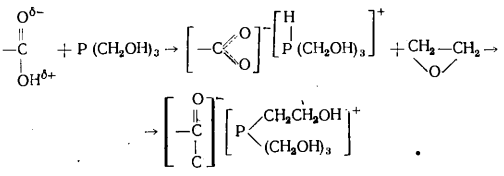
All the phosphorus-containing polymers obtained are plastics insoluble in water, acids, alkali, and organic solvents. They melt at 200–300 °C and have ion-exchange properties.

A method of synthesis of polyphosphonothioic acid with a high molecular weight by the reaction of polyisobutylene with phosphorus pentasulphide in the presence of sulphur and followed by hydrolysis of the reaction product has been proposed[116]. Phosphorus-, sulphur-, and halogen-containing polymers, distinguished by an enhanced resistance to acids, have been synthesised by the reaction of polymers of aliphatic hydrocarbons (or their copolymers with vinyl acetate or vinyl chloride) with phosphorus trihalides and sulphur at temperatures exceeding 140 °C.[117]



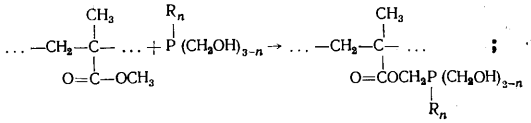
The reactions of carbonyl-containing polymers with phosphorus trichloride yielded polymers containing α-hydroxyphosphonic acid groups[118]:

The substrates can be both aliphatic polymers [for example, poly(methyl vinyl ketone)] and aromatic polymers (for example, acylated polystyrene).[119,120] The reaction also proceeds when an acylated styrene–divinylbenzene copolymer is used[121]. Treatment with phosphorus trichloride of a grafted *cis*-butadiene rubber–acrolein copolymer results in the formation of a structured product containing 0.5–0.7% of phosphorus and exhibiting an enhanced fire resistance[122]. The interaction of low-molecular-weight polybutadiene containing the OH and COOH groups with PCl_5 results in the phosphorylation of the polymer not only in the functional groups but also in the double bonds[123].



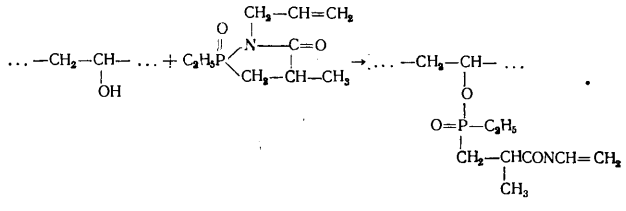
Phosphorus-containing polymers with ion-exchange properties have been obtained in the phosphorylation of polyacrolein[124] and acrolein-divinylbenzene copolymers by treatment with phosphorus trichloride[125].

Consecutive transformations of the copolymers of 2-methyl-5-divinylpyridine with divinylbenzene and di-isopropenylbenzene led to the synthesis of new phosphorus-containing pyridine polymers with ion-exchange properties[126]:



The products contain 8–9% of phosphorus and 5–6% of nitrogen and exhibit the maximum selectivity in relation to indium and uranyl ions.

The possibility of synthesising phosphorus-containing polymers by treating polyacrylic and polymethacrylic acid and also of copolymers containing carboxy-groups with tri(hydroxymethyl)phosphine (in the presence of epoxyethane) has been demonstrated[127]. The phosphorylation of polyacrylic and polymethacrylic acids was carried out using water as the solvent. The phosphorylation of carboxylate rubbers and methacrylic acid–styrene copolymers was performed in benzene or toluene. In the case of polymethacrylic acid in the presence of a threefold excess of phosphine, the degree of phosphorylation of the functional groups reaches 91%. For polyacrylic acid, the degree of phosphorylation is 59.8%. The properties of the products vary as a function of the amount of phosphorus introduced. Whereas the phosphorylated polyacrylic acid is a powdered product, polymethacrylic acid can be rubber-like after phosphorylation. The following reaction mechanism has been proposed:

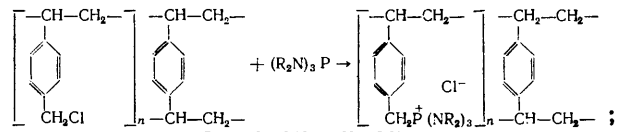


An attempt has been made to carry out the transesterification of poly(methyl methacrylate) by treating it with various phosphine derivatives[128]:

$R = CH_3$; C_3H_7; $C_6H_5CH_2$; $n = 0-2$

However, it was not possible to introduce phosphorus into the polymer, which the authors believe[128] can be explained by the influence of the substituent at the α-carbon atom, which hinders the transesterification.

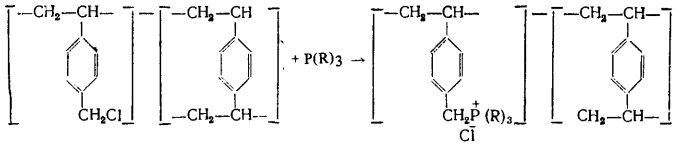
Azophospholan has been used as the phosphorylating agent for polyhydroxy-compounds[129,130]. The interaction of azophospholan with poly(vinyl alcohol) proceeds analogously to its interaction with low-molecular-weight alcohols:



Up to 6.1% of phosphorus is introduced into the final product.

Phosphorus-containing derivatives of polyhydroxy-compounds have also been obtained using the anhydride of 4-hydroxy-4-oxo-4-phosphocaproic acid[131], 1-chloro-3-methyl-1-oxo-phosphocyclopentane[132], and acetyl phosphites[133] as phosphorylating agents.

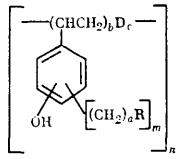
Diethylphosphonoacetals of poly(vinyl alcohol) have been obtained by the reaction of diethylphosphonoacetaldehyde with partially acylated poly(vinyl alcohol).[134] The products synthesised are soluble in water and contain up to 8% of phosphorus.



The reaction of the chloromethylated styrene–divinylbenzene copolymer with phosphorous acid amides yielded[135] the corresponding high-molecular-weight polymeric quasi-phosphonium salts:

$R = CH_3$; C_2H_5; C_3H_7; C_4H_9.

In order to increase the degree of phosphorylation, the reaction is carried out without a solvent in the presence of an excess of phosphorous acid amides in an argon atmosphere. The degree of phosphorylation is influenced not only by the reaction conditions but also by the structure of the groups in the amides, the degree of phosphorylation decreasing with increase of the bulk of such groups. It has been established that the maximum degree of phosphorylation is attained when the reaction is carried out at 120 °C for 10 h. The quasi-phosphonium salts are stable substances which do not change on refluxing ror 15 h in solution in aqueous dioxane in the presence of 0.1 *N* sodium hydroxide and in concentrated hydrochloride acid.

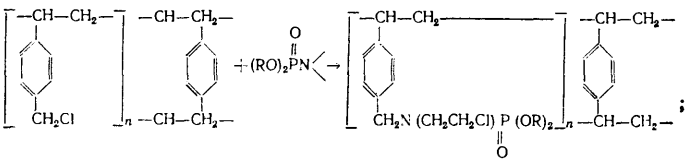


Phosphorus-containing polymers having the structure

$R = C_3H_7$; C_6H_5; CH_2OH

have been obtained by phosphorylating chloromethylated styrene–divinylbenzene or styrene–divinyl copolymers by various phosphines (in the presence of anhydrous aluminium trichloride as the catalyst or in its absence).[136,137]. Polymeric quaternary phosphonium salts containing more than 80% of phosphorus have been synthesised by the reaction of triethyl phosphite with chloromethylated styrene copolymers at 100–140 °C.[138]

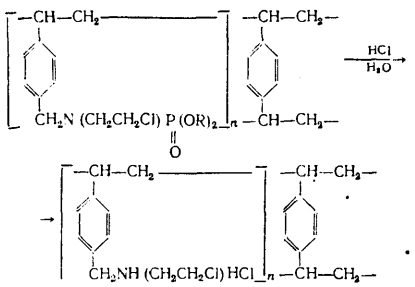
Hydroxystyrene polymers, which incorporate phosphonium groups of the type



where $a = 0$ or 1, $m = 0-2$, $n > 3$, b is an integer, $c = 0$ or is an integer, D is a copolymer unit, $R = \overset{+}{P}(OR^1)_p \cdot (R^2)_{3-p}X^-$, $p = 1$, 2, or 3, $R^1 = C_{1-20}$ alkyl, $R^2 = H$ or C_{1-20} alkyl, and X = Cl, Br, or I, are formed when halogenated polyhydroxystyrene interacts with the triester $P(OR^1)_pR^2_{3-p}$.[139]

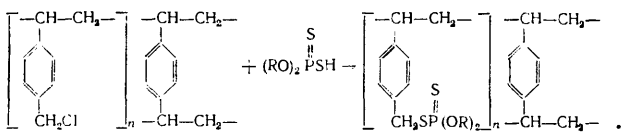
A method for the preparation, by an analogous reaction, of homogeneous ion-exchange membranes by phosphorylating with triphenylphosphine a chloromethylated polystyrene grafted to vinylidene fluoride–chlorotrifluoroethylene copolymer films has been described[140]. The membranes have a high exchange capacity and are incombustible.

According to Gorbunov et al.[141], phosphorus-containing polymers are formed when tri(hydroxymethyl)phosphines interact with the homopolymers and copolymers of unsaturated acid fluorides. The final products contain up to 12% of phosphorus and exhibit an enhanced fire resistance.



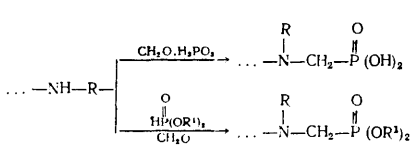
Water-soluble resins have been obtained as products of the reactions of a styrene–halogenomethylstyrene copolymer with a trisubstituted phosphine at 60 °C for 6 h.[142]

The interaction of the ethyleneamides of dialkylphosphoric acid with a chloromethylated styrene–divinylbenzene copolymer is accompanied by the cleavage of the ethyleneimine ring with formation of *N*-iminoethylation products[135]:

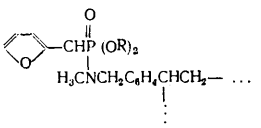


$R = CH_3;\ C_2H_5;\ C_3H_7$.

The *N*-phosphonaminoethylation products are unstable in an acid medium and are readily cleaved at the N–P bond with formation of dialkylphosphoric acid and the copolymer of the hydrochloride of (β-chloroethyl)vinylbenzylamine and divinylbenzene:

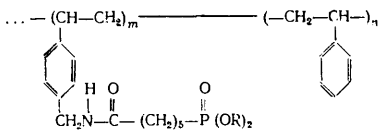


When a chloromethylated styrene–divinylbenzene copolymer is heated at 150 °C with *O,O*-dialkyl esters of phosphorodithioic acid in the absence of a hydrogen chloride acceptor or in its presence, copolymers of *O,O*-dialkyl *S*-(*p*-vinylbenzyl) esters of phosphorothioic acid and *p*-divinylbenzene are formed[143]:

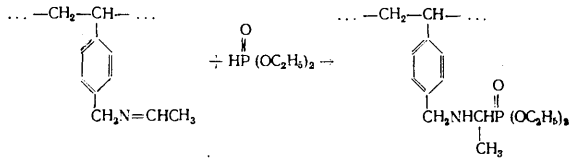


The degree of phosphorylation of the chloromethylated styrene–divinylbenzene copolymer depends on the size of the alkyl group in the *O,O*-dialkyl phosphorodithioic acid molecule and reaches 99.2%. With increase of the bulk of the hydrocarbon group, the degree of phosphorylation falls. The final product contains 3.9–9.6% of phosphorus and 8.7–19.7% of sulphur. The copolymers of *O,O*-dialkyl *S*-(*p*-vinylbenzyl) esters of phosphorothioic acid and *p*-divinylbenzene readily alkylate aliphatic and aromatic amines with formation of the salts of the corresponding tertiary amines and the copolymers of *O*-alkyl *S*-(*p*-vinylbenzyl) esters of phosphorothioic acids.

Primary and secondary amino-groups, introduced into the structure of the macroporous methacrylate–divinylbenzene copolymer by aminolysis with ethylenediamine and hexamethylenediamine condense with formaldehyde and phosphorous acid or its alkyl esters[144]:

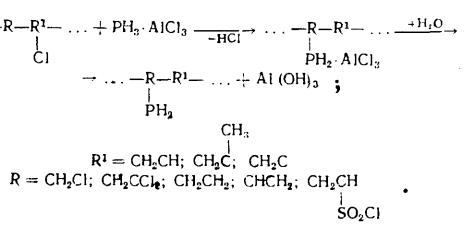


The phosphorylation of the aminated styrene–divinylbenzene copolymer proceeds via an analogous mechanism[145–147].



An anion-exchange resin, the elimination of the ester residue of which gives rise to an ampholyte with the *N*-methylamino-2-furylmethylphosphonic acid groups, has been synthesised by the amination of the chloromethylated polystyrene skeleton with the diethyl ester of *N*-methyl-α-amino-2-furylmethylphosphonic acid[148]:

A self-extinguishing polymer has been obtained by introducing a phosphorus-containing group into the *para*-position in the polystyrene molecule as a result of treatment of the polymer with 2-diethylphosphono-*N*-hydroxymethylacetamide, 2-dipropylphosphono-*N*-hydroxymethylacetamide, etc. in the presence of Friedel–Crafts catalysts[149]:



A polymeric complexone containing 8–9% of phosphorus and 5–7% of nitrogen has been synthesised by the condensation of dialkyl phosphites with the products of the interaction of aminomethylpolystyrene and acetaldehyde[150]:

Polymers containing phosphino-groups have been synthesised by the reaction of halogen-containing polymers [chloromethylated polystyrene, brominated polybutadiene, poly(vinyl chloride), and poly-*p*-bromostyrene] with metal phosphides in an inert solvent at temperatures from 40° to 200 °C.[151]

A self-extinguishing polystyrene containing the CH_2CH. $.[C_6H_4–CH_2P(O)(OR)_2]$ units, where R = alkyl or C_{1-8} cyclic alkyl, have been obtained by the interaction of alkali metal dialkyl phosphites with a partially chloromethylated polystyrene[152]. The reaction takes place at 40–90 °C for 6–8 h and the final product contains 5–10% of phosphorus.

The copolymer of chloromethylated polystyrene and divinylbenzene interacts with (β-diphenylphosphinoethyl)phenylphosphine treated with potassium in tetrahydrofuran, giving rise to three-dimensional products with diphosphine side groups[153]. Carbochain polymeric phosphines have been synthesised by phosphorylating halogen-containing carbochain polymers with a complex of phosphine and aluminium trichloride[154]:

The interaction is accompanied by a side reaction involving the elimination of hydrogen chloride and the consequent formation of polyene structures in the main macromolecular

chains. The degree of phosphorylation is greatly influenced by the temperature, the nature of the initial halogen-containing carbochain polymer and the Lewis acid. Depending on the reaction conditions, up to 18% of phosphorus is introduced into the treated polymers.

A mixture of red phosphorus and iodine can be used as the phosphorylating agent for chloromethylated styrene–divinylbenzene copolymers[155].

VII. APPLICATIONS OF PHOSPHORYLATED CARBOCHAIN POLYMERS

As mentioned above, phosphorylated carbochain polymers have found a wide variety of applications. Thus, phosphorylated styrene–divinylbenzene polymers containing phosphoric acid groups and exhibiting ion-exchange properties are widely used in the sorption of transition metal ions from solutions of alkali metal and ammonium orthophosphates, from chloride solutions with a complex salt composition, and from phosphoric acid[156–159]. Polyampholytes containing both nitrogen and phosphorus are capable of sorbing tellurium[160], beryllium[161], and nickel[162] ions from electrolyte solutions constituting the waste from the metal treatment industry and its waste water. Nitrogen- and phosphorus-containing amphoteric ion-exchange resins with aminomethylphosphonic acid groups can be used for the joint sorption of copper and zinc from sulphuric acid solutions[163], while polymers with hydroxyethylidenephosphinic acid have been recommended for the elimination of iron from phosphoric acid and electrolytes[164].

Ampholytes based on network copolymers of 2-methyl-5-vinylpyridine, combining in a single elementary unit of the network matrix both the pyridine and α-aminomethylphosphono-groups, are selective in relation to copper in the presence of cobalt, nickel, and iron[165]. Phosphorus-containing polymers with hydroxyaminoalkylphosphono- and ethylenediaminephosphono-groups sorb uranium from carbonate-containing solutions[166]. Carbochain polymers with difluoroalkyl phosphate groups in the side chain also exhibit complex-forming properties[167].

Phosphorylated copolymers of styrene with vinylphenols or the glycidyl ethers of vinyl phenols have been used as phosphorus-containing polymeric catalyst carriers, which are characterised by a pronounced ability to swell in hydrocarbon solvents and an enhanced stability[168]. Polymeric ligands for metal complex catalysts have been obtained by treating phosphorylated polymers containing aromatic rings with organometallic compounds[169]. Pyridinephosphineiridium complexes fixed on macroporous polystyrene–divinylbenzene polymers with phosphine groups have shown a high activity in the hydrogenation of olefins[170] and the hydridocarbonyltris(triphenylphosphine)rhodium complex on a styrene–divinylbenzene copolymer is an effective catalyst of the hydroformylation of propene[171].

Phosphorylated carbochain polymers have been used as stabilisers of the ageing of high-molecular-weight compounds. It has been shown for polyethylene that they are effective inhibitors of thermo-oxidative degradation[172] and can be used as anti-ageing agents for cured rubbers based on synthetic raw rubbers[173–175].

The products of the interaction of tri(hydroxymethyl)phosphine with carboxyl-containing chloroprene and nitrile elastomers have been used as adhesives for the attachment of various types of rubbers to metals[176], while cured rubbers based on phosphorylated carboxylate raw rubbers exhibit an enhanced resistance to benzene[177]. Phosphorus-containing ethylene–propene rubber increases the thermal stability and improves the working properties of lubricating oils[178]. The product of the interaction of low-molecular-weight polypiperylene with di-isopropylphosphorodithioic acid has been used as a polyfunctional additive to lubricating oils with effective antioxidant, antiwear, and antidrag properties[179]. Phosphorus-containing oligoisobutylene exhibits analogous properties[180].

The polyphosphonates obtained by phosphorylating polystyrene, poly(2,6-dimethyl-1,4-phenylene oxide), or the styrene–vinylidene chloride copolymer has been used to prepare semipermeable membranes capable of sorbing selectively individual organic liquids from their mixtures with other liquids[181].

The product of the interaction of the acrylic copolymer with phosphorus pentoxide has been used as a reactive organic phosphate catalyst for thermoreactive varnish coatings[182]. Phosphorus-containing polystyrene combined with carbon tetrachloride has been used in peptide synthesis[183]. Certain phosphorylated carbochain polymers exhibit bactericidal properties[184]. They have been used as polymerisation initiators[185], for the prevention of the formation of scale, and also as flocculants[186].

Thus the study of the phosphorylation of synthetic carbochain polymers is undoubtedly of both theoretical and applied importance and the search for new phosphorylating agents and the expansion of the assortment of polymers used in this process will create even greater possibilities for the practical utilisation of such products.

Lignins as Components of Polymeric Composite Materials

E.G.Lyubeshkina

The results of studies of natural, native, and technical lignins are surveyed. Data are presented on the structures and physicochemical properties of various technical lignins (hydrolytic, sulphite, and sulphate lignins), which constitute the waste of the cellulose-paper and hydrolytic industries. Considerable attention is devoted to the examination of the properties of lignins which are responsible for their employment for the reinforcement of elastomers and the modification of plastics.
The methods of utilisation and rational employment of technical lignins in the plastics industry as active ingredients of polymeric composite materials are examined.
The importance of sulphate lignins as the most active from the standpoint of structure and properties in relation to the polymer matrix for the creation of highly filled lignin-containing polymeric materials—lignoplastics of the type of poprolin—is specially emphasised.
The bibliography includes 160 references.

I. INTRODUCTION

The accelerated rate of growth of the industry of polymeric materials under the conditions of the world economic crisis, the exhaustion of the petroleum resources, and the deficiency of polymeric raw materials has faced science and industry with new tasks involving the extraction and effective employment of the existing reserves and also the rational utilisation of the available natural resources.

From this standpoint, one of the promising trends in the technology of the processing of polymers is the formation of polymeric blended and highly filled composite materials with high indices of physicomechanical and operational properties. For this reason fillers play a major role in the solution of this important problem[1].

Practical experience has shown that the introduction of low-molecular-weight and high-molecular-weight fillers of different chemical types into the polymer matrix makes it possible to alter specifically the physicomechanical, rheological, and thermophysical characteristics of the polymeric materials and the articles obtained from them[2].

The creation of highly filled polymeric composites containing more than 20% of the filler (by volume), which involves a decrease of the consumption of the scarce basic polymer and a reduction in the cost of the material, is exceptionally important. This requires in its turn the search for cheap mineral and organic fillers the raw materials for which are extensive and readily available.

Calcium carbonate, kaolin, talc, silicon dioxide, metal oxides, asbestos, wollastonite, etc. have come to be widely used as mineral fillers[3-5]. The waste from stone quarries and stone processing industries, namely finely fragmented tuff, is used for this purposes[7].

Among organic fillers, carbon black, cellulose, carbon and graphite fibres, sawdust, cotton, coke, starch, and certain other substances have found applications[5,8].

Lignin and their degradation products[9-11], as well as kerogens and their processing products[12,13], which constitute the waste of the sulphate-cellulose and shale industries, are extremely promising organic fillers.

In selecting the fillers for polymeric materials, preference is given to organic products active in relation to the basic polymer, which facilitates their "combination" and the conversion of the compositions into finished articles and improves their physicomechanical characteristics.

The most widely used organic fillers for polymers are various kinds of carbon black, which still remain of primary importance, particularly in the technical rubber industry, where they are used as agents reinforcing elastomers[9,14]. However, the group of thermoplastic materials, for which readily available fillers of organic origin must be sought, provides the greatest potential possibilities for the development of the manufacture of filled polymers.

Technical lignins, which were first used as reinforcing fillers in natural and cured rubbers[15,16] but which have hitherto found limited applications in the plastics industry, are of great theoretical and practical interest from this standpoint. Admittedly, in view of the deficiency of the primary polymeric raw material, interest in lignin as a filler for thermoplastics has greatly increased in recent years in connection with the possibility of its employment for the creation of composition materials based on thermoplastics and their industrial waste[10,11,17-21].

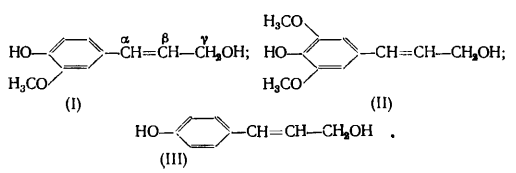
Lignins are natural organic raw materials, since they are constituents of wood and plants (their content in wood reaches 30%), where they play the role of lining agents[22], and are comparable in this sense to cement and iron concrete[23] (p.259). Thus lignins are one of the high-molecular-weight components of wood and occupy the second place (after cellulose) as regards their abundance throughout the world as organic polymeric substances of natural origin.

Lignins are not only lining materials but also reduce the permeability of cell walls and thereby play an important role in the transport of water, nutrient substances, and metabolic products. They also impart rigidity to the cell walls and, acting as an intercellular binder, impart to wood resistance to impact, compression, and bending. Lignification renders the woody tissue more resistant to the action of microorganisms.

The lignins present in plant tissues are referred to as natural lignins, protolignins, or lignins *in situ*. The term "native lignin" refers to the preparation isolated by Brauns's method[24].

When lignin is isolated from wood (delignification of wood), it undergoes significant chemical changes which depend on the method of isolation so that the lignins obtained under industrial conditions (technical lignins) are not identical in their structure to nature lignins.

Technical lignins constitute the waste of the cellulose-paper and hydrolytic industries and are utilised extremely irrationally—mainly by combustion[25,26]. However, the lack of reliable data concerning the structure of lignin precludes the determination of its behaviour in a polymer matrix and retards its employment as a filler of thermoplastics.



On the other hand, extensive theoretical and practical data have accumulated, which makes it possible to regard lignin as one of the promising fillers and modifying agents for polymeric composites (of the type of poprolin). It is therefore necessary to consider briefly the structure and properties of natural and technical lignins.

II. THE CHEMICAL STRUCTURE OF THE NATURAL LIGNIN MACROMOLCULE

The term "lignin" originates from the Latin word lignum (wood) and does not refer to an individual substance but to a group of related substances having common compositions, structures, and chemical properties for which Freudenberg suggested the term polylignols[27] and Shorygin suggested that they be referred to as lignin substances[28].

Lignin substances should be present in all plant tissues but some investigators hold the view that lignin appears in the course of the evolution of plants only in plants adopting a terrestrial mode of existence and that lignin is absent from seaweed[29].

At the present time lignins are understood as natural polymeric products formed by the enzymic dehydrogenation polymerisation of three main precursors: coniferyl alcohol (I), sinapyl alcohol (II), and *p*-coumaryl alcohol (III):[24]

The lignin macromolecule is formed in this process as a result of the combination of phenoxy-radicals, like other natural phenolic substances. Problems concerning the formation of the precursors of lignin and its biosynthesis in the plant cell walls *in vitro* and its chemical reactions have been described in detail in the literature[22,23,25-28,30-39] and there is therefore no necessity to dwell on them.

One should note that natural lignins undergo appreciable changes even on mild chemical treatment and for this reason methods permitting complete isolation of lignin from plants without the alteration of its chemical structure have not been found hitherto. The problem of obtaining ligning preparations analogous to natural lignin continues to be the most important in the chemistry of lignin.

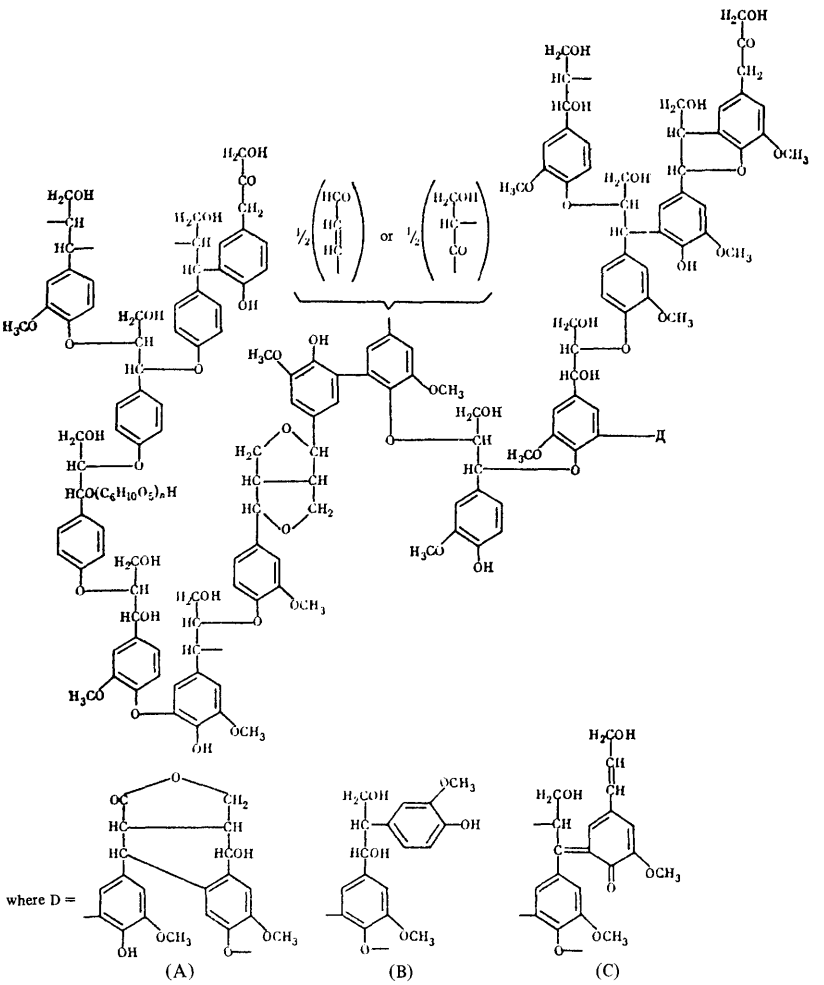
Natural lignins have a number of specific properties: they are readily oxidised, they readily interact with chlorine, which is an important factor in the bleaching of cellulose, and they are soluble in alkalies on heating. This ability of lignin constitutes the basis of the alkaline delignification of the sulphate and soda methods of manufacture of cellulose, while its ability to dissolve on heating in aqueous solutions of sulphurous acid and its acid salts is used in the delignification of wood by the sulphite method[25].

Lignins are resistant to the hydrolytic action of solutions of inorganic acids and contain a large number of methoxy-groups, which serve as sources of methanol and unpleasantly smelling methyl-substituted sulphur compounds, and also several per cent of phenolic hydroxyls, which play an important role in the modification of thermoplastics[24,25,40].

The ability of lignins to be readily oxidised is used not only in the bleaching of cellulose but also in the preparation of a number of valuable products such as vanillin, vanillic acid, etc.[24,30]

Lignins from different plants differ appreciably in their structure and for this reason one distinguishes (1) conifer wood lignins, (2) deciduous wood lignins, and (3) grassy plant lignins. Conifer wood lignins have been most thoroughly investigated—they form a fairly homogeneous group of substances and even lignins from different conifer species have very similar properties. On the other hand, the lignins from deciduous tress and grassy plants have been less well studied and are distinguished by a wide variety owing to their complex chemical structure[22,24].

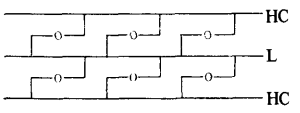
In the entire specialist literature on the chemistry of lignin, mention is made of the fact that its structure has been poorly investigated compared with a whole series of other substances with more complex chemical structures such as proteins, various enzymes, etc., which can be explained by the chemical inhomogeneity of the lignin macromolecule and the unsuitability of many classical methods of organic chemistry in the study of its structure. Therefore hitherto there is no formula which corresponds exactly to its real chemical structure.



Among all the known hypothetical formulae, reflecting the chemical structure of lignin, that proposed by Freudenberg is believed to be the most successful. A fragment of the molecule of native lignin is presented in Scheme 1,[24] where D represents the possible versions of the dimeric unit (A, B, C).

Adler proposed an ionic mechanism for the biosynthesis of lignin, but here too the initial stage proceeds via a radical mechanism and without electron transfer[34,41], which is of significant interest for the explanation of the character of the interaction of lignin with thermoplastics when it is introduced into the polymer matrix.

Investigators who have studied lignosulphonic acids, which are formed in the bisulphite digestion of Norway spruce, reached an interesting conclusion concerning the structure of the monomeric unit of natural lignin. They subdivide the aromatic compounds of spruce wood into lignin and hemilignin (by analogy with cellulose and hemicellulose) and believe that certain contradictions in the chemistry of lignins are associated with the different contents of hemilignin in the lignin preparations investigated[42,43]. It was shown in these studies that spruce lignin has a high degree of structural homogeneity and is a polymer consisting of identical monomeric units, each of which contains 16 guaiacylpropane and two *p*-hydroxyphenylpropane groups, which corresponds to Freudenberg's structure of lignin and confirms yet again the agreement between Freudenberg's hypothetical formula and the real structure of lignin.



Data concerning the structure of lignin *in vitro* permit the next step—the elucidation of its "secondary" structure in plants (*in vivo*) taking into account the polymers surrounding lignin in wood, which have different compositions and structures[40,44].

Scheme 1

As pointed out by a number of investigators, lignin exists in plant tissue as a carbohydrate complex and is linked to the cellulose and hemicelluloses in wood, mainly via an oxygen bridge[30,45–47]. Lignin bound to hemicelluloses, namely hemilignin, must have a branched structure. The relative distribution of hemilignin (L) and hemicelluloses (HC) in wood is represented in Scheme 2 taking into account the lignocarbohydrate linkages[40].

Scheme 2

The molecular weight (MW) of natural lignins is comparatively high (of the order of several thousands, but is lower than that of technical lignins); they have a fairly porous structure and a large specific surface (the specific surface of native lignin is 180–280 $m^2 g^{-1}$).[22]

Thus natural lignin has a fairly high molecular weight and is located in wood between cellulose fibrils and is therefore accessible to the action of reagents only after the hydrolysis of the cellulose or the loosening of the fibrils with rupture of hydrogen bonds. The delignification of wood under industrial conditions and the preparation of technical lignins are based on this principle[22,25,26].

III. INDUSTRIAL METHODS FOR THE DELIGNIFICATION OF WOOD AND THE PROPERTIES OF TECHNICAL LIGNINS

The methods for the isolation of lignin from wood and other plant materials are based either on the dissolution of the carbohydrates present in wood and the preparation of lignin in the form of an insoluble precipitate (in the preparation of hydrolytic lignin) or on the dissolution of lignin with its subsequent precipitation (in the preparation of alkaline lignins and lignosulphonates)[22,25,48].

Three methods of processing wood are used in the USSR and the side products of these industries are various technical lignins.

1. By a hydrolytic procedure, in which wood is treated with a dilute solution of sulphuric acid, hydrolytic lignin being obtained in the form of a non-hydrolysable residue[25].

2. By the sulphite method, in which wood is treated with a solution of calcium, magnesium, or ammonium bisulphite and

sulphurous acid, sulphite lignin or lignosulphonates being obtained[25].

3. By the sulphate method, in which wood is treated with a solution of caustic soda and sodium sulphide with formation of alkali lignins (sulphate alkali or soda alkali methods depending on which reagent is used to make good the loss of alkali)[48].

In conjunction with modern technology, the sulphate method is the most economical (compared with the soda method) since the chemical reagents are regenerated in a closed system with a high technical efficiency, which makes it possible to eliminate completely the pollution of soil and water reservoirs. These advantages of the sulphate method of the manufacture of cellulose explain its vigorous development both in the USSR and abroad, where sulphate lignin is known mainly as Kraft lignin[22,48].

Sulphate lignins have the highest chemical reactivity compared with other technical lignins.

The structure and properties of technical lignins depend on the type of tree from which the wood has been obtained and the method of its treatment, i.e. are determined by the type of digestion process.

Like native lignins, technical lignins are polyfunctional high-molecular-weight aromatic compounds made up of phenylpropane structural units whose characteristic feature is an irregularity of structure and a wide variety of linkages; their density is in the range 1330–1450 kg m^3 and they have high specific surfaces (from several units to several hundreds of $m^2\ g^{-1}$ depending on the moisture content of the product) and a high refractive index (1.61) as a consequence of their aromatic nature[32]. The difference between the structures of technical and natural lignins are indicated by the results obtained in their investigation and the invstigation of model lignin compounds by physical methods[45,49–60]. The EPR method, which helps to elucidate the mechanism of the modifying action of lignin on thermoplastics in the formation of polymeric composites such as poprolin and lignoplastics, has acquired considerable importance in recent times[61–67].

The first studies designed to detect free radicals (R) in lignin by EPR date back to 1960.[52] The absence of a signal from specimens in the form of fresh dry undamaged wood filings from several trees was reported and the concept of the absence of R in natural lignins was adopted. As a result of the employment of a more sensitive EPR spectrometer, such signals were later detected in undamaged wood of black spruce[53]. It was then observed that the intensity of the EPR signal increases in pulped wood after mechanical treatment and that the intensity of the signal in technical lignins depends on the delignification conditions[53–56].

The results led to the hypothesis that the radicals R are formed as a consequence of the comminution of the rigid lignin network due to the mechanical or thermal degradation in the course of digestion at 180–190 °C and that R should be present in all technical lignins. In all the lignins investigated (regardless of the method of delignification) the EPR signals did not exhibit an appreciable hyperfine splitting. It was found that the lignins from deciduous and conifer wood contain approximately 10^{18} spins per gramme with g-factors of approximately 2.00.[24] The factor $g = 2.00$ confirms that the source of signals in lignins are the radicals R formed on degradation of the lignins and consist of molecular fragments with radical centres having a specific structure[56]. The nature of these paramagnetic centres has not been established but it is believed that they are radicals of the semiquinonoid type. Stable phenoxy-radicals have also been detected, which can be attributed to the dehydrogenation of lignins[57].

Questions involving the study of the free-radical processes in the delignification of wood are important both for a more accurate determination of the structure of lignin and for the explanation of the mechanism of its action when it is introduced into a polymer matrix as an active ingredient of the polymer composition.

These reactions have been studied in greatest detail for sulphate alkali lignin; the results of these studies are examined in the next section.

The thermal properties of technical lignins are significant for their employment in the preparation of polymeric composites because the latter are processed at temperatures in excess of 200 °C. Unfortunately, the existing fairly extensive information in the literature[24,68–73] does not provide an unambiguous answer to the question of the thermal stability of lignins in general and technical lignins in particular, which can evidently be accounted for by objective difficulties which hinder the determination of their exact chemical structure.

The available data on the thermal degradation of lignins indicate their different thermal stabilities, which are determined both by the kind of tree from which the wood has been obtained and by the delignification method[68,69]. It has been established that the lignin obtained from spruce wood has a higher thermal stability, regardless of the method of its isolation, than deciduous lignin; this is caused by the enhanced capacity for condensation processes in coniferous lignin as a result of the accumulation of C–C bonds at high temperatures. There are data showing that lignins are pyrolysed by a free-radical mechanism[105].

It has been shown that the methoxy-groups have the highest thermal stability in the lignin molecule, being retained on heating above 350 °C, and it is therefore to be expected that methoxylation is one of the effective methods for the retardation of the rupture of the alkyl–aryl ether linkages, whose thermal stability is lowest.

Methylation of lignins inhibits the dissociation of the alkyl–aryl ether linkage and not only does not increase but actually somewhat diminishes the overall thermal stability of lignin. The reason for this is that the stabilising effect of the methoxy-group introduced is swamped by the reduction of the number of C–C bonds as a consequence of the cessation under these conditions of the primary condensation process and the decrease of the capacity of lignin for secondary condensation[69], since two competing processes take place in it during heat treatment (at temperatures of 150–300 °C): primary condensation with participation of the hydroxy-groups of the propane chain and the formation of the C–C bonds between the structural units of lignin and the disruption of the weakest alkyl–aryl ether linkages.

Thermographic studies of technical lignins have shown that their thermal stability is not as high as has come to be believed. The temperature range of the softening (glass formation) of lignins varies within wide limits (from 120° to 250 °C) and depends on the method of isolation, the molecular weight, and the moisture content. For example, the glass point of dry native lignin is T_g = 130 °C and that of moist lignin is 50 °C.[24,30]

The structural changes in sulphate lignins due to the softening and compaction of macromolecules are observed already at 150 °C and above and the temperature range 240–360 °C is the region of active thermal decomposition, which takes place with a sharp increase in the number of paramagnetic centres via a free-radical mechanism[74].

It has been noted that the thermolysis of lignins takes place in two stages. The first stage, which occurs at comparatively low temperatures (100–250 °C), involves dehydration; the second high-temperature stage (250–350 °C) proceeds via a radical mechanism[71,74]. Under these conditions, even in a high vacuum and at a low rate of heating the weight loss in the first stage is more than 40% and that in the second is 12%.

IV. HYDROLYTIC LIGNIN AND ITS UTILISATION

Hydrolytic lignin (HL) is a waste product of the hydrolytic industry, which exists only in the USSR, and also of the processing of agricultural waste. When the entire capacity of the hydrolytic industry is utilised, more than one million tons of HL will accumulate annually in the waste. The solution of the problem of the utilisation of such waste is therefore urgently required.

Wood and agricultural plant waste are hydrolysed in special apparatus by percolating a hot 0.5–1% solution of sulphuric acid through a layer of hydrolysable material at 180–185 °C and pressures up to 144 mN m^{-2}.

Hydrolytic lignin is a polydisperse product with a particle size up to 1 cm and is a blend of substances of different chemical types. It incorporates comminuted polymerised lignin proper, polysaccharide residues, monosaccharides which were not washed off in hydrolysis, inorganic and organic acids, resins, waxes, nitrogen-containing substances, and ash elements[25]. In addition, it contains traces of furfural or hydroxymethylfurfural and its structure is that of a cross-linked polymeric product whose molecular weight as well as its chemical structure have not been accurately determined; HL is insoluble in organic solvents, alkalies, and acids.

Hydroltyic lignin is a hygroscopic product, so the moist lignin must be regarded as a three-phase system consisting of solid HL proper, water, and air[25,26,75].

Technical HL obtained in factories is usually highly contaminated by various impurities and its chemical structure varies, which greatly hinders its processing and utilisation both as a reinforcing agent and filler for plastics and elastomers[25,26].

Since HL has a cross-linked structure, it must be improved and modified before being introduced into polymeric materials. The modification of hydrolytic lignin consists in its treatment with active chemical reagents followed by nitration, sulphonation, phosphorylation, chlorination, and certain other reactions. Chlorination is regarded as one of the promising methods for its modification[76].

A number of realistic methods for the activation of HL involves the treatment with alkalies of its aqueous solutions at elevated temperatures (180–200 °C).[26] The mechanism of this process is not yet sufficiently clear, but there exists the view that the dissolution of lignin on treatment with an aqueous solution of alkali takes place as a result of the rupture of ether linkages with loss of methoxy-groups and the formation of free phenolic hydroxy-groups. At the same time the side chains are partly oxidised to carboxy-groups. Alkaline HL is a reactive product and can be used successfully for the reinforcement of elastomers together with sulphate alkali lignin.

Since, as stated above, HL is extremely hygroscopic, its internal surface area is determined by the moisture content (it is 760–790 $m^2\ g^{-1}$ for moist lignin and only 6 $m^2\ g^{-1}$ for dry lignin). The moisture content also determines the specific gravity and bulk density of lignin, which amount to 1500 and 200 kg m^{-3} for the dry product, the specific gravity of the product with 15% moisture content is 1300 kg m^{-3}, and the specific gravity and bulk density of the products with a 65% moisture content are 1150 and 700 kg m^{-3} respectively[77]. The angle of the slope of repose for crude lignin is 40–43°.

Hydrolytic lignin has a porous structure (the pore radius reaches from 30 to 200 Å) and has a low bulk density in the dry state, which reaches 190–220 kg cm^{-3}.

Since HL contains an increased amount of moisture as a consequence of its hygroscopicity and is a coarsely disperse system with a particle size up to 1 cm, before its utilisation it must be subjected to an additional treatment to increase the degree of its dispersion, which is achieved by additional drying, vibromilling, etc. The structural-mechanical (rheological) properties of HL and its capacity to absorb moisture are important for a theoretical justification of the rational drying regimes.

The study of the rheological properties of HL subjected to different degrees of processing and with different moisture contents showed that the general postulates of the physicochemical mechanics of disperse structures can be applied to it[75].

The methods for the utilisation of HL available at present cannot be regarded as rational and scientifically well founded. One of the simplest procedures for its utilisation involves combustion, since the industrial product is highly contaminated by non-lignin impurities and has a cross-linked structure, which creates additional difficulties in its employment. However, moist HL has a low heat generating capacity, which is 5500–6500 cal kg^{-1} for absolutely dry lignin, 4400–4800 cal kg^{-1} for the product with an 18–25% moisture content, and 1500–1650 cal kg^{-1} for lignin with a 65% moisture content, so that its employment as a fuel is ineffective. The low caloric value of HL as a fuel can be explained by the fact that lignin ejected from the hydrolytic apparatus has a moisture content in excess of 90%, so that for each tonne of lignin it is necessary to remove 900 kg of water and this requires a large amount of heat. The drying of lignin is also complicated by the fact that, like cellulose, it can form hydrates with water–lignin-OH.[77]

There exist also other methods for the utilisation of hydrolytic lignin although not on an industrial scale. For example, HL can be used to prepare high-quality brands of activated charcoal. There exist technological schemes which make it possible to obtain charcoal and also other products of the dry distillation of HL. The charcoal obtained is used to manufacture carbon disulphide and carbon tetrachloride, for the preparation of activated charcoal, and also in the manufacture of polymeric materials[25,26,78,79].

More promising ways of using HL involve its chemical reactions.

The oxidative hydrolytic cleavage of HL in an alkaline medium leads to the formation of a mixture of organic acids, which can be used in the yeast industry in the accumulation of the protein and yeast mass, which makes it possible to increase the yeast resources by 20%.[80,81]

The HL nitration products can be used in the drilling for petroleum and gas as substances which reduce the viscosity of clay solutions and the products of nitration with more concentrated (30%) acid can be employed as growth substances[79].

The most promising products are chlorinated hydrolytic lignins which have found applications as substitutes for natural tanning agents and as reinforcing agents for natural rubbers and their activities are similar to those of sulphate lignins[82].

The hydrogenolysis of HL yields between 60 and 85% of low-molecular-weight ether-soluble products which include up to 70% of phenols, most of which are capable of condensing with formaldehyde to form resins of the phenol-formaldehyde type (Novolak and Reson resins)[26,83]. Thus HL can serve as a source of aromatic phenolic substances and cheap biologically active compounds with a quinonoid structure.

In the course of the oxidative degradation of hydrolytic lignins, which is carried out in solution in ammonia at high temperatures (above 300 °C) in the presence of oxygen, the formation of low-molecular-weight acids is accompanied by the simultaneous oxidative ammonolysis reaction; it has been noted that it proceeds via a multiplicity of pathways owing

to the presence in the lignin macromolecule of a large number of functional groups having both the electron-accepting properties of the conjugation system and the electron-donating properties of the protons in the aromatic rings. The product of the oxidative ammonlysis of HL is ammonised lignin, which is characterised by a high content of strongly bound nitrogen not hydrolysable by acids, whose pyrolysis at temperatures up to 500 °C does not entail the formation of tars[84].

In oxidative ammonolysis, conjugated bonds accumulate in the lignin and, as a result of the incorporation of nitrogen in its macromolecule, its electrical conductivity rises sharply and its EPR signal intensifies, which indicates an appreciable delocalisation of the π electrons of the double bonds both within and between individual parts of the lignin macromolecule. As a consequence of the presence in HL of a system with conjugated bonds, it has the properties of an organic semiconductor, exhibiting paramagnetism, and its electrical conductivity is low[60,84,85].

One of the interesting features of the ammonised lignin as a product with the properties of an organic semiconductor is its catalytic activity in the decomposition of hydrogen peroxide. A distinct correlation has been noted between the catalytic activity of polymeric semiconductors having a conjugation system and their paramagnetic properties[84].

Ammonised lignin is biologically active. When it is introduced into soil in small amounts, the vegetative growth of the plant mass is found to be accelerated and the resistance to the action of decay-causing bacteria is enhanced.

Other applications of activated HL are also known, for example, in the preparation of its derivatives which are used as flotation agents instead of cyanides[86].

Hydrolytic lignin has also found applications in the manufacture of thermoplastics and reactoplastics[25,26,87-89].

A technology for the preparation of press-powders with heat and moisture resistances and improved dielectric parameters (compared with the press-powder from traditional resins of the 03-010-02 type), which can be used in the manufacture of electrotechnical articles instead of traditional resins, has been developed on the basis of the waste from the hydrolytic industry and agriculture[87].

Yet another promising application of HL in the plastics industry is the preparation from it of press-compositions for the manufacture of pressed articles at an elevated temperature with effective physicochemical parameters and reduced capacity for the absorption of water and susceptibility to wear. The optimum content of lignin is 10–15 wt.%, the sump and neutraliser sludge from the hydrolytic industry being used as a modifying agent, which greatly extends the material base for the manufacture of such articles and reduces their cost[89].

Since, in contrast to cellulose, stable colours can be imparted to HL by basic vat dyes, it has been suggested that lignin be dyed in order to modify its surface[25,88].

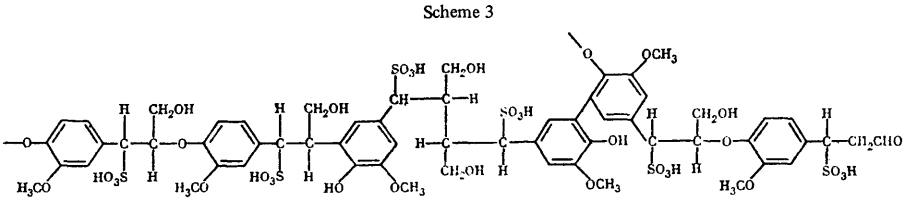
When insoluble dyes (Aniline Black, azo-dyes, etc.) are deposited on HL, its adsorption properties change significantly, so that the dyeing of lignin by appropriately selected dyes can be used in order to modify its surface properties. The dyed HL is of interest as an active filler for the poly(vinyl chloride) resin for the preparation of linoleum. The manufacture of such linoleum is very economical, because it makes it possible to reduce the consumption of the resin by 20–30% and the specific consumption of the plasticiser per m^2 of linoleum is reduced by 15–20%.[25] The dyed lignin can be employed as an active filler for thermoplastics, reactoplastics, and synthetic rubbers[88].

The considerable saving of thermoreactive resin is achieved by employing phenol-lignins or lignophenol-formaldehyde resins, obtained by the condensation of phenol and HL. Phenol-lignins are suitable for the manufacture of press-powders and their physicomechanical parameters are not inferior to those of the phenol-formaldehyde resin manufactured industrially[25].

One of the promising methods for the utilisation of lignin waste from the hydrolytic industry is its employment as thermally insulating materials; new methods of manufacture of constructional elements on their basis are being developed.

HL is used in the building industry, in the cement and brick industries (the preparation of lignoconcretes and other constructional materials based on lime, cement, and gypsum with added polymeric materials), in agriculture, and in other branches of the national economy[25,26,90], but the applications of lignin for these purposes are merely incidental and are not widely used on an industrial scale. Great potential possibilities for such employment of HL are inherent in the plastics industry, where the creation of filled polymeric materials using cheap active fillers constitutes an urgent problem[1].

V. SULPHITE LIGNIN (LIGNOSULPHONATES) AND ITS UTILISATION



Lignosulphonates constitute the waste from the cellulose-paper industry in the manufacture of cellulose by the sulphite method. In this manufacturing cellulose-producing process, wood is heated with the digesting acid (an aqueous solution containing 2–10% of SO_2 in the form of free sulphurous acid and 1.3–2.5% of SO_2 as calcium bisulphite) with a stepwise increase of temperature to 145 °C. During the digestion, lignin is sulphonated. Almost the entire lignin and a large proportion of the carbohydrates accompanying cellulose can then be dissolved[25].

The chemistry of the sulphonation of lignin in sulphite digestions has still not been unambiguously elucidated but it has been shown that it may entail not only the sulphonation of lignin with formation of SO_3H groups but also the introduction of sulphate groups with formation of acid sulphate esters $R-OSO_3H$, in which the bond between sulphur and lignin is formed via oxygen[91].

The spent sulphite liquors contain aromatic substances whose composition is similar to that of lignosulphonic acids.

The lignosulphonic acids obtained in the manufacture of sulphite cellulose in the form of salts (calcium, sodium, ammonium, or magnesium lignosulphonates) have a variable composition, particularly as regards the content of carbonyl groups,

Scheme 3

depending on the degree of sulphonation and the methods of isolation. They are soluble in water, are titrated like strong inorganic acids, and are polyelectrolytes[92].

These acids constitute a polydisperse system with a wide range of molecular weights (2000–100 000).[30] The molecular structure of such an acid consists of a disordered, entangled, branched helix. The chemical structure of lignosulphonates has not been established, but by convention it can be represented in terms of the formula in Scheme 3.[25] During sulphite digestion, a major proportion of the lignin, in the form of lignosulphonic acids containing 4–6% of sulphur which form acid-containing groups of different strengths in the lignin[93], a large proportion of hemicelluloses, and other polysaccharides (including a certain amount of cellulose), tannins, and many inorganic subbstances pass into solution in the sulphite liquor[94].

The waste from the sulphite-cellulose industry consists mainly of the calcium salts of lignosulphonic acids and sugars [polysaccharides (pentoses) and monosaccharides (hexoses)] in proportions of approximately 2 : 1.[25] The reactions occurring in sulphite digestions have been examined in detail in the literature[23–25]. Valuable information about the structure of sulphite lignin is quoted by Forss and Fremer[42].

The hydrolytic and sulphonation reactions occurring in the acid treatment convert lignin into lignosulphonic acids with an extremely wide variety of molecular structures, including high-molecular-weight products with molecular weights in excess of 40 000. The content of such high-molecular-weight products is insignificant.

In order to isolate the lignosulphonates, the sulphite liquors are subjected to biochemical processing after separating cellulose, which results in the formation of a concentrate used for technical purposes.

Lignosulphonates are also manufactured in the form of liquid products and their amount manufactured in this form is ten times greater than in the solid state[94].

Free radicals, probably formed in the depolymerisation of lignosulphonates which constitutes a set of free-radical processes, have been detected in the lignosulphonic acids obtained from sulphite digestions[42,46,56]. However, the nature of these radicals could not be identified.

Thus the sulphite lignin in the form of lignosulphonates is the lowest-molecular-weight product among all the technical lignins and is characterised by a high solubility, also in water, and its principal practical applications are associated with this factor.

The varied applications of lignosulphonates substituted by univalent, bivalent, or polyvalent metals in various branches of industry and agriculture are based on their use as ion-exchange compounds, dispersants, surfactants, and fillers for natural tannides; their adhesive properties are also employed[25,26,94].

Lignosulphonic acids are of great interest as raw materials for the preparation of vanillin and vanillic acids[94].

Other applications of lignosulphonates are also known and these can be expanded by developing an extremely interesting method of biochemical processing of the organic materials in the liquor using not only carbohydrates but also lignin substances[86].

VI. SULPHATE ALKALI LIGNIN (KRAFT LIGNIN) AND ITS APPLICATIONS IN THE MODIFICATION OF POLYMERIC MATERIALS

Among all the types of industrial lignins, sulphate lignin, whose manufacture reaches an appreciable volume in view of the fact that three-quarters of the world production of cellulose (approximately 10 million tonnes annually) involves the sulphate method (the Kraft process), is most widely used in all industrial countries possessing wood as a raw material.

Alkali lignin is obtained as industrial waste in the manufacture of Kraft cellulose, where a mixture of sodium hydroxide and sodium sulphides is used as the base. The soda and sodium sulphate methods of preparation of cellulose are available. In these procedures wood is treated with a solution of alkali at 165°–175 °C.[48]

The principal difference between the soda and sodium sulphate methods of preparation of cellulose consists in the fact that the losses of part of the alkali, inevitable in the manufacturing process, are made good in the first instance by the addition of soda and in the second by the addition of sodium sulphate. The soda lignins are less soluble in organic solvents and are apparently more condensed than the sulphate lignins[95].

The spent dark solution obtained as a result of the digestion is called the black liquor and contains, together with inorganic substances, approximately half of the organic components of the initial wood, most of which is lignin. Since the technological cellulose digestion process by the sulphate method does not differ significantly from the soda method and the economic gain is fairly considerable, the sulphate method has almost completely displaced the soda method at the present time and henceforth we shall be dealing with sulphate alkali lignin or Kraft lignin.

The sulphate alkali lignin is sometimes called (not entirely correctly) "thiolignin", since a certain amount of organically bound sulphur (up to 2.5–3%) has been detected in it. However, this question remains controversial. It is most likely that the sulphur bound in organic compounds at the beginning of the sulphite digestion is split off during the subsequent digestion process and that the residual sulphur in the final product—the sulphate lignin—is most likely to be merely part of a side product stabilised as a result of side reactions[23,95].

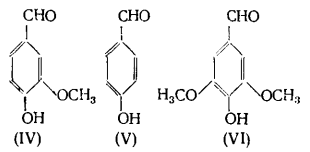
In the sulphate method of manufacture of cellulose, virtually the only method of utilising the lignin obtained in the form of the black liquor remains its combustion. The part of the lignin contained in the "weak" liquor resulting from the washing of the cellulose and in the waste from the decomposition of the sulphate soap enters the waste water and pollutes it (waste water lignin).

In the Soviet Union and abroad rational ways of utilising sulphate lignin are being sought. The solution of this problem is at present urgently required also because in the industrial manufacture of cellulose an enormous amount of black liquors and waste water accumulate and their main organic component is lignin. In contrast to the other technical lignins isolated, Kraft lignins contain an increased amount of active acid groups (phenolic and hydroxyl), which largely determines their reactivity and the possibility of their practical employment for the reinforcement of rubbers and in the plastics industry. Sulphate lignins are therefore the most reactive and exhibit the highest chemical stability.

The difficulties in the employment of sulphate lignin are associated with the necessity to isolate it from the black liquors with a high yield of the lignin itself and this requires the development of a special technology[96,97].

For economic reasons, only two neutralising agents can be used to isolate lignin from the black liquor: H_2SO_4 and CO_2. When CO_2 is used, the yield of lignin is from 30% (carbonation without the application of pressure) to 70% (carbonation under pressure) of the amount present in the black liquor, while in the case where sulphuric acid is used, the amount isolated is in excess of 90%. A technology for the isolation of the carbon

dioxide and sulphuric acid sulphate lignins has been developed in the USSR. The chemical reactivities of these lignins hardly differ. However, the intrinsic cost of the carbon dioxide lignin (135 roubles per tonne) is 1.5 times higher than that of the sulphuric acid lignin[98,99].



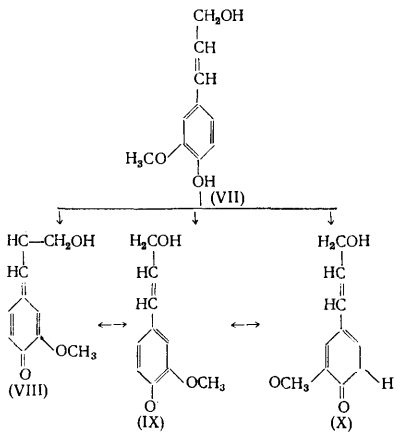
Pine, spruce, fir, larch, aspen, birch, popular and other types of wood as well as reeds, straw, and sawmill and wood processing waste are used as raw materials in the sulphate cellulose industry.

In the course of alkaline digestions and during the isolation of lignin from the black liquors, complex transformations associated with the rupture of hydrogen bonds under the influence of sulphide ions and alcoholic hydroxyls take place in the protolignin molecule, which greatly alters the structure of the Kraft lignin.

1. Characteristic Features of the Chemical Structure of Sulphate Lignin

Sarkanen, one of the senior foreign investigators of the chemistry of lignin, pointed out that the sulphate lignin precipitated from the black liquors on acidification is an ill-defined substance containing 2–4% of sulphur. However, its chemical structure is closest to that of natural lignin[72,100].

Bogomolov[48,96–98,101] and a number of foreign investigators[24†,55,102] have played a considerable role in the alkaline delignification of wood and the determination of the structure of sulphate lignin. The alkaline digestion of wood in the manufacture of cellulose constitutes a complex set of processes of different kinds, both chemical and physical. The chemical structure and properties of the resulting Kraft lignins are then significantly influenced by the conditions of the digestion and the origin of the wood employed (coniferous or deciduous)[24,25]. Lignins from gymnosperms (coniferous lignins) and lignins from angiosperms (deciduous lignins) differ in the products of their nitrobenzene oxidation: coniferous lignins give rise mainly to vanillin (IV) and small amounts of *p*-hydroxybenzaldehyde (V), while coniferous lignins produce vanillin and syringaldehyde (VI):



The chemical structure of the sulphate lignin isolated from the black liquors in the alkaline digestion has been examined and its various functional groups have been described in detail[24,102]. Reliable data have been obtained showing that the main bulk of the phenylcoumarin structures are converted during treatment into stilbene structures[30], which are formed when the radicals combine in accordance with Scheme 4 and apparently persist in the sulphate digestion and are present in Kraft lignin[28,30,102].

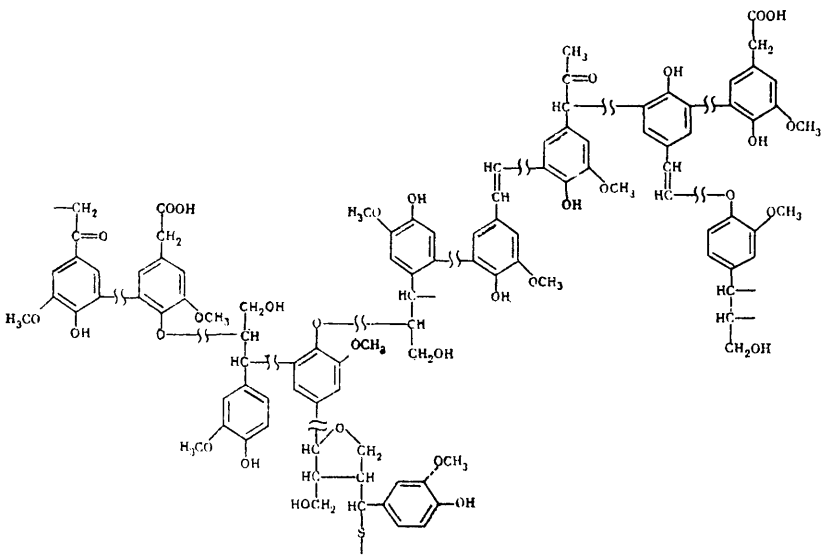
The stilbene structures cause the high reactivity of sulphate lignins and the reinforcement of polymers treated with such lignins.

† Chapter 12.

It has been established that Kraft lignin contains a considerable amount of phenolic hydroxyls, catechol groups, unsaturated quinonoid structures, aliphatic COOH groups, and other active structural elements containing double bonds.

Scheme 4

The principal distinctive feature of sulphate lignin is the presence of bound sulphur in amounts ranging from 1.5 to 3.0%, depending on the digestion conditions and the method of isolation of the lignin. A fragment of the structure of the sulphate lignin macromolecule is presented in Scheme 5:[28]



The alkaline digestion process constitutes a set of chemical reactions: the penetration of chemical reagents, the dissociation of lignin–carbohydrate linkages, thermal degradation of the lignin macromolecule, secondary reactions involving the condensation of fragments of this molecule, the removal of products from the reaction zone, etc. The reactions occurring in the alkaline digestion have been described in detail[24,30].

2. The Properties of Sulphate Lignin Responsible for Its Utilisation for the Reinforcement and Modification of Polymeric Materials

The EPR study of the paramagnetic properties of lignin provides great possibilities for the determination of the structures of native and technical lignins and also for the estimation of the modifying effect of Kraft lignin. As mentioned above, paramagnetic properties are characteristic of all kinds of technical lignins[42,56,60,85,94]. Free radicals were first detected in Kraft lignin by Kleinert and Marton[53] and these studies were continued in the cell of the EPR spectrometer in which wood was subjected to alkaline digestion[24,57,58]. It was established that the formation of the radicals R is the principal feature of the thermal wood delignification reactions and takes place when different methods are used for the delignification of wood at high temperatures (160° to 190 °C) regardless of the chemical nature of the raw material employed[24,54,56–58].

Free-radical reactions play a very important role in the alkaline delignification of wood particularly under the conditions of high speed digestions[54,55]. It has been noted that the concentration of the radicals R increases almost linearly with increase of the digestion time from 5 to 20 min (approximately in the first 0.5 h) and after the attainment of a

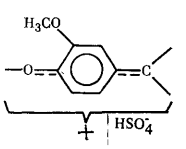
Scheme 5

maximum the concentration of R diminishes. This is probably a consequence of the fact that the alkaline delignification can involve two independent processes: degradation of the Kraft lignin macromolecules accompanied by an increase in the concentration of R and a decrease of the molecular weight and the subsequent condensation of the decomposition products accompanied by a decrease of the concentration of R and an increase of the molecular weight of the product.

However, when sulphate lignin is used for the modification of polymeric materials, it is necessary to know the character of the radicals R formed in it. Difficulties arise in the solution of this problem because it is impossible to resolve the hyperfine structure of the EPR spectra of the R formed. Many workers believe that natural lignins do not contain R at all and that the latter arise only on delignification of wood or in the course of its biological decomposition. The radicals R can also be formed as a result of the mechanodegradative processes during mechanical treatment with dissociation of covalent bonds[45,52,53,56,59].

This process has remained controversial hitherto, although recently it has been possible to obtain the EPR spectrum of Kraft lignin with a distinctive hyperfine structure at room temperature[45]. With increase of the digestion time, the spectrum changes: the signal loses its hyperfine structure and becomes of the singlet type. The EPR data for the soda and sodium sulphate treatments differ. Thus in the soda treatment the intensity of the EPR signal initially decreases and after a certain time (40 min) reaches a constant value, which permits the conclusion that two types of radicals are generated: unstable radicals whose concentration decreases with time from the start of the experiment and stable radicals whose concentration remains unchanged for 40 min.

In the sulphate treatment the hyperfine structure of the EPR spectrum was less distinct and disappeared faster than in the soda treatment. Furthermore, only a decrease of the EPR signal intensity was noted in the sulphate treatment.



Comparison of data for the variation of the intensity of the EPR signal of lignin in the soda and sodium sulphate digestions shows that the influence of sulphur in the alkaline treatments can be explained by the inhibition of radical processes. When reducing agents (for example, sodium tetrahydroborate) are added to the liquors, the concentration of R falls and the hyperfine structure decreases much faster than in the soda digestion. The primary electronic excitation centre in the lignocarbohydrate complex is a semiquinonoid radical formed, which is fairly stable for some time[45].

The reactions of the radicals formed in the alkaline digestion cause the cross-linking of lignin and the increase of its molecular weight during the initial periods of the digestions. Inhibition may be achieved by introducing reducing agents ($NaBH_4$, Na_2S, cysteine, hydrazine, and thioglycolic acid). whose reduction potential is higher than that of lignin and carbohydrates in an alkaline medium, and by recombination reactions between lignin radicals and a specially introduced substance[103].

There exist two points of view concerning the nature of the increase of the molecular weight of lignin in alkaline digestions: the first explains the increase of the molecular weight by polycondensation processes and the second—by the interaction of the radicals. Both concepts remain controversial.

In addition to the view which explains the paramagnetic properties of lignin by the formation of the radicals R, it has been suggested that the paramagnetism of lignin has a radical nature[104] which for technical lignins is attributed to the presence of paramagnetic carbonium centres in their molecules.

Stable carbonium centres are formed in all technical lignins, and their stability can be explained both by steric factors and by their ability to combine with anions in solution to form carbonium salts:

The proposed mechanism of the formation of carbonium centres makes it possible to discover the cause of the differences between the sodium sulphate and soda digestions and also to explain the sharp increase of the EPR signal intensity of alkaline preparations of lignin in protic solvents, for example, in concentrated sulphuric acid. The stability of the paramagnetic carbonium ions may be influenced favourably also by other nucleophilic additives, such as amines, mercaptans, etc.

Taking into account the latter data, one may assume that the real nature of the paramagnetism of lignin is of a dual kind.

Interesting results have been obtained on irradiation of lignin and its model compounds with ultraviolet light at a wavelength of 300–400 nm directly in the EPR spectrometer[68]. The resulting spectra permitted the conclusion that phenoxy-radicals are formed preferentially.

The formation of phenolic compounds in the thermal decomposition of lignins, including alkali lignin, has also been discovered[70,73].

The inhibiting role of lignin (as a result of the formation of quinone methide structures) is indicated by the data of Zoldners et al.[105] The results reveal yet another promising application of lignin as an inhibitor and stabiliser with respect to the action of light for polymeric materials and compositions based on them (particularly compositions based on polypropylene), since there is a correlation between the stability of organic free radicals and the efficiency of their reaction[106].

Sulphate lignin is a lamellar amorphous polymer with a polydisperse structure which tends to undergo association and is characterised by a definite molecular order in its structure[107,108].

The molecular weights of Kraft lignins were first determined by Marton, Marton, and Lindberg[102,109,110] by different procedures and in different solvents and showed a fairly wide scatter: the weight-average molecular weight $\overline{M}_w$ was in the range 5600–25 000 and the number-average molecular weight $\overline{M}_n$ was in the range 1000–20 000. The ratio $\overline{M}_w/\overline{M}_n$ was 2.2 for the sulphate lignin from conifers (pine lignin) and 2.8 for the sulphate lignin from deciduous trees, which may indicate an appreciable dispersity.

The study of the molecular weight and the molecular weight distribution (MWD) of sulphate lignins showed that $\overline{M}_w$ of lignin is determined both by the digestion temperature and the sulphide content of the digestion liquor[96,111,112]. The values of $\overline{M}_w$ obtained for sulphate lignin varied from 4000 to 24 000 for digestions according to isotypical plots and from 7000 to 31 000 for stepwise digestions. The soda lignins isolated from the mass of cellulose in the soda digestion had a higher value of $\overline{M}_w$ than sulphate lignins.

The wide range of variation of the $\overline{M}_w$ of sulphate lignins cannot be attributed solely to the method of measurement of their molecular weight. It is probably caused by the different degrees of degradation of the soluble lignin in the digestion process or, possibly, by the association of the alkali lignin in solution, which was not taken into account in the early investigations[30].

Like lignosulphonates, sulphate lignins with a low molecular weight exhibit a high dispersing power, which is determined from the decrease of the viscosity of an aqueous suspension of rutile (titanium dioxide) on dissolution of a specific amount of lignin. The high dispersing power of Kraft lignin led to its employment in the form of industrial colloids (dispersants, binders, fillers, and gel-forming agents)[24] (Chapter 13).

A sulphate lignin paste for the building materials industry and powdered sulphate lignin for the technical rubber article industry are manufactured in the Soviet Union. The study of the properties of sulphate lignins produced by industry showed that they consist of products with a fairly high molecular weight of 4500–7500 and a degrees of polydispersity of 3.3–3.9.[97]

Technical lignin is a brown powder with a particle size from 100 to 200 μm, the 100–125 μm particles constituting the largest fraction. Particles of this size are largely spherical in a slightly fused envelope, while the larger particles consist of aggregates of the spherical particles. When sulphate lignin is dried (in the upper drying chamber) and also when it is vibromilled, not only its aggregates but also the spherical particles themselves are disrupted.

The vibromilled lignin particles have a high specific surface (up to 23 $m^2\ g^{-1}$) and are characterised by an excess of free energy, which may be the cause of their adhesion to one another and the formation of a complex of secondary particles whose size approaches to the optimum particle size of the non-comminuted lignin. The density of Kraft lignin is approximately 1300 $kg\ m^{-3}$.[22]

When the optimal technological parameters are maintained in the manufacture of sulphate lignin, the finished product has a fairly constant functional composition in terms of the ash, acid, and sulphur contents as well as the contents of water-soluble and tarry substances.

The infrared spectra of industrial batches of sulphate lignin are fairly isotypical both as regards the presence of absorption bands at the same wavelengths and the relative optical densities.

The thermal properties of lignin were already noted above. The presence of lignin in wood is the cause of its thermal softening, which begins in the temperature range 120° to 160 °C. The softening temperature (glass point) of lignin varies appreciably depending on its source and method of isolation[24] (Chapter 13). Sulphate lignins sinter at approximately 200 °C and tend to pass to a fluid state at elevated temperatures.

Important properties of sulphate lignin include its capacity for adhesion, which is a function of temperature, and its sorption properties[24,113].

On treatment with water, the degree of sorption of moisture increases, moisture acting as a low-molecular-weight diluent which reduces the transition temperature (T_g).

The solubility of lignin in various solvents depends on its sorption properties. It has been established that the action of solvents on lignin is a function of the cohesion energy density and the ability of the solvent to form hydrogen bonds. The maximum solvent power in terms of the Hildebrand parameter δ, defined as the square root of the cohesion energy density, is then observed for $\delta = 11\ cal^{1/2}\ cm^{-3/2}$. The solvent power of solvents with δ between 10 and 11 in relation to lignin increases with increasing ability of the solvent to form hydrogen bonds.

The study of solubility data has shown that the behaviour of lignin with respect to solvents and other macromolecules cannot be explained solely on the basis of the parameter characterising the ability to form hydrogen bonds, whose measure is the shift $\Delta\lambda$ of the infrared absorption of the OD group when the solvent is mixed with CH_3OD. However, water, which is usually a "poor" solvent for lignin, has the very high parameter $\delta = 23.4\ cal^{1/2}\ cm^{-3/2}$. On this basis one may conclude that, in estimating the solubility, one must take into account the overall effect of the polarity of the solvent molecules[110].

It has been shown that the fractions of lignin with a smaller molecular weight are soluble in solvents with a wider range of δ and $\Delta\lambda$ than the fractions with higher molecular weights. "Good" solvents for lignins must have $\delta \cong 11$ and $\Delta\lambda \geq 0.14$.[114]

From this standpoint, "good" solvents for sulphated lignin are dimethyl sulphoxide, dimethyl formamide, acetone, dioxane, pyridine, ethanol, methylcellosolve, and certain others, while "moderate" solvents are ethyl acetate and others[110].

Evidently the infrared spectra and solubility parameters of lignin provide information about its molecular size, the nature of its intermolecular interaction, and the general properties of the product. This applies particularly to the interaction with a single solvent. When mixed solvents are used, the problem is greatly complicated, but, with the aid of the two-parameter theory, it is possible to predict roughly the relation between the structure and solubility of lignins in binary and even ternary systems in terms of the reaction parameter (the Flory parameter).

3. Other Types of Sulphate Lignins

(a) *The ligno-tail product of the sulphate-cellulose industry.* In the alkaline delignification of wood, not only lignin but also resin and aliphatic acids, neutral substances, phenols, a proportion of carbohydrates, and other substances of organic and inorganic origin forming part of wood pass into the digestion solution called the "black liquor"[48]. When the black liquor is allowed to stand, the resin and aliphatic acids in the form of sodium salts coagulate and rise to the surface entraining the accompanying substances. The coagulation product is called the sulphate soap which has a complex composition, containing lignin and lignin-like substances among others.

The sulphate soap is in its turn decomposed with sulphuric acid, after which the reaction mixture is divided into three-layers: the tall oil brick, crust, and solid salts. The reaction mixture prior to separation into three layers is called the ligno-tall product and is a valuable raw material for the regulation of polymeric materials. The ligno-tall product (a mixture of tall oil and crust—lignin and lignin-like substances) contains up to 60% of tall oil, which is a mixture of aliphatic and resin acids, an insignificant amount of non-hydrolysable products, and approximately 40% of lignin.

The ligno-tall product (LT) can be obtained by mixing the markedly dustlike sulphate lignin powder with tall oil in proportions of 2 : 1.

The waste from the sulphate-cellulose industry can also be used to obtain the LT product: the acid water from the sulphate soap decomposition apparatus, light oil, pitch, etc.[97] A distinctive feature of the LT substances obtained in this way is a high ash content, which necessitates the removal of inorganic substances from them.

The LT substances can be mixed with a suspension of sulphate lignin in proportions of 1 : 2 and the new suspension of tall oil and lignin then yields a crude ligno-tall product which has approximately the same characteristics as dry powdered sulphate lignin. The applications of these lignins in the polymeric industry are approximately the same.

(b) *Lignin obtained from waste water (sludge lignin) from the sulphate-cellulose industry.* When the waste water from the sulphate-cellulose industry is purified, a large number of wash waste is produced—a sludge, which consists of waste water lignin and is a valuable chemical raw material. The sludge lignin provides a virtually inexhaustible source of raw material, since it accumulates in enormous amounts in waste dumps after the waste water has passed through the biological and chemical purification stages[99,115].

Industrial waste water from the sulphate-cellulose manufacturing process contain a large amount of lignin and organic substances. The purification of such water and the processes whereby they are rendered safe are achieved by a biological or chemical method and in many instances, when extensive purification is required, a combined method of purification is used.

The biochemical purification consists in the reduction of the biological and chemical consumption of oxygen as a result of the oxidative action of the "active silt" and the adjustment of the oxygen content to the norms established by sanitary requirements for industrial water released into water reservoirs. However, after such purification a considerable amount of dissolved organic substances remains in the water.

In the subsequent chemical purification of waste water by treatment with flocculants (aluminium sulphate and polyacrylamide) coagulation takes place and the colloidally dispersed particles, which are not decomposed in the biological purification, are removed. The water untreated with the active silt can be purified chemically with alumina and polyacrylamide[99,115].

The sludge lignin isolated has a dark-brown colour, contains up to 98% of moisture which is difficult to remove, and gives rise to stable lumps on drying, which are difficult to grind. The sludge lignin must be dried and the drying process can be carried out twice.

The main part of the precipitate extracted from waste water is a modified sulphate lignin, since, after prolonged treatment with active silt, it undergoes a whole series of processes which alter somewhat its structure[116].

Sludge lignin has a high ash and active silt content. In its activity, the waste water lignin is not inferior to Kraft lignin and can find extensive applications for the reinforcement of rubbers in the technical rubber industry and for the modification of polymers in the plastics industry.

4. The Employment of Sulphate Lignins for the Modification of Polymeric Materials

The applications of sulphate lignins can be divided into three groups: (1) combustion; (2) the use of the surface-active properties of the water-soluble lignin salts; (3) condensation of lignin[24].
