Glushkova and Kocheshkov[87] noted in an early study the absence of polythallation products when thallium tri-isobutyrate is used. McKillop and co-workers indicated only one instance of polythallation[97]. Studies of substitution by thallium with the aid of thallium tris(trifluoroacetate) showed that, under severe conditions, it is possible to introduce two bis(trifluoroacetoxy)thallium groups into the aromatic ring; after decomposition with potassium iodide, the corresponding di-iodo-derivatives were obtained in an insignificant yield[98]. Deacon and Tunaley[95] showed that thallium tris(trifluoromethanesulphonate) is more electrophilic than thallium tris(trifluoroacetate); with its aid, it is possible to substitute by thallium many deactivated substrates which do not react with thallium tris(trifluoroacetate). Treatment of the thallium compound with an aqueous solution of sodium iodide leads to the corresponding iodides. Substitution by thallium using thallium tris(trifluoroacetate) with subsequent treatment by potassium iodide is used solely for the preparative synthesis of monoiodoarenes. On the other hand, the interaction of aromatic compounds with molecular iodine in the presence of thallium tris(trifluoroacetate) as the oxidant[92] can serve as a method of preparative synthesis of polyiodo-derivatives. Mono-, di-, tri-, and tetra-iodo-derivatives of benzene have been obtained by this method in high yields.

It was found that benzoic acid is substituted by thallium in the *ortho*-position with an unusually high yield (~98%).[88] Further studies[99] established that many oxygen-containing compounds form complexes with the thallium salt in a preliminary step. If intramolecular attack can lead to the formation of a five- or six-membered transition state, then thallium attacks the available *ortho*-position. A similar

discovery was also made for azobenzenes[100]. The arene thallation reaction is reversible[99]; using thermodynamic and kinetic control and also bearing in mind the formation of complexes, it is possible to select conditions under which the required isomer is obtained with the maximum yield[101]:

Subsequently it was shown that diarylthallium trifluoroacetates, readily obtainable from arylthallium bis(trifluoroacetates) on treatment with triethyl phosphite or warm aqueous acetone, react with iodine to form the corresponding aryl iodides in very high yields[102]. This method can be regarded as a procedure for the conversion of aryl bromides or aryl chlorides into the corresponding iodides, since one of the methods of synthesis of diarylthallium compounds consists in the interaction of Grignard reagents with tervalent thallium salts (halides or carboxylates).[103]

3. The Synthesis of Aryl Iodides Via Organomercury Compounds

In 1974 Deacon and Farquharson[104] established that arenes give rise to polymercurated derivatives on fusion with mercury trifluoroacetate. Treatment of these compounds with a solution of bromine and potassium bromide in methanol constitutes an effective method for the synthesis of polybrominated arenes[105]. Polyiodoarenes are formed analogously in high yields on reaction with iodine and potassium iodide in dimethylformamide, while treatment of polymercuriarenes with molecular chlorine gave rise to polychloroarenes[106]. It has been shown that liquid solutions of potassium tri-iodide can be used for the preparation of polyiodo-derivatives[107], but there is a risk of a side reaction involving protolysis, as a result of which the iodo-derivatives obtained are sometimes contaminated and only mass spectrometry can serve as a criterion of their purity[86].

An alternative method of synthesis of polyiodoarenes[108] is based on the Jacobsen cross-reaction. In sulphuric acid, mono- or di-iodoarenes disproportionate with formation of polyiodoarenes. Since the initial iodo-derivatives can be readily obtained by one of the direct iodination methods described above, this reaction has acquired undoubted synthetic interest.

4. Decomposition of Organic Compounds of Polyvalent Iodine

It is known that the thermal decomposition of iodonium salts can be used as a preparative method of synthesis of aryl iodides (see, for example, Beringer et al.[109]). A similar method has been used successfully in the synthesis of *o*-iodobiphenyls, which are relatively difficult to obtain[110,111]. In 1966–67 Leffler and co-workers[112,113] showed that aryl iodosocarboxylates having the general formula $ArI(OCOR)_2$ are capable of undergoing thermal decomposition via a heterolytic mechanism with the intermediate formation of acyl hypoiodites, which are decarboxylated to the corresponding iodides:

$$ArI(OCOR)_2 \rightleftarrows \overset{\oplus}{ArI}OCOR\ \overset{\ominus}{RCOO} \rightarrow ArOCOR + (RCOOI) \xrightarrow{-CO_2} RI\ .$$

This reaction has been hardly investigated in its synthetic aspect, although phenyliodoso *o*-phenylbenzoate§ gives rise to *o*-iodobiphenyl in a moderate yield on thermolysis[114], while iodobenzene has been obtained in a low yield on photolysis of 2,4,6-trimethylphenyliodoso benzoate¶ in the presence of iodine[115].

The development of a simple and reliable method of synthesis of aryliodoso carboxylates+ [116] makes the preparation of aryl iodides by the decomposition of these compounds of potential synthetic value.

IV. THE MECHANISM OF THE IODINATION OF ARENES

Although the number of publications on the mechanism of the iodination of arenes is much smaller than that of the communications devoted to the investigation of the mechanism of chlorination or bromination, they are quite sufficient to reject the erroneous hypothesis, migrating from textbook to textbook (see, for example, Nesmeyanov and Nesmeyanov[117]), that "hydrogen iodide reduces the iodobenzene obtained". It is known that iodobenzene does not change on heating with hydrogen iodide and red phosphorus for 5 h at 182 °C.[118]

Another widely held erroneous view is that Lewis acids do not catalyse the iodination reaction. It has been shown[47] that copper(II) chloride is an effective catalyst of this reaction.

Direct iodination is an electrophilic aromatic substitution reaction; the iodination of benzoic acid involves the formation of *m*-iodobenzoic acid in 75–80% yield, while the iodination of toluene gives rise to a mixture of *o*- and *p*-iodotoluenes. Electron-donating substituents accelerate the reaction, while electron-accepting substituents retard it. In the presence of sulphuric and nitric acids, the substrate is iodinated and not nitrated; on the other hand, when benzene is treated with iodine and much greater amounts of sulphuric and nitric acids than required for monoiodination, *p*-iodonitrobenzene is produced[120]. Consequently, the compound is initially iodinated and then nitrated; in the reverse order of reactions, the main product would have been the *m*-isomer. Benzene iodinated in the presence of nitronium tetrafluoroborate also gives rise to iodobenzene. It has been suggested that the iodine cation, formed with participation of the nitronium cation in accordance with the scheme

$$2H_2SO_4 + HNO_3 \rightarrow NO_2^{\oplus} + H_3O^{\oplus} + 2HSO_4^{\ominus}\ ,$$
$$I_2 + 2NO_2^{\oplus} \rightarrow 2I^{\oplus} + 2NO_2\ .$$

functions as the iodinating agent. However, this hypothesis must be treated with caution, since the existence of the iodine cation as a kinetically independent species is possible only in highly acid media (for an exhaustive review, see Arotsky and Symons[119]).

It has been suggested that the formation of acyl hypoiodite is a source of electrophilic iodine in many direct iodination reactions[46,55,56] (see above).

It has been found that the reactivity of toluene in the iodination reaction by the Tronov–Novikov method is 9.5 times higher than that of benzene[120]; under the same conditions, the relative rate of nitration of toluene compared with the nitration of benzene is 8.22.

---

§(*o*-phenylbenzoato-*O*)phenyliodine (Ed.of Translation).

¶(Benzoato-*O*)-2,4,6-trimethylphenyliodine (Ed.of Translation).

+(Carboxylato-*O*)aryliodine derivatives (Ed.of Translation).

In the iodination reactions investigated, the constant ρ is negative and varies from −4.5 to −6.4; $\rho = -4.5$ for iodination in the presence of a mixture of sulphuric and nitric acids[120], $\rho = -6.27$ for electrochemical iodination[121], and $\rho = -6.4$ for iodination by the tri-iodine cation[122].

Bearing in mind the foregoing factors, iodic and periodic acids can be recommended as oxidants for the monoiodination of reactive substrates; particularly satisfactory results have been obtained in the iodination of alkylbenzenes by the Tronov–Novikov method. In order to introduce two iodine atoms into the aromatic ring, one may recommend iodination in the presence of phenyliodoso trifluoroacetate. Deactivated compounds are probably best iodinated by the Tronov–Novikov method or in the presence of silver sulphate; in the iodination by the former method, benzil is oxidised to iodobenzoic acid, while in the presence of silver sulphate it is successfully iodinated[123]. Satisfactory results have been obtained in many instances of the iodination of condensed aromatic hydrocarbons using iodic and periodic acids as oxidants, although the latter sometimes oxidises polynuclear aromatic compounds[124].

If it is necessary to obtain an iodo-derivative containing substituents in the molecule in positions which are difficult or even impossible to ensure by means of direct iodination, then the synthesis of aryliodides via organometallic compounds, particularly via organothallium compounds has to be recommended. In particular, the direct iodination of *p*-toluic acid in the presence of potassium permanganate leads to *m*-iodo-*p*-toluic acid (in 90% yield),[125] while the synthesis via an organothallium compound makes it possible to obtain *o*-iodo-*p*-toluic acid (in 75% yield);[93] whereas the direct iodination of azobenzene in the presence of phenyliodoso acetate leads to 4-iodoazobenzene (in an insignificant yield),[63] the synthesis via the organothallium compound makes it possible to obtain 2-iodoazobenzene (in 55% yield).[96]

Despite certain advances achieved in the synthesis of aryl iodides, the direct iodination of certain deactivated substrates, particularly six-membered nitrogen-containing aromatic heterocycles, remains problematical. New advances in direct iodination will probably be associated with the application of both new oxidants[125] and with the search for systems whereby hydrogen iodide can be removed from the reaction sphere by another procedure[126,127].

Intramolecular Electronic Interactions in Phosphorus Compounds in the Light of Recent Structural Studies

R.P.Arshinova

The nature and mechanism of intramolecular electronic interactions in compounds of three- and four-coordinate phosphorus have been critically examined on the basis of a review of the results of the study of their three-dimensional structure and physical properties. The high π-acceptor power of phosphorus-containing groups, capable of stabilising conformations with the *trans*-orientation of the interacting orbitals of the donors (the *n*-orbitals of the unshared electron pairs of the heteroatoms or the π-orbitals of unsaturated systems) and the acceptors (bonds of the phosphorus atom) has been proved.
The bibliography contains 193 references.

I. INTRODUCTION

The development of the theory of intramolecular electronic interactions is related to the experimental and theoretical analysis of more complex hetero-organic compounds, among which a leading place is occupied by organophosphorus compounds (OPC). The exceptional ability of the phosphorus atom to take part in electronic interactions of the most varied types, due primarily to the possibility of a change in the coordination number of this atom from one to six, is well known. The presence of unoccupied orbitals and unshared electron pairs (UEP), the high polarisability and polarity of the bonds formed by phosphorus, and the ability to form donor–acceptor and multiple bonds make it possible to construct any required model of OPC for the study of intramolecular electronic interactions.

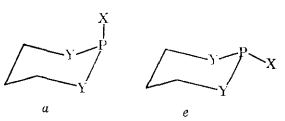
An important contribution to the solution of the problem of the nature of electronic effects has been made by the concepts of three-dimensional structure. The combined study of the three-dimensional and electronic structure makes it possible to formulate fundamentally new, deeper, and comprehensive ideas on the nature, mechanism, location, and spatial-directed character of intramolecular electronic interactions. For organic compounds, these ideas have made it possible to approach an understanding of general regular features, and an elegant and systematic structural theory has been developed[1,2], in which the qualitative model of a one-electron molecular orbital has been used as the theoretical basis for discussing most problems. This approach makes it possible to develop a general theory of three-dimensional structure and chemical reactivity.

The development of the quantum-mechanical theory of conformational analysis has led to the introduction of the following types of intramolecular electronic interactions, not dealt with in the classical theory of electronic displacements: 1) the π- and σ-interactions of non-bonded atoms; 2) π- and σ-conjugation interactions; 3) geminal interactions; and 4) the effects of the ionic character of bonds. In the opinion of Epiotis and co-workers[1], these interactions form an "alphabet" for predicting the characteristic structural features of organic compounds, and to a considerable extent make it possible to model systems with a required geometry. A monograph by Epiotis[2] clearly defines the three-dimensional and geometric restrictions and various physical characteristics (displacement of electron density, ionisation potentials, etc.) indicating the existence of different types of electronic interaction. This makes possible the further development of the theory as applied to more complex hetero-organic compounds on the basis of available factual material.

The electronic structure of OPC and the effects of the mutual influence of atoms which they show have been the subject of many studies. Most of them were carried out in the nineteen-sixties from the viewpoint of the "*d* orbital concept",[4,5] which has often been criticised[6], so that up to the present, the problem of the participation of the *d* orbitals of the atoms of non-transition elements in chemical bond formation has not been resolved. The approach in the form of a correlation analysis has been fairly widely developed[7–9]. Overall, however, an urgent need has grown for a systematic analysis of intramolecular electronic interactions in OPC on the basis of present-day views on the nature and mechanism of electronic interactions. The foundation for this approach should be provided by the extensive factual data on the conformational behaviour of OPC and their physical properties. The results of the conformational analysis of OPC have been summarised in a number of reviews[10–12]. Extensive additional information on the geometric parameters, the nature of electron displacements, and the energy characteristics of boundary orbitals is provided by various physical methods. Many of these results (electron and X-ray diffraction, NMR spectroscopy) are given in reviews of the conformational analysis of OPC,[10–12] and others are given in reviews of the use of photoelectron spectroscopy[13–15], dipole moments, and the Kerr effect[16,17] in the chemistry of OPC; an appreciable proportion of the results have been published in the past five years only in original papers.

The present review examines from this viewpoint the compounds of three- and four-coordinate phosphorus [P(III) and P(IV)] in order to detect and identify intramolecular electronic interactions. The important role played by the electronic nature and structure of reagents in determining a preferred reaction path (including OPC [18]) is well known, so that the development of present-day views on the mecha-

nism of the mutual influence in OPC should stimulate the interest of chemists in revealing the fundamental relationship between three-dimensional structure, electronic structure, and the chemical reactivity of hetero-organic compounds.



II. ELECTRONIC INTERACTIONS OF TERVALENT PHOSPHORUS WITH *n*-ELECTRON-DONOR SUBSTITUENTS

The directed study of various properties of cyclic P(III) compounds in the last ten years has provided a basis for a deep analysis of the effects of the mutual influence of atoms in the systems studied. The most comprehensive and complete studies by various physical methods have been carried out for 2-X-1,3,2-diheterophosphorinanes. The following brief review of studies carried out in this field will be restricted to an examination of the most fundamental characteristics of the molecule in order to investigate the nature and mechanism of intramolecular electronic interactions.

1. THE MANIFESTATION OF INTERACTION IN EXPERIMENTAL CHARACTERISTICS

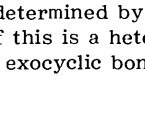
a) Three-dimensional Structure

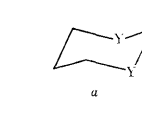
The most complete and extensive conformational studies have been carried out for 2-X-1,3,2-diheterophosphorinanes. The results have been summarised in a number of reviews[10-12, 19,20]. The conformations of cyclic systems with a P atom in the ring are determined by the nature of its intracyclic substituents. If this is a heteroatom (Y = NR, O, S), the chair form with the exocyclic bond in the axial (*a*) position predominates.

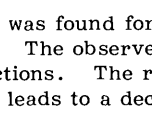
a *e*

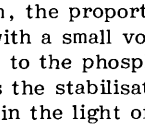
An exception was found for the dialkylamino-group (X = NR_2, Y = O).[21-27] The observed deviations are due chiefly to steric interactions. The replacement of the heteroatoms by carbon atoms leads to a decrease in the energetic preference for the *a*-form, the proportion of which increases when heteroatoms with a small volume are introduced in positions 3 and 5 relative to the phosphorus atom. This clearly defined trend towards the stabilisation of one form, which is unfavourable in the light of steric repulsion effects (for cyclohexane derivatives, the *e*-conformation is preferred) indicates the strictly stereospecific nature of the effect, leading to an energy gain in favour of the *a*-orientation of the exocyclic substituent.

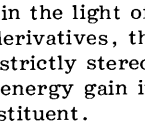
b) Electron Density Distribution

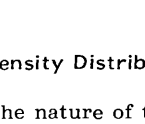


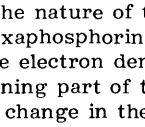


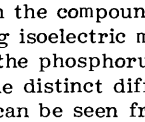


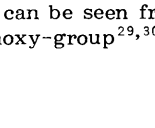












Change in the nature of the exocyclic substituent X in 2-X-1,3,2-dioxaphosphorinanes (Y = O) leads to consideragle changes in the electron density distribution in the phosphorus-containing part of the molecule. Quantitative information on the change in the polarity of the bonds formed by phosphorus in the compounds being considered has been obtained using isoelectric maps (Table 1).[16] These data indicate that the phosphorus bonds have a high electron mobility. The distinct differences in the properties of the substituents can be seen from Table 1: the chlorine atom[28] and the phenoxy-group[29,30] have acceptor properties, leading to the transfer of electron density from the ring oxygen and phosphorus atoms towards the substituent X; the dialkylamino-group is a UEP donor, and the migration of electron density takes place in the opposite direction, towards the ring oxygen atoms[27]. In 2-ethoxy- [16,29] and 2-phenyl-1,3,2-dioxaphosphorinanes[31], the nature of the electron density distribution differs little from that in the symmetrically substituted compounds[16], although the first compound shows slight non-equivalence of the P–O bonds. The increase in the polarity of the P–Cl bond in the ring compared with PCl_3 corresponds to a decrease in the frequency of the ^{35}Cl NQR signal (20.19 MHz compared with 26.208 MHz for PCl_3).[32]

Table 1. Dipole moments of the phosphorus bonds in 2-X-1,3,2-dioxaphosphorinanes and compounds PX_3.

Group	*m*, D	Substituent X				
		O (Ph) [30]	Cl [28]	O [R] [16, 29]	Ph [31]	N (R)$_2$ [27]
O_2PX	m_{P-O}	−0.8	−0.72	−0.32	−0.06	0.65
O_2PX	m_{P-X}	0.22	0.92	0.14	−0.95	0.37
PX_3	m_{P-X}	0	0.56	0	−1.18	−0.25

(VIII)		24.524	2.153 [35]	—
(IX)		25.79	—	−1.33
(X)	PCl_3	26.208	2.043	2.66

Notes: ν is the frequency of the signal in the ^{35}Cl NQR spectrum, l_{P-Cl} is the P–Cl bond length, and γ_{P-Cl} is the anisotropy of the polarisability of the P–Cl bond.

Note. Numbers in square brackets denote references (Ed. of Translation).

The frequency of the ^{35}Cl NQR signal, which reflects the shielding of the chlorine atom, is used to estimate the polarity of different bonds formed by the chlorine atom[33].

The ^{35}Cl NQR spectra of 2-X-1,3,2-diheterophosphorinanes have been studied[34]. The experimental data obtained (Table 2) make it possible to follow the change in the dipole moment of the P–Cl bond (m_{P-Cl}) with change in the nature of the substituent Y in the fragment Y_2PCl; the frequency decreases considerably (from 26.208 MHz to 17.08 MHz), so that the dipole moment increases in the following order of substituents: Cl > S > O > NR. On going from five- to six-membered rings, the frequency increases by approximately 1 MHz. The greatest displacement of electron density to the chlorine atom is observed for the 1,3,2-diaza-derivatives.

c) Bond Polarisability

The anisotropy of the bond polarisability (γ) is one of the most sensitive characteristics of different types of intramolecular electronic interaction. 2-X-1,3,2-dioxaphosphorinanes show extensive changes in the anisotropy of the polarisability of the P–O and P–X bonds, compared with the corresponding symmetrically substituted compounds[16] (Table 3). With increase in the acceptor properties of the substituent X in 2-phenoxy-[30] and 2-chloro-1,3,2-dioxaphosphorinanes[28] there is an increase in the longitudinal component of the polarisability ellipsoid of the P–O bonds. In the chloro-anhydride (VI) there is a marked increase in the perpendicular component of the polarisability ellipsoid of the P–Cl bond b_T and a corresponding decrease in γ ($\gamma = -0.67$ Å^3), compared with PCl_3 ($\gamma = 2.66$ Å^3).[28] An even greater increase in b_T is observed for 2-chloro-1,3,2-dithiaphosphorinane (IX) (see Table 2).[38] In the chlorophosphite series, the changes in γ for the P–O and P–Cl bonds of the O_2PCl group are inversely proportional: decrease in the longitudinal component for the P–Cl bond is accompanied by an increase in the longitudinal component for the P–O bond[16].

Table 3. Anisotropy of the polarisability of the phosphorus bonds in 2-X-1,3,2-dioxaphosphorinanes and in compounds PX_3.

Group	γ, Å^3	Substituent X			
		Cl [28]	O (Ph) [30]	C_{sp^2} (Ph) [36]	N (Me_2) [37]
O_2PX	γ_{P-O}	3.27	3.11	1.95	2.12
O_2PX	γ_{P-X}	−0.67	2.35	4.0	2.24
PX_3	γ_{P-X}	2.66	−0.59	--	2.81

Note. Numbers in square brackets denote references (Ed. of Translation).

d) Bond Lengths

The data obtained up to the present on the P–Cl bond lengths in various 2-X-1,3,2-diheterophosphorinanes and their five-membered analogues (Table 2) show wide changes in the P–Cl values in a range of 0.15 Å [from 2.043 Å in compound (X) to 2.190 Å in compound (I)]. The P–Cl bond length increases on going from PCl_3 to the dioxa-derivatives and then to the dithia- and on to the diaza-derivatives, which show the greatest increase in the antibonding character of this bond. A functional relationship has been established between the values of the anisotropy of the polarisability γ and the bond length l.[16,38] The bonding increases with increase in the positive contribution to γ. The greatest increase in the transverse component of the P–Cl bond, that is the greatest increase in the antibonding character of the bond, is to be expected in the oxaza- and diaza-derivatives of the chloro-anhydrides of acids of tervalent phosphorus.

e) Valence Angles

An interesting characteristic of the geometric structure of 2-X-1,3,2-diheterophosphorinanes with a P–X bond in the α-position, and of many acyclic P(III) compounds, is the increase in the valence angles at a heteroatom (O, N) adjoining the P atom, and there is a clearly defined trend towards the sp^2 hybrid state of the heteroatom. The intracyclic angle at the oxygen atom is close to 120° in 2-chloro-1,3,2-dioxaphosphorinane[39] and 5-spiro-2-methoxy-1,3,2-dioxaphosphorinane[40]. The sum of the angles at the nitrogen atom in 1,3,2-oxaza-[41,42] and diazaphospholans[43] and in amidophosphites[44–47] is close to 360°. According to Dewar's calculations[48], the planar form for the nitrogen atom becomes energetically favourable only when the conjugation energy $\delta E_\pi \geq 18$ kcal mole^{-1}. This condition is not satisfied even for aniline and amides. The flattening of the pyramid of a nitrogen atom situated next to phosphorus has been discussed many times[49], but no satisfactory explanation has yet been found; it is clear only that a non-standard sp^2 electronic state of the heteroatoms indicates considerable interactions with the "liberated" p unshared electron pair of the heteroatom.

f) Energies of the Highest Occupied Molecular Orbital (HOMO)

The interpretation of photoelectron spectra in the approximation of Koopmans' theorem makes it possible to estimate the orbital energies, which are equated to the ionisation potentials. Studies of this kind have been carried out for 2-X-1,3,2-dioxaphosphorinanes with X = NMe_2, OMe, Cl;[50,51] the ionisation energies of the HOMO n_P, n_N, and n_O have been obtained. There is no splitting of the orbitals of the unshared electron pairs (UEP) of the nitrogen and phosphorus atoms in the 2-dimethylamino-derivative. The ionisation potential of the orbital n_P does not obey the additivity rule, because of the interaction of the UEP of the phosphorus atom with the UEP of the adjacent heteroatoms: $n_O - n_P$, $n_N - n_P$, $n_{Cl} - n_P$. The ionisation potentials of the UEP of the oxygen atoms undergo smaller changes; the n_O orbital in the dimethylamino-derivative is destabilised to a much greater extent (10.0 eV), compared with chlorophosphite (10.76 eV). Overall, the cyclic compounds show an increase in the same sense in the energies of all the highest occupied molecular orbitals, and this can be attributed to the difference in the direction of the $n-\sigma^*$ hyperconjugation interaction.

2. THEORETICAL INTERPRETATION OF EXPERIMENTAL DATA

All the above factors prove the high electron lability of the Y_2PX group. The observed electronic effect (or set of effects) is strictly stereospecific, and leads to stabilisation of the α-orientation of the polar bond P–X in the 2-X-1,3,2-diheterophosphorinanes. In all cases the phosphorus atom is adjacent to a heteroatom whose electronic state, according to data on the valence angles, is close to sp^2 hybridisation, so that the heteroatom acts as a p_π-UEP donor. The phosphorus atom, together with the adjoining bonds, shows

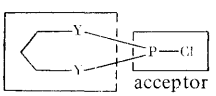
clearly defined π-electron-acceptor properties. The π-electron-acceptor effect is apparently not particular but universal in character, and is the main reason for the marked difference between the properties of the compounds of the elements in period II and subsequent periods. This problem was recently examined for compounds of silicon[52,53], arsenic[54,55], sulphur, and phosphorus[55,56]. The problem is of considerable importance for an understanding of the characteristic features of the chemical behaviour of heteroorganic compounds of the non-transition elements as a whole.

There arises the question of whether the high electron lability of P(III) compounds can be interpreted on the basis of existing ideas on intramolecular electronic interactions.

a) $d_{\pi}-p_{\pi}$ Interaction

The traditional explanation of the π-electron-acceptor properties of the phosphorus atom is related to the presence of its unoccupied 3*d* orbitals[4,5]. It is considered that $d_{\pi}-p_{\pi}$ conjugation leads to an increase in the strength of the bonding between the phosphorus atom acting as acceptor and the neighbouring heteroatom acting as donor. For 2-X-1,3,2-diheterophosphorinanes, the participation of the *d* orbitals of the phosphorus atom should have led to only an increase in the double-bond character of the bonds. In fact, however, as noted above, an increase in the antibonding character of the exocyclic P–Cl bond is observed. Even in those cases where the intracyclic substituents Y have a higher electronegativity (Y = NR, O) than the chlorine atoms in PCl_3 (which undoubtedly should have led to the participation of the d_{π} orbitals in bonding as a result of the increase in the positive charge on the central atom), the P–Cl bond is destabilised, compared with the same bond in PCl_3. Analysis of the direction of the displacement of electron density also indicates that the participation of 3*d* orbitals is unlikely. For $d_{\pi}-p_{\pi}$ conjugation, the displacement of electron density should take place towards the P atom; it follows from the data in Table 1, however, that for each case it is possible to show examples of the opposite direction of the effect (in 2-dialkylamino-1,3,2-dioxaphosphorinanes, the electron density is displaced towards the ring oxygen atoms). Moreover, the material obtained indicates that the effect is not localised on the central atom, and the electron acceptor in all cases is the neighbouring bond (the P–Cl bond in 2-chloro-1,3,2-diheterophosphorinanes).

Thus the increase in the antibonding character of the acceptor bond, the direction of the displacement of the electronic charge, and the extension of the transfer of electron density beyond the phosphorus atom towards the acceptor bond cast doubt on the possibility of interpreting the effect on the basis of the concept of $d_{\pi}-p_{\pi}$ conjugation.



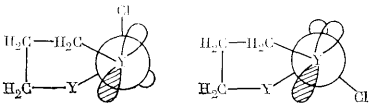
b) Electrostatic Geminal Interaction

Significant (analogous in strength and direction) effects of electron density displacement have been observed for organic compounds of the elements of Group IVb (E = Si, Ge, Sn) containing the group X–C(Cl)–E (X = Hal, O, N, S).[53] The magnitude of the interaction, as in the case of 2-X-1,3,2-diheterophosphorinanes, does not correspond to the electronegativity of the atoms and the inductive effect of the substituents. This effect has been called the geminal interaction of atoms or the α-effect+.[53] Systematic studies of the ^{35}Cl NQR spectra of compounds containing the Cl–C(Cl)–Si group led Feshin and co-workers[53] to conclude that the anomalous properties of the compounds are due to the electrostatic interaction of the charge of the atom E with the electron cloud of the C–X bond. The hypothesis of a possible electrostatic interaction by a field effect mechanism was verified for compound (VI).[59] Calculation showed that the dipole moment of the P–Cl bond should increase by 0.23 D. Under the influence of the electric field of the P–Cl dipole [0.56 D in compound (X) or 0.92 D in compound (VI), see Table 1], electron density is displaced from oxygen to phosphorus, and the dipole moment changes by 0.12 D or 0.17 D respectively. According to the isoelectric maps, however, the moment of the P–O bond increases by 0.72 D on going from the symmetrically substituted phosphites to compound (VI).[28] Thus electrostatic interactions, although acting in the appropriate direction, cannot fully explain the extensive changes in electron density taking place.

c) $n-\sigma^*$ Hyperconjugation Interaction

The stabilisation of the *a*-orientation of a polar substituent in 1,3,2-diheterophosphorinanes lies within the framework of the anomeric effect, the nature of which has been discussed many times[60] and is now related to the interaction between the *p*-type UEP of the ring heteroatom and the antibonding MO of the exocyclic polar bond. Moreover, the increase in the polarity of the P–Cl bond, the increase in its length, and the decrease in the frequency of the ^{35}Cl NQR signal, observed for 2-chloro-1,3,2-dioxaphosphorinane, correspond to the variations in these parameters in α-chloroethers containing the Cl–C–O group.[1,61–65] The anomalous behaviour of α-chloroethers has been widely studied, and has been called the α-effect,[61] the mechanism of which (the interaction of the *p* orbital of the UEP of the oxygen atom with the antibonding orbital of the C–Cl bond $n_O-\sigma^*_{C-Cl}$[61–65] is analogous to that of the anomeric effect. The possible existence of this interaction is 2-X-1,3,2-diheterophosphorinanes has also been examined in detail[59].

In 2-chloro-derivatives (XI), two fragments are clearly distinguished: an electron-acceptor fragment with a P–Cl bond, and an electron-donor fragment with 1,3-heteroatoms Y;[39–43,47] the best electron donor is a semi-localised orbital of the *n**-type formed by the reaction of two equivalent *p* orbitals of the UEP of the heteroatoms Y.[66,67]



(XI)

According to the values of the ionisation potentials of the orbitals of the UEP of the atoms in OPC,[15] the donor power decreases in the following order: $n_N > n_S > n_P > n_O > n_{Cl}$; the increase in the π-electron-donor power of the sulphur atom compared with the oxygen atom is attributed to the fact that it adjoins the low-lying unoccupied molecular orbital (LUMO) (σ^*_{P-Cl}).[68]

+The term "α-effect" has another meaning[57,58], which is used later in the present review (Russian page 603). To avoid ambiguity in terminology, and following Feshin and co-workers[53], the effect being discussed here will be called the effect of the geminal interaction of the atoms.

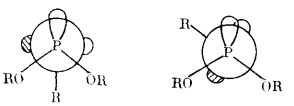
The acceptor power of bonds is also closely related to their ionisation potentials[1,15]; it increases on going to bonds formed by elements of period III. Unfortunately, data on the ionisation potentials of the phosphorus bonds are not so unambiguous as the values of the ionisation potentials of the higher-lying orbitals of the UEP.

The donor and acceptor fragments of the molecules of 2-X-1,3,2-diheterophosphorinanes interact with one another in different ways in the two alternative conformations with *a* and *e* P–Cl bonds.

a—P—Cl; (T) *e*—P—Cl; (G)

The *e* position of the P–Cl bond is characterised by the gauche orientation (G) of *n* and the P–Cl bond, and the axial position by the *trans*-orientation (T). The $n-\sigma^*$ interaction is a maximum for the T-orientation of the orbitals being considered[1]. This interaction leads to considerable stabilisation of the T conformer, and indicates that there is transfer of the charge of the *p*-UEP of the Y atoms to the P–Cl bond; this also leads to an increase in the charge on the chlorine atom and a decrease in the charge on the ring Y atoms. The greatest effect of electron density transfer is observed for 2-chloro-1,3,2-diazaphosphorinanes (the frequency of the ^{35}Cl NQR signal is a minimum), since the nitrogen atoms are better electron donors than the oxygen and sulphur atoms. The sulphur atoms in turn are characterised by stronger donor properties than the oxygen atom. This explains why the length of the P–Cl bond and the anisotropy of its polarisability have intermediate values, compared with the dioxa- and diaza-derivatives. According to the ^{35}Cl NQR frequencies, however, the transfer of electron density is slight; this is related to the diffuse character of the UEP of the sulphur atom compared with the 2*p* orbitals of the UEP of oxygen and nitrogen. The latter are not diffuse, the charge of the two electrons is concentrated in a small region, and for them the $n-\sigma^*$ conjugation is reflected in the form of the charge transfer.

The interaction should also lead to an increase in the length of the acceptor bond[1]; the bond formed by the donor atom, however, may become stronger (a decrease in the length of the C–O bond in α-chloroethers is observed[65,69]). In 2-chloro-1,3,2-diheterophosphorinanes, the P–Cl bond in fact becomes longer, the increase being greater, the greater the donor power of the heteroatoms Y (in the order O < S < N).



Change in the nature of the substituent X (in the P–X bond) should be reflected in the magnitude of the $n-\sigma^*$ interaction. The ionisation potentials of the bonds P–O(R) and P–C are approximately the same, and their absolute values are greater than those for the P–Cl bond[15,67], so that for the corresponding compounds the interactions are less clearly defined.

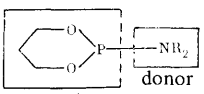
d) The α-Effect and the Acceptor Power of Bonds

Comparison of the above data for OPC and published data data[1,61–65] for α-chloroethers indicates that the effect of $n-\sigma^*$ hyperconjugation interaction in OPC is much greater. Calculations show that a position next to a low-lying unoccupied molecular orbital leads to an increase in the π-electron-donor power of heteroatoms[68]. In the present section, the factors leading to an increase in the acceptor power of bonds are examined. This increase is due to the decrease in the energy of the σ^* orbital, which is to a large extent related to the destabilisation of the acceptor bond. In the case of the P–Cl bond, the increase in the antibonding character is due to the familiar α-effect, typical of systems containing adjacent UEP.[3,57,58] The effect itself is often related to the stabilisation of the transition state[57], so that until recently, its influence on the physical properties was not examined. According to quantum-mechanical calculations[58], however, the α-effect is characterised formally by the destabilisation of the ground state, due to the interaction of the UEP of adjacent heteroatoms. Often (but not always), conditions are created for an antisymmetric combination of UEP, which leads to a more diffuse distribution of the electron density of the occupied molecular orbital with a nodal plane and perpendicular to the line of the bond; in the opinion of Bentrude and Tan[23], this should lead to a high "non-uniformity" of the polarisability of the bonds.

In this respect, the P–Cl bond is apparently one of the best acceptors; it has a high polarisability $b = 10.04$ Å^3,[16] due to the diffuse distribution of the electron density. Moreover, the destabilising repulsion of the n_P-n_{Cl} orbitals is appreciable for all orientations of the n_P orbital. In most other cases, however, the molecule can avoid unfavourable interactions of adjacent UEP by conformational rearrangements.

For other bonds formed by phosphorus, in which it is next to elements of groups V and VI b, the presence or absence of the α-effect depends on the conformational characteristics. In 2-alkoxy-1,3,2-dioxaphosphorinanes, the P–O bonds differ in their rotational-isomer properties: for steric reasons, the exocyclic bond cannot achieve the T-conformation characteristic of the ring bonds, and it has the G-orientation[29]

$n_O \perp n_P$; (T) $n_O \parallel n_P$; (G)



In the G-conformation, the repulsion between the UEP of the oxygen and phosphorus atoms n_O-n_P is a maximum. This conclusion is confirmed by an analysis of the photoelectron spectra. Studies of a whole series of trialkyl phosphites, in which there is a gradual change from GGG structures to structures with the T-orientation of all three alkoxy-groups[50,51], show that the n_O-n_P interaction is a maximum in the G-conformation, and can be estimated (by means of the parameter β_{OP}^{π}) as 0.58 eV. The interaction between the UEP of the oxygen and phosphorus atoms is so great that it leads to extensive variation in the ionisation potential of the orbital n_P (of the order of 1 eV), depending on the rotational-isomer properties of the P–O bonds.

Thus P–O bonds which are non-equivalent according to their conformational characteristics also differ in their energy parameters; the antibonding character of the exocyclic bond increases considerably, and it acts as the acceptor of the UEP of the ring oxygen atoms. The effect is reflected in the relative increase in the length of the exocyclic P–O bond, compared with the ring bonds (1.626 and 1.616, 1.611 Å according to X-ray diffraction data for 3,9-dimethoxy-2,4,8,10-tetraoxa-3,9-diphosphaspiro[5.5]undecane[40]), and also in the displacement of electron density, detected from the isoelectric maps, from the ring oxygen atoms towards the exocyclic P–O bond[16].

In 2-alkylamino-1,3,2-dioxaphosphorinanes, the α-effect of n_N-n_P repulsion is not detected by photoelectron spectroscopy[50,51]. The absence of splitting of the n_N and n_P orbitals shows that the interaction between them is slight, so that they are oriented at right angles to one another.

e) The Exo-anomeric Effect

The exo-anomeric effect was introduced[70] to explain the stabilisation of the structures with *e* C–O bonds in 2-alkoxytetrahydropyrans. In 2-X-1,3,2-diheterophosphorinanes, the *e* conformation is typical of compounds (XII) (X = NR_2 [10,27])

(XII)

In this compound, the best donor (the dialkylamino-group) is removed beyond the ring[39]. The orbital of the UEP of the nitrogen atom, situated next to P(III), has a comparatively low ionisation potential of 8.65 eV [for compound (XII) with R = Me [51]]. This is 2 eV lower than the ionisation potential of the orbital n_O; thus the $n_N-\sigma^*_{P-O}$ interaction must be comparable in strength and of opposite direction, compared with the $n_O-\sigma^*_{P-Cl}$ interaction in compound (VI). This effect is in fact observed; the displacement of electron density takes place from the exocyclic nitrogen atom in the direction of the P–O bond (see Table 1).[27]

In the compounds being considered, there are optimum structural conditions for $n-\sigma^*$ interaction, in spite of the fact that the dialkylamino-group occupies the equatorial position, and not the axial position typical of all other types of X. For the *e* conformation, the P–O bonds have the GG′ structure, in which the α-effect of the destabilising repulsion of the n_O-n_P orbitals is a maximum, so that the acceptor properties of the bond increase. Since the dialkylamino-group is not fixed, the UEP of the nitrogen atom can always take the T-orientation with respect to the P–O bond, favourable for hyperconjugation interaction. For the *e* position of the dialkylamino-group this should be the so-called perpendicular conformation, in which the UEP of the nitrogen and phosphorus atoms are mutually perpendicular. This structure also follows from an analysis of photoelectron spectroscopic data[51].

The possibility of $n_N-\sigma^*_{P-O}$ interaction for the *a*-position of the P–N bond should be emphasised, but in this case it is difficult for the bulky dialkylamino-group to adopt the perpendicular conformation, favourable for $n-\sigma^*$ interaction. The *a*-conformation becomes the preferred conformation only when the bulky NR_2 group is replaced by less bulky groups: NHR (R = Alk, Ph) [26,71,72] or aziridyl,[26] NPh_2, pyrryl[73], or NCO[74], where the nitrogen atom has a planar structure. In this conformation, however, the acceptor power of the ring P–O bonds, which have the TT structure, is decreased, so that the energy of the $n_N-\sigma^*_{P-O}$ interaction is lower than that in compounds with an *e* P–N bond.

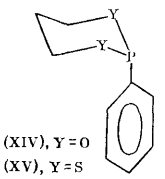
The *e*-conformation has also been established for 2-aminotetrahydrofuran[75]. To explain this, the authors cited introduce all possible types of orbital interaction, without distinguishing the predominant one [including interactions in exactly opposite directions, such as, for example, the interactions $n_O(\sigma\text{-type})-\sigma^*_{C-N}$ and $n_N-\sigma^*_{C-O}$]. The above experimental material for 2-alkylamino-1,3,2-dioxaphosphorinanes, together with an analysis of the characteristic stereochemical features of the bonds, make it possible to distinguish the key orbital interaction of the type $n_N-\sigma^*_{P-O}$.

Thus the combination of P(III) with different heteroatoms leads to a labile electronic system with a clearly defined ability to undergo electron-cloud rearrangement. This lability is due to related effects: the destabilising $n-n$ interaction (the α-effect), leading to an increase in the acceptor properties of the bonds; $n-\sigma^*$ hyperconjugation, strengthened by the α-effect; and the field effect. The magnitude of the displacement of the electron cloud of the UEP, the degree of antibonding character in the bond, and the rearrangement of its polarisability ellipsoid depend on the conformational parameters and on the position of the heteroatoms in the periodic system: the elements of period II are characterised by the transfer of the concentrated electron cloud of the 2*p* orbital of the UEP donor (which is responsible for the manifestation of the effect in changes in the dipole moments of the bonds and the ^{35}Cl NQR frequencies); the bonds of the elements of period III, as acceptor bonds, are more easily polarised, with an increase in their antibonding character, and this leads to an increase in their length and to an increase in the contribution of the perpendicular component of the polarisability tensor.

It should be noted that the observed intramolecular interactions are characteristic not only of cyclic compounds. Many of the above experimental observations for 2-X-1,3,2-diheterophosphorinanes are also observed for acyclic compounds[76,77]. The facts indicate that the effects of hyperconjugation interactions are also revealed to a considerable extent in P(IV) compounds[78].

The change from phosphorus compounds to the corresponding arsenic-containing compounds leads to an increase in the strength of the effect. The study of 2-chloro-,[79] 2-bromo-,[80] and 2-phenyl-1,3,2-dioxa-arsenanes[81] using isoelectric and isoanisotropic maps made possible a quantitative estimation of the degree of displacement of electron density and rearrangement of the bond polarisability ellipsoids. The results show that the observed orbital interactions are characteristic of a wide range of compounds, so that they must be taken into account in the interpretation of data on the physical and chemical properties of compounds.

III. CONJUGATION EFFECTS IN COMPOUNDS OF TERVALENT PHOSPHORUS WITH π-ELECTRON-DONOR SUBSTITUENTS



In organophosphorus compounds containing an unsaturated group next to a phosphorus atom, different types of conjugation are possible: $d-\pi$ conjugation, conjugation of the π-electrons of the unsaturated group with the UEP of the P(III) atom, and hyperconjugation of π-electrons with the vicinal bonds of the phosphorus atom. All these forms of intramolecular electronic interaction are strictly stereodirected, so that the study of the spatial characteristics of compounds to a large extent facilitates the identification of the predominant form of conjugation, determining the specific features of the physical and chemical properties of the compounds as a whole.

The monoaryl compounds of tervalent phosphorus $ArPX_2$ (XIII) can be considered, since they are less influenced by steric interactions than the diaryl and triaryl derivatives. The experimental study of these compounds has been carried out mainly in recent years.

1. THREE-DIMENSIONAL STRUCTURE

For monoarylphosphines (XIII) it is possible to have two three-dimensional structures, with parallel ($\omega = 0°$) or perpendicular ($\omega = 90°$) orientation of the UPE of the phosphorus atom (n_P) and the π-orbital of the benzene ring (Fig.1). Many compounds of this type have been studied by electron diffraction and the Kerr effect. An orientation of the *n*- and π-orbitals close to orthogonal has been

established for the following substituents: X = Cl (81°,[82] ~90° [83]); X = F (59° [84]); X = Alk (~90° [85]), X = CN (~90° [86]). The alternative conformation with $\omega \approx 0°$ has been found by infrared spectroscopy for the simplest compound of this series, phenylphosphine[86]. Relaxation NMR measurements have been used to determine the barriers to rotation of the PH_2 and PCl_2 groups (0.17–1.02 kcal mole^{-1} and 0.7 to 4.1 kcal mole^{-1} respectively) about the Ph–P bond[87,88]. Interesting results have been obtained for cyclic compounds with an exocyclic P–Ph bond (XIV) [36] and (XV).[38] In this case there is forced coplanar orientations of the n_P and π orbitals. Marked 1,3-synaxial interactions of the phenyl group in the α-position[31,36,38] rotate the benzene ring at an angle of 90° to the plane of symmetry of the molecule, which contains the UEP of the P(III) atom

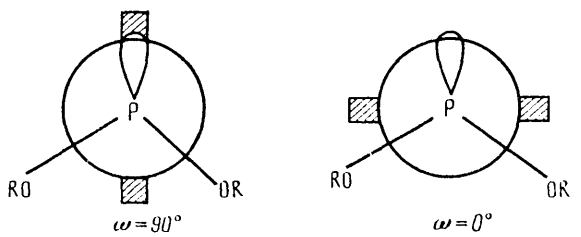


Figure 1. Boundary conformations of the benzene ring in arylphosphines.

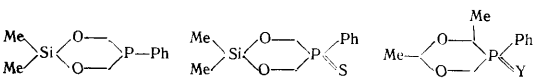
The structure of the simplest monophenylphosphines has been studied many times by quantum-mechanical calculations. Non-empirical calculations in an STO-3G basis set for phenylphosphine and phenyldifluorophosphine (X = H, F) show that the UEP of the P(III) atom lies at right angles to the plane of the aromatic ring[89]; when the H, F atoms are replaced by Cl atoms, the alternative conformation (ω = 90°) becomes preferred[89]. Semi-empirical calculations have been carried out by MINDO/3 and MNDO methods with complete optimisation of the geometry of all potentially low-lying conformations[90]. Both methods, and also the CNDO/2 method[91,92], confirm the stabilisation of the structure with an almost parallel orientation of the n and π orbitals in phenylphosphine. The same methods indicate that phenyldimethylphosphine has an analogous structure[90]. For the dichloroderivative (MNDO method[93]), an orthogonal structure has been established, in agreement with the above experimental data.



2. SPECTRAL STUDIES OF ELECTRONIC INTERACTIONS IN MONOARYLPHOSPHINES

Indirect information on structure, based on the analysis of the strength of the interaction between the phosphorus-containing substituent group and the π-electrons of the benzene ring, is provided by spectral methods. Most of the work on monoarylphosphines has been devoted to an analysis of the ultraviolet spectra.

The R-band in the range 230–260 nm is considered to be the most characteristic. It is due to the transfer of n_P to the benzene ring ($n \rightarrow \pi^*$ transition). Many authors assume that the intensity of the band is related to the relative orientation of the n and π orbitals. Evidence of the possible existence of this relationship is provided by the decrease in the intensity of the band on going from the cyclic 2,2-dimethyl-5-phenyl-1,3,2,5-dioxasilaphosphorinane (XVI) (9000 [94]) and the sterically unstrained compound (XIII) with X = Me (5550 [95,96]) to diethylphosphine (3920) and its dimesityl (1700) and di-t-butyl (1890) derivatives[95,96]. The decrease in the intensity of the R-band in phenyldialkylphosphines has been taken by many authors as proof that the compounds, in addition to the main conformer in which the n and π orbitals are orthogonal, also contain another conformer with geometry (ω = 0°) favourable for $n-\pi$ conjugation[95–97].

There are other viewpoints on the interpretation of the ultraviolet spectroscopic data. Some authors consider that when there is $p-\pi$ conjugation, the R-band should be absent, as observed for aniline derivatives[98–100]. It is suggested that the difference may be due to a difference between the energies of the orbitals of the UEP of the central atom and the π-orbitals of the benzene ring[101]; in aniline, the energy $E(n_N)$ is lower than $E(\pi)$, whereas in phenylphosphines (and phenylarsines), the order of the energies is the opposite [$E(n_P) > E(\pi)$], so that the $n \rightarrow \pi^*$ transition is observed in the ultraviolet spectra at long wavelengths.

The problem can apparently be solved by comparing the ultraviolet spectra of compounds whose three-dimensional structure has been studied. In the dialkyl phenylphosphonite series, the ultraviolet spectra have been characterised for the cyclic compound (XIV) with forced coplanar orientation of the n and π orbitals[101] and the acyclic diethyl phenylphosphonite $PhP(OEt)_2$ (XVII),[100] but there are no structural data for the latter. In the dialkylphenylphosphine R_2PPh series, no direct experimental results have been obtained on the structure of the cyclic analogue. Here, the ultraviolet spectra show an increase in the intensity of the R-band on going from the acyclic compounds ($\varepsilon \leq 5550$) to the cyclic compound (XVI) (ε = 9000).[94–96]

(XVI) (XVIII) (XIX), Y=O, S

The observed effect was attributed to the parallel orientation of the n_P and π orbitals in compound (XVI). A study of the three-dimensional structure of compound (XVI) using the Kerr effect did not make it possible to reach sufficiently definite conclusions about the orientation of the phenyl group[102]. Available data for the analogoues with P(IV) [for compounds (XVIII) [103] and (XIX) [104]], however, indicate a change in the conformation of α-Ph to the parallel conformation, compared with the corresponding 1,3,2-dioxaphosphorinanes, as a consequence of the fact that in these analogues there are no 1,3-synaxial interactions. In six-membered rings, the orientation of the plane of the benzene ring is determined primarily by steric effects[36], which are approximately the same in corresponding P(III) and P(IV) compounds. This indicates the need to obtain additional experimental data for systems of the 5-phenyl-1,3,5-dioxaphosphorinane type.

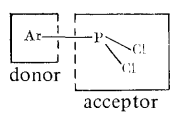
The above material on the structure and ultraviolet spectra show that it is as yet difficult to speak of the existence of a

direct relationship between the intensity and position of the *R*-band and the orientation of the *n* and π orbitals[101].

The electronic interactions in arylphosphines are analysed using the shielding parameters of the aromatic carbon atoms in ^{13}C NMR spectra[105-107]. The variation in these quantities on going from compounds (XIII) with X = H, Me to compounds with X = t-Bu is attributed[107,108] to conformational rearrangements; for compounds of the first type, in the opinion of the authors cited, there is free rotation of the phenyl group, whereas in the second case a conformation with orthogonal orientation of the *n* and π orbitals is produced.

The clearest picture of the magnitude and strength of the mesomeric interaction of a substituent X with a phenyl ring or an acetylenic bond can be obtained from the photoelectron spectra: the HOMO in phenylphosphines is formed by the interaction of the π-levels of benzene and the n_P orbital. The greater the splitting of the $b_1(n)$ and $b_1(\pi)$ orbitals from the photoelectron spectra, the greater the $n-\pi$ interaction. For compounds of the (XIII) series with X = Me,[100] X = Cl,[109] and X = OEt (XVII),[50,51] no significant splitting was detected. For phenylphosphine (X = H), the data obtained are not unambiguous[92,93,108-110], and they have been collected and examined with the introduction of data on other monophenylphosphines to refine the assignment of the bands in Ref.93; the splitting obtained (0.49 eV) indicates the existence of an interaction. It increases by a factor of 1.4 on going to t-butylethylphosphine[111]; for the corresponding chloro-derivatives, the splitting is much smaller[93,111].

An appreciable interaction of the phosphorus-containing group with the neighbouring π-electron system is indicated by an analysis of the photoelectron spectra of di-t-butylpheylphosphine and di-t-butylvinylphosphine[92]. The photoelectron spectra of the above compound (XVII), whose ultraviolet spectrum shows an *R*-band of medium intensity[100], have been discussed[50,51]. The second band in the spectrum of this compound is due to the ionisation of the π-electrons of the benzene ring. Its splitting into components corresponding to the orbitals $\pi(a_2)$ and $\pi(b_1)$ is slight, and is not recorded sufficiently clearly, but the components (9.22 eV and 9.40 eV) can be determined approximately[50,51]. The fact that the splitting of the π-orbitals is slight may indicate that their interaction with the UEP of the P(III) atom is slight. The experimental value of the ionisation potential of the n_P orbital obeys the additivity rule, and this is another indication that the mixing of the n_P and π orbitals is slight.



It follows from the above material on monophenylphosphines that the results obtained are often contradictory. The apparent reason is that the authors of almost all spectral studies assume that the π-orbitals of the benzene ring interact with the neighbouring fragment only in one form with ω = 0°, when $n-\pi$ conjugation is possible. An orbital examination (see next section) shows, however, that structural conditions are created for another form of conjugation, of the $\pi-\pi^*$ type, which undoubtedly also influences the position and character of the bands in the spectra (see for example Ref.92). Since spectral studies make it possible to reach conclusions only about the strength of the effects of conjugation with the π-orbitals of the benzene ring, it is obviously necessary to solve the problem of the manifestation of both types of conjugation in the spectral characteristics and their relation to the three-dimensional structure.

3. THE NATURE OF THE ELECTRONIC INTERACTIONS IN PHENYLPHOSPHINES

Drawing an analogy between the electronic structure of amines and phosphines with phenyl substituents, many authors at first assumed that compounds of tervalent phosphorus, like nitrogen compounds, should be stabilised by $p-\pi$ conjugation effects. Analysis of a large amount of experimental data and the electronic state of the P atom, however, led Tsvetkov and Kabachnik[112] to the conclusion that conjugation is inhibited in arylphosphines; these results led to extensive discussion[113]. In spite of this, in spectroscopic studies the results obtained are often interpreted from the viewpoint of possible $n-\pi$ conjugation; these studies have been criticised[114]. Overall, the structural data obtained[82-89], together with spectral characteristics[94-97], lead to the conclusion that there is limited $n-\pi$ interaction. A recent combined study[115] of the integral intensities of the bands due to the CH vibrations in the infrared spectra, the $^1J(C, H)$ spin–spin coupling constants, and the rate constants for deuterium exchange in the Me group in phenylphosphines showed the absence of $n-\pi$ conjugation.

In a paper[92] on the photoelectron spectra of vinyl- and phenylphosphines, it was suggested for the first time that the predominant form of electronic interactions in these systems is not $n-\pi$ or $d_\pi-p_\pi$ conjugation, nor an inductive effect, but $\pi-\sigma^*_{P-C}$ hyperconjugation. A similar conclusion was later reached[89] from an analysis of the values of the long-range spin–spin coupling constants $^5J(C, H)$ and $^5J(C, F)$ and the barriers to internal rotation in dihalogeno-derivatives of phenylphosphines[89]. Delocalisation of electron density in the direction from the phenyl group to P is detected from a comparison of the chemical shifts of the ^{13}C NMR signals of the benzene ring[116]. An analysis of the dipole moments of aryldichlorophosphines by a vector-statistical method[83,117] showed a significant displacement of the π-electron density of the aryl group towards the P–Cl bonds: the polarity of the $C_{Ar}-P$ bond decreases considerably on going from aryldichlorophosphines (1.43 D) to triarylphosphines (0.38 D [31]), arylphosphines (0.07 D [117]), and 2-phenyl-1,3,2-dioxaphosphorinane (0.25 D [31]); the dipole moment of the P–Cl bond increases to 1.87 D (compared with 0.56 D in PCl_3). The displacement of electron density from the aryl group to phosphorus cannot be explained within the framework of the concept of $n-\pi$ conjugation.

The dependence of the type of orbital interactions in aryldichlorophosphines on the spatial orientation of the aryl group can be considered. The molecule can be broken down into two fragments; the first, the aryl group, is a π-electron donor, and the second, as a result of the antisymmetric combination of unoccupied orbitals of the P–Cl bonds, forms a low-lying $\pi^*_{PCl_2}$ orbital (XX).

(XX)

With the parallel orientation of the n_P and π orbitals (see Fig.1, ω = 0°), steric conditions are created for $n-\pi$ conjugation, and with the perpendicular orientation (ω = 90°) for $\pi-\pi^*_{PCl_2}$ interaction[118]. For X = H, the energy of the orbital $\pi^*_{PH_2}$ is high, and $n-\pi$ interaction is more effective. The energy of the orbital $\pi^*_{PX_2}$ is lowered considerably when the H atom is replaced by Alk and more particularly by Cl, which leads to stabilisation of the bisector conformation. It should be noted that in vinylphosphines, interactions with the π-system should be more clearly defined, since in the phenyl compound they are weakened as a result of delocalisation of the π-electrons.

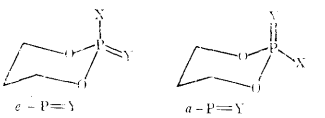
The analysis carried out makes it possible to explain the factual material which has now accumulated on the three-dimensional and electronic structure of arylphosphines. It shows that the increase in the π-acceptor properties of P-containing groups compared with their N-analogues radically alters the nature of the predominant form of electronic interaction, which, as in 2-X-1,3,2-dioxaphosphorinanes (see section II), is not limited to the phosphorus atom, but extends further towards the whole acceptor group.

In conclusion it should be noted that for arylarsines, electron diffraction distributions analogous to those observed for phosphorus compounds have been detected[117,119]; these can be fully explained within the framework of the concept of intramolecular electronic interactions discussed here.

IV. ORBITAL INTERACTIONS IN COMPOUNDS OF FOUR-COORDINATE PHOSPHORUS

The properties of P(IV) compounds of the type $X^1X^2X^3P{=}Y$ are to a large extent determined by the P=Y group, where Y = O, S, Se. The variation detected by different physical methods in various parameters of the P=Y bond with change in the nature of the substituent X [4,120,121] indicates that a significant role is played by electronic interactions with the P=Y bond. An analysis of the factors influencing such a fundamental characteristic of the bond as the electron density distribution must eventually make it possible to reach specific conclusions about its electronic structure. It is appropriate to follow from this viewpoint the influence of structural factors on the polarity m(P=Y) of the P=Y bond. Linear relationships have been established between the phosphoryl group wavenumbers in the infrared spectra and its dipole moment[122,123]. An attempt has been made to derive a relationship between m(P=Y) and the sum of the constants $\Sigma\sigma_i$ for Y = O, S, Se.[124] Recent detailed studies of the polarity[16,120,124,125], basic nature[126,127], and ionisation potentials[15] of heterophosphoryl bonds and the three-dimensional structure as a whole[10] are revealing a number of new relationships and the nature of the orbital interactions.

1. THE POLARITY OF THE P=Y BOND



In symmetrically substituted compounds $X_3P{=}Y$, the polarity of the P=Y bond is estimated as the vector difference in the dipole moments of the P(III) and P(IV) compounds (for non-regular substituents X, rigidly fixed bicyclic structures are used).[16,125] Values have been obtained in this way for m(P=O), D:[16,37,125] C_3P (3.40) > N_3P (3.27) > Cl_3P (3.13) > O_3P (2.95); for m(P=S):[16,37,125] C_3P (3.88) > N_3P (3.19) > O_3P (2.62) > Cl_3P (2.03); and for m(P=Se):[124,128] C_3P (4.0) > N_3P (3.88) > O_3P (2.50). The observed increase in the range of variation in the values of m(P=Y) in the order Y = O, S, Se is apparently due to the increase in the polarisability of the P=Y bond (the total polarisability of the bond is b = 4.95 Å^3 for Y = O;[16] b = 13.64 Å^3 for Y = S;[16] and b = 17.63 Å^3 for Y = Se [129]). The effect is naturally more clearly defined for the easily polarised sulphur and selenium atoms.

The reasons for the change in the order of increase in the polarity of the P=Y bond in a series of compounds of the type $YP(OR)_3$; m(P=O) > m(P=S) > m(P=Se), and in the series of compounds YPR_3: m(P=O) < m(P=S) < m(P=Se), have been discussed[121]. According to photoelectron spectroscopic data, the formation of the P=Y bond is regarded as involving the σ-donor transfer of the UEP of the P(III) atom to an unoccupied orbital of the Y atom. The two unshared p-pairs of the Y atom are able to undergo a π-donor interaction of opposite sign with a molecular orbital of the PX_3 group, and this interaction is not limited to the central atom, and can extend in the direction of the atoms of the substituents X.[130]. Quantum-mechanical calculations by the CNDO/2 method also confirm the existence of a hyperconjugation interaction of degenerate orbitals n_Y with σ-bonding molecular orbitals of the P–X bonds[130]. In P(IV) compounds, the first ionisation potential corresponds mainly to the ionisation of the four p_π electrons of the Y atom, and it can serve as a measure of the back transfer of electron density[15]. For the compounds $X_3P{=}Y$ with Y = O, S, the ionisation potential decreases in the following order of substituents X_3:[15] Cl_3P > $(EtO)_3P$ > $(Me_2N)_3P$ > Me_3P. The polarity of the P=Y bond increases in the same order. This indicates the important role of delocalisation effects due to n–σ hyperconjugation interaction in the production of the electronic structure of the P=Y bond, and as in the case of tervalent P compounds, this effect is greatest for P–Cl and P–O bonds[121].

The donor power of the p_π orbital of the UEP of the atoms O, S, Se, according to their ionisation potentials[15], increase in the order O < S < Se. It is increased in the reaction with low-lying UEP of neighbouring atoms (X = OR, Cl) and is decreased in interactions with high-lying pairs (X = NR_2). Thus in compounds of the type $R_3P{=}Y$ in which the donor power of the UEP and the acceptor power of the P–C bonds are lowered, delocalisation effects are shown to the smallest extent; the order of the increase in m(P=Y) corresponds to the order of the polarisability of the donor–acceptor bonds: (P → O) < (P → S) < (P → Se).

The degree of back transfer of the four p_π electrons from the heteroatom Y is greater, on the one hand, for compounds with X = Cl and OR, and on the other hand for compounds with Y = Se, and then Y = S and Y = O. The superposition of the delocalisation effect also leads to a change in the order of the increase in the dipole moment of the P=Y bond in the compounds $(RO)_3P{=}Y$ and $R_3P{=}Y$.

The influence of the nature of the substituent X on the polarity of the P=Y bond is revealed in a study of unsymmetrically substituted compounds of the 2-X-2-Y-1,3,2-dioxaphosphorinane type (XXI).[121,125] It also depends on the conformational characteristics, as was first pointed out in a study of the dipole moments of 2-methyl- and 2,4-dimethyl-2-thiono-1,3,2-dioxaphosphorinanes[16]: the a and e P=Y bonds have different polarities[121].

The greatest difference was found for the compounds with X = H: for the a and e P=O bonds, the values obtained were 3.25 D and 2.95 D;[121,132] for X = NR_2 the differences are 0.25 D (3.60 D and 3.33 D for the P=O bond[133], and 3.53 D and 3.33 D for the P=S bond[134]). The smallest difference was observed for phosphonates (X = Me), where for the a and e bonds, m(P=O) is 3.36 D and 3.33 D.[126,135]

For conformationally uniform compounds, only the polarity of the e P=Y bond has been determined; it is a minimum in chlorophosphates (X = Cl) [m(P=O) = 2.40 D and m(P=S) = 2.10 D [125]]; in phosphates (X = OMe) it increases to 2.95 D and 2.68 D respectively[125]; and in the phenoxy derivatives (X = OPh) it is slightly greater than in compounds with X = OR.[136] The polarity of the P=Y bond has been estimated graphically in 2-phenyl-1,3,2-dioxaphosphorinane oxide and sulphide; the values found were 3.0–3.5 D and

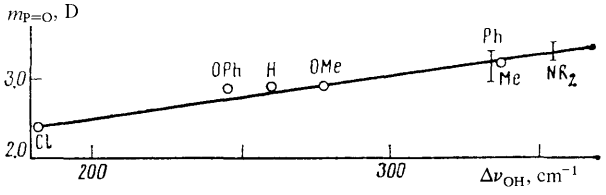
2.8 D respectively[31]. Quantum-mechanical calculations have also detected variation in the polarity of the phosphoryl group with change in the nature of the substituent X in compound (XXI),[127] but the high absolute values obtained have been criticised[121]. Thus the dipole moments of the P=Y bonds in 1,3,2-dioxaphosphorinanes evidently undergo appreciable changes with change in the nature of X (in the range 1.0–1.5 D) and with change in the orientation of the P=Y bond (~0.3–0.5 D).

2. BASIC NATURE OF THE PHOSPHORYL GROUP

Changes in the polarity of the P=Y bond are reflected in the variation in the physical and chemical properties of the compounds. For the phosphoryl group, these characteristics are the vibrational wavenumbers in the infrared spectra and the basic character. The order of the basic nature of 2-oxo-1,3,2-dioxaphosphorinanes, determined relative to $\Delta\nu_{OH}$ for phenol[127], correlates with the magnitude of the dipole moment of the phosphoryl bond, and changes in the following sequence of X (Fig.2):[121]

$$Cl < OPh \sim H \sim OMe < Ph < Me < NR_2.$$

The order obtained also reflects the regular features found above: for electron-acceptor substituents, $m(P{=}Y)$ and the basic nature of the phosphoryl group are smaller than those for electron-donor substituents. Here, as in the symmetrically substituted compounds, the influence of delocalisation is apparently being shown. Unfortunately, data on the photoelectron spectra of 2-oxo-1,3,2-dioxaphosphorinanes are extremely limited (only the first ionisation potentials have been obtained),[137] so that a correlation with delocalisation effects is not possible[121].



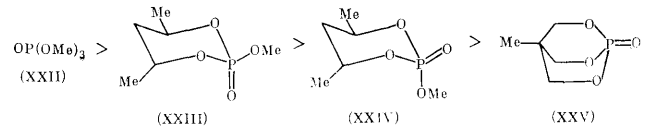


Figure 2. Correlation between the polarity and the order of basic nature of the phosphoryl group, determined relative to $\Delta\nu_{OH}$ for phenol[121].

In the discussion of the influence of the conformational characteristics on the basic nature and polarity of the P=Y bond, it is useful to compare the corresponding parameters of compounds with different three-dimensional structures and the same environment of the phosphorus atom. In 1,3,2-dioxaphosphorinanes, the more polar *a* P=Y bond should also be more basic. This order of basic nature of the phosphoryl oxygen atom was in fact established for the 2-hydro-2-oxo- and 2-methoxy-2-oxo-derivatives.[126] If however it is borne in mind that the *e*-orientation of the P=Y bond corresponds to the TT conformation of the P–O bonds, and the *a*-position to the GG′ conformation, it may be concluded that in the TT conformation, the degree of delocalisation of the p_π electrons of the Y atom is greater, and this leads to a decrease in the polarity of the P=Y bond[121].

An analogous relationship is revealed in the trialkyl phosphate series, for which the following order of decrease in the basic nature of the terminal oxygen atom was observed[126]:

The members of the series differ in their structural characteristics: for compound (XXII), the GGG conformation is preferred[138]; the second member of the series (XXIII) is characterised by equilibrium between the forms GGG ⇌ TGG′ (the conformation of the exocyclic group is given first);[139] the third member has the GTT conformation[139]; and the last member (XXV) has the TTT conformation[121]. As the T conformations accumulate, the effect of delocalisation increases, with a consequent decrease in the concentration of negative charge on the terminal oxygen atom and a corresponding decrease in its polarity and basic nature.

V. INFLUENCE OF PHOSPHORUS-CONTAINING GROUPS ON ELECTRONIC INTERACTIONS IN NEIGHBOURING FRAGMENTS (O-PHOSPHORYLATED PHENOLS)

Phosphorus-containing groups have such a marked ability to take part in different types of electronic interaction that they can also change the nature of the mutual influence of atoms in fragments adjoining them. An example is provided by O-phosphorylated phenols, for which a fairly large amount of factual material has been accumulated. They contain the fragment P–O–Ar. In organic compounds of this type, the anisoles R–O–Ar, $p-\pi$ conjugation between the oxygen atom and Ar predominates, leading to stabilisation of the conformations with the parallel arrangement of the *p* and π orbitals[140] and to transfer of electron density from the oxygen atom towards the benzene ring[141,142]. Extensive studies have also been carried out for anisoles in which, as a consequence of steric strain, inhibition of $p-\pi$ conjugation is observed[143–147], revealed by reversal of the sign of the dipole moment of the C_{sp^2}–O bond, which changes from −0.39 D in anisoles to 0.05 D in its sterically hindered analogues[144].

In O-phosphorylated phenols, the group joined to the Ar–O group is a strong competing π-electron acceptor, namely the phosphorus-containing group. The question of whether it is capable of inhibiting $p-\pi$ conjugation, and which of the effects is stronger, $p-\pi$ conjugation or π-electron-acceptor interaction, can be considered. The view is held that the introduction into anisoles of a second unsaturated group capable of conjugation does not inhibit conjugation, since it may involve both unshared *p*- and sp^2-pairs of electrons of the oxygen atom[142,148], whose energy difference is small[142]. Other data show, however, that the presence of two π-electron systems on an oxygen atom in the molecule of an organic compound weakens its conjugation with each system separately[141,143]. For the analogous silicon compounds, it is suggested that both UEP are involved in conjugation with the phenyl group and the group containing the heteroatom[52]. This interaction should lead to an appreciable decrease in the electron density on the oxygen atom. The competition between these two types of interaction facilitates the production of the one which is energetically more favourable. This should be reflected primarily in the three-dimensional structure of the compounds: for $p-\pi$ conjugation, the more favourable structure is that in which the plane of the benzene ring coincides with the plane of the C_{sp^2}–O–E bonds, and the *p* and π orbitals are coplanar (Fig.3, $\alpha = 0°$); in the alternative conformation, the planes being considered are

mutually orthogonal ($\alpha = 90°$), and the sp^2 orbital of the UEP is in the same plane as the phenyl π-electrons.

The available data on compounds containing the fragment Ar–O–P(III) or Ar–O–P(IV) can be considered in turn.

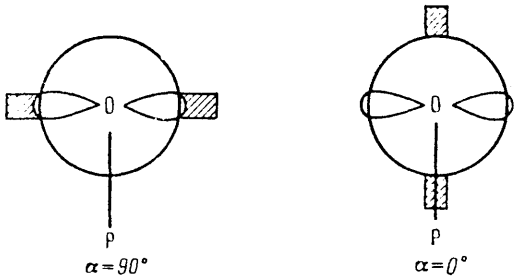

Figure 3. Boundary conformations of the benzene ring in O-phosphorylated phenols.

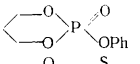

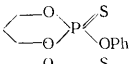

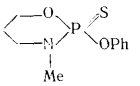

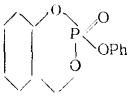

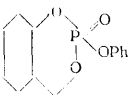

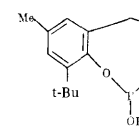

1. EXPERIMENTALLY MEASURED CHARACTERISTICS OF THE COMPOUNDS

a) Three-dimensional Structure of the Compounds

Within the framework of existing ideas, $p-\pi$ conjugation is energetically more favourable than $p_\pi-d_\pi$ conjugation, so that the production of conformations with parallel orientation of the p and π orbitals being considered is to be expected (Fig.3, $\alpha = 0°$). The results of most studies carried out up to the present, however, indicate the reverse: many types of phosphorus compound have a structure with an arrangement of the p orbital of the UEP and the π orbital of the benzene ring close to orthogonal (see later, Table 4). This orientation of the phenyl plane has been established by X-ray diffraction for phenoxythiophosphoryl hydrazide (XXXII), $\alpha = 87.2°$;[149] 2-phenoxy-2-thiono-5,5-dimethyl-1,3,2-dioxaphosphorinane (XXVII), $\alpha = 84.2°$;[150] 1,8-naphthalene phenyl phosphite (XXXI) [151] and the eight-membered 2-phenoxy-4,5,7,8-dibenzo-6H-1,3,2-dioxaphosphocine (XXXIII), $\alpha = 75.5°$.[152] In solution, 1,3,2-dioxaphosphorinanes retain the conformation characteristic of the crystalline state[136]; an analogous structure is shown by the phosphoryl analogue[136] and aryloxy-derivatives of tervalent phosphorus compounds[30]. The orthogonal orientation has also been established for pyrocatechol aryl phosphites[153]. According to NMR data, phenyl dichlorophosphate also has an appreciably non-planar structure[154]. The introduction of substituents in the p-position of the benzene ring in 2-aryloxy-1,3,2-dioxaphosphorinanes does not influence the angle of rotation of the aryl plane, indicating indirectly the absence of conjugation.

The orthogonal orientation of the p and π orbitals found for O-phosphorylated phenols is possibly not the exception but the rule for compounds containing elements of period III next to an aryloxy fragment. Thus phenyl silyl ether[155] and trichloro- and trimethylphenoxysilanes[156] have a structure close to orthogonal, and sulphur compounds, namely the aryl esters of arylsulphonic acids, also show appreciable non-coplanarity ($\alpha \cong 90 \pm 20°$).[157]

Table 4. P–O and C_{sp^2}–O bond lengths in O-phosphorylated phenols.

No.	Compound	Position	Bond length, Å				Refs.
			P–O (Alk)	P–O (Ar)*	C–O (Alk)	C–O (Ar)

*Here, r = ring, and e = exocyclic P–O bond.

b) Electron Density Distribution

To establish the mechanism of intramolecular electronic interactions, it is of value to analyse the polarity of the C_{sp^2}–O and P–O bonds of the Ph–O–P fragment. The high electronic lability of the C_{sp^2}–O bond in anisoles was noted above (range of change in the dipole moment from −0.39 D to 0.05 D [144]). Diphenyl ether also shows a reversal of the sign of the dipole moment of the bond compared with anisole; the moment is directed towards the oxygen atom[141]. The chemical shifts of the signals in the ^{13}C NMR spectra in various substituted phenols also confirm that variation in the polarity of the C_{sp^2}–O bond over a wide range, depending on the nature and position of the substituents in the benzene ring[158]. The polarity of the P–O bond also varies over a fairly wide range with change in the type of substituent on the phosphorus atom[16]. All these data indicate that the π-donor or π-acceptor transfer of electron density at the oxygen atom is reflected in the change in the dipole moments of the bonds.

Data have now been obtained on the polarity of the C_{sp^2}–O bond in the following phosphorus compounds: triphenyl phosphite[159], pyrocatechol phosphites[153], and 2-aryloxy-1,3,2-dioxaphosphorinanes[30]. In all cases the dipole moment of the C_{sp^2}–O bond (0.3–0.8 D) is directed towards the oxygen atom; this indicates inhibition of $p-\pi$ conjugation. The σ-acceptor transfer of electron density in the direction of the oxygen atom is of comparable magnitude to the π-donor transfer, and predominates in these systems.

The second fragment, that is the P–O bond, can now be considered. In symmetrically substituted trialkyl phosphites, the polarity of this bond is zero[16]. In 2-X-1,3,2-dioxaphosphorinanes, the magnitude and direction of the dipole moment of the bond change with change in the nature of the substituent X (see Table 1),[16,59] and in the aryloxy-derivatives (X = OAr) the ring and exocyclic P–O bonds are non-equivalent and have different polarities[30]: the former have a dipole moment of 0.8 D, directed towards the phosphorus atom, whereas the dipole moment of the second atom is 0.22 D and is directed towards the oxygen atom, that is overall, electron density is transferred from the ring oxygen atoms towards the exocyclic P–O bond, which has clearly defined electron-acceptor properties. The transfer is analogous to that observed in 2-chloro-1,3,2-dioxaphosphorinane, where the P–Cl bond acts as acceptor[16]. σ-Acceptor transfer of electron density towards the oxygen atom also follows from an analysis of the dipole moments of pyrocatechol phosphites[153].

The data obtained from dipole moments on the polarity of the P–O bond in the P–O–Ph fragment exclude the possibility of π-acceptor interaction of the UEP of the oxygen atom with the phosphorus-containing group (p_π–d_π conjugation or hyperconjugation). In all the examples studied, the P–O–Ph fragment behaves as an electron density acceptor.

c) Bond Lengths

The additional bonding produced as a result of the conjugation effect (including p–π and p_π–d_π conjugation) is reflected in changes in the bond lengths. Increase in the length of a bond indicates a decrease in its double bond character and an increase in its antibonding character. For example, the C–O(Ph) bond length increases from 1.361 Å in anisole (XXXV) [160] to 1.38 Å in the sterically strained compound (XXXVI),[161] in which the methoxy groups are displaced from the plane of the benzene ring. In *p*-fluoroanisole, theoretical calculations have established an increase in the length of the C–O(Ph) bond by 0.014 Å on going from the planar to the orthogonal structure[162]. Table 4 gives the results of an X-ray diffraction study of the bond lengths in O-phosphorylated phenols. In all cases, an increase (by 0.03–0.05 Å) is observed in the C–O(Ph) bond length, indicating a decrease in its double-bond character compared with anisole and even with its sterically strained analogues.

The characteristics of phosphorus–ether bonds can also change with change in the type of intramolecular electronic interactions. The data in Table 4 show that in most cases [except compound (XXX)], the bonds next to Ar are longer than the P–O(Alk) bond, indicating that there is no additional bonding in the P–O(Ar) fragment. Thus this fragment has greater acceptor character than the P–O(Alk) group. For all the cyclic compounds given (XXVI)–(XXXII), the endo- and exocyclic P–O bonds are non-equivalent. In 1,3,2-dioxaphosphorinanes with a phenoxy group in the axial position, (XXVI)–(XXIX) and (XXXI), the increase in the antibonding character of the exocyclic bond is greater, and the bond is 0.02–0.03 Å longer than the ring bonds.

This effect is not related to a change in the nature of the substituent (Alk or Ar) on the O atom, since it is also observed in the compounds (XXXI) and (XXXII),[151,152] although in the last case the increase in the antibonding character of the P–O(Ar) bond is greater. This difference is related to the conformational characteristics of the bonds: in 1,3,2-dioxaphosphocine[152] and also in the bicyclic *trans*-isomer of 1,3,2-dioxaphosphorinane (XXX),[166] the exocyclic P–O(Ph) bonds occupy the *e* position, in contrast to all other compounds, where this bond is in the axial position. For the *e* position there is a change in the three-dimensional structure of the entire P–O–Ph fragment; from the "*cis*" conformation characteristic of the *a*-phenoxyl group,[30,136,150,151,163] the phenyl group changes to the T structure relative to the UEP of the P atom[152]; 1,3-synaxial interactions do not prevent the production of the T conformation. Change in the confirmations also leads to a change in the bond lengths: the conformations of the ring and exocyclic P–O bonds in compounds with the OPh group are described by the TTC [or TTG for P(IV)] structure, and with the *e* group by the GG'T structure. In all the examples given in Table 4, an increase in length is observed for the bonds characterised by the T conformation.

d) Photoelectron Spectra

Unfortunately, almost no studies have been carried out for compounds containing the P–O–Ph fragment. The photoelectron spectra of phenyl dichlorophosphate have been published[168]; splitting of the $\pi(b_1)$ and $\pi(a_2)$ orbitals of the benzene ring was not detected, and this may indicate that there is no p–π conjugation.

e) ^{13}C NMR Spectra

The π-electron density distribution in derivatives of phenol and anisole can also be estimated from the chemical shifts in the ^{13}C NMR spectra;[142,169,170] here, the changes in the chemical shifts of the carbon atom in the *para*-position of the benzene ring are due to the effect of conjugation. In alkyl phenyl ethers, with inhibition of p–π conjugation, a decrease in the shielding of C_n compared with anisole was detected[145,158,170]. According to published data, in O-phosphorylated phenols[171,172] and anilines[173] the deshielding of the C_n atom increases and reaches 2.7–6.3 p.p.m. The weak-field displacements of the C_n signal in phosphorus compounds (by analogy with systems in which steric inhibition of the p–π conjugation effect is observed) can be attributed to a decrease in or even the absence of interaction between the p orbitals of the oxygen atom and the π orbitals of the benzene ring.

f) Ultraviolet Spectra

The participation of the π-electron of the benzene ring in conjugation with the UEP of the oxygen atom can be studied from the ultraviolet spectra; it is revealed in a bathochromic shift and an increase in the intensity of the λ_2 and λ_1 absorption bands of benzene (in anisole, 217 nm, ε = 8050; 271 nm, ε = 1500 [140]). In t-butyl phenyl ether and 2,6-dimethylanisole, where conjugation is sterically inhibited, the intensity of the λ_3 band is low (460,[174] 334 [146]).

The ultraviolet spectra of derivatives of 2-phenoxy-1,3,2-dioxaphosphorinanes have been studied[172].

For the 2-oxide and the 2-sulphide, a complete analogy with the spectra of the sterically strained anisoles is observed: the λ_2 band does not undergo the bathochromic shift characteristic of anisole, the fine vibrational structure of the λ_3 band is preserved, and its intensity does not exceed 440. The general form and position of the λ_3 band are also preserved for the compound with P(III), ε_{max} = 520. The analysis of the λ_2 band is made difficult by the presence of

additional absorption in the region of ~200 nm, due to the $n-\sigma^*$ transfer of the UEP of the P(III) atom[172,175]. The preservation of the autonomous organisation of the benzene ring in 2-phenoxy-1,3,2-dioxaphosphorinanes indicates that $p-\pi$ conjugation is inhibited in these compounds. Additional analysis of *p*-bromo- and *p*-alkyl-substituted dioxaphosphorinanes indicates that the O-phosphorylated group has electron-acceptor properties[172].

g) Reactivity

The study of the ionisation constants and reactivity of pyrocatechol phosphites and other cyclic systems containing the P–O–Ph fragment indicates an increase in the acceptor properties of these groups, compared with the analogous systems in which the phenyl group is replaced by an alkyl group[176,177]. A fundamental difference has been detected in the distribution of the products of the nitration of acetyl and phosphorylated derivatives of aniline and phenol; in the organophosphorus compounds, nitration takes place more rapidly in the *m*-position, and not in the *o*- and *p*-positions, as in the derivatives of aniline and phenol[178]. The authors cited[178] consider that this difference cannot be explained on the basis of existing ideas about the effects of substituents. Data on the dual behaviour of the oxygen atom, depending on the nature of the substituents round it, make it possible to attribute the preferential formation of the *m*-products in the nitration of O- and N-phosphorylated phenols and anilines to the acceptor properties of the oxygen atom in these systems.

2. THEORETICAL EXAMINATION

The above experimental data show that fairly extensive material has now accumulated on the three-dimensional and electronic structure of O-phosphorylated phenols and their chemical behaviour, indicating that the phosphorus-containing group has a specific influence on the nature of the interaction between the phenyl group and a neighbouring oxygen atom on the one hand, and the oxygen atom and the phosphorus-containing group on the other. The data obtained, that is the approximately orthogonal orientation of the π-orbitals of the benzene ring and the *p*-orbitals of the UEP of the oxygen atom, the change in the direction of the dipole moment of the C_{sp^2}–O(P) bond compared with anisole, the preservation of the autonomous organisation of the absorption bands of the benzene ring in the ultraviolet spectra, and the increase in the acceptor properties of the P–O–Ph fragment compared with P–O–Alk, show that the predominant properties are not the π-donor properties usually observed for organic oxygen compounds, but σ-acceptor properties. In the O–C_{sp^2}(Ph) fragment, $p-\pi$ conjugation is inhibited, and in the P–O(Ar) group the signs of π-acceptor interaction are poorly defined. The dual behaviour of the O atom is due to the difference in the electronic structure of the substituents on it[179].

A theoretical examination by the non-empirical SCF method has shown that the σ-acceptor power of the oxygen atom is increased if the neighbouring fragment has a low-lying lowest unoccupied molecular orbital LUMO.[179] These properties are characteristic of the bonds formed by the phosphorus atom. According to the photoelectron spectra, their ionisation potentials are lower than the ionisation potentials of ether bonds[15]. This indicates an increase in the energy of the σ-occupied molecular orbitals, and probably a corresponding decrease in the energy of the LUMO.

The difference in the strength of the manifestation of the effect for P(III) and P(IV) compounds is also explained on the basis of these concepts. The bonds in the P(IV) compounds are more stable, as revealed by the fact that the P^{IV}–X bonds are shorter than the P^{III}–X bonds, and is detected thermochemically[5]. As noted above, the additional increase in the antibonding character of the bonds in the P(III) compounds is due to the α-effect. The increase in the antibonding character leads to a decrease in the energy of the σ-orbitals of the bonds and an increase in the strength of the manifestation of the π-acceptor properties of the O atom.

The dependence of the effect on the spatial characteristics was noted above. For P–O bonds, the greatest increase in antibonding character is observed in the T conformation (section II), in which the *p*-orbital of the UEP of the neighbouring oxygen atom is close to the T-position relative to the P–O bond, so that steric conditions are created for $n_O-\sigma^*_{P-O}$ interaction. This approach makes it possible to explain the non-equivalence of the P–O bonds in cyclic aryl phosphites (Table 4). The interaction affects the whole O_2POAr group, and is so effective that it is able to block the $p-\pi$ conjugation between O and Ar.

The additional compensation may be related to $\pi-\sigma^*$ interaction, so characteristic of benzyl halides[180–185], methylallylsilanes[186], and benzylphosphines[92]. A necessary condition for this interaction is the mutually perpendicular arrangement of the plane of the benzene ring and the σ-bond.[184,185] Fig. 3 shows that it is also fulfilled for O-phosphorylated phenols. An analysis of 2-phenoxy-1,3,2-dioxaphosphorinanes[30,172] shows that the picture of the electron density distribution in these compounds is consistent with this interaction: electron density is transferred from the phenyl group towards the oxygen atom.

Thus the introduction of a phosphorus atom next to an aryloxy fragment radically alters the nature of the orbital interactions of the central oxygen atom with neighbouring fragments, one of which contains π-electrons (the benzene ring), while the other is a strong π-acceptor (the phosphorus-containing group). The inhibition of $p-\pi$ and $p_\pi-d_\pi$ conjugation and the change in the nature of the electron density distribution and chemical reactivity of the compounds indicates that the predominant properties in these systems are not the usual π-donor but the σ-acceptor properties of the oxygen atom, due to the proximity to a low-lying unoccupied molecular orbital of the phosphorus-containing group of atoms.

* *
*

A systematic combined examination of the spatial and electronic characteristics of P(III) and P(IV) bonds has revealed the exceptional importance of many types of specific orbital interactions with low-lying unoccupied π^* and σ^* orbitals of the phosphorus bonds. It was previously assumed that these interactions did not take place or played an insignificant role in organic compounds. In recent years, the position has changed. Analysis of the conformational behaviour of a number of organic molecules has shown that these interactions play an important role in determining the three-dimensional structure of molecules of this kind[1,2]. Even for butadiene, which has become the classical example of a compound in which $\pi-\pi$ conjugation predominates, recent non-empirical calculations have shown that the energy of conjugation in the planar form is only slightly (~1.5 kcal $mole^{-1}$)

greater than the energy of hyperconjugation in the perpendicular conformation[187]. In phosphorus compounds, the acceptor power of the bonds is much greater, as a consequence of the decrease in the energy of the π^* or σ^* orbitals. Unfortunately, there are no accurate quantitative data.

The CNDO/S method has been used to estimate the energy of the π^* orbitals of the PX_2 fragment in vinylphosphine oxides. It amounts to 0.82 eV for X = F, −0.80 eV for X = Cl, and 2.34 eV for X = OMe; on going to the corresponding methyl derivative, the energy increases sharply to 6.0 eV.[188] Indirect confirmation of the marked decrease in the energy of the unoccupied orbitals of the bonds compared with organic compounds is provided by the decrease in the ionisation potentials of the phosphorus bonds, which indicates an increase in the energy of the occupied MO and apparently a corresponding decrease in the energy of the LUMO. The increase in the acceptor power of the P bonds compared with N is not an exception, and is characteristic of all elements of period III. It is a maximum in P(III) compounds as a consequence of the destabilising effect of the repulsion of the UEP of adjacent heteroatoms. The reasons for the decrease in the acceptor properties of P(IV) bonds compared with P(III) were noted above.

All the above material reveals the close relationship between the effects of the mutual influence of atoms and the three-dimensional structure of organophosphorus compounds. The nature of orbital effects is closely related to the conformational characteristics of the interacting orbitals: the effect of $n-\sigma^*$ hyperconjugation predominates for the *trans*-orientation of the orbital of the UEP and the σ-polar bond, whose acceptor properties are a maximum with the destabilising $n-n$ repulsion of the UEP of the adjacent heteroatoms forming this bond (the α-effect); $\pi-\sigma^*$ interaction in $ArPX_2$ becomes decisive with the parallel orientation of the π-orbitals of the benzene ring and $\pi^*_{PX_2}$, leading to the production of the bisector form. The same structural restrictions are revealed in P–O–Ar systems. From the last example it can be seen that the introduction of a phosphorus atom into organic compounds leads to changes in the nature of the electronic interactions not only in the groups directly adjoining this atom, but also in neighbouring fragments.

Comparison of the physical properties of compounds with their three-dimensional structure makes it possible to take a fresh look at the nature of the orbital interactions. Traditional theoretical ideas often not only cannot predict but even cannot explain the observed changes in various properties of the bonds in OPC. The present review presents clear proof that so-called "non-specific" electronic interactions often predominate. In the opinion of the present author, they can be called non-specific only in relation to organic compounds; as far as OPC are concerned, they are typical. For example, the above model of the destabilisation of the σ-bond in the T-position to the p orbital of the UEP of a heteroatom ($n-\sigma^*$ interaction) is being used increasingly to explain the reactivity of organic[189] and organophosphorus[18,190–192] compounds.

The present review gives the available experimental data for phosphorus compounds. Many of the above characteristic features, however, are also observed for the compounds of other elements of periods III and IV.[52–56] Thus for aryloxy-derivatives of S and Si, as for O-phosphorylated phenols, stabilisation of the structure with the orthogonal orientation of the p and π orbitals has been detected[155–157], and it has been reported[193] that there is no $p_\pi-d_\pi$ conjugation between the Si and O atoms in these systems. The combined study of the compounds by different physical methods, together with an analysis of the spatial characteristics, will make it possible to find a final theoretical basis for the observed phenomena.

An attempt has been made above to classify the observed effects from the viewpoint of perturbation theory. The problem examined requires a penetrating theoretical description at a higher level. There are grounds for hoping that the use of non-empirical methods of calculation will make an important contribution to the elucidation of the characteristic features of intramolecular electronic interactions in OPC. Moreover, there have as yet been few rigorous experimental studies to establish the nature, mechanism, and spatial-directed character of the effects of the mutual influence of atoms in phosphorus compounds (this applies particularly to photoelectron and X-ray spectroscopic studies).

Tertiary Phosphines with Functional-group Substituents

O.A.Erastov and G.N.Nikonov

The methods of synthesis of substituted tertiary phosphines and the characteristic features of the mutual influence of the phosphino-group and the substituent, manifested in physicochemical properties (equilibrium between the conformers or stereoisomers, geometrical parameters of the molecules) and in the reactivity (pathways leading to the decomposition of phosphonium compounds, reactions of functional groups with electrophiles, nucleophilic substitution, tautomerism, rearrangements), are examined.
The bibliography includes 248 references.

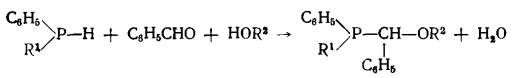
I. INTRODUCTION



Tertiary phosphines containing electron-accepting substituents possess a high and varied reactivity. Firstly, they enter into reactions typical for tertiary phosphines and the functional groups present. The mutual influence of the active centres is manifested in the reaction rates and in the stability of the products formed. Secondly, features determined by the presence of closely linked functional groups are characteristic of such compounds. They react with electrophiles to form phosphonium compounds which are unstable and are stabilised as a result of proton transfer to the negative centre of the electrophile with formation of new tertiary phosphines or ylides. These reactions exhibit an analogy in reactivity between tertiary phosphines with functional-group substituents and primary or secondary phosphines and also esters of tervalent phosphorus acids. The presence of an electron-accepting substituent facilitates nucleophilic substitution at the carbon atom attached to the phosphorus atom and both the phosphino-group and the functional group can be eliminated. The closeness in space of the phosphino-group and the substituent creates favourable conditions for rearrangements. The accumulation of electron-accepting substituents at the carbon atom attached to the phosphorus atom leads to prototropic diad phosphorus–carbon tautomerism.

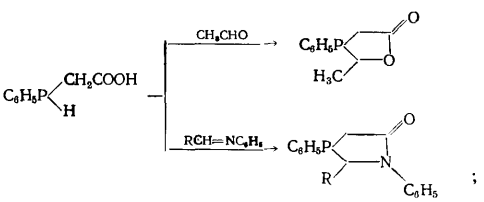
The synthesis of tertiary phosphines with functional-group substituents is based on the available starting material such as phosphine, tervalent phosphorus acid chlorides, and white phosphorus. It is therefore not surprising that during the last decade there has been a rapid development of the chemistry of compounds of this class and many investigations, which need to be surveyed, have been published. This review deals with the methods of synthesis and properties of tertiary phosphines with functional-group substituents. These problems have been partly discussed in other communications[1-5].

II. METHODS OF SYNTHESIS

Tertiary phosphines with functional-group substituents can be obtained from phosphines, silylphosphines, phosphides, tervalent phosphorus acid chlorides, and derivatives such as phosphonium salts, phosphine oxides, and phosphine sulphides.

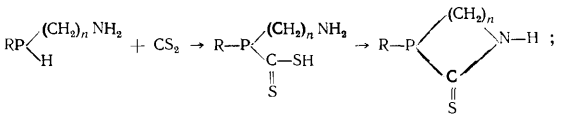
The most general method of synthesis involves the addition of phosphines via the P–H bond to unsaturated compounds. Phosphine[1] and primary and secondary phosphines[6-10] react with aldehydes in a neutral medium to form α-hydroxyalkylphosphines. Halogen-containing aldehydes also enter into the reaction; thus crystalline tris(α-hydroxy-β,β,β-trichloroethyl)phosphine has been obtained from PH_3 and chloral[11]. α-Alkoxyalkylphosphines are formed in the presence of alcohols[12]:

R^1=CH_3, C_6H_5; R^2=CH_3, C_2H_5, iso-C_3H_7, C_4H_9 .



Ketones react similarly to aldehydes. Substituents do not influence the mode of reaction. α-Alkoxycarbonyl-α-hydroxyethylphosphines have been obtained by reaction with pyrubic acid esters[13,14]:

R^1=CH_3, C_6H_5; R^2=$COOCH_3$, $COOC_2H_5$, P (O) $(OC_2H_5)_2$, CN, H .



The addition of phosphines to thiobenzophenone[15], azomethines[16], isocyanates, and carbodi-imides[17,18] has been described. The interaction of phenylphosphine with azomethines and benzaldehyde leads to the formation of *N*-substituted 2,4,5,6-tetraphenyl-1,3,5-oxazaphosphorinanes[19].

The addition of primary and secondary phosphines to ethylenesulphonyl fluoride[20], vinyl sulphones[21], vinylsilanes[22,23], vinylphosphines[24], allylamines[25], and unsaturated acid esters[26] has led to the corresponding β- and γ-substituted tertiary phosphines. The reactions of primary phosphines take place stepwise and can be arrested in the first stage, which makes it possible to substitute the hydrogen atoms in succession by various functional groups. 1,3-Azaphospholan-5-ones and 1,3-oxaphospholan-5-ones[27,28], 1,3-oxaphospholans[29], 1,3-oxaphosphorinanes[30], and 1,3-azaphosphepanes[31] have been obtained in this way, for example:

$R=CH_3$, C_2H_5, C_6H_5 .

The introduction of carbon disulphide into the reaction with aminoalkylphosphines made it possible to obtain 1,3-azaphospholanes and 1,3-azaphosphorinanes with thiocarbonyl groups in the ring[32]:

n=2, 3; R=C_4H_9, C_6H_5, cyclo-C_6H_{11} .

Acylphosphines[33] and γ-hydroxypropylphosphines[34] have been obtained by the addition of phosphines to ketens and oxetan respectively.

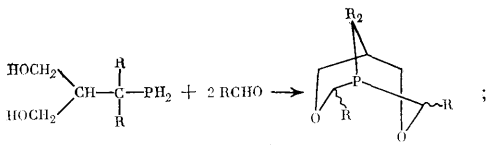
Tertiary phosphines with functional-group substituents can be obtained from phosphines also with the aid of the substitution reaction. Aminomethylation of phosphines by alkoxymethylamines and diaminomethanes yielded aminomethylphosphines[35-37]:

$$R^1R^2PH + R_2^3NCH_2OCH_3 \rightarrow R_2^3NCH_2PR^1R^2 ;$$

R^1= iso-C_3H_7, t-C_4H_9; R^2= iso-C_3H_7, $CH_2C_6H_5$;

R_2^3=O $(CH_2CH_2)_2$;

$$[(CH_3)_2N]_2CH_2 + R_2PH \rightarrow (CH_3)_2NCH_2PR_2 ;$$



R= iso-C_3H_7 .

Secondary phosphines react with orthoformates in the presence of BF_3 at 20 °C to form phosphinoformals[38]:

$$R_2P{-}H + HC(OR)_3 \rightarrow R_2PCH(OR)_2 + ROH$$

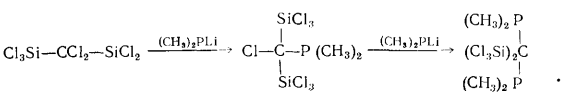
R=C_2H_5, C_4H_9

3,7-Dioxa-1-phosphabicyclo[3.3.1]nonanes have been synthesised by the reaction of aldehydes with a primary phosphine containing two β-hydroxy-groups[39]:

R = H, CH_3, iso-C_3H_7 .

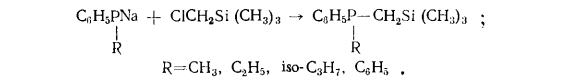
Silylphosphines are used widely to obtain tertiary phosphines with functional-group substituents. Like phosphines, which contain the P—H bond, silylphosphines react with carbonyl compounds to form siloxyalkylphosphines[40-42]:

$$R_n^1P(SiR_3^2)_{3-n} + (3-n)R^3CHO \rightarrow R_n^1P\left(CHOSiR_3^2\right)_{3-n} ;$$



n=1, 2; R^1=C_6H_5; R^2=CH_3; R^3=H, C_6H_5, C $(CH_3)_3$, CN .

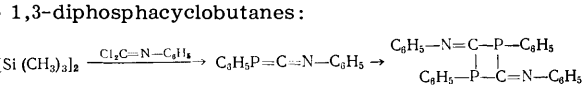
Reactions of diorganylsilylphosphines with carboxylic acid chlorides yield acylphosphines[40,43-45]. The trimethylsilylphenyl group adds to carbodi-imides[18] and substitues the chlorine atom in dichloromaleic ester[46].



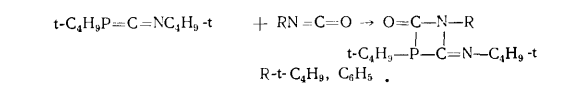
In the reactions with halogen-containing compounds, it is possible to employ metal phosphides instead of silylphosphines. Trialkoxycarbonylphosphines have been obtained from sodium phosphide and chlorocarbonic acid esters[47], while trifluorovinylphosphines are formed in small amounts from lithium phenylphosphides and trifluorovinyl halides[48]. Lithium or sodium phenyl- and methyl-phosphides react with 3-chloropropyldiphenylphosphine to form γ-diphosphines[49]. The reaction of sodium diphenylphosphide with methylene chloride results in the formation of tetraphenylmethylenediphosphine[50]:

$$2(C_6H_5)_2PNa + CH_2Cl_2 \rightarrow (C_6H_5)_2PCH_2P(C_6H_5)_2 .$$

α-Chloromethyldimethylbis(α-trichlorosilyl)phosphine, which is capable of undergoing many further transformations, has been obtained from lithium dimethylphosphide. The substitution of the mobile chlorine atom in this compound leads to new derivatives of tertiary phosphines[51]:



Together with the electron-accepting substituents enumerated above, the use of metal phosphides has made it possible to introduce the electron-donating trimethylsilylmethyl group in the α-position with respect to the phosphorus atom[52]:

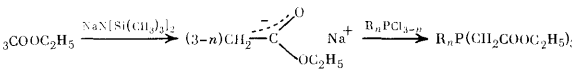


R=CH_3, C_2H_5, iso-C_3H_7, C_6H_5 .

One of the methods of synthesis of heterocyclic phosphines with functional-group substituents is the dimerisation of compounds of dicoordinate phosphorus. The interactions of disilylphosphines with carbon disulphide[53] or phenyl isocyanide dichloride[54], of lithium silylphosphide with carbonyl compounds[55], and of disilylphosphines and primary phosphines with ketones and dimethylformamide[56] lead to the formation of compounds with a dicoordinate phosphorus atom, which dimerise to 1,3-diphosphacyclobutanes:

The cycloaddition of isocyanates to "carboimidophosphene" yields 1,3-azaphosphetidines with imino- and carbonyl groups[57]:

R-t-C_4H_9, C_6H_5 .



Tervalent phosphorus acid chlorides readily react with compounds having a mobile hydrogen atom or with organometallic compounds. The abstraction of hydrogen chloride by triethylamine has been observed in the phosphorylation of methyl trifluoromethyl sulphone and malonic acid esters by chlorodialkylphosphines[58,59]:

$$CH_3SO_2CF_3 + (C_2H_5)_2PCl \rightarrow (C_2H_5)_2PCH_2SO_2CF_3 + HCl ;$$
$$CH_2(COOR)_2 + (C_2H_5)_2PCl \rightarrow (C_2H_5)_2PCH(COOR)_2 + HCl ;$$

R=CH_3, C_2H_5 .

This yielded tertiary phosphines with trifluoromethanesulphonyl and alkoxycarbonyl groups. The latter are also formed in the phosphorylation of triethylstannylacetic acid esters[60] and sodio-derivatives of carboxylic acid esters having the enolate structure[61]:

$$2(C_2H_5)_3SnCH_2COOC_2H_5 + RPCl_2 \rightarrow RP(CH_2COOC_2H_5)_2 ;$$
R=CH_3, C_6H_5 ;

R= iso-C_3H_7, C_6H_5; n = 0, 1, 2 .

The interaction of tetrachloromethylenediphosphine with organomagnesium compounds leads to diphosphinomethanes[62]:

$$Cl_2PCH_2PCl_2 \xrightarrow{4RMgCl} R_2PCH_2PR_2 ;$$
R=CH_3, C_2H_5, iso-C_3H_7, s-C_4H_9, C_6H_5 .

The phosphorylation of the lithio-derivatives of these compounds makes it possible to introduce yet another phosphino-group[63,64]:

$$LiHC[P(CH_3)_2]_2 + (C_6H_5)_2PCl \rightarrow (CH_3)_2P{-}CH(P(C_6H_5)_2){-}P(CH_3)_2 .$$

Di- and tri-(*o*-hydroxyphenyl)phosphines[65] phosphorus-containing alkenes[66], and 2-vinylphosphiran[67] have also been obtained from organometallic compounds and phosphorus chlorides:

$$o\text{-}LiOC_6H_4Li + PCl_3 \rightarrow (o\text{-}HOC_6H_4)_3P;$$

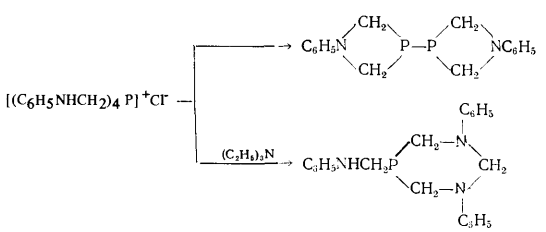
$$(C_6H_5)_2PCl + BrMgCH{=}CHR \rightarrow (C_6H_5)_2PCH{=}CHR;$$

$R = CH_3,\ C_6H_5;$

$$RPCl_2 + \overbrace{MgCH_2CH{=}CHCH_2} \rightarrow \overbrace{RP(-CH_2CHCH{=}CH_2)}$$

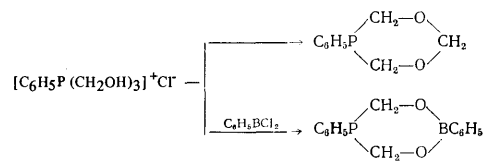
$R = CH_3,\ C_6H_5,\quad t\text{-}C_4H_9.$

The methods of synthesis of tertiary phosphines with functional-group substituents and the corresponding derivatives of quinquevalent phosphorus, namely phosphonium salts, phosphine oxides, and phosphine sulphides, are also important. The cleavage of tetra(hydroxymethyl)phosphonium salts by bases yields tri(hydroxymethyl)phosphine[1,68]. Tertiary phosphines can be used as the bases[69]:



$$[(HOCH_2)_4P]^+Cl^- + (C_4H_9)_3N \rightarrow (HOCH_2)_3P + [(C_4H_9)_3PCH_2OH]^+Cl^-$$

When tetra(chloromethyl)phosphonium chloride is treated with alkali, tri(chloromethyl)phosphine is formed[70]:



$$[(ClCH_2)_4P]^+Cl^- \xrightarrow{NaOH} (ClCH_2)_3P.$$

Methylcarbamate derivatives of tri(hydroxymethyl)phosphine have been obtained from methylcarbamate derivatives of phosphonium salts[71].

The disproportionation of phosphonium salts involves the formation of various products including tertiary phosphines with functional group substituents. Refluxing of tetra-anilinomethyl)phosphonium chloride in ethanol leads to the formation of 1,1'-diphenyl-1,1'-diaza-3,3'-diphosphetidine[72], while its treatment with triethylamine gives rise to 5-anilino-methyl-1,3-diphenyl-1,3,5-diazaphosphorinane[73]:

2,5-Diphenyl-1,3,2,5-dioxaboraphosphorinane has been obtained by heating tri(hydroxymethyl)phenylphosphonium chloride with dichlorophenylborane[74]. 5-Phenyl-1,3,5-dioxaphosphorinane is formed in the absence of dichlorophenylborane[75]:

There exist examples of the reduction of phosphine oxides containing fucntional groups. Many aromatic tertiary phosphines containing hydroxy-, cyano-, alkoxycarbonyl, and formyl groups as well as other substituents in the *ortho*-, *meta*-, and *para*-, positions in the aromatic ring have been obtained in this way[76,77]. Trichlorosilane has been used as the reducing agent. The oxides can be converted into sulphides in a preliminary step with subsequent removal of sulphur by treatment with triphenyl phosphite[78]:

$$(ClCH_2)_2\overset{O}{\overset{\|}{P}}Cl \xrightarrow{P_2S_5} (ClCH_2)_2P(S)Cl \xrightarrow{(C_6H_5O)_3P} (ClCH_2)_2PCl \xrightarrow{RMgBr} (ClCH_2)_2PR;$$

$R = CH_3,\ C_2H_5.$

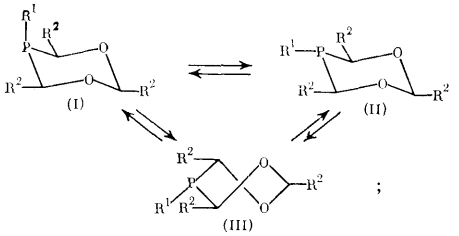
The products of the addition of hypophosphorous acid to unsaturated compounds[79,80] as well as tertiary phosphine oxides with nitro-[81], amino-[82,83], phenoxy-[84], and alkoxycarbonyl groups[5], particularly those obtained from white phosphorus[85], are of interest as compounds to be reduced.

In addition to the above discussion, attention should be drawn to the possibility of obtaining tertiary phosphines with functional-group substituents by adding aluminophosphines[86] and germylphosphines[87] to unsaturated compounds:

$$R_2AlP(C_6H_5)_2 \xrightarrow{R^1C\equiv N} R_2AlN{=}CR^1P(C_6H_5)_2;$$

$R = C_6H_5,\ n\text{-}CH_3C_6H_4,\ изо\text{-}C_4H_9;\ R^1 = C_6H_5,\ CH_3;$

$$(CH_3)_3GeP(CH_3)_2 \xrightarrow{(CH_3)_3SiC(O)C_6H_5} (CH_3)_3GeC(C_6H_5)P(CH_3)_2.$$



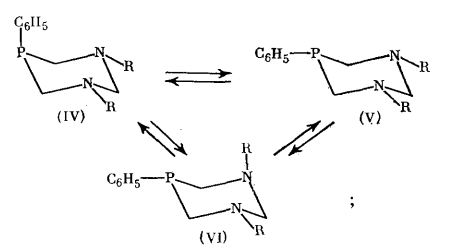
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad OSi(CH_3)_3$$

The last reaction proceeds with a rearrangement.

III. PHYSICOCHEMICAL PROPERTIES

Tertiary phosphines with functional-group substituents contain two or more groups capable of interacting with one another. Such interaction should lead to the appearance of unusual features in the structure and reactivity of the compounds. The position of equilibrium between the conformers or stereoisomers and the geometrical characteristics of the molecules are the most sensitive to the mutual influence of atoms.

The equilibrium between the conformers of unsubstituted 1,3,5-dioxaphosphorinanes or between the stereoisomers of their substituted derivatives has been investigated[88–97]:

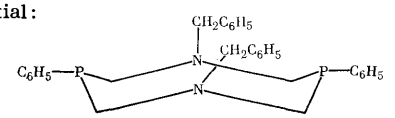


(I) ⇌ (II); (I) ⇌ (III); (II) ⇌ (III);

$R^1 = H,\ CH_3,\ C_6H_5,\ Cl;\ R^2 = H,\ CH_3,\ iso\text{-}C_3H_7,\ C_6H_5.$

The contents of form (I) in the equilibrium (I) ⇌ (II) with $R^1 = C_6H_5$ are 72 and 86% for $R^2 = H$ and CH_3 respectively. In the case of 1-phenylphosphorinane[98], 4-t-butyl-1-phenylphosphorinane[99], and 1-phenylphosphorinan-4-ones[100–102], its content is 30–40%. Comparison shows that the replacement of the CH_2 group by the oxygen atom shifts the equilibrium towards form (I). This effect indicates the interaction between the heteroatoms and is anlogous to that observed in heterocycles with the N–C–O fragment[103–105].

The equilibrium between the conformers of *N*,*N*-disubstituted 5-phenyl-1,3,5-diazaphosphorinanes has been studied[106,107]:



(IV) ⇌ (V); (IV) ⇌ (VI); (V) ⇌ (VI);

$R = C_6H_5,\ C_6H_4CH_3\text{-}p,\ C_6H_4Br\text{-}p,\ CH_2C_6H_5.$

In the case of aryl substituents at the N atoms, conformer (VI) is absent from the equilibrium. The contents of form (IV) in the equilibrium (IV) ⇌ (V) are 24,34, and 0% for R = C_6H_5, $C_6H_4CH_3$-*p*, and C_6H_4Br-*p* respectively. 1,3-Dibenzyl-5-phenyl-1,3,5-diazaphosphorinane is a mixture of conformers (V) and (VI) (64:36). This has been confirmed by X-ray diffraction[107]; it was found that in the crystalline state the compound has the chair conformation with axial orientation of the benzyl group at one of the N atoms. In terms of the position of the conformer equilibrium, 1,3-dibenzyl-5-phenyl-1,3,5-diazaphosphorinane differs little from 1,3-dimethyl-1,3-diazane (40% of the form with the axial orientation of the methyl group[104]). Hence it follows that in 1,3,5-diazaphosphorinanes there is an interaction between the N atoms in which the P atom is not involved.

In the case of 1,5-diaza-3,7-diphosphacyclo-octanes, there are no competing interactions, which makes it possible to solve the problem of the mutual influence of the atoms in the P–C–N system. According to X-ray diffraction data[108], 1,5-dibenzyl-3,7-diphenyl-1,5-diaza-3,7-diphosphacyclo-octane exists in the crown conformation. The P and N atoms are involved in a trigonal-pyramidal coordination (the sums of the valence angles are 297° and 343° respectively). The positions of the phenyl groups at the P atoms are pseudo-equatorial while those of the benzyl groups of the N atoms are pseudoaxial:

The pseudoaxial orientation of the substituents at the N atoms can be regarded as a consequence of the interaction between the heteroatoms in the P–C–N system; it is analogous to that observed in the N–C–N system[103–105].

According to one concept[109], the interaction between the heteroatoms in the N–C–O and N–C–N systems, stabilising the axial orientation of the substituent at the N atom, involves the transfer of electron density from the orbital of the unshared electron pair of the nitrogen atom to the unoccupied orbital of the C–O or C–N bond. From this standpoint, the electron shifts in the P–C–O and P–C–N systems should be of different types, since they stabilise the axial orientation of the substituent at the P atom in the former case and of the substituent at the nitrogen atom in the latter case.

The influence of the interaction of the groups in tertiary phosphines with functional-group substituents can be manifested not only by the position of the conformational equilibrium or the equilibrium between the stereoisomers but also by other characteristics of the molecule: bond lengths, bond angles, dipole moments, NMR parameters, etc. 2,6,7-Trioxa-4-phosphabicyclo[2.2.2]-octanes are of interest in this connection. There exist X-ray diffraction data for the bicylcic phosphorothioate $S{=}P(OCH_2)_3P$ and its derivatives[110] as well as the complex $P(OCH_2)_3P.Fe(CO)_5.P(OCH_2)_3P$.[111] The P–C bond lengths and valence angles at the phosphorus atoms in these compounds are close to the normal values. The experimental dipole moments of $P(CH_2O)_3P$ (3.10 D) and $P(CH_2O)_3As$ (1.58 D) agree well with the calculated values (2.94 and 1.49 D respectively)[112]. The ^1H NMR spectra of the compound $P(CH_2O)_3P$ and certain analogous bicyclic compounds and their derivatives have been examined[113–116]. The spin–spin coupling constants $^2J_{PH}$ for all phosphorus(III) compounds are close to the expected values; it was not possible to observe deviations in the case of 2,6,7-trioxa-4-phosphabicyclo[2.2.2]octanes.

X-Ray diffraction data for 1,3,5-triaza-7-phospha-adamantane and its derivatives have been published[117,118]. The C–N bond length and the angles at the N atoms are close to the normal values. There are appreciable differences between the P–C bond lengths and the latter deviate from the usual value (1.841 Å). However, it is not possible to find a correlation between the observed changes and the interaction of the heteroatoms.

Such correlation has been postulated for 1,5-dibenzyl-3,7-diphosphacyclo-octane[108] and 1,3-dibenzyl-5-phenyl-1,3,5-diazaphosphorine[107]. The decrease of the C–N bond lengths (on average 1.452 Å) and the increase of the P–C bond lengths (on average 1.888 Å) in the former compound and also the decrease of the C–N bond length to 1.424 Å in the latter compound can be explained by the transfer of electron density from the unshared electron pair orbital of the N atom to the unoccupied orbitals of the P–C and C–N bonds respectively. In tetraphenyl-1,5-diaza-3,7-diphosphacyclo-octane[119] the endocyclic bond lengths agree with those found for 1,5-dibenzyl-3,7-diphenyl-1,5-diaza-3,7-diphosphacyclo-octane[108].

Apart from the results examined above, there exists also data obtained by X-ray diffraction for 2,4-di-t-butyl-2,4-bis(trimethylsiloxy)-1,3-diphosphetan[120], 4-phosphorinanones[121,122], and complexes of tri(β-cyanoethyl)phosphine[123]. The vibrational spectra of acylphosphines have been investigated[124]. In the liquid phase these compounds exist in the form of a single conformer having a plane of symmetry. The considerable decrease of the barriers to pyramidal inversion of the phosphorus atom in acylphosphines compared with tertiary phosphines have been explained by the conjugation of the unshared electron pair of the P atom with the C=O group in the planar transition state[125].

IV. CHEMICAL PROPERTIES

Tertiary phosphines with functional-group substituents undergo oxidation reactions and addition reactions involving the C atom, which are typical for tertiary phosphines. They give rise to phosphine oxides, sulphides, and selenides, phosphonium salts, and other tertiary phosphine derivatives. The influence of the functional groups is manifested by changes in the rates of reaction and in the stability of the products formed[1]. In addition there are many reactions characteristic of these compounds which are due to the presence of functional groups; these are the substitution reactions on treatment with electrophiles or nucleophiles, prototropic phosphorus–carbon diad tautomerism, and rearrangements.

1. Reactions with Electrophiles

The introduction of electron-accepting substituents leads to the appearance of new pathways to the decomposition of the phosphonium compound formed initially; they are associated with the position of the mobile hydrogen atom in the molecule. If the mobile hydrogen atom is in the α-position relative to the phosphorus atom, the phosphonium compound can be stabilised by its elimination in the form of a proton and an anion, the compound itself being converted into an ylide. When the mobile hydrogen atom is in the β-position with respect to the phosphorus atom, there is a possibility of proton transfer from this position to the anionic centre of the molecule with the dissociation of the P–C bond. As a result, the phosphonium compound can decompose into an unsaturated compound and a new tertiary phosphine. In both cases there is a possibility of a competing reaction involving the nucleophilic centre of the functional group. The anions of tertiary phosphines with functional-group substituents undergo competing reactions.

(a) Phosphines with a Mobile α-Hydrogen Atom

The stabilisation of a phosphonium compound by the elimination of a proton from the α-carbon atom with formation of phosphorus ylides has been observed in the reaction of (diethoxycarbonylmethyl)diethylphosphine with ethyl iodide in the presence of triethylamine[126]:

$$R_2PCH(COOR)_2 \xrightarrow{RI} [R_3PCH(COOR)_2]^+I^- \xrightarrow[-HI]{} R_3P{=}C(COOR)_2 ;$$

$$R = C_2H_5 .$$

Ylides are obtained on disproportionation of (dialkoxycarbonylmethyl)diethylphosphines and diethyl(trifluoromethanesulphonylmethyl)phosphine[127,128] and also on their interaction with chlorodiethylphosphine in the presence of triethylamine[129]:

$$2R_2^1P{-}CHR_2^2 \longrightarrow R_2^1\overset{+}{P}(R_2^1P)\text{–}CR_2^2(H)\text{–}CHR_2^2 \longrightarrow R_2^1P{=}CR_2^2 + CH_2R_2^2 ;$$

$$R_2^1P{-}CHR_2^2 + R_2^1PCl \xrightarrow[-HCl]{} R_2^1P{-}CR_2^2(R_2^1P){-}Cl ;$$

$$R^1 = C_2H_5;\ R^2 = COOCH_3,\ COOC_2H_5 \text{ or } CR_2^2 = CHSO_2CF_3 .$$

The reactions of these compounds with carbon tetrahalides proceeds analogously[130,131]:

$$R_2^1P{-}CHR_2^2 \xrightarrow{CX_4} R_2^1\overset{+}{P}(X)\text{–}CR_2^2(H)\text{–}CX_3 \xrightarrow[-CHX_3]{} R_2^1P(X){=}CR_2^2 ;$$

$$R^1 = \text{alkyl},\ C_6H_5;\ CR_2^2 = CH_2,\ CHSO_2CF_3,\ C(SO_2C_6H_5)_2,\ C(CO_2CH_3)_2;\ X = Cl, Br .$$

The activation of the molecule as a result of the formation of hydrogen bonds involving the functional group can lead to the elimination of the phosphino-group on nucleophilic attack. Similar behaviour has been observed in the interaction of the esters of diphosphinoacetic acids with compounds having a mobile hydrogen atom[132]:

$$R_2^1P{-}CH(COOR){-}PR_2^1 + HX \rightarrow R_2^1PCH_2COOR^2 + R_2^1PX ;$$

$$R^1 = \text{iso-}C_3H_7;\ R^2 = C_2H_5;\ X = OH,\ OC_2H_5,\ NR_2,\ OCOCH_3 .$$

Thus electrophilic substitution reactions leading to an increase of the coordination number of the phosphorus atom are characteristic of phosphines having a mobile α-hydrogen atom.

(b) Phosphines with a Mobile β-Hydrogen Atom

There exist numerous instances of the decomposition of phosphonium derivatives with elimination of a proton from the β-position and the liberation of an unsaturated compound, which results in the formation of a tertiary phosphine. Thus, when tri(hydroxymethyl)-phosphine was treated with alkyl halides, the hydroxymethyl groups were substituted by the alkyl groups[133]. Tri(acetoxymethyl)phosphine reacts analogously in the presence of alkali[134]:

$$P(CH_2OCOCH_3)_3 \xrightarrow{NaOH+RX} [RP(CH_2OCOCH_3)_2(CH_2OH)]^+X^- \xrightarrow[-CH_3O,-HX]{} RP(CH_2OCOCH_3)_2 ;$$

$$R = C_2H_5,\ C_3H_7,\ C_4H_9,\ C_5H_{11},\ C_6H_{13};\ X = Br, I .$$

Dimethyl sulphate has been used together with alkyl halides[135]. In the latter case the interaction of the phosphonium salts with hydrochloric acid leads to the formation of chloromethylphosphine oxides[136].

Tri(hydroxymethyl)phosphine[137] as well as di(hydroxymethyl)phosphines[138] react with acrylonitrile in a neutral medium to form the corresponding β-cyanoethylphosphines. The reaction of tri(hydroxymethyl)phosphine with acrylic acid esters proceeds analogously[139]. In an aqueous alcoholic medium β-cyanoethylphosphines are converted into β-alkoxycarbonylethylphosphines[140].

Substitution products have been obtained in the reaction of alkyldi(hydroxymethyl)phosphines with epoxides[141,142]:

$$R^1P(CH_2OH)_2 + 2H_2C\text{—}CHR^2(O) \rightarrow R^1P(CH_2CHOH)_2 ;$$

$$R^1 = CH_3,\ C_2H_5,\ C_3H_7,\ C_4H_9,\ \text{iso-}C_6H_{11};\ R^2 = H,\ CH_3 .$$

The conclusion that intermolecular exchange of hydroxymethyl groups takes place in the case of tri(hydroxymethyl)-phosphine was reached on the basis of the study of the temperature-induced changes in the NMR spectra[143–145]. The possibility of such a reaction has been confirmed by the isolation of tri(α-hydroxyalkyl)phosphines on interaction of tri(hydroxymethyl)phosphines with aliphatic aldehydes[146]:

$$P(CH_2OH)_3 \xrightarrow[-3CH_2O]{3R^1CHO} P(CHOH)_3 \xrightarrow[-HI,-R^1CHO]{R^2I} R^2P(CHOH)_2 ;$$

$$R^1 = CH_3,\ C_3H_7,\ \text{iso-}C_3H_7,\ C_6H_{13};\ R^2 = CH_3,\ C_2H_5,\ C_3H_7 .$$

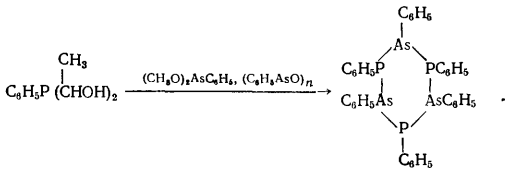
The hydroxyalkyl derivatives of the phosphines obtained in this way react with alkyl halides. After treatment of the products with triethylamine, the corresponding alkyldi-(α-hydroxyalkyl)phosphines were isolated. They were also obtained from alkyldi(hydroxymethyl)phosphines and aldehydes[146].

The hydroxymethyl groups are also displaced on interaction with unsaturated ketones[147,148]. Imidoylphosphines have been obtained by the reaction of di(hydroxymethyl)-phenylphosphine with isobutyl diphenylborinate in the presence of nitriles[149]:

$$C_6H_5P(CH_2OH)_2 \xrightarrow{\text{iso-}C_4H_9OB(C_6H_5)_2+RCN} C_6H_5P(CH_2\text{—}O)(C=N(H)R)B(C_6H_5)_2 ;$$

$$R = CH_3,\ C_6H_5 .$$

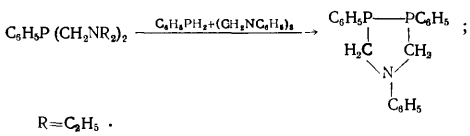
In the absence of nitriles the product is 5-hydroxymethyl-2,2,5-triphenyl-2-borata-5-phosphonia-1,3-dioxan[150].



Tri(hydroxymethyl)phosphine reacts with aryl bromomethyl ketones to form aroylmethyltri(hydroxymethyl)phosphonium bromides. Their decomposition by tri(hydroxymethyl)-phosphine results in cyclisation to 4-aryl-1-phospha-3,5-dioxabicyclo[2.2.1]heptanes[151]. The reaction of tris(trimethylsiloxymethyl)phosphine with aryl bromomethyl ketones proceeds differently; when triethylamine is added, hydrogen bromide is split off with formation of ylides[152]:

$$P(CH_2OR^1)_3 \xrightarrow{R^2C_6H_4COCH_2Br} [R^2C_6H_4COCH_2P(CH_2OR^1)_3]^+Br^- \xrightarrow[-HBr]{} R^2C_6H_4COCH{=}P(CH_2OR^1)_3 ;$$

$$R^1 = Si(CH_3)_3;\ R^2 = H,\ CH_3,\ OCH_3,\ Br,\ NO_2 .$$



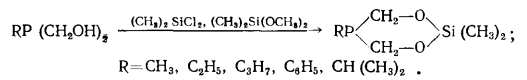
In the former case the reaction proceeds with participation of the β-hydrogen atom and in the latter case with that of the α-hydrogen atom.

There exist examples of the substitution of hydroxyalkyl groups by organoelemental groups. When di(α-hydroxyethyl)phenylphosphine was allowed to react with phenylarsine oxide or dimethyl phenylarsonite, hexaphenyl-1,3,5-triphospha-2,4,6-triarsacyclohexane was obtained[153]:

Aminomethyl groups are also capable of being substituted by organic and organoelemental groups. The reaction of 5-*p*-toluidinomethyl-1,3-di-*p*-tolyl-1,3,5-diazaphosphorinane with methyl iodide led to the isolation, instead of the addition products, of one of the symmetrisation products—5,5-dimethyl-1,3-di-*p*-tolyl-1,3,5-diazaphosphonarinane iodide having two methyl groups at the phosphorus atom[154]. A product with two aminomethyl groups at the phosphorus atom has been obtained by treating di-isopropylmorpholinomethylphosphine with methyl iodide[155]. The overall result of these two reactions is the formation of both symmetrisation products.

When bis(diethylaminomethyl)phenylphosphine is heated with phenylphosphine, diethylmethylamine and diethylamine are produced together with the formation of $(C_6H_5P)_5$ and $(C_6H_5P)_4CH_2$.[156] In the presence of 1,3,5-triphenyl-1,3,5-triazane, the product is 1,3,4-triphenyl-1,3,4-azadiphospholan[157]:

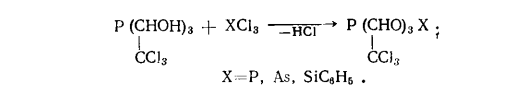
R=C_2H_5 .



Tri(β-cyanoethyl)phosphine also reacts with methyl iodide to form substitution products[158].

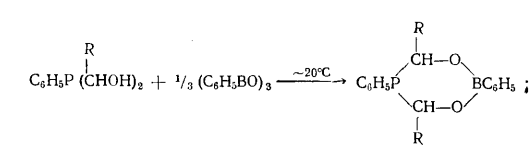
An interesting instance of electrophilic substitution is provided by the reactions of tri(hydroxymethyl)phosphine leading to compounds with a dicoordinate phosphorus atom. Phosphacyanines[159] and 2,4,6-triphenylphosphabenzene[160] have been obtained in this way.

Tris(trimethylsiloxymethyl)phosphine without mobile hydrogen atoms give rise to dihalogenotris(trimethylsiloxymethyl)phosphorane on interaction with PCl_5 and HCl.[161]



Reactions involving the functional group are extremely characteristic of phosphines having a mobile β-hydrogen atom. The interaction of alkyldi(hydroxymethyl)phosphines with phenyl and *m*-chlorophenyl isocyanates, leading to alkyldi(arylaminocarbonyloxymethyl)phosphines, takes place readily[162]. Alkyldi(hydroxymethyl)phosphines react vigorously with di-isocyanates to form polyurets[163]. Apart from isocyanates, carbonyl compounds have been used as the organic electrophiles. On heating di(hydroxymethyl)phenylphosphine or tri(hydroxymethyl)phosphine in a mixture of acetic acid and acetic anhydride, the corresponding acetates were obtained[6,134]. The reaction of di(α-hydroxyalkyl)-phenylphosphines with aldehydes leads to the formation of 1,3,5-dioxaphosphorinanes[95]. When tri(hydroxymethyl)-phosphine was heated with trimethyl orthoformate or trimethyl orthoacetate, trioxaphosphabicyclo[2.2.2]octane derivatives were obtained[164,165].

Organoelemental electrophiles can also react via the functional group. Tri(hydroxymethyl)phosphine[166,167] and alkyldi(hydroxyalkyl)phosphines[168] have been silylated. Chlorotriethylsilane and hexamethyldisilazane can be used instead of chlorotrimethylsilane. The employment of dichlorodimethylsilane and dimethoxydimethylsilane leads to the formation of 1,3,2,5-dioxasilaphosphorinanes. In the former case the reaction takes place in ether in the presence of triethylamine and in the latter on refluxing in toluene in the presence of sodium methoxide[169]:

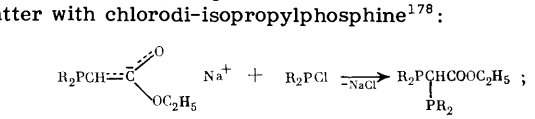


R=CH_3, C_2H_5, C_3H_7, C_6H_5, $CH(CH_3)_2$.

2,6,7-Trioxa-1,4-diphosphabicyclo[2.2.2]octane[170] and its arsenic and silicon analogues[171,172] have been obtained by the reaction of tri(hydroxymethyl)phosphine with trimethyl phosphite, trimethyl arsenite, and trichloromethylsilane. The reactions of tri(α-hydroxy-β,β,β-trichloroethyl)-phosphine with PCl_3, $AsCl_3$, and $C_6H_5SiCl_3$ in the presence of triethylamine lead to the formation of bicyclic compounds[173]:

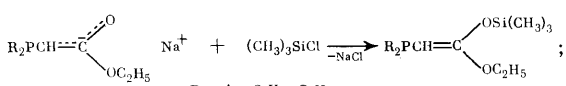
Di(β-hydroxyethyl)phenylphosphine reacts with dichloromethylphosphine to form 1,3-dioxa-2,6-diphosphacyclooctane[174].

Organoelemental electrophiles of yet another type, which react under mild conditions with the functional group, are derivatives of boric acids. The isobutyl ester of diphenylborinic acid reacts with di(hydroxymethyl)phenylphosphine to form a *trans*-esterification product[175]. 1,3,2,5-Dioxaboraphosphorinanes have been obtained by the reaction with the diethyl ester or anhydride of phenylboronic acid[176,177]:



R=H, CH_3, iso-C_3H_7, C_6H_5 .

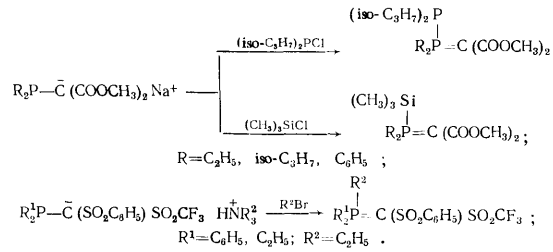
In contrast to phosphines with a mobile α-hydrogen atom, electrophilic substitution reactions without change in the coordination number of the phosphorus atom are characteristic of phosphines having a mobile β-hydrogen atom.



(c) Phosphine-containing Anions

Tertiary phosphines with functional-group substituents having a mobile α-hydrogen atom give rise to phosphine-containing carbanions on treatment with bases. These anions can react with chlorine-containing electrophiles both at the carbon atom and at the phosphorus atom. If the functional group contains the carbonyl moiety, the reaction can also proceed via the oxygen atom of the latter. Substitution at the carbon atom has been observed for the anions derived from phosphinoacetic esters on treatment of the latter with chlorodi-isopropylphosphine[178]:

R= iso-C_3H_7 .



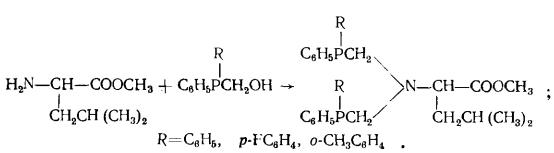
On the other hand, when the same compound was treated with chlorotrimethylsilane, the product of substitution at the oxygen atom was obtained[179]:

R= iso-C_3H_7, C_6H_5 .

Substitution at the phosphorus atom is characteristic of di(alkoxycarbonyl)methylphosphines and trifluoromethanesulphonylmethylphosphines. P–P– and P–Si– substituted ylides were obtained in the former case[180], while in the

latter case the products were alkyl-substituted phosphorus ylides[181]:

Electron-accepting substituents stabilise the $-\overset{\backslash}{P}-\overset{/}{C}R_2$ group; their accumulation increases the thermodynamic stability of the product of substitution at the phosphorus atom and drives the reaction towards its formation.



The study of the reactions with electrophiles has shown that there is an analogy in the behaviour of tertiary phosphines with a mobile hydrogen atom and the primary or secondary phosphines. Substitution at the phosphorus atom is also characteristic of the latter (examples of such reactions have been given in connection with the description of the methods of synthesis of tertiary phosphines with functional group substituents). The analogy is based on the ability of the phosphonium salts, obtained from all three types of compounds, to be stabilised by proton transfer to the negative centre of the electrophile. This method of stabilisation is related to that observed in the reactions of phosphorus(III) acids with electrophiles[182], which indicates considerable synthetic possibilities of the reactions examined. It must be emphasised that the phosphorus atom frequently does not prevent reactions with electrophiles also via the functional group.

2. Reactions with Nucleophiles

The carbon atom attached to the phosphorus atom is the electrophilic centre in the molecules of tertiary phosphines. The introduction of electron-accepting substituents should increase its reactivity. The departing groups can be both the substituent and the phosphino-group.

Nucleophilic substitution at the carbon atom has been most widely investigated for the hydroxy- and aminomethyl derivatives of phosphines. The nucleophiles employed have been primary, secondary, and tertiary amines. Various linear and cyclic products have been obtained.

The reactions of hydroxyalkylphosphines with primary and secondary amines proceed with the evolution of heat and lead to products of the substitution of the hydroxy-groups by amino-groups. Bis(diethylaminomethyl)phenylphosphine has been obtained from di(hydroxymethyl)phenylphosphine and diethylamine[183]. On treatment with hydroxymethyl derivatives of secondary phosphines, aminoacid esters have also given rise to derivatives of phosphorus-containing aminoacid[184]:

The reactions of the hydroxymethyl derivatives of secondary phosphines with ammonia and hydrazine have produced tri-(phosphinomethyl)amines, tri(phosphinomethyl)hydrazine, and tetra(phosphinomethyl)hydrazine[185]. The reactions of tri(hydroxymethyl)phosphine with secondary chiral amines and of hydroxymethyl derivatives of secondary amines with primary chiral amines proceeded analogously with formation of chiral tri(aminomethyl)phosphines and *N,N*-di(phosphinomethyl)amines respectively[186].

It has been shown that aminomethylphosphines can be obtained by heating acetoxymethylphosphines with secondary amines in methyl alcohol in the presence of alkali[187]:

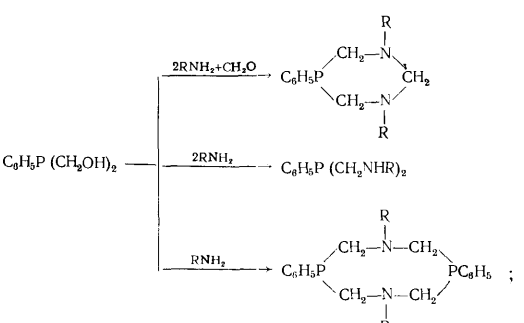
$$R^1_nP(CH_2OCOCH_3)_{3-n} \xrightarrow{KOH} R^1_nP(CH_2OH)_{3\ n} \xrightarrow{R^2_2NH} R^1_nP(CH_2NR^2_2)_{3-n}\ ;$$

R^1=CH_2OH, C_2H_5, C_4H_9; R^2=CH_3, C_2H_5, C_3H_7, iso-C_4H_9; n=0—2 .

β-Hydroxyethylphosphines react with amines under the same conditions as hydroxymethylphosphines. When secondary amines are added to alkyldi(β-hydroxyalkyl)phosphines, an exothermic reaction is observed with formation of alkyldi(β-dialkylaminoalkyl)phosphines[188]:

$$R^1P(CH_2\underset{R^2}{C}HOH)_2 + 2R^3_2NH \rightarrow R^1P(CH_2\underset{R^2}{C}HNR^3_2)_2 + 2H_2O\ ;$$

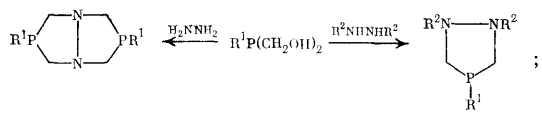
R^1=CH_3, C_2H_5, C_3H_7, C_4H_9; R^2=H, CH_3; R^3=C_2H_5, C_4H_9 .



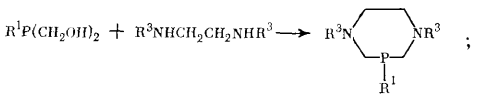
Monomeric products have been obtained by the reaction of tri(hydroxymethyl)phosphine with mono- or di-substituted ureas[189]:

$$3R^1R^2NCONH_2 + P(CH_2OH)_3 \rightarrow (R^1R^2NCONHCH_2)_3P{=}O\ ;$$

R^1=CH_3, C_2H_5, $CH_3(CH_2)_{11}$, $(CH_3)_3C$, C_6H_5; R^2=H, C_6H_5 .

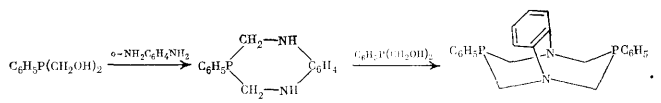


The oxidation of the product is attributed to the presence of formaldehyde in the reaction mixture.

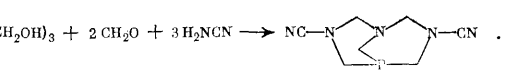


The reactions of di(hydroxymethyl)phenylphosphine with primary aromatic amines and benzylamine have attracted attention. They have been carried out in a solvent or in its absence, in the presence or absence of paraformaldehyde, and with different reactant ratios[190–192]. In all cases the reaction took place with evolution of heat. The structure of the *N,N*-disubstituted 5-phenyl-1,3,5-diazaphosphorinane was attributed to the product obtained in the presence of paraformaldehyde and two moles of the amine, while the products obtained in the absence of paraformaldehyde and in the presence of two and one moles of the amine were assumed to have the structure of *N,N*-disubstituted di(aminomethyl)phenylphosphines and 3,7-diphenyl-1,5-diaza-3,7-diphosphacyclo-octanes respectively:

The reactions of di(hydroxymethyl)phenylphosphine with boric acid esters took place analogously[193–197]. 1,5-Diaza-3,7-diphosphacyclo-octanes have also been obtained from diols containing aliphatic substituents at the phosphorus atom and a wide range of amines, including aliphatic amines[198].

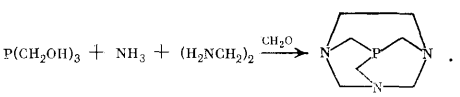


The reactions of di(hydroxymethyl)phosphines with hydrazine, substituted hydrazines, and ethylenediamine under the same conditions led to the formation of new heterocycles[199,200]:



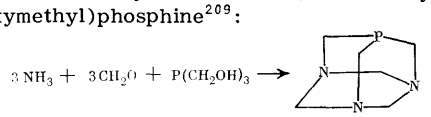
$R^1 = C_6H_5$, cyclo-C_6H_{11}, CH_3, C_2H_5; $R^2 = CH_3$, iso-C_3H_7; $R^3 = C_6H_5CHCH_3$.

o-Phenylenediamine reacts with di(hydroxymethyl)phenylphosphine only on heating and the products are 3-phenyl-6,7-benzo-1,5-diaza-3-phosphepane and 3,7-diphenyl-9,10-benzo-1,5-diaza-3,7-diphosphabicyclo[3.3.2]decane[201]:

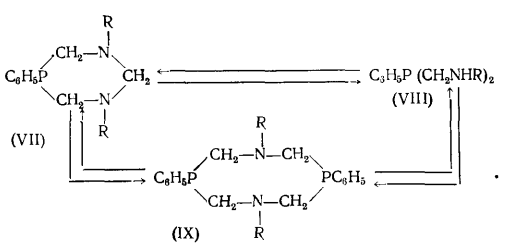


For a 1:1 reactant ratio, the product of the first stage of the reaction is obtained.

3,7-Dicyano-3,5,7-triaza-1-phosphabicyclo[3.3.1]nonane, which is capable of being oxidised and of combining with methyl iodide at the phosphorus atom, has been obtained by the reaction of tri(hydroxymethyl)phosphine with formaldehyde and cyanamide in the presence of phosphoric acid[202,203]:

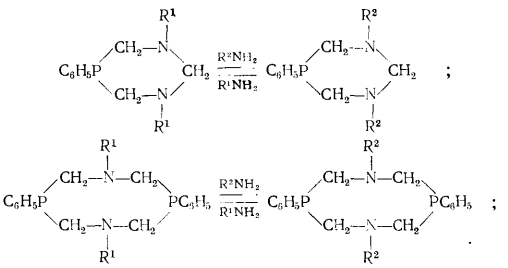


The reaction of tri(hydroxymethyl)phosphine with hexamethylenetetramine and formaldehyde (in portions of 1:1:4) has led to 1,3,5-triaza-7-phospha-adamantane[204,205]. This compound combines with methyl iodide and picric acid via one of the nitrogen atoms[206,207].



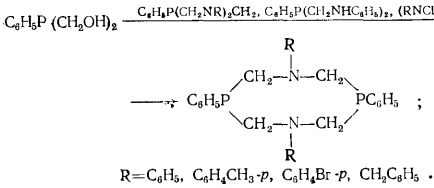
The synthesis of the next member of this series has been described[208]. Triazaphosphahomoadamantane is formed when ethylenediamine and ammonia react with tri(hydroxymethyl)phosphine in an excess of formaldehyde:

In contrast to triazaphospha-adamantane, it does not react with methyl iodide. 1,3,5-Triaza-7-phospha-adamantane is also obtained directly from ammonia, formaldehyde, and tri(hydroxymethyl)phosphine[209]:



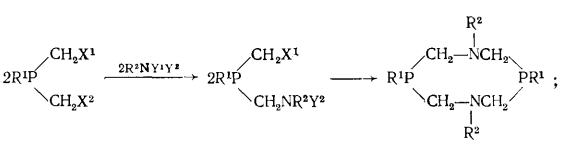
Not only the hydroxy-groups but also the amino-groups of tertiary phosphines with functional-group substituents readily undergo nucleophilic substitution. Thus the following interconversions of the aminomethyl derivatives of phenylphosphine have been demonstrated[210]:

Compounds (VII) and (IX) are converted into compound (VIII by amines. Diazadiphosphacyclo-octane (IX) can be obtained from compounds (VII) and (VIII) by the elimination of azomethines or amines respectively. The addition of azomethines to compounds (VIII) and (IX) gives rise to compound (VII). These reactions constitute nucleophilic substitution of one amino-group by another and proceed under fairly mild conditions.



The substitution of one amino-group by another is also possible without alteration of the molecular skeleton[211]:

$R^1 = C_6H_5$; $R^2 = C_6H_4CH_3$-*p* .



The interconversions are reversible; the direction of the reaction is determined by the conditions and the solubilities of the substances.

The hydroxy-group can be substituted by the amino-group on treatment not only with primary and secondary amines but also with triazanes or aminomethyl derivatives of phosphines. Thus di(hydroxymethyl)phenylphosphine and its borate esters give rise to 1,5-diaza-3,7-diphospha-cyclo-octanes on reaction with both primary amines and with 1,3,5-triphenyl-1,3,5-triazane, di(anilinomethyl)phenylphosphine, or 5-phenyl-1,3,5-diazaphosphorinanes[212]:

R=C_6H_5, $C_6H_4CH_3$-*p*, C_6H_4Br-*p*, $CH_2C_6H_5$.

The numerous methods of synthesis of 1,5-diaza-3,7-diphosphacyclo-octanes can be reduced to a single scheme[212]:

R^1 and R^2 — alkyls, aryls; $Y^1 = Y^2 = H$; $Y^1 = H$, $Y^2 = CH_2P$ (R) CH_2NHR; $X^1 = X^2 = OH$; $X^1 = OH$, $X^2 = OB(C_6H_5)_2$; $Y^1Y^2 = CH_2NRCH_2NRCH_2$, $X^1X^2 = OB(C_6H_5)O$, $NRCH_2NR$; $Y^1Y^2 = CH_2PRCH_2NRCH_2$, $X^1 = X^2 = NHR$.

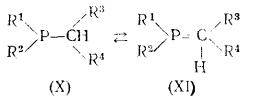
The formation and transamination reactions and interconversions of the aminomethyl derivatives of phosphines, which constitute nucleophilic substitution at the carbon atom of the P–C–O or P–C–N fragment, proceed under milder conditions than the analogous reactions of alcohols, amines, and their derivatives. This is due to the involvement of the phosphino-group in intramolecular interactions. Examination of steric effects shows that the electron density in the P–C–O system is displaced towards the oxygen atom, while in the P–C–N system it is displaced towards the phosphorus atom. The transfer of electron density facilitates nucleophilic attack. In the former case the departing group is

the phosphino-group while in the latter it is the amino-group. The rupture of the P–C bond has been postulated in the reactions of di(hydroxyalkyl)phosphine oxides with amines[213].

The interactions of hydroxy- and amino-methylphosphines with nucleophiles have been fairly thoroughly investigated. Examples of such reactions for other tertiary phosphines with functional-group substituents are rarer. Tri(ethylchloromethyl)-phosphine is converted into tri(ethylthio)-phosphine on treatment with ethanethiol or sodium ethanethiolate[70]:

$$P(CH_2Cl)_3 \xrightarrow{3C_2H_5SH} P(CH_2SC_2H_5)_3 .$$

The addition of primary and secondary amines to diphenylvinylphosphine has been described[214]:



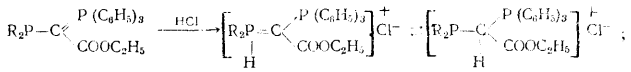
$$(C_6H_5)_2PCH_2CH_2NR_2 \xleftarrow{R_2NH} (C_6H_5)_2PCH=CH_2 \xrightarrow{+RNH_2} RN(CH_2CH_2P(C_6H_5)_2)_2 ;$$

$R = C_6H_5,\ C_2H_5$.

The amine attacks the β-position relative to the phosphorus atom.

3. Tautomerism

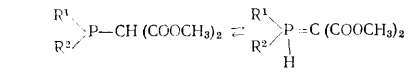
Prototropic tautomerism is possible for tertiary phosphines with functional-group substituents having a mobile hydrogen atom in the α-position. If centres capable of stabilising the proton are absent from the functional group, diad phosphorus-carbon tautomerism takes place:



(X) (XI)

In the presence of such centres, other types of tautomerism cannot be excluded. The possibility of tautomerism depends mainly on the substituents at the carbon and phosphorus atoms.

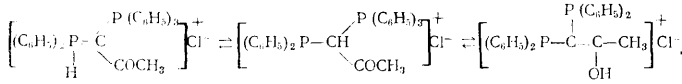
The study of various tertiary phosphines has shown that, in the presence of alkyl and aryl substituents at the carbon atom, they exist in form (X). The stabilisation of the ylide form requires the introduction of strongly electron-accepting substituents such as the triphenylphosphonium, alkoxycarbonyl, and sulphonyl groups.



The presence of two triphenylphosphonium groups fully displaces the equilibrium towards form (XI). In the presence of butyl substituents at the phosphorus atom, the ylide has been isolated in a crystalline state[215,216]. The dependence of the equilibrium position on the substituents at the phosphorus atom has been observed for compounds containing the triphenylphosphonium and alkoxycarbonyl groups[217,218]:

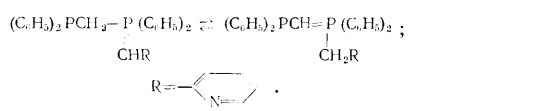
$R = C_4H_9,\ C_6H_5$.

The butyl substituent stabilise the ylide formed. The replacement of butyl by phenyl leads to the establishment of a mobile tautomeric equilibrium and the relative contents of the different forms in solution depend on the temperature and the polarity of the medium. Only form (X) exists in trifluoroacetic acid. The substitution of the alkoxycarbonyl group by the tosyl group displaces the equilibrium towards the ylide form[219].



The occurrence of the diad phosphorus–carbon tautomerism has also been demonstrated for dialkyl(dimethoxycarbonylmethyl)phosphines[220–223]:

$R^1 = t\text{-}C_4H_9,\ R^2 = iso\text{-}C_3H_7,\ s\text{-}C_4H_9,\ (CH_3)_3SiCH_2,\ C_6H_5,$
$iso\text{-}C_4H_9;\ R^1 = R^2 = iso\text{-}C_4H_9,\ C_6H_5$

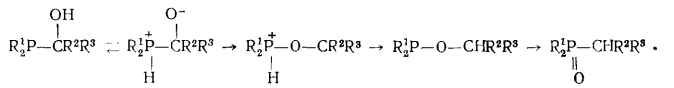


When R^1 = iso-C_4H_9 and R^3 = iso-C_3H_7, s-C_4H_9, or $(CH_3)_3SiCH_2$, the compounds are in the ylide form in the crystalline state. On fusion, a considerable proportion of the ylide is converted into a tertiary phosphine, which again crystallises in the ylide form. In solution, the compounds exist as tautomeric mixtures of forms (X) and (XI). The equilibrium position depends on the temperature, the nature of the solvent, the concentration, and the character of the substituents at the phosphorus atom. Heating shifts the equilibrium towards form (X). Bulky substituents stabilise the ylide form and in terms of their influence can be arranged in the following sequence: C_5H_9 < iso-C_4H_9 < iso-C_3H_7 < s-C_4H_9 < $(CH_3)_3SiCH_2$ < t-C_5H_9.

The substituted tertiary phosphines examined above exhibit only the diad phosphorus–carbon tautomerism despite the presence of carbonyl groups. The tetrad phosphorus–carbon tautomerism has been observed on substitution of the alkoxycarbonyl group in these compounds by the acetyl group[217,218]:

This type of tautomerism includes the diad phosphorus–carbon tautomerism and the keto-enol tautomerism.

The introduction of an ylide group as a substituent into the molecule of a tertiary phosphine results in the transfer of the mobile hydrogen atom to this group. The process can be both reversible and irreversible[224]:

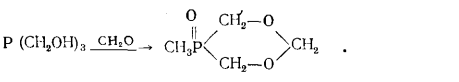


Proton transfer to the phosphorus atom has been observed in acetonyldiphenylphosphine under the influence of tin tetrachloride[225]:

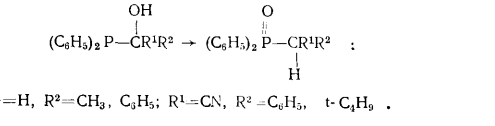
The observation of the prototropic diad phosphorus–carbon tautomerism emphasises the powerful influence of substituents on the properties of tertiary phosphines.

4. Rearrangements

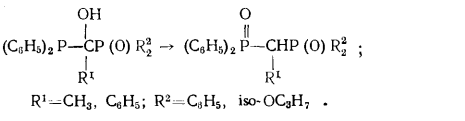
The lability of the P–C bond and the close proximity in space of the substituents at the phosphorus atom in tertiary phosphines with function-group substituents can lead to rearrangements whose character depends on the nature of the solvents. The rearrangements of hydroxyalkylphosphines have been most thoroughly investigated. It has been suggested that the hydroxyalkylphosphine molecule is in equilibrium with the dipolar ion formed as a result of proton transfer to the phosphorus atom. This dipolar ion can rearrange to another dipolar ion containing the P–O–C group. The rearrangement is irreversible and the ion is stabilised by proton transfer to the carbon atom with formation of a phosphinite; the subsequent isomerisation yields



the compounds most stable in the given system—tertiary phosphine oxides[226]:

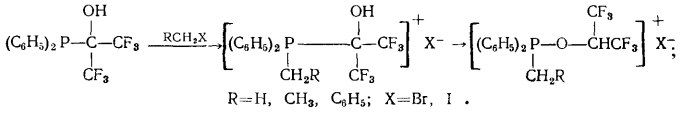


Tri-(hydroxymethyl)phosphine isomerises on heating to di(hydroxymethyl)methylphosphine oxide[227-231]:



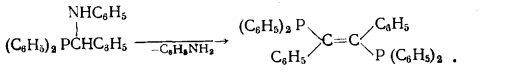
When paraformaldehyde is added, 5-methyl-5-oxo-1,3,5-dioxophosphorinane is formed[232]:

In the case of the hydroxyalkyl derivatives of diphenylphosphine, the rearrangement was observed for different C-substituted compounds[226,233]:

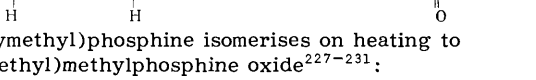


Replacement of the phenyl group at the phosphorus atom by the ethyl group does not affect the possibility of this rearrangement[226]. α-Phosphorus-substituted phosphinomethanols also give rise to rearrangement products on heating[234,235]:

The isomerisation of hydroxyalkylphosphines to tertiary phosphine oxides can occur under the influence of acids and bases[233,236]. Acetoxymethylphosphines rearrange in an acid medium[237,238]:

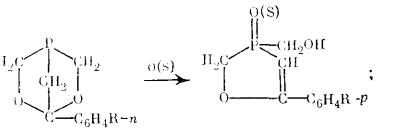


In the examples quoted above the oxygen atom is transferred to the phosphorus atom and the reaction cannot be arrested at the phosphinite formation stage. Phosphonium compounds with the P–O–C group have been obtained by treating with alkyl halides hydroxyalkylphosphines having trifluoromethyl groups at the carbon atom[236]:



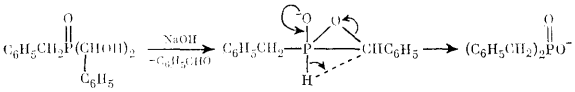
The study of mercaptoalkylphosphines has shown that they too are capable of rearranging to tertiary phosphine sulphides. The mechanisms of the rearrangements are apparently analogous. This follows from the conversion of α-mercaptobenzhydryldiphenylphosphine in benzhydryldiphenylphosphine sulphide[15]:

The organonitrogen analogues of hydroxyalkylphosphines are converted into 1,2-diphosphinoethylenes. This is accompanied by the formation of the corresponding arylamines[239]:



The rearrangement of α-halogenophosphines, formed on interaction of phosphinous acid chlorides with α-halogenomethyl sulphones in the presence of triethylamine or the sodio-derivatives of α-halogenodi(benzenesulphonyl)-methanes, to *P*-halogenoylides has been described[240,241]:

It has been suggested that the rearrangement involves the concerted bimolecular transfer of a halogen atom via a six-membered transition state. This reaction has also been examined in other studies[242,243]. α-Halogenophosphines with alkyl substituents at the carbon atom are stable[244].



Many rearrangements are known for substituted phosphines, which can proceed under the conditions of oxidation or sulphur addition reactions. 4-Aryl-1-phospha-3,5-dioxabicyclo[2.2.1]heptane gives rise on oxidation or addition of sulphur to the oxide or sulphide of 4-aryl-1-hydroxymethyl-1-phospha-3-oxacyclopent-4-ene respectively[245,246]:

The migration of the phenyl group from the phosphorus atom to the carbon atom has been observed in the reactions of ferrocenyldiphenylphosphines, leading to the formation of phosphonium betaines and binylphosphonium salts[247]:

When benzyldi(α-hydroxybenzyl)phosphine oxide is heated with an equimolar amount of alkali in benzene, the sodium salt of dibenzylphosphinic acid is formed in an almost quantitative yield[248]:

Hydride transfer from the phosphorus atom to the carbon atom in the intermediate anion has been postulated in this reaction.

---o0o---

Thus the introduction of substituents alters significantly the properties of tertiary phosphines; new pathways to the decomposition of the phosphonium compound appear and reactions with nucleophiles as well as rearrangements become characteristic of these compounds. The high and many-sided reactivity of tertiary phosphines with functional-group substituents together with the existence of a large number of convenient methods of their synthesis makes it useful to investigate this class of compounds.

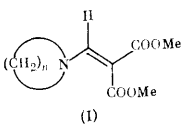
Advances in the Chemistry of Enamines

V.G.Granik

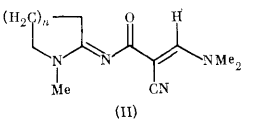
The review surveys the results of studies on the physicochemical and chemical properties of enamines. Special attention has been devoted to the employment of enamines in the synthesis of various heterocyclic systems.
The bibliography includes 236 references.

CONTENTS



I. Introduction 383
II. Structural studies, protonation, and hydrolysis of enamines 383
III. Oxidation and reduction of enamines 385
IV. Addition to the enamine double bond, cycloaddition, and rearrangements 386
V. The reactions of enamines with nucleophiles and electrophiles 387
VI. Enamines in the synthesis of heterocyclic compounds 390

I. INTRODUCTION

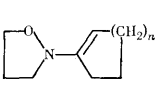


The chemistry of enamines is at present one of the most vigorously developing fields of organic synthesis and the number of publications concerning the properties and reactions of these compounds continuously increases. Because of this and despite a whole series of reviews dealing with various aspects of the chemistry of enamines and related compounds[1-14], it is useful to survey the extensive data published in recent years (mainly in 1977–1982), obtained in the study of various types of enamine systems. The present review does not deal specially with publications describing the methods of synthesis of various enamines since fundamentally new data have not become available in this field and the known methods of synthesis of enamines have already been discussed in detail[1]. As a rule, studies on the chemistry of different classes of enamines which have been included in the reviews mentioned above are also not dealt with.

II. STRUCTURAL STUDIES, PROTONATION, AND HYDROLYSIS OF ENAMINES

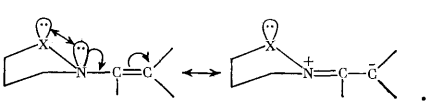
The spectroscopic studies on enamines published in recent years were devoted mainly to stereochemical aspects of these compounds[15-24]. The study of the hindered rotation about the enamine C–C bond in enaminoesters of type (I) has shown that the main factors which determine the kinetic and thermodynamic parameters of this process are the degree of conjugation of the nitrogen atom with the double bond in the ground state and the extent of the non-bonding interaction between the amino-fragment and the *cis*-COOMe group which is non-planar in the ground state[15]:

(I)



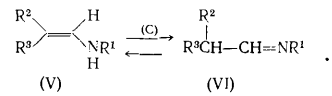
(II)

Another problem, that of hindered rotation about the single N–C bond, was also investigated in the above study[15]. An analogous process has been discovered and investigated for enaminoacylamidines (II)[16]. The study of the ^{13}C NMR spectra of a large group of enamines[17-19] established that the chemical shifts of the β-carbon atom in these compounds are extremely sensitive to the steric factor[17]. On the other hand, if this factor does not vary in various compounds, the chemical shift of the β-carbon atom serves as a characteristic of the electron density. In cyclic enamines the electron density and hence the degree of conjugation of the nitrogen atom with the C–C bond is highest for the pyrrolidine enamines[18]:



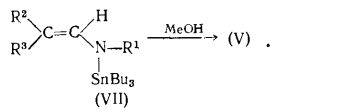
(III)

The study of the ^{15}N NMR spectra led to the conclusion that the nitrogen atom in enamines has the sp^2 configuration[19]. On the other hand, photoelectron spectroscopic data indicate a pyramidal configuration of the nitrogen in enamines, in contrast to the corresponding radical-cation where the configuration is planar[20]. It is extremely interesting that the ^{15}N NMR spectra are not correlated with ^{1}H NMR and ^{13}C NMR spectroscopic data in the sense that the chemical shifts in ^{15}N NMR are almost indistinguishable for pyrrolidine and piperidine enamines. The authors attribute this inconsistency to the fact that in their view a change in electron density at the nitrogen atom is not in this instance a decisive characteristic of the chemical shift of this atom[21]. One must agree with this view, since extensive chemical and physicochemical data leave no doubt at the present time that the degree of the "enamine" conjugation in the pyrrolidine enamines [III, X = $(CH_2)_4$] is greater than in the piperidine and morpholine analogues. This is also supported by the results of the X-ray diffraction analysis of enamines[22], which indicate a higher degree of planarity of the enamine fragment in the pyrrolidine enamines than in the piperidine and morpholine analogues. The literature concerned with the differences between the $p\pi$ conjugations in enamines of type (III) has been analysed in detail[23]; the authors attempted to increase the extent of this conjugation still further by replacing the pyrrolidine ring by the tetrahydroisoxazole ring:



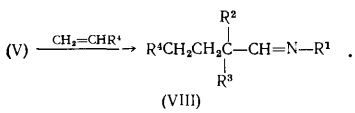
(IV)

(A) (B)



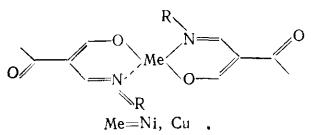
The idea was that the repulsion of the neighbouring free electron pairs leads to an increase of the extent of the enamine conjugations (A) ↔ (B). However, it has been established both spectroscopically (^{1}H and ^{13}C NMR) and chemically (reaction with acrylonitrile) that in enamines (IV) the

degree of $p\pi$ conjugation and hence the reactivity with respect to electrophiles are lower owing to the negative inductive effect of the oxygen atom. Among the studies devoted to the imine–enamine tautomerism[25–27], we shall note those dealing with the secondary enamines (V) lacking β-electron-accepting substituents[25]:



(V) (VI)

Such enamines are usually unstable and the equilibrium (C) is displaced towards the corresponding imines (VI). However, the authors[28] were able to isolate the kinetic product (V) by the methanolysis of the organometallic derivatives (VII) in the presence of a deficiency of methanol:

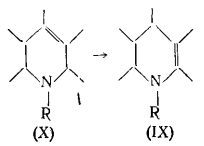


(VII)

It is known that the reactions of the imine (VI) with unsaturated compounds, which proceed via equilibrium (C), require prolonged heating (for 24 h at 80 °C) and in many cases do not occur at all. On the other hand, when the pure enamine (V) is used in such processes, a rapid exothermic reaction is observed even at 0 °C with formation of a substituted imine (VIII):

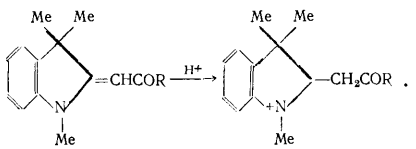
(VIII)

The formation of extremely stable copper(II) and nickel(II) complexes of enaminoketones and enaminoamides is accompanied by the conversion of the enaminocarbonyl compounds into the iminoenol form[28]:

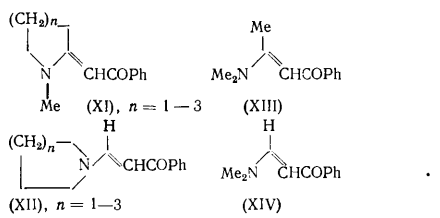


Me=Ni, Cu .

The communication of Martinez and Joule[29], which includes extensive literature and experimental data on the allylamine → enamine isomerisation, was devoted to the problem of the stability of the enamine structure:



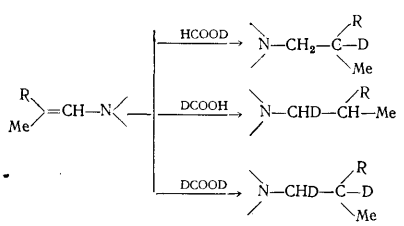
It was established that the enamines 2-piperideines (IX) are thermodynamically more stable than 3-piperideines (X) and that isomerisation takes place in the presence of bases:



(X) (IX)

The energy gain is due to the $p\pi$ conjugation and has been estimated as 2.5 kcal mol^{-1}.

The problem of the protonation and hydrolysis of enamines occupies a notable place in their chemistry[1,11]. Investigations of the traditional type, dealing with the study of the insufficiently clear problems of the mechanism of the hydrolysis of enamines of various types and the factors determining the particular site of the protonation of these compounds, and studies in which the protonation of enamines is used as an intermediate stage for the attainment of synthetic aims have been published in recent years. Among the investigations of the first kind, we may point to those dealing with the protonation of enamines in the gas phase[20,31], where it was shown that in cases where there is no steric inhibition of the $p\pi$ conjugation in enamines the protonation proceeds via the β-carbon atom. A number of studies have been devoted to the problem of the protonation of enaminoketones, but, whereas Kozerski[32] established with the aid of ^{13}C NMR what is in general an unusual fact[1,11], namely the *O*-protonation of these compounds, Bailey et al.[33] indicate a rare instance† of the protonation of enaminoketones at a carbon atom:

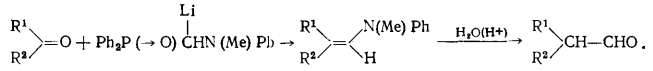


The study of the basicity and ^{1}H NMR spectra of the cyclic enaminoketones (XI) and (XII) and their acyclic analogues (XIII) and (XIV) showed that compounds (XI) and (XIII) are more basic approximately by 2–3 orders of magnitude than compounds (XII) and (XIV), which is caused by the different sites of protonation [compounds (XI) and (XIII) are protonated at the β-carbon atom, while compounds (XII) and (XIV) are protonated at the oxygen and nitrogen atoms[35]]:

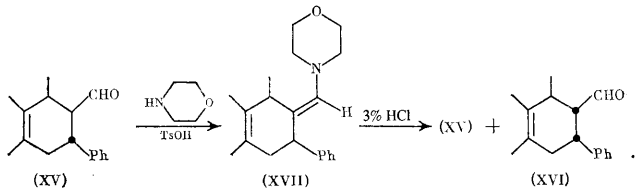
(XI), $n = 1-3$ (XIII)

(XII), $n = 1-3$ (XIV)

The use of deuterated acids as protonating agents made it possible to obtain deuterated compounds from the enamines[36]:



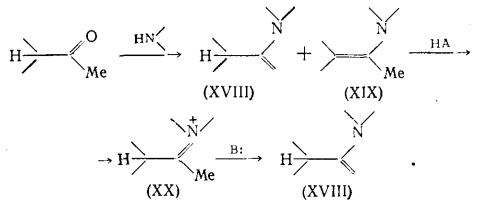
The mechanism of the hydrolysis of enaminoketones has been investigated at different pH of the solution[37] and the stages determining the rate of the overall process have been established. For the enamines RNHC(Me)=CHCOMe (R = alkyl) these stages involve the addition of water (at pH > 2) and the decomposition of the carbinolamine (at pH < 2). When R = aryl, hydration is the slow stage in all the media investigated. The kinetics of the hydrolysis of the enaminoketones (XI)–(XIV) have been investigated in a number of



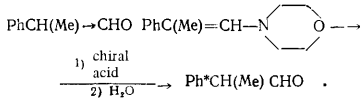
† Bailey et al.[33] state that this is the first instance of the *C*-protonation of enaminoketones. In fact this is not the case—the *C*-protonation of enaminoketones had been observed for the first time much earlier[34].

studies[38,39]. It has been shown that the rate of C-protonation limits the rate of hydrolysis at pH 3–6 and that the rate and direction of the process depend significantly on the ring size#.

The protonation of enamines with formation of immonium cations followed by their hydrolysis made it possible to develop a series of interesting synthetic methods. Thus enamines are intermediates in a new synthesis of homologous aldehydes from ketones[41]:

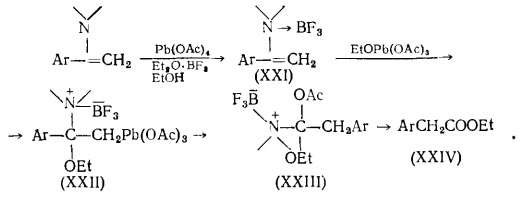


The formation of the *cis*-isomer (XVI) from the *trans*-compound (XV) was required[42]. The usual isomerisation procedures were unsuccessful but treatment of the intermediate enamine (XVII) with hydrochloric acid leads to a mixture of isomers containing 52–56% of the *cis*-compound (XVI):

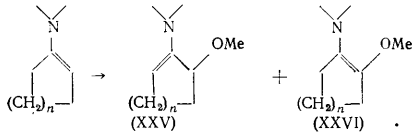


The required isomer (XVI) was isolated from this mixture by crystallisation[42].

The conversion of enamines into immonium salts has been used for the selective synthesis of enamines with a terminal double bond[43]. It has been shown[43] that, although treatment of ketones with amines gives rise to a mixture of the enamines (XVIII) and (XIX), the conversion of this mixture into the salt (XX) followed by treatment with t-butylamine or secondary amines leads to the selective formation of the enamine (XVIII):

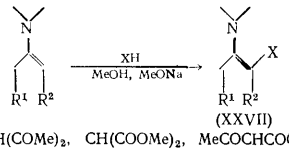


The intermediate synthesis of immonium salts also serves as a basis for the preparation of optically active carbonyl compounds[44–46]. For example, it has been established that, when enamines are protonated by chiral acids with subsequent hydrolysis, the initial carbonyl compounds undergo "deracemisation" and the degree of formation of optically active aldehyde and ketones depends on the configuration of the enamine and the structure of the optically active acid[45]:



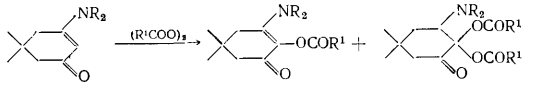
The dependence of various properties, including the protonation and hydrolysis, of enamines on ring size has been discussed in a review[40].

III. OXIDATION AND REDUCTION OF ENAMINES

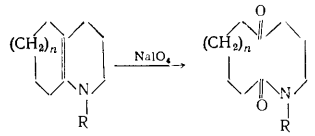


The number of studies devoted to the oxidation of enamines of different types is relatively small. It has been established that, when enamines are oxidised by lead tetra-acetate in the presence of boron trifluoride etherate[47], a rearrangement involving the formation of the adducts (XXI)–(XXIII) with BF_3 takes place and results in the formation of arylacetic acid esters (XXIV):

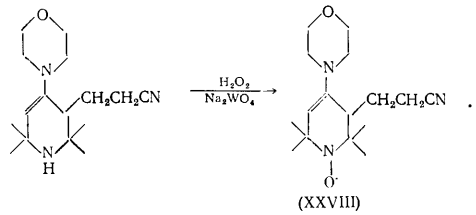
The anodic oxidation of enamines in methanol leads to the methoxyenamines (XXV) and (XXVI)[48]:



Substituted enamines of type (XXVII) have been obtained in the presence of organic anions[49]:

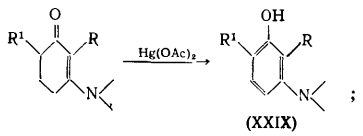


X =CH(COMe)$_2$, CH(COOMe)$_2$, MeCOCHCOOMe .

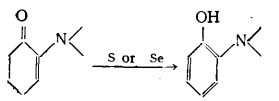


When alicyclic enaminoketones interact with diacyl peroxides, acyloxylation products are formed[50]:

The oxidation of bicyclic enamines is one of the ways of synthesising macrocyclic compounds[51]:

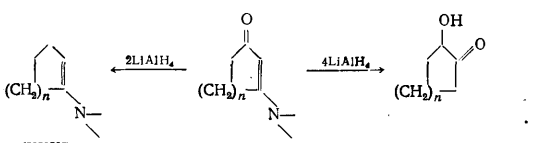


The nitroxy-radicals (XXVIII) have been obtained by the oxidation of certain heterocyclic enamines[52]:

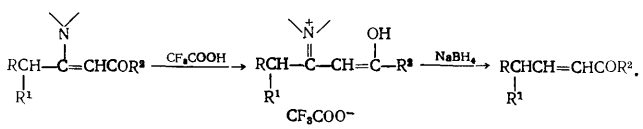


Enaminoketones can serve as the starting compounds in the synthesis of derivatives of *m*-aminophenol (XXIX) or *o*-aminophenol (XXX)—either the oxidation of enaminoketones[53] or

their dehydrogenation with sulphur or selenium[54] are used for such purposes:

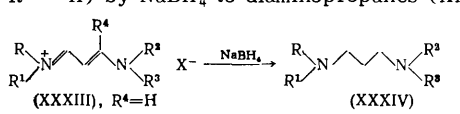


(XXIX)



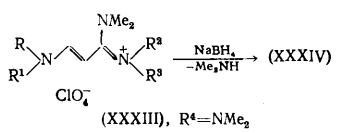
(XXX)

The reduction of enaminoketones with lithium tetrahydroaluminate was investigated in the same study[54] and it was established that, depending on the excess of the reductant, enamines or acyloins, (XXXI) and (XXXII) respectively, are formed:

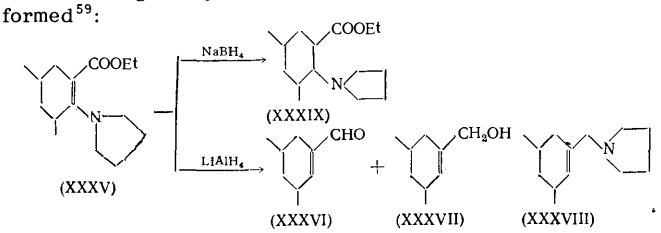


(XXXI) (XXXII)

A successful method of the reduction of enaminoketones to the corresponding unsaturated ketones was used by Nilsson[55]:



The reduction of enaminoketones by diborane to alkyl vinyl ketone derivatives[56] and the polarographic reduction of enaminoketones to the corresponding aminoalcohols[57] have also been described. Like enaminoketones, enaminoimines can be reduced in the form of the enaminoimmonium salts (XXXIII, $R^4 = H$) by $NaBH_4$ to diaminopropanes (XXXIV)[58]:



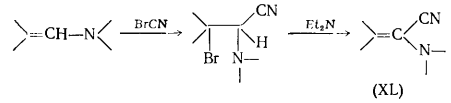
(XXXIII), R^4=H (XXXIV)

It is of interest that in the case of the salts of the enaminoamidines (XXXIII, $R^4 = NMe_2$) the reaction is accompanied by the elimination of dimethylamine[58]:

(XXXIII), R^4=NMe_2

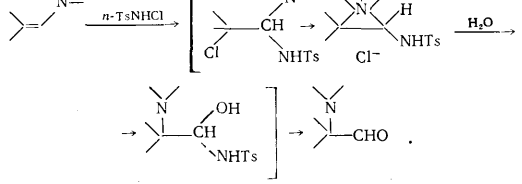
In the reduction of the enaminoesters (XXXV) with lithium tetrahydroaluminate, a mixture of derivatives of unsaturated aldehydes (XXXVI), hydroxymethylalkenes (XXXVII), and aminomethylalkanes (XXXVIII) is formed[59]. The reaction of compound (XXXV) with sodium tetrahydroborate proceeds more unambiguously and the aminoesters (XXXIX) are formed[59]:

(XXXV) (XXXIX) (XXXVI) (XXXVII) (XXXVIII)



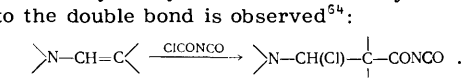
Orthophosphorous acid is an effective reagent for the reduction of enamines; saturated amines are formed in this case in high yields[60]. Finally, we may note a study[61] in which the asymmetric synthesis of β-aminoacids was achieved by the reduction of chiral enamines either catalytically over palladium or with $NaBH_3CN$:

In the former case (catalytic reduction) the process proceeds with retention of the configuration, while in the latter case the configuration is inverted[61].

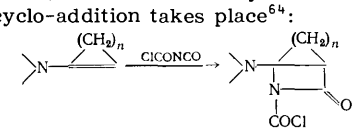


IV. ADDITION TO THE ENAMINE DOUBLE BOND, CYCLOADDITION, AND REARRANGEMENTS

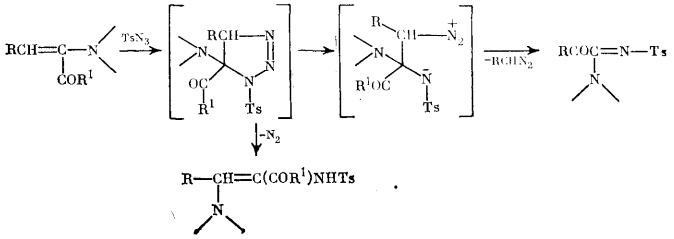
The addition of bromocyanogen to the double bond of enamines with subsequent elimination of hydrogen bromide has been a convenient method of synthesis of α-cyanoenamines (XL)[62]:



(XL)

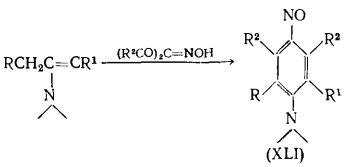


The reaction of enamines with chloramine-T is also accompanied by the initial addition of the latter to the C–C bond and ultimately leads to α-aminoaldehydes[63]:

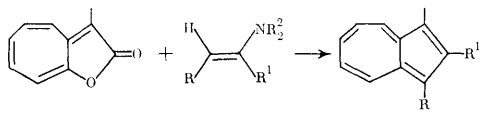


When chloroformyl isocyanate reacts with acyclic enamines, addition to the double bond is observed[54]:

On the other hand, on treatment of cyclic enamines with this reagent, 1,2-cyclo-addition takes place[64]:

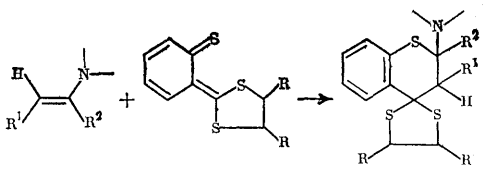


Cycloaddition reactions occur also in the interaction of enamines with aryl azides and arenesulphonyl azides[65–67]. For example, enamines having an α-keto-group react with sulphonyl azides in two ways[67]:



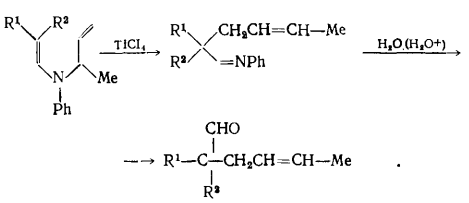
The interaction of enamines with diazoacetic ester, which also proceeds via a type of cycloaddition mechanism, leads to pyrazolines[68]. The reactions with enamines of α,α′-dibromoketones (with formation of cyclopentenones)[69], of unsaturated ketones (with formation of pyran derivatives)[70],

and of acetylenedicarboxylate ester (with formation of condensed cyclobutenes)[71] proceed via this same mechanism.
A new method of synthesis of nitrosoanilines (XLI) by the reaction of enamines with isonitroso-β-dicarbonyl compounds has been published recently[72]:

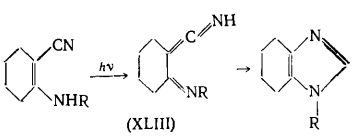


(XLI)

A number of studies have been devoted to the synthesis of azulenes (XLII) from bicyclic lactones (XLIII) and enamines[73–75]:

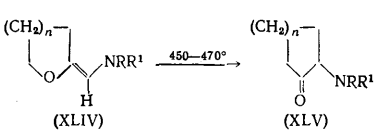


(XLIII) (XLII)



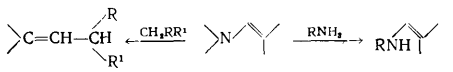
The reaction of enamines with *o*-thioquinone methide[76] results in the formation of [1:1]-adducts:

The reactions of enamines with thioacylketen thioacetals were described in the same communication[76]. In many instances the reactions of enamines are accompanied by rearrangements. It was mentioned above that, when enamines are oxidised in the presence of boron trifluoride etherate, a transformation of the type of the Favorskii rearrangement is observed[47]. In the presence of titanium tetrachloride enamines having substituents at the nitrogen atom with a terminal carbon–carbon double bond undergo the aza-Claisen arrangement[77]:



The photochemical rearrangement of enaminonitriles results in the formation of imidazole derivatives[78] with the aminoketimine (XLIII) as an intermediate[79]:

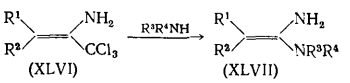
(XLIII)



It has been established recently that enamines of type (XLIV) are converted at high temperature into the aminoketones (XLV) in high yields[80]:

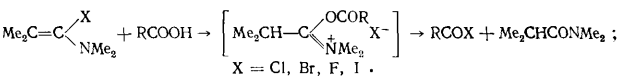
(XLIV) (XLV)

V. THE REACTIONS OF ENAMINES WITH NUCLEOPHILES AND ELECTROPHILES



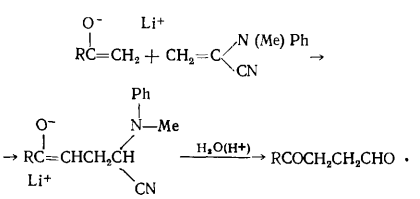
The reactions of enamines with nucleophiles which are most frequently used are those with various amines (transamination)[81–87] and with compounds having an active methylene unit[88]:

The kinetics of the transamination reactions of various enamines have been investigated[82,87]. In the study of the interaction of the enaminoketones MeCOCH=C(Me)NHR with phenylhydrazine, it was established[82] that the rate of the process depends on the character of the substituent (electron-donating groups accelerate the reaction) and the configuration of the initial enaminoketone (the *E* derivatives react more slowly than the *Z* derivatives). The rate-limiting stage of the reaction is *C*-protonation[82].

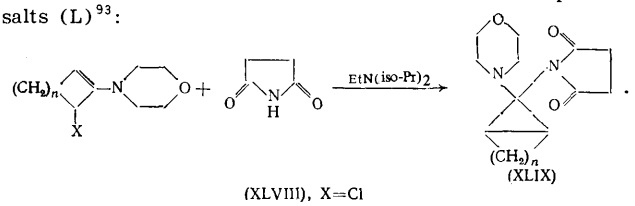


It has been shown[87] that the rate of transamination depends on the degree of delocalisation of the negative charge of the enamines by β-substituents and the possibility of the stabilisation of the transition state as a result of the formation of an intramolecular hydrogen bond. It was established that the rate of the process depends on the solvent—the rate of transamination in ethylene glycol is 40 times higher than in dimethylformamide.

In those cases where a readily removed group (for example a halogen) is attached to the β-carbon atom of the enamine, the reactions with nucleophiles are accompanied by the substitution of this group[89–91]. It is of interest that α-trichloromethyleneamines (XLVI) react with amines to form enediamines (XLVII), i.e. a reaction of the type of haloform cleavage takes place[90]:

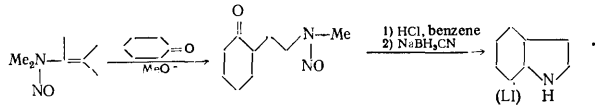


(XLVI) (XLVII)

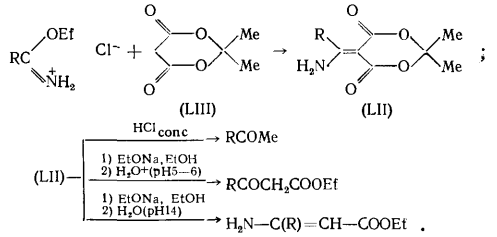


The reaction of α-halogenoamines with carboxylic acids constitutes a convenient method of synthesis of acid halides[91]:

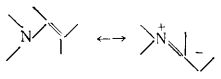
The interaction of enamines with enolate anions is the basis of a new synthesis of 1,4-dicarbonyl compounds[92]:



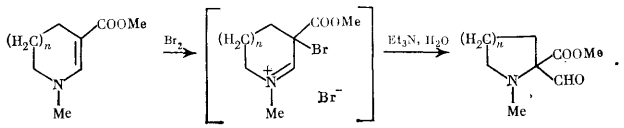
The succinimide anion reacts with chloroenamines (XLVIII) to form the bicyclic compounds (XLIX) having the *trans*-configuration. The corresponding *cis*-bicyclic compounds are formed when succinimide reacts with enaminosulphonium salts (L)[93]:



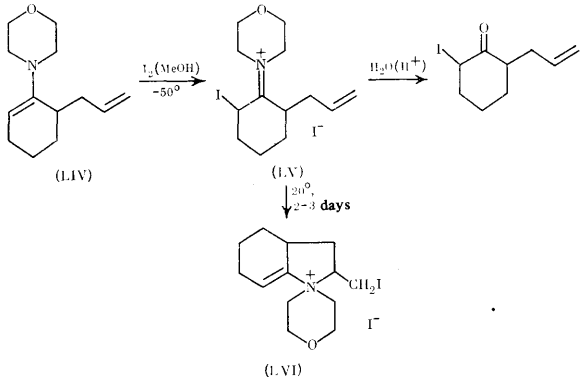
(XLVIII), X=Cl
(L), X=$Me_2\overset{+}{S}$ (anion—FSO_3^-)
(XLIX)



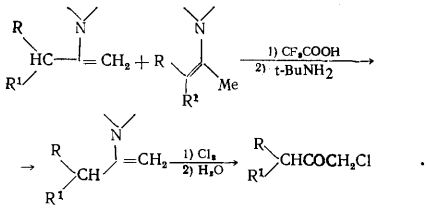
N-Nitrosoenamines are also capable of reacting with nucleophiles[94]. For example, perhydroindoles (LI) can be obtained as a result of such reactions:



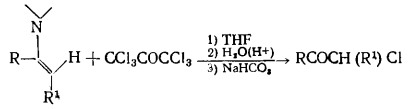
The enamines (LII), synthesised by the reaction of iminoesters or lactim-esters with Meldrum's acids (LIII), proved to be convenient intermediates for the preparation of β-monosubstituted enamines, β-dicarbonyl compounds, and substituted ketones[95–97]:



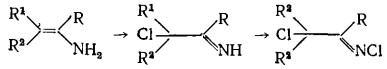
The interaction of enamines with electrophiles can proceed via two centres (in enaminoketones there is yet another centre—the oxygen atom): the nitrogen atom and the β-carbon atom:



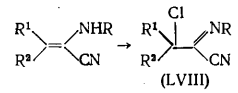
The halogenation of enamines has been studied in extremely great detail and usually proceeds via the β-carbon atom. Thus β-bromination is an intermediate stage in the synthesis of azacyclic aldehydes[98]:



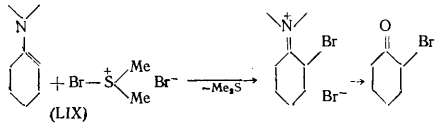
When the enamine (LIV) is iodinated at a low temperature, it is possible to isolate the intermediate immonium salt (LV), which is converted into the corresponding iodoketone on treatment with water and, on being kept at 20 °C, cyclises to an indolinium derivative (LVI)[99]:



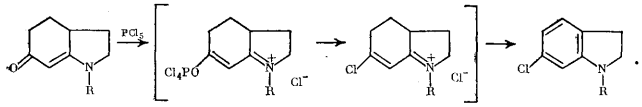
A new simple synthesis of halogenomethyl ketones[100] is based on the phenomenon already discussed (see above), according to which the treatment of immonium salts with bases leads to the selective formation of enamines with a terminal double bond:



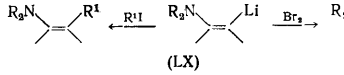
It has been established recently[101] that hexachloroacetone can be used as a chlorinating agent in the reaction with enamines at −78–0 °C in tetrahydrofuran (THF):



When β,β-disubstituted primary enamines are chlorinated, the reaction involves initially the β-carbon atom and then the nitrogen atom with formation of *N*,β-dichloro-derivatives (LVII)[102]:

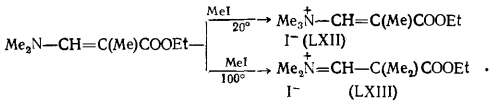


The C-chlorination of cyanoenamines by *N*-chlorosuccinimide[103] leads to α-halogenoimidoyl cyanides (LVIII):

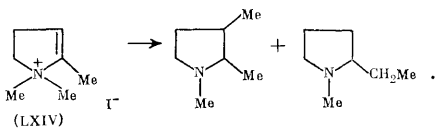


α-Bromoketones have been synthesised recently by the reaction of bromodimethylsulphonium bromide (LIX) with enamines and subsequent hydrolysis of the intermediate immonium bromides[104]:

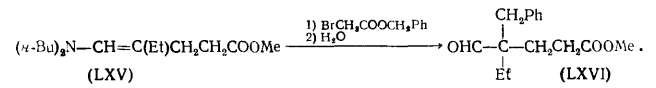
The reactions of enaminoketones with reagents such as phosphoryl chloride or phosphorus pentachloride[105] proceed in accordance with the same principle as the reactions of amides with these compounds—there is initial electrophilic attack on the oxygen atom. In many instances the process is accompanied by aromatisation:



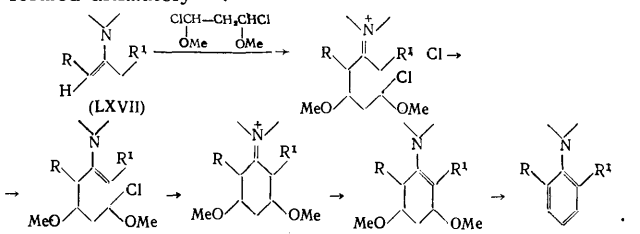
Finally, the introduction of the halogen atom into the "enamine" β-position can be achieved also via the lithioenamines (LX). In the study by Duhamel and Poirier[106] and others by the same workers[13,107,108], lithioenamines were introduced into reactions not only with the halogens but also with other electrophiles such as alkyl halides and aldehydes:



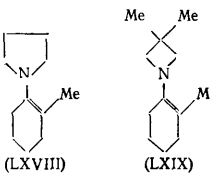
Studies of the alkylation reactions of enamines occupy a very notable place in their chemistry[107–124], much attention being devoted to factors which determine the site of attack by the



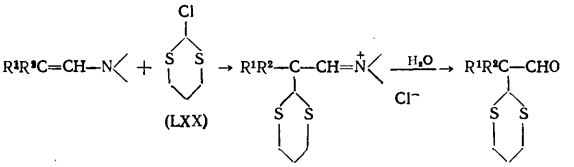
alkylating agent (*N*- or *C*-alkylation). The study of the alkylation of α-methyl-β-(*N*,*N*-dimethylamino)acrylic acid ester (LXI) by methyl iodide established[109] that the pathway followed in the process depends on the temperature—the enammonium salt (LXII) is formed at a low temperature, while the product at a high temperature is the immonium salt (LXIII):



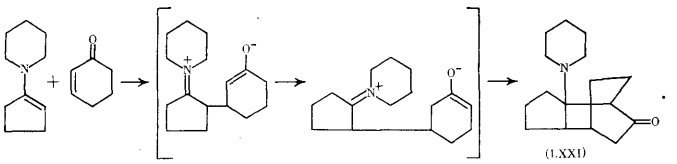
The question whether the β-*C*-alkylation of enamines is an independent process or whether the *N*-alkyl derivatives formed initially rearrange to the *C*-alkyl derivatives has been considered[112]. The enammonium salt (LXIV) was heated to 240 °C and the mixture reduced with formic acid was analysed by gas–liquid chromatography. It was established that, on heating, the *N*-methyl group migrates to the enamine carbon atoms:



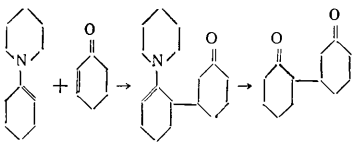
The authors[112] also showed that, when a mixture of enammonium salts is heated, the migrating *N*-alkyl substituents are distributed in both enamines formed, which indicates the intermolecular character of the N→C transfer of the alkyl substituent. An unusual β-*C*-alkylation has been described[113]. It was established that the interaction of the enamine (LXV) with benzyl α-bromoacetate leads to the β-benzylaldehyde (LXVI) (after hydrolysis) and not to the expected alkoxycarbonylmethyl derivative:



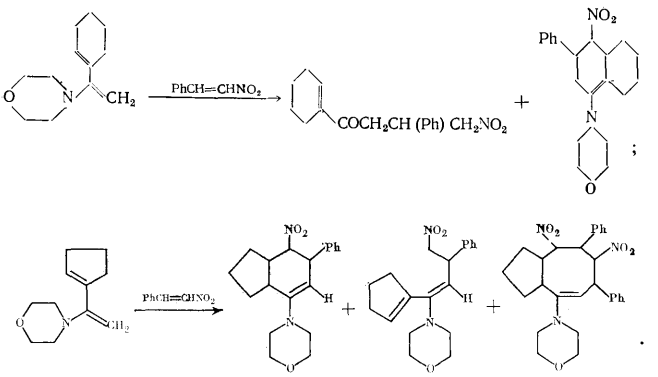
Regardless of the nature of the alkylating agent, the alkylation of *N*-monosubstituted-cyanoenamines proceeds at the N atom and the best results are obtained when triethyloxonium fluoroborate is used[114]. The same reagent has been employed successfully for the *O*-alkylation of enaminoamides[86] The reaction of the enamines (LXVII) with 1,3-dichloro-1,3-dimethoxypropane proceeds in an interesting manner—in this case double *C*-alkylation takes place and aniline derivatives are formed ultimately[115]:



Comparison of pyrrolidine and azetidine enamines (LXVIII) and (LXIX) in reactions involving alkylation by methyl iodide[116] showed that the iodide is involved in *N*-alkylation to a greater extent:

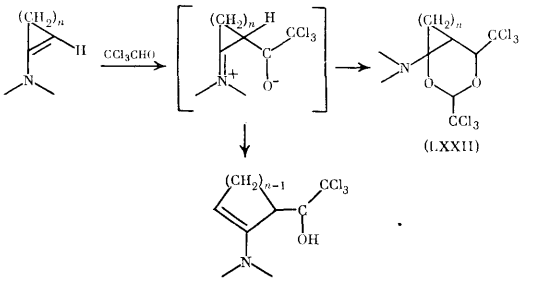


The alkylation of enamines by 2-chloro-1,3-dithian (LXX) has served as the basis of a new method of synthesis of malonodialdehyde with one protected aldehyde group[117]:

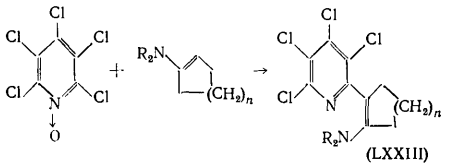


Compounds with an active double bond also readily alkylate enamines[118–122]. Thus the reaction of an enamine derived from cyclopentanone with cyclohexen-2-one results in the formation of compound (LXXI)[120]:

It is of interest that the reaction of the enamine derived from cyclohexanone proceeds differently[120]:

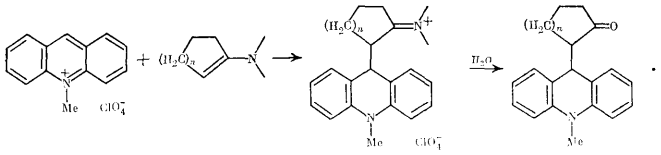


The influence of ring size on the alkylation reaction also follows from an examination of the reactions of β-nitrostyrene with cyclohexynylenamines[121] and cyclopentynylenamines[122]:

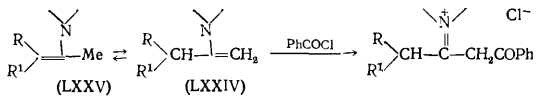


It is noteworthy that such differences are observed also in acylation reactions—in the interaction with methanesulphonyl chloride[121,122].

It has been shown recently that cyclic enamines readily enter into the Mannich reaction in the β-position[123]. The reaction of enamines with chloral also proceeds extremely smoothly[124] and, when the interaction involves two molecules of chloral, bicyclic compounds of type (LXXII) are formed:

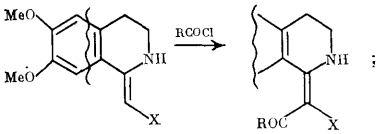


In the presence of a sufficiently mobile halogen atom, aromatic halogeno-compounds can react with enamines. Thus polyhalogenopyridines or their *N*-oxides react with enamines[125] to form β-pyridyl derivatives (LXXIII):

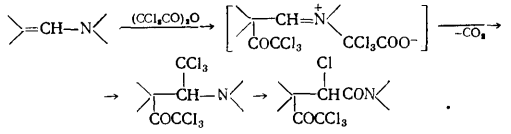


(LXXIII)

Another pathway leading to the β-arylation of enamines has been demonstrated by Chupakhin and co-workers[126,127]— heteroaromatic systems with a marked π-electron deficit were introduced into the reaction. For example:

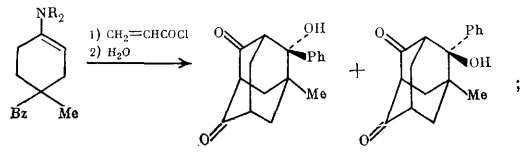


Like alkylation, the enamine acylation reaction can proceed via the nitrogen and/or β-carbon atoms. It has been established[128,129] that, when an isomeric mixture of the tertiary enamines (LXXIV) and (LXXV) is acylated, only the less substituted isomer (LXXIV) reacts:



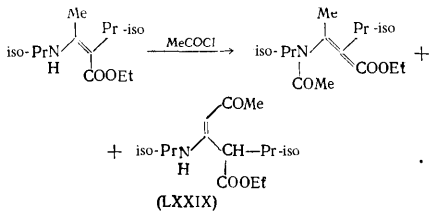
(LXXV) (LXXIV)

Secondary enamines of the isoquinoline series (LXXVI) are *C*-acylated on interaction with acid chlorides[130]:

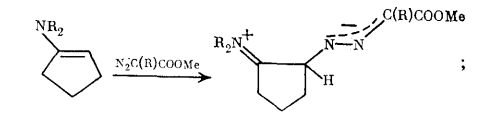


(LXXVI), X = CN, $CONH_2$.

The β-*C*-acylation of enamines by trichloroacetic anhydride is a convenient method of synthesis of amines with α-trichloromethyl and β-trichloroacetyl groups[131]. The subsequent hydrolysis of the compounds obtained is also unusual and leads to α-chloroamides[131]:

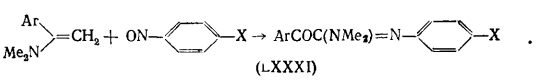


A new interesting method of synthesis of the adamantanediones (LXXVII) and (LXXVIII) is based on the acylation of enamines by unsaturated acid chlorides[132]:



Bz = COPh . (LXXVII) (LXXVIII)

When β-aminocrotonic ester is acylated by acid halides, two (*Z* and *E*) *N*-acylated and *C*-acylated isomers are formed in each case[133]. The reaction of aminocrotonic ester with trifluoroacetic anhydride leads analogously to a mixture of *N*- and *C*-acylenamines[134]. However, if α-alkyl-β-aminocrotonic ester is introduced into the reaction with $(CF_3CO)_2O$, the acylation process proceeds selectively via the amino-group[134]. Similarly, the *N*-alkyl-β-aminocrotonic ester is acylated by acetyl chloride only at the carbon atom and its α-alkyl derivative only at the nitrogen atom[135]. However, in one instance it has been possible to isolate also the *C*-acylation product (LXXIX)[136]:

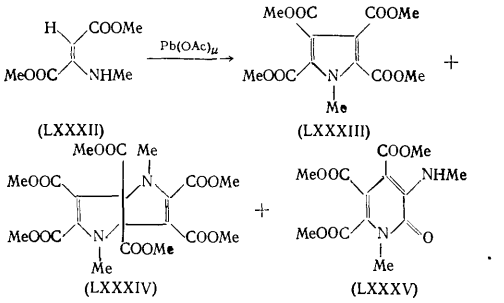


(LXXIX)

It is also noteworthy that β-amino-β-methylvinyl methyl ketone and its *N*-aryl derivative are acylated exclusively at the nitrogen atom[137,138]. In conclusion of this section, we shall mention the reaction of enamines via the β-carbon atom with arenesulphonyl isocyanates (the corresponding *N*-arenesulphonylcarbamido-derivative is formed)[139], the interaction of certain enamines with diazoacetic ester[140] which resulted in the isolation of zwitter-ion of type (LXXX), and the unusual reaction of α-arylenamines with *p*-substituted nitrobenzenes[141], which proceeds with formation of amidines (LXXXI):

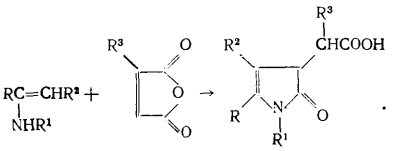
(LXXX)

(LXXXI)



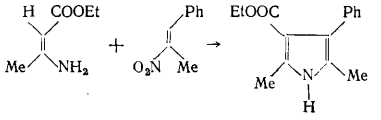
VI. ENAMINES IN THE SYNTHESIS OF HETEROCYCLIC COMPOUNDS

The most promising aspect of the development of the chemistry of enamines at the present time is their employment for the synthesis of various heterocycles. The greatest number of publications concerning the properties and reactions of enamines have been devoted to the problem of such synthesis and this field of study of the class of compounds under consideration is developing most vigorously. As a consequence of this, the syntheses of heterocyclic compounds on the basis of enamines can be usefully surveyed in a single Section of the review, although many of the reactions examined below could naturally be classified also as reactions with nucleophiles or electrophiles, oxidation reactions, reduction reactions, etc. As already mentioned above, many of the heterocyclisation reactions of enamines, which have already been described in recently published reviews[2,5,6], will not be considered in this Section.

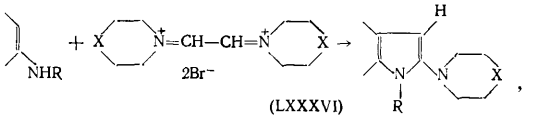


1. Synthesis of Five-Membered Heterocycles

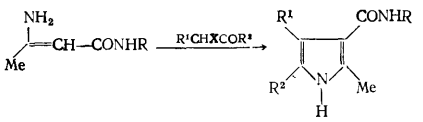
Perhaps the greatest number of publications concerning the synthesis of five-membered heterocycles have been devoted to the preparation of various derivatives of pyrrole.



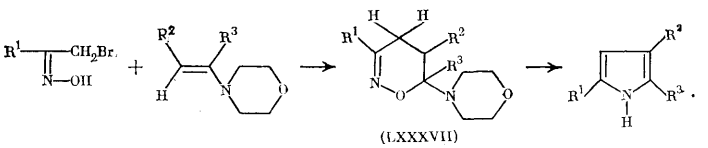
When β-methoxycarbonyl-β-methylaminoacrylic ester (LXXXII) is oxidised with lead tetra-acetate[142], a mixture of 2,3,4,5-tetramethoxycarbonyl-1-methylpyrrole (LXXXIII), pyrrolopyrrole derivatives (LXXXIV), and 2-pyridone (LXXXV) is formed:



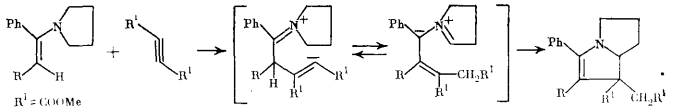
The condensation of secondary enamines with maleic anhydride derivatives leads to 2-pyrrolinone derivatives[143,144]:



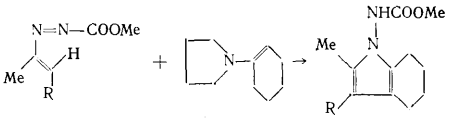
An interesting reaction of primary and secondary enamines with nitroalkenes, which results in the formation of substituted pyrroles, has been described recently[145]:



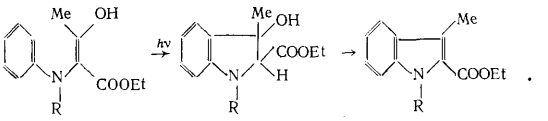
If cyclic enamines or enaminoketones are introduced into this reaction, the products are indole derivatives[145]. Substituted pyrroles have also been obtained by the reaction of enamines with di-immonium dibromide (LXXXVI)[146], i.e.



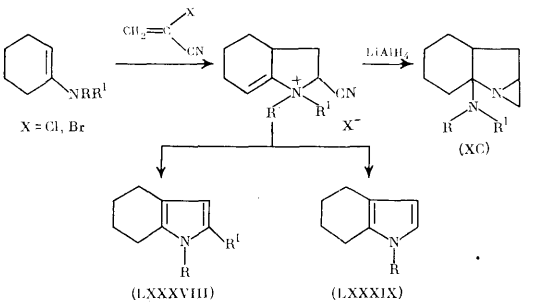
and of enaminoamides with carbonyl compounds[147]:



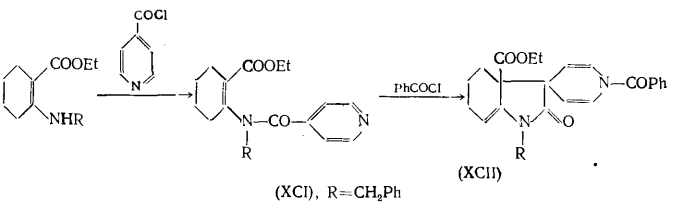
The reaction of enamines with α-bromoximes followed by the decomposition of the intermediate oxazine derivative (LXXXVII) by iron carbonyls also leads to pyrroles[148]:



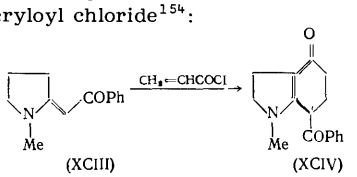
The acetylenedicarboxylic ester attacks β-monosubstituted enamines at the β-carbon atom with subsequent cyclisation to pyrrolizidine derivatives[149]:



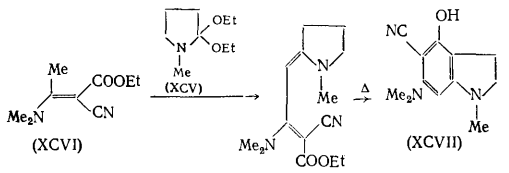
In many instances the employment of enamines ensures a simple and convenient approach to indole derivatives. Thus the condensation of enamines with aza-alkenes leads to hydrogenated indoles[150]:



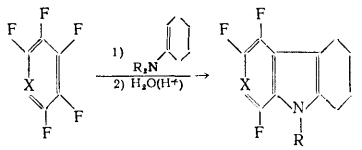
Indoles have also been obtained by the photochemical cyclisation of *N*-arylenamines[151]:



The interaction of enamines with α-halogenoacrylonitriles leads to hydrogenated 2-cyanoindolinium derivatives, which, on treatment with potassium t-butoxide, undergo the Stevens rearrangement and Hofmann elimination with formation of 4,5,6,7-tetrahydroindoles (LXXXVIII) and (LXXXIX), while on reduction with lithium tetrahydroaluminate they are converted into tricyclic hydrogenated indoles of type (XC)[152]:



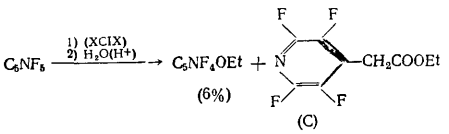
The reaction of the cyclic enamine (XCI) with isonicotinoyl chloride leads to the formation of an *N*-acyl derivative, which cyclises to the spiro-compounds (XCII) on treatment with benzoyl chloride[153]:



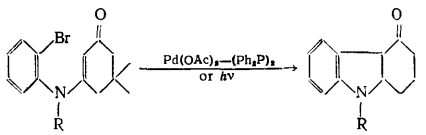
Another method of synthesis of indole derivatives is based on the use of cyclic enamines incorporating in their structure the pyrrolidin-2-ylidene ring[154,155], the functional groups of the side chain of which make possible the growth of an additional benzene ring. Thus hexahydro-4-indolone (XCIV) has been synthesised by the reaction of the enaminoketone (XCIII) with acryloyl chloride[154]:

The reaction of *N*-methylpyrrolidinone acetal (XCV) with the enaminoester (XCVI) followed by thermal cyclisation led to the synthesis of the indoline (XCVII)[155]:

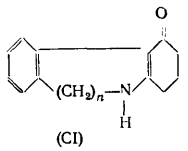
The corresponding benzene, quinoline, and benzazepine derivatives were synthesised in the same investigations[154,155] in accordance with analogous schemes. A number of carbazole derivatives have been obtained by the reaction of hexafluorobenzene with enamines derived from cyclohexanone[156,157]. Pentafluoropyridine reacts analogously[157]:



(XCVIII), X=C—F or N

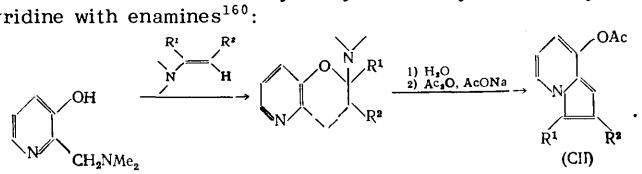


It is of interest that the reaction of compound (XCVIII, X = C—F) with keten *O,N*-acetals (XCIX) leads only to *O*- and *N*-arylation products[157]:

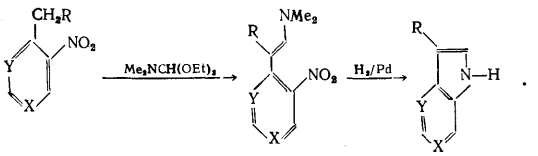


On the other hand, compound (XCVIII, X = N) is capable of β-*C*-arylation of compound (XCIX) with formation of the pyridylacetic ester (C)[157]:

N-Arylenaminoketones having a bromine atom in the *o*-position in the benzene ring cyclise to carbazoles in the presence of a palladium catalyst[158] or on ultraviolet irradiation[159]:

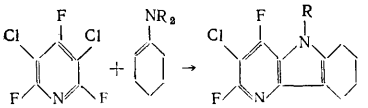


Derivatives of phenanthridine, benzazepine, and benzazocine (CI) have been obtained analogously on irradiation of the corresponding enaminoketones[159]:



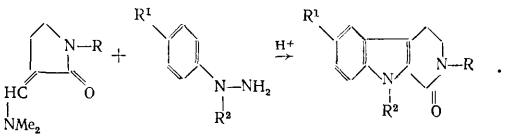
(CI)

An interesting synthesis of pyrrolo[1,2-*a*]pyridine (CII) is based on the reaction of 3-hydroxy-2-dimethylaminomethylpyridine with enamines[160]:

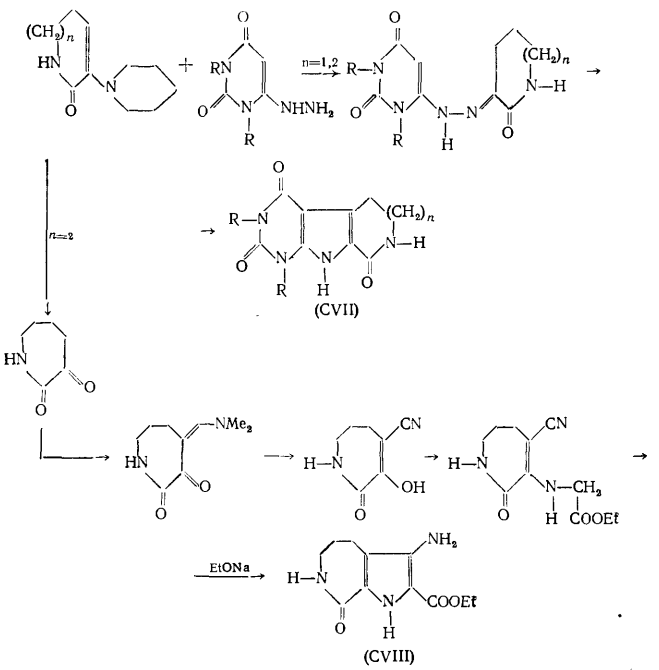


(CII)

Pyrrolo[1,2-*c*]- and pyrrolo[2,1-*b*]-pyridines (CIII) and (CIV) have been synthesised by the reduction of the corresponding nitroenamines (CV) and (CVI)[161–163]:



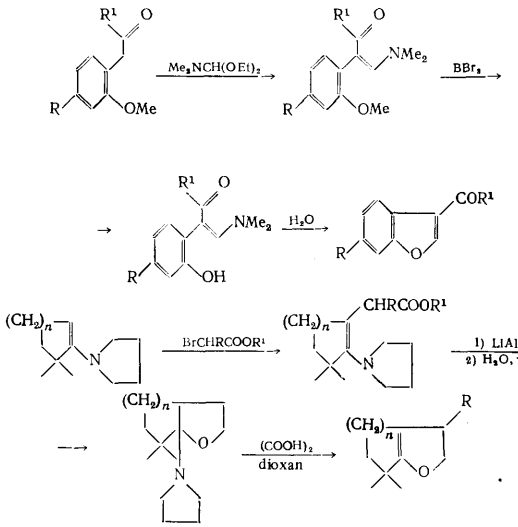
(CV), X = N, Y = CH
(CVI), X = CH, Y = N



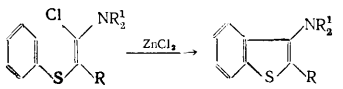
The arylation of enamines by polyhalogenopyridines[125] leads to carbolines:

Another pathway leading to carbolines has been found recently[164] in the study of the reaction of enamines derived from 3-formylpyrrolidinones with arylhydrazines:

Finally we may mention the syntheses of diazacarbolines (CVII)[165] and pyrrolo[2,3-*c*]azepines (CVIII)[166], based on the use of enamines derived from α-oxolactams:

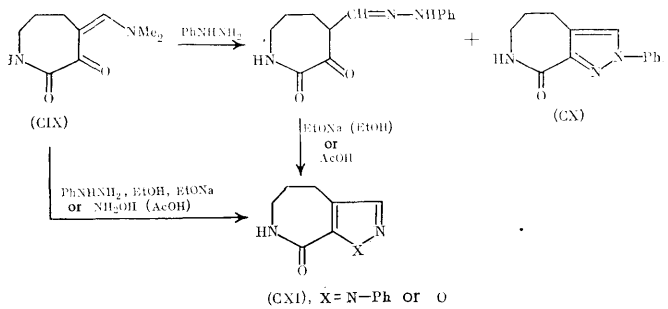


(CVII)

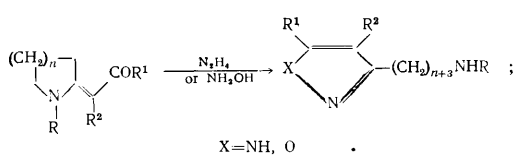


(CVIII)

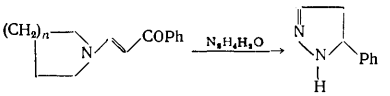
Comparatively few studies devoted to the synthesis of furan and thiophen derivatives from enamines have been published recently. Furans have been obtained by the cyclisation of the enamine and phenolic groups in the *ortho*-positions relative to one another[167] and by the reaction of cyclic enamines with bromoacetic ester followed by the reduction of the



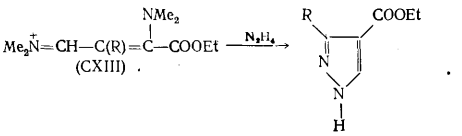
resulting β-*C*-substitution product with lithium tetrahydroaluminate[168]:



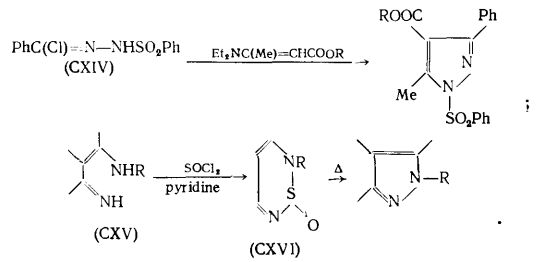
The synthesis of benzothiophens is based on the Friedel–Crafts reaction[169]:



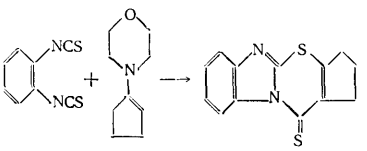
A number of studies have been devoted to the synthesis of azoles, in the first place pyrazoles. Pyrazoles are most often obtained by the reaction of enaminoketones with hydrazine derivatives[84,170-173]. The reaction of enaminoketolactam (CIX) with phenylhydrazine makes it possible to obtain the isomeric pyrazoles (CX) and (CXI) in which X = NPh[84]:



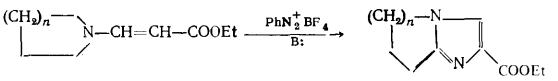
On treatment wth hydroxylamine, compound (CIX) is readily converted into a derivative of isoxazolo[5,4-*c*]azepine (CXI, X = 0).[84] The synthesis of pyrazole (and isoxazole) derivatives by the reaction of cyclic enaminoketones with hydrazine hydrate or hydroxylamine is of interest[173]:



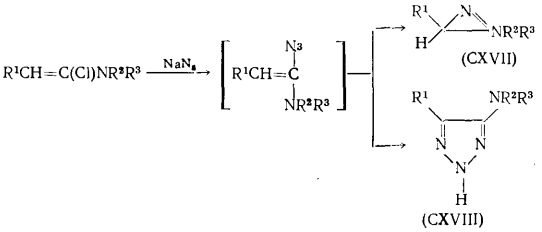
We may also point out that acid catalysis has proved extremely effective in the reactions enaminoketones (CXII) with hydrazine hydrate[171]:



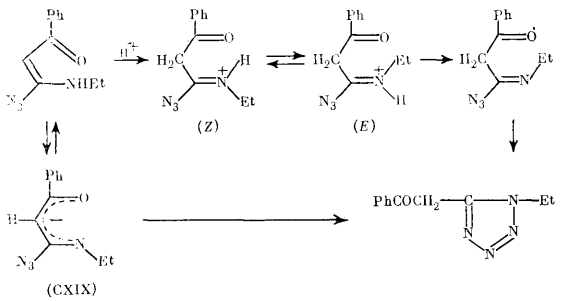
In addition it has been established that the rate of this reaction depends on the ring size and is a maximum for the six-membered cyclic enamine (CXII, $n = 2$) and a minimum for the seven-membered enamine (CXII, $n = 3$)[171]. The interaction of hydrazine with the enaminoimmonium salt (CXIII) is closely related to the above syntheses[174]:



Pyrazoles have also been obtained by the condensation of enamines with diazo-compounds[175] and *N*-(benzenesulphonyl)-benzohydrazonoyl chloride (CXIV)[176] and by the reaction of enaminoimines (CXV) with thionyl chloride and subsequent thermal decomposition of the intermediate 1,2,6-thiadiazine *S*-oxide (CXVI)[177]:

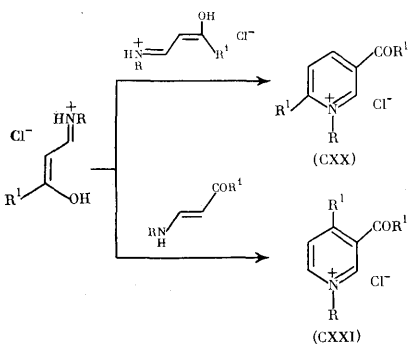


The reactions of cyclic enamines with *o*-phenylene di-isothiocyanate lead to the closure of the imidazole and thiazine rings[178]:



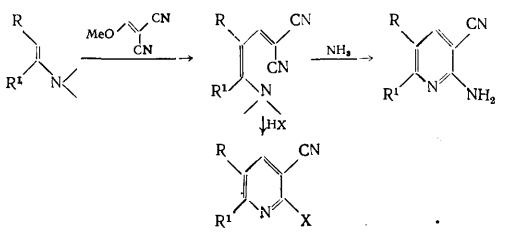
Imidazole derivatives can also be obtained from enaminoesters and arenediazonium salts in the presence of bases[179]:

The interaction of α-chloroenamines with sodium azide[180] leads to various products depending on the substituent at the enamine nitrogen: the azirines (CXVII) are formed from *N*-arylenamines, while the more basic *N*-alkylene-enamines give rise to the triazoles (CXVIII):



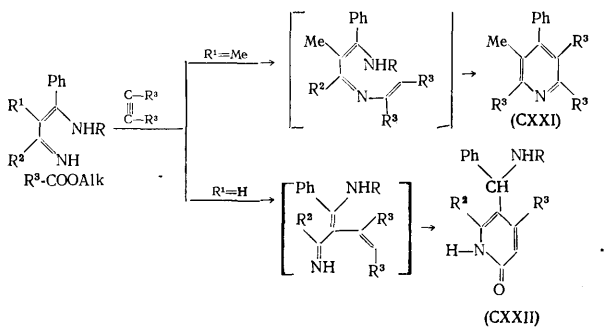
α-Azidoenamines containing the benzoyl group in the β-position (azidoenaminoketones) readily cyclise to tetrazoles[181] and in an alkaline medium the rate-limiting stage of the process is the formation of the anion (CXIX), while in an acid medium the rate-limiting stage is *Z*–*E* isomerisation:

(CXIX)



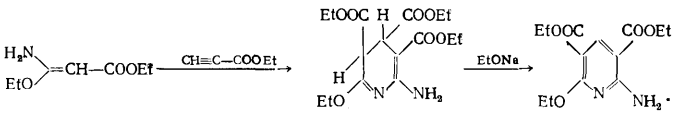
2. Synthesis of Six-Membered Heterocycles

Most of the studies concerning the synthesis of six-membered heterocycles from enamines have been devoted to the synthesis of various pyridine systems and it has been possible to synthesise both monocyclic pyridines and pyridines condensed with various carbocyclic and heterocyclic compounds. Substituted pyridinium salts are formed extremely readily when enaminoketones are treated with acids[182]. However, in this case there is a possibility of both the condensation of two molecules of the *O*-protonated forms and of the interaction of the *O*-protonated form with a neutral molecule. Accordingly, the isomeric pyridinium salts (CXX) and (CXXI) are produced:

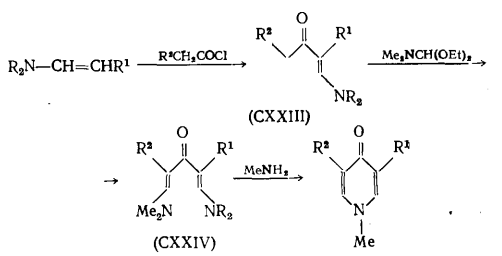


(CXXI)

The interaction of enamines with methoxymethylenemalononitrile followed by treatment with ammonia or acids leads to 3-cyanopyridines[183]:

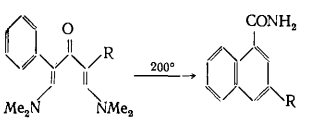


Acetylenedicarboxylic ester can react with enaminoimines[184] in two ways—alkylation of the enamine nitrogen atom results in the formation of derivatives of esters of nicotinic acids (CXXI), while alkylation at the β-carbon atom leads to derivatives of 2-pyridone (CXXII):

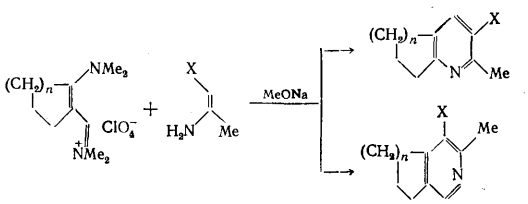


(CXXII)

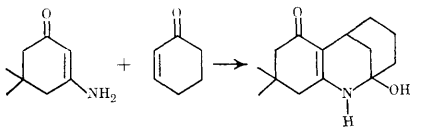
The interaction of propiolic ester with α-alkoxyenaminoesters leads to derivatives of 2-aminopyridine[185]:



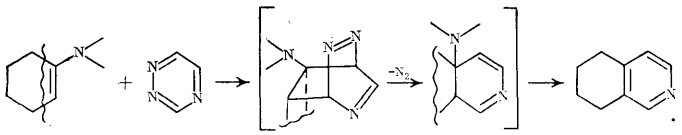
The reaction of two molecules of β-aminocrotonic ester with formaldehyde leads to the formation of 3,5-diethoxycarbonyl-2,6-dimethyl-1,4-dihydropyridine[186]. A convenient synthesis of 4-pyridone derivatives has been developed[187,188] on the basis of the ability of enamines to undergo β-acylation and transamination with primary amines:



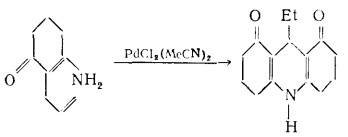
(CXXIV)



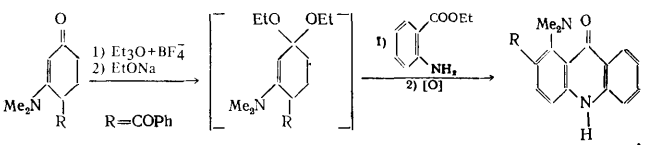
It is of interest that enamines of types (CXXIII) and (CXXIV) are capable of being converted into naphthalene, biphenyl, or diphenyl ether derivatives on heating[189], for example:



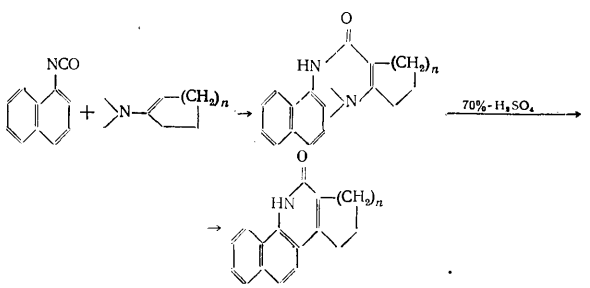
Hydrogenated quinoline derivatives have been synthesised in various ways—by the [4 × 2] cycloaddition of enamines to benzylideneanilines[190], by the reaction of enamines with acrylamide[191], and by the reaction of imines in the form of enamine tautomers with acrylic acid derivatives and propiolactone[192]. The reactions of enamines with enaminoammonium salts proceed via two pathways with formation of isomeric condensed pyridines[193]:



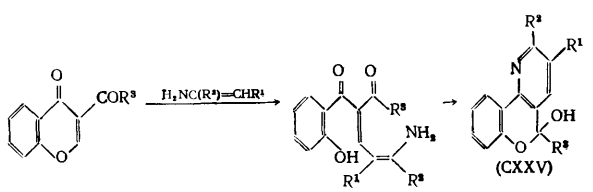
The first stage of the reaction of the enamine derived from dimedone with cyclohexene is *C*-alkylation of the enamine[194]:



The Diels–Alder reaction, in which enamines behave as dienophiles, is also extremely interesting[195]:

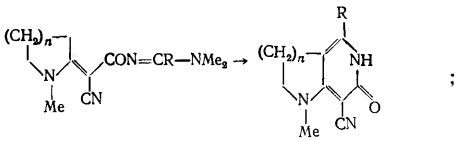


New syntheses of acridines have been developed as a result of the study of the reactions of primary enaminoketones having an unsaturated group in the β-position with the complex $PdCl_2(MeCN)_2$,[196] i.e.

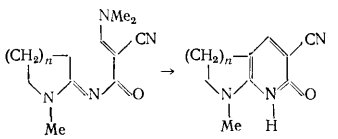


and of the reaction of tertiary enaminoketones with an alkylating agent and then anthranilic ester in accordance with the scheme[197]:

Complex tetracyclic systems containing the pyridone ring have been obtained in the reactions of cyclic enamines with α-naphthyl isocyanates[198,199]:

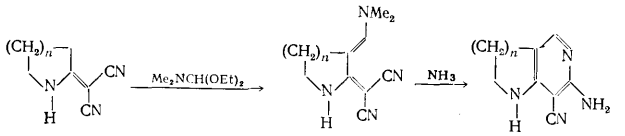


It has been possible to use enamines in a number of syntheses of pyridines condensed with oxygen-containing heterocycles–benzopyranopyridines (CXXV)[200], as well as derivatives of pyrano[4,3-c]pyridines[201], pyrano[2,3-*b*]pyridine[202], and pyrido[4,3-*b*]benzofuran[203]:

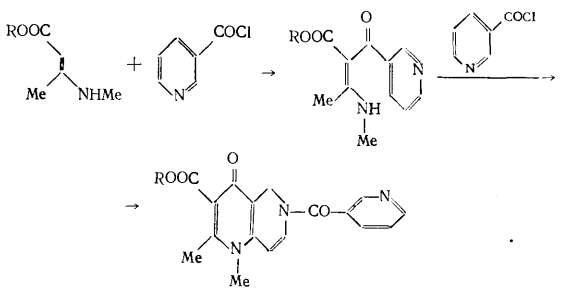


(CXXV)

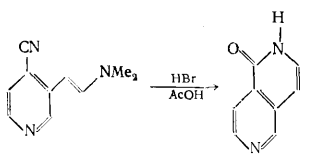
A number of studies have been devoted to the synthesis of condensed pyridines from enaminoamides[204–208]. The synthesis is based on the preparation and intramolecular cyclisation of enaminoacylamidines of the type (CXXVI, R = H) and (CXXVII)[204,207]. Condensed 2-pyridones can also be obtained from enaminoacylguanidines (CXXVI, R = Me_2N)[209]:



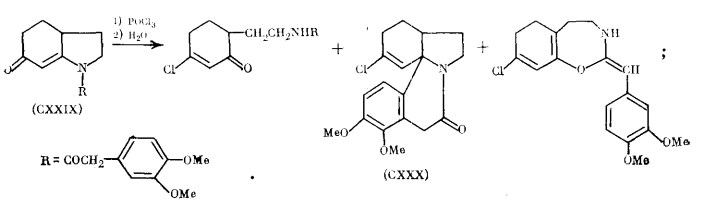
(CXXVI), n=1–3



(CXXVII), n = 1–3

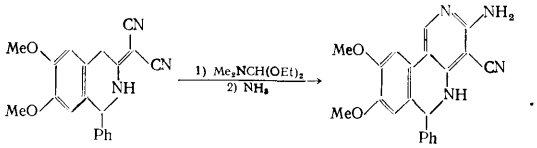


The study of the kinetics of these reactions showed that the cyclisation of compounds (CXXVI) is much faster than that of compounds (CXXVII)[205]. It has been established recently that enaminodinitriles are also convenient compounds for the synthesis of condensed pyridines[210]:

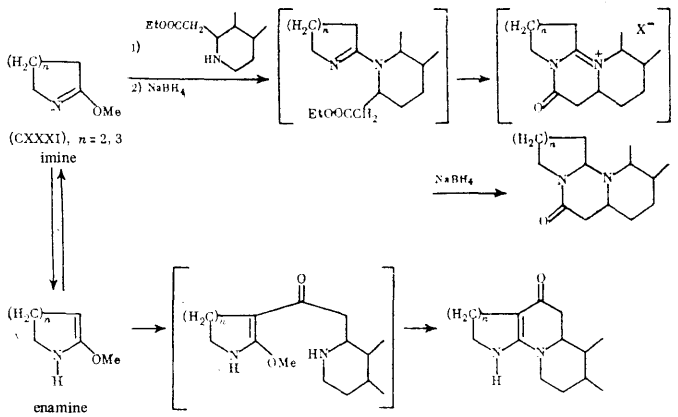


β-*C*-acylation of secondary amines by nicotinoyl chloride with subsequent cyclisation by means of the same reagent leads to 1,5-naphthyridines[153]:

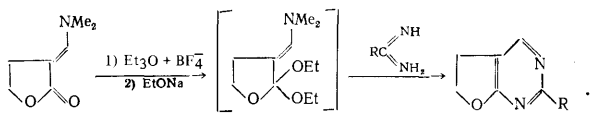
2,6-Naphthyridines have been obtained by the cyclisation of 4-cyano-3-(β-dimethylaminovinyl)pyridines[211]:



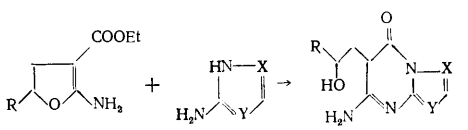
The reactions of certain enaminoketones with phosphoryl chloride and phosphorus pentachloride were discussed above[105]. When this reaction is carried out in acetonitrile, several compounds, including benzoxazepine and indoloquinolone (CXXX), are formed from the enaminoketone (CXXIX)[105]:



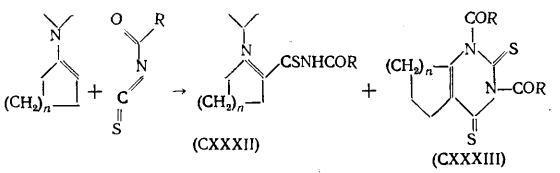
(CXXIX) (CXXX)



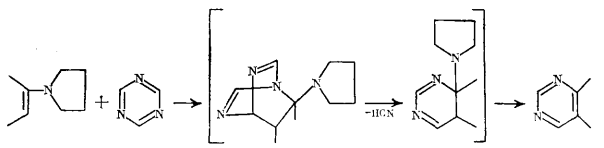
Pyrido[2,1-*a*]isoquinolines have been obtained by the reactions of enamines with 3,4-dihydroisoquinolines[212], while derivatives of the isomeric pyrido[4,3-*c*]isoquinoline system have been synthesised from enamines of the isoquinoline series[212] in accordance with a scheme analogous to that for the synthesis of condensed 2-aminopyridines:



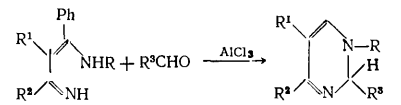
It is of extremely great interest to employ for synthetic purposes[26] the phenomenon of the imine–enamine tautomerism discovered previously[213] in the series of lactim esters. It has been shown[26] that *O*-methylvalerolactim and *O*-methylcaprolactim (CXXXI) react with derivatives of 2-ethoxycarbonylmethylpiperidine as both imines and enamines, giving rise to a mixture of condensed pyridines and pyrimidines:



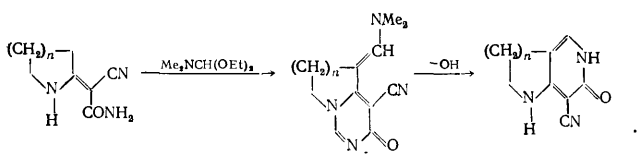
Enaminocarbonyl compounds react fairly readily with guanidine and amidines to form pyrimidine derivatives[197,214]. In a number of instances the carbonyl group must be activated, usually by alkylation[197,215], for example,



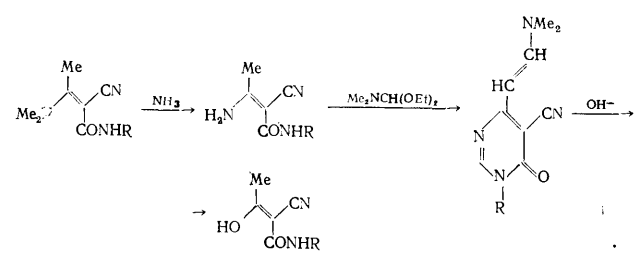
Heterocyclic enaminoesters react with aminoazoles to form azolopyrimidines[216,217]:



The reactions of enamines with carbonyl isothiocyanates[218] are accompanied by the formation of [1:1] adducts (CXXXII) and [1:2] adducts (CXXXIII):

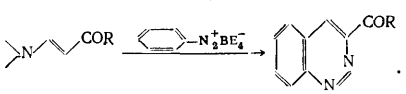


The cycloaddition of enamines to *sym*-triazine leads to pyrimidines[219]:

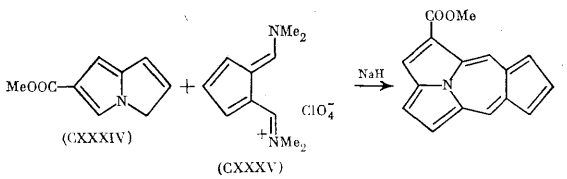


Pyrimidines are also formed when enaminoimines react with aldehydes under the conditions of the Friedel–Crafts reaction[220]:

The condensation of dimethylformamide and dimethylacetamide diethyl acetals with enaminoamides leads smoothly to derivatives of 5-cyanopyrimidine[130,206,210,221–224]. It is significant that the pyrimidines synthesised in this way are readily cleaved in an alkaline medium with subsequent recyclisation to pyridine derivatives. This method of synthesis of pyridine derivatives condensed with a saturated azaheterocycle is in fact preparatively most convenient:

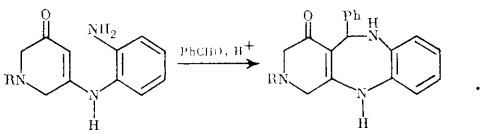


The kinetics of the cleavage of the pyrimidine ring have been investigated[210]. It is of interest that a change in the location of the substituent in the pyrimidine ring lowers the rate of its cleavage and recyclisation does not then occur[224]:



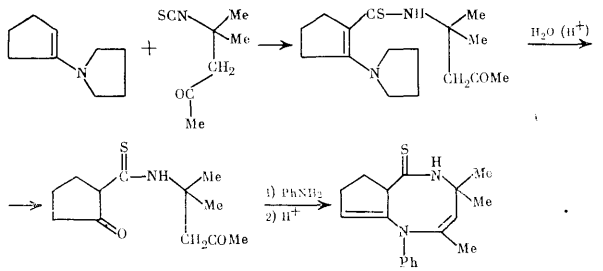
R=PhCH$_2$

A number of studies have been devoted to the closure of six-membered rings other than the pyridine and pyrimidine rings. Thus the interaction of enamines with 1-dialkylaminomethyl-2-hydroxynaphthalenes leads to condensed pyrans[225]. Condensed pyrans are also formed on reduction of 3-(β-ethoxycarbonyl)enamines by lithium tetrahydroaluminate[226]. The reactions of enaminoketones with ketones in the presence of lithiotetramethylpiperidine followed by cyclisation lead to 2,3-dihydro-4-pyrones[227]. Derivates of 2-pyrone have been obtained by the reaction of *N*-carbamidoenaminoketones with cyanoacetic ester and related compounds[228], while 2-morpholino-3-phenyl-3-isoflavene has been obtained by the reaction of 2-hydroxybenzaldehyde with morpholine enamine derived from phenylacetaldehyde[229]. The synthesis of pyridazines, based on the reaction of enaminocarbonyl compounds with diazonium salts[230], and the synthesis of condensed oxadiazines formed when enamines react with diacyldi-imides[231] or with arylacyldi-imides[232] have been described recently:



3. The Synthesis of Seven- and Eight-Membered Heterocycles

There have been relatively few studies of the synthesis of heterocycles containing more than six units from enamines. The interaction of *H*-pyrrolizinones (CXXXIV) with the enaminoimmonium salt (CXXXV) in the presence of sodium hydride has been described[233]:



(CXXXIV) (CXXXV)

Condensed diazepines have been synthesised by the reaction of 3-ethoxycarbonylcyclopentanone with 4-nitro-o-phenylenediamine[234] or by the interaction of *N*-arylenamine derived from piperidinedione (CXXXVI) with benzaldehyde[123]:

Finally we shall mention yet another study in which condensed diazocines have been obtained by the reaction of isothiocyanates with the cyclopentanone-based enamine[235] and subsequent treatment with aniline:

Thus the results, presented above, of studies of the properties and the possibility of the employment of enamines in organic synthesis indicate the desirability and likely usefulness of the development of the chemistry of compounds of this class. Further development of studies directed towards the synthesis of various classes of heteromonocyclic, heterobicyclic, and heterotricyclic systems on the basis of enamines is of special interest.

During the preparation of this article for the press, a review was published on the chemistry of enamines[236], which, in contrast to the present review, is concerned mainly with enamines without electron-donating or electron-accepting substituents in the β-position.

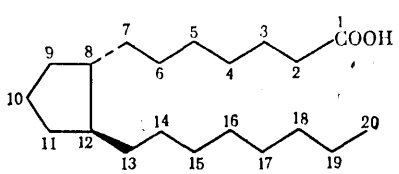
The Synthesis of Prostaglandins From Cyclopentane Derivatives

V.A.Dombrovskii, D.Yu.Fonskii, V.A.Mironov, and P.M.Kochergin

The advances in the synthesis of prostaglandin derivatives are examined.
The bibliography includes 129 references.

CONTENTS

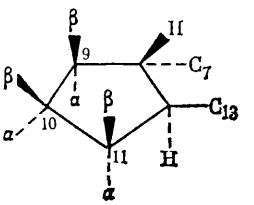
I. Introduction 401
II. The synthesis of prostaglandins 402



I. INTRODUCTION

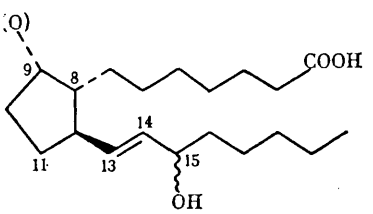
Prostaglandins (PG) are biologically active substances with an extremely broad spectrum of action. The influence of PG on the smooth musculature of various organs, their hormone-like and antihormonal activity[1,2], etc. are being investigated at the present time. The therapeutic effect of these compounds is achieved when they are administered in extremely low amounts, of the order of nanograms. This justifies the use of PG as promising medicinal preparations in medicine (cardiology, gastroenterology, midwifery, gynaecology, etc.) and animal husbandry (regulation of the reproductive function of animals). PG and their principal precursors—polyunsaturated aliphatic acids (eicosatetraenoic and eicosatrienoic acids)—are contained in all mammalian tissues but as a rule in extremely small amounts. The highest content of PG is present in the seminal fluids of mammals and man. Thus the overall content of PG in human seminal fluid is on average 213–240 μg ml^{-1} and varies with age and state of health. The seminal fluid of the ram contains approximately 50 μg ml^{-1} of PG. PG has been found also in prostate glands, ovaries, brain tissue, the mucous membranes of the stomach and the intestine, spleen, kidneys, liver, pancreas, and the iris of the eye[3] but at a concentration many times smaller than in the seminal fluid of the ram and man, so that such tissues cannot serve as sources of large amounts of pure PG preparations.

The main natural sources of PG are their close precursors present in the gorgonia *Plexaura homomalla* at an unusually high concentration—2.6 wt.% relative to the dry weight[4].



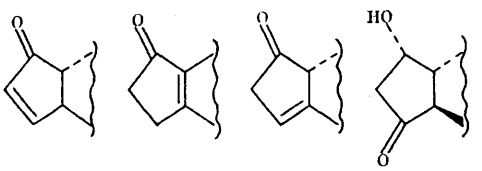
The need for large amounts of PG, which are essential for experimental and clinical studies, combined with the high cost of the preparations (up to 3000 dollars per gram) promoted a vigorous development of methods for the isolation and purification of PG and also stimulated the search for methods of synthesis of PG or their analogues.

PG are derivatives of the hypothetical prostanoic acid (I), the C(8)–C(12) atoms of which are incorporated in the cyclopentane ring (CPR):

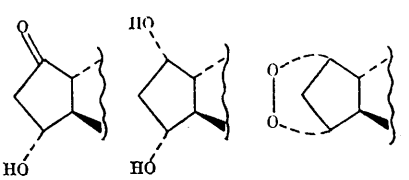


(I)

The CPR substituents are designated by the letter α when they are located on the same side of the plane of the ring as the carbon atom in the 7-position and by the letter β when they are on the other side:



The C(1)–C(7) chain, terminating in a carboxy-group, is designated by convention as the α-chain (or the upper chain) and is located behind the CPR plane. All the PG are characterised by the presence of an oxygen-containing functional group (OH or C=O) at C(9), a hydroxy-group at C(15), and a *trans*-double bond between C(13) and C(14):

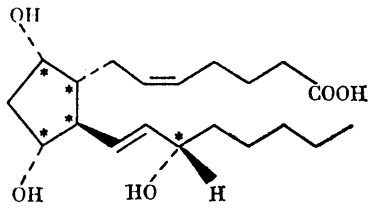


(II)

Depending on the number and type of the oxygen-containing functional groups, the degree of unsaturation of the CPR, and the position of the double bond in the latter, PG are divided into groups designated by the Latin letters, A, B, C, D, E, F, G, and H:

A B C D

E F_α G, H



The degree of unsaturation, i.e. the number of double bonds in the PG molecule (in the side chains), is designated by the corresponding numerals: for example PGE_1 has only one C(13)–C(14) *trans*-double bond, PGE_2 has an additional

cis-double bond in the C(5)–C(6) position, and PGE_3 is characterised by the presence of a third *cis*-double bond in the C(17)–C(18) position. Analogous double bonds are also encountered in PG of other groups. As a consequence of the asymmetry of their molecules, PG exist in several isomeric forms. In natural PG the hydroxy-groups in the C(9), C(11), and C(15) positions always have the α-configuration (the PG in group F can exist in two isomeric forms relative to the hydroxy-group at the C(9) atom, namely α and β, which are always indicated after the numeral). Only the isomeric α-forms $PGE_{1,2,3\alpha}$ are encountered in nature. The PG in groups G and F are usually referred to as "basic" or "primary". In a pure form, PG are colourless crystalline powders readily soluble in organic solvents.

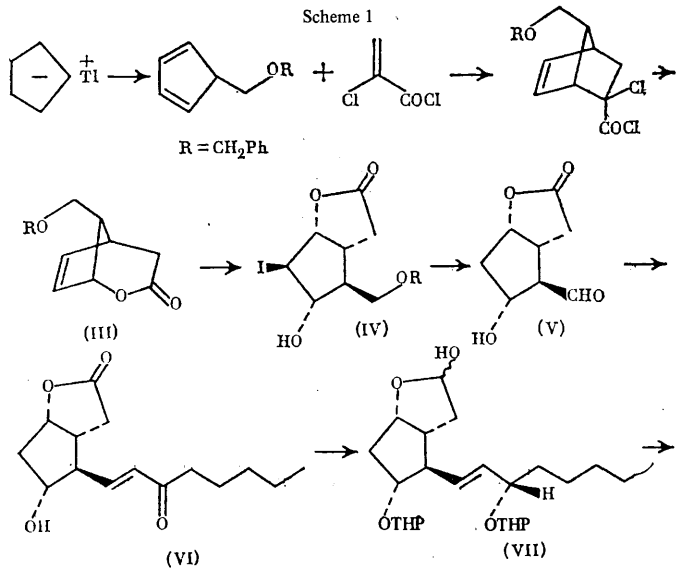
When the basic PG molecule is modified chemically by a particular group which is accompanied by a shortening of the alkyl chain, the prefix "nor" is added to the name of the PG; nor implies the shortening of the chain by one methyl group, dinor the shortening by two methyl groups, trinor the shortening by three methyl groups, etc. The number of the missing methyl group is also indicated. When the alkyl chain is lengthened, the prefix "homo" is added to the name of the PG with the simultaneous indication of the number of the new methyl groups (homo- dihomo-, trihomo-, etc.) and the number of the carbon atom to which the methyl group has been attached.

II. THE SYNTHESIS OF PROSTAGLANDINS

After the structure of the PG had been established[5], the synthesis of hormones of this class aroused much interest among synthetic chemists. The total synthesis of natural PG presents considerable difficulties not so much because of the lability of the compounds as due to the complexity of their chemical structure. PG can contain in their molecules up to five asymmetric centres, four of which are in the prostanoid ring and one in the side chain at the C(15) atom, so that the main problem in the total synthesis of PG is the stereospecific construction of these asymmetric centres. Thus the stereocontrolled syntheses of natural PG are in the main multistage processes and the yields of the final products are comparatively low:

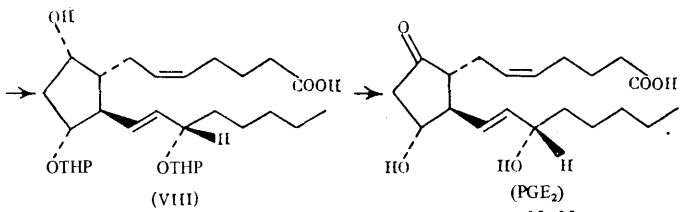
($PGF_{2\alpha}$)

Analysis of the literature data makes it possible to divide the methods of synthesis of PG into three main groups:



1. The synthesis of acyclic long-chain compounds in which the CPR is closed in one of the last stages.
2. The syntheses of PG from cyclopentane derivatives.
3. The enzymic synthesis from polyenoic acids (biosynthesis).

The growing interest in the second group of methods can be accounted for, on the one hand, by the relative availability of the initial cyclopentane derivatives and, on the other, by the comparative simplicity of the subsequent building up of the PG molecule. However, numerous studies in this field have been scarcely treated systematically and have not been surveyed. Mitra's monograph[6] is devoted to the synthesis of PG or their analogues without referring to the employment of cyclopentanes with functional-group substituents†; the review of Levkoeva and Yakhontov[7] is concerned with the synthesis of heterocyclic analogues of PG. Only a small amount of attention is devoted to PG in Azhgikhin's book[3]. A review dealing with the steric control in the synthesis of PG from bicyclic and tricyclic intermediates was published in 1980.[8] We therefore thought it useful to examine the most important studies on the synthesis of PG from cyclopentane derivatives.

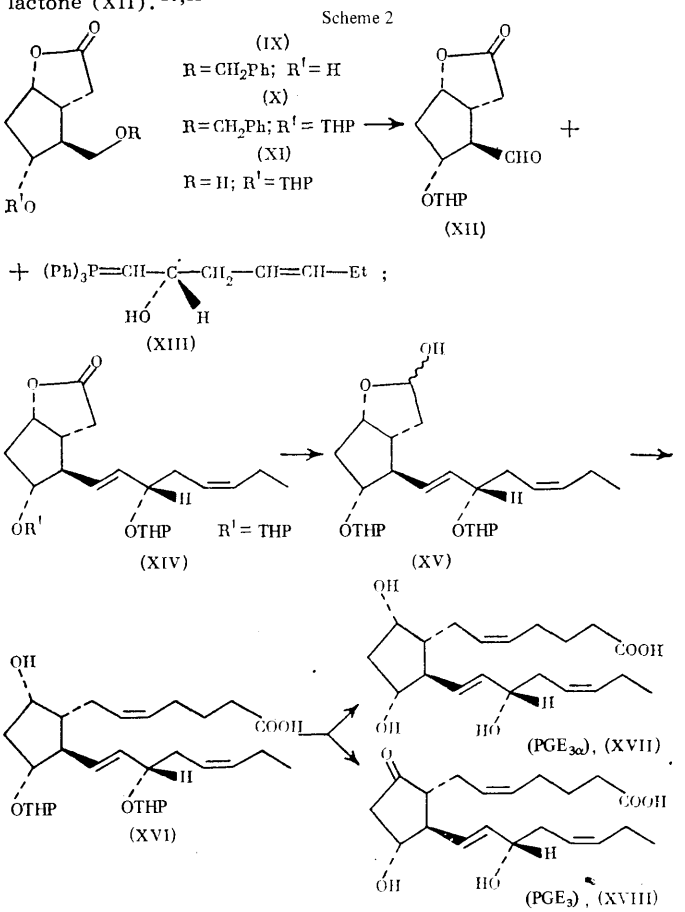


1. Synthesis From Bicyclic Compounds

One of the most significant achievements in the synthesis of PG is the practical application of bicyclic compounds which subsequently make it possible to proceed readily to the total synthesis of PG or their analogues. The key compound in these syntheses is the aldehydolactone (V) which is known in the literature as "Corey's aldehyde". One of the methods of synthesis of this compound[9–12], from cyclopentadienylthallium, is indicated in Scheme 1. The product of the interaction of the thallium derivative with benzyl chloromethyl ether is condensed with the dienophile, namely the chloride of 2-chloroacrylic acid, and the corresponding bicyclic compound is obtained, which is then converted by a series of reactions into 2-oxabicyclo[3.2.1]nonane (III). After the hydrolysis of compound (III) and subsequent treatment with potassium tri-iodide, the iodolactone (IV) is formed. This compound has the necessary configurations of all the nuclear centres. Its acylation, deiodination, and the conversion of the hydroxybenzyl group into an aldehyde group lead to the aldehydolactone (V), which then undergoes the Wittig condensation with the corresponding phosphorane to form compound (VI). The C(15)-keto-group is stereospecifically reduced and, after the conversion of the lactone into the lactol (VII), the α-chain is introduced by the Wittig reaction. Mild hydrolysis of the ester group leads to the intermediate (VIII). After the oxidation of the hydroxy-group at C(9) in compound (VIII) and the removal of the tetrahydropyranyl (THP) protecting group, PGE_2 is isolated. The conversion of compound (VIII) into PGE_1 is achieved by hydrogenating the former over a palladium catalyst.

Scheme 1

† See also J.S.Bindra and R.Bindra, "Prostaglandin Synthesis", Acad.Press, New York–San Francisco–London, 1977.

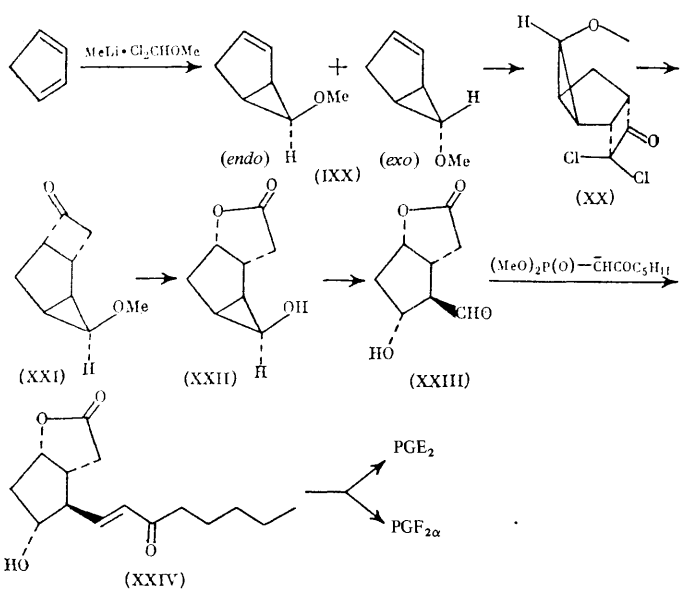


(VIII) (PGE$_2$)

Corey's aldehyde and its various modifications[13–18] have become key compounds in the various syntheses of PG. Thus the optically active PGE$_3$ and PGF$_{3\alpha}$ were synthesised for the first time from the optically active hydroxylactone (IX) (Scheme 2). The lactone (IX) was converted into the aldehyde (XII) after the protection of the hydroxy-group with THP, hydrogenation over Pd/C, and Collins oxidation ($2C_5H_5N.CrO_3$ in CH_2Cl_2) of the resulting alcohol. By condensation with the (*S*)-(+)-phosphonium salt (XIII), the aldehyde (XII) was converted stereospecifically into the unsaturated alcohol (XIV). After conversion into the bis-THP derivative, the allyl alcohol (XIV) was reduced with di-isobutylaluminium hydride (DIBAH) to the lactol (XV). The upper chain in compound (XVI) was built up stereospecifically by the Wittig reaction between the lactol (XV) and 5-triphenylphosphonovaleric acid. The removal of the THP protecting group on acid hydrolysis gives rise to PGF$_{3\alpha}$ (XVII) with $[\alpha]_{D^{26}} = +29.6°$. The oxidation of compound (XVI) with the Jones reagent (chromic acid–acetone) and subsequent removal of the THP protecting group and chromatographic separation lead to PGE$_3$ (XVIII) with $[\alpha]_{D^{24}} = -48.9°$.

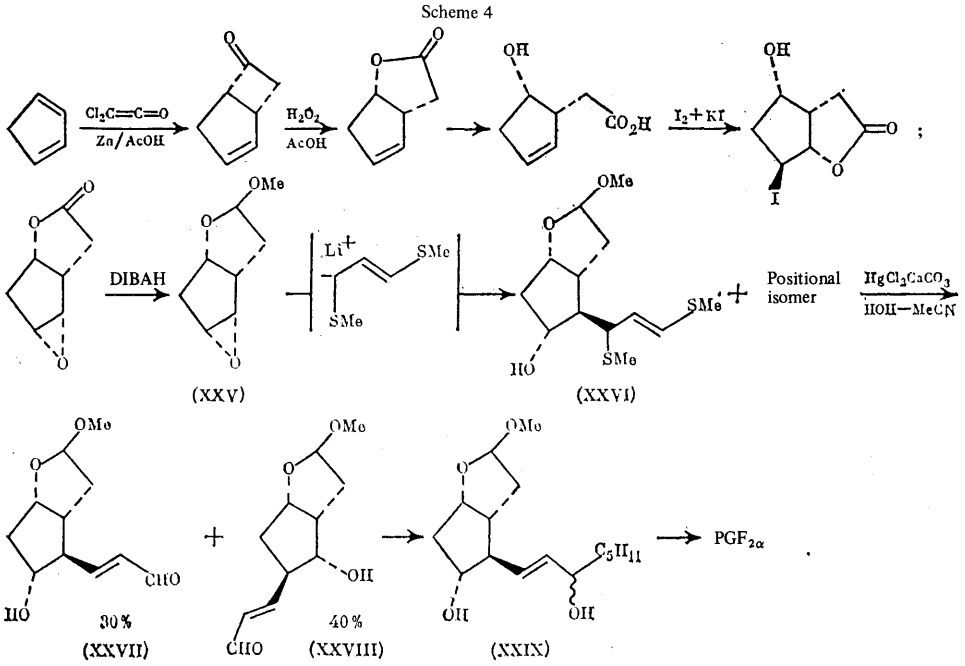
PGE$_1$ and PGF$_{1\alpha}$ have been obtained analogously from the lactone (XII).[20,21]

Scheme 2



After the successful synthesis of PG using Corey's aldehyde, new methods of synthesis of key compounds from readily available reagents permitting an easy transition to the total synthesis of PG were sought. Thus Corey et al.[22] used 6-methoxybicyclo[3.1.0]hex-2-ene (XIX) as the key compound in the synthesis of PGE$_2$ and PGF$_{2\alpha}$ (*dl*), which were obtained by the condensation of dichloromethyl ethyl ether with cyclopentadiene as a 4:1 mixture of the *endo*- and *exo*-forms (Scheme 3). Refluxing of the 4:1 mixture with dichloroacetyl chloride in an excess of triethylamine leads to the tricyclic ketone (XX) whose dechlorination with zinc dust in glacial acetic acid followed by treatment of compound (XXI) with boron tribromide in CH_2Cl_2 results in the formation of the *endo*-cyclopropanol (XXII). The oxidation of compound (XXII) with a solution of H_2CrO_4 and $Ce(NH_4)_2(NO_3)_6$ in aqueous acetic acid leads to a mixture of three products, one of which is the required hydroxyaldehyde (XXVI). The aldehyde (XXIII) is fairly unstable and for this reason it is immediately condensed with the sodium derivative of 2-oxoheptylphosphonate whereupon a mixture of products is obtained, from which the lactone (XXIV) is isolated chromatographically. Next the lactone (XXIV) is converted into the acetate derivative and then into PGE$_2$ and PGF$_{2\alpha}$ by standard methods.

11-Deoxy-PGE was synthesised in accordance with an analogous scheme by the reaction of 2-(6′-methoxycarbonylhexyl)cyclopent-2-en-1-one with dimethylsulphuranylidene acetate[23,24].

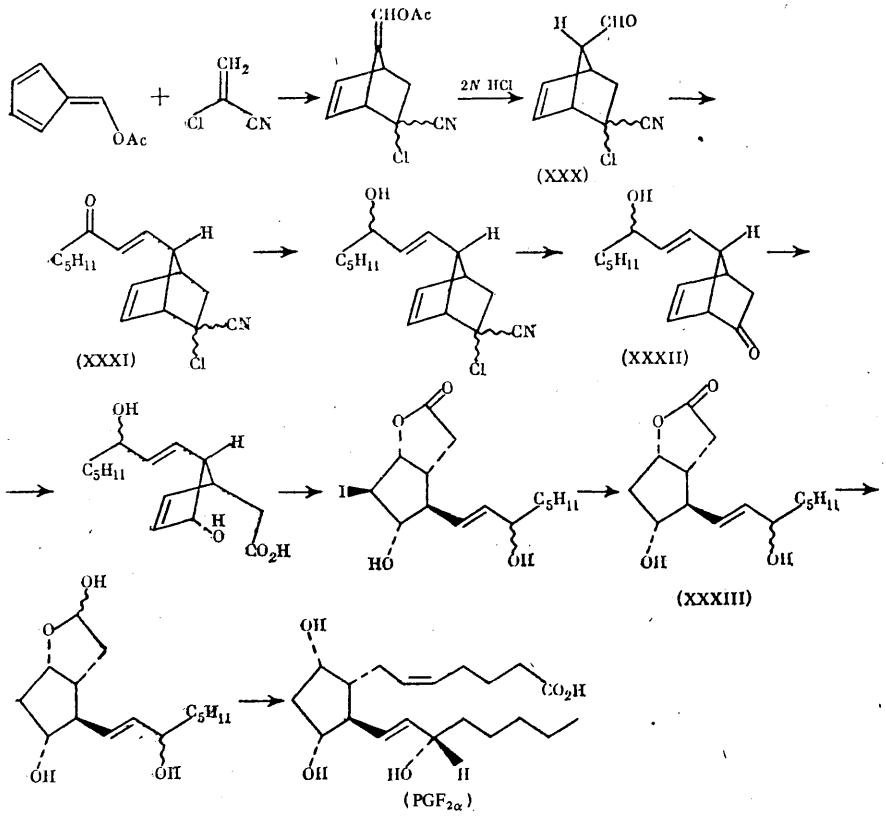


However, the oxidative opening of the cyclopropanol (XXII) ring to give the aldehyde (XXIII) proceeds with a low yield and for this reason Corey and Hayozi[25] developed a new approach to the synthesis of PGF$_{2\alpha}$ via the epoxidation of unsaturated bicyclic derivatives of cyclopentanone with subsequent regioselective opening of the oxide ring by the lithio-derivative of the vinyl sulphide MeS–CH_2–CH=CH–SMe (the β-nucleophilic equivalent of –CH=CH–CHO) which contains the potential C(13)–C(14) *trans*-double bond (Scheme 4).

Scheme 3

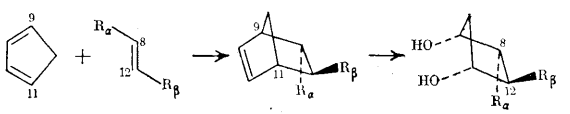
Condensation of the epoxyacetal (XXV) with 1,3-di(methylthio)allyl-lithium gives a mixture of the required product (XXVI) and its postional isomer. Hydrolysis of the mixture leads to a mixture of two unsaturated aldehydes, (XXVII) and (XXVIII), which were separated on a preparative scale.

Scheme 4



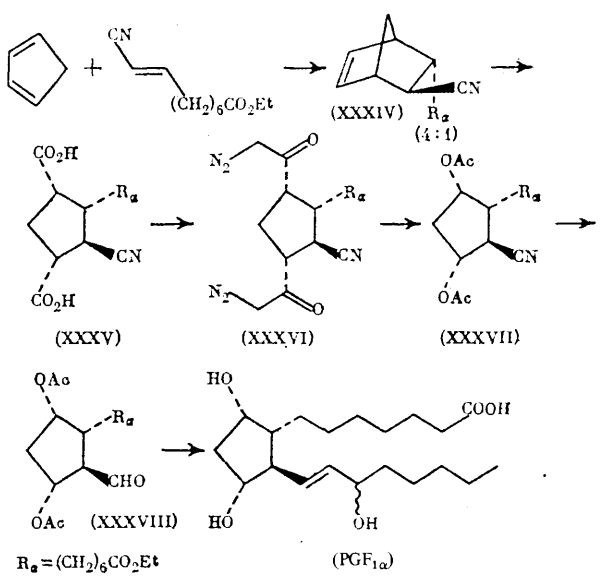
The condensation of the more polar aldehyde (XXVII) with n-butyl-lithium leads to a mixture of approximately equal amounts of the epimeric secondary alcohols. The acid hydrolysis of the more polar compound (XXIX) with subsequent isolation of the lactol and its condensation with the sodium derivative of 5-triphenylphosphonopentanoic acid yields $PGF_{2\alpha}$. The less polar epimer (XXIX) was converted in two stages into *dl*-15-epi-$PGF_{2\alpha}$ in the same way.

In a later study ring opening in the tricyclic epoxide (XXV) in the total synthesis $PGF_{2\alpha}$ was achieved with a higher regioselectivity on treatment with divinyl cuprate[26].



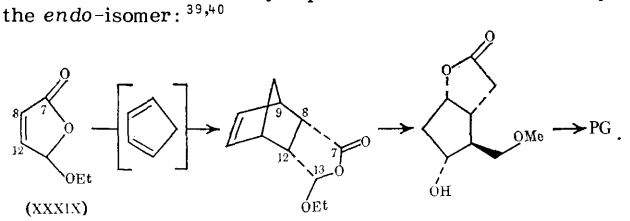
An alternative synthesis of $PGF_{2\alpha}$ is based on the employment of acetoxyfulvene as the starting compound[27-31] in the synthesis of the key compound (XXX) via Scheme 5:

Scheme 5



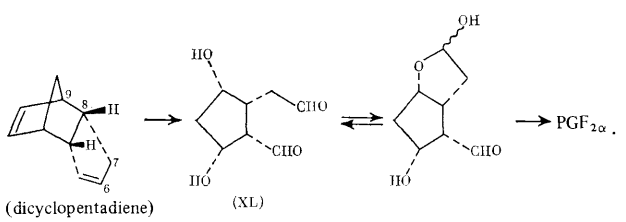
The bicycloheptenal (XXX) reacted with the lithio-derivative of dimethyl 2-oxoheptylphosphonate with formation of the *trans*-enone (XXXI) whose reduction with DIBAH and subsequent alkaline hydrolysis of the chloronitrile group lead to the ketone (XXXII). Baeyer–Villiger oxidation (H_2O_2, KOH) of compound (XXXII) and the iodolactonisation of the hydroxyacid salt formed *in situ* lead to the iododiol whose deiodination with tri-n-butyltin hydride affords the diol (XXXIII). After the reduction of compound (XXXIII) by DIBAH to the *gem*-acetal (XXXIV) and its condensation with the sodium salt of (4-carboxybutyl)triphenylphosphorane, $PGF_{2\alpha}$ was obtained together with the C(15)-epimer. Chromatographic separation of this mixture makes it possible to obtain the racemic $PGF_{2\alpha}$. The conversion into PGE_1 of the A and B series was achieved by standard methods[9].

5,6-Disubstituted bicyclo[2.2.1]hept-2-enes can serve as convenient precursors for the construction of PG. This strategy in the synthesis was first developed and modified by Katsube and co-workers[32–36]. The disubstituted bicyclo[2.2.1]-heptene is obtained by the Diels–Alder reaction between cyclopentadiene and the corresponding substituted *trans*-olefine, the dienophile giving rise to the C(8) and C(12) atoms incorporated in the cyclopentane ring:



One of the examples of this approach is the synthesis of $PGE_{1\alpha}$ [32] (Scheme 6).

Scheme 6



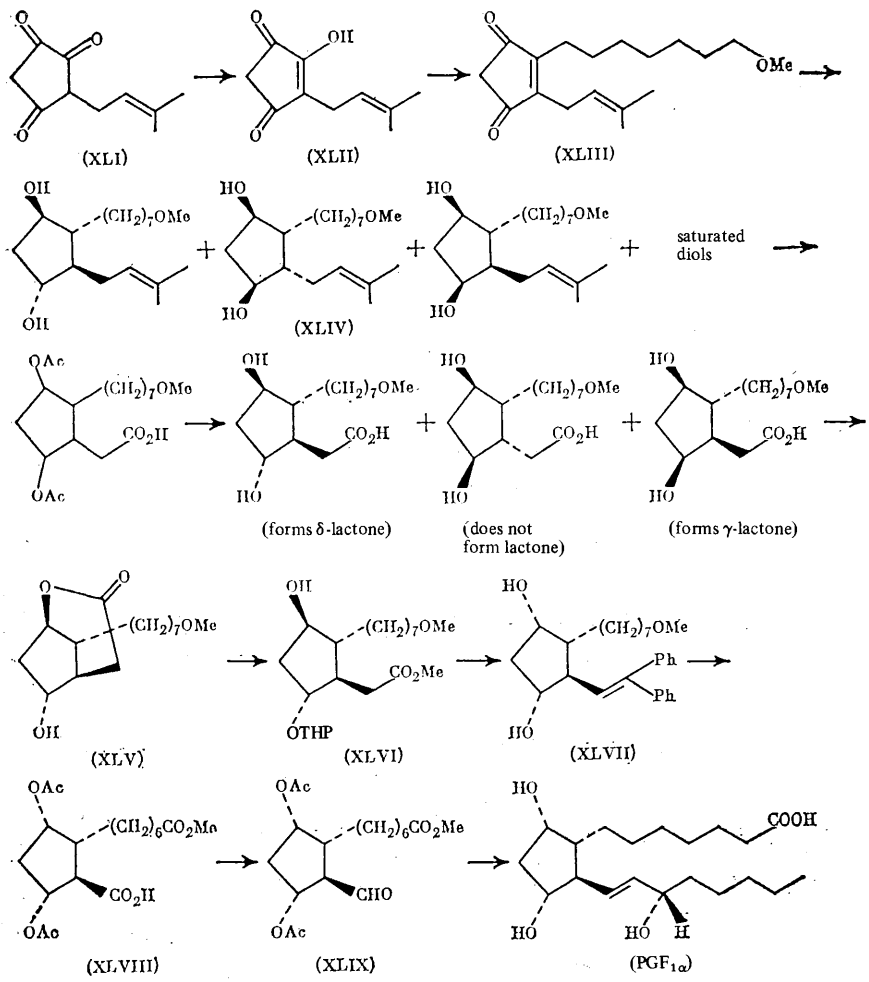
The Diels–Alder reaction between 2-cyano-9-ethoxycarbonyl-*trans*-non-2-ene, obtained by a standard method in four stages from diethyl suberate and cyclopentadiene at 150 °C in an autoclave, leads to a mixture of *exo*-2-cyano-3-(6'-ethoxycarbonylhexyl)bicyclo[2.2.1]hept-5-ene (XXXIV) and the corresponding *endo*-derivatives in proportions of 4:1, which were separated by chromatography on silica gel (SG). The ozonolysis of the *exo*-derivative of compound (XXXIV) and subsequent oxidative decomposition of the ozonide with an aqueous solution of performic acid yielded 3,5-dicarboxy-1α-cyano-2-β-(6'-ethoxycarbonylhexyl)cyclopentane (XXXV). Treatment of the latter with phosgene in a DMF–benzene mixture led to an acid dichloride, which gave rise, after treatment with a solution of diazomethane in ether, to the corresponding bisdiazoketone (XXXVI), which was converted into 3,5-diacetyl-1α-cyano-2β-(6'-ethoxycarbonylhexyl)cyclopentane (XXXVII). The oxidation of compound (XXXVII) with *m*-$ClC_6H_4CO_3H$ in $CHCl_3$ gave rise to 3,5-diacetoxy-2β-(6'-ethoxycarbonylhexyl)-1α-formylcyclopentane (XXXVIII), which was subsequently made to react with $Bu_3P{=}CH{-}CO{-}(CH_2)_4Me$, the condensation product was separated chromatographically, the C=O group at C(15) was reduced with sodium tetrahydroborate, the acetate protecting group was removed by hydrolysis, and $PGF_{1\alpha}$ was obtained.

It is noteworthy that this approach[32–38] to the synthesis of PG suffers from a significant disadvantage, since the reaction between cyclopentadiene and the corresponding substituted *trans*-olefin produces a mixture of the *exo*- and *endo*-adducts whose separation creates additional difficulties. However, the use of compound (XXXIX) (the β-formylacrylic acid pseudoester) as the dienophile in the Diels–Alder reaction with cyclopentadiene leads exclusively to the *endo*-isomer:[39,40]

An interesting 13-stage stereoselective synthesis of $PGF_{2\alpha}$, where the key compound is Turner's intermediate (XL), obtained from the readily available *endo*-dicyclopentadiene by successive oxidation, has been achieved[41,42]:

However, in this case the Diels–Alder reaction with symmetrically substituted dienophiles should not be carried out. The cyclopentene ring in dicyclopentadiene serves as a source of one or two aldehyde groups which are essential for the subsequent construction of the α- and β-chains of PG respectively.

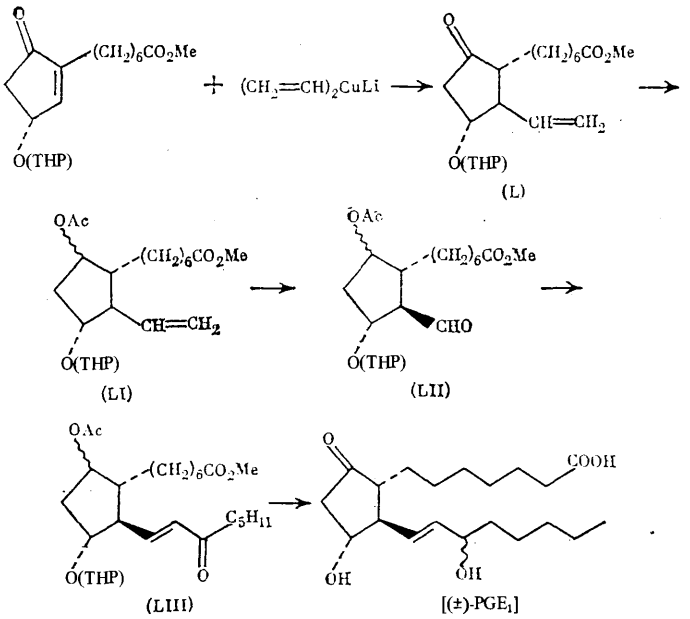
It is also possible to use 3-alkylcyclopentane-1,2,4-triones but only to a limited extent, since in this case the synthesis consists of many stages[43–48]. Thus the synthesis of *dl*-$PGF_{1\alpha}$ has been achieved (Scheme 7). 5-Ethoxycarbonyl-3-(3-methylbut-2-enyl)cyclopentane-1,2,4-trione (XLI) has been obtained by the cyclisation of two molecules of 6-methylhept-5-en-2-one and four molecules of $(COOC_2H_5)_2$. Subsequent treatment with alkali and then acid yields compound (XLII) and conversion into the acetal following treatment with orthoformic ester and subsequent condensation with 1-heptyl-7-methoxymagnesium bromide lead to the dione (XLIII). The latter was reduced initially with Zn/HOAc and then with Li/NH_3 to form a mixture of diols, whose catalytic hydrogenolysis gave rise to the corresponding cyclopentanediols (XLIV). Treatment



of the diols (XLIV) with acetic anhydride and oxidation with a mixture of $KMnO_4$ and $NaIO_4$ produced the corresponding diacetates of the acids, whose hydrolysis afforded the diols. The latter were converted into the δ-lactone (XLV) on treatment with TsOH. The OH group at C(11) in the δ-lactone (XLV) was protected with THP, after which the product was subjected to alkaline hydrolysis and was treated with an ethereal solution of diazomethane. The OH groups at C(9) in the resulting ester (XLVI) were protected and the latter was condensed in the form of the acetate with phenylmagnesium bromide. The diol (XLVII) was obtained on acidification. After the protection of the hydroxy-groups in compound (XLVII) with acetic anhydride, the methoxy-group was cleaved with boron tribromide to give the hydroxy-group and the subsequent oxidation of this group with the RuO_4–$NaIO_4$ mixture and esterification with diazomethane led to the ester-acid (XLVIII). The reduction of the carboxy-group with diborane and its subsequent Collins oxidation afforded the required aldehyde (XLIX), whose condensation with the corresponding phosphonate, the reduction of the C=O group at C(15) with $Zn(BH_4)_2$, and acid hydrolysis produced $PGF_{1\alpha}$.

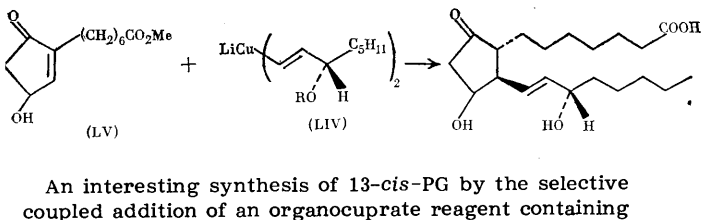
2. Synthesis via the Coupled Addition of Organometallic Derivatives

The 1,4-addition of organometallic reagents to 4-alkoxy-2-alkylcyclopent-2-enones, which makes it possible to proceed readily to the total synthesis of PG, has been fairly widely used recently. The addition of divinyl cuprates to substituted cyclopentenones has been studied independently by two groups of investigators[49,50]. The method is used widely, employing various soluble complexes of copper iodides. This approach also permits the development of methods of synthesis of 4-alkoxycyclopentenones. (±)-PGE_1, (±)-11-deoxy-PGE_1, the corresponding $F_{1\alpha}$ and $F_{1\beta}$ derivatives, and (±)-9-oxo-13-*cis*-prostanoic acid[49] have been obtained by this procedure. The synthesis of PGE_1 is illustrated in Scheme 8.[49]

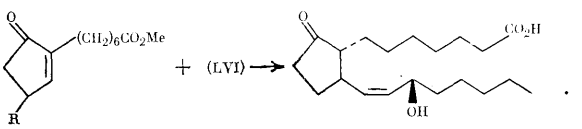


The main reaction is the coupled addition of $(CH_2{=}CH)_2CuLi$ {prepared from bis(trimethyl phosphite)copper cyanide $[(MeO)_3P]_2CuCN$ and vinyl-lithium in ethereal solution} to 4-O(THP)-2-(6'-methoxycarbonylhexyl)cyclopent-2-en-1-one with formation of (±)-vinylcyclopentanone (L) having the required steric configurations of all three asymmetric centres

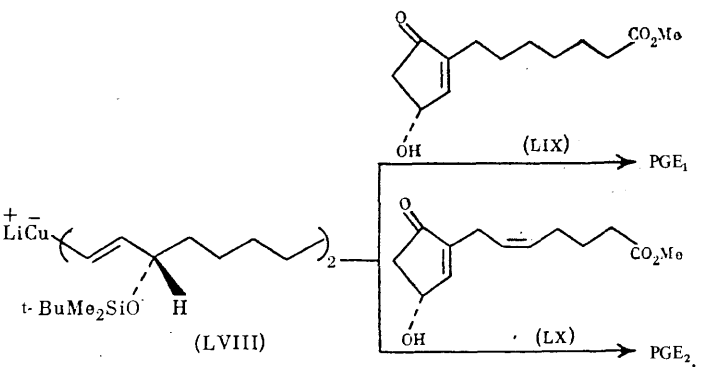
Scheme 7



of the cyclopentane ring. The subsequent stages in the synthesis of the required PG were performed without the purification of the intermediate compounds. The reduction of the vinyl ketone (L) with sodium tetrahydroborate and subsequent acetylation with acetic anhydride yielded the C(9)-epimeric acetate (LI), whose ozonolysis led to the unstable aldehyde (LII). Its condensation with dimethyl 2-oxoheptylphosphonate yielded the α,β-unsaturated ketone (LIII). The subsequent reduction of the keto-group at C(15) with $Zn(BH_4)_2$, the alkaline hydrolysis of the ester groups at C(9) and C(1), and oxidation of the OH group at C(9) with the Jones reagent led to a mixture of (±)-PGE_1 and (±)-15-epi-PGE_1. The mixture was separated by preparative thin-layer chromatography (TLC), yielding (±)-PGE_1 (3.6%) and (±)-15-epi-PGE_1 (3.2%). (±)-11-Deoxy-PGE_1 and the corresponding $F_{1\alpha}$ and $F_{1\beta}$ derivatives were synthesised by the same procedure from other cyclopentenone derivatives.

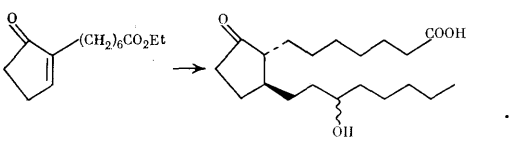


Scheme 8



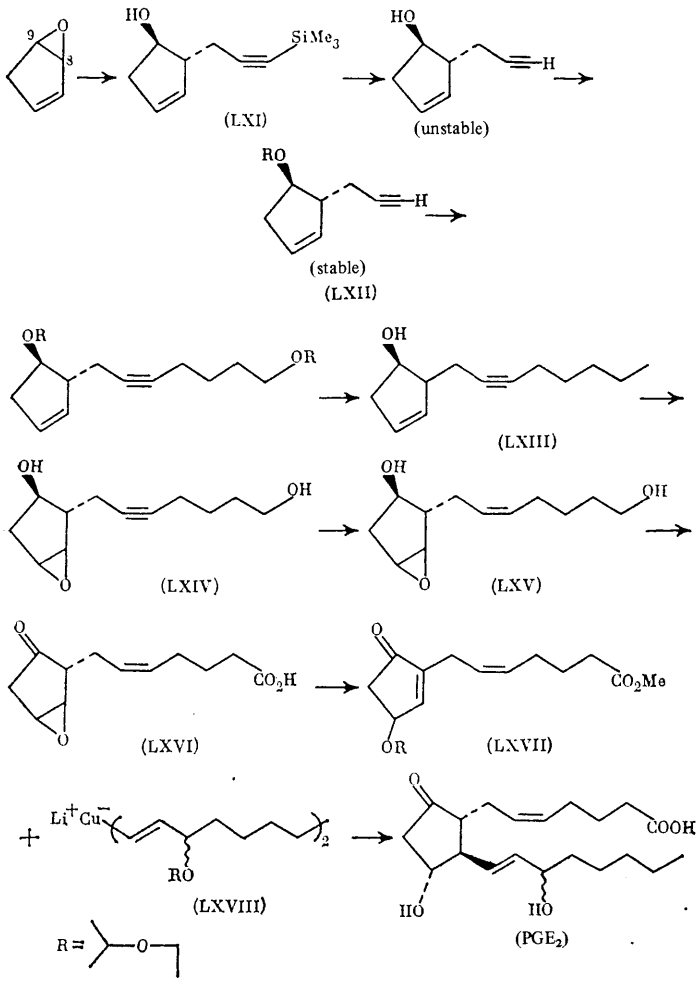
Another approach[50-61] to the synthesis of PG consists in the coupled addition of the corresponding substituted organocuprate reagent (LIV) to the enone (LV):

An interesting synthesis of 13-*cis*-PG by the selective coupled addition of an organocuprate reagent containing functional groups has been carried out[62]. It has been established that *cis*-LiCu[CH=CHCH(C_5H_{11})OC(Me)$_2$.OCH_2]$_2$ (LVI) gives rise to high yields of 1,4-adducts with a high degree of stereoselectivity, in contrast to the *trans*-isomer. Thus the interaction of compound (LVI) and 4-R-2-methoxycarbonyl-hexylcyclopent-2-enone (R=H) leads to the racemic 11-deoxy-13-*cis*-PGE_1 after mild hydrolysis (with 20% CH_3COOH). The interaction of compound (LVI) with compound [LVII, R=OC(Me)$_2$OMe] under the same conditions results in the formation of *dl*-11-hydroxy-13-*cis*-PGE_1:



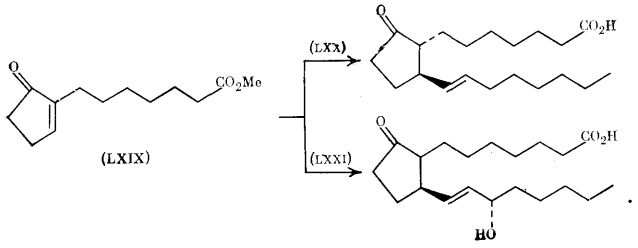
The bio-organic asymmetric synthesis of (−)-PGE_1 and (−)-PGE_2,[63-65] carried out by the coupled addition of organocuprate derivatives (LVII) [obtained from *trans*-3(*S*)-hydroxy-1-iodooct-1-ene] to the enones (LIX) and (LX) respectively may also be of interest:

It is noteworthy that the chiral centres in the key synthons (LIX) and (LX) were produced with the aid of microbiological enzymes. Different microbiological oxidation and reduction methods were used to convert the prochiral substances into optically active prostaglandin synthons. The microbiological reactions have been discussed and compared with the corresponding non-enzymic reactions used in the total synthesis of PGE_1 and PGE_2.[51]



In connection with the synthesis of the racemic 11-deoxy-13-dihydro-PGE_1,[66-68] the coupled addition of t-butoxy-1-octylmagnesium bromide to 2-(6'-ethoxycarbonylhexyl)-cyclopent-2-en-1-one in the presence of Cu(I)I.PBu_3 has been described:

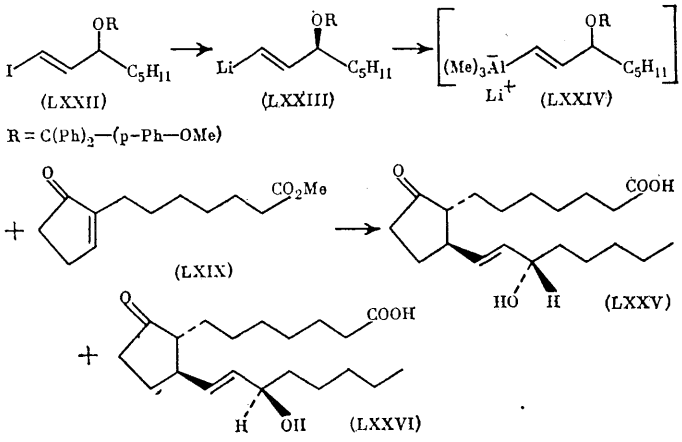
A general method of synthesis for 4-hydroxycyclopentenes—convenient key compounds for the direct synthesis of the PGE series—has been developed[69-71] (Scheme 9). The reaction of the epoxide derived from cyclopentadiene with the lithium salt of trimethylprop-1-ynylsilane leads to *trans*-2-(prop-2-ynyl)cyclopent-3-enol (LXI), whose interaction with ethyl vinyl ether results in the formation of the α-ethoxyethyl ether (LXII). The lithium salt of the latter is alkylated by the α-ethoxyethyl ether of 4-bromobutanol followed by the removal of the protecting groups and the formation of the diol (LXIII). The double bond of the diol (LXIII) is oxidised to the epoxy-group in (LXIV) and, after hydrogenation over 5% $Pd/BaSO_4$ in the presence of traces of quinoline, the *cis*-olefin (LXV) is obtained, its hydroxy-group being oxidised by the Jones reagent to give compound (LXVI). The epoxy-ring in compound (LXVI) is opened by successive treatment with triethylamine and trichloroacetaldehyde to



give compound (LXVII). The coupled addition of the lithium dialkylcuprate (LXVIII) (obtained from the ethyl ether of *trans*-1-iodo-oct-1-en-3-ol) to compound (LXVII) leads to a mixture of the C(15)-epimers of PGE_2.

Scheme 9

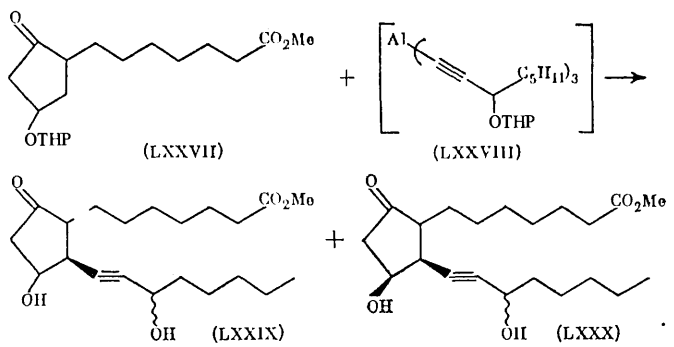
It is noteworthy that the conversion of epoxycyclopentanones (LXVI) into 4-hydroxycyclopentenones requires specific conditions for the opening of the epoxy-ring and for this reason their practical employment in the synthesis of PG is limited.



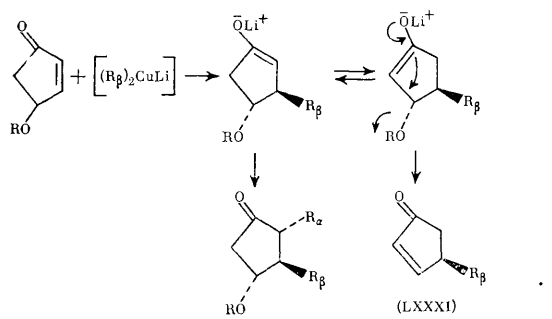
A preparatively significant synthesis of an important intermediate in the preparation of PG, namely 2-(ω-methoxycarbonylhexyl)cyclopent-2-enone (LXIX), and its single-stage conversion into the prostane skeleton have been described[72]. Octa-1,7-diene has been hydroborated by the Brown method (B_2H_6 in THF, I_2, NaOH, and HCl in aqueous THF) to form 8-iodo-oct-1-ene, from which a Grignard reagent was prepared. The latter reacts with 2-methoxycyclopent-2-enone, forming 2-(oct-7-enyl)cyclopent-2-enone. This ketone is oxidised in succession by *m*-$ClC_6H_4CO_3H$ and then H_5IO_6 to give the corresponding aldehyde, which is oxidised by the Jones reagent to the acid from which the ester (LXIX) is obtained. The reaction of compound (LXIX) with *trans*-$C_6H_{13}CH{=}CHLi$ (LXX) in the presence of $n\text{-}Bu_3PBuI$ and subsequent hydrolysis led to the formation of *dl*-11,15-dideoxy-PGE_1 in 75% yield relative to compound (LXIX). When compound (LXIX) is treated with (3*S*)-*trans*-$MeCH(OEt)OCH(C_6H_{11})CHCHLi$ (LXXI), equal amounts of 11-deoxy-PGE_1 and 11-deoxy-15-epi-PGE_1 are formed:

Like other organometallic reagents, alanates and alanes are capable of 1,4-addition to 4-alkoxycyclopentenones[73-76]. Lithium alanates are obtained from alanes by the reduction of 3-alkoxyacetylenes, the reaction usually proceeding with a 40% yield and leading to an olefin having the *cis*-configuration. However, when the alcoholic protective group at the C(15) atom is bulky, only the *trans*-olefin is formed. The simplest method of synthesising the alanate reagent involves the reaction of *trans*-vinyl-lithium with R_3Al.

A method of synthesis of 11,15-dideoxy-PGE_1, the corresponding E_2 and $F_{1\alpha}$ derivatives, 11-deoxy-PGE_1, and PGE_1 by the stereospecific coupled addition of lithium *trans*-1-alkenylalanate to the α-alkylated cyclopentene ring has been proposed[73] (Scheme 10):



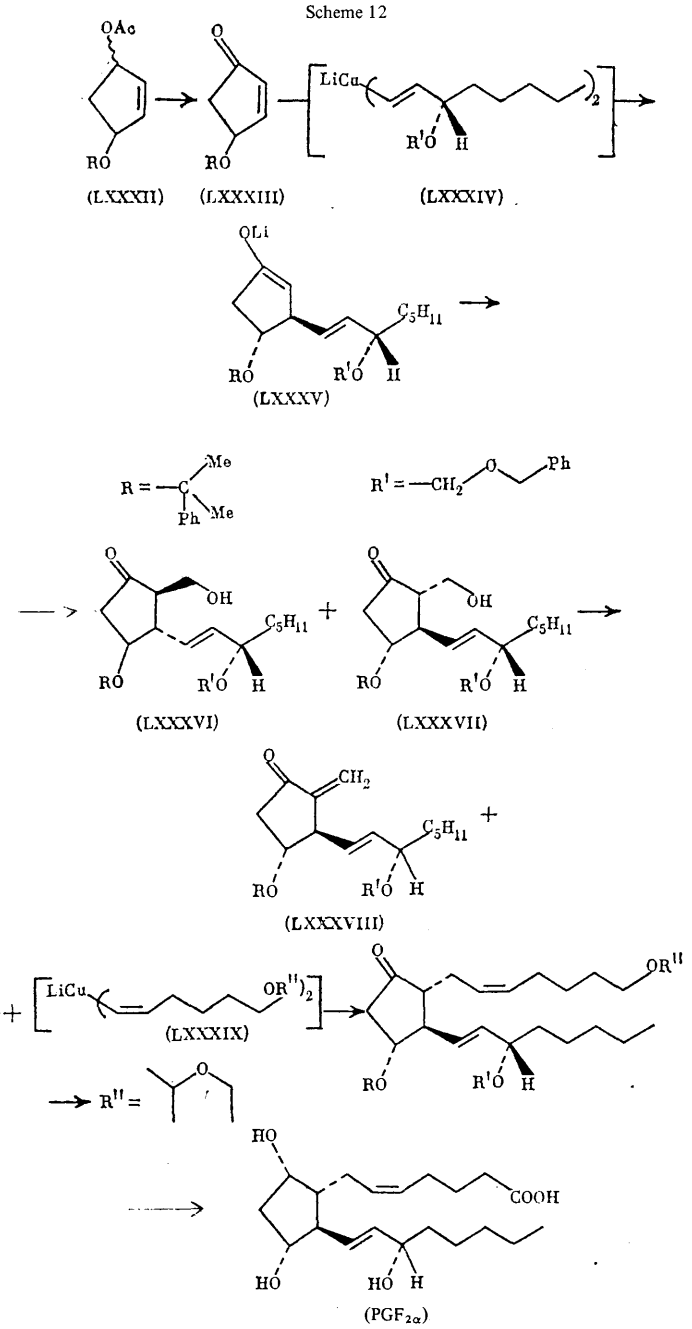
Scheme 10



The protected 1-iodo-*E*-oct-2-en-3-ol (LXXII), obtained from the corresponding acetylenic derivative, is metallated by n-BuLi to compound (LXXIII), whose treatment with trimethylaluminium leads to the lithium alanate reagent (LXXIV). The coupled addition of the alanate (LXXIV) to the cyclopentenone (LXIX) leads, after chromatographic separation, the removal of the protective group, and hydrolysis, to *dl*-11-deoxy-PGE_1 and its C(15)-epimer (LXXVI) in proportions of 44:56 respectively.

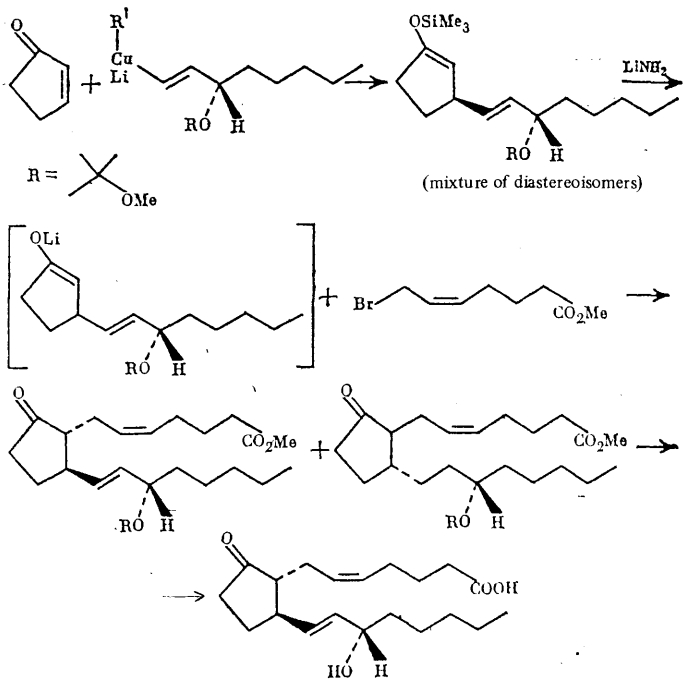
Alanes also add to 4-alkoxycyclopentenones[77,78] with formation of PG. The reaction of the key compound (LXXVII) with tri(3-tetrahydropyranyloxyoct-1-ynyl)aluminium (LXXVIII) results in the formation, after hydrolysis and chromatography on silica gel, of the methyl ester of (±)-11β, 15(*RS*)-dihydroxy-9-oxoprost-3-ynoic acid (LXXIX) and the methyl ester of (±)-11β, 15(*RS*)-dihydroxy-9-oxo-8-isoprost-13-ynoic acid (LXXX) (Scheme 11):

Scheme 11



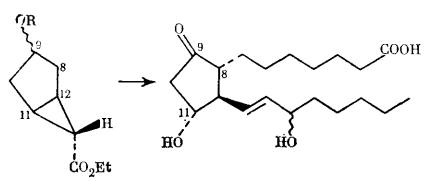
The 1,4-addition of the β-chain to 4-alkoxycyclopent-2-enone and the trapping of the resulting enolates with a finished α-chain or a potential α-chain may be regarded as one of the simplest approaches to the synthesis of PG and one involving a small number of stages. The β-chain is added in the *trans*-position of the C(11)-alkoxy-group by the Michael reaction and the subsequent trapping of the enolate leads to the complete *trans*-orientation of the three substituents in the cyclopentane ring. The main criterion of the successful application of this method of synthesis of PG is the selection of a suitable trapping agent. The low rate of trapping of the enolate of 4-alkoxycyclopent-2-enone leads to equilibrium between the enolates, which results in the elimination of the alkoxy-group with formation of the cyclopentenone (LXXXI). For example, alkylation even by reactive electrophiles, such as allyl halides, hinders only slightly the attainment of the state of equilibrium of the enolate:

An interesting solution of this problem involves the use of formaldehyde, which is an extremely reactive electrophile, in the synthesis of $PGF_{2\alpha}$ and 15-epi-$PGF_{2\alpha}$, where 4-cumenyloxycyclopenten-2-one (LXXXIII) was employed as the key compound[79-82]. The synthesis of $PGF_{2\alpha}$ was achieved in eight stages with an overall yield of 17% (Scheme 12).



An aqueous solution of $Fe_2(SO_4)_3$ is added to cyclopentadiene, cumenyl peroxide, and $Cu(OAc)_2$ in acetic acid and 4-cumenyloxycyclopent-2-enyl acetate (LXXXII) is obtained, its alkaline hydrolysis and subsequent Jones oxidation resulting in its conversion into compound (LXXXIII). The addition of the cuprate reagent (LXXXIV) to compound (LXXXIII) in the presence of Bu_3P/CuI leads to the regiospecific enolate ion (LXXXV), whose interaction with an ethereal solution of formaldehyde produces a mixture of the alcohols (LXXXVI) and (LXXXVII) in proportions of 1 : 1.3. The dehydration of compound (LXXXVII) produces the exocyclic enone (LXXXVIII). The 1,4-addition of compound (LXXXIX) to the enone (LXXXVIII), the successive reduction of the C=O group at C(9), and the removal of the protective groups and hydrolysis lead to $PGF_{2\alpha}$, with $[\alpha]_D$ = +22.7°, and 15-epi-$PGF_{2\alpha}$.

Scheme 12

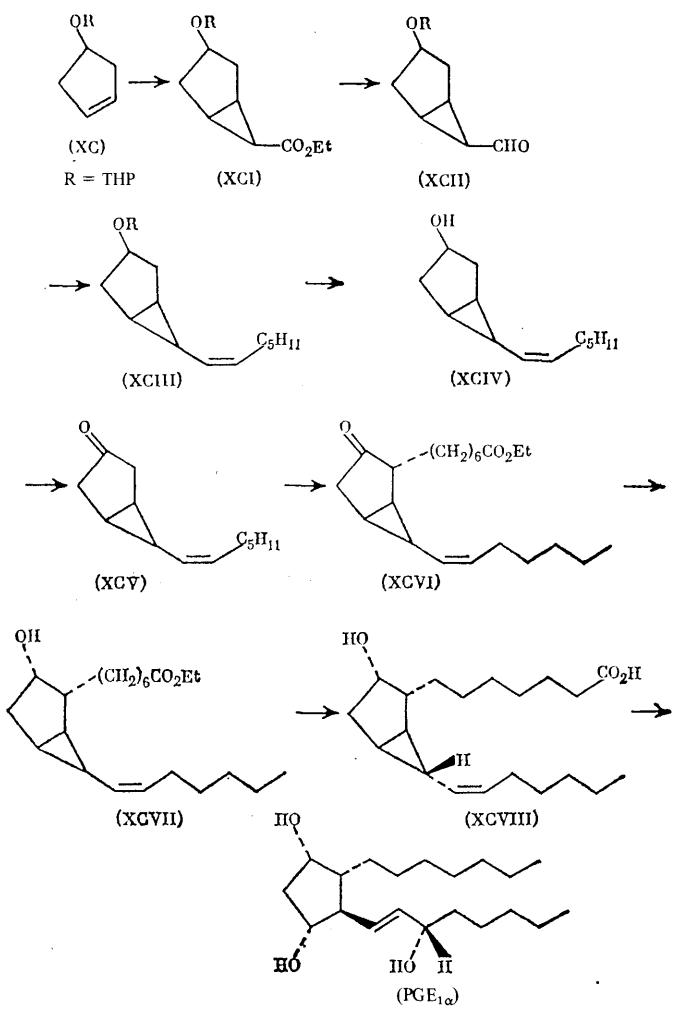


A three-stage synthesis of 11-deoxy-PGE_2 with an overall yield of 20–60%, where the β-chain was introduced by the coupled 1,4-addition of the mixed cuprate to Δ^2-cyclopentenone and the α-chain was introduced by the alkylation of a specifically oriented enolate ion, has been developed[83] (Scheme 13):

Scheme 13

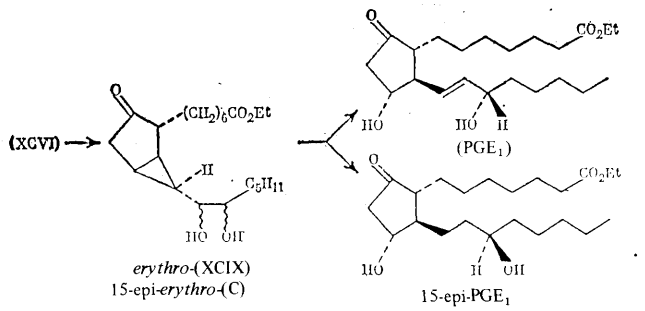
3. Synthesis Based on Symmetrical Intermediate Compounds

Just and Simonovitch[84] were the first to show that a symmetrical intermediate can be used to construct the asymmetric PG molecule:



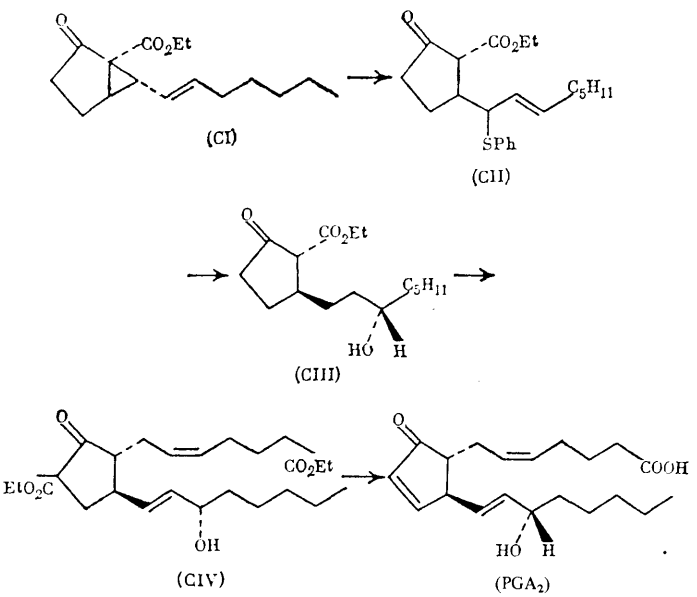
The main condition is the formation of the allyl alcohol system in the β-chain on solvolysis of the corresponding substituted cyclopropylmethanol derivative. This procedure was developed further and modified in other studies[85,86].

Scheme 14 illustrates the general method of synthesis of *dl*-$PGF_{1\alpha}$.[84] When cyclopentenol is treated with dihydropyran in the presence of $POCl_3$, the THP ether (XC) is formed quantitatively, its interaction with ethyl diazoacetate in the presence of copper powder leading to a mixture of the *syn-anti*- and *exo-endo*-isomers. When the mixture is refluxed with sodium methoxide in methanol, only the *exo*-isomer (XCI) (*syn–anti* mixture) is obtained. The ester group in the *exo*-isomer (XCI) is reduced with lithium tetrahydroaluminate to the alcoholic group (*syn–anti* mixture), which is oxidised with dilute Jones reagent to the aldehyde (XCII). The condensation of the latter with the phosphorane $(C_6H_5)_3P{=}CHC_5H_{11}$ leads to four isomers, which were separated by chromatography on Al_2O_3 with isolation of the required olefin (XCIII), whose acid hydrolysis yields the alcohol (XCIV) in the form of a mixture of four isomers, which can also be separated with the aid of TLC. The mixture (XCIV) is oxidised with a dilute Jones reagent and the resulting mixture of ketones (XCV) is also separated by TLC. The ketone (XCV) interacts with the methyl ester of 7-iodoheptanoic acid in demthylcellosolve in the presence of t-BuOK with formation of compound (XCVI), which, without being purified, is reduced with $NaBH_4$ to compound (XCVII). Alkaline hydrolysis of compound (XCVII) leads to the acid (XCVIII), a 1% solution of the latter (without purification) in 97–100% formic acid being treated with sodium carbonate, the mixture is then treated with 30% H_2O_2, the mixture of products is isolated and separated by TLC, and $PGF_{1\alpha}$ is obtained.



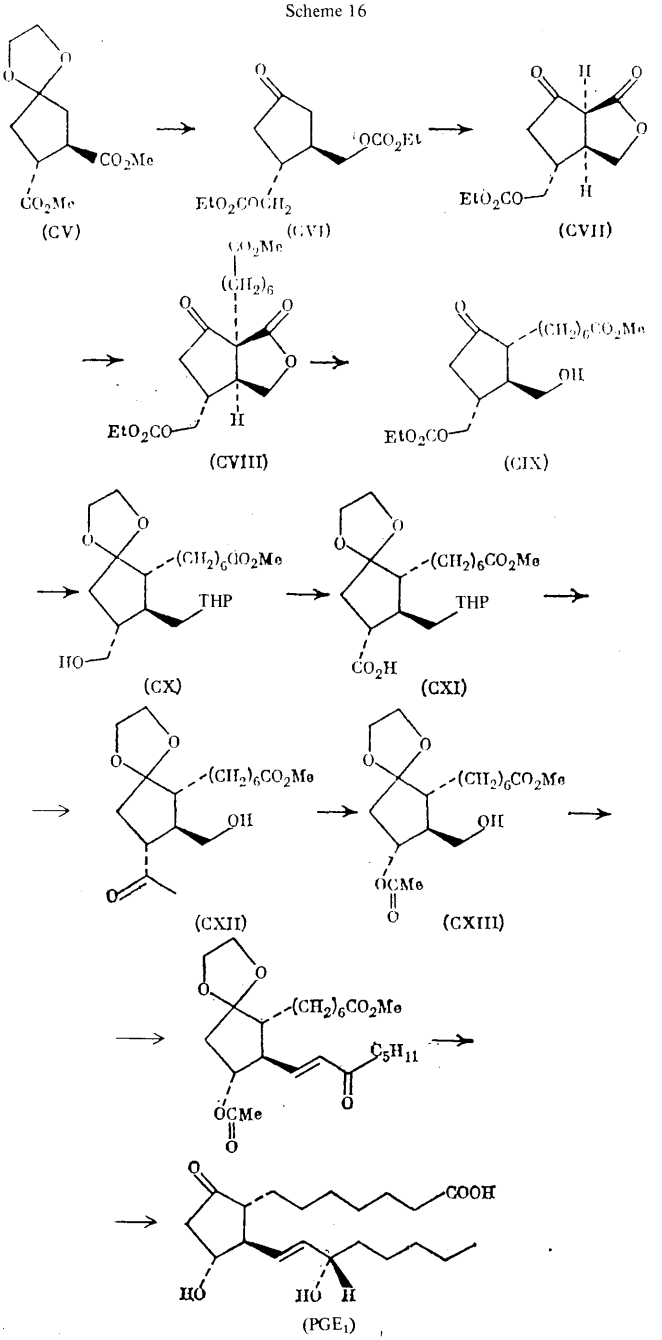
PGE_1 is obtained analogously by treating compound (XCVI) with a mixture of HCOOH and H_2O_2.

Scheme 14



Subsequent studies showed[87–90] that, among all the approaches to the synthesis of PG via the bicyclo[3.1.0]hexane system, the best results have been obtained when the stage involving the transition from compound (XCVI) to PG was modified. Thus the hydroxylation of compound (XCVI) with OsO_4 leads to two glycols (XCIX) and (C) in approximately equal amounts[87]. The conversion of the less polar glycol (XCIX) into its bismethanesulphonate with subsequent solvolysis in a 2:1 acetone–water mixture leads to the ethyl ether of (±)-PGE_1 [17–18% relative to the glycol (XCIX)] and 19% of the ethyl ether of (±)-15-epi-PGE_1. The more polar glycol (C) produces a 19% yield of the ethyl ether of (±)-PGE_1 and a 16–17% yield of the ethyl ether of 15-epi-PGE_1.

PGE_3, (±)-PGE_2, $PGF_{2\alpha}$, and $PGF_{2\beta}$ have been obtained under the same conditions[88-90].

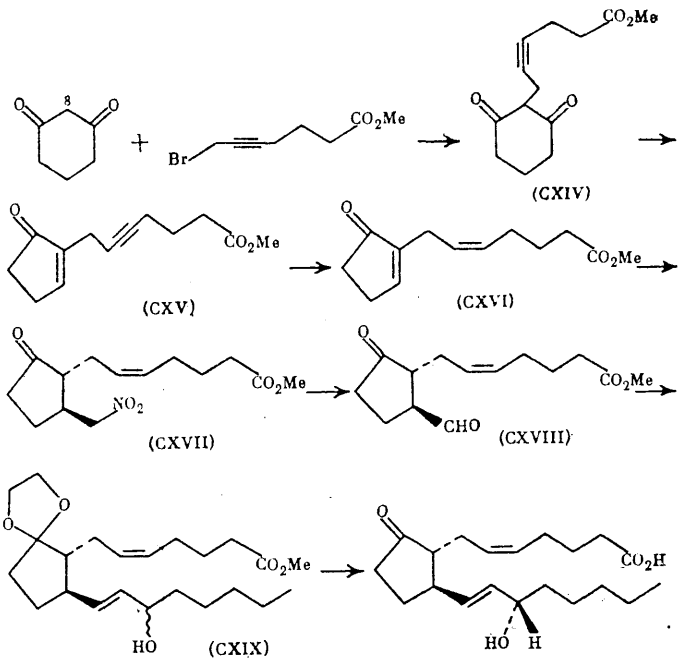


An interesting method for the opening of the cyclopropane ring has been proposed by a group of investigators[91-94]. In the stereoselective synthesis of PGA_2,[88] the cyclopropane ring in the key compound (CI) is readily opened by thiophenol in the presence of t-BuOK to give compound (CII). Subsequent oxidation with m-$ClC_6H_4CO_3H/CH_2Cl_2$ and reductive rearrangement of the sulphide (CII) by trimethyl phosphite in methanol lead to the hydroxyester (CIII). The alkylation of compound (CIII) with subsequent retro-Dieckman cyclisation give rise to the ketoester (CIV), which yields PGA_2 after hydrolysis and oxidation (Scheme 15).

Scheme 15

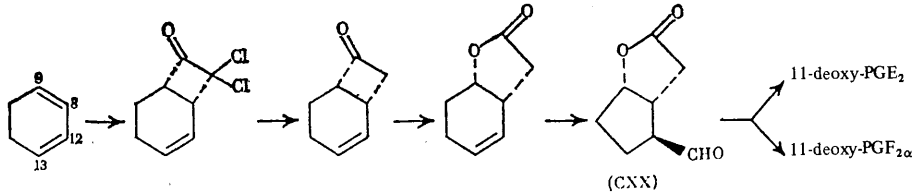
The syntheses of PGE_1, 11-deoxy-PGE_2, and 11α-hydroxymethyl-PGE_2 [95-97] from a symmetrical key compound, namely 3,4-dimethoxycarbonylcyclopentanone ethylene ketal (CV), obtained by the dimerisation of dimethyl maleate, has been proposed. The reduction of the ester groups in compound (CV) to alcoholic groups with $LiAlH_4$ and subsequent treatment with $ClCO_2C_2H_5$ in pyridine and then with aqueous toluene-p-sulphonic acid lead to the ketone (CVI), whose treatment with t-BuOK affords the lactone (CVII). Alkylation of the latter with methyl 7-iodoheptanoate in the presence of t-BuOK leads to the lactone (CVIII). Refluxing of compound (CVIII) in aqueous dioxan with Na_2HPO_4 and subsequent conversion into an acetal by the ethylene glycol/toluene-p-sulphonic acid mixture make it possible to obtain the corresponding hydroxyketal (CIX). Protection, alkaline hydrolysis, and transesterification with ethereal CH_2N_2 of compound (CIX) lead to the formation of the alcohol (CX), which is oxidised with CrO_3 in pyridine to the acid (CXI). On treatment with $(COCl)_2$ and condensation with Me_2CuLi, the potassium salt of the acid (CXI) is converted into the methyl ketone (CXII), whose oxidation with CF_3CO_3H/Na_2HPO_4 in CH_2Cl_2 leads to the acetate (CXIII). The latter is converted into dl-PGE_1 on oxidation of the hydroxymethyl group to the aldehyde group followed by its Wittig condensation with the corresponding phosphorane $(n\text{-}C_4H_9)_3P{=}CH{-}CO{-}C_5H_{11}$, the reduction of the oxo-group at the C(15) atom to the hydroxy-group, and the removal of the acetal protective group (Scheme 16).

Scheme 16



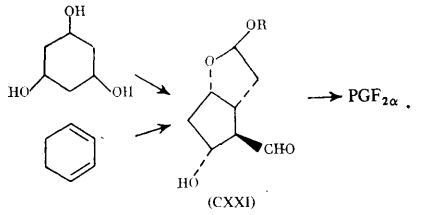
4. Synthesis Using Methods for Ring Contraction and Expansion

Bagli and Bogri[98] were the first to use the ring contraction method for the construction of the prostane ring in the synthesis of (±)-11-deoxy-PGE_1, PGE_2, and their C(15)-epimers in accordance with Scheme 17.



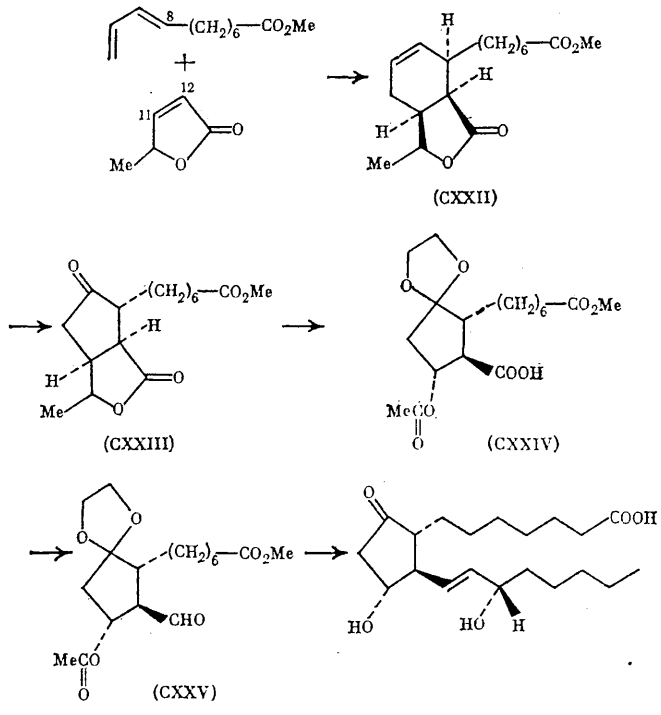
Cyclohexane-1,3-dione interacts with the methyl ester of 7-bromohept-5-ynoic acid in the presence of sodium hydride in DMF to form compound (CXIV). When the latter is treated with t-BuOCl and sodium carbonate, a rearrangement gives rise to compound (CXV), whose reduction with hydrogen (in the presence of the Lindlar catalyst) leads to the *cis*-olefin (CXVI) and the latter reacts with nitromethane in methanol in the presence of sodium methoxide to form the nitroketone (CXVII). Its treatment with sodium methoxide and subsequent hydrolysis with dilute H_2SO_4 (the Nef reaction) results in the formation of the aldehyde (CXVIII), whose condensation with the corresponding phosphonate and subsequent reduction of the C=O group at C(15) to the alcoholic group and the removal of the acetal protective group lead to 11-deoxy-PGE_2.

A similar ring contraction method was later employed to synthesise $PGF_{2\alpha}$.[99,100]



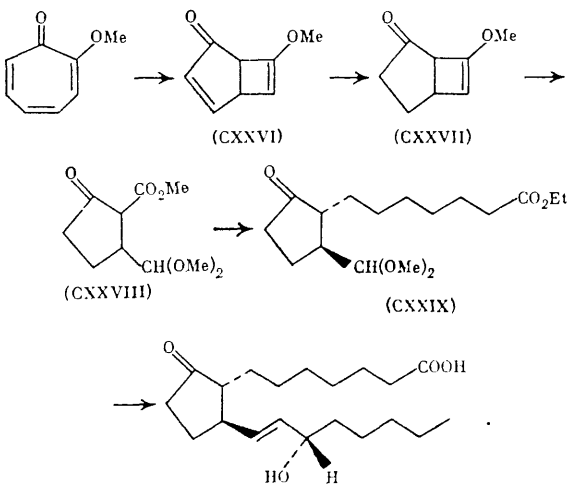
Scheme 17

Corey's approach[101] to the synthesis of 11-deoxy-PGE_2 and $PGF_{2\alpha}$ involves the contraction of the cyclohexa-1,3-diene ring and includes the following stages: (1) treatment with dichloroacetic acid in the presence of $(C_2H_5)_3N$; (2) reduction with Zn/AcOH; (3) oxidation with H_2O_2/H_2O–AcOH; (4) rearrangement under the influence of $Tl(NO_3)_3$ and oxidation with H_2O–$HClO_4$, $NaClO_4$ to the aldehyde (CXX), which is subsequently converted by standard methods into 11-deoxy-PGE_2 and 11-deoxy-$PGF_{2\alpha}$.



Syntheses have been described where *cis*-cyclohexane-1,3,5-triol[102] and cyclohexa-1,3-diene[103] are used as the starting materials for the synthesis of the key aldehyde (CXXI), which is readily converted into $PGF_{2\alpha}$:

An unusual solution of the problem of the synthesis of PGE_1 [104] consists in the Diels–Alder reaction between the methyl ester of undeca-8,10-dienoic acid and β-angelica lactone, leading to the *cis*-lactone (CXXII), which is oxidised with O_3 in CH_2Cl_2 and then with H_2O_2 in acetic acid to the lactone derived from the cyclopentanone (CXXIII), whose conversion into the acetal and alkaline hydrolysis lead to a lactonoacid, whose lactone ring is opened by a series of reactions to give the acid (CXXIV). It was found that the conversion of the carboxy-group into the aldehyde group without involving the methoxycarbonyl group at C(1) (Scheme 18) is impossible and the acid (CXXIV) was therefore reduced in the form of the acylimidazole derivative with $AlH(OBu\text{-}t)_3$ to the aldehyde (CXXV), which was subsequently converted by standard methods into PGE_1 in a yield higher than 50%.

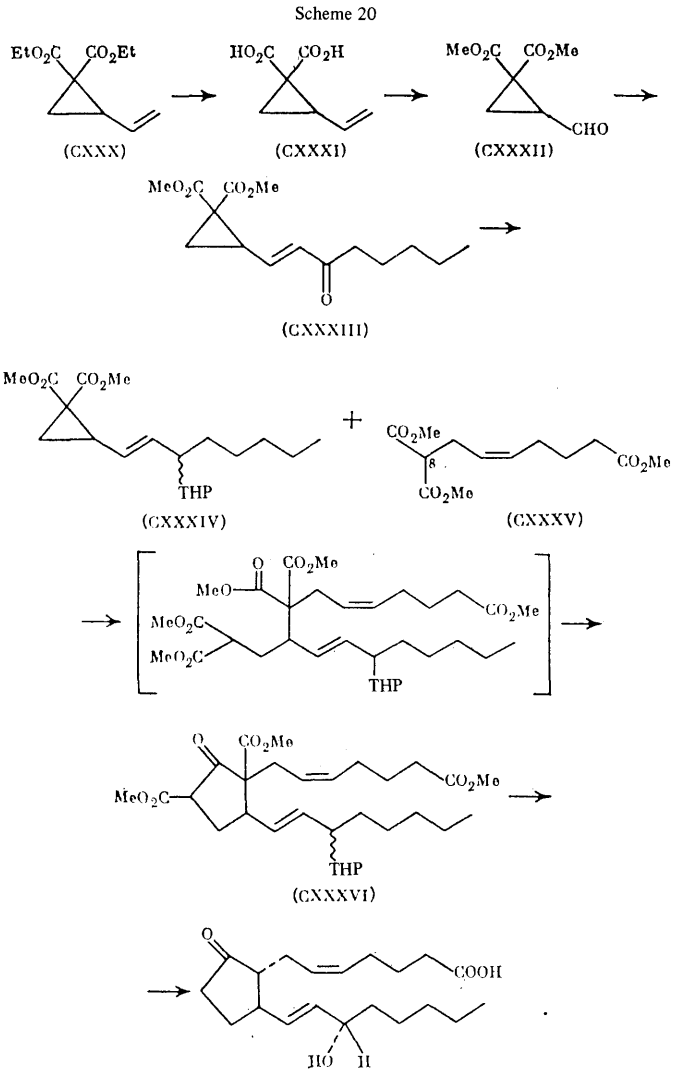


Scheme 18

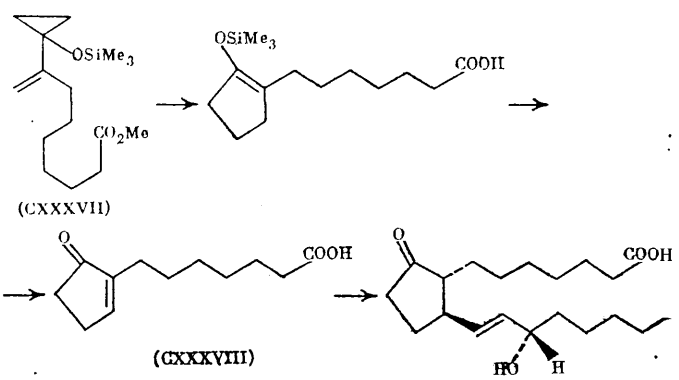
The capacity of the methyl ether of α-tropolone for ring contraction on photochemical valence tautomerisation has been used successfully in the synthesis of *dl*-11-deoxy-PGE_1.[105]

The methyl ether of α-tropolone is irradiated with the light of a high-pressure mercury lamp to form 7-methoxybicyclo[3.2.0]hepta-3,6-dien-2-one (CXXVI), which is hydrogenated over platinum to compound (CXXVII). The latter is subjected to ozonolysis in a mixture of CH_2Cl_2 and methanol, the product is treated with liquid SO_2, and cyclopentanone acetal (CXXVIII) is obtained. The latter is alkylated with ethyl 7-iodoheptanoate in the presence of KH/DMSO with subsequent decarboxylation to the *trans*-cyclopentanone (CXXIX). The acetal group is removed and compound (CXXIX) is condensed with the corresponding phosphonate. After a series of simple operations, *dl*-11-deoxy-PGE_1 is isolated (Scheme 19).

Scheme 19



A number of syntheses of PG involve as the key stage the ring expansion reaction of cyclopropane derivatives. Thus an effective synthesis of *dl*-11-deoxy-PGE_2 and its C(15)-epimer is based on the familiar reaction in which the diethyl ester of 1-vinylcyclopropane-2,2-dicarboxylic acid (CXXX) is converted into 2,3-diethoxy-carbonyl-3-vinyl-1-cyclopentanone on treatment with sodiomalonic ester[106,107].



(±)-2-Vinylcyclopropane-1,1-dicarboxylic acid (CXXXI), obtained by alkaline hydrolysis from compound (CXXX), is resolved into its optical isomers with the aid of brucine; (−)-(CXXXI) is esterified with CH_2N_2 to the dimethyl ester, which is converted by ozonolysis and subsequent decomposition of the resulting ozonide with Me_2S into the aldehyde (CXXXII).

The condensation of the latter with $(MeO)_2P(O)CH_2CO.C_5H_{11}$-n leads to compound (CXXXIII), which is reduced with $NaBH_4$ to a mixture of the epimeric alcohols, whose THP ethers (CXXXIV) are allowed to react with the methyl ester of *cis*-hept-3-ene-1,1,7-tricarboxylic acid (CXXXV) in the presence of sodium methoxide with formation of compound (CXXXVI). The subsequent removal of the protective group, hydrolysis with alkali, and chromatographic separation of the epimers lead to 11-deoxy-PGE_2 in a yield up to 68% (Scheme 20):

Scheme 20

The rearrangement of the trimethylsilyl derivative of the cyclopropanol (CXXXVII) to the cyclopentanone (CXXXVIII), which is a key product in the synthesis of 11-deoxy-PGE_1, has been described[108]:

A series of new approaches to the synthesis of PG, for example, on the basis of a photochemical method, have been described in recent years[109-112]. (±)-$PGF_{2\alpha}$ has been synthesised in this way using the photolysis of a bicyclic cyclobutanone to give a γ-lactol as the key stage[109].

A synthesis of $PGF_{2\alpha}$ via carbopalladisation involving a small number of stages has been achieved[113]. The key reaction is that between cyclopentenyldimethylamine, obtained by the addition of HCl to cyclopentadiene followed by treatment with dimethylamine, and lithium tetrachloropalladate and sodiomalonic ester.

A new direct method for the conversion of castor oil into PGH_1 has also been developed[114].

However, the above approaches to the synthesis of PG have not found extensive applications.

Studies designed to obtain PG analogues, which are synthetically more readily available than natural PG and which have the same and in certain cases a higher or comparable biological activity, have been developing vigorously in recent years.

The search for synthetic analogues of PG is also dictated by other causes. In the study of the action of PG on the human organism, undesirable side effects are frequently observed (a deficiency of natural PG as therapeutic agents is the short time of their action, which necessitates frequent repeated administration of the preparations). Preparations whose structure if close to that of natural PG but which act more selectively on individual systems and functions of the organisms and are more stable, less toxic, and better tolerated by man are therefore being sought.

After the preparation of the review for publication, a number of communications on the same subject were published[115–129].

Negative Temperature Coefficient in Chemical Reactions

I.A.Leenson and G.B.Sergeev

A systematic analysis of reactions whose rate decreases with increase of temperature is presented. The possibility of a negative temperature coefficient in the elementary reactions is examined from the standpoint of the transition state theory and of collision theory. The mechanisms of complex reactions in which the temperature dependence of the rate is anomalous are discussed, and possible reasons for the anomaly are examined.
The bibliography contains 175 references.

I. INTRODUCTION

Temperature is one of the most important factors affecting the rate of chemical reactions. The temperature range of chemical reactions in nature is very great: from a few tens of degrees Kelvin in interstellar clouds to thousands of degrees in flames, electrical discharges, etc. We need means of calculating the rates of processes at temperatures where experimental measurements are difficult or impossible. One usually assumes that if the rate constant measured at room temperature is very high (equivalent to 10% or more of the collision frequency) the activation energy is close to zero, and the rate of the reaction is almost independent of temperature. However, often this assumption is an oversimplification, and in many cases it is simply not true[1]. This can have serious consequences when attempts are made to extrapolate experimental results over a wide temperature range.

For most reactions the rate increases with temperature according to the Arrhenius equation

$$k=A\exp(-E_a/RT), \qquad (1)$$

where k is the rate constant, A is the pre-exponential factor, and E_a is the experimentally determined activation energy. However, there are many reactions whose rate decreases with increase of temperature, in obvious contradiction of the Arrhenius equation. There have been no attempts so far to discuss systematically the reactions which have a negative temperature coefficient (NTC) and to analyse the causes of the phenomenon, yet the need for such a review is urgent, both from the theoretical and from the practical point of view. Thus the rate of a reaction with a NTC could decrease very considerably on raising the temperature. A process which is predominant at moderate temperatures may be replaced (partially or fully) by competing processes with normal temperature coefficients. Conversely, a decrease in temperature should cause greater selectivity towards these reactions, and this may be important both under laboratory and under industrial conditions.

The NTC phenomenon is of interest also in astrophysics and in the physics and chemistry of the upper atmosphere, because the rate of reaction in those environments could increase by many orders of magnitude when the temperature

is lowered by hundreds of degrees[2]. Evidently, allowance for these anomalous temperature effects is needed, for example, in models of processes in interstellar clouds, of the reactions involved in the destruction of ozone in the stratosphere, etc.

Reactions with NTC are of interest also in chemical reaction theory, since many of their features are incompatible with classical chemical kinetics (collision theory and transition state theory). Therefore an analysis of these reactions could be important as a test of the theory of elementary chemical reactions, of exact or semi-empirical methods of calculating the dynamics of molecular interactions, etc.

Lastly, we note that in chemical kinetics a knowledge of the formal parameters of the rate equation (for example, the order with respect to each of the reactants) is very important in establishing the mechanism of the reaction. The detection of a NTC and the study of its origin can give valuable information on the reaction mechanism. However, it is important to remember that the NTC phenomenon could be due to the reaction itself (i.e. to its mechanism) or it could be merely a manifestation of "external" factors (an increase in the concentration of reactants caused by a decrease in temperature of the solution, the temperature dependence of the physicochemical properties of the solvent, etc.). These topics also will be discussed in this review.

A NTC was first reported for the termolecular reaction $2NO + O_2 \rightarrow 2NO_2$: together with a few similar reactions; this was treated as a rare exception, especially since the temperature coefficient was small in absolute value. However, mainly as a result of the development of sensitive new methods for monitoring the kinetics of fast reactions and of various methods for generating active species[3], the number of gas-phase reactions in which the temperature dependence of the rate is anomalous has increased in recent years. The number of reactions of this type discovered in the liquid phase and studied by traditional methods has also increased. This review will be concerned mainly with studies of the NTC published during the last 10 years, but we shall also discuss some of the older work to give the reader a more balanced view of the problem, since there are no suitable bibliographies.

II. THEORETICAL VIEWS ON THE NATURE OF THE NEGATIVE TEMPERATURE COEFFICIENT IN SIMPLE REACTIONS

1. Formal Methods of Describing the Temperature Dependence of the Rate of Chemical Reactions

In 1889 Arrhenius proposed an empirical equation to describe the temperature dependence of the rate constant of chemical reactions [Eqn.(1)]. The equation had an enormous success and became one of the fundamental equations of physical chemistry, for at least two reasons. Firstly, the vast majority of experimental data could successfully be fitted to a straight line in the Arrhenius coordinates ($\ln k$, $1/T$). As recently at the 1950's it was stated that "there are no data on unimolecular or bimolecular reactions which cannot be described by the Arrhenius equation within likely experimental error[4]". Secondly, the development of the theory of absolute reaction rates (the "activated complex" or "transition state" theory)[5] has given a clear physical meaning to the empirical parameters A and E_a.

Most of the early kinetic measurements were confined to a narrow range of temperature, for which the parameters (A and E_a) of Eqn.(1) can be treated as temperature-independent. It was difficult to encompass a wider temperature range because the conventional kinetic methods could not be used to measure rates differing by more than two orders of magnitude. For example, it was recently assumed[6] that the minimum error in the determination of the activation energy for the addition of atoms and radicals to alkenes, alkynes, and arenes in the gas phase was 4–8 kJ mole^{-1}, with a corresponding error in A between 0.6 and 1.2 litre mole^{-1} s^{-1} at 350 K. (The method of calculating mean values and standard errors of the rate constants and of their temperature dependence are discussed in Ref.7.) In many cases the reaction kinetics could be described by Eqn.(1) only because of the low precision of the determination of the rate constants and of the relatively narrow temperature range.

Improved techniques in experimental kinetics led to more precise values of the rate constants over a wider temperature range (by up to an order of magnitude). In some cases Eqn. (1) was found to apply over the extended temperature range. The "record" in this respect can be claimed by the reaction of hydrogen atoms with ethane, which obeys the Arrhenius relationship between 330 and 1350 K.[8] However, in many other reactions the Arrhenius equation was not applicable, especially in some gas-phase exchange reactions and in dissociation and recombination reactions[9]. Indeed, it has been suggested[9] that improvements in experimental techniques and theoretical developments will force us to consider not why some Arrhenius plots are curved but the very opposite problem: why so many experimental Arrhenius plots are found to be rectilinear.

The experimentally observed failure (or near-failure) of Arrhenius equation to describe various types of reaction may be due to the following factors.

1. In reactions with low or vanishingly small activation energies (or, in general, for $E_a \ll RT$) the temperature dependence of the rate constant is mainly (or even wholly) determined by the temperature dependence of the pre-exponential term A, whereas in reactions with a high activation energy the dependence of A on temperature is almost totally masked by the exponential term in the Arrhenius equation. As a result the formal application of Eqn.(1) gives a curvilinear plot, and the E_a value determined over a limited range of temperature cannot be identified with the true activation energy[10].

2) The parameter A in Eqn.(1) is not constant over a wide range of temperature, introducing a curvature into the plot of $\ln k$ against $1/T$ for any activation energy. This problem is reviewed in detail for reactions in the gas phase in Ref.9, and more generally in Ref.11, which discusses the temperature dependence of the "experimental" activation energy.

3) The Arrhenius equation assumes that the temperature of the system is uniquely defined and can be measured during the reaction. This assumption is valid if the translational and rotational degrees of freedom of the molecules are in equilibrium (or nearly so), i.e. if T is the thermodynamic equilibrium temperature. In real systems this condition is not always met, especially in the reactions taking place at high temperatures behind the front of a shock wave, in an electric arc, etc. At low temperatures deviations from the equilibrium distribution are found in fast reactions, for example in some reactions between ions and neutral molecules[12]. In these cases the rate of the process is a function of the quantum states and of the velocities of the reacting particles, and a special approach is needed[13].

In a wider range of reactions the formal application of Eqn.(1) leads to negative values of the activation energy E_a, from −1 to −40 kJ mole^{-1} or more. The statistical interpretation of the activation energy as the difference between the average energies of the activated and of the non-reacting molecules[14] formally allows the activation energy to be

negative. However, it is almost inconceivable that the activated molecules could contain less energy than the non-reacting molecules, since the activation process consists in raising the energy of a particle with respect to its normal state[15]. For this reason many workers have stated (in different ways) that a negative activation energy is physically meaningless, at least in the case of an elementary bimolecular reaction[1,2,15–19]. It is therefore preferable to use the concept of a NTC than to attempt to define a negative activation energy.

The failure of the Arrhenius equation to describe an increasing number of systems has stimulated a search for other mathematical relationships between the rate constant and the temperature of reactions. The best known is the three-parameter equation[20]

$$k=AT^n \exp(-E_a/RT) \qquad (2)$$

or

$$\ln k=A'+n \ln T-E_a/RT, \qquad (2a)$$

The three-parameter equation is theoretically justified[11] (the collision theory giving $n = 1/2$ and the transition state theory giving $n = 1$), but its application requires very precise measurements of the rate constants over a wide temperature range[7].

A simplified form of Eqn.(2) is often used for reactions with small, zero, or "negative" values of the activation energy:

$$k=A(T/T_0)^n , \qquad (3)$$

where T_0 is an arbitrary fixed temperature (for example, 298 K). In reactions with a NTC the parameter n is negative in Eqns.(2) and (3). In many systems a linear plot of $\ln k$ against $\ln T$ was obtained by Eqn.(3) over a wide range of temperature (up to 500 K), whereas in Arrhenius coordinates the plot was not linear[2].

A four-parameter $k(T)$ dependence has also been proposed[21] ($k = A \cdot \exp(-B/T) + C(T/T_0)^n$), as well as a polynomial in powers of temperature[11]. However, these equations have not been widely used, partly because of their excessive formality and partly because of the difficulties encountered in determining their parameters exactly and interpreting them physically.

Some workers have used an alternative presentation of their results: for example, by Eqns.(1) and (3) simultaneously. Often the same experimental data are described equally well by different types of equation. As an example we may quote a series of gas-phase reactions involving the t-butyl cation, which were shown[22] to obey Eqn.(3) with $n = -3$ between 190 and 570 K. In order to establish the extent to which the validity of Eqn.(3) excludes Eqn.(1), i.e. the existence of an activation energy, the authors[22] re-calculated their results by Eqn.(2a) for different assumed values of E_a, and for each E_a they chose the value of n which gave the best agreement with experiment. For $E_a > 8$ kJ mole^{-1} agreement could not be obtained with any combination of the parameters, but for $E_a = 8$ kJ mole^{-1} agreement was obtained with $n = -6$. This means that if these reactions have an activation energy it must be small. The choice of the correct equation for the temperature dependence of the rate constant is relatively unimportant for interpolation of experimental data within the experimental temperature range, but it becomes important if the data have to be extrapolated over a wider range of temperature.

2. The Negative Temperature Coefficient in the Transition State Theory

The theory of the transition state was developed for bimolecular gas-phase reactions[5]. Various mechanism are possible for the elementary act of bimolecular reactions (rebound, direct dislodgment, stripping, or pick-up)[23,24]. In the transiton state theory only a rebound mechanism of the A + BC → [A...B...C]$^{\neq}$ → AB + C type is usually considered. Let us examine the possibility of a NTC in a reaction of this type.

We should note first of all that a NTC is unusual in an elementary bimolecular reaction[25]. Most bimolecular processes have a significant activation energy, i.e. the temperature dependence of the reaction rate is determined by the exponential term in the canonical equation of the transition state theory:

$$k = \kappa \frac{k_B T}{h} \left(\frac{Q^{\neq}}{Q_A Q_B}\right) e^{-\frac{E_0}{RT}} , \qquad (4)$$

where κ is the transmission coefficient of the activated complex through the energy barrier E_0, k_B is Boltzmann's constant, h is Planck's constant, and $Q^{\neq}$, Q_A, and Q_B are the full partition functions for the activated complex and the initial reactants. If $E_0 \gg RT$ the temperature dependence of the pre-exponential term can be ignored. In the opposite limit ($E_0 \ll RT$) the temperature dependence of the reaction is determined by the ratio of the partition functions. In intermediate cases ($E_0 \cong RT$) both terms make a contribution, and a more complex temperature dependence of the reaction rate can be expected.

In the transition state method any inaccuracy in the choice of the activation barrier has a much stronger effect on the calculated rate constants than the uncertainty in the geometric parameters of the activated complex, which are used to calculate the partition functions. Therefore the transition state method is used only to calculate the pre-exponential factor in the Arrhenius equation[24]. Let us consider the cases in which a NTC can be expected, and its likely magnitude.

Obviously, a NTC in a bimolecular reaction can be expected only through the temperature dependence of the pre-exponential term in Eqn.(4), which is determined by the ratio of partition functions on the assumption that $\kappa = 1$. Usually the contribution from nuclear and electronic terms can be ignored, and the translational, rotational, and vibrational partition functions per degree of freedom can be expressed by the equations[5]

$$q_t = (2\pi m k_B T)^{1/2}/h, q_r = (8\pi^2 I k_B T/\sigma h^2)^{1/2},$$

and

$$q_v = [1 - \exp(-h\nu/k_B T)]^{-1}$$

It follows from these formulae that $q_t \propto T^{1/2}$ and $q_r \propto T^{1/2}$ always, whereas $q_v \propto T^0$, i.e. it is independent of temperature, for high-frequency vibrations and low temperatures ($h\nu \gg k_B T$), and $q_v \propto T$ for low-frequency vibrations and (or) high temperatures ($h\nu \ll k_B T$). Thus the result depends both on the vibration frequency and on the temperature[26]. For example, at 80 K $q_v \cong 1$ for practically all the frequencies of molecular vibrations, whereas at 300 K $q_v = 1.0000005$ for $\nu = 3000$ cm^{-1}, 1.008 for $\nu = 1000$ cm^{-1}, and 1.097 for $\nu = 500$ cm^{-1}, so that the error caused by assuming $q_v \cong 1$ is greater than 10% only for frequencies lower than 500 cm^{-1}. In molecules of moderate complexity the number of low-frequency vibrations is small, and therefore the q_v value begins to deviate significantly from 1 only at high temperatures, where the condition $k_B T \ll h\nu$ is not satisfied.

The ratio $Q^{\neq}/Q_A Q_B$ has been determined[27], together with the temperature dependence of the pre-exponential, for some bimolecular reactions with different configurations of the reactants in the activated complex. It was assumed in the calculations that the formation of the activated complex is

accompanied by the loss of three translational degrees of freedom in one of the reactants and by the appearance of new vibrational degrees of freedom, including one in the direction of the reaction coordinate. This low-frequency vibration is responsible for the appearance of the factor k_BT/h in formula (4). It is also assumed that the reactants and the activated complex can rotate as a single entity: for example, in the reaction between an atom and a linear molecule with a linear activated complex two rotational degrees of freedom (each) from the reactants and the complex cancel.

Table 1. Temperature dependence of the pre-exponential factor A for different types of bimolecular reaction.

No.	Reactants and activated complex*	A	$A(T)$	
			$h\nu \gg k_BT$	$h\nu \ll k_BT$
1	A + A → (AK)$_{lin}$	$(k_BT/h)\,(q_t^2/q_t^3)$	$A \sim T^{1/2}$	$A \sim T^{1/2}$
2	A + M$_{lin}$ → (AK)$_{lin}$	$(k_BT/h)\,(q_V^2/q_t^3)$	$A \sim T^{-1/2}$	$A \sim T^{3/2}$
3	A + M$_{lin}$ → (AK)$_{non\text{-}lin}$	$(k_BT/h)\,(q_Vq_r/q_t^3)$	$A \sim T^0$	$A \sim T^1$
4	A + M$_{non\text{-}lin}$ → (AK)$_{lin}$	$(k_BT/h)\,(q_V^3/q_t^3q_r)$	$A \sim T^{-1}$	$A \sim T^2$
5	A + M$_{non\text{-}lin}$ → (AK)$_{non\text{-}lin}$	$(k_BT/h)\,(q_V^2/q_t^3)$	$A \sim T^{-1/2}$	$A \sim T^{3/2}$
6	M$_{lin}$ + M$_{lin}$ → (AK)$_{lin}$	$(k_BT/h)\,(q_V^4/q_t^3q_r^2)$	$A \sim T^{-3/2}$	$A \sim T^{5/2}$
7	M$_{lin}$ + M$_{lin}$ → (AK)$_{non\text{-}lin}$	$(k_BT/h)\,(q_V^3/q_t^3q_r)$	$A \sim T^{-1}$	$A \sim T^2$
8	M$_{lin}$ + M$_{non\text{-}lin}$ → (AK)$_{lin}$	$(k_BT/h)\,(q_V^5/q_t^3q_r^3)$	$A \sim T^{-2}$	$A \sim T^3$
9	M$_{lin}$ + M$_{non\text{-}lin}$ → (AK)$_{non\text{-}lin}$	$(k_BT/h)\,(q_V^4/q_t^3q_r^2)$	$A \sim T^{-3/2}$	$A \sim T^{5/2}$
10	M$_{non\text{-}lin}$ + M$_{non\text{-}lin}$ → (AK)$_{lin}$	$(k_BT/h)\,(q_V^6/q_t^3q_r^4)$	$A \sim T^{-5/2}$	$A \sim T^{7/2}$
11	M$_{non\text{-}lin}$ + M$_{non\text{-}lin}$ → (AK)$_{non\text{-}lin}$	$(k_BT/h)\,(q_V^5/q_t^3q_r^3)$	$A \sim T^{-2}$	$A \sim T^3$

*Symbols. A is an atom, M$_{lin}$ and M$_{non\text{-}lin}$ are linear or non-linear molecules, AK is the activated complex.

The results of the calculation and estimates of possible temperature dependences of the pre-exponential are given in Table 1. We note that an inverse temperature dependence of the pre-exponential is theoretically possible, and that the effect is most marked for reactions at moderately high temperatures involving complex molecules giving a non-linear activated complex without low-frequency vibrations, i.e. for $h\nu \gg k_BT$. Under these conditions the exponent in Eqns.(2) and (3) becomes† $n = -2$. If Eqn.(3) is used to describe the temperature dependence of the reaction rate the negative values of n obtained according to Table 1 are easily converted into "negative activation energies" by the formula $E_a = nRT$.

Thus according to the transition state theory the magnitude of the NTC should increase as the temperature increases. The maximum possible NTC at 300 K ($n = -2$) corresponds to $E_a = -5$ kJ mole^{-1}, and therefore the presence of even a small activation barrier can fully compensate the inverse temperature dependence of the pre-exponential. Hence according to transition state theory a NTC can be expected for bimolecular reactions with a small (or zero) activation energy (for example, reactions involving free radicals). From the standpoint of the transition state theory the NTC phenomenon has been analysed for the addition of OH$^\cdot$ radicals to unsaturated compounds[28,29] as well as the addition of oxygen atoms[1] and other atoms and radicals[6], and for the reaction of NO with BrO$^\cdot$ [30] and with $CH_3OO^\cdot$.[31]

† Case 10 in Table 1, which gives $n = -2.5$, is hardly likely to be realisable in practice.

The formulae in Table 1 give only an approximate estimate of the pre-exponential because of the incorrectly assumed equality of the partition functions of the reactants and of the activated complex[32]. The change in the vibrational partition functions accompanying the formation of the activated complex was allowed for in an analysis[32] of the temperature dependence of the steric factor in the expression $A = Pz$, where A is the pre-exponential terms P is the steric factor, and z is the frequency factor: it was found that for simple unimolecular reactions the parameter P is only weakly temperature-dependent. For example, in the decomposition of ethane P increases approximately 10-fold when the temperature is increased from 300 to 400 K, but the effect is completely masked by the increase of 2^{10} in the Boltzmann factor.

For bimolecular reactions the dependence of the steric factor on temperature was found to be

$$\mathrm{d}\ln P/\mathrm{d}T = -3{,}5/T - (h^2c^2/k_B^2T^3) \times \times \sum \{\nu_i^2 \exp(h\nu_i/k_BT)/[\exp(h\nu_i/k_BT) - 1]^2\} \quad (5)$$

where ν_i are the vibration frequencies, and terms in the summation appear with the "plus" or "minus" sign according to whether they refer to the reactants or to the activated complex. Thus a negative temperature coefficient of the steric factor is a characteristic feature of bimolecular reactions. In replacement reactions at $T > 273$ K the second term in formula (5) can be ignored, so that $\mathrm{d}\ln P/\mathrm{d}T = -3.5/T$, i.e. $P \propto T^{-3.5}$. The frequency factor varies with temperature according to the law $z \propto T^{1/2}$, and therefore in this type of reaction we expect $A \propto T^{-3}$.

When analysing the temperature dependence of $Q^{\neq}/Q_AQ_B$ we must also allow for possible internal rotations in the reactants and in the activated complex. Several gas-phase reactions between ions and neutral molecules have been examined from this standpoint[2,22,26,33,34]. In the expression for the ratio of the full partition functions only the q_V values corresponding to vibrational degrees of freedom unchanged by the transition from the reactants to the activated complex were retained. However, the initial molecules may have internal rotational degrees of freedom (for example, the rotation of methyl groups). The formation of the activated complex converts some of the internal rotations of the reactants into torsional vibrations of the complex, which contribute an additional term to the temperature dependence of the pre-exponential.

The following expression has been obtained[26] for the temperature dependence of the rate constant:

$$k = CT \frac{(T_t^{\neq})^{3/2}(T_r^{\neq})^{j/2}}{\prod_i (T_t)_i^{3/2}(T_r)_i^{j/2}} T_{\text{int.rot.}}^{\Delta r/2} \exp(-E_0/RT) \quad (6)$$

where C includes the temperature-independent terms, Δr is the total number of new internal rotations, i.e. the difference between the number of new internal rotational degrees of freedom in the activated complex and the number of frozen internal rotational degrees of freedom in the reactants, $j = 0$ for atom reactions, $j = 2$ for linear molecules, and $j = 3$ for non-linear molecules, and the subscript to T indicate the origin of the various temperature terms. It is assumed (to simplify the problem) that the torsional vibrations of the activated complex produced by the suppression of the internal rotations have a fairly high frequency and do not contribute significantly to the temperature dependence of the rate constant: for this reason Eqn.(6) does not include explicitly a term for this vibration. For the opposite assumption each low-frequency torsional vibration would contribute a temperature-dependent term, and in the limit of $\nu \to 0$ we would obtain the $q_V \propto T$ dependence.

The temperature dependences of the pre-exponential factor calculated with the above assumptions for bimolecular reactions of atoms and molecules with different configurations of the reactants and of the activated complex are given in Table 2. Unlike the data in Table 1, those in Table 2 show that the absolute value of the NTC depends on the complexity of the reacting molecules. Thus the maximum NTC (for negative Δr) will be observed when the largest number of internal rotations in the reactant molecules is suppressed without forming new internal rotations in the activated complex. This can be expected in rigid activated complexes: in "loose" complexes the reactants retain their rotational degrees of freedom and the temperature dependence of the pre-exponential is weak. The parameter Δr can be calculated from experimental data. Thus the temperature dependence $k \propto T^{-3}$ mentioned above for the reaction of the t-butyl ion with isopentane[22] can be compared with the equation $k \propto T^{(\Delta r - 4)/2}$ (last line in Table 2), giving $(\Delta r - 4)/2 = -3$, and $\Delta r = -2$, which corresponds to the suppression of only two internal degrees of freedom in the activated complex. At the same time if a rigid activated complex is formed in the same system up to six internal rotational degrees of freedom can be frozen, and in general the model can be used to interpret experimental data without difficulty[22].

Table 2. Temperature dependence of the pre-exponential factor for bimolecular reactions allowing for the loss of internal rotations in the activated complex.

No.	Reactants and activated complex*	$A(T)$
1	$A + A \rightarrow (AK)_{lin}$	$A \sim T^{1/2}$
2	$A + M_{lin} \rightarrow (AK)_{lin}$	$A \sim T^{(\Delta r-1)/2}$
3	$A + M_{lin} \rightarrow (AK)_{non\text{-}lin}$	$A \sim T^{\Delta r/2}$
4	$A + M_{non\text{-}lin} \rightarrow (AK)_{lin}$	$A \sim T^{(\Delta r-2)/2}$
5	$A + M_{non\text{-}lin} \rightarrow (AK)_{non\text{-}lin}$	$A \sim T^{(\Delta r-1)/2}$

11	$M_{non\text{-}lin} + M_{non\text{-}lin} \rightarrow (AK)_{non\text{-}lin}$	$A \sim T^{(\Delta r-4)/2}$

*Symbols as in the footnote to Table 1.

Let us now examine termolecular reactions in terms of the transition state method. These reactions include the recombination of atoms and simple radicals. The NTC phenomenon was observed in the recombination of halogen atoms[35–40], in the reactions $H^{\cdot} + O_2 + M \rightarrow HO_2^{\cdot} + M$ [41] and $OH^{\cdot} + NO_2 + M \rightarrow HNO_3 + M$ (where M is any third body able to take up the excess energy),[42] and also in some processes accompanied by light emission in which electronically excited particles are first formed[43]. Some reactions involving NO have also been classified as termolecular[44,45]. Lastly, the termolecular mechanism probably applies to some reactions involving ions, for example $N^+ + N_2 + He \rightarrow N_3^+ + He$;[26] many of these reactions have a high NTC (see Refs. 46–48 for experimental data on their kinetics).

In termolecular reactions the total number of participating atoms is usually small, internal molecular rotations are usually absent, and the temperature dependence of the pre-exponential factor can be calculated as in Table 1. From the formulae thus obtained (Table 3) we note that the transition state theory predicts the possibility of a NTC for any termolecular reaction. There is no energy barrier to the recombination of atoms, and therefore according to the theory we can expect a NTC for these reactions in the form of Eqn. (3), with $n = -1$ or $n = -1/2$.

Table 3. Temperature dependence of the pre-exponential factor in termolecular reactions.

*Symbols as in the footnote to Table 1.

A stronger temperature dependence should be observed for reactions involving complex molecules. The maximum value ($n = -11/2$) of the NTC is found in case 11 of Table 3 for a zero activation energy and no low-frequency vibrations ($q_V \propto T^0$, i.e. it is independent of temperature). However, if a reaction of this type has a small positive activation energy the rate constant will go through a maximum[5,49]. The condition for a maximum in the function $T^n \exp(-E_0/RT)$ gives $T_{max} = -E_0/nR$. The greater the activation energy for a given n, the higher the temperatures at which a NTC will be observed. For example, for $n = -5$ and $E_0 = 8$ kJ mole^{-1} the NTC will be found at $T > 200$ K. In the presence of low-frequency vibrations, when q_V increases with temperature, the NTC effect may be compensated by the contribution from the vibrational partition functions. Thus we note from Table 3 that the q_V terms appear in the numerators of the formulae for the pre-exponential factor raised to a high power, so that the positive temperature dependence will increase steeply with temperature, as shown in Table 3 by the second limiting value (when $h\nu \ll k_BT$ and $q_V \propto T$).

We can allow for the low-frequency vibrations as follows[5,49]. Consider, for example, the reaction of three linear molecules with a non-linear activated complex (case 8 of Table 3, which can be realised by the reaction between NO and O_2). For this reaction Eqn. (4) becomes

$$k = \varkappa C T^{-7/2} \left\{ \prod_{j=1}^{11} [1 - \exp(-h\nu_j/k_BT)]^{-1} \Big/ \prod_{i=1}^{3} [1 - \exp(-h\nu_i/k_BT)]^{-1} \right\} \times \exp(-E_0/RT), \quad (7)$$

where the term C includes all the temperature-independent factors, the subscripts i denote the reactants, and j denotes the activated complex, in which 1 of 12 vibrational degrees

of freedom is converted into the reaction coordinate. Eqn. (7) can be re-written

$$\frac{d}{d(1/T)} \ln \{k\Pi [1-\exp(-h\nu_i/k_B T)]^{-1} T^{7/2} / \Pi [1-\exp(-h\nu_j/k_B T)]^{-1}\} = -E_0/R \quad (8)$$

Thus a plot of the polynomial

$$\ln k + \ln \Pi [1-\exp(-h\nu_i/k_B T)]^{-1} - \ln \Pi [1-\exp(-h\nu_j/k_B T)]^{-1} + {}^7/_2 \ln T$$

against reciprocal temperature should give a straight line of slope $-E_0/R$. This approach allows us to calculate the "true" activation energy from the experimental dependence of the rate constant on temperature[49,50]. The calculation assumes a knowledge of all the vibration frequencies in the initial molecules and in the activated complex.

In termolecular reactions involving complex molecules we can allow for the internal rotations of non-linear activated complexes as was done for bimolecular reactions. For example, in case 8 of Table 3 the addition of one free rotation to the activated complex converts the $T^{-7/2}$ term into T^{-3} in formula (8). If the initial molecules are diatomic the frequencies are high enough to make the corresponding q_V values independent of temperature, leading to a simplified form[49] of Eqn.(8):

$$\frac{d}{d(1/T)} \left\{ \ln k + 3 \ln T - \ln \prod_{j=1}^{\bar{r}} [1-\exp(-h\nu_j/k_B T)]^{-1} \right\} = -E_0/R \ .$$

Thus in the framework of the transition state method the conditions for the appearance of a NTC in simple bimolecular and termolecular reactions are the following: a small or zero activation energy (the NTC can be expected mainly in fast reactions[51]), the absence of low-frequency molecular vibrations, which produce compensation of the NTC for $h\nu \ll k_B T$, and the suppression of the internal rotations of the reactant molecules without forming new internal rotational degrees of freedom in the activated complex. More detailed discussions of problems in the activated complex theory are given in Refs.52–68.

The requirements on the activation energy must be examined specifically, because the conventional expression for the rate constant does not successfully predict the temperature dependence of the rate of reactions with a small or zero activation energy[55,56]. This has been demonstrated, for example, by analysing more than 60 elementary reactions in the gas-phase photochlorination of various compounds[54]. Several workers have pointed out[58] the shortcomings of the Rice–Ramsperger–Kassel (RRK) theory, which uses a model with a fixed activated complex to calculate the partition functions of the transition state in elementary reactions of the radical recombination type[59,60]. The limitations of the standard transition state theory when applied to reactions with a low or zero activation energy stimulated the development of new methods of calculation in which the position of the activated complex on the reaction coordinate is chosen near the maximum in the free energy rather than in the potential energy[55,57], or by using empirical parameters[61,62].

We should also note that the transition state theory and its corollaries are very sensitive to the assumed structure of the activated complex, especially in the case of low-frequency vibrations[9,30]. In many cases the experimental data can be described satisfactorily (including the appearance of a NTC) by postulating a set of "reasonable" parameters for the activated complex, but in other cases the observed inverse dependence of the reaction rate on temperature can only be explained by the transition state theory by ascribing unrealistic properties to the activated complex (for example, chemical bonds stronger than those of the initial molecules[1,67]). In these cases it is always assumed that the transmission coefficient in formula (4) depends on temperature[9,68].

Great care is needed[17,44] in applying the transition state theory to termolecular reactions, since most of the formally "termolecular" reactions take place by a complex mechanism rather than in a single step. Hence many of the dependences listed in Table 3 have only a theoretical significance.

3. The Negative Temperature Coefficient in the Collision Theory

Consider the temperature dependence of the rate constant of a reaction in terms of the classical collision theory[11]:

$$k = Pz \exp(-E_0/RT) \ . \quad (9)$$

This expression allows only for the translational degrees of freedom, and the molecules are treated as hard spheres. Formula (9) shows that the classical collision theory is incompatible with the NTC phenomenon, since both the energy term and the collision factor ($z \propto T^{1/2}$) increase with temperature. The steric factor P is usually assumed to be independent of temperature. For fast reactions with small or zero E_0 values the rate is determines by the pre-exponential factor $A = Pz$. If $A \propto T^n$, where n is a small positive number, the rate constant given by the simple collision theory will vary with temperature like the transport coefficients of the system, which are usually proportional to $T^{1/2}$ (viscosity, thermal conductivity) or to $T^{3/2}$ (diffusion)[69].

The development of theoretical and of experimental methods for studying fast bimolecular reactions resulted in the insertion into the formula of a reaction cross-section which is a function of the energy of the reactants[70]. In this case the temperature dependence of the rate constant is a function not only of the temperature dependences of the frequency factor z and of the Boltzmann factor $\exp(-E_0/RT)$, but also of the dependence of the reaction cross-section on the energy of the particles, which is related to temperature. If the energy of the molecules has its equilibrium distribution, the expression for the rate constant is[71]

$$k = (\pi\mu)^{-1/2} (2/k_B T)^{3/2} \int_0^\infty \sigma(E) E \cdot \exp(-E/k_B T) \, dE \ , \quad (10)$$

where μ is the reduced mass of the two reacting molecules, E is the relative translational energy, $\sigma(E)$ is the energy-dependent reaction cross-section, i.e. the probability of a collision between two particles having the relative energy of translational motion resulting in reaction. The parameter σ is sometimes called the "excitation function": its dimensions are cm^2 $molecule^{-1}$. Eqn.(10) implies that the reaction cross-section is unaffected by the internal states of molecules.

By introducing the function $\sigma(E)$ into the collision theory it became possible to describe formally many experimental data on the kinetics of elementary reactions[72]. In reactions with a barrier $E_0 \gg RT$ the Maxwell–Boltzmann distribution "selects" for the reaction only those molecules for which the reaction cross-sections correspond to the energies of the reacting pairs near the barrier ($E \cong E_0$). In this case the number of collisions between particles with $E \gg E_0$ is negligibly small, i.e. the reaction is confined to the "tail" of the energy distribution of the molecules, and the effect of the $\sigma(E)$ function can be ignored as in the classical collision theory.

In reactions with a small or zero threshold energy E_0 the exact form of the $\sigma(E)$ dependence becomes important. In principle these dependences can be determined both theoretically and experimentally. The former method relies either on quantum-chemical calculations or on the method of classical trajectories[23,70,72], in which the classical equations of motion are integrated numerically for given interaction potentials and initial conditions.

Important advances have been made in recent years in the theoretical calculation of reaction rates by analysing the trajectories of motion of reacting species. The calculations assumed a model interaction potential: this implies constructing the potential energy surface and solving the dynamic problem of the motion of the reacting particles on this surface (for example, by using classical mechanics). In these calculations the rate constants are obtained directly from the parameters of the intermolecular interactions, and they can be used to calculate $\sigma(E)$. Calculations by the classical trajectories method have given important results (in particular, on the dependence of the reaction cross-section on the energy of the reactants), but their description of the system is at best semi-quantitative because they often rely on arbitrary initial potentials[24].

As an example of this type of calculation we shall examine the reaction $D^{\cdot} + I_2 \rightarrow DI + I^{\cdot}$.[73] The calculations suggest that the vast majority of the collisions between deuterium atoms and iodine molecules cause a transition through the col of the potential energy surface, but only 30% of the collisions lead to reaction. In the remaining collisions the heavy iodine atoms are unable to move apart even by a distance of ~0.1 Å, and the deuterium atom passing through the saddle point of the potential surface rapdily reaches the far steep side, loses energy, and "slips" back into the region of the reactants. This phenomenon is characteristic of reactions between light atoms and heavy molecules: it is due to the fact that the relative velocity of the approaching deuterium and iodine atoms is much greater than the velocity with which the two atoms move apart in the iodine molecule. It is possible that, as the velocity of approach of the reactants increases, a steadily smaller proportion of the light atoms is able to negotiate the bend in the potential surface after passing through the saddle point, and this effect could be responsible for the appearance of a NTC of the reaction rate.

Calculations of the classical trajectories for elementary bimolecular reactions between particles of similar mass indicated that even in these reactions the cross-section can fall as the energy of the colliding particles increases[74]. However, the rate of decrease of the function $\sigma(E)$ is insufficient to account for a NTC of the rate constant, because the decrease in $\sigma(E)$ with temperature is masked by the positive temperature dependence of the collision frequency[67]. On the basis of these calculations[74] it was concluded that a NTC is unlikely to be found in an elementary bimolecular reaction between neutral molecules. However, a NTC has been observed experimentally in this type of reaction[75–78]. In other reactions (for example, the reaction of ions with neutral molecules) the possibility of the function $\sigma(E)$ decreasing fast enough with increase of E to cause a NTC of the reaction rate cannot be excluded. Further calculations with more precise interaction potentials are needed to reach unambiguous conclusions.

The second approach to formulating the function $\sigma(E)$ is to determine it experimentally, either from molecular beam experiments[70] or by a reverse transformation of kinetic data for the rate constant[75]. Methods of calculating rate constants from a given function $\sigma(E)$ are discussed in Ref.71.

Experimental or calculated data on the function $\sigma(E)$ for specific reactions are still scarce, and we usually need to rely on a defined model. Let us analyse some models from the standpoint of the possible existence of a NTC in the corresponding reaction.

Model 1. We assume that $\sigma(E)$ is a delta-function:

$$\sigma(E)=\sigma_0 \quad \text{for} \quad E=E_0,$$
$$\sigma(E)=0 \quad \text{for} \quad E \gtrless E_0,$$

i.e. that the reaction can take place only at the reactant energy E_0.[1] In this case we obtain from Eqn.(10)

$$k=(\pi\mu)^{-1/2}(2/k_B T)^{3/2}\sigma_0 E_0 \exp(-E_0/k_B T),$$

and if the activation barrier is small the temperature dependence is determined by the term $T^{-3/2}$. This model is not likely to apply to a real system because it is difficult to see how a reaction could be confined to a single value of the energy of the reactants (or even to a narrow band).

Model 2. Expressing the function $\sigma(E)$ as[11,72]

$$\sigma(E)=0 \quad \text{for} \quad E<E_0,$$
$$\sigma(E)=C \quad \text{for} \quad E \geqslant E_0,$$

where $C = \pi(r_A + r_B)^2$, and r_A and r_B are the effective radii of the molecules, leads to the following expression for the rate constant:

$$k = 2(r_A + r_B)^2(2\pi k_B T/\mu)^{1/2}(1 + E_0/k_B T)\exp(-E_0/k_B T).$$

If the probability of the reaction is independent of the excess energy of the reactants above the threshold value we have $k \propto T^{1/2}$ for $E_0 \ll k_B T$, and for $E_0 \gg k_B T$ the temperature dependence of k is determined by the term $T^{-1}\exp(-E_0/k_B T)$, and stays positive because of the rapid increase of the Boltzmann factor with temperature.

Model 3. This is a more realistic model, in which the reaction cross-section depends on the energy of the reactants. One of the simplest of these models assumes that the reaction between the reactants (represented as hard spheres) takes place when the relative energy of the particles along the collision line exceeds the threshold value E_0, and that the reaction cross-section increases to a limiting value of $C = \pi(r_A + r_B)^2$ as the energy increases above the threshold[9,24,72,77]:

$$\sigma(E)=0 \quad \text{for} \quad E<E_0,$$
$$\sigma(E)=C(1-E_0/E) \quad \text{for} \quad E \geqslant E_0.$$

It is assumed that the barrier is surmounted only by virtue of the relative energy of translational motion, and that the reaction probability is independent of the way in which the vibrational energy is distributed in the molecules. In this case Eqn.(10) becomes

$$k=2(r_A+r_B)^2(2\pi k_B T/\mu)^{1/2}\exp(-E_0/k_B T),$$

giving the classical formula of the collision theory. This is formally analogous to an Arrhenius with an activation energy $E_a = E_0 + RT/2$. This model gives a poor description of processes with energies near the threshold, or with very large energies[9].

So far we have examined models in which the reaction cross-section increases with the energy of the reacting molecules, or stays constant. Experiments with crossed molecular beams have shown that in many reactions $\sigma(E)$ increases from zero at some threshold energy E_0 and rapidly reaches a maximum before falling again. Obviously, a decrease in the probability of reaction as the energy of the molecules increases can lead to a NTC. Let us examine the models of the reaction cross-section which allow for the possibility of a decrease of $\sigma(E)$ with increase of E.

Model 4. In reactions with a small or zero activation energy the dependence of the cross-section on energy takes the simple form[11,72,75]

$$\sigma(E)=0 \quad \text{for} \quad E<E_0,$$
$$\sigma(E)=CE^n \quad \text{for} \quad E \geqslant E_0,$$

where C = const. This type of dependence is found, for example, in reactions of molecules with ions, where in most cases $n = -0.5$ ("Langevin cross-section", which never

leads to a non-equilibrium distribution of the molecular velocities[80]). In general this model gives a complex expression for the rate constant and the experimental activation energy E_a.[72] For integral and half-integral values of n the expressions become simpler and can be formulated analytically or tabulated in the usual way. If the reaction has no threshold energy ($E_0 = 0$ and $\sigma(E) = CE^n$) we have $E_a = 0$ for $n = -0.5$ and $E_a < 0$ for $n < -0.5$, i.e. we have a NTC.[75] The steeper the decrease of $\sigma(E)$ with temperature, the greater is the NTC. For example, for $n = -1.25$ a $k \propto T^{-0.17}$ dependence was found[75], and for $n = -1.5$ the dependence was $k \propto T^{-1}$. Plots of E_a against temperature for different values of n are given in Ref.72.

Model 5. The cross-sections of many reactions between neutral molecules can be fitted to the function[11,72]

$$\sigma(E)=0 \quad \text{for} \quad E<E_0,$$
$$\sigma(E)=C(E-E_0)^n\cdot\exp[-m(E-E_0)] \quad \text{for} \quad E\geqslant E_0,$$

where C = const, and m, $n > 0$. The presence of an exponential term ensures that as the energy E increases, the function $\sigma(E)$ goes through a maximum at $E = E_0 + n/m$, and then decreases again at a rate determined by the parameter m. In general the dependences of k and E_a on temperature are also complex, and therefore we shall limit the discussion to a few special cases. Thus for $m = n = 0$ the model reduces to model 2. If $m = 0$ the function $\sigma(E)$ can only increase with E, and in this case a NTC is not observed. If $m \neq 0$, E_a is always negative at high enough temperatures, and for $m \gg 0$ the function $\sigma(E)$ approaches the delta-function of model 1. Under these conditions $E_a = E_0 - 3RT/2$. Lastly, if the threshold energy is high enough ($E_0 \gg RT$) we have $E_a \cong E_0 + RT(n - 1/2)$, and only a positive and weakly temperature dependent activation energy can be expected. In the opposite limit, when the threshold energy is zero, $\sigma(E) = CE^n\cdot\exp(-mE)$, and the activation energy is always finite and temperature-dependent: $E_a = RT(n + 1/2) - m(n + 2)(RT)^2/(1 + mRT)$. If $mRT \gg 1$ a NTC is observed: $E_a = -3RT/2$.

Model 6. This model is similar to model 5, and is used to describe reactions between hard spherical molecules: in contrast to model 3, we put $\sigma(E) \to 0$ for $E \to \infty$:[11,72]

$$\sigma(E)=0 \quad \text{for} \quad E<E_0,$$
$$\sigma(E)=C[(E-E_0)^n/E]\exp[-m(E-E_0)] \quad \text{for} \quad E\geqslant E_0$$

where C = const. Model 3 is therefore a special case of model 6, for $n = 1$ and $m = 0$.

The general expression for the rate constant is very complex in this model, and the activation energy is $E_a = E_0 + RT(n - 1/2) - m(n + 1)(RT)^2/(1 + mRT)$, so that the observed activation energy can be both positive and negative.

All these models can lead to unexpected results, incompatible with the classical collision theory. For example, in model 6 with $m = 0$ and $n \gg 1$ at high temperatures the activation energy can be much higher than the threshold energy, so that E_a becomes temperature-dependent. For $m \neq 0$, when the function $\sigma(E)$ goes through a maximum, the activation energy at high temperatures is always negative. This form of the function is especially important in reactions with a low threshold energy E_0, because in this case the NTC phenomenon is observable even at intermediate temperatures. For reactions with $E_0 = 0$ model 6 gives $\sigma(E) = CE^{n-1}\cdot\exp(-mE)$, which is essentially the same as the corresponding expression for model 5. The compatibility of model 6 with the Arrhenius equation and the reality of the various n values are discussed in Ref.79.

In the last three models the reaction probability decreases as the energy increases. This is because both the translational and the internal energy of the colliding particles contribute to the reaction[2,81]. For example, the probability of the reaction K + HCl → KCl + H decreases almost 2-fold for a one-quantum increase in the rotational angular momentum with J = 1–4.[82]

The physical significance of the form of the function $\sigma(E)$ in models 4–6 can be inferred from the relationship between the absolute value of the threshold energy E_0 and the activation energy of the reaction. By inserting into the equation $E_a = RT^2(\mathrm{d}\ln k/dT)$, which follows from Eqn.(1), the value of k given by Eqn.(10) we find that the activation energy of the reaction is the difference between the average energy of the collisions leading to reaction and the average energy of all the collisions between pairs in the system[14,75]: $E_a = \bar{E}_{\text{reac}} - \bar{E}$. As we have already pointed out, in most bimolecular reactions with a large threshold energy E_0 a very small fraction of all the molecules (those in a "tail" of the energy distribution) is able to react, and we can only observe the rising branch of the $\sigma(E)$ function. Under these conditions $\bar{E}_{\text{reac}} > \bar{E}$, and the activation energy is positive. On the falling branch of the $\sigma(E)$ function (for a small or zero threshold energy) it is possible to find $\bar{E}_{\text{react}} < \bar{E}$, which formally corresponds to a negative activation energy. The physical significance of this observation is that the rate of reaction is higher for molecules whose energy is less than the average thermal energy of the molecules in the system. Increasing the temperature lowers the concentration of those molecules, and therefore it lowers the reaction rate. These effects are most marked at high temperatures.

The falling branch of the $\sigma(E)$ function is usually obtained in fast reactions (for example, in the recombination of free radicals). An interesting phenomenon is sometimes observed: a formally negative activation energy, indicating that the activation energy for the reverse process (the unimolecular decomposition into radicals) is lower than the spectroscopic dissociation energy D_0, since $D_0 = E_{\text{diss}} - E_{\text{reac}}$.[14,81,83] Expressing the temperature dependence of the recombination rate constant by the empirical relationship (3) gives $E_{\text{diss}} = D_0 - nRT$. Both phenomena (the NTC for the recombination reaction and the decrease in E_a for the reverse (dissociation) reaction) are usually observed at low pressures, and they denote the participation of the internal degrees of freedom of the molecules in the reaction. Thus the analysis of recombination reactions with a NTC relies on the theories of unimolecular decomposition for the reverse dissociation reactions: the relationship between the two processes and the development of a unified theory are specially examined in Ref.84. An analysis of the NTC in terms of the temperature dependence of the reaction cross-section has been reported[75] for the reaction between ClO˙ and BrO˙ radicals.

The analysis of termolecular reactions by the collision theory involves some fundamental difficulties. The first is that in the simplest form of the theory the reacting molecules are treated as hard spheres: in these circumstances the concept of a termolecular reaction is meaningless, since the probability of simultaneous contact between three hard spherical molecules is zero[44]. We therefore need to define more precisely what is meant by a three-body collision. For example, we could define a distance δ within which molecules are treated as colliding. The problem then becomes to calculate the probability of finding three molecules at distances not greater than δ. Alternatively we could introduce the time τ, defined as the duration of the binary collision (the life time of the quasi-molecule), and equate it (to a first approximation) to one vibration period, i.e. 10^{-13} s. The calculated frequencies of ternary collisions are 2 or 3 orders of magnitude lower than those of binary collisions[49,85,86].

This is why elementary reactions are almost invariably bimolecular: the only exceptions are the reactions which can only take place by a termolecular mechanism (for example, atom recombination reactions). As the number of participating atoms increases, the reaction adopts an "indirect" termolecular mechanism, with preliminary formation of a binary complex, and can no longer be considered to be elementary[87]. For example, instead of the reaction A + BCD + E → ABCD + E we have a two-step process, A + BCD → (ABCD)* followed by (ABCD)* + E → ABCD + E or (ABCD)* + E → AE + BCD, etc. (see theoretical analysis in Section III).

It has long been known that the simplest termolecular reactions in the gas phase (atom recombination reactions) have a NTC. This is inconsistent with the simple gas-kinetic theory of termolecular collisions, which gives[87] $k \propto T^{1/2}$. The classical collision theory is similarly unable to account for the absolute rate of these reactions, which are anomalously slow.

In the framework of the elementary termolecular mechanism the NTC phenomenon can be explained by postulating a reaction cross-section dependent on the energy of the reactants. It is usually assumed that the reaction is barrier-less, and that the function $\sigma(E)$ decreases as the temperature increases. "Head-on" collisions between three particles are very rare, and nearly all the collisions have an angular momentum, which increases with temperature. As a result, more energy is needed for the close approach, since some energy is dissipated in surmounting the rotational barrier. This lowers the effectiveness of the collisions and the probability of reaction at higher temperatures[81].

As in the case of bimolecular recombination reactions, which are associated with the reverse unimolecular dissociation reactions, termolecular reactions of the A + B + C → D + E type can be associated with the reverse bimolecular reactions D + E → A + B + C. This allows us to use one of the above models for bimolecular processes in the description of termolecular reactions, and hence to calculate their rate constants. Thus if we use model 5 for the cross-section of the bimolecular reaction we obtain four types of temperature dependence for the rate constant of the termolecular reaction[88]. The observed activation energy can be strongly temperature-dependent, and it can be either positive or negative depending on the threshold energy E_0 and on the parameters m and n of the model. For example, for $E_0 = 0$ and $0 < n \leq 1$ the rate constant has a maximum at $T = 0$ and falls monotonically to zero as the temperature rises. On the other hand if $n > 1$ with $E_0 = 0$, or if $n > 0$ with $E_0 > 0$, we have $k = 0$ at $T = 0$, after which the rate constant increases to a maximum before beginning to fall back again as the temperature is increased. In every case we can expect a NTC at high temperatures, since $k \propto T^{-3}$. The main weakness of this analysis of the possibility of a NTC in various bi- and termolecular reactions is the lack of a theoretical method of predicting reliably the form of the $\sigma(E)$ function for specific reactions.

In liquid-phase reactions the molecules react in a "cage" of solvent rather than by free collisions, as in the gas phase[89], and a "third body" is not needed to make possible a recombination reaction: the solvent can always act as the third body. For this reason it is impossible to lower the reaction cross-section in a solvent by raising the temperature.

In solutions bimolecular reactions with small activation energies are limited by diffusion, and therefore have a positive temperature coefficient of velocity. Thus, in the gas phase the recombination of perfluorinated ethyl, propyl, and butyl radicals at 297–457 K has a NTC,[90] whereas the recombination of ethyl radicals in liquid ethane at 94–154 K has a positive activation energy $E_a = +3.3$ kJ mole^{-1}, consistent with the activation energy for diffusion[91].

Termolecular processes are possible in solutions, since the solvent molecules in the "wall" of the cage can act as reactants. If the process is diffusion-limited it cannot have a NTC. On the other hand if the rate of the reaction is much lower than the rate of diffusion as a result of a large negative entropy of activation, and if the activation energy is close to zero, a NTC becomes possible, and we can use the transition state theory to express the temperature dependence of the rate constant.

Thus both the transition state theory and the collision theory predict the possibility of a NTC in elementary reaction under specified conditions. Most chemical reactions take place in a succession of steps, each of which (in theory) could have a positive or a negative temperature coefficient. The overall temperature coefficient of such reactions is discussed in the next Chapter of this review.

III. NEGATIVE TEMPERATURE COEFFICIENT IN COMPLEX MULTI-STEP REACTIONS

1. Negative Temperature Coefficient in Reactions Involving an Intermediate

The formation of an intermediate compound (complex) can lead to a NTC for the overall reaction. As in the definition of the concept of a termolecular collision we must define more precisely what is meant by a complex. It is usually assumed that if the reacting particles experience attractive forces and the energy of the reaction is not very great the reactants will form a "long-lived" intermediate compound. Direct experiments with molecular beams have shown that this does not always happen, and that reaction can take place by a direct mechanism[92]. We shall adopt as a formal criterion for the formation of a complex the ability of the reactants to remain at a mutual distance corresponding to a normal chemical bond for the duration of several rotation periods (i.e. for times of more than 10^{-12} s).[92]

In solutions the reactant molecules experience ~10^2 collisions in the solvent cage at each encounter, and therefore any encounter of a pair of reactants can be formally treated as a weak complex, A + B ⇌ AB.[85,89] For this equilibrium the rates of the forward and the reverse process and the equilibrium constant are, respectively, $w_1 = A_e[A][B]$, $w_{-1} = (1/\tau)[AB]$, and $K = A_e\tau$, where A_e is the encounter frequency and τ is the life time of the molecules in the cage.

We shall begin our analysis of the possibility of a NTC in reactions with an intermediate complex by considering the fast and reversible formation of a complex by the scheme

$$A + B \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} AB \xrightarrow{k_p} P \quad , \qquad (I)$$

where $k_1 \gg k_p$ and $k_{-1} \gg k_p$. This type of system is often found in solutions. For example, molecular donor–acceptor complexes in solution are formed almost without activation energy at rates close to the diffusion rate. However, the rapid conversion of the complex into the product can be prevented by a large negative entropy of activation even if the activation energy of this step is small: such an entropy may arise from the need to transfer the molecular complex from a state of relatively free motion to the more rigid configuration of the activated complex during the conversion of AB into the product P. We may quote as an example the diene synthesis reaction of tetracyanoethylene with 9,10-dimethylanthracene, for which a NTC has been observed in various solvents[93].

Fast and reversible complex formation is possible also in gas-phase reactions at high enough pressures if the complex is in thermodynamic equilibrium with the initial substances. We may assume that under these conditions the termolecular complex formation reaction (in which the function of the third body is to dispose of the excess energy of the complex and to stabilise it) is kinetically of the second order (k_1 corresponds to k_1^∞ in the high-pressure limit), and the monomolecular decomposition reactions of the complex by two paths are in the first-order region (k_p corresponds to k_p^∞, and k_{-1} corresponds to k_{-1}^∞).

For [B] ≫ [A] the rate of reaction (I) is given by the expression

$$d[P]/dt = k_p[AB] = k_pK[A][B]/(1 + K[B]) = k_p\alpha[A] , \quad (11)$$

where $K = k_1/k_{-1} = K_0 \cdot \exp(-\Delta H/RT)$ is the equilibrium constant, and $\alpha = K[B]/(1 + K[B])$ is the extent to which component A is bound in the complex. The temperature dependence of the reaction rate is a complex function, determined by the activation energy E_p (positive), the enthalpy of complex formation ΔH (negative), and the concentration of the reactant B. It follows from Eqn.(11) that for $K[B] \gg 1$ (strong binding, $\alpha = 1$) $d[P]/dt = k_p[A]$, and for $K[B] \ll 1$ (weak binding, $\alpha = K[B]$) $d[P]/dt = k_pK[A][B]$. For strong binding the activation energy $E_a = E_p$ is positive; for weak binding $E_a = E_p + \Delta H$, so that the observed activation energy can be either positive (for $E_p > |\Delta H|$) or negative (for $E_p < |\Delta H|$). In the latter case the initial rate of reaction or the effective rate constant, depending on [B], will increase with temperature initially, go through a maximum at the temperature

$$T_{max} = \frac{-\Delta H}{R[\ln(-\Delta H/E_p - 1) - \ln(K_0[B])]} ,$$

and decrease at still higher temperatures. Similar results are obtained for the formation of intermediates of more complex composition (for example, AB_2): under these conditions the absolute value of the NTC may be higher than for the 1 : 1 complexes, since the enthalpy of formation is usually higher in the larger complexes[94].

In many fast gas-phase reactions we find three competing processes: decomposition of the complex into the initial substances, decomposition into the reaction products, and stabilisation of the vibrationally excited complex by collision with a third particle[2,52]:

$$A + B \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} (AB)^* \begin{cases} \xrightarrow{k_p} P \\ \xrightarrow[k_m]{M} AB \end{cases} . \quad (II)$$

The stationary state condition gives

$$[(AB)^*] = k_1[A][B]/(k_{-1} + k_p + k_m[M]) .$$

The expression for the reaction rate is

$$d[A]/dt = -d[B]/dt = k_1[A][B] - k_{-1}[(AB)^*] = k_1(k_p + k_m[M])[A][B]/(k_{-1} + k_p + k_M[M]) .$$

The experimentally determined rate constant of the bimolecular reaction is a complex function of the temperature and pressure of the system:

$$k_{exper} = k_1(k_p + k_m[M])/(k_{-1} + k_p + k_m[M]) . \quad (12)$$

Let us examine some special cases of scheme (II).

1) For low pressures and short life-times of the complex we have $k_m[M] \ll k_p$, and scheme (II) becomes $A + B \rightleftharpoons (AB)^* \rightarrow P$. It follows from Eqn.(12) that under these conditions $k_{exper} = k_1k_p/(k_{-1} + k_p)$, i.e. the rate constant is independent of pressure. If the predominant reaction path is the decomposition of the complex into products ($k_p \gg k_{-1}$) we have $k_{exper} = k_1$ and we observe the "forward" reaction. The possibility of a NTC for these reactions has already been discussed. This case is met, in practice, when the activation energy barrier opposing the conversion of the complex into the product is small.

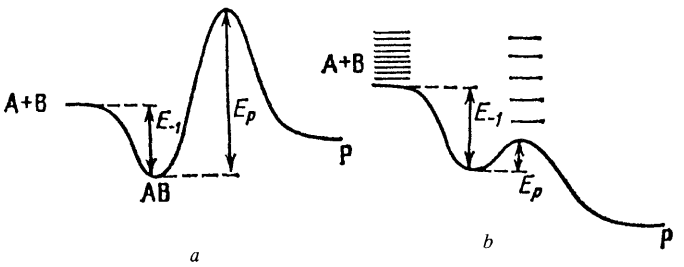

Figure 1. Energy profile of the reaction A + B ⇌ AB → P for zero vibrational level and different relative values of E_{-1} and E_p.

In the opposite limit ($k_p \ll k_{-1}$) we have $k_{exper} = k_1k_p/k_{-1}$. Since the activation barrier to the formation of the complex is usually small or zero, the temperature dependence of k_{exper} will be determined by the relative values of E_p and E_{-1}. For the temperature coefficient to be negative the energy of the activated complex for the k_p step should be lower than the energy level of the reactants ($E_p < E_{-1}$, see Fig.1). At first sight the condition $E_p < E_{-1}$ is incompatible with the condition $k_p < k_{-1}$. However, the density of energy levels for the k_{-1} reaction is much greater than the density of levels for the forward reaction (k_p) for equal internal energies (Fig.1*b*), i.e. the entropy factor strongly favours the reverse reaction and thus compensates the energy factor of the forward reaction[52,95,96]. Therefore the condition $k_p < k_{-1}$ can be satisfied even if $E_p < E_{-1}$.

In the general case ($k_p \cong k_{-1}$) the activation energy of the reaction is determined by the equation[2,97]

$$E_a = E_1 + (E_p - E_{-1})k_{-1}/(k_{-1} + k_p) ,$$

and if $E_1 \cong 0$ and $E_{-1} > E_p$ we find $E_a < 0$. This equation for E_a also shows that the absolute value of the NTC should increase with temperature, since the ratio $k_{-1}/(k_{-1} + k_p)$ increases with temperature.

Both the decomposition paths of the complex are unimolecular processes, with rate constants k_{-1} and k_p, and they can be analysed by standard methods (for example, the RRK theory[2,58,96]). The pre-exponential factors for the k_p and k_{-1} steps were calculated[67,98], and it was shown that if these factors (A_{-1} and A_p) are similar, $k_p \gg k_{-1}$, i.e. the forward reaction takes place. In order to observe the NTC associated with the reversibility of the complex formation we must satisfy the condition $A_{-1} \gg A_p$, which has been shown theoretically to be easily possible in real systems[98].

2) At high enough pressures the rate of deactivation of the complex is much greater than the rate of conversion into products ($k_m[M] \gg k_p$), i.e. scheme (II) is converted into the scheme $A + B \rightleftharpoons (AB)^* \xrightarrow{M} AB$. In this case it follows from Eqn.(12) that $k_{exper} = k_1k_m[M]/(k_{-1} + k_m[M])$; the main reaction is the association of the initial molecules A and B

into the product AB (a stable complex or molecule[28,58,99]). Stabilisation of the transition complex (AB)* usually takes place through collision with a third body, but radiative stabilisation has also been reported[58,100]. If $k_m[M] \gg k_{-1}$, we have $k_{exper} = k_1$, and we observe the "forward" reaction; if $k_m[M] \ll k_{-1}$, $k_{exper} = k_1 k_m[M]/k_{-1}$. The possibility of a NTC in these cases was discussed above.

In the general case ($k_m[M] \cong k_{-1}$) we can assume that the rate constants of the bimolecular processes k_1 and k_m are not very different from the frequency factors, and weakly dependent on temperature. Under these conditions the temperature dependence of k_{exper} will be determined by the temperature dependence of the function $1/k_{-1}$. Some workers have used the RRK theory to describe the constant k_{-1} qualitatively[2,58]: for small molecules at moderately high temperatures this gives $k_{-1} \propto T^{s-1}$, where s is the number of oscillators. Thus for small molecules $k_{exper} \propto T^{1-s}$, and if $s > 1$ this gives a NTC.[2]

Other bimolecular reaction mechanisms with formation of an intermediate complex are also possible. For example, the product may be formed from the stabilised (rather than from the excited) complex by the scheme[2] $A + B \rightleftharpoons (AB)^* \overset{M}{\rightarrow} AB \overset{C}{\rightarrow} P$. This scheme also can produce a NTC. Thus, if $[C] \ll [M]$ and $[AB] \ll [A]$ we have $k_{exper} = k_p K[M]$, whence $E_a = E_p + \Delta H$, and a NTC is observed when $E_p < |\Delta H|$, where ΔH is the enthalpy of the process $A + B \rightleftharpoons (AB)^*$.

The NTC has been attributed to the reversible formation of an intermediate complex in reactions involving atoms of oxygen and other elements of Group VI,[66,68,101,102] in the interaction between BrO· radicals[103], in the gas-phase reaction of mercury with ammonia and with hydrogen iodide[104], in proton transfer reactions of ion–molecule processes[105], and in the reactions $HO_2^{\cdot} + NO \rightarrow OH^{\cdot} + NO_2$,[106] $CH_3O_2^{\cdot} + HO_2^{\cdot} \rightarrow CH_3OOH + O_2$,[107] and $OH^{\cdot} + C_6H_5CH_3 \rightarrow$ products[108].

More complex schemes, involving several complexes[2,34], have also been used to explain experimental results.

The participation of two types of complex is postulated in many gas-phase organic reactions[33,96,109]. For example, it has been shown by the ion cyclotron resonance method that typical nucleophilic substitution reactions can be acclerated by up to 20 orders of magnitude by transition from an aqueous solution to the gas phase: this is explained by the large change in the energy profile of the reaction on changing from strongly solvated to totally non-solvated particles[109] (Fig.2). In the gas phase the approaching particles form the ($OH^- \cdot CH_3Br$) complex, which is converted into the product (with a small activation barrier) through the intermediate complex $CH_3OH \cdot Br^-$. We see from Fig.2 that under these conditions the energy profile is similar to that of Fig.1*b*. Obviously, in the gas phase the reaction should be fast, with a NTC. In an aqueous solution the reaction is slow because of the high energy barrier resulting from the difference in solvation between the reactants and the activated complex and because of the need to break down the solvation shell of the transition state. The solvation also hinders the attractive forces between the reactants and the formation of the complex.

The kinetics of a reaction in the gas phase with stepwise solvation of the reactants by one, two, etc. water molecules are discussed in Ref.109. Solvation by only two water molecules is sufficient to raise the energy barrier opposing the conversion of the complex to the level of the initial substances, or even higher (Fig.2). Thus solvation suppresses the reaction, and the NTC is replaced by a positive temperature coefficient.

In the gas phase these reactions show an effect analogous to the Polanyi–Semenov rule. A study of 22 reactions of the type of $R_1^+ + R_2H \rightarrow R_2^+ + R_1H$ (whose energy profile is shown in Fig.1*b*) has shown that the rate increases with the exothermicity of the process[33]. This effect is due to the lowering of the activation barrier in the more exothermic reactions. An even more interesting correlation is that between the parameters k and n of the equation $k = At^n$: it was found that for a fixed temperature these parameters are linearly related in a series of reactions. Therefore the slower reactions of this type have a higher NTC, and they are more strongly retarded by an increase of temperature[33].

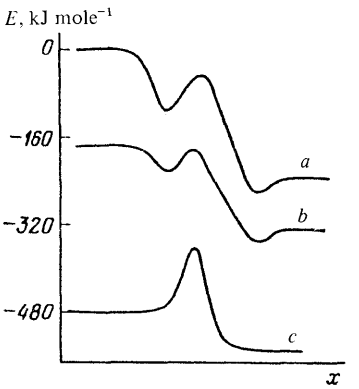

Figure 2. Energy profile of the reaction $OH^- + CH_3Br \rightarrow CH_3OH + Br^-$ for non-solvated reactants (*a*), and reactants solvated with two water molecules (*b*) or in an aqueous solution (*c*); x is the reaction coordinate.

The presence of two types of intermediate complex, mutually in equilibrium, has been suggested also for several liquid-phase reactions (for example, addition to multiple bonds[94,110]). These reactions show a NTC if the barrier to the conversion of the complex into the product is lower than the enthalpy of complex formation. The NTC phenomenon has been observed also in the gas-phase addition of hydrogen chloride to propene: in this case it was due to the reversible formation of the $(HCl)_2$ dimer and its subsequent reaction with the $C_3H_6 \cdot HCl$ complex[111].

The intermediate compound is not necessarily a complex. For example, in the scheme

$$P \overset{k_1}{\leftarrow} A \overset{K}{\rightleftarrows} B \overset{k_2}{\rightarrow} P \qquad \text{(III)}$$

A and B are isomers mutually in equilibrium, having different reactivities or different solvations. If the equilibrium is established rapidly the observed activation energy is given by the expression

$$E_a = E_1 - \frac{K}{1+K}\Delta H + \frac{Kk_2/k_1}{1+Kk_2/k_1}(\Delta H - E_1 + E_2), \qquad (13)$$

where ΔH and K are the enthalpy and the equilibrium constant for the $A \rightleftharpoons B$ process, and E_1 and E_2 are the activation energies for the conversion of A and B into the product[11]. If $|\Delta H| > |E_1 - E_2|$, for $\Delta H > 0$ and a low enough temperature ($K \ll 1$) we have $E_a = E_1$, whereas at high temperatures ($K \gg 1$) $E_a = E_2$. In either case the NTC is not observed. However, for $\Delta H < 0$ the Arrhenius dependence of the reaction rate can have several extrema, giving a NTC in some temperature ranges. Similar effects may be found in enzyme reactions when all the forms of the enzyme are present in equilibrium. Plots of the change in activation energy with temperature are shown in Ref.11.

If only one of the species reacts in scheme (III) Eqn.(13) reduces to the simpler expression $E_a = E_1 - K\Delta H/(1 + K)$ for $Kk_2/k_1 \ll 1$, or to the expression $E_a = E_2 + \Delta H/(1 + K)$ for $Kk_2/k_1 \gg 1$. In both cases a NTC can arise for certain ratios of the parameters E_1, E_2, and ΔH.

Various theories have been proposed to explain the NTC in termolecular reactions with formation of an intermediate complex (for example, the recombination of atoms and simple radicals)[81]. Most workers adopt a mechanism involving a third molecule M as well as the intermediate complex[112] (the Radical-Molecular Complex (RMC) or Intermediate Complex (IC) mechanism). If both the reactants R_1 and R_2 can form a complex with M the recombination scheme $R_1 + R_2 \rightarrow R_1R_2$ can be written, in general, as a system of many elementary steps[60,113]:

$$\begin{array}{ll} R_1 + M \rightleftarrows R_1M^* & R_2 + M \rightleftarrows R_2M^* \\ R_1M^* + M \rightleftarrows R_1M + M & R_2M^* + M \rightleftarrows R_2M + M \\ R_1M^* + R_2 \rightleftarrows R_1R_2 + M & R_2M^* + R_1 \rightleftarrows R_1R_2 + M \\ R_1M + R_2 \rightleftarrows R_1R_2 + M & R_2M + R_1 \rightleftarrows R_1R_2 + M \text{ etc.} \end{array}$$

A large number of kinetic equations is needed to describe the system fully in the general case, but far fewer equations are sufficient if $R_1 = R_2$. Even greater simplification is achieved if the equilibrium $R + M \rightleftharpoons RM$ can be assumed: in this case the recombination is third-order at low pressures and second-order at high pressures[113].

The simplified recombination scheme gives $k_{rec} = A \cdot \exp(\Delta E/RT)$ at low temperatures and $k_{rec} = A \cdot \exp[(\Delta E - RT)/RT]$ at high temperatures, where ΔE is the bond energy in the RM complex[113]. Since $\Delta E > 0$ always, we observe a NTC increasing in magnitude with the strength of the complex. For example, in the recombination of iodine atoms[44] E_a is found to vary from -5.9 kJ mole^{-1} for M = He to -22.3 kJ mole^{-1} for $M = I_2$. The complex RM is weak if M is an inert gas atom, but it can be quite strong and comparable to that in a chemical compound (for example, I–NO and I–NO_2).

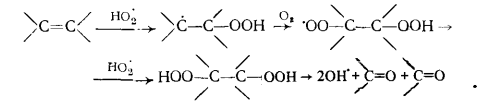
Many recombination reactions have been studied over a wide range of temperature and pressure for a variety of "third molecules" (M). Heavy and complex "inert" molecules like SF_6 were found to be the most effective in recombination reactions, the NTC of the reaction increasing with the effectiveness of M. Even gases like He, Ar, and N_2 are not fully inert in practice, and they always form an RM complex[114] as well as RM_n clusters (at higher pressures[60]).

Mechanisms including the formation of an intermediate complex do not always satisfactorily describe experimental data. Thus the magnitude of the NTC is often inconsistent with the energy of the R–M bond. For example, in the reaction $I^\cdot + I^\cdot + He \rightarrow I_2 + He$ an I–He bond several times stronger than expected from the van der Waals forces had to be postulated[115]. Problems are met also in attempting to explain the temperature dependence of the activation energy of these reactions. There is no doubt that at least one more mechanism is possible for the recombination:

$$\begin{array}{l} R_1 + R_2 \rightleftarrows R_1R_2^* \\ R_1R_2^* + M \rightleftarrows R_1R_2 + M \end{array} .$$

This mechanism (Energy Transfer, or ET mechanism) competes with the formation of an intermediate complex, and it can be predominant (for example, in the NO + Cl → NOCl [116] and NO + O → NO_2 reactions[117]). This mechanism also gives a NTC, as was found above for scheme (II) with $k_m[M] \gg k_p$. In the ET mechanism the temperature dependence of the reaction rate is determined by the expression AT^n, and the observed activation energy varies with temperature ($E_a = nRT$), whereas in the intermediate complex mechanism the parameter E_a is almost independent of temperature.

The relative contribution of the two mechanisms depends on the temperature; it is difficult to extract quantitative information on the force of the R–M interaction from the temperature dependence of the recombination rate constant alone, and additional data on the dependence of k_{rec} on pressure, nature of M, etc. are needed[60]. The contribution of each mechanism depends on a number of factors: the strength of the R–M and R–R* interactions, the relative concentration of particles, and their size and complexity[87]. In the recombination of halogen atoms with M = Ar, Xe the intermediate complex mechanism is dominant at low temperatures, and the ET mechanism at high temperatures, but with M = He the latter mechanism is always predominant[114,118].



The contribution from each mechanism is harder to predict when M is a complex molecule (HCl, HBr, SO_2).[118] Keeping all other conditions the same, the relative importance of the two mechanisms is a complicated function of pressure, since clusters of M can take part in the reaction[60]. For example, in the reaction $Br^\cdot + Br^\cdot + He \rightarrow Br_2 + He$ the contribution from the ET mechanism is 40% at $p < 150$ bar and almost zero at $p > 400$ bar. In the presence of other M molecules the intermediate complex mechanism is predominant at all pressures[119]. The same is true of other reactions involving free radicals, for example $HO_2^\cdot + HO_2^\cdot \xrightarrow{M} H_2O_2 + O_2$ (M = NH_3, H_2O).[80,97,120]

2. Negative Temperature Coefficient in Gas-phase Hydrocarbon Oxidation Reactions

The oxidation of hydrocarbons is a branching chain process whose rate is a function of temperature. In most cases an increase in temperature causes a large increase in rate[121]. However, some exceptions to this rule are known. In the oxidation diagrams (in T, p coordinates) of some reactions a region in which the reaction rate decreases with increase of temperature is found above the cold flame region, i.e. a NTC is present. This NTC region lies between the low-temperature and the high-temperature oxidation region[122]. It has been suggested that the cold flame is a suppressed chain explosion which has failed to develop because of the passage of the system into the NTC zone[123].

The NTC phenomenon is observed even in the oxidation of ethane, but is more marked with the higher hydrocarbons. Thus in the oxidation of propane the reaction rate increases to a maximum in the region of 300–350 °C before falling steeply to zero when the temperature is increased to 450 °C. The reaction re-starts at 475 °C, and becomes explosive[123]. So far a NTC has been reported for the gas-phase oxidation of alkanes, alkenes, aromatic hydrocarbons, and ketones. The phenomenon is discussed in many monographs and reviews[122–126], many experimental studies have been made of it, but so far the mechanism of the NTC is not entirely clear.

Some of the early workers attributed the NTC to the presence of two parallel reactions[123], or to reactor wall effects[127]. The hypothesis of two different chain breaking mechanisms with very different activation energies was tested by kinetic calculations[128]. In the most widely used hypotheses an increase of temperature lowers the probability of chain propagation because of the presence of a competing reaction[123]. According to one of these hypotheses the NTC is due to the reaction $HO_2^\cdot + HO_2^\cdot \rightarrow H_2O_2 + O_2$, which suppresses the chain-branching reaction[124]

However, this hypothesis has been shown to be incorrect by the kinetic isotope effect method[129]. According to other interpretations a branching reaction of the type of

$(CH_3)_2CHOO^{\cdot} + C_3H_8 \rightarrow (CH_3)_2CHOOH \rightarrow CH_3CHO + OH^{\cdot} + CH_3^{\cdot}$ is replaced by a chain propagation reaction at higher temperatures[130].

It has also been suggested that in the oxidation of hydrocarbons one of the intermediate products (the aldehyde) loses its ability to cause chain branching at high temperatures[123]. The kinetics of the formation of the main intermediates and products (including free radicals) in the NTC region have been studied in detail by advanced measurement techniques[131], including continuous monitoring in a cold trap by ESR.[132,133] In the NTC region the maximum concentration of free radicals (like the reaction rate) was found to go through a maximum. However, at short times, when the branching reactions can be ignored, the concentration of free radicals in the same region increases with temperature, indicating a relationship between the NTC and the branching reactions. Thus a study of the kinetics of the high-temprature oxidation of ethane has shown that the branching steps are associated with the accumulation of intermediate products of the reaction, whereas in the initial stages a non-branching chain process is taking place[134]. The experiments also showed that in the NTC region and at even higher temperatures there was no qualitative difference in the composition of the oxidation products and only a slight quantitative difference[128]. Yet, the chain length must decrease in the NTC region, since the active radicals which propagate the chain ($H^{\cdot}$, $RO^{\cdot}$) are replaced by less active radicals as a result of the reactions between active particles and intermediate products of the HCHO and CH_3CHO type[135]. Thus the NTC in these reactions arises from a decrease in the effectiveness of chain branching at high temperatures.

3. Other Reactions

NTC have been observed also in other reactions of various types: in some cases the origin of the NTC is clear, but in other cases detailed studies of the mechanism of the process are needed to account for the effect. Thus a NTC will always be found in parallel reactions ($B \overset{k_1}{\leftarrow} A \overset{k_2}{\rightarrow} C$) if the temperature dependence of the yield of the substance formed with the lower activation energy is measured. At any instant the relationship $[B]/[C] = [B]_\infty/[C]_\infty = k_1/k_2$ applies[136]. If $E_2 > E_1$ the relative yield of the product B decreases as the temperature increases. This behaviour has been observed, for example, in the radical decomposition of azo compounds in solution[137]. It was found that an increase in temperature lowers the fractional number of radicals which recombine in the solvent cage. For azoethane in iso-octane solution this fraction (f) is 0.852 at −80 °C, 0.670 at 0 °C, and 0.539 at +85 °C. The quantity $F = f/(1 - f)$ corresponds to the ratio of the probabilities of the radicals recombining in the cage or emerging from it. In Arrhenius ($\lg F$, $1/T$) coordinates a straight line is obtained, giving an effective activation energy $E_a = E_{cage} - E_{diff}$ which is independent of the nature of the solvent and varies from −5.5 to −11.8 kJ mole^{-1} for different azo compounds.

The presence of parallel reactions can also account for the decreased rate of sulphochlorination of paraffins by the scheme $RH + SO_2 + Cl_2 \rightarrow RSO_2Cl + HCl$ when the temperature is raised, as a result of the increased rate of the direct chlorination $RH + Cl_2 \rightarrow RCl + HCl$.[138] An increase in temperature also lowers the rate of liquid-phase sulpho-oxidation of paraffins[139]. In this case the mechanism is similar to the development of a NTC in the gas-phase oxidation of hydrocarbons. The main product, the sulphonic acid RSO_3H, is formed by the gradual accumulation of persulphonic acid in the chain reaction

$$R^{\cdot} + SO_2 \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} RSO_2^{\cdot} \xrightarrow{O_2} RSO_2O_2^{\cdot} \xrightarrow{RH} RSO_2O_2H\ ,$$

followed by degenerate branching by the scheme $RSO_2O_2H \rightarrow RSO_3^{\cdot} + OH^{\cdot}$, $RSO_3^{\cdot} + RH \rightarrow RSO_3H + R^{\cdot}$. On raising the temperature we make the formation of the $RSO_2^{\cdot}$ radical less probable: this lowers the equilibrium concentration of persulphonic acid and favours side reactions. For $R = CH_3$ the ratio of the constants k_1/k_{-1} is 200 at 25 °C, 40 at 65 °C, and 1 at 150 °C.[140]

Another example of NTC in a liquid-phase chain reaction is the oxidation of β-ionone by atmospheric oxygen[141]: for a constant rate of initiation the chain length and the reaction rate decrease with increase of temperature. In this case the NTC phenomenon is associated with a change in the chain breaking mechanism, quadratic chain breaking being replaced by linear chain breaking as the temperature is raised.

A decrease in the reaction rate with increase of temperature has been observed also in the iodination of silver films[142], the bromination of 2-chloro-3-t-butyl- and 3-carbomethoxyphenanthrene in CCl_4 solution[143], the oxidation of alkaline-earth metal vapours in NO_2, Cl_2, and Br_2 atmospheres at high temperatures[144], and in the reactions of solvated electrons in irradiated melts of alkali metal halides[145].

IV. NEGATIVE TEMPERATURE COEFFICIENT DUE TO THE EFFECT OF THE MEDIUM

So far we have examined reactions in which the NTC phenomenon arises from the properties of the reacting system. In many cases a NTC may be induced by "external" causes, independent of the mechanism of the reaction. We shall discuss some cases of the development of a NTC under the stimulus of external conditions.

1. Volume Expansion of the Solvent

Reactions in solution usually take place at constant pressure, and the volume of the solution and the concentration of the reactants can vary with temperature. The thermal volume change of liquids is determined by the coefficient of volume expansion[146]

$$\alpha_t' = (1/V)(dV/dt)\ (K^{-1}), \tag{14}$$

where V is the volume and t is the temperature (°C). Putting $V = V_0$ for $t = t_0$ and changing to absolute temperatures we obtain, after integration of Eqn.(14),

$$V = V_0 \exp[\alpha_t'(T - T_0)]\ . \tag{15}$$

The contribution (E') to the observed activation energy due to the volume expansion of the solution if the corresponding changes in the concentration of reactants are not allowed for in the kinetic measurements can be calculated. If the rate of the reaction is described by the equation $w = k[A]^n$ the contribution E' due only to the change in [A] caused by the change in volume (i.e. for k = const) is given by the expression

$$E' = RT^2(d\ln w/dT) = RT^2 n(d\ln[A]/dT). \tag{16}$$

If m is the number of moles of A, $[A] = m/V$, and according to Eqn.(15) we have $[A] = m/V_0 \exp[\alpha_t'(T - T_0)$. Inserting this expression into (16) gives

$$E' = -RT^2 n\alpha_t'\ . \tag{17}$$

For a third-order reaction ($n = 3$) we obtain $E' = 2.14 \times 10^3 \alpha_t'$ kJ mole^{-1} at 293 K. Using tabulated data[146] for α_t' we

arrive at the following values of E' for typical solvents by formulae (17):

Solvent	H_2O	$(CH_3)_2CO$	C_6H_6	CH_3OH	$CHCl_3$	$(C_2H_5)_2O$	Petroleum ether
$10^3\alpha_t'$ (K^{-1})	0.21	1.49	1.24	1.26	1.27	1.66	2.25
E', kJ $mole^{-1}$	−0.45	−3.20	−2.66	−2.70	−2.72	−3.55	−4.85

Thus even in solvent with a large value of α_t' the contribution of E' to the observed activation energy is small (within experimental error limits). A negative temperature coefficient could be observed only in reactions with a very small or zero "true" activation energy, but these reactions are diffusion-limited in solutions.

2. Changes in the Physicochemical Characteristics of the Solvent

In reactions involving ions or molecules with a dipole moment the rate is very dependent on parameters such as the dielectric constant of the medium, the ionic strength of the solution, the pH, etc. The contribution to the experimental activation energy from terms arising from the temperature dependence of the properties of the medium (i) is given by the equation[110]

$$E' = -R\sum_j \frac{\partial \ln k_{exper}}{\partial i_j} \cdot \frac{\partial i_j}{\partial (1/T)} \quad . \qquad (18)$$

If the change in the property i and the corresponding change in k_{exper} caused by the change in temperature are such that the two factors in the summation of Eqn.(18) have the same sign, a NTC can be observed if the contribution E' is greater in absolute value than the true (isoparametric) activation energy. The calculation assumes a knowledge of the temperature dependence of the properties of the medium and of the effect of these properties on the reaction rate.

Detailed studies of the dependence of the rate constant of many reactions on the dielectric constant of the medium ε have been reported. If only ε is taken as the parameter i Eqn.(18) can be re-written[147]

$$E' = -R\frac{\partial \ln k_{exper}}{\partial \varepsilon} \cdot \frac{\partial \varepsilon}{\partial (1/T)} \quad . \qquad (19)$$

If the reactants are two ions of the same sign, or two dipolar molecules whose dipole moments are smaller than that of the transition state, the rate of the reaction increases with ε, whereas ε itself usually increases with decrease of temperature. If both tendencies are well developed we can expect a NTC even in reactions with a high isodielectric energy of activation.

Since the dependence of the reaction rate on ε is usually expressed in $\ln k$, $1/\varepsilon$ coordinates in both theoretical and experimental work, and the dependence of ε on temperature is given as $\varepsilon = \varepsilon_0 \exp(-LT)$ or $L = -\partial \ln \varepsilon/\partial T$,[148] it is convenient to insert these relationships into Eqn.(19). Since

$$\frac{\partial \ln k}{\partial \varepsilon} = -\frac{1}{\varepsilon^2}\frac{\partial \ln k}{\partial (1/\varepsilon)} \text{ and } \frac{\partial \varepsilon}{\partial (1/T)} = -\varepsilon T^2 \frac{\partial \ln \varepsilon}{\partial T},$$

we obtain

$$E' = R\frac{\partial \ln k}{\partial (1/\varepsilon)} \cdot \frac{\partial \ln \varepsilon}{\partial T} \cdot \frac{T^2}{\varepsilon} = -R\frac{\partial \ln k}{\partial (1/\varepsilon)}\frac{L}{\varepsilon}T^2 \quad . \qquad (20)$$

Let us calculate possible values of E'. For ionic reactions the point-charge model gives[89]

$$\partial \ln k/\partial(1/\varepsilon) = z_A z_B e^2/r_{AB}k_B T \quad ,$$

where z_A and z_B are the charges on the ions, e is the electronic charge, and r_{AB} is the distance between the charges. If $z_A = z_B$, and $r_{AB} = 3$ Å, we find $\partial \ln k/\partial(1/\varepsilon) = 185$, which agrees in order of magnitude with the value calculated[89] for the reactions of the mono-anions of dibasic acids with OH^- ions. A similar value is obtained from the Kirkwood model for the reactions of dipolar molecules. The second factor in Eqn.(20) can be calculated from tabulated values of L, which for the majority of solvents lie in the range from 10^{-3} to 10^{-2} K^{-1}.[148] It is evident from Eqn.(20) that under otherwise identical conditions the contribution E' will be a maximum when the ratio L/ε is a maximum. This ratio for a number of solvents is tabulated below:

H_2O	CCl_4	$CHCl_3$	CH_3OH	$C_2H_4Cl_2$	$(CH_3)_2CO$	$(C_2H_5)_2O$	$n\text{-}C_6H_{14}$
0.058	0.40	0.78	0.19	0.52	0.23	1.18	0.44 .

Inserting (for a reaction in $(C_2H_5)_2O$) the values $L/\varepsilon = 1.18$ and $\partial \ln k/\partial(1/\varepsilon) = 185$ into Eqn.(20) we obtain $E' = -140$ kJ $mole^{-1}$ at 300 K.

This calculation shows that in some solvents the increase in rate on lowering the temperature caused by an increase in ε can be so large as to mask the decrease in rate due to the Arrhenius factor, and it can thus produce a NTC, whereas in aqueous solutions (where L/ε is small) a NTC is much less likely. This theoretical prediction[149] was experimentally confirmed in the oxidation of naphthoquinone derivatives by potassium periodate in aqueous-alcoholic solutions[147]. At pH 6.3 it was found that $E_a = -8.2 \pm 0.9$ kJ $mole^{-1}$, whereas the isodielectric activation energy is 80 ± 2 kJ $mole^{-1}$: this corresponds to a contribution $E' = -88$ kJ $mole^{-1}$.

A similar correction to the observed activation energy can be calculated for the change in other parameters of the medium. For example, if we identify the parameter i with the pH we can use the Brønsted relation[110] $\partial \ln k/\partial(\text{pH}) = \alpha$. Since changes in pH can cause large changes in reaction rate (in either sense) the observed activation energy may be higher of lower than the true activation energy by several tens of kJ $mole^{-1}$. The temperature dependence of the influence of the properties of the medium on the kinetics of reactions in the liquid phase is discussed in Ref.150.

3. Freezing of the Solvent

If reactants in a solvent (which can also take part in the reaction as one of the reactants) are mutually miscible in the solid as well as in the liquid phase, i.e. if they form a continuous series of solid solutions, the region of existence of the liquid phase at temperatures below the melting point of the solvent can be very small. Therefore a decrease in temperature in these systems rapidly suppresses the reaction because of the freezing of the solution. On the other hand if the reactants are not accommodated in the crystal lattice of the solidifying solvent and the system forms a simple eutectic system the region of existence of the liquid phase can extend for several tens of degrees below the melting point of the pure solvent before the freezing point of the eutectic is reached. In this case when the temperature is lowered the pure solvent freezes first and the effective local concentration of the reactant in the liquid phase increases, with a corresponding increase in reaction rate in keeping with the law of mass action. Under certain conditions this contribution may exceed the Arrhenius dependence in absolute value and give rise to a NTC.[151]

By comparing experimental data on the reaction rate in frozen solutions with calculations by the Arrhenius equation for the same temperature we find that the acceleration can be as high as several orders of magnitude. The following theoretical equation has been proposed for the rate constant:

$$k = \frac{T_0 - T}{\Delta}\exp(-E_a/RT) \quad ,$$

where T_0 is the freezing point of the solvent and Δ is its cryoscopic constant[110]. The maximum rate is found at the temperature $T_{max} = [E_a^2/4R^2 + E_aT_0/R]^{1/2} - E_a/2R$. Experimental data for many systems agree satisfactorily with these equations[110].

4. Other Mechanisms

An unusual phenomenon, consisting in a large increase in the reaction rate following the rapid cooling of a solid matrix, has recently been reported. For example, an equimolar mixture of methylcyclohexane and chlorine in which free radicals are photolytically generated reacts explosively when the frozen system is cooled further[152]. The velocity of propagation of the reaction front under these conditions is ~1 m s^{-1}. According to the authors[152], internal stresses in the sample are mainly responsible for this phenomenon. Active centres can be generated in various ways in these systems. Thus if a chlorine–butyl chloride, chlorine–methylcyclohexane, or hydrogen bromide–ethylene system frozen at 77 K is exposed to γ radiation from ^{60}Co and then slowly cooled to 4.2 K no changes are observed. However, if the system is cooled rapidly a "flash" reaction is observed, preceded by mechanical disintegration of the sample. These observations suggest that the thermal mechanism does not play a major role, and that the reaction may be propagated by a self-exciting process[153–155].

An increase in temperature can suppress many heterogeneous catalytic reactions if the heat of adsorption is greater in absolute value than the activation energy of the step leading to formation of the product[156]. In biocatalytic reactions a similar reversible retardation can be produced by the reversible denaturing of the enzyme over a limited temperature range. Under these conditions we expect a bell-shaped temperature dependence of the reaction rate, characterised by an optimum temperature for the reaction[157,158].

---o0o---

In conclusion we should stress that the discovery of a negative temperature coefficient in a particular system can tell us a great deal about the mechanism of the reaction. First of all we must establish whether the NTC is caused by "external" conditions or whether it is inherent in the reaction system. In the former case the appropriate external factors can be isolated by an analysis of the experimental data, and the isoparametric kinetic characteristics of the reacting system itself can be identified. In the latter case a more detailed study of the reaction kinetics over a wide range of parameters is needed (mainly, a range of temperature). It is equally important to establish the possibility of various reversible processes in the system, and if necessary to obtain their thermodynamic characteristics by independent methods.

While this review was being written several reports of NTC in new systems and of more detailed studies of known NTC were published. For gas-phase processes the following studies should be noted: the recombination of $HO_2^{\cdot}$ radicals at low pressures[159], the reactions of $OH^{\cdot}$ and $O^{\cdot}$ at temperatures typical of the upper layers of the atmosphere[160], the reactions of allyl radicals with each other and with NO over a wide range of temperature[161], etc. The NTC phenomenon has been studied in several gas-phase radical reactions: $OH^{\cdot} + HNO_3 \rightarrow$ products[162,163], $NH_2^{\cdot} + O_2 \rightarrow NH_2O_2^{\cdot}$,[164] $OH^{\cdot} + SO_2 \rightarrow HOSO_2^{\cdot}$,[165] and $Cl^{\cdot} + ClONO_2 \rightarrow Cl_2 + NO_3^{\cdot}$;[166] in this type of process the highest NTC was reported for the reaction $OH^{\cdot} + C_3H_6 \rightarrow C_3H_6OH$, in which the bimolecular rate constant decreases 15-fold as the temperature is raised from 255 to 458 K, corresponding to the equation $k = AT^{-4.4}$.[167]

Activation energies $E_{obs} = -3.2$ and -7.1 kJ $mole^{-1}$ were obtained for trimethylethylene and tetramethylethylene respectively in studies of the addition of diphenylcarbene to olefins. The results were attributed to the formation of an intermediate complex which isomerises into the cyclopropane derivative[168].

A much larger NTC was observed for the bromination of hept-1-ene,[169] and for the chlorination[170] and bromination[171] of styrene in non-polar solvents. Thus in the bromination of heptene the temperature dependence of the reaction rate is bell-shaped, with $E_{obs} = -60$ kJ $mole^{-1}$ in the range 240 to 270 K. The negative temperature coefficient in these reactions is ascribed to the participation of molecular complexes in the dark radical generation step. The NTC phenomenon in the hydrochlorination of unsaturated compounds is discussed in a recent review[172]. Model calculations of the kinetics of reactions involving molecular complexes and showing a NTC are given in Ref.173.

The relationship between the changes in physicochemical properties of the medium and the NTC has been studied in detail for the oxidation of the phosphate esters of hydroquinone by potassium periodate in aqueous-ethanolic solutions[174]. A NTC has been observed also in the solid-phase oxidation of hydrazobenzene by a stable nitroxyl radical at 238–258 K.[175]

Synthesis of Diamond in Its Thermodynamic Metastability Region

D.V.Fedoseev, V.P.Varnin, and B.V.Deryagin

Heterogeneous and homogeneous processes in the formation of diamond at low pressures, where diamond is a metastable modification of carbon, are discussed. Data on the kinetics of the growth of diamond from hydrocarbons under conditions which give codeposition with graphite are reported, together with data on the influence of hydrogen on this process and on the resulting fractionation of the stable carbon isotopes. Chemical and plasma-chemical methods of preparing diamond and diamond-like layers are discussed, as well as methods based on the use of atomic and ionic beams. The most recent theoretical and experimental results on the homogeneous formation of diamond in the gas phase are presented.
The bibliography includes 73 references.

I. INTRODUCTION

Before the first successful synthesis of diamond from the gas phase[1] research in this area was confined to the USSR and the USA. Most of the papers published at that time dealt with the growth of diamond on diamond seed crystals by the pyrolysis of methane. Work on the synthesis of diamond in its thermodynamic metastability region is now in progress in Poland, West Germany, Britian, Japan, and other countries. New methods of synthesis of diamond have been developed, using atomic or ionic beams, and low-temperature or high-temperature plasmas. Lastly, homogeneous nucleation of diamond directly in the gas phase has been demonstrated.

The rapid development of research on the synthesis of diamond in its metastability region was stimulated by the unique properties and great technological importance of this material. Whereas the only technical use of diamond until recently was as an abrasive, the material now has potential applications in electronics and in insulating and wear-resistant coatings. Existing methods of synthesis at low pressures can be used to prepare diamond powders and to grow diamond layers (both on diamond and on other surfaces) and diamond crystals. Work on the low-pressure synthesis of diamond is also relevant to an understanding of the origin of diamonds in nature, and to a number of problems in astrophysics.

This review deals with research on the growth of diamond, one of the family of carbon forms which includes hexagonal and rhombic graphite, cubic carbon, carbynes, diamond, and lonsdalite (though even more phases have been reported in the carbon system). The review will be concerned mainly with work published since 1975: earlier work is reviewed fully in Ref.2 and partially in Ref.3.

1. Phenomenological Survey of the Synthesis of Diamond from the Gas Phase

Metastability is not a bar to the formation of diamond (or of any other form of carbon). The process of diamond growth (or of crystal growth in general) can be divided into two main stages: the formation of seeds (or nucleation stage) and the further growth of existing, stable seeds of the new phase.

The free energy of diamond is higher than that of graphite. Therefore the equilibrium partial pressures of carbon-containing gases are higher over diamond than over graphite. The equilibrium pressure of methane over diamond at 1000 K is calculated to be double the corresponding value for graphite. Therefore, for a given partial pressure of methane, the supersaturation is always smaller over diamond than over graphite. Depending on the temperature and on the total pressure, the supersaturation difference between diamond and graphite can decrease, and thus it can influence the relative rates of nucleation of diamond and graphite. Increasing the pressure of methane decreases the supersaturation difference, thereby increasing the ratio of the nucleation rates for the metastable and the stable phase[4].

In spite of its metastability at low pressures diamond is more inert towards atomic oxygen and hydrogen than graphite. The chemical bonds in the diamond lattice show sp^3 hybridisation of the atomic orbitals, whereas in graphite the hybridisation is sp^2. Replacing two neighbours of a carbon atom in the diamond lattice by hydrogen has practically no effect on the electronic interaction between neighbouring atoms, whereas the same operation in graphite alters the nature of the electronic bonds in the whole graphite ring. The differences between the interactions of diamond and of graphite with hydrogen can be likened to the differences in hydrogenation behaviour between ethane and acetylene or between cyclohexane and benzene. The differences in kinetic activity between graphite and diamond form the basis of methods of purifying diamond.

Thus by combining two processes (deposition of carbon, which yields mainly graphite with a small amount of diamond, and gasification by atomic hydrogen, which affects mainly the graphite) we can obtain a product consisting mainly of diamond. In the deposition from atomic or ionic beams the gasification process is replaced by sputtering under the influence of atoms or ions (again, diamond is more impervious to sputtering than graphite).

Let us discuss the growth and gasification of diamond and graphite as in Ref.5, using the subscripts α and β to denote diamond and graphite respectively.

The rates of growth of diamond and graphite can be expressed approximately as

$$v_\alpha = k_\alpha c_1$$
$$v_\beta = k_\beta c_1 ,$$

where c_1 is the concentration of hydrocarbon, and k_α and k_β are the rate constants for the formation of diamond and graphite respectively.

If the surrounding medium contains atomic hydrogen at a concentration much greater than the equilibrium value for the given temperature the rates of the reverse (gasification) reactions can be expressed as

$$v_{-\alpha} = k'_{\alpha} c_2$$
$$v_{-\beta} = k'_{\beta} c_2 ,$$

where c_2 is the concentration of atomic hydrogen, and k'_{α} and k'_{β} are the rate constants of the appropriate gasification reactions. The condition for the deposition of carbon exclusively in the diamond form is

$$v_{\beta} = v_{-\beta} .$$

Hence the minimum concentration of atomic hydrogen can easily be calculated for a given pressure of hydrocarbon:

$$c_2 = \frac{k_{\beta}}{k'_{\beta}} c_1 .$$

The rate of growth of diamond is the sum of the rates of the forward and the reverse reaction:

$$v = v_{\alpha} - v_{-\alpha} .$$

Inserting the critical concentration of atomic hydrogen we find that the rate of growth of diamond not contaminated by graphite is

$$v = v_{\alpha}\left(1 - \frac{k_{\beta}}{k_{\alpha}} \cdot \frac{k'_{\alpha}}{k'_{\beta}}\right) .$$

The above calculation ignores the effect of molecular hydrogen on the crystallisation of diamond and graphite. The corrected formulae are unacceptably cumbersome, without introducing any fundamentally new considerations.

Thus the problems in the synthesis of diamond in its metastability region do not concern the formation of diamond itself: they relate to the prevention of the appearance of the stable phase (graphite), which would otherwise block the diamond nuclei.

The most specific property of carbon is its ability to form strong interatomic bonds with different types of hybridisation of the electronic orbitals, giving different crystal structures which are stable under normal conditions. The chemical potentials of these structures differ only by a small amount, and during crystallisation under high supersaturation this difference plays a negligible role. At the same time the energy barrier to be surmounted in the conversion of diamond into graphite is quite high. Therefore a carbon layer deposited by crystallisation at a high rate will (in general) contain structural fragments corresponding to sp^3, sp^2, and sp hybridisation of the atomic orbitals. This explains the difficulty in preparing perfect crystals of any allotropic modification of carbon (not only diamond).

In the growth processes at relatively high temperatures the energetically less favourable structures are partly converted into the more stable forms. Therefore the relative content of the various types of bond in carbon condensates produced at high temperatures cannot be used to characterise directly the kinetics of their formation from the gas phase.

Another important consideration concerns the two distinct aspects of the synthesis of diamond in general (not only in the metastability region). The first aspect is "purely chemical", and concerns the preparation of a carbonaceous substance in which the atoms are joined by bonds of the type found in a diamond crystal. The second aspect is crystallographic. It is not enough to prepare a carbonaceous substance with bonds of the diamond type if the aim is to produce a diamond: we must also organise the ordering of the crystal structure over regions of adequate size. The solution of this problem presents some major (and well known) difficulties even in substances with far fewer polymorphic modifications. The difficulties increase with the degree of crystalline perfection required. We consider that the main difficulty in the synthesis of diamond in its metastability region lies in identifying conditions compatible with the successful solution of both aspects of the problem.

We know that in organic chemistry the production of metastable compounds is the rule rather than the exception. In this sense the possibility of preparing a diamond-like carbon substance should not appear too remote to a chemist. Obviously, at moderately high temperatures ($\lesssim$1200 °C) the product will be obtained in the solid phase. However, unless precautions are taken to prevent the formation of graphite or carbyne carbon, one is faced with the difficult problem of isolating the diamond-like carbon in a pure form and identifying all the components of the deposited layer. The widely different properties of carbon condensates are due to differences in their content of diamond-like, carbyne-like, and graphite-like bonds.

This "mixed" state of the carbon layer is of interest because it should mirror some properties of the carbon modifications, which are determined by the nature of the interatomic bonds. For example, we know that in semiconductors the principal features of the energy spectrum are retained after transition into the amorphous state. Thus we could expect amorphous carbon to display a combination of the energy spectra of carbyne, graphite, and diamond, except for the contributions from long-range order effects. Thermodynamically such a phase must, of course, be unstable even with respect to the metastable crystalline modifications. At high temperatures solid-state reactions of the $sp^3 \rightarrow sp^2$ and $sp \rightarrow sp^2$ type are possible in the condensed layer, accompanied by annealing of the energetically less favourable types of bond, which brings the system closer to equilibrium (i.e. to the graphite phase).

It is reasonable to ask whether amorphous carbon can be produced at low pressures in a state displaying the short-range order of graphite or of diamond. Amorphous diamond is easily envisaged, by analogy with amorphous silicon and germanium, but amorphous graphite is almost impossible to conceive. Nearly all the specific properties of graphite arise from its strongly developed layer structure. The nearest atom from a neighbouring layer comes only into the fourth coordination sphere. Merely to retain the graphite properties due to the presence of hexagonal rings in the base planes of the graphite crystal requires a higher structural organisation than is usually assumed in amorphous substances (retention of the short-range order only, i.e. second coordination sphere). At best we can expect the existence of amorphous carbon with sp^2 hybridisation of the electronic orbitals of the C atoms.

Thus the problem of preparing diamond under conditions of thermodynamic metastability is found (on closer inspection) to be wider than expected. It should be formulated as a problem in the crystallisation of carbon at relatively low temperatures. We should stress that diamond is a classical three-dimensional ordered structure with a high degree of symmetry. A graphite crystal consists of two-dimensionally ordered networks. Carbyne is classified as a linearly ordered chain structure. Diamond, graphite, and carbyne can themselves exist in several modifications.

II. GROWTH KINETICS OF DIAMOND POWDERS

1. Co-crystallisation of Diamond and Graphite

The kinetics of diamond growth in the pyrolysis of hydrocarbons have been studied mainly during growth on diamond seed powders[6-8], using a gravimetric method (MacBain balance) to

determine the rate of deposition of carbon from the gas phase. The growth of diamond on the diamond seed powder is accompanied by deposition of graphite, which blocks the surfaces on which diamond can form. The rate of growth of graphite from hydrocarbons is lower than the rate of growth of diamond, and therefore the overall rate of deposition of carbon (by weight) decreases with time. From the initial linear portion of the plot of weight against time we can identify the growth rate of the diamond.

Most of the experiments (in different laboratories) were carried out with methane. It was shown that the growth of diamond is proportional to the partial pressure of methane over a wide range of pressure[2], i.e. the reaction is described by a first-order equation. At pressures of 0.01–0.5 mmHg and 1100–1300 K the activation energy of the diamond growth reaction was found[6] to be 80 kcal mole^{-1}.

The kinetic equation for the growth of diamond is

$$v_\alpha,\ \text{g cm}^{-2}\,\text{s}^{-1} = 3.5\cdot 10^{11}\cdot c_0 \exp(-80\,000/RT),$$

where c_0 is the concentration of methane (g cm^{-3}).

The growth rate of diamond and its activation energy are sensitive to the experimental details of the deposition process, the previous history of the sample, and the form of the diamond powder used as a seed. A gravimetric method was used also by Chauhan and co-workers[7], who heated the scale pan containing the diamond seed powder by radiation. In this way the methane not in contact with the diamond seed was kept cool. Pressures up to 44 mmHg were used. The rate of growth of diamond was found to be proportional to the pressure of methane, and an activation energy of 55 kcal mole^{-1} was obtained. Tesner and co-workers[8] studied the growth of diamond at pressures up to 3 atm and observed a slight change in growth rate above 0.5 atm, possibly due to the accumulation of hydrogen in the grown layers of the powder.

Defects on the surface of the diamond powder have a large effect on the rate of growth of diamond. Irradiated diamond powders have been used[9] in a study of the growth of diamond by the gravimetric method and by electrical conductivity measurements. Changes in electrical conductivity are due to the formation of a conducting layer of graphite on the surface of the particles. Diamond powders of ASM-10/7 grade (synthetic diamond powder of 7–10 μm particle size) were irradiated at room temperature by an electron beam of 1 MeV energy to a total dose of 3.6×10^{22} eV cm^{-2} or by γ rays from a cobalt source to a dose of 4.8×10^9 rad. Growth took place from a 1 : 2 mixture of methane and hydrogen at a total pressure of 0.35 mmHg and temperatures of 950 and 1000 °C. The sample was heated to the experimental temperature and cooled back to room temperature in a stream of hydrogen. The aggregate quantites of deposited diamond and graphite were measured by the increase in weight, and the relative amount of graphite by the conductance of the layer.

These experiments showed that the electrical conductivity after the growth is higher, and the increase in weight is lower, for irradiated diamond powders than for powders used without previous irradiation. This suggests a strong deposition of graphite on the irradiated powder, evidently due to an increase in the rate of nucleation of graphite in the presence of surface defects. The dependence of the conductivity on the growth time shows that irradiation of the powder increases the rate of formation of non-diamond carbon but does not cause marked graphitisation of the existing surface. Thus the imperfections in the diamond crystal lattice weaken the orienting effect of the surface forces leading to auto-epitaxial growth of the diamond crystal, and favour the formation of the stable carbon phase (graphite).

Methods used to free the grown diamond powder from graphite include gasification in hydrogen at 50 atm and 1000 °C, oxidation by atmospheric oxygen[2], and gasification by atomic hydrogen generated by a hot tungsten wire[10]. In a recently developed method the graphite is removed in the plasma of a glow discharge in air. The method relies on the difference between the activities of diamond and of graphite towards reactions with oxygen atoms and ions[11–13]. At low temperatures the difference between the specific rates of oxidation of diamond and graphite is five orders of magnitude. On raising the temperature the rate of oxidation of diamond in the air plasma is found to increase much faster than the rate of oxidation of graphite. The activation energy for the interaction of diamond with the air plasma is 46 kJ mole^{-1}, whereas that of graphite is 5.0 kJ mole^{-1}. At temperatures above 500 °C the activation energy for diamond increases because the interaction with molecular oxygen becomes appreciable. The nitrogen in the air plasma was shown (in separate experiments) to be almost inert at temperatures up to 800 °C.[11]

Exposure of the grown diamond powder to the air plasma completely removes the graphite from the surface, leaving a layer of grown diamond. The effective depth of penetration of the gasification reaction is determined mainly by the loss of active particles in the layer of already purified diamond. Similar results were obtained for the gasification of diamond and graphite in the plasma of a glow discharge in hydrogen[14]. This work has shown that atomic oxygen and atomic hydrogen are the main components of the gas mixture during its reaction with graphite.

Three growth rates can be defined in studies of the growth of diamond powders: $v_{\alpha\alpha}$ (the rate of growth of diamond on diamond), $v_{\beta\alpha}$ (the rate of growth of graphite on diamond), and $v_{\beta\beta}$ (the rate of growth of graphite on graphite). A suggested method[15] of determining these three rates is based on Kolmogorov's theory of the growth and merging of planar nuclei. According to the experimental results[15], at a methane pressure of 0.3–10.0 mmHg, 1 : 1 dilution with hydrogen, and 930 °C temperature the rates $v_{\alpha\alpha}$, $v_{\beta\alpha}$, and $v_{\beta\beta}$ are approximately in the ratio of 7 : 2 : 1. The quantity of diamond formed during the growth was determined[15] by gasification in a glow-discharge plasma.

Defect "healing" processes, and annealing of internal stresses, can take place during growth on diamond powders. A study[16] of the effect of over-growing in methane at temperatures up to 1600 °C on the crushing strength of diamond powders has shown that the thermal stability of the grown powder is increased by the treatment.

2. Mechanism of the Growth of Diamond on Seed Crystals

The kinetics of heterogeneous chemical reactions with formation of a new phase depend on the reactivity of the gas molecules and on the nature of the surface. The effect of the surface is two-fold. Firstly, the surface influences the kinetics of formation of the new phase through its molecular and valence forces. Formally this effect consists in a change in the energy of formation of the critical nucleus of the new phase (i.e. the nucleus capable of further growth). Secondly, the nature of the surface determines the collision frequency in the two-dimensional adsorption layer, and the frequency of encounters of "incident" molecules and atoms with sub-critical nuclei. This effect of the surface is expressed through the adsorption characteristics of the surface–gas system.

The diamond growth mechanism described below applies to systems without a super-equilibrium concentration of atomic hydrogen, in which the supersaturation is due exclusively

to a super-equilibrium concentration of methane. By analysing experimental results it was shown[17] that the rate of growth of diamond is the sum of two terms:

$$v_\alpha = k_{\alpha 1}(1-\theta_1-\theta_2)p_1 + k_{\alpha 2}\theta_2 p_1 \ , \qquad (1)$$

where θ_1 and θ_2 are the fractions of the surface occupied by methane and by hydrogen respectively, p_1 is the partial presssure of methane, $k_{\alpha 1}$ and $k_{\alpha 2}$ are the rate constants, b_1 and b_2 are the adsorption constants of methane and hydrogen respectively, and p_2 is the partial pressure of hydrogen. A theory of the growth of diamond was developed by using an adsorption equation of the Langmuir type in the form (for a binary mixture)

$$\theta_1 = \frac{p_1/b_1}{1+p_1/b_1+p_2/b_2}, \quad \theta_2 = \frac{p_2/b_2}{1+p_1/b_1+p_2/b_2} \ . \qquad (2)$$

The first term in the right-hand side of Eqn.(1) corresponds to the mechanism of direct addition on a part of the surface of the diamond seed crystal which is free from adsorbed molecules. The second term corresponds to the growth of diamond through the chemisorbed hydrogen.

We note that according to the physicochemical theory[18] of graphite growth the growth rate is given by the expression

$$v_\beta = k_{\beta_1}\theta_1^2 + k_{\beta_2}\theta_1 j_1 \ , \qquad (3)$$

where $k_{\beta 1}$ and $k_{\beta 2}$ are the rate constants and j is the flux of methane molecules per unit surface per unit time. Eqn.(3) satisfactorily describes the rate of growth of graphite at 800–1800 °C and methane pressures between 10^{-5} and 30 atm. The first term in Eqn.(3) describes the growth of graphite from the adsorbed two-dimensional gas, the second describes the growth by direct collisions. At low temperatures the graphite grows by the Langmuir mechanism, at high temperatures by the Rideal mechanism. Eqn.(3) was obtained by assuming that the formation of critical nuclei (nucleation step) is rate-limiting in the growth of graphite.

3. Growth of Diamond from Different Hydrocarbons and from Their Mixtures

The study of the growth of diamond from different hydrocarbons[19] is of interest for several reasons. Firstly, it had been suggested[20] that diamond can grow from the gas phase only in the presence of compounds whose decomposition produces methyl radicals. Secondly, the rate of growth of diamond in several hydrocarbons is higher than in methane. Lastly, the problem is of interest also in relation to the formation of natural diamonds outside the Earth's mantle.

In these experiments[19] the hydrocarbon pressure was varied between 10^{-2} and 1 mmHg, and helium was used as the carrier gas. Electrification effects were minimised by coating the quartz helix, the support, and the quartz pan of the MacBain balance with a thin layer of pyrolytic carbon. Diamond growth was confirmed by cleaning the seed powder in an air plasma after the growth: after removal of the non-diamond carbon the diffraction patterms of the samples showed only reflexions from the diamond lattice. Growth was at temperatures between 1000 and 1300 K. In all the hydrocarbons the rate of growth of diamond was directly proportional to the partial pressure of the hydrocarbon. Therefore the results can be described by the rate constant for a first-order reaction (g cm^{-2} $mmHg^{-1}$).

The activation energy for the growth of diamond was calculated[19] from the temperature dependence of the rate constant of the reaction. The lowest rate constant and the highest activation energy (80 kcal $mole^{-1}$) were obtained for the growth of diamond from methane, and the highest rate constant and lowest activation energy for the growth from acetylene. The straight-line kinetic plots for other hydrocarbons lie between those for methane and acetylene.

If these kinetic lines are extrapolated towards higher temperatures they all intersect at ~1400 K. This is the temperature above which diamond cannot be grown with the substrate and the gas at the same temperature[1,2,7,20] unless the gaseous medium is additionally activated (for example, by an electric discharge). At 1400 K and above only graphite grows on the diamond seed powder, completely suppressing the growth of diamond, because at these temperatures the rate constant for the growth of graphite from all the hydrocarbons becomes greater than the rate constant for the growth of diamond. We may assume that at high temperatures the orienting (auto-epitaxial) effect of the substrate on the formation of the new phase becomes weaker, allowing the carbon to crystallise in the stable form.

However, it should be possible in principle to obtain diamond at temperatures up to the spontaneous graphitisation temperature (~2000 K). An increase in temperature at constant total pressure in the system lowers the equilibrium partial pressure of methane over graphite and diamond, i.e. it increases the supersaturation. As a result the relative difference in the work of formation of the critical nucleus between diamond and graphite decreases, and the relative probability of the nucleation of diamond increases.

The growth of diamond from methane at high temperatures has been studied[21] by using laser heating. A diamond single crystal in a methane atmosphere was heated by the focussed radiation from a laser. The temperature of the crystal was measured by an optical pyrometer. After the growth the crystals were washed in boiling perchloric acid to remove graphite, and the remaining film was studied by reflection electron diffraction. The temperature range was 1300–2000 K, the pressure range of carbon-containing gases was 1–50 mmHg. The experiments with acetylene and ethylene gave only graphite layers. Growth from methane gave polycrystalline diamond films up to 3 μm thick. Structural studies showed that the films contain some highly dispersed graphite. The diamond and diamond–graphite films were prepared from methane at temperatures above 1600 K.

If the direct collision mechanism is applied to the crystallisation from a mixture of hydrocarbons, additivity of the reaction rates is always expected. The reaction rate is directly proportional to the flux of molecules to the surface of the seed crystal, which is linearly dependent on the partial pressure of the hydrocarbon (ignoring the changes in diffusion coefficient if the process is known to be activation controlled).

Additivity of the reaction rates was observed for the growth of graphite in methane–acetylene and ethane–ethylene mixtures[22,23]. However, deviations from additivity of the reaction rates were also noted[24,25] in the growth of diamond and of graphite, i.e. the growth rate of diamond and graphite from a mixture of hydrocarbons was not equal to the sum of the growth rates from the individual hydrocarbons at the same partial pressures. This is because in the growth of a new phase from adsorbed molecules the rate is proportional to the coverage of the surface, which in the case of a mixture of hydrocarbons is not (in general) equal to the sum of the coverages by the individual hydrocarbons. This interpretation is confirmed by experiments on the synthesis of diamond from methane–acetylene and ethane–ethylene mixtures[25] in which the growth rate of diamond from the mixtures was shown to be lower than the sum of the rates of growth from the separate gases. The apparent activation energy was a function of the composition of the mixture.

4. Effect of Added Hydrogen on the Growth of Diamond

The addition of hydrogen affects the growth of diamond from hydrocarbons in several ways. Firstly, the addition of hydrogen to the initial hydrocarbon lowers its rate of decomposition, and therefore also the rate of formation of the solid phase. Secondly, the dissociation of molecular hydrogen produces atomic hydrogen, which can gasify the graphite formed in the reaction. In the presence of a super-equilibrium concentration of atomic hydrogen the formation of graphite can be completely suppressed. According to the proposed mechanism, the rate of growth of diamond can be increased by diluting the hydrocarbon with hydrogen[26]. At temperatures above 1050 °C the rate of growth of diamond from methane–hydrogen mixtures is higher than from pure methane. Similar effects were found in ethane and propane. We can assume that the decrease in the growth rate of diamond from pure hydrocarbons caused by an increase in temperature is due to the preferential deposition of carbon in the graphite form. Dilution with hydrogen suppresses the formation of graphite by lowering the coverage of the surface with methane or methyl radicals. Under these conditions the rate of growth of graphite (on a graphite surface) is strongly lowered.

Experiments on diamond growth on an ASM-10/7 powder from methane–hydrogen mixtures and from pure methane at 1000 °C have been reported[26]. Growth was stopped at a prescribed value of the electrical conductivity of the powder, i.e. for a constant amount of graphite in the product. The weight of powder in all the experiments was the same (400 mg). We note from the results (Table 1) that for a fixed amount of deposited graphite the increase in weight of the diamond powder is greater when the methane is diluted with hydrogen than in the pure methane. On increasing the pressure the influence of added hydrogen on the growth rate of diamond is found to decrease.

Increase in mass (Δm) of the new phase during growth on a diamond powder from methane and its mixtures with hydrogen[26] (τ is the duration of the experiment, $\varkappa$ is the conductivity).

p_{CH_4}, mmHg	p_{H_2} mmHg	Δm, mg	τ, min	$10^{-3}\varkappa$, arbitrary units
0.03	0	0.12	45	
0.03	0.27	0.72	153	
0.30	0	0.80	60	170
0.30	0.30	1.15	120	170

The growth rate of diamond from hexane and from cyclohexane, and from their mixtures with hydrogen, has been found[19] to be independent of the degree of dilution (up to a ratio of 1 : 19) for a partial pressure of the hydrocarbon of 0.03 mmHg. In general the effect of dilution with hydrogen on the growth of diamond and graphite depends on the total and on the partial pressures, and on the temperature of the synthesis. However, dilution with hydrogen always lowers the rate of growth of graphite more markedly than that of diamond, owing to the difference in growth mechanism between the stable and the metastable carbon phase.

5. Fractionation of the Stable Carbon Isotopes

The forms of carbon found in nature as minerals contain a well defined ratio of the stable isotopes ^{12}C and ^{13}C. Without bringing the geochemical side of the problem into the discussion we can nevertheless note that diamonds are "heavier" than natural graphite in isotopic composition, i.e. they contain a greater proportion of the heavier ^{13}C isotope. Furthermore, in the kimberlite pipes the diamonds are isotopically "heavier" than the carbonates in the surrounding minerals. A study[27] of the fractionation of the carbon isotopes during the growth of diamond and graphite from methane has confirmed that the grown diamond is enriched in the heavier ^{13}C isotope whereas the graphite is enriched in the ^{12}C isotope.

The thermodynamic isotope effect is probably irrelevant here, since at 1000 °C (the temperature of the synthesis) its separation coefficient[28] is only 1.002 whereas the experimental value[27] is 1.025. The extent of separation of the stable carbon isotopes is strongly influenced by the rate of crystallisation. At very low or very high rates of crystallisation no separation is observed. The separation can be interpreted in terms of the mechanism of growth of diamond and graphite. The diamond surface is covered with a layer of chemisorbed hydrogen. Therefore one of the steps in the addition of a carbon atom to the diamond lattice is the formation of a $CH_4 \cdot H$ complex, whereas the growth of graphite involves mainly methyl radicals (as has been shown by extensive work[7]).

The separation coefficient can be equated (approximately) to the ratio of the reaction rates for the two isotopic forms[28]:

$$\alpha = \frac{k_1}{k_2} = \frac{s_1 s_2^{\neq}}{s_1^{\neq} s_2} \left(\frac{\mu_2}{\mu_1}\right)^{1/2},$$

where k_1 and k_2 are the rate constants of the reactions for the two isotopic forms, s_1 and s_2, $s_1^{\neq}$ and $s_2^{\neq}$ are the symmetry numbers for the isotopic forms of the compounds and of the transition complexes, and μ_1 and μ_2 are the reduced masses of the isotopic forms. Calculations by the above formula give $\alpha(CH_4 \cdot H) \approx 1.025$ and $\alpha(CH_3) \approx 0.975$, in good agreement with the largest experimentally observed[27] separation coefficients of the stable carbon isotopes.

The discussion so far has dealt exclusively with diamond and graphite. However, many other phases are present in the carbon system[29], and could be formed during the pyrolysis of hydrocarbons. Cubic carbon and alpha-carbyne have been observed[30] during the growth of diamond on powders from methane.

III. PREPARATION OF DIAMOND LAYERS AND CRYSTALS

1. Chemical and Plasma-chemical Methods of Preparing Diamond Layers and Crystals

As was shown above, the main problem in the synthesis of diamond is not organising the formation of the diamond solid phase but preventing the deposition of carbon in its stable form (graphite). Therefore all the studies of the growth of large and thick diamond films are essentially developments of methods for removing graphite and preventing its formation.

In the chemical methods this is achieved by gasifying the graphite with atomic hydrogen and with the radicals formed by activating the gaseous medium. In the first successful method of growing diamond single crystals (the pulse method[1]) the graphite nuclei formed on the surface of the seed crystals

were "re-absorbed" (gasified) in the periods between two pulses, when their diameter was still subcritical. The method gave not only monocrystalline diamond films up to 10 μm thick but also filamentary and isometric diamond crystals.

Diamonds have been grown[31,32] in a methane–hydrogen mixture activated by a glow discharge. Excitation of the electrical discharge brings the gas mixture into a strongly non-equilibrium state, with a concentration of atomic hydrogen well above the equilibrium value for the given temperature. This atomic hydrogen can interact very actively with the graphite. If a layer of graphite is previously deposited on the surface of the diamond seed crystal it is possible to remove this layer and then begin to grow a diamond layer on the clean seed surface by this method. At first only natural diamonds in the octahedral habit were used as substrates in these experiments. It was shown that a thin film of diamond grows initially in the same orientation as the substrate. This is followed by a fully mis-oriented diamond layer, and lastly by diamond layers with a rhombododecahedral texture axis. This change in orientation suggests that at high supersaturations the effect of the substrate is not very marked. Polycrystalline diamond films were deposited on silicon, molybdenum, and rhenium by the same method.

Diamond layers on a diamond substrate (and also on tungsten and gold surfaces) have been prepared by chemical transport reactions[33,34]. The method also gave separate single crystals of diamond up to 50 μm in diameter on metallic substrates[35].

The properties of diamond films prepared by chemical reactions are identical to those of natural single crystals of diamond. Unlike the diamond films deposited from ionic and atomic beams, the chemically deposited films have a high graphitisation temperature. This is obviously due to their higher crystallinity, resulting from the higher synthesis temperatures used in the chemical methods.

In the plasma-chemical methods the plasma acts both as a source of carbon and as a source of ions, which bombard the surface of the growing crystal. The ions (for example, hydrogen) and the radicals formed in the plasma can remove non-diamond forms of carbon by chemical reaction or by sputtering. The first plasma-chemical synthesis of diamond was reported in Ref.36: a black layer of carbon, with a surprisingly high hardness, was found on the cathode when a glow discharge was struck under certain conditions in an atmosphere of gaseous hydrocarbons. A layer several μm thick was obtained from a glow discharge in acetylene. Laue diffraction patterns from separate regions of the layer, which were easily recognised, indicated a cubic structure, and the Debye diagrams clearly showed two strong diamond lines but no strong graphite lines.

The electrical conductivity and the optical absorption of films prepared by the decomposition of acetylene in a direct current glow discharge at 25–375 °C have been studied[37]. The electrical conductivity of the films covers a range of 11 orders of magnitude, depending on the growth temperature. The width of the energy gap, calculated from optical absorption data, lies between 0.9 and 2.1 eV and decreases as the deposition temperature is raised. The films become graphitic[37] at temperatures above ~425 °C.

Semiconducting films of hydrogenated amorphous carbon obtained by this method were doped with boron and phosphorus during their growth[38]. Diamond crystals of various shapes (polyhedra, platelets, needles) have been obtained[39] from a plasma excited in a low pressure of aliphatic hydrocarbons by a high-voltage d.c. or a.c. (10^7 Hz frequency) source.

The pulsed crystallisation of diamond and diamond-like carbon has been described[40], using either the gas and the cathode material or the cathode material alone as the source of material for the crystallisation. In either case the carbon is present as excited atoms or ions. Chemical reaction takes place during the expansion of the plasma, when the high-temperature components should condense. The crystallisation products are deposited on a substrate (monocrystalline silicon, glass, polycrystalline aluminium) at 300 K. Layers up to 1 μm thick had good adhesion and an electrical resistance of ~10^8 Ω in the transverse direction. Diamond, lonsdalite, and other phases were detected in the deposited layers. When the substrate temperature was raised to 723 K an amorphous layer giving diffuse diffraction lines was obtained. Applying a potential of ±800 V to the sample did not affect the stucture or the properties of the deposited layers.

A study[41] by X-ray photoemission spectroscopy of films prepared by a high-frequency plasma in butane showed that diamond-like material is obtained at moderate applied power and low rates of deposition. However, the authors stress[41] that these layers are not true diamond material and should be called diamond-like.

2. Deposition of Diamond Layers from Atomic and Ionic Beams. Physical Methods

Physical methods have been used increasingly in recent years; they consist in the deposition of carbon on various (usually cooled) substrates from beams of fast carbon ions or atoms. Depending on the deposition conditions we can distinguish the condensation from atomic beams from that from ionic beams, and from flows of carbon plasma. The condensation from atomic beams uses a stream of atoms produced by cathodic sputtering of graphite electrodes. In contrast to the stream of carbon vapour produced by thermal evaporation or in an arc, in this case there are no polyatomic groups to act as nuclei for the growth of graphite. According to calculations[42] the average energy of the atoms is greater than 100 eV. The most characteristic feature of deposition from an atomic beam is the low temperature of the substrate (usually the temperature of liquid nitrogen). This, together with the low growth rates (up to 10 Å min^{-1}) and the associated low energy flux (~3×10^{-3} W cm^{-2}), ensures that the deposited layer is amorphous and homogeneous. These features also explain the stringent purity requirements on the starting materials and the need for ultra-high vacuum conditions (better than 10^{-9} mmHg).

In deposition from atomic beams the energy of the condensing atoms is difficult to control. This problem disappears when ionic beams or streams of carbon plasma are used for the deposition. It has been suggested[43] that the techniques and procedures previously used to prepare crystals of the stable modifications could be used also in the preparation of carbon condensates with the diamond structure. The basic assumption in this method is that the energy needed for the nucleation and growth of a thin layer can be supplied as kinetic energy of the condensing material rather than by heating the substrate. It is thought[43] that by using ion beam techniques both amorphous and crystalline carbon films can be prepared, and the deposited layer should be crystalline whereas its surface layers are amorphous, since not all the surface atoms have enough energy to migrate instantly to a crystalline region. The mobility of the surface atoms can be increased by adding inert gas atoms (for example, argon) to the stream of carbon atoms. This scheme was subsequently adopted in practical applications and called the double beam method[44].

As was pointed out above, the general considerations concerning the organisation of the crystal structure are equally applicable to diamond, but only under conditions which ensure the suppression of the stable modification of carbon (graphite). Therefore the conditions of the irradiation of the growing surface with accelerated atoms of carbon or of an inert gas should be chosen primarily with the aim of preventing the formation of non-diamond forms of carbon.

The importance of suppressing the formation of non-diamond forms during the crystallisation of diamond from an ionic beam has been stressed in a paper[45] describing studies of the structural and other properties of condensates prepared by this method. The energy of the carbon and argon ions (when argon was used as a carrier) was ~50 eV. The structure of the resulting layers was determined by X-ray diffraction. The technique needed long exposure times and layers at least 2 μm thick. In many cases definite but weak diamond reflexions were observed. Much thinner (100 Å) films were studied by transmission high-energy electron diffraction, in selected areas containing relatively large crystals. In this way diffraction patterns for both monocrystalline and polycrystalline material were obtained. Bright-field photography shows many monocrystalline regions with a fourth-order symmetry axis extending over cross-sections of 1–5 μm. We note that the diffraction patterns include reflexions which are forbidden for diamond, corresponding to the interplanar spacings $d_{100} = 3.57$ Å and $d_{110} = 2.52$ Å. Some diffraction patterns show sharp reflexions from the (211) planes ($d_{211} = 1.44$ Å). The presence of forbidden reflexions is attributed[45] (by analogy with the diffraction patterns of natural diamonds) to the regular occurrence in the lattice of atoms of the inert gas used as a carrier, giving rise to superlattices. The preferred (111) orientation of the layers suggests that the growth rate of the crystallites is a maximum in this direction. This was ascribed to the greater stability towards graphitisation of the (111) plane in a diamond crystal.

These results have been confirmed by a study[46] of the dependence of the phase composition and structure of the deposited layers on the composition of the beam, the energy of the ions, and their density in the beam. By using a high-current mass spectrometer with magnetic mass separation of the ions it was possible to deposit layers from spectrally pure beams of ions of the required mass and 30–100 eV energy under ultra-high vacuum conditions (5×10^{-9} mmHg). Deposition on KCl crystals gave a preferential (≥80%) orientation of the crystallites in the (100) direction, corresponding to the orientation of the substrate, but a small number of samples showed a (110) orientation. In the whole energy range (30–100 eV) the diamond phase was formed at current densities between a few hundredths and a few units of mA cm^{-2}.

It has been pointed out[47] that in the crystallisation of diamond the situation is entirely different from the formation of stable crystals (for example, silicon) not only because diamond is metastable under the conditions of deposition of the phase but also because of the possibility of irreversible graphitisation of the diamond by radiation-induced defects. In an attempt[47] to prepare epitaxial layers on diamond it was shown that in growth from low-energy ion beams even slight surface imperfections can have a strong effect on the reproducibility of the results. The best results were obtained by deposition with ions of ~900 eV energy on carefully cleaned diamond plates heated to 700 °C. Layers a few μm thick prepared at rates of deposition of a few tenths of μm per hour invariably contained inclusions of low-density carbon. The formation of these inclusions during the epitaxial growth of diamond determines the upper limit of thickness to which a monocrystalline layer can be grown in practice.

A method of preparing diamond-like layers using two ion sources has been described[44,48]. In this case one ion source generates argon ions with an energy of up to 10 keV at current densities of 0.5–1 mA cm^{-2}, which sputter the carbon target, giving a growth rate of 5–10 Å min^{-1} of the carbon layer on the substrate. The layers have properties similar to those of ordinary thermally deposited layers unless they are simultaneously irradiated with argon ions from another source at energies between 0 and 2 keV and current densities between 0.2 and 5 mA cm^{-2}. The growth rate of the layer can be controlled between 5 and 10 Å min^{-1} (allowing for back-sputtering) by suitably choosing the current density and energy of the ions. Layers prepared in this way have properties very different from those of thermally deposited layers. In a variant of this method of deposition[49] the carbon source was a diamond powder evaporated by laser heating.

A method of preparing carbon coatings from a carbon plasma has been described[50–55]. A cooled metallic substrate is located in a plasma flow generated by an arc, and connected to a d.c. potential source negative with respect to the plasma, or to a high-frequency a.c. potential. The mechanical, electrophysical, and structural properties of the resulting condensates were studied by various methods.

To explain the formation of a diamond structure under these conditions it was suggested[53] that high temperatures and pressures (corresponding to the stability region of diamond in the carbon phase diagram) may be produced locally when the substrate is bombarded with high-energy ions and atoms. Metastable crystalline forms, including diamond, are formed by the removal of energy from the "hot" points as a result of the substrate cooling. A similar explanation[48] of the mechanism uses a dynamic concept of the synthesis of diamond and gives a rough estimate of the temperatures and pressures generated by the impact of the accelerated particles on the growth surface.

The dependence of the density of carbon condensates on the initial energy of the carbon ions has been studied[54]. For ion energies of ~50 eV the density of the condensate (4.1 g cm^{-3}) is higher than that of diamond. This large increase in density is attributed[55] to the presence of diamond and a new (C_8) carbon phase in the condensate for ion energies in the range 40 eV $\leq \varepsilon \leq$ 70 eV. The nature of the structure-formation processes under ion bombardment is discussed[54] by the following qualitative model of the dependence of the density of the condensate on the ion energy: at energies greater than 10 eV the ion can penetrate into the condensate to a depth of several interatomic distances, causing local rearrangements of the structure and the formation of point defects (mainly interstitials and vacancies). The accumulation of vacancies in the dense phases at $\varepsilon > 70$ eV and the consequent conversion into more open phases explain the decrease in density of the layers.

IV. HOMOGENEOUS FORMATION OF DIAMOND IN THE GAS PHASE

1. Theoretical Discussion of the Homogeneous Nucleation of Metastable Carbon Phases

The homogeneous nucleation of diamond in the gas phase and subsequent growth on the resulting seeds produces other forms of carbon as well as diamond. At high supersaturations the work of formation of the critical nucleus of the new phase becomes comparable to the quantity $kT = \Theta$ (a measure of the energy of the thermal motion of the atoms and molecules). However, the exact theory of nucleation is limited to low[56–58] or intermediate[59] supersaturations. At

high supersaturations some difficulties arise from the need to consider entities consisting of a small number of atoms or molecules. Therefore the analysis of the rates of nucleation at high supersaturations is only qualitative. It has been shown[60-62] that an increase in supersaturation increases the probability of nucleation of diamond as compared with graphite. A more detailed analysis is given in Ref.63.

The rate of homogeneous nucleation from the vapour is defined[56-58] as the number of critical nuclei formed in unit volume per unit time:

$$I = \frac{\alpha p^2}{\rho} \cdot \frac{(\sigma m)^{1/2}}{\Theta^2} \exp\left(-\frac{U}{\Theta}\right) , \quad (4)$$

where p is the vapour pressure, σ is the surface tension, ρ is the density of the condensed phase, m is the mass of the atom (or molecule), U is the work of formation of the critical nucleus, and α is the condensation coefficient. The rate of nucleation at constant pressure has a maximum at a value of Θ given by the condition $(\partial I/\partial\Theta)_p = 0$. Ignoring the dependence of the surface energy on the curvature of the surface and assuming a constant condensation coefficient we obtain

$$(\partial U/\partial\Theta)_p - U/\Theta + 2 = 0 . \quad (5)$$

The work of formation of the critical nucleus in the classical nucleation theory is

$$U = \frac{16}{3} \frac{\pi\sigma^3 v^2}{\Theta^2 \ln^2 (p/p_e)} , \quad (6)$$

where p_e is the pressure of the vapour in equilibrium with the condensed phase, and v is the volume occupied by each particle in the condensed state. To a first approximation we can use an expression of the type of

$$p_e = A \exp(-H/\Theta) , \quad (7)$$

where H and A are the heat of evaporation and a constant factor respectively, and have different values for the different allotropic forms. From Eqn.(6) we now obtain

$$\frac{U}{\Theta}\left[1 - \frac{^2/_3 H}{\Theta \ln p/A + H}\right] = \frac{2}{3} . \quad (8)$$

In general Eqn.(8) gives a fourth-power equation for Θ. However, because of the approximations in the analysis, the treatment has been simplified[63] by considering only the case of $p = A$, when the supersaturation is $\Theta = \infty$. This gives

$$\Theta_m = U/2 .$$

Thus different phases will have maximum rates of nucleation at different temperatures (assuming constant pressure). Each phase has a supersaturation for which its rate of nucleation is a maximum. The maximum rates of nucleation of the different phases occur at different Θ values and have different magnitudes. Increasing the surface energy lowers the maximum. The published analysis[63] is applicable to many systems as well as to the carbon system. An analysis of Eqn.(8) indicates that the probability of formation of metastable phases increases with pressure.

2. Experimental Studies of the Homogeneous Nucleation of Diamond

The homogeneous nucleation (and growth) of diamond in the gas phase has been studied by using an electrical discharge in hydrocarbon vapours[64], by explosions in carbon-containing substances[65,66], and by laser heating[62,67].

By using the energy of an explosion the synthesis of diamond is carried out (in spite of the high dynamic pressures) at a temperature higher than the equilibrium temperature of the graphite–diamond phase transition, i.e. the process takes place in the thermodynamic stability region of graphite. This method gives very small (up to 1000 Å) diamond particles, often coloured. All the diamond crystals obtained by this method are defective and stressed.

The homogeneous synthesis of diamond has been achieved under cleaner conditions by using laser heating[63]. Liquid hydrocarbons were placed in a burette with a capillary tip. The radiation of an LG-25 infrared laser was focussed on the falling drop of octane, nonane, hexane, and other hydrocarbons. By varying the drop height (from the tip of the capillary to the focus of the lens) the time of interaction of the laser beam with the drop could be varied. The diameter of the drop was determined by the bore of the capillary. The repetition frequency of the drops was controlled by the air pressure in the burette. When the drop crossed the laser beam it was violently evaporated, and radiation was absorbed by the vapour. The vapour was strongly heated, and an aerosol containing both liquid and solid particles was formed round the drop. Some of the particles were entrained by the falling drop and collected in the cell. Samples for the structural studies were taken either directly from the aerosol on suitably located substrates or from the liquid residue.

Particles up to 20 μm in diameter (usually consisting of groups of much smaller particles) were observed in the electron microscope[63]. The average size of the particles was ~0.1 μm, their shape varied from irregular to accurately spherical. Structural studies (by X-ray and electron diffraction) identified the solid particles as diamond, graphite, and carbyne. After removal of the graphite by gas etching the solid phase contained only diamond and carbyne.

The electron diffraction patterns obtained from the diamond particles suggest the presence of strong stresses and a block structure, indicated by the line broadening. Most of the spherical particles were "amorphous to electrons", though in some cases diffraction patterns from a highly distorted diamond structure, close to amorphous, were obtained. We should note that in this work[63] particles of the hypothetical forms of carbon proposed in Ref.55 were observed (for example, C_8). The exact identification of the hypothetical forms of carbon, and their place in the carbon phase diagram, are still unsolved problems. The high stresses and defect densities in diamond particles obtained by homogeneous synthesis in the gas phase are probably due to the high growth rates under these conditions. Thus in the laser method the growth time of the diamond particle is 10^{-3} s, and in the explosion method 10^{-6} s.

An important requirement for the presence of diamond among the products of the homogeneous synthesis is rapid cooling of the resulting particles[63,65]. It has also been shown[68] that rapid cooling of polycrystalline graphite from high temperatures can induce the conversion of graphite crystals into carbyne and diamond. In these experiments[68] the temperature of the graphite did not exceed 3000 K. The mechanism of the solid-phase graphite–diamond transition at atmospheric pressure is not self-evident. It may involve compression of the graphite crystallites during rapid cooling. It has been shown[69] that the bonds of the graphite lattice are broken in molten carbon. Fast cooling may "freeze" the states which exist at high temperatures.

3. Some Consequences of the Homogeneous Nucleation of Diamond

These results may help to explain the origin of the natural diamonds found in kimberlite pipes. The diamonds could have been nucleated by local explosions, with gaseous hydrocarbons as the source of carbon. Evolution of hydrocarbons

occurs (as it did at the relevant time) in practically all the pipes containing diamonds. However, calculations show[70] that the strength of the rocks is insufficient to contain the pressures corresponding to the region of thermodynamic stability of diamond.

Very interesting reports of the possible existence of very fine diamond particles in interstellar space have been published[71]. Carbon is the most probable constituent of cosmic dust, and carbon particles could be formed from matter ejected by stars. The carbon–nitrogen cycle, formulated by Bethe in 1939, is a source of thermonuclear energy in hot stars. When matter is ejected from a star and rapidly cooled the carbon vapour can condense into very small particles. At this stage various forms of solid carbon can also be formed: graphite, carbyne, diamond, and others. The nucleation of solid carbon takes place in the presence of hydrogen. We have shown[1] that hydrogen can markedly lower the growth rate of graphite, but its effect on the growth rate of diamond from hydrocarbons is much smaller. The difference in the rates of interaction with different carbon phases is even greater with atomic hydrogen. A study[14] of the interaction of atomic hydrogen generated by a glow discharge with graphite and diamond showed that up to 500 °C the gasification of diamond by atomic hydrogen is negligible, whereas the rate of gasification of graphite is substantial. This allows complete gasification by atomic hydrogen of the graphite particles formed by the condensation of carbon atoms from the plasma of stellar matter.

The diffuse luminescence of the Galaxy is said[71] to be incompatible with the hypothesis that interstellar dust consists of particles of graphite or of graphite covered with ice. It is suggested[71] that the dust probably consists of diamond particles up to 0.1 μm in diameter. The lack of direct experimental data on the homogeneous nucleation of diamond was noted with regret, and it was stated that the diamonds in the Galaxy must have a high concentration of defects (as has been found in the experiments discussed above). The phase composition of the carbon in interstellar dust could have a direct bearing on the conversion of the initially atomic hydrogen in interstellar matter almost totally into molecular hydrogen[72].

The recombination of two hydrogen atoms into a molecule requires the presence of a third particle, which could be a particle of interstellar dust. Many different organic compounds, containing hydrogen, nitrogen, oxygen, and other atoms, are found in dense interstellar clouds. When considering the evolution of such a cloud we must allow for the fact that the reactivity of graphite towards atomic hydrogen and oxygen is very high, whereas that of diamond is negligibly small. The reaction of hydrogen atoms with graphite at low pressures can produce various radicals and compounds, some of which have been observed by radio-astronomical methods in interstellar space (see Table 1 of Ref.72). Therefore the formation of organic compounds in interstellar clouds may be due (at least, partially) to the gasification of graphite particles in the interstellar dust. On the other hand the recombination of hydrogen atoms could take place on diamond particles, whose presence in interstellar space seems likely.

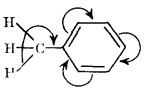
The Spectroscopy of Organic Compounds of Silicon Subgroup Elements and Hyperconjugation

A.N.Egorochkin



The general and theoretical aspects of the problem of hyperconjugation are examined. The factors determining the magnitude of the effect and its major role in organoelemental compounds compared with organic compounds are discussed. Various types of hyperconjugation (σ,π-, σ,σ-, and σ,p-conjugation) in the ground electronic state of organoelemental compounds of Group IV elements are considered.
The bibliography includes 226 references.

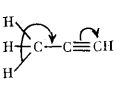
I. Introduction 445
II. Theoretical ideas about hyperconjugation 447
III. Experimental studies of hyperconjugation in organoelemental compounds 448

I. INTRODUCTION



The concept of hyperconjugation was introduced into organic chemistry in connection with the study of the reactivity of aromatic compounds, the influence of alkyl substituents of which cannot be described solely in terms of the inductive effect[1,2]. By analogy with π,π- and p,π-conjugation (the interaction of π or p electrons with the π-electron system), the σ,π-conjugation (hyperconjugation) of the σ electrons of the C–H bonds π-electron systems in the ground electronic state can be represented schematically as follows[3,4]:

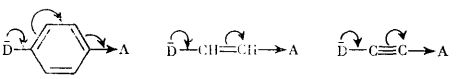
(I)

(II)

(III)

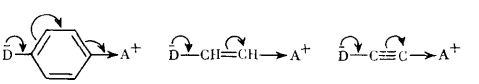
In the system of Hammett–Taft equations the possibility of σ,π-conjugation is attributed to the presence in the alkyl group of a considerable resonance component having the same sign as the positive inductive effect. For example, the inductive (σ_I) and resonance (σ_R) constants for the CH_3 group are respectively -0.05 and -0.12.[3] For transition states in which a positive charge arises at the reaction centre (aromatic ring, multiple bond, or a substituent linked to them in the *para*-position relative to the alkyl group), the electron-donating properties of the alkyl groups are enhanced when the hyperconjugation effect is intensified[3,4].

The enhancement of the electron-donating properties as a consequence of the positive charge is reflected in the transition from the Hammett σ_n constants ($\sigma_n \approx \sigma_I + \sigma_R$) to the Brown-Okamoto σ_n^+ constants (see, for example, Exner[5]). For the CH_3, CH_3CH_2, $(CH_3)_2$, and $(CH_3)_3C$ groups, the constants σ_n and σ_n^+ (given in brackets) are respectively -0.17 (-0.31), -0.15 (-0.29), -0.15 (-0.28), and -0.20 (-0.26).[5]



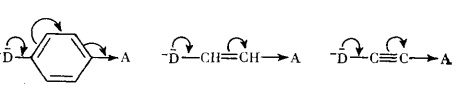
Thus the influence of alkyl groups can be twofold. The first case refers to the ground state and to transition states in which there is no direct resonance interaction between the alkyl substituent and the charged reaction centre. The influence of the substituents is then described by the Hammett σ_n constants, which vary irregularly on successive transition from CH_3 to $(CH_3)_3C$, reflecting the joint influence of the inductive effect and hyperconjugation. In this situation it is difficult to obtain information about hyperconjugation and there is a widely held view that this effect is absent in the ground state[3,6-8].

The second case refers to a transition state with a strong resonance interaction between the alkyl substituent and the positively charged reaction centre. Here the influence of the substituent is described by the σ_n^+ constants, which diminish in absolute magnitude on passing from CH_3 to $(CH_3)_3C$, i.e. vary in direct opposition to the inductive effects of these groups. This situation obtains in experiments where the concept of hyperconjugation has been resorted to in order to account for the results (see, for example, Refs.1,4, and 7–9).



The smallness of the σ,π-conjugation effect in organic compounds and the difficulty of isolating it from the set of other factors influencing the reactivity have led some investigators to doubt the reality of this effect[3,8]. At the same time there are also many arguments in support of the existence of hyperconjugation in organic compounds[4,6,9]. As regards hyperconjugation in organic compounds with participation of C–C σ-bonds, the data on this question are extremely contradictory.

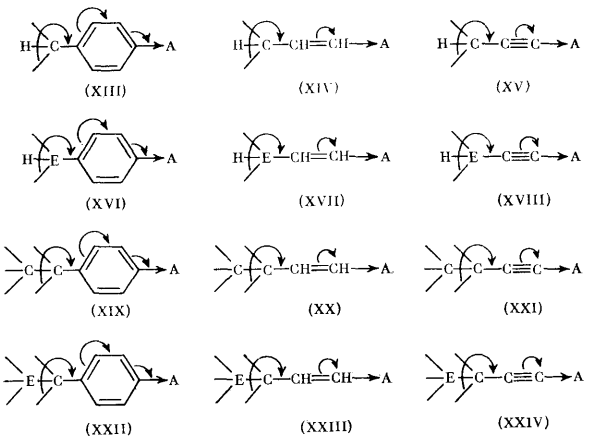
Summarising the data examined[1-4,6,8,9], taking into account the work of Kreevoy and Taft[10,11], one can conclude, following Palm[7], that hyperconjugation is one of a variety of direct polar conjugation. This conclusion is extremely significant for the understanding of the characteristic features and the major role of hyperconjugation in organoelemental compounds.



The common features of the direct polar conjugation effects in organic compounds are known (see, for example, Johnson[12] and Minkin et al.[13]). The direct polar or "through" conjugation is a resonance interaction between the *para*-substituents of the donor (D) and acceptor (A) type in the ground state (or between the *para*-substituent and the charged reaction centre in the transition state) via the π-electron system:

(IV) (V) (VI)

(VII) (VIII) (IX)

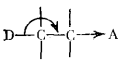


(X) (XI) (XII)

The magnitude of the "through" conjugation effect depends on the relative contributions of the donor–acceptor properties of the substituents D and A, increasing with enhancement of the electron-donating properties of D and the electron-accepting properties of A. The generation of a positive charge on A or a negative charge on D in the transition state [transition from compound (IV) to compounds (VII) and (X), from compound (V) to compounds (VIII) and (XI), and from compound (VI) to compounds (IX) and (XII)] enhances the effect considered.

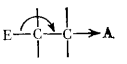
When the substituent A(D) is kept constant and D(A) is varied, the magnitude of the direct polar conjugation effect varies linearly with the constants σ_R^+ of electron-donating substituents (or σ_R^- of electron-accepting substituents)[12,13].

It is also important that the polarisability of the π-electron system through which the D and A fragments interact is significant for polar conjugation[13,14]. These factors, characterising the direct polar conjugation and hence also hyperconjugation (σ,π-conjugation), which is a variety of the latter, should be especially important for organoelemental compounds for the following reasons. The electronegativities of all the central elements in organoelemental compounds are lower than the electronegativity of carbon[15]. Therefore fragments of the type EH_3 (where E are Group IV elements—silicon, germanium, tin, and lead) and EH_3CH_2, which are isostructural with respect to the methyl (CH_3) and ethyl (CH_3CH_2) groups respectively, should have more pronounced electron-donating properties than their carbon analogues as a result of the inductive mechanism. This has been frequently confirmed experimentally[5,16]. As regards the hyperconjugation mechanism, organoelemental fragments also manifest more pronounced electron-donating properties than the isostructural carbon groups[17–19].



This is associated with the influence of a number of factors which are considered below, mainly with the greater polarisability of the bonds in the organoelemental compounds. By virtue of the higher polarisability of organoelemental fragments compared with the analogous carbon fragments, the effectiveness of the involvement of these fragments in the overall direct polar conjugation system is also improved. Thus the influence of the inductive effect and of the polarisability leads to an enhancement of the electron-donating properties of the substituents D in schemes (IV)–(XII), i.e. to an enhancement of the hyperconjugation in organoelemental compounds compared with their carbon analogues.

In view of the factors considered above, the influence of hyperconjugation should increase on passing from carbon compounds of types (XIII), (XIV), and (XV) to the corresponding organoelemental analogues (XVI), (XVII), and (XVIII) and also on passing from compounds (XIX), (XX), and (XXI) to compounds (XXII), (XXIII), and (XXIV).



We may note that the effect of the $(p-d)\pi$ interaction between the electrons of the multiple bonds and the vacant *nd* orbitals of the E atoms is observed, together with hyperconjugation, in compounds (XVI)–(XVIII) containing the element E linked directly to a π-donor centre[20]. These effects operate in opposite directions, the $(p-d)\pi$ interaction exerting a dominant influence, as will become apparent below.

The idea of the greater role of hyperconjugation in organoelemental compounds compared with organic compounds was put forward for the first time and justified by Nesmeyanov[21] in a study of the characteristic features of the reactivities of organometallic compounds. A profound analogy is observed between the reactivities of classical test systems of the π,π- and *p*,π-types and σ,π- and σ,σ-conjugated systems (the concept of such systems was introduced by Nesmeyanov[21]). The idea of second-order hyperconjugation (σ,σ-conjugation) is indissolubly linked with the high polarity and polarisability of organoelemental compounds. The effect of the σ,σ-conjugation, expressed by scheme (XXV)

(XXV)

therefore plays a notable role only when there is a significant difference between the electronegativity of the D (donor) and A (acceptor) atoms and when the polarisability of the D–C bond is high; this can be ensured sufficiently only for organometallic compounds [as in a scheme of type (XXVI)]:

(XXVI)

where E is a silicon subgroup element or some other central atom of the organometallic compound.

The ideas concerning the effects of σ,π- and σ,σ-conjugation were initially developed in order to elucidate the characteristics of the reactivity of organoelemental compounds—its specific features compared with the properties of organic compounds. The results obtained refer to a transition state. Subsequent investigations of the effect by molecular spectroscopic and quantum-chemical methods confirmed the reality and importance of hyperconjugation in the ground and excited electronic states of organoelemental compounds and also the dependence of such conjugation on the electronic state of the molecule. In these studies the first steps were taken towards the investigation of the role of hyperconjugation on passing from a non-reacting to a reacting molecule, which is also significant for theoretical organoelemental chemistry. As a consequence of the low magnitude of hyperconjugation effects compared with other resonance effects and the complexity of the intramolecular interactions in organoelemental compounds, the experimental data for hyperconjugation are not reliable in all cases and their interpretation is not always unambiguous. Furthermore, data for hyperconjugation in organoelemental compounds are fragmentary and systematic studies in this field are only just beginning.

The main task of the present review is therefore a critical examination of data for hyperconjugation in organic compounds of mercury (as model and thoroughly investigated systems) and silicon subgroup elements, obtained by molecular spectroscopic and quantum-chemical methods.

It seems useful to characterise in a general form the criteria employed in theoretical and experimental studies in order to establish the existence of hyperconjugation and to

estimate the magnitude of the given effect. As stated above, the absence of fundamental differences between the classical conjugation effect and hyperconjugation was emphasised in the studies by Mulliken[2] and Nesmeyanov[21]; the hyperconjugation effect is merely smaller, but, on passing from organic to organoelemental compounds, the hyperconjugation becomes abruptly much more pronounced[21]. The influence of the organoelemental fragments of the molecules involved in hyperconjugation is comparable to the effect of the strongest organic donors, as will be demonstrated in detail below. Therefore the study of hyperconjugation, as a task for physical organic chemistry, consists primarily in the separation of the effects of substituents into the inductive and resonance components and, if the latter component consists of several contributions, in isolating the contribution associated with hyperconjugation. In relation to specific molecular spectroscopic methods, the solution of this problem presupposes the selection of spectroscopic parameters sensitive to the influence of electronic effects (especially conjugation effects), the correct isolation of the contributions due to hyperconjugation, and the determination of the relation between these contributions and the characteristics of the structure of the compounds studied.

As a task for quantum chemistry, the study of hyperconjugation does not reduce solely to the selection of the correct methods of study and the demonstration of the existence of this type of conjugation but consists mainly in a more profound consideration of the results of experimental studies. It is shown below that the experimental characteristics of hyperconjugation, such as the dependence on the donor–acceptor properties of the conjugated bonds and on the sign of the charge on the π-electron system, the nature of the central element in the organoelemental compounds, and stereoelectronic factors, have been justified theoretically in the quantum-chemical analysis of the total energy, the bond orders, the geometrical characteristics, and the conformations of the molecules.

II. THEORETICAL IDEAS ABOUT HYPERCONJUGATION

The work of Eaborn[22], Traylor and co-workers[23], Bock[24], and Pitt[25], which demonstrated experimentally the important role of σ,π-conjugation in systems with a positive charge in the highest occupied molecular orbital (HOMO) of the π-type in benzene derivatives, was a development of Nesmeyanov's classical ideas and stimulated a series of theoretical studies of the effect of hyperconjugation in derivatives of carbon and organometallic compounds by both non-empirical (*ab initio*) and semiempirical (different versions of the zero differential overlap procedures—CNDO and INDO) quantum-chemical methods. Strong resonance interaction between a substituted cyclopropane ring and groups of the type CH_3, $CH_2^{\cdot}$, and CH_2^+ bound to it was demonstrated by the INDO and CNDO/2 methods. For CH_2^+, such interaction is the strongest[26] and hyperconjugation is apparently partly responsible for it, although the separation of the contributions to the given interaction by the σ- and π-components is difficult[26]. (The questions concerning the electronic effects, including hyperconjugation, have been considered in relation to unsaturated cyclic compounds[27].) The possibility of resonance interactions of the type of hyperconjugation (intermediate in magnitude between the effects of saturated and unsaturated substituents) between the cyclopropane (or cyclobutane) ring and a double bond has been indicated by *ab initio* calculations[28]. The conformations and stabilities of the substituted ethyl, propyl, and butyl cations have been investigated by the same method[29].

Substituents stabilise cations to a greater extent compared with the corresponding hydrocarbons[29] and radicals[30]. The stabilising capacity of the substituent depends on the hyperconjugation and the inductive effect. The effect of hyperconjugation, which determines the preferred conformation of the cations, depends on the capacity of the bonds at a β-carbon atom for such conjugation. According to the results of Radom et al.,[29] the C–C bond has a capacity for hyperconjugation just as great as the C–H bond. The same conclusion was reached in a study of norbornylbenzenes, in which the C–C bonds involved in hyperconjugation have a marked *p* character[31]. The existence of preferred conformations of the cations $XCH_2CH_2^+$ or anions $XCH_2CH_2^-$ due to hyperconjugation follows from *ab initio* calculations[32]. Hyperconjugation determines the geometries of the given ions and the degree of conjugation depends on the nature of X.[32–34]

Within the framework of the molecular orbital theory, the stabilisation of vinyl, isopropyl, and butyl carbonium ions and of protonated toluene as a result of hyperconjugation is regarded as the interaction of the σ orbitals of strained C–H or C–C bonds (having a higher energy in the ions than in in the neutral compounds) and a suitable *p* orbital of the ion. The interaction lowers the energy of the bonding molecular orbitals of the ion[35]. These conclusions[35] can be extended also to organometallic systems having high-energy σ orbitals of the E–C bonds.

The state of the problem of the interaction of the methyl group with π-electron system has been most fully considered by Libit and Hoffmann[36]. Numerous quantum-chemical data summarised by the above workers[36] indicate a slight electron transfer from the CH_3 group to the double bond and the aromatic ring and an appreciable polarisation of the π-electron system. The polarisation involves the hyperconjugation of the σ orbital of the methyl group with the π-electron system of the double bond or the aromatic ring[36]. Some aspects of hyperconjugation have already been examined[37,38]. Thus it follows from calculations on siladispiroheptane by the extended Hückel method that, together with conjugation involving the *d* orbital of silicon, there is hyperconjugation involving the electron-accepting antibonding orbitals of the Si–H bond[38].

A series of theoretical estimates of the capacity of the E–C bonds for hyperconjugation, where E is an element other than carbon or hydrogen, have been made. Thus virtually identical capacities of the C–S and C–H bonds for hyperconjugation have been demonstrated[39,40]. According to quantum-chemical and photoelectron spectroscopic data the energy of the HOMO of the π-type in benzyl halides depends on the inductive and resonance (hyperconjugation) effects. After the separation of the effects, the energies of hyperconjugation involving the C–Hal bonds have been estimated as 0.16, 0.28, 0.33 and 0.44 eV for Hal = F, Cl, Br, or I respectively (the hyperconjugation of the C–H bonds with the benzene ring amounts to 0.12 eV)[41]. Similar estimation of the hyperconjugation energy between the C–Hal and C=C bonds yielded 0.22, 0.31, 0.45 0.63 eV for Hal = F, Cl, Br, or I respectively[42].

The hyperconjugation in organomercury compounds has been investigated by the extended Hückel method[43,44]. The calculations showed that benzylmercury bromide is most stable in the electronic ground state in the conformation which ensures the interaction of the polarisable Hg–C bond with the π-electron system of the ring (the Hg–C–C angle is 90°). As a result of the σ,π-conjugation, the $BrHgCH_2$ fragment is typically electron donating in proton exchange processes[43,45]. In conformity with Nesmeyanov's work[21], it follows from the calculations of the total energies and bond orders[43] that the replacement of the bromine atom in

$BrHgCH_2C_6H_5$ by the electron-donating CH_3 group enhances the σ,π-conjugation, while its replacement by the more electron-accepting chlorine atom weakens the effect. The effect of the σ,π-conjugation is benzylmercury bromide is much stronger than in benzyl bromide[43]. The Hg–C bond in allylmercury bromide is at right angles to the nodal plane of the olefinic π-electron system[44] and the degree of σ,π-conjugation increases in the transition state compared with the ground state. The hyperconjugation weakens on passing from allylmercury bromide to the cation $^+HgCH_2CH=CH_2$,[44] since the electron accepting properties of the mercury-containing fragments $^+HgCH_2$ in the cation are apparently enhanced.

Hyperconjugation in compounds of Group IV elements has been frequently confirmed by *ab initio* calculations and by the CNDO method. Although the non-empirical calculations[46,47] for propene and vinylsilane did not provide an unambiguous answer concerning the $(p-d)\pi$ interaction in vinylsilane (like the calculations by the CNDO/2 method[48]), they indicated definitely the existence of hyperconjugation in this compound. The latter has also been confirmed by calculations using the CNDO/2 method, which agree for allyl- and vinyltrimethyl-silanes with photoelectron spectroscopic data[49,50]. The σ,π-conjugation plays a significant role in allylsilane, which has been recently demonstrated[51] also by the MINDO/3 method. In vinyltrimethylsilane the effects of the $(p-d)\pi$ interaction and hyperconjugation act in opposite directions[49]. These conclusions for silicon-containing ethylene derivatives agree with other data[52–54] and with calculations by the extended Hückel method for the compound $(CH_3)_3ECH_2CH=CH_2$,[55] in which the significant role of the σ,π-conjugation on passing from E or C to silicon subgroup elements has been demonstrated.

The increase of the multiplicity of the bond between silicon and ethynyl groups is apparently ensured both by the σ,π-conjugation of the σ orbitals of the silicon atom with the π orbitals of the C≡C fragment[46] and by the $(p-d)\pi$ interaction of the π electrons of the multiple bond with the unoccupied 3*d* orbitals of the silicon atom[56]. It is striking that both experiment and calculations show that the inductive effect of the CH_3 group predominates over hyperconjugation in methylacetylene but at the same time they also show that hyperconjugation plays a greater role in silylacetylene than the inductive effect of the SiH_3 group[57]. Calculations for phenylsilane in terms of the CNDO/2 approximation[55] demonstrated the significance of three effects—the inductive effect, the $(p-d)\pi$ interaction, and σ,π-conjugation, which has also been confirmed by calculations using the MINDO/3 method[59] for related systems—trimethylphenyl- and trimethylbenzyl-silanes. The importance of all three effects for the former compound and the appreciable role of hyperconjugation for the latter[59] and also for benzyl derivatives of germanium and tin[54] was then established. The greater role of hyperconjugation in silylanilines compared with the carbon analogues has been demonstrated in calculations using the CNDO/2 method[60]. As in the carbon compounds[29,30,32–34], hyperconjugation has a significant influence on the conformation of ions of the type $H_3ECH_2CH_2^{\pm}$ (E = Si or Ge).[61] One cannot rule out the possibility that hyperconjugation obtains also in tetramethylsilane[62].

The familiar work by Pitt[17], in which the role of σ,π-conjugation was estimated by analysis of experimental data for compounds of Group IV elements combined with an application of molecular orbital perturbation theory and of calculations by the CNDO/2 method, has been a significant development of the problem of hyperconjugation in organoelemental compounds. The author, having developed the initial concept of, for example[63] the dominant role of hyperconjugation, emphasises the importance not only of hyperconjugation but also of the inductive effect and the $(p-d)\pi$ interaction for the interpretation of the properties of organoelemental compounds. The perturbation energy δE, arising as a result of δ,π-interaction (hyperconjugation), is defined by the expression

$$\delta E = \pm \frac{a^2(\pi)a^2(\sigma)P^2}{\Delta E},$$

where $\Delta E = E(\pi) - E(\sigma)$ is the difference between the energy of the unperturbed π and σ orbitals, $a^2(\pi)$ and $a^2(\sigma)$ are the electron densities in the *p* orbitals of the bonding atoms in the HOMO of the π- and σ-systems, and *P* is the perturbation integral, including the overlap of the *p* orbitals connecting the π- and σ-systems.

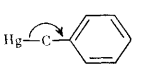
For a series of isostructural compounds with a variable central element E, for example for $(CH_3)_3ECH_2C_6H_5$, the quantities $a^2(\pi)$, $E(\pi)$, and *P* remain constant, while $E(\sigma)$ and $a^2(\sigma)$ vary, the principal contribution arising from $E(\sigma)$.[19,64,65] Since ΔE diminishes from Si to Pb, the degree of σ,π-conjugation involving the E–C bonds (characterised by the perturbation energy δE) increases as E is varied in the sequence Si < Ge < Sn < Pb,[19] which also agrees with the traditional ideas and, as will be shown below, with all the experimental data. For organoelemental compounds of the type $R_3EE'R_3$ and R_3EER_2X, there is a possibility of σ,σ- and σ,*p*-conjugation effects as a result of the pseudo-π-conjugation of the formally localised σ(ER) orbitals and, in the case of σ,*p*-conjugation, also accompanied by the involvement of the orbitals of the unshared electron pair of the atom X.[17]

The effects of the σ,σ- and σ,*p*-conjugation enhance the similarity of the molecular orbital energies, the increase of the perturbation integral *P*, and the bond polarity, which increases the electron density in the *p* orbitals of the bonding atoms. Pitt's calculations[17] confirm the increased stabilisation of the cationic centres by the R_3ECH_2 groups with increase of the atomic number of E and also the possibility of the manifestation of electron-accepting properties by the H_3SiCH_2 group relative to anionic centres.

The idea of more marked electron-donating properties of the R_3ECH_2 group compared with R_3E (although on the basis of the inductive effect alone for these groups, the opposite behaviour should have been observed—see, for example, Egorochkin et al.[66]) is very common in reviews of the properties of silicon-subgroup elements (E)[20,67–70]; this is usually attributed to the character of the σ,π-conjugation between R_3ECH_2 and the π-electron system.

III. EXPERIMENTAL STUDIES OF HYPERCONJUGATION IN ORGANOELEMENTAL COMPOUNDS

1. Organomercury Compounds as Model Systems



Organomercury compounds, which are widely used as model systems in organic and organoelemental chemistry, have also fulfilled this function in the study of σ,π-conjugation. These compounds were in fact the main objects of the study of the reactivity of which led Nesmeyanov and Lutsenko to the conclusion that the σ,π-conjugation plays an important role in organoelemental compounds[21,71].

In molecules containing the E–C–C=C or E–C–C=O fragments (E is a mercury or another metal atom), the σ,π-conjugation of the E–C σ-bond and the π-bond of the C=C or C=O group induces a series of specific properties. The

considerable difference between the electronegativities of mercury and carbon atoms (1.9 and 2.5 respectively) and the higher atomic number of mercury, which is in the VIth Period, are responsible for the polarity of the $Hg^{\delta+}-C^{\delta-}$ bond and its high polarisability. These factors favour the σ,π-conjugation in fragments of the type

Conjugation leads to the lability of the mercury–carbon bond and in many instances to the transfer of the reaction centre in reactions with electrophiles to the carbonyl group[71-73] and, for compounds with the fragments

to the aromatic ring[74].

The effect of σ,π-conjugation leads to the stabilisation of the transition state in the acid decomposition of allylmercury halides[44]. Hyperconjugation influences the properties of organomercury compounds not only in the transition state but also in the ground electronic state. This has been established in a series of experiments undertaken to demonstrate the very fact of the existence of σ,π-conjugation and to investigate the influence of molecular structure on the magnitude of this effect. Physicochemical experiments have confirmed the occurrence of the transfer of electron density via the conjugated system from the mercury atom to the electron-accepting molecular fragments (the multiple bond, the aromatic ring, the carbonyl group) and demonstrated the dependence of such transfer on the nature of the electron-accepting fragment and the decisive influence of the molecular geometry not only on the magnitude but also on the very possibility of the existence of the effect of σ,π-conjugation.

The data concerning the dependence of the energy of σ,π-conjugation on the molecular geometry are extremely clear. The greatest effect of σ,π-conjugation should be attained for the maximum overlap of the σ orbital of the Hg–C bond with the π orbital of the C=O (C=C, C_6H_5) group. Such overlap is ensured by the coplanar disposition of the Hg–C bond and the axis of the π orbital. When there is a marked deviation from such disposition of the interacting molecular fragments, there should be no σ,π-conjugation or it should be greatly weakened.

Experiment confirms this. Thus the closeness of the Hg–C–C angles to 90° in compounds with σ,π-conjugation was noted above[43,44]. Another characteristic example is provided by Raman spectroscopic data[75]. The intensity of the ν(C=O) bands in the Raman spectra of acyclic compounds having the Hg–C–C=O fragment and also in the spectrum of α-chloromercuricyclohexanone is appreciably higher than the intensity of the corresponding bands in the spectra of the non-conjugated ketones. On the other hand, the frequency of the ν(C=O) bands is lower in the spectra of organomercury compounds, which reflects the electron-donating properties of the mercury-containing molecular group relative to the C=O group in terms of the σ,π-conjugation mechanism and also apparently it reflects the higher polarity of the C=O bond owing to conjugation.

When the mercury-containing and carbonyl fragments are rigidly fixed in space, which rules out a resonance interaction between them, the spectroscopic characteristics of σ,π-conjugation disappear. Thus, judging from the positions and intensities of the ν(C=O) bands in the Raman spectra, α-chloromercuricamphenilone is a typical non-conjugated cyclic ketone[75].

The allyl derivatives of mercury containing the Hg–C–C=C fragment have, like the mercuriketones, Raman spectra with higher intensities of the ν(C=C) bands as a consequence of σ,π-conjugation[76,77]. However, the increase of the intensity of the ν(C=C) bands in the spectra of allyl derivatives of mercury is smaller by a factor of approximately two than the increase of the intensity of the ν(C=O) bands in mercuriketones due to σ,π-conjugation[76,77]. Thus, for unaltered electron-donating properties of the mercury-containing fragment, the intensity of the σ,π-conjugation increases with enhancement of the electron-accepting properties of the multiple bond. The latter properties are more pronounced for the C=O group (compared with the C=C group mainly owing to the greater electronegativity of the oxygen atom). The greater extent of hyperconjugation, approximately by a factor of two, in mercuriketones compared with the allyl derivatives[77] clearly illustrates Nesmeyanov's classical ideas (see Section I), according to which the hyperconjugation energy increases with the increase of the difference between the electron-accepting properties of the bonds involved in the conjugation.

Detailed study of the vibrational (infrared and Raman) spectra of organomercury compounds showed that the molecules of allyl- and benzyl-mercury halides in solutions have a non-planar configuration with the Hg–C bond located in a plane perpendicular to that of the double bond or the aromatic ring[78,79]. This constitutes yet another piece of evidence in support of the existence of σ,π-conjugation. Subsequent studies showed that a configuration favourable for σ,π-conjugation arises in the benzyl derivatives of mercury not only in solutions[33,78,80] but also in the crystalline[81] [for example, in the case of $C_6H_5CH_2HgSC(C_6H_5)_3$] and gaseous states[82] (benzylmercury chloride). The photoelectron spectroscopic data for benzylmercury chloride indicate the destabilisation of the HOMO of the π type as a result of the σ,π-conjugation and make it possible to estimate the interaction integral between the π and σ orbitals of the Hg–C type (0.99 eV). This quantity is extremely close to the value (0.98 eV) for allylmercury chloride, which, like the benzyl analogue, is a configuration necessary for σ,π-conjugation also in the gaseous phase[83].

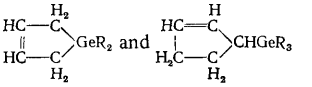
Convincing data supporting the existence of σ,π-conjugation in organomercury compounds have been obtained by NMR spectroscopy[76,84-86]. The ^{199}Hg NMR data provide most information. The study of benzylmercury chloride and its derivatives showed that the introduction of methyl groups in the *ortho*- (but not in the *meta*- or *para*-) positions in the aromatic ring increases the fraction of conformers in which the Hg–C bond is not in the plane of the aromatic ring, favours the σ,π-conjugation, leads to an increase of the positive charge on the mercury atom (as a result of conjugation), and deshields the ^{199}Hg nucleus.

The stereochemistry of the σ,π-conjugation is also reflected in other parameters of the ^{199}Hg NMR[86] and ^{13}C NMR[76,84,86] spectra. According to chemical data, for example those of Nesmeyanov and Kritskaya[87], owing to the increase of the lability of the Hg–C bond as a consequence of σ,π-conjugation, polarographic reduction with dissociation of the bond takes place at much lower potentials for conjugated systems than for non-conjugated systems[75,76]. The electronic spectroscopic data for charge-transfer complexes (CTC) of benzyl derivatives of mercury with tetracyanoethylene are of fundamental importance[80,88]. This method makes it possible to investigate σ,π-conjugation under conditions where there is a positive charge in the π orbital of the aromatic ring. In this situation hyperconjugation constitutes a very powerful resonance effect with rigorous stereoelectronic requirements[25,80,88]—the breakdown of σ,π-conjugation (on passing to compounds where the Hg–C bond is located in the nodal plane of the π-electron system) diminishes the rates of certain electrophilic reactions by a factor of 10^8.[88]

An increase of the extent of σ,π-conjugation following the enhancement of the electron-donating properties of the substituents X has been established for systems with the cationic centre in the π-electron system (the compound $XHgCH_2C_6H_5$ under the experimental conditions according to electronic spectroscopic data for CTC)[80], which has been confirmed by ^{19}F NMR in the ground electronic state[89]. This constitutes convincing confirmation of Nesmeyanov's classical idea that the difference between the donor–acceptor properties of conjugated bonds has a significant influence on the hyperconjugation energy[21]. The negative ion mass spectra of σ,π-conjugated systems have a lower energy at the resonance maxima (destabilisation of the molecular orbitals due to conjugation) compared with the non-conjugated systems[76].

Thus Nesmeyanov's hypothesis[21,77] that the effect of σ,π-conjugation has a significant role in organoelemental compounds has been fully confirmed in a combined study of model derivatives of mercury[77].

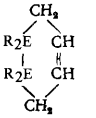
We shall next consider data for hyperconjugation in compounds of silicon sub-group elements.



2. σ,π-Conjugation in Compounds of Silicon Subgroup Elements

The effect of σ,π-conjugation is clearly manifested in the study of compounds of silicon subgroup elements by vibrational spectroscopic methods[90–93]. An increase of the intensity of the bands corresponding to the vibration of the C=C bond and the vibration with a preferential extension of the $E-C_{all}$ bond as well as an increase of the degree of depolarisation of these bands have been observed in the Raman spectra of the compounds $(CH_3)_3ECH_2CH=CH_2$ (where E = C, Si, Ge, or Sn). On passing from silicon to tin, the exaltation of the molecular refraction in the allyl group increases. In the Raman spectra of the halogeno-derivatives Hal_3ECH_2. $CH=CH_2$ (E = Si or Ge), the intensity of the ν(C=C) line increases in the sequence F < Cl < Br and for fluoro-derivatives the line intensities are lower than for the methyl derivatives, which can be interpreted as a decrease of the extent of the σ,π-conjugation following the overall enhancement of the electron-accepting properties of the substituents R and the R_3ECH_2 fragment as a whole.

This conclusion as well as the conclusion that the σ,π-conjugation becomes more intense with increase of the atomic number of the element E on passing from Si to Ge and Sn evidently follows from the analysis of the highly characteristic out-of-plane vibrations of the $=CH_2$ group in the infrared spectra of the allyl derivatives[66,94] and has been confirmed by the study of the ^1H NMR spectra of the alkenyl derivatives of silicon and germanium[94]. Infrared spectroscopic study of a hydrogen bond of the type π...H–O– involving phenol indicates more pronounced π-donor properties of the allyl derivatives of silicon, germanium, and tin than for their carbon analogues. The differences between the electron-donating capacities cannot be accounted for by the differences between the electronegativities of the central atoms E. The increase of the electron density in the double bond with increase of the atomic number of E are a consequence of the increasing role of the σ,π-conjugation[95].



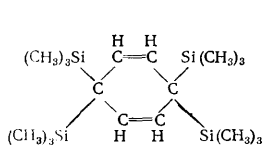
A method for the study of the electronic effects of the substituents at the π-donor centres (derivatives of ethylene, benzene, acetylene, etc.), which yields much information, is the electronic spectroscopy of charge-transfer complexes, for example, complexes of the π,π-type with tetracyanoethylene as the π-electron acceptor[96]. The principal spectroscopic parameter, the frequency of the charge-transfer band, contains information about the influence of the substituents not in the ground electronic state but in the charge-transfer state, where there is a positive charge in the π orbital of the donor. The presence of the charge can promote an increase of conjugation (including hyperconjugation) of typical electron-donating substituents of the +*M* type with the π-donor centre. Therefore in the state with charge transfer, modelling reaction systems with an ionic transition state [schemes of types (VII)–(IX)], the effect of σ,π-conjugation should be manifested most clearly[96]. This has been frequently confirmed experimentally for different compounds starting with the studies of Hanstein et al.,[23] Bock and Alt[24], and Pitt[25], and in particular for the allyl derivatives of silicon[97].

The fact that the electronic effects of the substituents R_3ECH_2 in $R_3ECH_2CH=CH_2$ are not limited to the inductive effect but include also a powerful σ,π-conjugation effect, which increases on passing from E = Si to E = Ge, is clearly manifested in the state with charge transfer[98]. A fairly strong σ,π-conjugation can occur only for a non-coplanar disposition of the E=C and C=C bonds, since this ensures a more effective overlapping of the electron clouds of the interacting bonds. Experimental confirmation of this fact has been obtained for allylsilane by infrared[99] and microwave[100] spectroscopic methods. In two compounds with the β-disposition of the germanium atom in relation to the C=C bond, i.e.

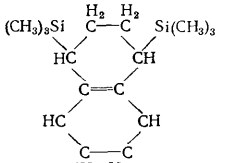
in the former (where the Ge–C and C=C bond are in the same plane) there is no hyperconjugation and in the latter (where the Ge–C bond deviates from the plane of the cyclopentene ring) the spectroscopic features of σ,π-conjugation are observed[101–103]. For the related silicon compounds, the stereospecificity of the σ,π-conjugation is shown just as clearly[104].

In contrast to sila- and germa-cyclopentenes having a planar ring structure, systems of the type

(E = Si or Ge) are non-planar and σ,π-conjugation in them has been established by vibrational and NMR spectroscopic methods[105]. In the electronic spectra of the trimethylallyl derivatives the absorption band near 55000 cm^{-1} (for E = C) undergoes a bathochromic shift and its intensity increases following a successive transition from carbon compounds to tin derivatives. According to the authors[106,107], these data indicate σ,π-conjugation in compounds of silicon subgroup elements, the extent of which increases with increasing atomic number not only in Group IV but also in the Periodic System as a whole. The cause of this phenomenon is apparently the more ready polarisability of the element with increase of its atomic number[107].



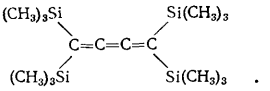
Important information about hyperconjugation has been obtained by photoelectron spectroscopy, which makes it possible to measure the vertical ionisation potentials[23], approximately equal to the energies of the corresponding molecular orbitals (with the sign reversed)[108]. In ethylene derivatives containing hydrocarbon substituents and their silicon-containing analogues, the highest occupied molecular orbital is of the π type[49,109]. The substituents $(CH_3)_3SiCH_2$ and H_3SiCH_2 increase the HOMO energy to a significant extent (the HOMO ionisation potentials are 9.0 and 9.49 eV)



relative to the substituents $(CH_3)_3CCH_2$[49] and CH_3CH_2[110] (9.6 and 9.72 eV) as a consequence of the intense σ,π-conjugation in the silicon derivatives. The increase of the extent of σ,π-conjugation with increase of the atomic number of the Group IV element is accompanied by a further destabilisation of the π-type HOMO which is manifested by a decrease of the first ionisation potential[111,112] in trimethylallylgermane and trimethylallylstannane to ~ 8.8 and ~ 8.5 eV respectively (8.7 eV according to the data of Brown et al.[113]). The same conclusion concerning the influence of σ,π-conjugation on the ionisation potentials of HOMO have been reached using the mass-spectrometric method not only for trimethylallylsilane[114,115] but also for the disilyl derivatives of ethylene[116].

Thus the first vertical ionisation potentials, reflecting the influence of the substituents on the energy of the HOMO of the π type in the compounds *trans*-XHC=CHX when X is varied, are (in eV) 10.54 for H, 9.32 for $(CH_3)_3Si$, 8.99 for $(CH_3)_3C$, and 7.95 for $(CH_3)_3SiCH_2$.[116] The substituents X influence the HOMO energy via the inductive and conjugation mechanisms. Whereas the +*I* effect of the t-butyl group exerts the main influence on passing from X = H to $(CH_3)_3C$, when X changes from $(CH_3)_3C$ to $(CH_3)_3Si$, the $(p-d)\pi$ interaction (partial shift of the π electrons of the double bond to the unoccupied 3*d* orbitals of the silicon atom) has a dominant influence on the HOMO energy. This can be explained by the fact that the greater +*I* effect of the trimethylsilyl group compared with the t-butyl group (the inductive constants of these groups are respectively −0.9 and −0.3)[16] in the absence of the $(p-d)\pi$ interaction should have caused an increase of the ionisation potential in the disilyl derivative compared with its di-t-butyl analogue.

Judging from the ionisation potentials, the $(CH_3)_3SiCH_2$ group is the strongest donor although its σ* constant, amounting to −0.3,[66] is close to that of the t-butyl group and higher than the value for the trimethylsilyl group. The anomalously pronounced electron-donating properties of the substituents $(CH_3)_3SiCH_2$ are due to σ,π-conjugation. This effect increases regularly with increase of the number of substituents $(CH_3)_3SiCH_2$ at the double bond[117]. This is manifested experimentally by a decrease of the ionisation potentials, which are 7.7 eV for $CH_3[(CH_3)_3SiCH_2]C{=}C(CH_3).[CH_2Si(CH_3)_3]$ and 7.15 eV for $[(CH_3)_3SiCH_2]_2C{=}C[CH_2Si.(CH_3)_3]_2$, and also by an increase of the energy of the HOMO of the π type and the enhancement of the π-donor properties of the compounds[118]. The last compound does not form complexes with tetracyanoethylene of the usual type of olefins and the interaction involves the formation of radical-ion salts.



The following compounds have record low ionisation potentials[119]:

(7,00 eV)

(6,98 eV)

The large steric effects of the substituents at the multiple bonds make preferable the conformations of these molecules in which the Si–C bonds are arranged at right angles to the nodal plane of the olefin π-electron system, which ensures the most favourable conditions for σ,π conjugation. In the one-electron oxidation of a compound of this type, the products are radical-cations, which can be readily detected by EPR and which are stabilised as a result of σ,π-conjugation[118–120] (see also Bock and co-workers[121,122]).

An instructive example of the stabilisation of radical-ions by silicon-containing substituents is provided by butatriene derivatives:

The neutral silylbutatriene is unknown, but its radical-cation and radical-anion do exist[120]. Silylbutatriene formally contains π-electron systems of two types: the central ethylene bond and the butadiene system. The substituent $(CH_3)_3Si$ is a π-electron acceptor in relation to the butadiene system via the $(p-d)\pi$-interaction mechanism and therefore promotes the stabilisation of the radical-anions. The substituent $(CH_3)_3SiC\lesssim$ is an electron donor in relation to the ethylene bond via the σ,π-conjugation mechanism and stabilises the radical-cation[120]. The stabilisation of the radical-cation, sufficient for its detection by EPR at 220 K, confirms yet again the important role of σ,π-conjugation in systems with a positive charge in the π-electron system. The effective stabilisation of the radical-cations formed on electron transfer from allylsilanes via σ,π-conjugation with participation of an Si–C bond is an important factor in photochemical allylation reactions[123].

We shall now consider the σ,π-conjugation in the benzyl derivatives of silicon subgroup elements. It is known[22] that, as the substituent X in the ring, the $(CH_3)_3SiCH_2$ group exhibits anomalously pronounced electron-donating properties in electrophilic aromatic substitution reactions involving silicon derivatives of the type $(CH_3)_3SiC_6H_4X$. These properties cannot be accounted for by the inductive influence and they are related to the donation of electron density from $(CH_3)_3.SiCH_2$ to the ring via the σ,π-conjugation mechanism. With increase of the number of trimethylsilyl groups *n* in $[(CH_3)_3Si]_nCH_{3-n}Ar$ (where Ar = aryl), the degree of σ,π-conjugation also increases, which is indicated by the rates of cleavage of the Ar–Si bond in the compounds $[(CH_3)_3Si]_n.CH_{3-n}C_6H_4Si(CH_3)_3$ and the chemical shifts in the ^{19}F NMR spectra of the compounds p-$[(CH_3)_3Si]_nCH_{3-n}C_6H_4F$.[124] In the σ,π-conjugated systems in the transition state (and in its model consisting of a charge transfer state), there is a strong resonance interaction of substituents of the type R_3ECH_2 with the positively charged reaction centre. The constants σ^+, characterising the influence of the substituents in such a situation, indicate exceptionally marked electron-donating properties of R_3ECH_2, which become more pronounced with increase of the atomic number of E[23,96,125–128]. The accuracy of the determination of the constants σ^+ for organoelemental substituents depends on the quality of the initial correlation equations. The parameters of these equations differ somewhat when data for tens of compounds[125,126] and only a few compounds[23,127,128] are used. It has been suggested[128] that the accuracy of the initial equations and of the constants σ^+ increases when only a few compounds rather than tens of compounds are used. Although this view is not evident and requires special consideration, the order of magnitude of the quantities σ^+, established in a number of studies[23,125–128], makes it possible to place the substituents R_3ECH_2 in the same series with the strongest organic electron donors of the type of OAlk and $NAlk_2$.

Further investigation of the influence of σ,π-conjugation in the transition state[64,129,130] and comparison of the reactivities of benzyl derivatives of silicon subgroup elements with

the spectroscopic parameters of charge-transfer complexes of these compounds stimulated the study of the effects of organoelemental substituents in the ground electronic state of σ,π-conjugated systems. Thus the constants σ_R^0 (which characterise the conjugation of the substituent with the benzene ring) of the substituents R_3SiCH_2,[131] R_3GeCH_2,[126] and R_3SnCH_2,[131], calculated on the basis of infrared spectroscopic data, indicate marked electron-donating properties of these substituents in the ground electronic state due to the σ,π-conjugation.

The anomalously high intensity of the bands corresponding to the multiple bond vibration, the bathochromic shift of the ultraviolet bands, and exaltation of the molecular refraction have been observed in the vibrational spectra of benzyl derivatives of the type $R_3SiCH_2C_6H_5$ as well as allylsilanes[90]. Thus benzylsilanes exhibit the characteristic properties of σ,π-conjugated systems. This conclusion follows evidently also from the analysis of the ionisation potentials of wide series of benzene derivatives with silicon-containing substituents. The ionisation potentials and the approximate HOMO energies have been obtained by the mass-spectrometric method[114,115,132] from the frequencies of the charge-transfer bands in electronic absorption spectra of the complexes with tetracyanoethylene[17,24,25,80,115,133–136] and (the most accurate values) from photoelectron spectra[48,59,112,122,137,138].

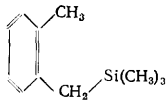
The introduction of the $(CH_3)_3SiCH_2$ group into the benzene molecule entails a sharp decrease of the first ionisation potential (i.e. the destabilisation of the HOMO of the type) from 9.24 to 8.35 eV. The ionisation potentials of di- and tetra-substituted derivatives (in the 1- and 3- and 1-, 2-, 4-, and 5-positions) decrease further to 7.75 and 7.10 eV.[137] The ionisation potentials of the carbon analogues are significantly higher. For example, they are 8.25 and 7.75 eV for n-$(CH_3)_3CCH_2C_6H_4CH_2C(CH_3)_3$ and p-$(CH_3)_3SiCH_2C_6H_4CH_2Si.(CH_3)_3$.[122] Thus the large electron-donating effect of the trimethylsilylmethyl group increases as these groups accumulate in the molecule and hence there is an increase of the overall effect of σ,π-conjugation. This increase is not entirely additive, since the presence of several bulky $(CH_3)_3SiCH_2$ groups in the molecule prevents the establishment of the conformation most favourable for σ,π-conjugation. This is particularly marked for the *ortho*-disposition of the substituents and also for polysubstituted benzenes. Thus, on passing from the tetra- to the hexa-derivatives, there is no decrease but an actual increase of the ionisation potential from 7.10 to 7.40 eV.[137] The intense electron-donating properties of the trimethylsilylmethyl groups, comparable in their influence to the effects of the methoxy- or amino-substituents and increasing in the presence of a positive charge on the π-electron system, promotes the stabilisation of the radical-cations.

In the radical-cations formed from benzene derivatives containing substituents of the type $[(CH_3)_3Si]_nCH_{3-n}$ with ionisation potentials below 7.8 eV, the incorporation of one-electron oxidants can be readily detected by EPR[122,137–139]. Analysis of the parameters of the EPR spectra indicates (like the ionisation potentials of the initial compounds) the delocalisation of spin density over the substituting group and the existence of a preferred conformation of the radical-cations determined by steric factors and the degree of σ,π-conjugation[137–139].

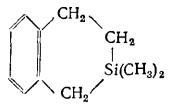
It follows from the photoelectron spectra of the trimethylbenzyl derivatives of silicon, germanium, and tin that the ionisation potentials decrease steadily and the effect of σ,π-conjugation increases with increase of the atomic number of the silicon subgroup element[59,112]. Although it is difficult to estimate quantitatively the relative contributions of σ,π-conjugation and the +*I* effect to the overall electronic effect of the $(CH_3)_3ECH_2$ groups, there is no doubt (at least in systems with a positive charge in the π orbital) that σ,π-conjugation predominates[140], exerting a very marked influence on the rates of chemical reactions and stabilising effectively the carbonium ions.

A clear proof of the enhancement of the effect of σ,π-conjugation on benzyl derivatives has been obtained on comparing the π-donor properties of these compounds in the ground electronic state and in the charge-transfer state, i.e. in the presence of a positive charge in the aromatic ring[125,140–143]. The infrared spectroscopy of π...H–O hydrogen bonds between benzyl derivatives and phenol is used to investigate the π-donor properties in the ground state[144]. The parameter characterising the π-donor properties is the shift of the stretching vibration frequency of the bond involving phenol in the infrared spectrum ($\Delta\nu$) on formation of the hydrogen bond. As for the allyl derivatives of silicon subgroup elements, a steady enhancement of the π-donor properties is observed for the benzyl analogues with increase of the atomic number of E, which cannot be explained by the variation of the electronegativity of E and which reflects the enhancement of the σ,π-conjugation on passing from silicon to tin[125,144].

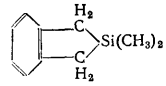
The same conclusion was also reached in the study of the electronic absorption spectra of charge-transfer complexes of benzyl derivatives with tetracyanoethylene[125,126,141,142] or iodine[143]. The charge-transfer frequency (ν_{CT}) characterises the π-donor properties of the given derivatives in the charge-transfer state, i.e. when, under the conditions of the electronic spectroscopic experiment, the electron from the HOMO, localised mainly in the aromatic ring, is almost fully transferred to an unoccupied orbital of tetracyanoethylene or iodine and a positive charge is formed in the HOMO of the π type. Analysis of the type of relation between $\Delta\nu$ and ν_{CT}[125,141] shows that the positive charge in the ring enhances the effects of the π,π-, *p*,π-, and σ,π-conjugations of the substituents with the ring.



On transition to the state with charge transfer, a greater enhancement of the σ,π-conjugation is observed for the benzyl derivatives of germanium than for benzylsilanes[125,141].



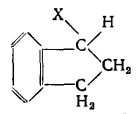
Systematic studies of the ^{13}C and ^{19}F NMR spectra of compounds containing the $(CH_3)_3ECH_2$ and $(C_6H_5)_3ECH_2$ fragments (where E = Si, Ge, Sn, or Pb), linked to the benzene or naphthalene ring and the biphenyl group, showed[19,145–147] that in the ground electronic state these fragments possess electron-donating properties and influence the π-electron system mainly via the σ,π-conjugation mechanism. The conjugation is intensified with increase of the atomic number of E in the sequence Si < Ge < Sn < Pb. (The effect of σ,π-conjugation in the benzyl derivatives $R_3SiCH_2C_6H_5$ has also been established by ^{29}Si NMR.[148])



Yet another confirmation of the important role of hyperconjugation in organometallic compounds has been obtained by the joint application of the ^{13}C NMR and quantum-chemical methods[147]. A correlation has been established for derivatives containing the fragments $(CH_3)_3ECH_2$ (E = C or Sn) between the chemical shift difference in the ^{13}C NMR spectra of the tin and carbon compounds, on the one hand, and the change in the π-electron density, calculated by quantum-chemical methods, on passing from neutral to charged compounds modelling the intense conjugation of the substituent with the π-electron system, on the other. This correlation constitutes confirmation of the strong σ,π-conjugation of the $(CH_3)_3SnCH_2$ group with the benzene and naphthalene rings and the biphenyl group.

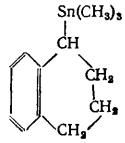
When the photoelectron spectroscopic data for benzyl derivatives were considered[137], the dependence of the degree of conjugation on stereoelectronic factors was noted above.

The influence of all these factors is clearly seen also from the Raman and NMR spectra. The characteristic features of σ,π-conjugation (high intensity of the band corresponding to the vibration of the multiple bond in the Raman spectra and exaltation of the molecular refraction) have been observed[149] for compounds (A) and (B) but not for compound (C).



(A)

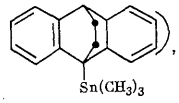
(B)



(C)

For the same compounds but with one fluorine indicator atom in the ring (instead of hydrogen), the above conclusion was confirmed by ^{13}C NMR[150] and ^{19}F NMR[151] methods. On passing to the bicyclic 2-silaindan (C), having a planar structure, from compound (A), the intense σ,π-conjugation in the latter breaks down owing to the disposition of the Si–C bond in the nodal plane of the π-electron system. In the conformationally non-rigid silatetralin (B), σ,π-conjugation becomes possible for certain conformations, but this effect is weaker than in compound (A).

The same conclusions were reached in the analysis of the ionisation potentials of these compounds and also of a number of organoelemental derivatives of indan[25]



X=Si(CH$_3$)$_3$, Si$_2$(CH$_3$)$_5$, Ge(CH$_3$)$_3$

and indene[152]. In these compounds the angle between the E–C σ-bond and the π-electron system is ~ 30°. The ionisation potential of the π-electron system therefore increases steadily with increase of the atomic number of E[152] owing to σ,π-conjugation. When X = Sn(CH$_3$)$_3$ and also for another conformationally labile compound

the conformation in which the maximum σ,π-conjugation obtains is preferred according to ^{13}C NMR data[89].

If the Sn–C bond is fixed in the nodal plane of the π-electron system (as in the model compound

then there is no σ,π-conjugation[89], as in the organomercury compound with a related structure[88].

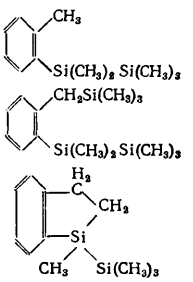
One cannot rule out the possibility that hyperconjugation obtains in the substituent–aromatic ring system in derivatives of benzene, naphthalene, and anthracene containing substituents of the type ER$_3$ bound directly to the π-electron system. The possibility, in principle, of hyperconjugation follows from both general considerations, described in the introduction, and from the theoretical examination of the problem (for example, by Pitt[17]).

Considerable difficulties are encountered in the experimental study of hyperconjugation of this type. When E=C, the above effect is apparently extremely small and is possibly absent in the ground electronic state[3,6–8]. For silicon compounds, hyperconjugation of the type considered (consisting in the transfer of electron density from R$_3$Si to the aromatic ring) is masked by the influence of the stronger effect of the $(p–d)\pi$ interaction acting in the opposite direction[20,67–70], the traditional explanation of the mechanism of which consists in the concept of the transfer of π-electron density from the aromatic ring to the unoccupied 3*d* orbitals of the silicon atom.

On successive transition from E = Si to Ge, Sn, and Pb, the $(p–d)\pi$ interaction weakens[20] and hyperconjugation should be intensified according to all the available literature data. However, even under the most favourable conditions for the study of hyperconjugation in systems of the type R$_3$E–Ar (i.e. for E = Sn or Pb), unambiguous experimental data supporting the occurrence of hyperconjugation have not been obtained. Thus detailed analysis of the parameters of the ^{13}C NMR spectra led the authors[153] to the conclusion merely that hyperconjugation is likely in the compounds R$_3$E–Ar, where E = Ge, Sn, or Pb. The conclusion that, of the two factors—hyperconjugation and $(p–d)\pi$ interaction—the former predominates in phenylsilane and trimethylphenylsilane, while the latter, discovered in the analysis of photoelectron spectra and by quantum-chemical calculations, predominates in trifluorophenylsilane[154], also appears ambiguous. Furthermore, numerous literature data, including those examined above as well as the results of a number of other studies[20,67–70], show that the SiR$_3$ fragments bound to the aromatic ring have electron accepting properties in relation to the groups CR$_3$, which is traditionally thought to be due to the $(p–d)\pi$ interaction.

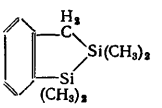
Thus in compounds of the type R$_3$SiCH$_2$Ar the group R$_3$SiCH$_2$ (where R is an alkyl substituent) is a typical electron donor involving the σ,π-conjugation mechanism and also the inductive effect. The R$_3$Si fragment in the compounds R$_3$SiAr is a powerful electron donor operating via the inductive effect and is probably also a donor operating via the mechanism involving hyperconjugation with the ring, while, in terms of the mechanism involving the $(p–d)\pi$ interaction, this group is an electron acceptor.

The overall electronic effect of the R$_3$Si fragment is such that, compared with the isostructural carbon group R$_3$C, the silyl fragment is an electron acceptor in relation to the π-electron system. An unusual combination of the properties of the R$_3$SiCH$_2$ and R$_3$Si fragments is observed in the group R$_3$SiSiR$_2$ bound to the aromatic ring[143]. It is to be expected, firstly, that this group is as strong an electron donor as the R$_3$Si group in terms of the inductive effect. Secondly, like R$_3$Si, this group should exhibit electron-accepting properties in relation to the π-electron system of the aromatic ring in terms of the mechanism involving the $(p–d)\pi$ interaction. Thirdly, the R$_3$SiSiR$_2$ group, involved in σ,π-conjugation with the π-electron system, should exhibit electron-donating properties and the latter should be more marked than those of the R$_3$SiCH$_2$ group as a consequence of the higher polarisability of the Si–Si bond compared with Si–C. The overall electronic effect of the R$_3$SiSiR$_2$ group consists of the contributions listed above. It is therefore difficult to estimate *a priori* the resultant electronic effect of the R$_3$SiSiR$_2$ and R$_3$SiCH$_2$ groups relative to π-electron systems.



We shall now consider experimental data referring to systems of the type R$_3$SiSiR$_2$–Ar. Pentamethylphenyldisilane, its derivatives, and related compounds, as well as their complexes with tetracyanoethylene have been studied systematically by electronic spectroscopy (see Sakurai's review[155]). It was established that the Si–Si bond is involved in conjugation with the benzene ring and the multiple bond[155–161]. Whereas in the initial study the mechanism of the conjugation

was believed to involve the unoccupied 3*d* orbitals of the silicon atom[159], subsequently the important role of the σ,π-conjugation of the σ orbitals of the Si–Si bond with the π-electron system was established[155,162,163].



In relation to the benzene ring, the $Si(CH_3)_3Si(CH_3)_2$ group behaves as an electron donor in terms of the overall electronic effect, although its electron-donating properties are weaker than those of the $(CH_3)_3SiCH_2$ fragment[155]. This conclusion, reached in the analysis of the ultraviolet spectra, has been confirmed from σ^+ and σ^- constants for the group $Si(CH_3)_3Si(CH_3)_2$ determined by infrared and NMR spectroscopy[164,165]. These constants indicate a typical electron-donating character of the $Si(CH_3)_3Si(CH_3)_2$ group compared with $Si(CH_3)_3$ owing to σ,π-conjugation with participation of the Si–Si bond, although the numerical values of the constants require revision. The increase of the number of trimethylsilyl groups in the sequence $Si(CH_3)_2Si(CH_3)_3$ < $Si(CH_3)[Si(CH_3)_3]_2$ < $Si[Si(CH_3)_3]_3$ is accompanied by an enhancement of the electron-donating properties of the group characterised by the constant σ^+.[165] On the other hand, the trimethylsilyl and pentamethyldisilyl groups exhibit in the ground electronic state similar electron-accepting properties in relation to the ring[164].

The dual functions of the $Si(CH_3)_3Si(CH_3)_2$ group [electron-donating as a consequence of σ,π-conjugation and electron-accepting due to the $(p-d)\pi$ interaction] make it possible to understand[143] the regularities in the electronic absorption spectra of the charge-transfer complexes of π-donors containing this and similar groups[24,162,163,166-169] as well as the variation of the ionisation potentials of π-electron systems containing disilyl substituents[48,162,163,166]. The weaker electron-donating properties of the $Si(CH_3)_3Si(CH_3)_2$ fragment compared with $(CH_3)_3SiCH_2$ are not a result of the decrease of the effect of σ,π-conjugation with participation of the Si–Si bond (as was believed, for example, by Sakurai and Kira[163]) but are a consequence of the competition between two opposed conjugation effects [of the σ,π- and $(p-d)\pi$-types] in disilyl derivatives. If only the effect of σ,π-conjugation operated, then, owing to the greater polarisability of the Si–Si bond compared with Si–C, the disilyl fragment would have exhibited more pronounced electron-donating properties than the $(CH_3)_3SiCH_2$ fragment.

A test of the fulfillment of the stereoelectronic conditions for σ,π-conjugation by ultraviolet spectroscopy showed[169,170] that the compounds

and a number of their analogues[169] have ultraviolet spectra characteristic of systems with σ,π-conjugation. On the other hand, in a compound of the type

the conjugation is weakened[169], while according to other data[170] it is altogether absent.

Important information about the characteristic features of σ,π-conjugation is provided by the analysis of the character of the HOMO of pentamethylphenyldisilane. The ionisation potential of the π electrons of the Si–Si bond (8.69 eV) in hexamethyldisilane[171] is lower than the ionisation potential of the π electrons of benzene (9.24 eV). The HOMO of pentamethylphenyldisilane, which is a linear combination of the symmetrical HOMO of benzene and the molecular orbital of the Si–Si σ-bond, contains a dominant contribution by the σ orbital of the Si–Si bond (72% according to quantum-chemical calculations[166]). As a result of this, the long-wavelength absorption bands in the electronic spectra of the charge-transfer complexes of phenyldisilanes[155,162,163,166] and vinyldisilanes[98] with tetracyanoethylene are assumed to involve intermolecular charge transfer from an orbital of the σ(Si–Si) type, like the bands in the spectra of complexes of methylpolysilanes[172,173]. The contribution of the σ(Si–Si) orbital to the HOMO of the compounds

depends on the nature of X and increases with enhancement of the electron-accepting properties of X.[166] From the standpoint of classical ideas about hyperconjugation, this can be interpreted as the intensification of the direct polar conjugation between the substituents $Si_2(CH_3)_5$ and X (or the intensification of the σ,π-conjugation of the Si–Si bond with the π-electron system) as the electron-accepting properties of the substituent X become more marked [Schemes (IV), (VII), and (X)].

Thus the effect of σ,π-conjugation has been studied in fair detail for derivatives of benzene and ethylene. The literature data on this effect involving other π-donor centres are limited but are consistent with the data for benzene and ethylene derivatives.

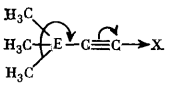
Thus the Si–Si fragments exhibits electron-donating properties via the σ,π-conjugation mechanism not only in relation to the benzene ring but also in relation to the double bond as well as the cyclopentadienyl ring, which follows from the EPR spectra of the cyclopentadienyl and silylcyclopentadienyl free radicals[174].

The effect of σ,π-conjugation in h^1-cyclopentadienyl derivatives $C_5H_5ER_3$ leads to a decrease of the ionisation potentials with increase of the atomic number of E on passing from silicon to tin[175], can influence the angles between the E–C bonds and the average planes of the rings[176,177] (although the structure of compounds of this type is still the subject of discussion[178]), and is also manifested in a series of other physicochemical properties[175].

The study of naphthalene derivatives by NMR[19,145,147], ultraviolet spectroscopy[162], the ultraviolet spectroscopy of charge-transfer complexes with tetracyanoethylene[160,162,163], and polarography[162] has shown that the substituent $(CH_3)_3SiCH_2$ is involved in σ,π-conjugation with the ring[19,145,147,160,162,163] and the overall electronic effect of the $Si(CH_3)_3$.$Si(CH_3)_2$ group is less electron-donating than the influence of the trimethylsilylmethyl group[162,163]. It has been shown[162,163] that the HOMO pentamethylnaphthyldisilane is a linear combination of the π-type HOMO of naphthalene and the molecular orbital of the Si–Si σ-bond. However, in contrast to the corresponding disilyl derivative of benzene[166], the HOMO in the naphthalene derivative has a preferential π character[162,163], since the ionisation potential of the π electrons of naphthalene (8.11 eV)[179] is lower than that of the π electrons of benzene (9.24 eV) and the σ electrons of the Si–Si bond (8.69 eV)[171]. The increase of the atomic number of E on passing from Si to Pb intensifies the σ,π-conjugation of the R_3ECH_2 fragment with the naphthalene

ring[19,145]. According to electronic spectroscopic data for complexes with tetracyanoethylene[180], the $(CH_3)_3SiCH_2$ fragment linked to the furan ring also exhibits anomalously pronounced electron-donating properties due to σ,π-conjugations which cannot be accounted for by the inductive effect.

Analysis of the positions and intensities of the absorption bands in the electronic spectra of 2-substituted pyridines[181] indicates the intensification of the σ,π-conjugation with increase of the atomic number of the element E in the $(CH_3)_3.ECH_2$ fragment and also on passing from substituents of the type $(CH_3)_3ECH_2$ to $[(CH_3)_3E]_2CH$. On the other hand, the diminution of the electron-donating properties of three substituents of the atom E, for example, on passing from $CH_2Si(CH_3)_3$ to the silatranyl derivative $CH_2Si(OCH_2CH_2)_3N$,[182]



is accompanied by a weakening of σ,π-conjugation.

A significant role of effects of the type of π,π- and p,π-conjugation in acetylene derivatives has been noted in the literature[14]. According to Muller's estimates[9], hyperconjugation, treated as one of the conjugation effects, should be twice as intense on conjugation with a triple bond [Schemes (III), (VI), (IX), (XII), (XV), (XVIII), (XXI), and (XXIV)] as in conjugation with a double bond [Schemes (II), (V) (VIII), (XI), (XIV), (XVII), (XX), and (XXIII)]. This powerful influence of hyperconjugation on the properties of acetylenes is clearly manifested in organoelemental derivatives. Among all the π-donors investigated (derivatives of benzene[115], naphthalene[162,163], furan[180], thiophen[183], pyridine[181], ethylene[98,115], and buta-1,4-diene[115]), only acetylene derivatives exhibit anomalies in the character of the influence of substituents of the type $(CH_3)_3C$, $(CH_3)_3Si$, and $(CH_3)_3SiCH_2$.[115,184]

The substituents can usually be arranged in the sequence $(CH_3)_3Si < (CH_3)_3C < (CH_3)_3SiCH_2$ in terms of their electron donating properties in relation to the π-electron system. The diminution of electron-donating properties in $(CH_3)_3Si$ compared with $(CH_3)_3C$ in accordance with the above sequence is traditionally attributed to the influence of the electron-accepting (relative to the π-electron system) effect of the $(p-d)\pi$ interaction and the enhancement of the electron-donating properties of the $(CH_3)_3SiCH_2$ group relative to $(CH_3)_3C$ is due to σ,π-conjugation. If the possibility of effective hyperconjugation with a π-donor centre is ensured for the substituent $(CH_3)_3Si$ (this is apparently never attained for aromatic compounds and ethylene derivatives, as stated above), then the positions of the substituents $(CH_3)_3Si$ and $(CH_3)_3C$ in the series based on the electron-donating properties can change.

The inversion of the usually observed electron-donating order has been established as an experimental fact[115,184] for the acetylenes $HC\equiv CR$, where the electron-donating properties of the substituents R vary in the sequence $(CH_3)_3C < (CH_3)_3Si < (CH_3)_3SiCH_2$. On the other hand, judging from the charge-transfer frequency in the electronic spectra of the complexes of tetracyanoethylene[185], the usual sequence based on the electron-donating properties of the substituents is observed for the phenylacetylenes $C_6H_5C\equiv CR$. In the disubstituted derivatives $R-C\equiv C-R$ and $R-C\equiv C-C\equiv C-R$, the electron-donating properties of R also lead to the usual sequence $(CH_3)_3Si < (CH_3)_3C < (CH_3)_3SiCH_2$,[184] while the methyl group at the triple bond is a stronger donor than the silyl group[186].

The study of a wide range of silicon-, germanium-, and tin-containing acetylenes and their carbon analogues established the important role of hyperconjugation in organoelemental derivatives not only in the charge-transfer state (with a positive charge on the π-donor centre—electronic spectroscopy of the iodine complexes) but also in the ground state (infrared spectroscopy of the hydrogen bond with phenol)[187]. The hyperconjugation

is intensified with increase of the atomic number of E in the sequence Si < Ge < Sn and with enhancement of the electron-accepting properties of the substituents X. When the donor–acceptor properties of the substituents $(CH_3)_3E$ and X are equalised, the intensity of the hyperconjugation diminishes sharply but in compounds of the type $(CH_3)_3E-C\equiv C-E'(CH_3)_3$, i.e. when $X = E'(CH_3)_3$, it still remains fairly effective. Despite the similar donor–acceptor properties of the substituents $(CH_3)_3E$ and $(CH_3)_3E'$, the high polarisability of the atoms E' and E (silicon, germanium, and tin) and of the triple bond as well as the high sensitivity of the acetylenic π-electron system to the electronic effects of the substituents favour hyperconjugation in acetylene derivatives containing two silicon subgroup elements attached to the triple bond[187].

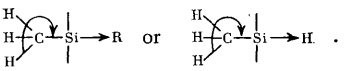
Thus, in compounds with the fragments $\geq E-\overset{|}{C}-X$ or $\geq E-\underset{|}{E}-X$ (E is a silicon subgroup element and X is an aromatic ring or a multiple bond), the interaction between the E—C and E—E bonds and the group X involves a σ,π-conjugation mechanism. The effect operates in the direction from the element E to the group X. If the substituent X is an atom with unshared electron pairs, then the mechanism of the interaction between E and X changes fundamentally[69] and involves the transfer of electron density in the direction from X to E (see the relevant reviews[188,189]). The traditional treatment of the interaction between X and E involves in this instance the concept of intramolecular coordination with participation of the unshared electron pairs of X and the unoccupied *nd* orbitals of the atom E,[190] but there exist also alternative approaches[191].

Apparently in certain systems there is a possibility of both types of interaction. This probably cannot be ruled out for silyl ketones where the presence of the C=O double bond and of the unshared electron pair of the oxygen atom is responsible for the complexity of the intramolecular interactions and the ambiguity of the conclusions concerning hyperconjugation[160,192,193]. Both intramolecular coordination and hyperconjugation apparently occur in cyclic silyl- and germyl-ketones[194].

3. The σ,σ- and σ,*p*-Conjugation in Compounds of Silicon Subgroup Elements

The effect of σ,σ-conjugation is a specific feature of organometallic compounds to an even greater extent than that of σ,π-conjugation. Systematic studies of the effect of σ,σ-conjugation have not been published and the few data available on this question can be consistently interpreted mainly in those cases where σ,σ-conjugation influences the reactivity of organometallic compounds in the transition state. Many clear examples of such influence have been quoted by Nesmeyanov[21,71], who established, in particular, a fairly profound analogy between the properties of the conjugated systems (π,π-, *p*,π-, σ,*p*-, σ,π-, and σ,σ-) which makes it possible to treat them from the same general standpoint[9]. It follows from the last conclusion that the absence of fundamental discrepancies with the rules established for

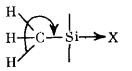
other conjugated systems constitutes an indirect confirmation of the validity of the conclusions reached in the study of σ,σ-conjugation in the ground electronic state.



On the basis of the proton chemical shifts in the methyl groups in the ^{1}H NMR spectra of the tetramethyl derivatives $(CH_3)_4E$, Allred and Rochow[15] proposed an electronegativity scale for Group IV elements: C(2.60) > Pb(2.45) > Ge(2.00) > Sn(1.93) > Si(1.90). It was then postulated that there is a possibility of hyperconjugation in the tetramethyl derivatives $\rangle E^- = CH_2H^+$, but the authors assumed that this effect should be equally important for all the compounds of silicon subgroup elements. (In Section II it was noted that the occurrence of hyperconjugation in tetramethylsilane follows from quantum-chemical calculations[62].) According to Allred and Rochow[15], hyperconjugation should therefore make a constant contribution to the electronegativities.

Criticism of the Allred–Rochow electronegativity scale by Egorov[195] was based on the fact that this scale is not only a measure of the inductive effect but also includes the so called *C* effect and hyperconjugation. However, we believe that the *C* effect and hyperconjugation are synonymous terms. Indeed, analysis of the vibrational spectra established that an electron-accepting *C* effect is characteristic of the E atoms, increasing monotonically on passing from silicon to germanium and tin[195]. The presence of this effect has been demonstrated sufficiently rigorously only for methyl derivatives and the nature of the *C* effect has not been elucidated. Bearing in mind that hyperconjugation in methyl derivatives (like σ,π-conjugation in benzyl derivatives) does not constitute a constant contribution but increases in the sequence Si < Ge < Sn < Pb with increasing polarisability of the elements E, the conclusion that the terms "*C* effect" and "hyperconjugation" describe the same electronic σ,σ-conjugation effect becomes evident.

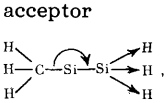
The concept of hyperconjugation has been used in the interpretation of the infrared and ^{1}H NMR spectra of silane[196] and stannane[197] derivatives. In the absence of extreme steric effects of the substituents[198], the frequency ν of the highly characteristic stretching vibration of the Si–H bond in the vibrational spectra of R_3SiH depends almost exclusively on the electronic effect of the substituents R.[199] If there are no resonance effects, then the frequency depends only on the inductive effect of R. However, the equation relating ν and the inductive constants σ* of the substituents R has an insufficiently high correlation coefficient. The frequency ν decreases when R is varied in the sequence CH_3 > iso-C_4H_9 > H = C_3H_7 ≅ n-C_4H_9 ≅ C_2H_5 > iso-C_3H_7; this series deviates from the σ* constant scale apparently owing to σ,σ-conjugation[196]. Shielding of the hydrogen atom in the Si–H group increases in the following sequence according to ^{1}H NMR spectra: CH_3 ≅ iso-C_4H_9 < n-C_4H_5 < C_2H_5 < iso-C_3H_7. The explanation[196] of the discrepancy between this sequence and the variation of the constants σ* by σ,σ*-conjugation is not quite so unambiguous in the given instance (as in the case of the frequencies ν), since the shielding revealed by ^{1}H NMR spectra can involve contributions due to magnetic anisotropy, which mask the donor–acceptor effects of the substituents.



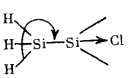
According to the ^{1}H NMR spectra of the stannane derivatives R_3SnH, R_2SnH_2, and $RSnH_3$, hydrogen atom shielding in the Sn–H group increases in the sequence iso-C_3H_7 < n-C_4H_9 ≅ n-C_3H_7 ≅ C_2H_5 < CH_3 and the frequencies of the stretching vibrations of the Sn–H bond in the infrared spectra of the methyl derivatives are anomalously high and are close to those for the phenyl derivatives. This also indicates the presence of hyperconjugation, which is particularly pronounced for the methyl derivatives[197]. An anomalously high frequency ν(Ge–H) is also observed in the infrared spectrum of trimethylgermane compared with other trialkylgermanes[200]. The greater role of σ,σ-conjugation in organogermanium compounds compared with organosilicon compounds is apparently the main cause of the higher intensity of the ν(Ge–H) bands compared with ν(Si–H) in the infrared spectra of compounds of the type R_3EH having an analogous structure (where E = Si or Ge)[201].

A semiquantitative estimate of the effects of σ,σ-conjugation has been made for the methyl derivatives of silicon. As mentioned above, the frequencies ν(Si–H) in the infrared spectra of the compounds R_3SiH depend mainly on the inductive effect of the substituents R. If R is not involved in strong conjugation with the silicon atom [of the type of $(p-d)\pi$ interaction], then the equation $\nu_{ind} = 23.1\Sigma\sigma^* + 2112$ holds[199]. Although the frequency ν is in fact influenced by σ,σ-conjugation, the inductive effect makes a dominant contribution to ν. The low contributions of σ,σ-conjugation are due to the fact that the substituents R, which exert only an inductive effect, have as a rule small inductive constants and the difference between the donor–acceptor properties of the conjugated bonds in compounds with such substituents R is therefore small and the extent of hyperconjugation is likewise slight:

Nevertheless the dipole moment of the Si–C bond in methylsilane has the direction $H_3C \rightarrow SiH_3$.[202]



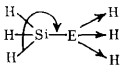
The introduction into the molecule of the substituents X forming $(p-d)\pi$ bonds with the silicon atom (and exerting a powerful inductive $-I$ effect) reduces the experimental values of ν_{exp} compared with ν_{ind}. The difference $\Delta\nu = \nu_{ind} - \nu_{exp}$ characterises the conjugation effects and for the methyl derivatives is smaller than for the ethyl derivatives. The effect of σ,σ-conjugation



operates in opposition to the $(p-d)\pi$ interaction and the decrease of Δν for the methyl derivatives is a result of the stronger σ,σ-conjugation than for the ethyl derivatives[203–207].

Careful analysis taking into account the magnetic anisotropy of chemical bonds shows that, in terms of the ^{1}H NMR spectra, hyperconjugation decreases the shielding of the methyl protons compared with the CH_2 protons in the ethyl group[203]. The high polarisability and low ionisation potential of the silicon–silicon bond lead to extremely specific properties of polysilanes[208], which has been noted, in particular, in the study of σ,π-conjugation involving the pentamethyldisilyl group[143]. σ,σ-Conjugation is also manifested to an appreciable extent in polysilanes[209].

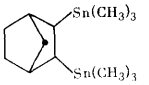
Depending on the nature of R in R_3SiSiH_3, the inductive constants σ* of the groups SiH_3, calculated on the assumption that only the inductive effect operates in disilanes, assume unrealistic values in the range from +1.5 to −1.5. As a partner in σ,σ-conjugation, the substituent R_3Si regulates the donor–acceptor properties of the silyl group which can function both as an acceptor



and as a donor

in hyperconjugation[209].

Thus, as for acetylene derivatives containing two organoelemental substituents[187], the variable contributions from σ,σ-conjugation impose fundamental limitations on the possibility of calculating the inductive constants of organoelemental substituents from infrared spectroscopic data for polysilanes. This applies equally to compounds of the type



where σ,σ-conjugation becomes more intense on passing from E = Ge to E = Sn.[209]

The study of the ionisation potentials of cyclopropylmethyl-(trimethyl)stannane, allyltrimethylstannane, and a series of related compounds by photoelectron spectroscopy established[113] low values of the potentials in the first compound as a result of the σ,σ-conjugation of the C–Sn bond with the cyclopropane ring and in the second compound as a consequence of σ,π-conjugation. The similar energies of the σ,σ-interaction (1.6 eV) and the σ,π-interaction (2.2 eV) are consistent with the results of a study of silicon-containing derivatives of benzene, ethylene, and cyclopropane by the electronic spectroscopy of their iodine complexes[210]. This observation has been checked in order to compare the characteristics of σ,π- and σ,σ-conjugations.

The presence of a positive charge on the cyclopropane and benzene rings as well as the double bond in the charge-transfer state leads to a qualitative indistinguishability of the characteristic features of the conjugation in all three systems[210]. We may note that in small strained cyclic systems of the type of bisbicyclobutane hyperconjugation plays an appreciable role also in the absence of organoelemental substituents[211].

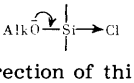
Theoretical study[17] and experiments on photoelectron spectroscopy[212] indicate the interaction of the E–C σ-bonds via the σ,σ-conjugation mechanism in compounds of the type $(CH_3)_3ECH_2CH_2E(CH_3)_3$, where E = Si or Sn. The ionisation potentials of these compounds are appreciably lower than those of the related compounds where there is no hyperconjugation and the example of the compound

with rigidly fixed C–Sn bonds emphasises the importance of the stereoelectronic factors not only for σ,π-conjugation but also for σ,σ-conjugation[212].

Systematic studies of the effect of σ,*p*-conjugation have not been made and most of the existing data have been obtained by the NQR method for chloro-derivatives of carbon and silicon subgroup elements. It is known, for example[213], that the frequencies in the ^{35}Cl NQR spectra of compounds of the type Cl–X increase with increasing electronegativity of X. The frequency therefore increases with increase of *n* in compounds of the type CCl_nH_{4-n}. As a consequence of the greater electronegativity of fluorine compared with chlorine, the increase of *n* in CF_nCl_{4-n} should also increase the frequency of the ^{35}Cl NQR signal, but the frequency is in fact somewhat reduced[213]. In order to account for this anomaly, which cannot be interpreted in terms of the inductive effect (electronegativity), the author[214] resorted to the concept of σ,*p*-conjugation:

As a result of the conjugation, the electron-accepting properties of the fluorine atom are diminished and the frequency of the ^{35}Cl NQR signal decreases compared with the value anticipated if only the inductive effect of the fluorine atom operated. Subsequently it was established[215] that hyperconjugation intensifies when fluorine atoms accumulate in the molecule. These problems were examined in greater detail by Semin et al.[213]

The initial data concerning σ,*p*-conjugation were developed significantly and generalised in the analysis of the ^{35}Cl NQR spectra of the compounds $R'R''R'''CCl$.[213,216–218] The compounds were combined in two groups. The first group included compounds whose substituents R did not contain unshared electron pairs. The NQR frequencies of these derivatives are linearly related to the sum of the inductive constants of the three substituents R: $\nu = 33.9 + 10.64\Sigma\sigma_I$. The compounds of the second group have R with unshared electron pairs (F, Cl, Br, I, or O) and their NQR frequencies deviate from the linear relation towards lower values. The deviation Δ is linked by the relation $\Delta = 13.32\Sigma\sigma_R$ with the sum of the constants σ_R characterising the capacity of R for conjugation.



The two-parameter equation $\nu = 33.9 + 10.64\Sigma\sigma_I + 13.32\Sigma\sigma_R$ indicates an important role of the effects of σ,*p*-conjugation

in carbon compounds[213,219,220]. According to classical ideas concerning hyperconjugation, when the electron-accepting properties of the chlorine atom remain unchanged, the σ,*p*-conjugation intensifies (Δ increases) as the electron-donating properties of the atom with unshared electron pairs are enhanced (the constants σ_R increase).

Systematic study of the dependence of the ^{35}Cl NQR frequencies on the electronic effects of the substituents in chlorosilanes[217] and chlorogermanes[220] showed that the inductive effect of the substituents is not the only cause of the changes in the frequencies[213,218,221,222]. Statistical treatment of the literature data on the frequencies of the ^{35}Cl signal in the spectra of $(R_1)_3E–Cl$[223] established the significance of the resonance effects.

At the same time the interpretation of the resonance effects within the framework of σ,*p*-conjugation was not found to be quite as evident as for the carbon compounds. Thus the extent of σ,*p*-conjugation in organosilicon compounds

and probably also the direction of this effect[221] depend greatly on the nature of the two other substituents at the silicon atom. The effect of σ,*p*-conjugation is observed for compounds in which the substituents exert the maximum influence on the central silicon atom via the $(p–d)\pi$ conjugation and inductive mechanisms. Significant changes in the positive charge on the silicon atom and of the bond polarities apparently influence greatly the extent of σ,*p*-conjugation, but this problem has not so far been studied. It is believed that such studies permit a deeper understanding of the relative contributions of σ,*p*-conjugation and electrostatic interaction, the latter being sometimes put forward as an alternative to the former[222].

The ^{35}Cl NQR frequencies in the spectra of alkoxychlorogermanes are lower[222] than might have been expected on the basis of the inductive effect alone[213]. As in the case of alkoxychlorosilanes and the corresponding carbon derivatives, we believe that this is caused by σ,*p*-conjugation:

In the infrared spectroscopic study of compounds where the existence of σ,p-conjugation can be postulated[204,224-226], the possibility of interpreting the experimental data within the framework of the inductive effect and the $(p-d)\pi$ interaction alone was demonstrated. This conclusion was also reached in the analysis of the dependence of the frequencies and intensities of the highly characteristic stretching vibrations of the Si–H and Ge–H bonds in the infrared spectra on the electronic effects of the three substituents at the atoms E. The frequencies ν(Si–H) confirmed the presence of σ,p-conjugation in alkoxychlorosilanes[204] and chlorodimethylaminosilanes[224]

and also in silanes of the type Alk_2NSiH_3 and $(Alk_2N)Alk_2.SiH$.[224] The effect of σ,p-conjugation in compounds of the latter type

is possible in view of the exceptionally high capacity of dialkylamino-groups for conjugation, including hyperconjugation. The polarity of the Si–H bond in dialkylaminosilanes increases as a consequence of σ,p-conjugation, which is clearly manifested in the intensities of the Si–H bands in the infrared spectra[225]. The anomalous increase of the intensities of the stretching vibration bands of the Ge–H bond as a result of σ,p-conjugation in compounds containing the fragments

has been established[226].

Thus the studies of hyperconjugation in organic derivatives of silicon subgroup elements by spectroscopic methods resulted in the accumulation of fairly extensive experimental data concerning mainly σ,π-conjugation. The principal characteristics of σ,π-conjugation, confirmed by quantum-chemical methods (the sharp intensification of the effect on passing from carbon compounds to silicon derivatives and its further intensification with increase of the atomic number of silicon subgroup element; the dependence on the stereoelectronic factors which in the limiting cases determine the very possibility of hyperconjugation; the significant dependence of the magnitude of the effect on the difference between the donor–acceptor properties of the conjugated bonds and the possibility of regulating these properties by varying the substituents at the donor and acceptor fragments of the molecule; the intensification of the effect in the presence of a positive charge on the π-electron system) are not only features of the ground electronic state but also the most important factors which determine the reactivity of σ,π-conjugated compounds.

The effects of σ,σ- and σ,p-conjugation have been so far inadequately investigated. However it is of fundamental importance that the same features which are characteristic of σ,π-conjugated compounds are observed in σ,σ- and σ,p-conjugated systems. The hypothesis of a major role of hyperconjugation in organoelemental compounds and of a profound analogy between the conjugation effects in general, which was put forward 35 years ago[21,71], is thereby fully confirmed.

In future studies of hyperconjugation in organoelemental compounds, derivatives of Group IV elements and mercury will probably play the role of model systems. The characteristics of the hyperconjugation in these model systems are important both for the solution of the overall problem of the relation between the structure and reactivity of organoelemental compounds and for the investigation of many specific problems, for example of the role of σ,p-conjugation and other resonance effects in organoelemental compounds, the characteristics of the influence of σ,σ-conjugation in the ground and excited electronic states, and the role of hyperconjugation in compounds with a chain of metal atoms and highly polarisable chemical bonds.

Exchange Reactions in the Chemistry of Organophosphorus Compounds

P.S.Khokhlov

The results of studies of reactions involving the exchange of alkoxy-, aryloxy-, acyloxy-, phosphorus-containing, amino-, alkylthio-, arylthio-, and hydrocarbon groups between phosphorus compounds are surveyed. The influence of the structure of the organophosphorus compounds, the role of catalysis, and the available information about the mechanisms of these reactions are considered.
The bibliography includes 229 references.

CONTENTS

I. Introduction 463
II. Intermolecular exchange of organic substituents in phosphorus compounds 463
III. Conclusion 472

I. INTRODUCTION

Exchange reactions are important in the chemistry of organophosphorus compounds (OPC). Some of them serve as a basis for convenient methods of synthesis of OPC, while others occur in side processes during the preparation, isolation, and storage of OPC. The exchange reactions assume particular importance as a procedure for the introduction of a radioactive label into physiologically active OPC. The study of exchange reactions is also of interest from the standpoint of estimating the stability of OPC and of discovering the pathways in their chemical and metabolic transformations. The exchange reactions with participation of OPC are also of interest from the theoretical standpoint.

The study of exchange reactions involving OPC was developed greatly particularly during recent years, which has been partly reflected in a monograph[1]. However, the reviews on the exchange reactions of OPC [2,3] cover the literature only up to 1968 and are not exhaustive. The intramolecular exchange reactions involving OPC, induced by the migration of substituents in molecular rearrangements, have been adequately surveyed in a number of communications[4-7].

This review deals with intermolecular exchange reactions at the phosphorus atom which proceed without a change in its coordination number.

II. INTERMOLECULAR EXCHANGE OF ORGANIC SUBSTITUENTS IN PHOSPHORUS COMPOUNDS

The tendency of organophosphorus compounds to undergo exchange reactions is determined primarily by the mobility of the bond between phosphorus and the exchanging group, which depends both on the environment of the phosphorus atom and on the structure of the exchanging group; organic substituents linked to phosphorus via heteroatoms exchange more readily. Accordingly, it is useful to consider the OPC exchange reactions after subdividing them in terms of the types of exchanging groups.

1. Exchange of Alkoxy- and Aryloxy-Groups

The reactions involving the exchange of alkoxy-groups between phosphorus compounds and the isotypical reactions in which aryloxy-groups are exchanged have been subjected to most fundamental investigations in the series of derivatives of tricoordinate phosphorus. With rare exceptions, the alkoxy-groups in isotypical OPC exchange more readily than the aryloxy-groups.

Trialkyl phosphites enter into exchange reactions with PCl_3 merely on mixing the reactants[8]. In a mixture of triethyl phosphite with PCl_3 at 20°C, equilibrium is established after two days and faster on heating[9]:

$$(C_2H_5O)_3P + PCl_3 \rightleftarrows (C_2H_5O)_2PCl + C_2H_5OPCl_2 .$$

The kinetic characteristics of this and other exchange reactions of OPC have been published in a review[2].

Alkyl phosphorodichloridites, formed in the reaction of trialkyl phosphites with PCl_3, interact under similar conditions with the initial trialkyl phosphites to form dialkyl phosphorochloridites[10]:

$$(C_3H_7O)_3P + C_3H_7OPCl_2 \rightleftarrows 2(C_3H_7O)_2PCl .$$

The composition of the products of the exchange reactions between trialkyl phosphites and phosphorus trihalides therefore depends on the ratio of the initial reactants. The main products of the reactions of trialkyl phosphites with PCl_3, taken in molar proportions of 2 : 1, are dialkyl phosphorochloridites, which are in fact mainly obtained by this procedure[11-19]:

$$2\,(RO)_3P + PCl_3 \rightarrow 3\,(RO)_2PCl ;$$
$$R=CH_3,\ C_2H_5,\ C_3H_7,\ C_4H_9,\ C_8H_{17},\ C_{12}H_{25},\ C_3H_5OC(O)CH_2 .$$

The composition of the exchange products and the rate of reaction depend to some extent also on the electron density at the phosphorus atom and on the structure of the ester groups. In the series of trialkyl phosphites the rate of exchange depends little on the length of the alkoxy-groups. Thus the reactions of the lowest trialkyl phosphites with PCl_3 reach completion comparatively rapidly at 20 °C, while the analogous reaction of tridodecyl phosphite is rapidly completed at 50 °C.[15]

The introduction of electron-accepting substituents into the alkoxy-group of the trialkyl phosphite lowers its reactivity in the exchange reactions with PCl_3. The disproportionation of the chloro-substituted phosphites has been noted only on heating[20]. The exchange between tris(perfluoroalkyl) phosphites and PCl_3 is in general difficult[21]. The exchange between tris(trifluoroethyl) phosphites and PCl_3 at 90 °C reaches completion in 4 h:[22]

$$(CF_3CH_2O)_3P + PCl_3 \rightleftarrows (CF_3CH_2O)_2PCl + CF_3CH_2OPCl_2 .$$

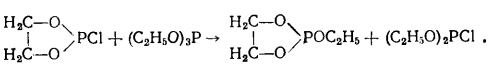
Triaryl phosphites enter into exchange reactions with phosphorus trihalides with much more difficulty than trialkyl phosphites. The reactions of triphenyl phosphite with PCl_3

and PBr_3 take place on heating above 150 °C and mixtures of diphenyl phosphorohalidites and phenyl phosphorodihalidites are then formed[23,24]. According to NMR data, the half-exchange period at 160 °C in the reaction of triphenyl phosphite with PCl_3 is 15 h:[10]

$$(C_6H_5O)_3P + PCl_3 \rightarrow (C_6H_5O)_2PCl + C_6H_5OPCl_2 .$$

In the reaction between triphenyl phosphite and PCl_3 at 180 °C, equilibrium is established in 60 h between the initial reactants, diphenyl phosphorochloridite and phenyl phosphorodichloridite[24], but, on raising the temperature to 200° to 230 °C and using an excess of PCl_3, the triaryl phosphites can be fully converted into aryl phosphorodichloridites[25]:

$$(ArO)_3P + 2PCl_3 \rightleftarrows 3ArOPCl_2 ,$$
$$Ar = C_6H_5,\ p\text{-}CH_3C_6H_4,\ m\text{-}CH_3C_6H_4,$$
$$2,\ 4\text{-}(CH_3)_2C_6H_3 .$$

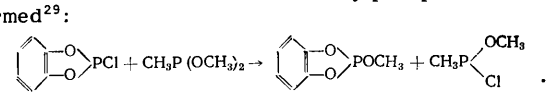


The nature of phosphorus halides exerts a significant influence on the direction and rate of the exchange reactions. Phosphorus trihalides undergo exchange reactions with trialkyl phosphites most vigorously and in terms of their reactivity can be arranged in the sequence[10] $PF_3 < PCl_3 < PBr_3$.

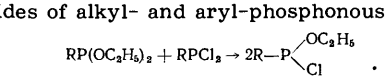
The interaction of trialkyl phosphites with phosphorus iodides leads to the formation of a complete mixture of products even under the conditions of intense cooling. The reactions of trialkyl phosphites with PBr_3 proceed exothermically and, like those with PCl_3, are completed by the formation of exchange products[10]:

$$2(C_3H_7O)_3P + PBr_3 \rightleftarrows 3\,(C_3H_7O)_2PBr .$$

The reactions between trialkyl phosphites and phosphorus trifluoride proceed with greater difficulty. The reaction between $(CH_3O)_3P$ and PF_3 is completed in 40 h at 80 °C but at a higher temperature it is complicated by the formation of phosphorus(V) derivatives[26].

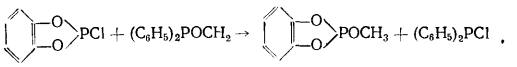


Trialkyl phosphites react with alkyl phosphorochloridites more slowly than PCl_3, but the reactions with ethylene phosphorochloridite and phenylene phosphorochloridite, like those with PCl_3, proceed with evolution of heat, which can be accounted for by the favourable conditions for the formation of the intermediate complex[27]:



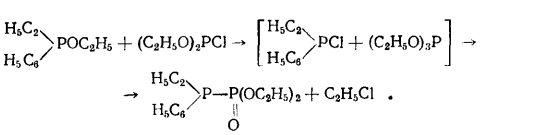
An increase of electron density at the phosphorus atom in phosphorus acid esters increases their reactivity in exchange reactions. Dialkyl phosphonites are more reactive than trialkyl phosphites; the interaction of dialkyl phosphonites with PCl_3 is exothermic and leads to the complete exchange of the alkoxy-groups and the formation of dichlorophosphines[28]:

$$RP(OR')_2 + PCl_3 \rightarrow RPCl_2 + (R'O)_2PCl .$$



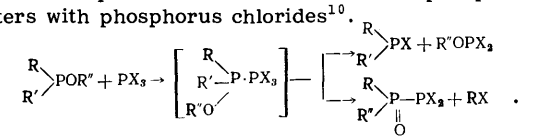
The analogous reaction with PBr_3 leads to a complex mixture of products[10]; the reaction with phosphorochloridites is slower and the ester-chlorides of alkylphosphonous acids are formed[29]:

The reactions of dialkyl phosphonites with dichlorophosphines can serve as a convenient method of synthesis of the ester-chlorides of alkyl- and aryl-phosphonous acids[30,31]:



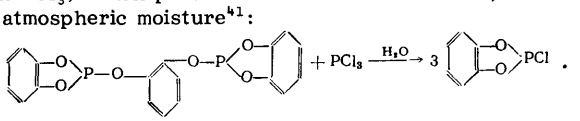
The esters of phosphinous acids react with phosphorus halides even more vigorously. The reactions of dialkyl phosphinites with PCl_3 give rise to a complex mixture of products[10,28], but the reaction with phenylene phosphorochloridite results in the formation of exchange products[29]:

Rapid exchange has also been observed in the reaction of butyl dibutylphosphinite with dipropyl phosphorochloridite[10]:



$$(C_4H_9)_2POC_4H_9 + (C_3H_7O)_2PCl \rightarrow (C_4H_9)_2PCl + (C_3H_7O)_2POC_4H_9 .$$

In the reaction of ethyl ethylphenylphosphinite with diethyl phosphorochloridite the products formed initially subsequently condense to form a P–P bond with alteration of the coordination number of one of the phosphorus atoms[32,33]:



This competing reaction occurs in almost all cases when acid esters of tervalent phosphorus interact with phosphorus chlorides and, depending on the structure of the initial compounds and the exchange products, lead to the formation (in greater or smaller amounts) of side products containing a P–P bond. When trialkyl phosphites react with PCl_3, the exchange reaction is mainly observed and condensation products are formed in insignificant amounts[9]. However, in the reactions of trialkyl phosphites with certain chlorophosphines[29,33,34] and iodophosphines[35,36], the latter pathway becomes the main one, which can be used to synthesise compounds containing a P–P bond[35–40].

The formation of compounds with a P–P bond can be a result of an alternative pathway to the decomposition of the intermediate complex formed in the reaction of phosphorus acid esters with phosphorus chlorides[10].

The available information about the structure of the intermediate complex in the reactions of trialkyl phosphites with phosphorus chlorides is inadequate. The question of the mechanism of these exchange reactions is complicated by catalysis. Both acids and bases have a catalytic effect in reactions involving the exchange of alkoxy- and aryloxy-groups between tricoordinate phosphorus compounds. HCl is a powerful catalyst in the reactions of trialkyl phosphite with PCl_3 and it is extremely difficult to eliminate admixtures of this acid[10]. The acid esters of tervalent phosphorus, which can be formed when the neutral esters are acted upon by HCl or traces of H_2O, are also effective catalysts in these reactions[10]. Boron trichloride and triethylamine have likewise been found to be catalytically active in the exchange reactions of neutral phosphites with phosphorus chlorides[27]. It has been shown by ^{31}P NMR that exchange between tricoordinate phosphorus esters and chlorides catalysed by HCl is preceded by the formation of compounds with a P–P bond[32].

Catalysis can be observed even when the reaction mixture is insufficiently protected from atmospheric moisture. Thus it has been shown that the reaction of phenylene phosphite with PCl_3, which proceeds under mild conditions, is catalysed by atmospheric moisture[41]:

The disproportionation of phenyl phosphorodichloridite when the latter is stored for a month can be accounted for by the catalytic effect of HCl or traces of water[42]:

$$3C_6H_5OPCl_2 \rightarrow (C_6H_5O)_3P + 2PCl_3 .$$

The isotope exchange between phenyl phosphorodichloridite and the radioactive $^{32}PCl_3$ at 20 °C is apparently induced by the same factors[43]:

$$C_6H_5OPCl_2 + {}^{32}PCl_3 \rightleftarrows C_6H_5O^{32}PCl_2 + PCl_3 .$$

Nor can one rule out the phenomenon of autocatalysis in reactions involving the exchange of ester groups at the phosphorus atom. Thus aryl phosphorodi-iodites undergo symmetrisation to triaryl phosphites and phosphorus triiodide on storage, the symmetrisation reaction being accelerated by the addition of PI_3:[44]

$$3\,ArOPI_2 \rightarrow [(ArO)_3P + 2PI_3] \rightarrow (ArO)_3PI_2 + P_2I_4 ;$$
$$Ar = C_6H_5,\ o\text{-}CH_3C_6H_4,\ m\text{-}CH_3C_6H_4,$$
$$p\text{-}CH_3C_6H_4,\ o\text{-}ClC_6H_4,\ p\text{-}ClC_6H_4 .$$

Acids and bases can also catalyse the exchange of ester groups between neutral phosphites. In the presence of HCl the reaction between triethyl and trimethylphosphites takes place in 2 h at 20 °C with formation of mixed phosphites[45]

$$(C_2H_5O)_3P + (CH_3O)_3P \overset{HCl}{\rightleftarrows} (C_2H_5O)_2POCH_3 + (CH_3O)_2POC_2H_5 .$$

This reaction is apparently reversible because in the presence of acid reagents, for example, trifluoroacetic acid, rapid symmetrisation of the mixed neutral phosphites is observed at the same temperature[46]. It has been suggested that HCl protonates the oxygen of the alkoxy-group of the phosphite with its subsequent cleavage to dialkyl phosphorochloridite, which then interacts with another phosphite molecule to form the exchange products[32,45].

Under the condition of base catalysis, the exchange of ester groups between neutral phosphites proceeds under much more severe conditions. According to NMR data, the exchange between triethyl and tributyl phosphite is completed in 4 h at 170–180 °C:[47]

$$(C_2H_5O)_3P + (C_4H_9O)_3P \xrightarrow{C_4H_9ONa} (C_2H_5O)_2POC_4H_9 + (C_4H_9O)_2POC_2H_5 .$$

An interesting process involving the exchange of alkoxy-groups for aryloxy-groups has been observed in the presence of alkyl halides. The exchange is accompanied by the Arbuzov reaction, which results in the formation of mixed esters of alkylphosphonic acids[48,49].

The redistribution of ester groups with participation of trialkyl phosphites, triphenyl phosphite, and phosphorous acid takes place at 80–100 °C with formation of mixed acid esters of phosphorous acid[50]:

$$(C_6H_5O)_3P + (RO)_3P + H_3PO_3 \rightarrow 3\ \begin{matrix} RO \\ C_6H_5O \end{matrix}\!\!>\!P(O)H .$$

The marked acidophilic properties of both aliphatic and aromatic neutral esters of tervalent phosphorus promote their involvement in exchange reactions with various phosphorus acids. Neutral phosphites interact with phosphorous acid at 20 °C to form mixtures of acid phosphites[51]:

$$(RO)_3P + H_3PO_3 \rightarrow (RO)_2P(O)H + ROP(O)H$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad |$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad OH \quad .$$

The composition of the products of this reaction depends on its conditions and on the ratio of the initial reactants. When a mixture of neutral phosphites and phosphorous acid taken in proportions of 2 : 1 is heated at 100 °C for 2 h, dialkyl or diaryl phosphites are formed as the main products[52–55]:

$$2\,(RO)_3P + H_3PO_3 \rightarrow 3\,(RO)_2P(O)H ;$$
$$R = CH_3,\ C_2H_5,\ C_3H_7,\ C_4H_9,\ C_5H_{11},\ C_6H_{13},$$
$$C_6H_5CH_2,\ C_6H_5,\ p\text{-}CH_3C_6H_4,\ o\text{-}CH_3C_6H_4,$$
$$m\text{-}CH_3C_6H_4,\ p\text{-}ClC_6H_4,\ o\text{-}ClC_6H_4 .$$

Under the same conditions, neutral phosphites interact also with acid phosphites, which can result in the formation of mixed acid phosphites. This reaction is particularly convenient for the synthesis of mixed acid phosphites containing alkoxy- and aryloxy-groups[50,56]:

$$(RO)_3P + R'OP\!<\!\begin{matrix}(O)H \\ OH\end{matrix} \rightarrow \begin{matrix} RO \\ R'O \end{matrix}\!\!>\!P(O)H + (RO)_2P(O)H .$$

The exchange reactions of triaryl phosphites with phosphorous acid are apparently reversible, because diaryl phosphites are symmetrised on slow vacuum distillation to triaryl phosphites. This process is accelerated in the presence of bases[57,58]:

$$3\,(C_6H_5O)_2P(O)H \rightarrow 2\,(C_6H_5O)_3P + H_3PO_3 .$$

Such symmetrisation is not characteristic of dialkyl phosphites, but sodium dialkyl phosphorothioites undergo symmetrisation on heating[59]:

$$2(RO)_2PSNa \rightarrow (RO)_3P + ROP(SNa)_2 .$$

When salts of dialkyl phosphites are heated, the products of the Arbuzov rearrangement are usually formed[60], but, when a mixture of di(s-butyl) phosphite was heated with its sodium salt, the exchange products were obtained, which was apparently caused by the steric hindrance to the Arbuzov rearrangement[61]:

$$(s\text{-}C_4H_9O)_2P(O)H + (s\text{-}C_4H_9O)_2PONa \rightarrow$$
$$\rightarrow (s\text{-}C_4H_9O)_3P + (s\text{-}C_4H_9O)P(O)H$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\quad |$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\quad ONa \quad .$$

It is noteworthy that in the reactions of mixed neutral alkyl aryl phosphites with phosphorous acid, the alkoxy-group is more mobile[56]:

$$(C_2H_5O)_2POC_6H_5 + H_3PO_3 \rightarrow \begin{matrix} C_2H_5O \\ C_6H_5O \end{matrix}\!\!>\!P(O)H + C_2H_5OP(O)H .$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad |$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad OH$$

The reactions of neutral phosphites with phosphorous acid take place stepwise. The dialkyl phosphite formed initially interacts at a higher temperature with phosphorous acid to form monoalkyl phosphites[62,63]:

$$(RO)_2P(O)H + H_3PO_3 \rightarrow 2\,ROP(O)H .$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad |$$
$$\qquad\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad OH$$

Neutral phosphites esterify phosphonous acids at 20 °C with formation of acid phosphonite esters[64]:

$$(RO)_3P + C_6H_5P(O)H \rightarrow (RO)_2P(O)H + C_6H_5P(O)H ;$$
$$\qquad\qquad\quad |\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad |$$
$$\qquad\qquad\quad OH\qquad\qquad\qquad\qquad\qquad\qquad\qquad\quad OR$$
$$R = CH_3,\ C_2H_5,\ C_3H_7,\ C_4H_9,\ iso\text{-}C_4H_9 .$$

Further esterification of phosphonous acid by neutral phosphites takes place at a higher temperature and is complicated by the rearrangement of the neutral phosphonite to the phosphinate[65]. Like phosphites, neutral phosphonites interact with phosphonous acids to form acid phosphonites[66,67]:

$$C_6H_5P(OR)_2 + C_6H_5P(O)H \rightarrow 2\,C_6H_5P(O)H ;$$
$$\qquad\qquad\qquad\quad |\qquad\qquad\qquad\qquad\quad |$$
$$\qquad\qquad\qquad\quad OH\qquad\qquad\qquad\qquad\quad OR$$
$$R = C_6H_5,\ iso\text{-}C_8H_{17},\ ClCH_2CH_2 .$$

Alkoxy-groups can be exchanged also between acid phosphites. When a mixture of symmetrical dialkyl phosphites is heated for 15 h at 100–150 °C, asymmetric dialkyl phosphites

are formed in yields from 30 to 70%.[67,68] It has been demonstrated by gas–liquid chromatography (GLC) that the exchange takes place even at 24 °C:[69]

$$(RO)_2P(O)H + (R'O)_2P(O)H \rightleftarrows 2\ \begin{matrix} RO \\ R'O \end{matrix}\!\!>\!P(O)H\ ;$$

$R = CH_3,\ C_2H_5;\ R' = C_2H_5,\ C_3H_7,\ C_4H_9$
$C_5H_{11},\ C_6H_{13},\ C_8H_{17},\ ClCH_2CH_2,$
$(ClCH_2)_2CH$.

This reaction is reversible and mixed dialkyl phosphites are gradually symmetrised during storage[70,71]. The symmetrisation is accelerated on distillation[72] and in the presence of bases[70]. Alkylene diphosphites are symmetrised on heating[73]:

$$\begin{matrix} RO \\ H(O) \end{matrix}\!\!>\!POR'OP\!<\!\begin{matrix} OR \\ (O)H \end{matrix} \rightarrow R'\!<\!\begin{matrix} O \\ O \end{matrix}\!\!>\!P(O)H + (RO)_2P(O)H\ .$$

Under the influence of the full esters of tervalent phosphorus acids, the acids of quinquevalent phosphorus are also readily esterified. Thus triethyl phosphite is cleaved by phosphoric acid with the simultaneous formation of monoethyl phosphate[73,74]:

$$(C_2H_5O)_3P + H_3PO_4 \rightarrow (C_2H_5O)_2P(O)H + C_2H_5O\overset{O}{\overset{\|}{P}}(OH)_2\ .$$

The esterification of phosphoric acid by trialkyl phosphites takes place stepwise. Depending on the ratio of the initial reactants, mono-, di-, and tri-alkyl phosphates can be formed on heating in nitromethane[75,76]. The reaction of triphenyl phosphite with phosphoric acid also takes place stepwise under the same conditions:[77,78]

$$(RO)_3P + H_3PO_4 \left|\begin{array}{l} \xrightarrow{1:1} ROP(O)(OH)_2 + (RO)_2P(O)H \\ \xrightarrow{2:1} (RO)_2P(O)OH + 2(RO)_3P(O)H \\ \xrightarrow{3:1} (RO)_3PO + 3\,(RO)_2P(O)H\ . \end{array}\right.$$

The esterification of phosphoric acid by neutral phosphites is a complex process. The study of the mechanism of the esterification of diethyl phosphate showed that the process involves a stage in which the neutral phosphate is protonated and a mixed anhydride is formed[79]:

$$(RO)_3P + (C_2H_5O)_2P(O)OH \left|\begin{array}{l} \rightleftarrows (RO)_3\overset{+}{P}H\overline{O}P(O)(OC_2H_5)_2 \\ \rightleftarrows (RO)_3P{-}\overset{\uparrow\downarrow}{O}{-}P(O)(OC_2H_5)_2 \\ \quad\ \ H \\ \rightleftarrows (RO)_2P(O)P(O)(OC_2H_5)_2 + ROH \end{array}\right. \rightarrow$$

$$\rightarrow (C_2H_5O)_2\overset{O}{\overset{\|}{P}}OR + (RO)_2PHO\ .$$

The reactions of neutral phosphites with phosphonic acids apparently proceed in accordance with an analogous mechanism and here too neutral acid phosphonates can be obtained depending on the reactant ratio[80]:

$$(C_2H_5O)_3P + C_6H_5CH_2\overset{O}{\overset{\|}{P}}(OH)_2 \left|\begin{array}{l} \xrightarrow{1:1} C_6H_5CH_2\overset{O}{\overset{\|}{P}}\!<\!\begin{matrix} OC_2H_5 \\ OH \end{matrix} + (C_2H_5O)_2P(O)H \\ \xrightarrow{2:1} C_6H_5CH_2\overset{O}{\overset{\|}{P}}(OC_2H_5)_2 + 2(C_2H_5O)_2P(O)H\ . \end{array}\right.$$

The thioacids of quinquevalent phosphorus are readily esterified by the full esters of tervalent phosphorus acids. The reactions of trialkyl phosphites, dialkyl phosphonites, or alkyl phosphinites with dialkyl phosphorodithioates take place with evolution of much heat and trialkyl phosphorodithioates are formed. It has been suggested that the protonation of the tricoordinate phosphorus is an intermediate stage[81,82]:

$$R\!<\!\begin{matrix} R' \\ POR'' \end{matrix} + (R'''O)_2\overset{S}{\overset{\|}{P}}SH \rightarrow \left[R'\!\!-\!\overset{+}{P}H\overset{-}{S}\overset{S}{\overset{\|}{P}}(OR''')_2\right] \rightarrow (R'''O)_2\overset{S}{\overset{\|}{P}}SR'' + R'\!<\!\begin{matrix} R \\ P(O)H \end{matrix}\ .$$

Neutral phosphites and phosphonites react less vigorously with the acid esters of phosphoromonothioic acids. The esterification of *O,O*-dialkylphosphoromonothioic acid by trialkyl phosphites proceeds with evolution of a small amount of heat and is completed by the formation of thiono-isomers[81]:

$$(R'O)_2PR + (R''O)_2POSH \rightarrow (R''O)_2\overset{S}{\overset{\|}{P}}OR' + R'O\!<\!\begin{matrix} R \\ P(O)H \end{matrix}\ .$$

We may note that the analogous reaction of triphenyl phosphite with diethylphosphorothioic acid stops at the stage involving the formation of the mixed anhydride[83]:

$$(C_6H_5O)_3P + (C_2H_5O)_2POSH \rightarrow (C_6H_5O)_3POP\overset{S}{\overset{\|}{(}}OC_2H_5)_2 + C_6H_5OH\ .$$

Neutral esters of tricoordinate phosphorus acids also esterify phosphonodithioic acids and the completion of the reaction then requires heating for 1 h at 40–50 °C:[84]

$$(CH_3O)_3P + C_6H_5CH_2\overset{S}{\overset{\|}{P}}\!<\!\begin{matrix} OC_4H_9 \\ SH \end{matrix} \rightarrow C_6H_5CH_2\overset{S}{\overset{\|}{P}}\!<\!\begin{matrix} OC_4H_9 \\ SCH_3 \end{matrix} + (CH_3O)_2P(O)H\ .$$

The esters of quinquevalent phosphorus acids are much more inert in the exchange reactions, which can be explained by their coordination unsaturation, which hinders the formation of the intermediate reaction complex from the exchanging reactants. A competing pathway involving the formation of pyrophosphates occurs preferentially in the reactions of esters of phosphorus(V) acids with phosphorochloridites[85–88]. Pyrophosphoryl compounds are formed preferentially also in the reactions of neutral phosphates with phosphoramidochloridates[89–91], phosphorochlorothioates[92], thiophosphoryl trichloride[93], and phosphorus pentoxide[94]. Only the reaction of phosphorus trichloride with the chloroalkyl esters of phosphonic acids, which may be formed when aldehydes interact with PCl_3 in accordance with the scheme

$$3RCHO + PCl_3 \rightarrow [(RCHClO)_3P \rightarrow RCHClO\overset{O}{\overset{\|}{P}}(OCHClR)_2] \xrightarrow{PCl_3} RCHClO\overset{O}{\overset{\|}{P}}Cl_2\ ,$$

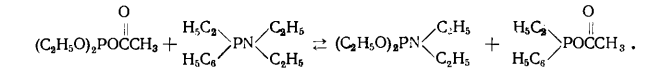
is an exception[95–97].

In contrast to triaryl phosphates[99], trialkyl phosphates[98] undergo the exchange reaction with phosphoric acid, which is catalysed by stronger acids[98]:

$$2(RO)_3PO + H_3PO_4 \rightarrow 3\,(RO)_2P(O)OH\ .$$

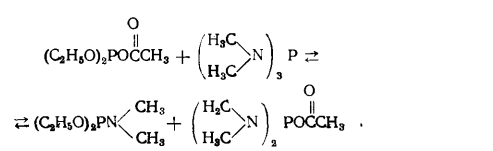
Acid catalysis can also explain the incorporation of the radioactive ^{32}P label into neutral phosphates on interaction with labelled iron phosphate[100]:

$$(RO)_3PO + Fe^{32}PO_4 \cdot 2H_2O \xrightarrow{200°C} (RO)_3{}^{32}PO\ .$$



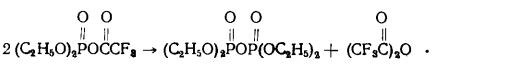
The incorporation of radioactive phosphorus has been observed also on heating tributyl phosphate with radioactive phosphoric acid[101]:

$$2\,(C_4H_9O)_3PO + H_3{}^{32}PO_4 \rightleftarrows (C_4H_9O)_3{}^{32}PO + \\ + (C_4H_9O)_2\overset{O}{\overset{\|}{P}}OH + C_4H_9O\overset{O}{\overset{\|}{P}}(OH)_2\ .$$

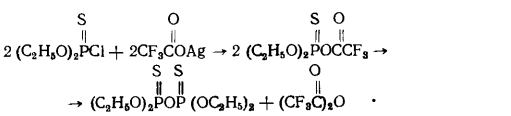


It is noteworthy that the enzyme-catalysed exchange reactions of monophosphates with radioactive phosphoric acid are faster and proceed under milder conditions[102].

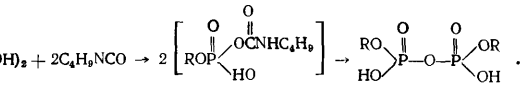
2. The Exchange of Acyloxy-Groups



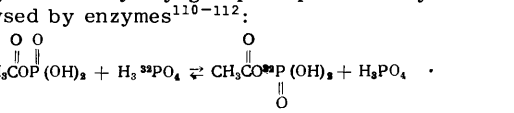
O-Acyl derivatives of phosphorus acids constitute a broad class of mixed anhydrides. Among them, acylphosphites have been studied in greatest detail (the bibliography includes more than 100 items[103]). It has been shown by ^{31}P NMR that, when acetyl diethyl phosphite is heated with the diethylamide of ethylphenylphosphinous acid at 50 °C, a mobile equilibrium is established between these compounds and the exchange products[104]:



When these reagents are heated at a higher temperature, diphosphine oxide and acetic anhydride are formed. Their formation is most probably associated with the symmetrisation and isomerisation reactions of the mixed anhydrides. There are no data in the literature on the symmetrisation of acyl phosphites, but the formation of pyrophosphites when dialkyl phosphites interact with isocyanates can serve as direct confirmation of the possibility of the occurrence of such reactions[105]. The formation of pyrophosphorous acid derivatives has been observed also in the reactions of acyl phosphites with phosphorous acid triamides[14,106]. It was shown by NMR that under these conditions the formation of pyrophosphoryl compounds is preceded by the exchange of the acyloxy-group between the phosphorus compounds[104]:

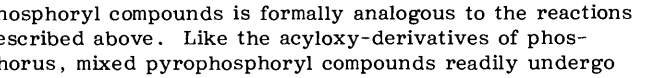


O-Acyl derivatives of phosphorus(V) acids readily undergo symmetrisation as a consequence of their high reactivity. Thus the mixed anhydride of *O*,*O*-diethylphosphoric and trifluoroacetic acids is wholly converted into tetraethyl pyrophosphate and trifluoroacetic acid anhydride after 24 h at 20 °C:[107]

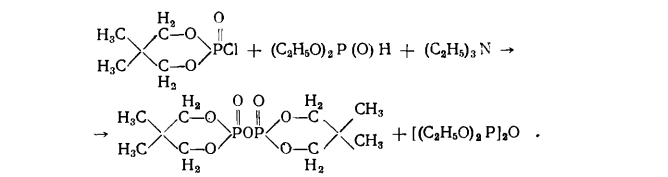


Ethoxycarbonyl diethyl phosphate, which persists for several months, is very stable[107]. The tendency towards analogous reactions has been noted also for *O*-acyl derivatives of phosphoromonothioic acid[108]:

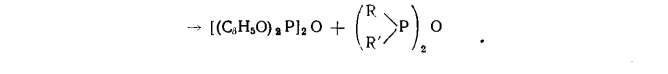
The tendency of the acyloxy-derivatives of phosphorus towards symmetrisation can be used to synthesise pyrophosphoryl compounds which are difficult to obtain. Thus disubstituted pyrophosphates have been prepared by the interaction of phosphoric acid monoesters with butyl isocyanate[109]:



The exchange of the acyloxy-groups is promoted by acids and is catalysed by enzymes[110–112]:



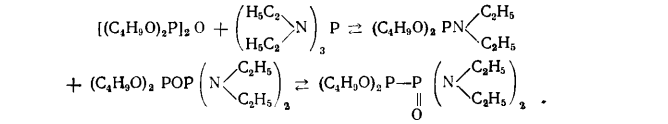
3. The Exchange of Phosphorus-Containing Groups



The exchange of phosphorus-containing groups in pyrophosphoryl compounds is formally analogous to the reactions described above. Like the acyloxy-derivatives of phosphorus, mixed pyrophosphoryl compounds readily undergo symmetrisation. In many instances symmetrisation takes place even during the preparation of the mixed anhydrides, for example, the anhydride of *O*,*O*-diethylphosphoric and *O*,*O*-diethylphosphorous acids[113–115]:

Only the symmetrical anhydrides have been obtained in the reaction of diethyl phosphite with dimethyl propylene phosphorochloridate[115]:

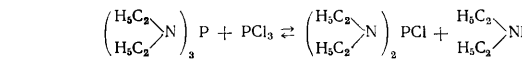
The interaction of acid phosphites[116,117] and phosphonites[118] as well as phosphinous acids[119,120] with the chlorides of tervalent phosphorus acid in the absence of hydrogen chloride acceptors leads to the exchange of the hydroxy-group for chlorine and, in the presence of bases, results in the formation of mixed anhydrides, which then undergo symmetrisation[121–123]:



Symmetrical phosphorus acid anhydrides can be obtained also directly by treating the mixed anhydrides of phosphorus acids with the acids themselves[124,125].

We may note that the symmetrisation of the mixed anhydrides of phosphinous and *O*-alkylphosphinous acids is reversible[123]:

The interaction of tetrabutyl pyrophosphite with phosphorous acid tris(diethylamide) leads to the formation of the diethylamide of *O*,*O*-dibutylphosphorous acid and dibutyl *N*,*N*,*N*′,*N*′-tetraethylpyrophosphorodiamidite, which is in tautomeric equilibrium with diphosphine monoxide[126]:

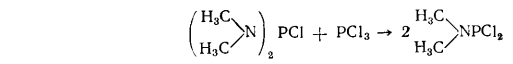


This reaction is of interest also because the exchange of the phosphorus-containing groups proceeds with the cleavage of not only the P–O but also the P–P bonds[127]. Instances of the tautomeric transformation of diphosphine oxides into anhydrides have been examined[128]. A similar preliminary isomerisation has also been postulated in the exchange reaction of diphosphine disulphides with phosphorus-acid chlorides[129]. However, the exchange involving the P–P bond can proceed also without the preliminary isomerisation of diphosphine oxides. Thus dialkyld'phenoxydiphosphine and

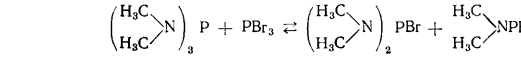
dialkyl phosphorochloridite have been obtained by the reaction of diphenyl phosphorochloridite with dialkoxydialkyldiphosphine[129].

The exchange reactions involving the cleavage of the P–P bond have been examined in reviews[131,132].

4. The Exchange of Amino-Groups

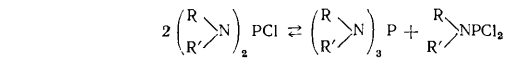


Phosphorus acid amides are more reactive in exchange reactions than their esters. The reaction of phosphorous tris(diethylamide) with PCl_3 takes place almost instantaneously with evolution of much heat and is accompanied by the redistribution of the substituents[9]:

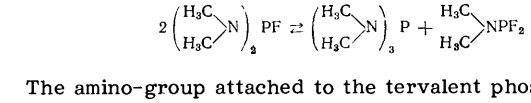


By altering the ratio of the initial reactants, the reaction can be directed towards the preferential formation of phosphorodiamidous chlorides[133–136]:

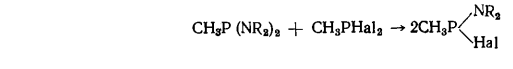
$$2\,(R_2N)_3\,P + PCl_3 \rightleftarrows 3\,(R_2N)_2\,PCl\,;\quad R=CH_3,\ C_2H_5,\ C_3H_7,\ C_4H_9\,.$$



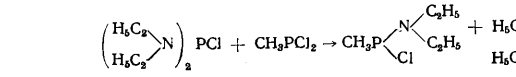
The half-life of this reaction at 20 °C is 30 s.[137] The *N,N,N',N'*-tetra-alkylphosphorodiamidous chlorides formed react in their turn with PCl_3 to produce *N,N*-dialkylphosphoramidous dichlorides[138]:



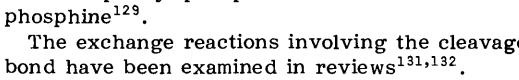
Phosphorus triamides react extremely vigorously also with PBr_3, but the *N,N,N',N'*-tetra-alkylphosphorodiamidous bromides formed are unstable and disproportionate to the initial compounds even on vacuum distillation[134]:



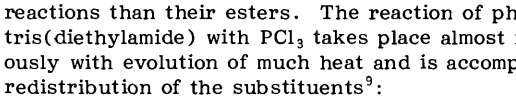
N,N,N',N'-Tetra-alkylphosphorodiamidous chlorides, which disproportionate to the extent of 15% with formation of phosphorous triamides and phosphoramidous dichlorides after storage for 1 month at 20 °C, are also relatively unstable[139]:



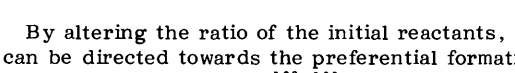
N,N,N',N'-Tetra-alkylphosphorodiamidous fluorides disproportionate even faster and for this reason it is difficult to isolate them in a pure form[140]:



The amino-group attached to the tervalent phosphorus atom is readily exchanged in the reactions of a wide variety of OPC with phosphorus chlorides[27,137,141,142]. The reactions of bis(dialkylamino)phosphorines with dichloro- and dibromophosphines take place at high rates[137,142]:

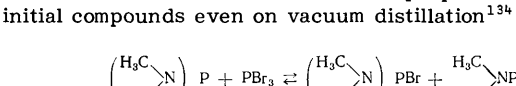


N,N,N',N'-Tetra-alkylphosphorodiamidous chlorides react with alkyldichlorophosphines under mild conditions[137]:

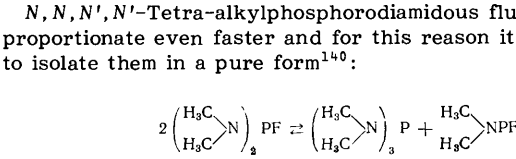


The exchange between phosphorous triamide and diethyl phosphorochloridodithioite is rapid[141]:

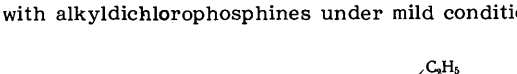
The *N,N,N',N'*-tetra-alkylphosphorodiamidous chloride formed in this reaction reacts under the same conditions with the excess of diethyl phosphorochloridodithioite and *N,N*-diethylphosphoramidous dichloride is formed[141]:



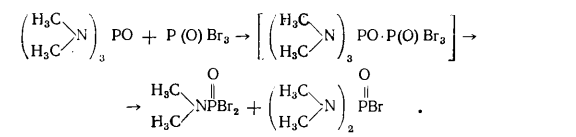
N,N-Diethylphosphoramidous dichloride can also be obtained by the reaction of phosphorous tris(diethylamide) with ethyl phosphorodichloridothioite[141]:



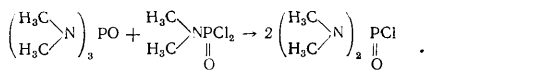
The exchange of the amino-group for chlorine is also observed in the interaction of the ester-amides of phosphorous acid with phosphorochloridites. Ethylene *N,N*-diethylphosphoramidite and diethyl phosphorochloridite have been obtained by the reaction of diethyl *N,N*-diethylphosphoramidite with ethylene phosphorochloridite, which takes place with spontaneous heating[27]:



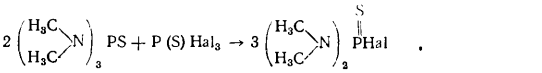
Diethyl *N,N*-diethylphosphoramidite interacts less vigorously with phenylene phosphorochloridite. The catalytic effect of HCl was noted in this reaction[27]:



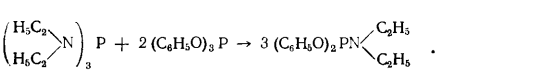
The exchange of a nitrogen-containing functional group in phosphoramidites and phosphonamidites for chlorine goes to completion and the formation of only a small amount of red condensed products, tentatively assumed to be monomers with a P–P bond, is observed[136]. However, the final product of the reaction of ethylphenylphosphinous diethylamide with diethyl phosphorochloridite is a compound with a P–P bond, which is formed after the completion of the exchange reaction[27]:



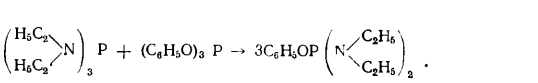
The amides of phosphorus(V) acids enter into exchange reactions with phosphorus chloride under more severe conditions than the analogous derivatives of tervalent phosphorus. Phosphoric triamides react with $POCl_3$ to form stable complexes which withstand heating to 150 °C. At a higher temperature they decompose with formation of phosphoromonoamidic dichloride and phosphorodiamidic chloride, i.e. an exchange reaction takes place[143,144]:



Phosphoryl bromide reacts similarly[144]:

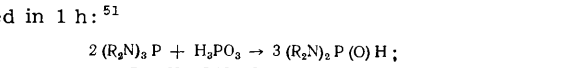


Phosphoric tris(dimethylamide) reacts with *N*,*N*-dimethylphosphoramidic chloride[144]:

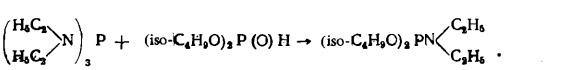


It is noteworthy that the thioamides of phosphorus acids undergo the exchange reaction under milder conditions. Phosphorothioic tris(dimethylamide) reacts with $PSCl_3$ and $PSBr_3$ on refluxing in toluene. The formation of a complex was not observed in these reactions and *N*,*N*,*N*',*N*'-tetramethylphosphorodiamidothioic halides were obtained in high yields[144]:

Instead of exchange products, pyrophosphoryl compounds and an alkyl halide are formed in the reactions of phosphorus(V) acid chlorides with the ester-amides of the same acids containing at least one alkoxy-group at the phosphorus atom[89-92]. However, in the series of aryloxyamides there is a possibility of the exchange of the amino-groups for chlorine and even for an aryloxy-group. When a mixture of phosphorous tris(diethylamide) is heated with triphenyl phosphite for 5 days at 100 °C, complete exchange takes place with formation of diphenyl *N*,*N*-diethylphosphoramidite in 93% yield[9,145]:

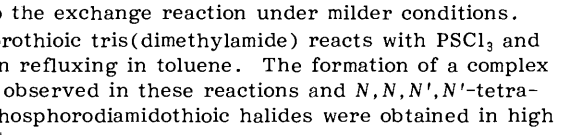


In the presence of an excess of phosphorous tris(diethylamide), phenyl *N*,*N*,*N*',*N*'-tetra-alkylphosphorodiamidite was obtained under the same conditions[146]:



The occurrence of this reaction shows that diaryl phosphoramidites can undergo a reaction involving a redistribution of the amido- and aryloxy-groups at 100 °C and above[145].

The presence of the nitrogen atom in phosphorus acid amides promotes the formation of complexes with proton-donating reagents[27,147-149] and hence the occurrence of exchange reactions between phosphorus acids and their amides. The exchange between phosphorous triamides and phosphorous acid is observed even at 20 °C and at 60 °C is completed in 1 h:[51]



Although the yields of this reaction are approximately 60%, it nevertheless constitutes the most convenient method of synthesis of phosphoramidites[150,151]. On heating for 6 h at 100 °C, the exchange between phosphorous tris(diethylamide) and di-isobutyl phosphite is observed[152]:

The analogous reaction of butyl *N*,*N*,*N*',*N*'-tetraethylphosphorodiamidite with an acid phosphite stops at the stage involving the formation of a mixed anhydride[152]:

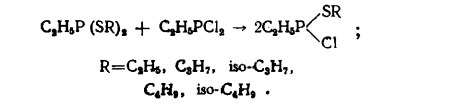
The interaction of tervalent phosphorus acid amides with quinquevalent phosphorus acids is more complex. Together with exchange reactions, pyrophosphoryl compounds are formed and a free amine is liberated in this instance[148]; by removing the amine from the reaction mass, it is possible to drive the reaction fully towards the formation of pyrophosphates and their thio-analogues[153-155]:

The reactions of phosphorus(V) acids with their amides stop at the stage involving the formation of only pyrophosphoryl compounds and ammonium salts of phosphorus acids[156,157], which is apparently associated with the high stability of these salts. In this connection it is of interest to note that, when phosphoric acid triamides react with carboxylic acid salts, an amino-group is exchanged for a hydroxy-group[158].

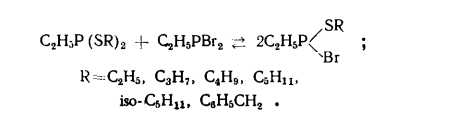
5. The Exchange of Alkylthio- and Arylthio-Groups

As regards their chemical properties, phosphorus acid thioesters differ significantly from their oxygen analogues. The thioesters show a smaller tendency towards being protonated, but their molecules are more polarisable. The sulphur atom in the thioesters of phosphorus(III) acids is capable of competing effectively with the phosphorus atom in reactions with electrophiles[159]. The thiophosphoryl group dissociates more readily than the phosphoryl group. These features have a significant influence on reactions involving phosphorus acid thioesters.

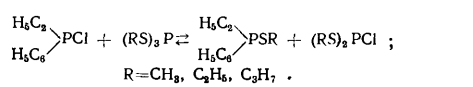
The reaction of trialkyl phosphorotrithioites with PCl_3 proceeds without the liberation of heat, but its completion requires heating[160]:



Since the equilibrium in this reaction is established slowly, the exchange products can be separated by vacuum distillation, which makes it possible to use the reaction for the synthesis of dialkyl phosphorochloridodithioites. Thus diethyl phosphorochloridodithioite has been obtained in 74% yield by heating a mixture of triethyl phosphorothioite with a stoichiometric amount of PCl_3 at 110–130 °C for 4 h:[141]

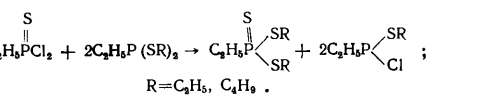


Diethyl phosphorobromidodithioite has been obtained in 70% yield under the same conditions by the reaction of triethylphosphorotrithioite with PBr_3.[141]

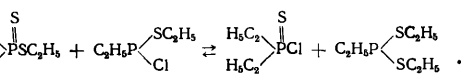


With increase of electron density at the phosphorus atom in the thioesters, the exchange of thiol groups is accelerated. The reactions of alkyl phosphonodithioites with dichlorophosphines are completed in 1 h at 100 °C and constitute a convenient method of synthesising the ester-chlorides of alkylphosphonothious acids[161,162]:

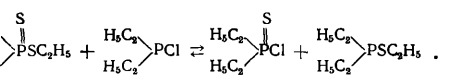
However, with increase of electron density at the phosphorus atom, the mobility of the equilibrium also increases, which can hinder the isolation of the reaction products by distillation. The yield of the ester-bromides obtained by the reaction of the full esters of alkylphosphonodithious acids with alkyldibromophosphines is only 30–60%:[163,164]



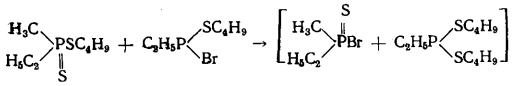
The equilibrium involving chlorophosphines is even more mobile. The reaction of chloroethylphenylphosphine with trialkylphosphorotrithioites is fully reversible and the attempts to isolate the exchange products by vacuum distillations were therefore unsuccessful[141]:



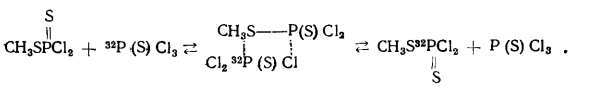
A mobile equilibrium is also established in the interaction of ethyl phosphorodichloridothioite with phosphoramidites; according to NMR data, the reaction of ethyl phosphorodichloridothioite with phosphorous tris(diethylamide) results in the formation of ethyl *N,N*-diethylphosphoramidochloridothioite, but vacuum distillation led to the isolation of only its disproportionation products[141]:



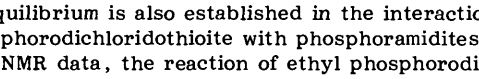
The exchange of alkylthio-groups is observed also in the reactions of dialkyl ethylphosphonodithioites with ethylphosphonothioic dichloride[165]:



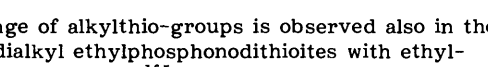
In contrast to their oxygen analogues, the thioesters of phosphorus(V) acids can enter into an exchange interaction with phosphorus halides. The exchange of the thiol group for a halogen then proceeds smoothly only in sulphur-containing compounds without an oxygen atom attached to the phosphorus atom. The exchange between phosphinodithioates and phosphorus chlorides proceeds under the mildest conditions. In a mixture of ethyl diethylphosphinodithioate and the ester-chloride of ethylphosphonothioic acid, the exchange is completed in 3 h at 100 °C. However, the exchange products have been isolated in a low yield apparently owing to the high mobility of the equilibrium[166]:



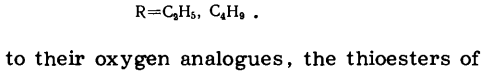
An analogous reaction with chlorodiethylphosphine has been observed on heating in a sealed tube at 140 °C, but the separation of the exchange products by distillation proved to be difficult[167]:



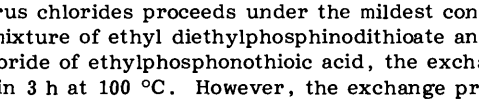
When butyl ethylmethylphosphinodithioate was allowed to react with butyl ethylphosphonobromidothioite, only dibutyl ethylphosphonotrithioate was isolated (in a low yield)[168]:



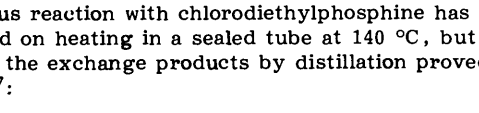
The thiol groups are exchanged for chlorine under more severe conditions in the interaction between the esters and chlorides of phosphorothioic and phosphonothioic acids. The isotope exchange between methyl phosphorodichloridodithioate and $^{32}PSCl_2$ proceeds at an appreciable rate on heating to a temperature above 150 °C and at 200 °C is 50% complete after 5 h. The isotope exchange takes place as a result of the exchange of the methylthio-group for Cl and apparently involves an associative mechanism[43]:



Phosphorotetrathioates react with $PSCl_3$ under the same conditions. Dialkyl phosphorochloridotrithioates have been obtained in 60–70% yield from trialkyl phosphorotetrathioates after 4 h at 180–200 °C:[169]



This reaction always results in the formation also of small amounts of alkyl phosphorodichloridodithioates, which become the main reaction products when an excess of thiophosphoryl chloride is used. Triphenyl phosphorotetrathioate has been converted into phenyl phosphorodichloridodithioate by an analogous procedure[169–171]:



Dialkyl phosphorochloridotrithioates react with $PSCl_3$ under the same conditions to form phosphorodichloridodithioates[170]:

Like the phosphorotetrathioates, phosphonotrithioates react with alkyl- or aryl-phosphonothioic dichlorides, but the completion of the reaction requires in this case heating for ~12 h at 180–200 °C:[172]

Thioesters of phosphorus acids containing an oxygen atom attached to the phosphorus atom form as a rule pyrophosphoryl compounds and not exchange products in the reaction with phosphorus chlorides. The exchange products have been obtained only from certain phosphorodichloridothioates and $PSCl_3$:[173–176]

The thioesters of phosphorus acids also enter into a reaction with thioanhydrides in which the thiol groups are redistributed. When a mixture of phosphorotetrathioates is

heated with P_4S_{10} at 150 °C, an equilibrium is established between the initial compounds and the redistribution products[177]:

$$2\,(RS)_3PS + P_4S_{10} \rightleftarrows 3\,(RSPS_2)_2 .$$

A redistribution of alkylthio-groups is observed also in the interaction between unlike trialkyl phosphorotrithioites, the reaction being accelerated by HCl. Heating of a mixture of trimethyl and tributyl phosphorotrithioites in the presence of traces of HCl leads to rapid exchange of the alkylthio-groups[160]:

$$(CH_3S)_3P + (C_4H_9S)_3P \xrightarrow{HCl} (CH_3S)_2PSC_4H_9 + (C_4H_9S)_2PSCH_3 .$$

However, phosphorotrithioites and phosphonodithioites are not quite so highly acidophilic as their oxygen analogues and instances of the exchange of thiol groups between phosphorus thioesters and acids have not been described in the literature. It is only known that the acid phosphorus thioesters readily disproportionate. Thus *S,S*-dialkyl phosphorodithioites disproportionate even at room temperature or on slight heating into trialkyl phosphorotrithioites and *S*-alkyl phosphorothioites[178-180]:

$$2\,(RS)_2P(O)H \rightleftarrows (RS)_3P + RSP\begin{matrix}(O)H\\ OH\end{matrix} .$$

The monothiol esters of phosphorus acids are unstable in a free state and decompose with liberation of a thiol and phosphorus compounds[181,182].

6. The Exchange of Hydrocarbon Groups

The phosphorus–carbon bond is very strong. Until recently, it was believed that reactions accompanied by the cleavage of the P–C bond are rather anomalous in phosphorus chemistry[183] and that radioactive phosphorus attached to a carbon atom is not involved in isotope exchange[6]. However, careful studies have been carried out recently on a series of OPC with a P–C bond and resulted in the discovery of a number of new reactions involving the cleavage of the P–C bond[43,184-190] and indicating the possibility of the exchange of organic substituents between phosphorus compounds.

The conversion of dichlorophenylphosphine into chlorodiphenylphosphine has been known since the previous century[191]:

$$2\,C_6H_5PCl_2 \rightleftarrows \begin{matrix}H_5C_6\\ H_5C_6\end{matrix}\!\!>\!PCl + PCl_3 .$$

In the absence of a catalyst, this reaction takes place at 300 °C under pressure[191] or on pyrolysis in a quartz tube[192]. Under the catalytic influence of $AlCl_3$, the reaction is completed faster at a lower temperature and in the absence of pressure[193]. Zinc chloride, tin tetrachloride, slightly moistened $AlCl_3$, and other transition metal chlorides have also been proposed as catalysts of the symmetrisation of aryldichlorophosphines to diarylchlorophosphines[194-196]:

$$2ArPCl_2 \xrightarrow{AlCl_3} Ar_2PCl + PCl_3 ;$$
$$Ar = C_6H_5,\ o\text{-}ClC_6H_4,\ n\text{-}ClC_6H_4 .$$

We may note that benzyldihalogenophosphines disproportionate to dibenzylhalogenophosphines more specifically in the absence of catalysts and that this process is apparently reversible, since the removal of phosphorus trihalide from the reaction sphere is accompanied by an increase of the yield of the dibenzylhalogenophosphine[197]:

$$2C_6H_5CH_2PHal_2 \rightarrow (C_6H_5CH_2)_2PHal + PHal_3 .$$

It was found that $AlCl_3$ catalyses also the reverse reaction involving the redistribution of phenyl groups between the phosphorus compounds; thus ethylenebisdichlorophosphine has been obtained by the reaction of ethylenebisdiphenylphosphine with PCl_3 in the presence of $AlCl_3$ in a closed system at 280 °C:[198]

$$(C_6H_5)_2PCH_2CH_2P(C_6H_5)_2 + 2PCl_3 \xrightarrow{AlCl_3} Cl_2PCH_2CH_2PCl_2 .$$

The interaction of phosphines with phosphorus chlorides is a complex process. In the initial stage of the reaction, the C–P bond is not involved and adducts are formed which undergo various reactions depending on the conditions. In the reactions of tertiary phosphines with phosphorus(V) chlorides under mild conditions, dichlorophosphoranes and polymeric products are formed[199-203]; on further heating to 180–200 °C, the initial tertiary phosphines and phosphorus chlorides are reformed[204,205]. Heating of the same reactants at still higher temperatures (220–260 °C) is accompanied by the cleavage of the C–P bond and the exchange of the hydrocarbon groups for Cl:[206]

$$(C_4H_9)_3P + PCl_3 \rightarrow (C_4H_9)_2PCl + C_4H_9PCl_2 .$$

The complete conversion of trialkylphosphines into alkyldichlorophosphines requires heating to 280–350 °C and the use of an excess of PCl_3:[206]

$$(C_4H_9)_3P + 2PCl_3 \rightarrow 3C_4H_9PCl_2 .$$

Tertiary phosphines interact with PBr_3 under similar conditions, which leads to the formation of dibromophosphines[207]:

$$(C_6H_5)_3P + 2PBr_3 \rightarrow 3C_6H_5PBr_2 .$$

The interaction of primary and secondary phosphines with PCl_3 under conditions where the mixture is cooled or slightly heated also does not involve the phosphorus–carbon bond[208-210], but at a higher temperature (~200 °C and above) the phosphorus–carbon bond is ruptured. This has been confirmed by the isotope exchange between alkyl- or aryldichlorophosphines and $^{32}PCl_3$ at 200–250 °C:[43,211]

$$RPCl_2 + {}^{32}PCl_3 \rightleftarrows R^{32}PCl_2 + PCl_3 .$$

The reaction is bimolecular, which indicates an associative mechanism, and proceeds at a fairly high rate; at 250 °C the degree of exchange reaches 50% after 5 h.

Isotope exchange has been observed also for phosphonothioic dichlorides[211]:

$$C_6H_5CH_2\overset{\overset{S}{\|}}{P}Cl_2 + {}^{32}PCl_3 \rightleftarrows C_6H_5CH_2{}^{32}\overset{\overset{S}{\|}}{P}Cl_2 + PCl_3 .$$

It is noteworthy that phosphonothioic dichlorides are involved in isotope exchange also with the radioactive $^{32}PSCl_3$ under the same conditions[211]:

$$C_6H_5CH_2\overset{\overset{S}{\|}}{P}Cl_2 + {}^{32}P(S)Cl_3 \rightarrow C_6H_5CH_2{}^{32}\overset{\overset{S}{\|}}{P}Cl_2 + P(S)Cl_3 .$$

The oxygen analogues do not enter into a similar reaction apparently because the formation of an intermediate complex is difficult for compounds of tetracoordinate phosphorus. The exception, which is observed for phosphonothioic dichlorides, can be accounted for by the fact that on heating they are capable of dissociating into sulphur and tricoordinate dichlorophosphines, which readily enter into an exchange reaction with PCl_3 or $PSCl_3$. This reaction constitutes a convenient method for the introduction of the radioactive ^{32}P label into pesticidal OPC.[212]

The exchange of hydrocarbon groups with phosphoryl chloride is also not observed in the series of oxygen-containing compounds of tetracoordinate phosphorus. Tertiary

phosphine oxides react with $POCl_3$ to form salt-like adducts which dissociate into the initial reactants on heating above the melting point and undergo pyrolytic decomposition[213–216]. The exchange of phenyl groups for Cl has also not been observed in the reaction of triphenylphosphine oxide with PCl_5, but this reaction was carried out under comparatively mild conditions[217–219].

The presence of a hydroxy-group in the hydrocarbon substituent in the α-position relative to the phosphorus atom increases significantly the lability of the phosphorus–carbon bond[185,220]. The exchange reactions involving a series of substituted OPC can also be facilitated in this way. Indeed tetra(hydroxymethyl)phosphonium hydroxide reacts with PH_3 under mild conditions to form tri(hydroxymethyl)phosphine[221]:

$$3\,(HOCH_2)_4\overset{+}{P}\overline{OH} + H_3P \rightarrow 4\,(HOCH_2)_3P + 3H_2O\ .$$

The high reactivity of the hydroxymethyl derivatives of phosphorus is also manifested in the exchange reactions of hydroxymethylphosphonium salts with tertiary phosphines, which results in the transfer of the hydroxymethyl group from the less nucleophilic to the more nucleophilic phosphorus centre[192–195]:

$$(HOCH_2)_4\overset{+}{P}\overline{Cl} + (C_4H_9)_3P \rightarrow (HOCH_2)_3P + (C_4H_9)_3\overset{+}{P}{-}CH_2OHCl^-\ .$$

The exchange of hydrocarbon groups between OPC can be catalysed by alkali metals[225]

$$(C_6H_5)_4\overset{+}{P}\overline{Br} + (p\text{-}CH_3C_6H_4)_2PK \rightarrow (C_6H_5)_3P + (p\text{-}CH_3C_6H_4)\,PC_6H_5\ .$$

---o0o---

Analysis of published data has shown that organophosphorus compounds can enter into numerous reactions involving the intermolecular exchange of organic substituents at the phosphorus atom. The ability of OPC to participate in these reactions depends significantly on the coordination number of the phosphorus atom. Substituents bound to a tricoordinate phosphorus atom via N, O, and S atoms exchange most readily. The exchange of hydrocarbon groups at the C–P bond (including those at a tricoordinate phosphorus atom) proceeds with much more difficulty. Compounds of tetracoordinate phosphorus enter into exchange reactions under more severe conditions than the analogous derivatives of tricoordinate phosphorus.

There are no literature data concerning the exchange reactions of organic substituents attached to dicoordinate and pentacoordinate phosphorus atoms. Nor have there been any communications about the exchange of substituents bound to phosphorus via heteroatoms such as Se and Si. The exchange reactions of phosphorus isotopes, which are of interest from both practical and theoretical points of view, have been little studied.

It has been shown that the exchange reactions of organic substituents attached to the phosphorus atom can be greatly influenced by acid and basic catalysts; however, the role of the catalysis has been studied thoroughly only in reactions involving compounds of tricoordinate phosphorus[41,45,160,226,227].

Study of the mechanisms of reactions involving the intermolecular exchange of organic substituents attached to the phosphorus atom show that these reactions proceed via stages in which intermediates are produced[9,10,79]. The formation of an unstable intermediate has been established by ^{31}P NMR in reactions involving compounds of both tricoordinate[228] and tetracoordinate[229] phosphorus. Further development of this branch of the chemistry of OPC will be associated with a more profound study of the mechanisms and characteristic features of the exchange reactions.

Organometallic Chelate Complexes of the $\pi-\pi$ and $\pi-n$ Type

N.I.Rybinskaya and V.V.Krivykh

Organometallic chelate complexes in which either organic fragments π-bonded to the metal (chelates of the $\pi-\pi$ type) or complexes where heteroatomic groups with an unshared electron pair (NR_2, PR_2, AsR_2, OR, etc.) linked to the metal via an n-type bond (chelates of the $\pi-n$ type) are present together with the π-bonded fragments are examined. Data on complexes with polydentate ligands, including different combinations of fragments π- and n-coordinated to the metal are also surveyed. The characteristic features of the formation of organometallic chelates of the $\pi-\pi$ and $\pi-n$ types, which depend on the properties of the chelating ligand and the nature of the metal, are discussed.
The bibliography includes 267 references.

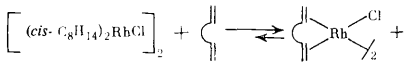
I. INTRODUCTION

Chelate complexes have found extensive applications in many fields of technology, medicine, and agriculture. The activity of complexones, pesticides, certain medicinal preparations, analytical reagents, etc. is based on their capacity for chelation. However, among such compounds, the so-called inorganic chelates, in which the bond between the metal and the ligand is achieved via a heteroatomic group, have been most widely and comprehensively investigated. Organometallic chelates in which at least one of the bonds of the chelating ligand and the metal atom or ion is a metal–carbon σ- or π-bond are much less well known and have been altogether very little investigated. These compounds are distinguished by a wide variety of types. At the same time the study of the problem of chelation in the chemistry of organometallic compounds of transition metals is important for a number of reasons. In the first place the increase of stability owing to the chelate effect makes it possible to synthesise and investigate new types of complexes. Furthermore, chelation is closely related to problems such as cyclisation, matrix synthesis, and the *cis*-effect. The chelate effect is also of practical importance; in particular, chelation is important in homogeneous catalytic reactions widely used in industry at the present time.

Studies on organometallic chelates began comparatively recently and have not so far been systematic. The main cause holding back the development of this field is lack of information about the characteristics of the formation of organometallic chelates. This review is an attempt at a survey of the data which have accumulated on the compounds indicated in order to discover both similarities between organometallic and inorganic chelates and differences due to the specific features of their coordinated organic ligands and the types of their bonds with the metal. The review analyses for the first time certain rules governing the formation as well as the characteristic features of the structures and geometries of organometallic chelates.

Since the significant differences between chelate compounds are determined by the nature of the coordinating group of the ligand and the bonds which they form with the metal, different chelate compounds can be classified in terms of the types of bond. Since three main types of bonds between the metal and the organic ligand are known [the n-bond (using the free electron pair of the heteroatom) and the σ- and π-bonds], in principle all chelates with bidentate ligands can form six types of complexes: $n-n$, $n-\sigma$, $n-\pi$, $\pi-\pi$, $\pi-\sigma$, and $\sigma-\sigma$ and the last five refer to organometallic chelates. In the present review attention has been concentrated on organometallic chelates with $\pi-\pi$ and $\pi-n$ bonds formed by bidentate chelating ligands containing two unsaturated fragments of the type C=C, C=X (X = N, O, or another heteroatom), C≡C, C≡N,  ,  ,  , and  (chelates of the $\pi-\pi$ type) or, together with the unsaturated fragment, they contain a heteroatomic group with an unshared electron pair of the type NR_2, PR_2, AsR_2, SR_2, OR, etc.) (chelates of the $\pi-n$ type); complexes with polydentate ligands forming π- and n-bonds in different combinations are also considered (chelates of these types constitute the most complex and interesting case). The synthesis and certain properties of chelate complexes with σ-coordination (intramolecular) have been recently described in a series of reviews[1-6] and in the present review we shall therefore consider only data for chelates of the $\pi-\pi$ and $\pi-n$ types.



II. THERMODYNAMIC AND KINETIC CHELATE EFFECTS IN $\pi-\pi$ AND $\pi-n$ ORGANOMETALLIC CHELATES

There are no special grounds for the expectation of large differences between the thermodynamic and kinetic characteristics of the chelate effect (CE) in organometallic and inorganic chelates. However, a significant difference between the natures of the bond in organometallic compounds should lead to specific features which can be manifested in the properties of the bond between the metal atom and the coordinating group. Since the problem of stability is important in the chemistry of organometallic compounds of transition metals, the CE, as an effect involving an increase of stability, plays an important role. It is sufficient to state that the existence of many new types of compounds is due precisely to the CE. Furthermore, chelation and related phenomena, for example, synthesis in a matrix, are important for a homogeneous catalytic process. This is the reason for the importance of the analysis of the regularities and features characteristic of the CE in organometallic chelates.

Unfortunately, complexes with chelating ligands and the analogous complexes with related monodentate ligands are known in only a few instances. However, comparison of even

these scanty data shows that the complexes of monodentate ligands are as a rule less stable. For example, among the bismono-olefin complexes of metals, only rhodium(I) and iridium(I) complexes are stable, but their stability is again lower than that of the corresponding complexes with chelating diolefins. This is confirmed by the fact that, when a diolefin is added to complexes of this kind, a spontaneous reaction takes place with displacement of the mono-olefin and the formation of a diolefin complex. In complexes with volatile mono-olefins, the occurrence of such reactions can be explained (at least partially) by a shift of the equilibrium owing to the removal of the mono-olefin from the reaction sphere.

However, in the case of the complexes with cyclo-octene, one may claim, even in the absence of quantitative data, that the equilibrium in the reaction with cyclo-octa-1,5-diene[7] or cyclo-octatetraene[8] is almost wholly displaced to the right ($K \gg 1$) precisely as a result of the CE:

The question of the relative magnitudes of the CE in organometallic chelate complexes and of the dependence of this effect on various factors is much more complicated. Unfortunately there are very few quantitative data. Some of them are presented in Tables 1–4. The manifestation of the CE is supported by the formation constants of the silver complexes of unsaturated alcohols (of the π–n type) (Table 1).

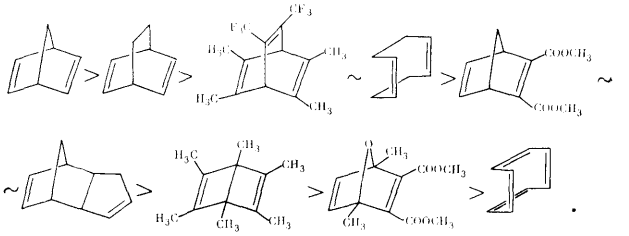
Table 1. The formation constants (K, litre mol^{-1}) of Ag^+ complexes of unsaturated alcohols and their derivatives in water (partition method, 25 °C; reproducibility 10%)[9].

Olefin	K			
	X = H	X = OCOCH$_3$	X = OH	X = OCH$_3$
3-X-Prop-1-ene	—	0.35	12[a]; 22[b]	—
4-X-But-1-ene	—	0.31	26	—
5-X-Pent-1-ene	—	0.44	51	0.34
6-X-Hex-1-ene	0.095[a]	0.15	29	0.10
7-X-Hept-1-ene	—	<0.1	8.2	—
11-X-Undec-1-ene	—	<0.1	<0.1	—
5-X-5-Methylpent-1-ene	—	0.07	25	—
3-X-1-Methylenecyclohexane	0.096[c]	<0.1	19	—
3-(β-X-Ethyl)cyclopentene	0.119[c,d]	<0.1	38	—
5-X-Cyclo-octene	0.005[c]	<0.1	29	—

Note. $K = [\text{complex}]_{H_2O}/[\text{olefin}]_{CCl_4}[Ag]^+_{H_2O}$; [a] partition method[10]; [b] potentiometric method in water[11]; [c] value for cyclopentene[12]; [d] $K < 0.1$ for cyclo-octanol.

Thus the formation constant for *cis*-cyclo-oct-4-en-1-ol ($K = 29$) exceeds by several orders of magnitude the formation constants of the complexes with monodentate ligands of similar structure—*cis*-cyclo-octene ($K = 0.005$) and cyclo-octanol ($K < 0.1$). Analogous formation constants of the silver complexes of certain unsaturated alcohols have been obtained by the potentiometric method[13]. It is also noteworthy that, according to the data in Table 1 and Wilcox and Gaal[13], the character of the variation of the formation constants of chelate complexes as a function of the distances between the olefin and hydroxy-groups, considered in detail below, can be clearly traced. A similar trend in the variation of K has been observed[14] also for the reaction $Ag^+ + L \rightleftharpoons [AgL]^+$ (Table 2), where L are sulphur- and selenium-containing unsaturated ligands; however, the most interesting feature of this system is the fact that ΔH and not ΔS makes a decisive contribution to the CE.

Table 2. Thermodynamic parameters (kcal mol^{-1}) of the silver complexes[14]: $Ag^+ + L \rightarrow [AgL]^+$.



Ligand	$-\Delta G$	$-\Delta H$	$-T\Delta S$	$\delta(\Delta G)$	$\delta(\Delta H)$	$\Delta(T\Delta S)$
$C_4H_9SCH_2COO^-$	5.35	6.81	1.46	1.16	4.21	3.06
$CH_2{=}CH(CH_2)_2SCH_2COO^-$	6.51	11.02	4.52			
$CH_2{=}CH(CH_2)_3SCH_2COO^-$	5.71	8.39	2.68			
$C_4H_9SeCH_2COO^-$	6.24	7.79	1.55	0.78	5.23	4.42
$CH_2{=}CH(CH_2)_2SeCH_2COO^-$	7.05	13.03	5.97			
$CH_2{=}CH(CH_2)_3SeCH_2COO^-$	6.31	9.13	2.87			

The formation constants of silver complexes with various diolefins (complexes of the π–π type), listed in Table 3, illustrate the different contributions of the CE depending on the structure of the diolefin[15] (for comparison, Table 3 also includes complexes with mono-olefins of similar structure).

Table 3. The formation constants of the silver complexes of olefins in ethylene glycol at 40 °C[15] (gas–liquid chromatographic method).

Olefin	K, litre mol^{-1}	Olefin	K, litre mol^{-1}
But-1-ene	7.7	Cyclohexene	3.6
Buta-1,3-diene	4.2	Cyclohexa-1,4-diene	4.9
Penta-1,4-diene	10.2	1-Methyl-4-(2-propenyl)cyclo-hex-1-ene	5.9
Hexa-1,5-diene	28.8	4-Vinylcyclohex-1-ene	11.2
2-Methylhexa-1,5-diene	22.1	Norbornene	62
2,5-Dimethylhexa-1,5-diene	13.3	Norbornadiene	33.7
Hepta-1,6-diene	14.7	Cyclo-octa-1,3-diene	3.2
Octa-1,7-diene	11.3	Cyclo-octa-1,4-diene	14.4
Nona-1,8-diene	10.4	Cyclo-octa-1,5-diene	75
Deca-1,9-diene	7.8	Cyclo-octatetraene	91

The contribution of the CE is particularly large in the case of a cyclic diolefin—cyclo-octa-1,5-diene. For cyclic dienes, a marked dependence of the CE on the geometry of the chelating ligand has been observed and the equilibrium constants determined by the ^1H NMR method for the complexes [(diene)$RhCl_2$], vary by five orders of magnitude[16]. The chelating capacity of dienes diminishes in the following sequence:

Important results have been obtained by the direct determination of the enthalpies of formation (Table 4).[17]

The results show that in chelates of the π–*n* and π–π types both the entropy and enthalpy factors make an important contribution to the CE, as in inorganic chelates. The relative importance of these factors apparently varies as a function of the different features of the complexes.

The kinetic CE can be illustrated by data[18] obtained for the reaction

$$DQNi(diene) + P(OCH_3)_3 \rightleftarrows Ni[P(OCH_3)_3]_4 + DQ + diene,$$

where DQ is duroquinone and 'diene' is duroquinone, cyclo-octa-1,5-diene, *endo*-bicyclopentadiene, norbornadiene, and cyclo-octatetraene. It has been suggested that the first stage is the bimolecular reaction of trimethyl phosphite with the nickel complex in which one bond between the chelating diene and the metal is ruptured. The rate constants for this stage vary in the following sequence: DQ << cyclo-octadiene< bicyclopentadiene < norbornadiene < cyclo-octatetraene. The sequence obtained agrees with that found[19] on the basis of the ligand exchange reaction. Thus, in the given instance, the kinetic and thermodynamic CE act in the same direction.

Table 4. The heats of the reactions of chelating olefins and other ligands with $(CH_3CN)_2PdCl_2$ in methylene dichloride[17].

Ligand	$-\Delta H$, kcal mol^{-1}
Bicyclopentadiene	4.9±0.1
Cyclo-octatetraene	5.6±0.1

1-Methyl-4-(2-propenyl)cyclohex-1-ene	6.8±0.3
Hexa-1,5-diene	8.0±0.4
Cyclo-octa-1,5-diene	13.0±0.4
Norbornadiene	13.3±0.8
Pyridine	26.0±0.7
Tetramethylethylenediamine	27.3±1.7
o-Phenylenebisdimethylarsine	35.2±0.7
Bis(diphenylphosphino)ethane	50.5±1.7

Together with quantitative thermodynamic and kinetic data, the decomposition temperatures as well as the results of physical methods of investigation and even qualitative chemical data are used to estimate the stabilities of the compounds. It is necessary to treat such results, particularly those of the last type, with caution. The overall stability of chelate π–π and π–*n* complexes is usually determined by the strength of the bond between the metal atom and the unsaturated fragment of the chelating ligand, since the heteroatom (possibly with the sole exception of oxygen) is usually more strongly bound to the metal (Table 4). However, this is true only when the complex does not contain other ligands bound still less strongly. The thermal stabilities of the compounds considered in terms of the thermodynamic and kinetic aspects should depend also on the mechanism of the decomposition reaction. In discussing the relative stabilities of the complexes on the basis of their decomposition temperatures (provided that these have been determined correctly), only data for isotypical complexes provide much information.

Physical methods as a rule give only indirect data about the metal–ligand bond strength. Infrared spectroscopy has been used most frequently for this purpose. For example, the shift of ν(C=C) on complex formation has been proposed[20–22] as a measure of metal–olefin bond strength. Since in the vast majority of cases the π–*n* and π–π chelates contain a double bond, one should note that this criterion can be used only to a first approximation. It has been found[23,24] that the vibration with the ν(C=C) frequency is not characteristic, since it is appreciably mixed with the δ(=C–H) deformation vibrations. It has therefore been suggested[25] that the overall percentage decrease of the ν(C=C) and δ(=C–H) frequencies in the coordination of an olefin be used. The frequency (or force constant) of the metal–olefin bond vibration can serve as another criterion[26]. However, few such data are available. Furthermore, the fact that the assignment of ν(C=C) on coordination (in many cases only tentative) has been carried out, with rare exceptions, only on the basis of infrared spectra without Raman spectroscopic data reduces the value of the results for the discussion of the stabilities of chelate complexes containing a double bond in the chelating ligand. Indeed it is difficult to discover a correlation between the character of the changes in the equilibrium constants[16] and the decrease of the vibrational frequency of the double bond on coordination in the complexes $[Rh(diene)Cl]_2$ (Table 5). On the basis of the values of ν(C=C), one can only assume that the strength of the M–$\overset{C}{\underset{C}{\|}}$ bond in the chelate complexes of this type is greater than that in the analogous complexes $[Rh(olefin)_2Cl]_2$ with monodentate olefins.

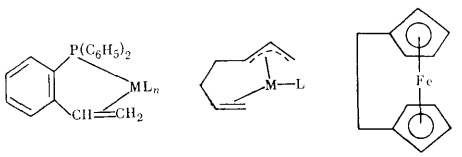
Table 5. The decomposition temperatures and changes in the stretching vibration frequencies of the double bond on coordination for complexes of the type $[Rh(diene)Cl]_2$ and $[Rh(mono\text{-}olefin)_2Cl]_2$.

Ligand	Decomp.temp.,°C	ν^{fl}(C=C)	ν^{c}(C=C)	$\Delta\nu$(C=C)
Norbornadiene	240 [27]	1550 [16]	1449 [16]	101 [16]
Norbornadiene	>170 [28]	—	—	150 [28]
Hexachloronorbornadiene	296—298* [29]	1604 [29]	1380 [29]	224
Bicyclo[2.2.2]octa-2,5-diene	—	1630 [16]	1430 [16]	200
Cyclo-octa-1,5-diene	>235 [30]	—	—	180 [28]
Tetrafluorobenzobarrelene	>270 [31]	—	—	—
Bicyclopentadiene	205 [32]	—	—	—
Hexamethylbicyclo[2.2.0]hexa-2,5-diene	—	1685 [16]	1505 [16]	180
Cyclo-octatetraene	145 [27]	1640 [16]	1412 [16]	228
Cyclo-octatetraene	—	1630 [8]	1410 [8]	220
Cyclodeca-1,6-diene	215—220 [32]	1650 [32]	1446 [32]	204
4-Vinylcyclohex-1-ene	>145 [33]	—	—	—
Hexa-1,5-diene	160 [34]	1642 [34]	1488, 1505 [34]	154, 137
2,5-Dimethylhexa-1,5-diene	>160 [28]	1646 [28]	1510 [28]	136
Cyclo-octene	>150 [28]	1650 [28]	1555 [28]	95
Cycloheptene	>115 [28]	1650 [28]	1560 [28]	90

Note. ν^{fl}(C=C) is the stretching vibration frequency of the double bond in the free ligand, ν^{c}(C=C) the stretching vibration frequency of the double bond in the coordinated ligand, and $\Delta\nu$(C=C) the shift of the stretching vibration frequency of the double bond on coordination.

* Melting point for fusion accompanied by decomposition.
Note. The numbers in square brackets denote references (Ed. of Translation).

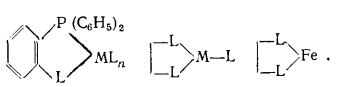
Table 5 shows that the decomposition temperatures are in many instances better correlated with the strength of the bond between the metal and the ligand. Examination of the thermodynamic stabilities[16] (see above) and thermal stabilities (Table 5) of isotypical complexes leads to the same conclusion: complexes of norbornadiene and its analogues as well as those



of cyclo-octa-1,5-diene are the most stable, while the complexes of *endo*-bicyclopentadiene and particularly cyclo-octatetraene are less stable.

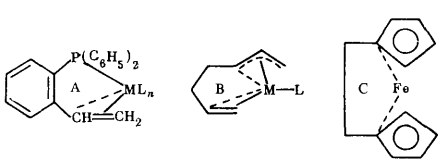
In addition, the very fact of the formation of a chelate complex together with qualitative chemical reactivity data can be used to discuss various factors influencing the relative stabilities of the chelates.

III. THE INFLUENCE OF THE PROPERTIES OF THE CHELATING LIGAND ON THE STABILITY OF THE CHELATES



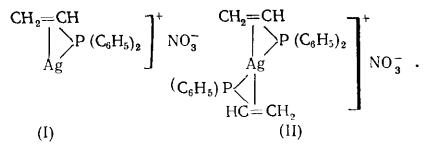
1. The Size of the Chelate Ring

The properties of chelate complexes are influenced most significantly by the nature of the chelating ligand, namely the nature of its coordinating groups, its geometry in the free state, the size and geometry of the bridging fragment separating the coordinating groups, and many other factors. However, before beginning the discussion of its influence, one must decide how to define the size of the chelate ring in π–*n* and π–π chelates. The point is that, in contrast to chelating ligands containing coordinating *n*- and σ-groups, ligands with π-fragments form chelate rings whose size is more difficult to define. We shall consider π–*n* and π–π chelates containing coordinating groups of different types:

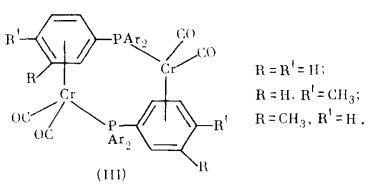


Even in the simplest case—in the chelate complex of diphenyl-*o*-styrylphosphine— the ring size can be defined in different ways. In the system of formulation for π-complexes usually employed a line connects the centre of the double bond with the metal atom. In this case one can assume that the size of the chelate ring amounts to 5.5 units[3,6]. When a metal–olefin bond is treated as a three-membered ring, we arrive at the conclusion that two rings are formed on chelation: a three-membered ring and a five-membered ring.

This treatment does not solve the problem in the case of more complex π-groups—allyl, butadiene, cyclopentadienyl, and arene, i.e. groups containing a system of conjugated bonds. However, one can propose a simple solution to this problem if one disregards the nature of the coordinating group and the latter is denoted by L, i.e. it is assumed that any coordinating group constitutes one unit in the ring. In this case the formulae of chelate complexes assumes the following form:

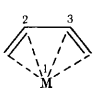


As a result, the chelate ring in the complexes considered must be regarded as five-membered. The activation of the chelate rings A, B, and C proper in these complexes leads to the same conclusion:



Despite the apparent arbitrary nature of this approximation, the latter "works" in most cases and, as will be seen from the foregoing, such calculations show that the greatest stability of the complexes and the maximum tendency towards their formation obtain in five- and six-membered rings, as for inorganic chelates.

For example, the simplest ligands which can form π–*n* chelates are heteroatomic substituted ethylenes. It is believed that diphenylvinylphosphine forms complexes (I) and (II) with silver cations[35]:

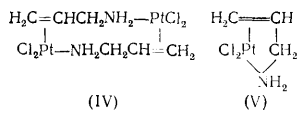


(I) (II)

Although the structure of the complexes has been assigned on the basis of a fairly broad set of data—analytical, spectroscopic (infrared, ^{1}H, and ^{31}P NMR), and cryoscopic—it cannot be regarded as finally established without resorting to X-ray diffraction analysis (XDA), particularly since chelation involving three-membered rings has not been observed in any one instance in the formation of metal complexes of heteroatomic substituted ethylenes. The fact that the formation of three-membered rings is unfavourable can sometimes lead to a dimeric product containing six-membered rings, as happens, for example, in the thermal interaction of $Cr(CO)_6$ with triarylphosphines. Here complexes (III) were isolated and acyclic compounds of the type arene. $Cr(CO)_2PAr_3$ were not detected[36].

(III)

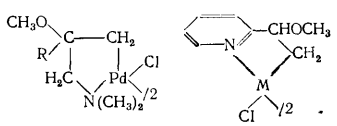
Using the proposed method for the calculation of the number of units in the chelate ring, the numerous group of transition metal complexes with conjugated dienes should be classified as three-membered π–π chelates in terms of their formal features (see, for example, the relevant reviews[37–39]).



Indeed the term "chelates" is frequently used in the literature in relation to such compounds. However, we excluded them from consideration because the reduced energy of the antibonding π^* orbital of these ligands makes a significant contribution to the stability of complexes of this type (see, for example, Streitwieser[40] and Rybinskaya[41]), which masks the CE proper in these complexes.

Four-membered chelate rings are also relatively uncommon. Thus the high thermodynamic and kinetic stability of complexes of allyl alcohol, namely $[C_3H_5OH.PtCl_3]^-$,[42] can be explained by the additional coordination of the OH group to the platinum atom. This can also be indicated by the infrared spectra of compounds of the type of *trans*-$[C_3H_5OH.PtCl_2.amine]$ [a decrease of ν(OH) by 140–160 cm^{-1}].[43,44] An analogous situation has been noted for platinum complexes of β-hydroxyalkylacetylenes[43,44].

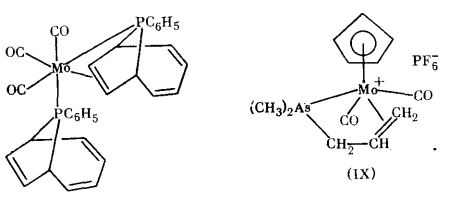
According to infrared spectroscopic data, in the 1:1 complex of C_3H_5OH with copper(I) chloride both the double bond [$\Delta\nu$(C=C) ≅ 95 cm^{-1}] and the OH group [$\Delta\nu$(C–O) ≅ 20 cm^{-1}] are coordinated. On this basis, a dimeric structure has been postulated for the chelating ligand CH_2=CH–CH_2OH.[45] The formation constant of the complex C_3H_5OH.CuCl is higher than that of the complex of C_3H_5Cl with CuCl.[46] A significant difference between the formation constants of the complexes with the $AgNO_3$ in water has been observed for C_3H_5OH and alkylethylenes (Table 1).[8,9]



The higher heat of formation of complexes of the copper(I) halides CuCl and CuBr with allylamine compared with propylamine can also be explained by chelation[47] ($\Delta H_{C_3H_5NH_2} - \Delta H_{C_3H_7NH_2}$ = 10–12 kcal mol^{-1}). Infrared spectroscopic data [the decrease of the frequencies ν(C=C), $\nu(NH_2)$, and $\delta(NH_2)$] also agree with the chelate structure of the complexes.

The question of the formation of platinum(II) chelate complexes of $C_3H_5NH_2$ cannot be regarded as finally solved. On the basis of infrared spectra, it has been suggested[48] that, together with the dimeric form (IV)[49,50], the monomeric form (V) is present, albeit in a smaller amount:

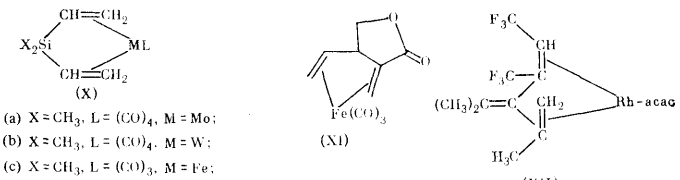
(IV) (V)



In addition, the intermediate formation of four-membered chelate rings of the π–n type[51,52] has been suggested in the interaction of $C_3H_5NH_2$ with palladium(II) salts[53] and also of 2-vinylpyridine with palladium(II) and platinum(II)[54] in methanol with subsequent conversion into stable five-membered n–σ chelate complexes (VI) and (VII)—the products of nucleophilic addition to the coordinated double bond:

(VI) (VII)

An analogous reaction of allyl- and propargyl-phosphines with platinum is also known[55].



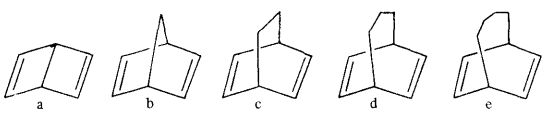
The structure of complexes (VIII) and (IX) with ligands containing a heteroatom in the allyl-position, namely 9-phenyl-9-phosphabicyclo[4.2.1]nonatriene[56] and allyldimethylarsine[57], has been demonstrated more reliably:

(VIII) (IX)

The molecular weights were determined in these instances by osmometry or mass spectrometry. The relative stability of the four-membered chelate ring in compound (VIII) can be explained by the fact that the phosphorus atom is incorporated in a rigid bicyclic system. The formation of four-membered chelate rings is characteristic of bicyclic dienes (see below). The large radius of the arsenic atom in complexes (IX) can lead to the same result.

The formation of four-membered chelate rings with linear dienes is a fairly rare phenomenon. Such complexes of type (X) have been obtained from di- or tetra-vinylsilanes with molybdenum, tungsten[58,59], and iron[60,61] carbonyls [compounds (X, a–d)] and rhodium acetylacetonates[62] [compound (Xe)]:

(X)



(a) X = CH_3, L = $(CO)_4$, M = Mo;
(b) X = CH_3, L = $(CO)_4$, M = W;
(c) X = CH_3, L = $(CO)_3$, M = Fe;

(e) X = CH_3, L = acac, M = Rh.

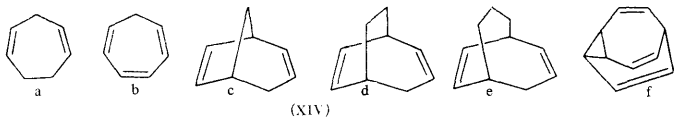
(XI)

(XII)

Complexes (XI)[63] and (XII)[64] with linear 1,4-dienes, in which a carbon atom is a bridge separating olefinic groups, have been obtained recently. The structure of complexes (Xd), (XI), and (XII) has been demonstrated by X-ray diffraction.

Metal complexes with cyclic dienes in which the double bonds are also separated by carbon atoms are much more common. Cyclohexa-1,4-diene itself rarely behaves as a bidentate ligand (see, for example, Birch et al.[65])†, while its derivatives (XIII, a – e) with a bridge connecting the 1,4-positions have a geometry favouring chelation (see below).

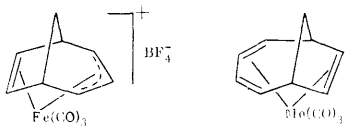
a b c d e



(XIII)

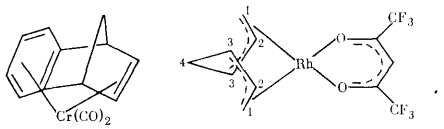
A single complex of palladium chloride with unsubstituted bicyclo[2.2.0]hexa-2,5-diene (Dewar benzene) (XIIIa) has been described[66], while complexes with the hexamethyl derivative of Dewar benzene are somewhat more common (see, for example, Huttner and Mills[67] and the references quoted therein).

Chelate complexes with bicyclo[2.2.1]hepta-2,5-diene (norbornadiene) (XIIIb) are widely known. It is not possible to include these data in the present review and we shall therefore only refer to other surveys[37–39] and certain communications on X-ray diffraction studies[70–79]. Complexes based on bicyclo[2.2.2]octadiene (XIIIc)[16] or its derivatives[31,80,81] and bicyclo[2.2.3]nona-2,5-diene (XIIId) and its derivatives[82,83] have also been described. A complex of iron tricarbonyl with a ligand of type (XIIIe), in which the bridge consists of a conjugated diene coordinated to $Fe(CO)_3$, is known[84].



† The formation of stable complexes with quinones[68] and their isostructural analogues (1,4-difluoro-1,4-diboracyclohexa-2,5-dienes)[69] can be explained by a significant contribution of electronic factors (decrease of the energy of the π^* orbital of the ligand—see, for example, Rybin[68]). The geometrical factors are in this case apparently no less unfavourable than for cyclohexa-1,4-diene.

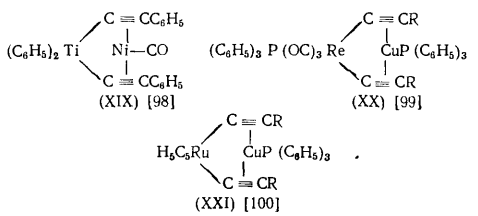
A four-membered ring is formed in chelates of cyclic 1,4-dienes and in the case of cyclohexa-1,4-dienes two four-membered rings are produced, while in other cases there is a possibility of the formation, together with a four-membered ring, of rings of another size, which happens in the case of cyclohepta-1,4-diene (XIVa)[85,86] and related compounds: cycloheptatriene (XIVb)[87], bicyclo[3.2.1]octadiene (XIVc)[88,89], and derivatives of bicyclo[3.2.2]nona-2,5-diene (XIVd)[83], bicyclo[2.3.3]deca-2,5-diene (XIVe)[90], and bullvalene (XIVf)[91].



(XIV)

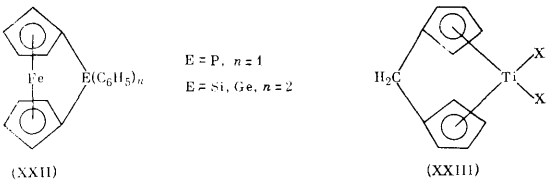
Several examples of chelate complexes of the π–π type with four-membered rings in which ligands other than olefins are present as one or both coordinating groups are also known. These are allylolefin[83,88,89,92–94] and diene-mono-olefin chelates[59,95]—for example in complexes (XV) (its structure has been demonstrated by X-ray diffraction[88]) and (XVI)[95]:

(XV) (XVI)



An arene ligand may function as one of the chelating groups, as happens in the chromium dicarbonyl complex of benzonorbornadiene (XVII)[96]. In compound (XVIII) both coordinating groups are π-allyl ligands[97]:

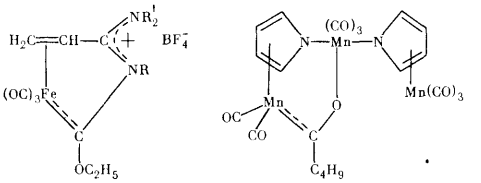
(XVII) (XVIII)



Here the chelating bis-π-allyl ligand is not incorporated in a bicyclic system, as in the cases described previously, and the chelate ring is therefore appreciably strained. The decrease of the Rh–C(1) and Rh–C(2) interatomic distances and partial rehybridisation of C(3) can be followed on the basis of X-ray diffraction data.

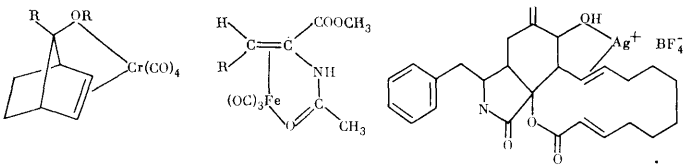
The increased stability of complexes (XIX)–(XXI)[98–100] with chelating diyne ligands# can be explained by the increased size of the atom separating the acetylenic groups, which should lead to a decrease of strain in chelate rings of this type. In addition, such strain depends also on the hybridisation of the atom indicated (see below):

Doubts have been expressed[102] about the results reported in a communication concerning dinitrile chelate complexes with the ligands $N{\equiv}C(CH_2)_nC{\equiv}N$ (n = 1–3)[101] involved in π-type coordination. See also Farona and Kraus[103].



An analogous situation has been observed also in the case of ferrocenophanes, which can likewise be regarded as chelates. The replacement of a carbon atom by atoms with larger radii, namely silicon, germanium, and phosphorus, made it possible to obtain one-membered ferrocenophanes (XXII)[104], whose carbon analogues are unknown:

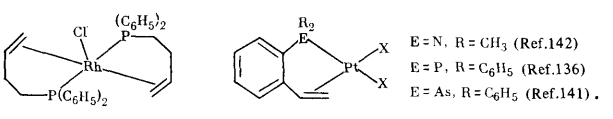
(XXII) (XXIII)



According to X-ray diffraction data, complexes (XXII) are appreciably strained[105]. On the other hand, the presence of a single carbon atom in the bridge is sufficient for wedge-shaped sandwich compounds—for example, compound (XXIII)[106].

Complexes containing five-membered rings are commonest among π–n and π–π chelates. In the case of π–n chelates a double bond and allyl, cyclopentadienyl, and arene groups function as the unsaturated fragment, while the atoms providing the electron pair for coordination are those of C, O, S, Se, N, P, and As. Examples of chelates in which a carbon atom is involved in n-type coordination are provided by the carbene complexes (XXIV)[107] and (XXV)[108] obtained recently:

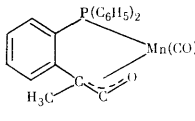
(XXIV) (XXV)



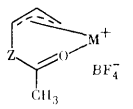
syn-Alkoxynorbornenes[109], acetamidoacrylates and acetamidocinnamates[110], and also the antibiotic Phomin[111], which form complexes (XXVI)–(XXVIII), have been used as oxygen-containing ligands:

(XXVI) (XXVII) (XXVIII)

The structure of compounds (XXIV), (XXV), (XXVII), and (XXVIII) has been established by X-ray diffraction.



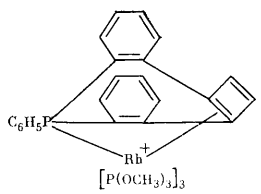
Ligands in which the 1-butenyl group is linked to oxygen[112], sulphur[113], selenium[114], and phosphorus[115–122] are fairly common. 2-Allylpyridine also has a geometry convenient for chelation[123,124], but ligands of the types considered which are most often employed are *o*-styryl derivatives of phosphorus[125–139], arsenic[137–141], or nitrogen[142]. Compounds (XXIX)[122] and (XXX), whose structure has been demonstrated by X-ray diffraction, have been quoted as examples:



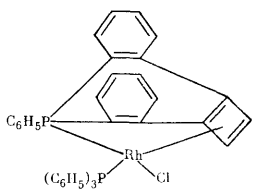
(XXIX) (XXX)

o-Styrylphosphine usually enters as such into the coordination sphere, but, on interaction with $CH_3Mn(CO)_5$, it is transformed into the oxoallylphosphine ligand [complex

(XXXI)][143]. Complexes with allyl [compound (XXXII)][144–146] or cyclobutadiene [compound (XXXIII)][147] and compound (XXXIV)[148]] fragments in the chelating ligand have also been obtained as a result of reactions in the coordination sphere of the metal and cyclobutadienes can be involved in the coordination of both η^2-type [compound (XXXIII)] and η^4-type [compound (XXXIV)].

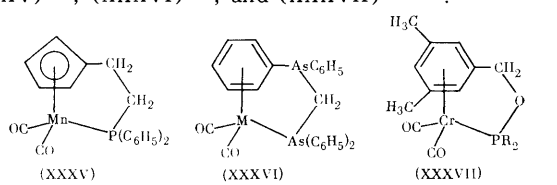


(XXXI)



(XXXII)

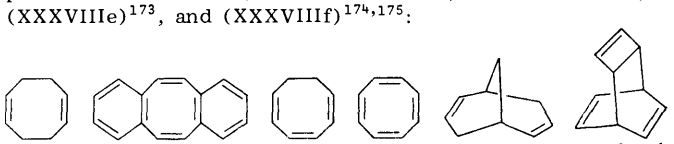
Z = CH_2, M = $Fe(CO)_3$ (Ref.144)
Z = O, M = $Fe(CO)_3$ (Ref.145)
Z = CH_2, M = RhC_5H_5, IrC_5H_5 (Ref.146).



(XXXIII)

(XXXIV)

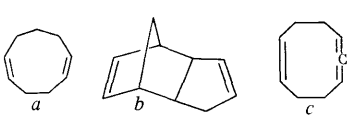
The following examples of cyclopentadienyl and arene chelate complexes of the π–n type are known: complexes (XXXV)[149], (XXXVI)[150], and (XXXVII)[151,152]:



(XXXV) (XXXVI) (XXXVII)

(a) M = Cr; (b) M = Mo (a) R = C_6H_5; (b) R = OC_6H_5.

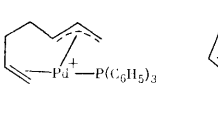
The structures of complexes (XXXI)[153], (XXXIII)[147], (XXXVIa)[154], and (XXXVIIb)[155] have been confirmed by X-ray diffraction.



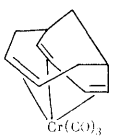
However, five-membered chelate complexes of the π–π type are undoubtedly the commonest. This applies primarily to complexes of cyclo-octa-1,5-diene (XXXVIIIa) (see, for example, Refs.37–39 and 156–169) and the related compounds (XXXVIIIb)[170], (XXXVIIIc)[171,172], (XXXVIIId)[37–39], (XXXVIIIe)[173], and (XXXVIIIf)[174,175]:

a b c d e f

(XXXVIII)

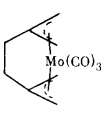


Complexes of cyclonona-1,5-diene (XXXIXa)[176] and compounds (XXXIX, b and c)[37–39,177–179] are close to this type of compound:

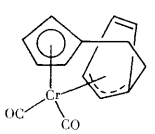


a b c

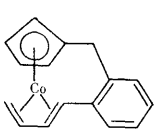
(XXXIX)



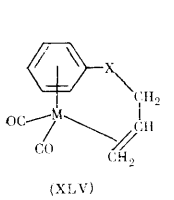
Complexes with linear dienes are fairly common among five-membered chelate complexes of the π–π type (see, for example, Refs.28, 34, and 180). The chain connecting the two double bonds can be incorporated in a six-membered ring[181,182]. One double bond can be endocyclic as, for example, in 4-vinylcyclohexene[183–185] or 5-methylenecyclopentene complexes[186]. Furthermore, various allylolefin [compound (XL)][187] (see also Lewis and Parkins[94]) or diene-olefin [compound (XLI)][188] (see also Ward and Pettit[189]), bisallyl [compound (XLII)][190], cyclopentadienylallyl [compound (XLIII)][191], cyclopentadienyldiene [compound (XLIV)][192], arene-olefin [compound (XLV)][193–195], arene-allene [compound (XLVI)][196], and arene-allyl [compound (XLVII)][197] chelates are known in addition:



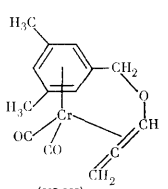
(XL)



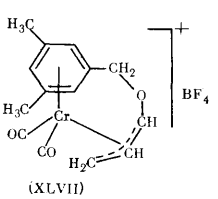
(XLI)



(XLII)



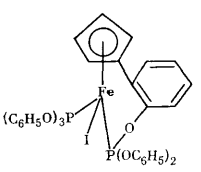
(XLIII)



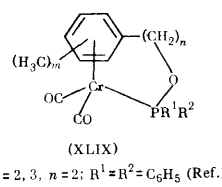
(XLIV)

(XLV)

(XLVI)



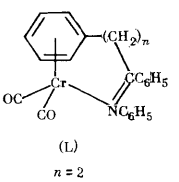
(XLVII)



X = O, M = Cr; X = CH_2, M = Cr, Mo, W.

The structures of compounds (XLI) and (XLIV) have been established by X-ray diffraction. [2]Ferrocenophanes belong to chelates of the same type[5,198].

Although complexes with six-membered rings are encountered more rarely than those of five-membered rings, they are also fairly stable. As a rule, these are derivatives of platinum(II) and rhodium(I), which form the strongest bonds with olefins. The ligands of π–n type are mainly pentenyl derivatives of sulphur[113], selenium[114], phosphorus[116,120], and arsenic[199,200] as well as *o*-allylphenyl derivatives of phosphorus[128,129,201,202] or arsenic[201,202]. Complexes with *O*-alkyl-*N*-allyldithiocarbamates coordinated as bidentate ligands have been described[203–205]. Apart from olefin-containing six-membered π–n chelates, only the cyclopentadienyl chelate complexes (XLVIII)[206] and the arene chelate complexes (XLIX)[151,152,207–209] and (L)[210] are known. The structures of complexes (XLVIII)[211] and (L)[210] have been confirmed by X-ray diffraction:



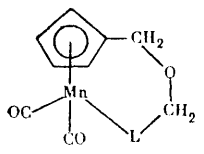
(XLVIII)

(XLIX)

m = 2, 3, n = 2; $R^1 = R^2 = C_6H_5$ (Ref.152)

(L)

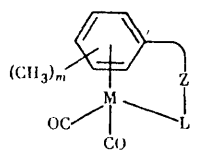
n = 2



OC_6H_5 (Ref.151), F (Ref.205), ½  (Ref.206)

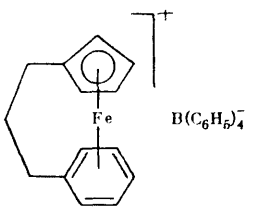
$R^1 = F$, $R^2 = OC_2H_5$ (Ref.207)

In some cases cyclodeca-1,6-diene does not exhibit chelating properties. Thus it forms a six-membered chelate with rhodium(I), gives rise to coordination polymers on reaction



with palladium(II) salts, and does not react at all with platinum(II)[32,182,212]. The same can also be said of linear dienes, for example, diallyl ether[213-215]. The structure of some of its complexes has been established by X-ray diffraction[216,217].

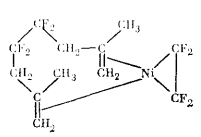
Together with diene complexes, chelates containing one or two cyclic π-ligands of types (LI)[218], (LII)[193-196,219], and (LIII)[220] have been described:



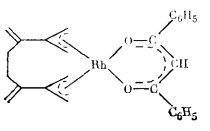
(LI)

L = CH=CH$_2$, C≡CH

(LIIa-e)

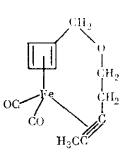


(a) M = Mo, W; Z—L = $(CH_2)_3CH{=}CH_2$;
(b) M = Cr; Z—L = $(CH_2)_3CH{=}CH_2$;
(c) M = Cr; Z—L = $CH_2OCH_2CH{=}CH_2$;
(d) M = Cr; Z—L = $CH_2OCH{=}C{=}CH_2$;
(e) M = Cr; Z—L = $CH_2OCH_2C{\equiv}CR$ (R = H, CH_3).



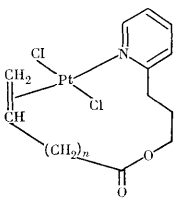
(LIII)

[3]Ferrocenophanes constitute the commonest type of six-membered π—π chelates[5,198].



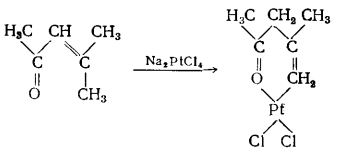
There are few data on compounds with seven-membered chelate rings. As examples, one may quote complexes (LIV)–(LVI)[221-223] (see also Refs.224 and 225). The structure of compound (LV) has been confirmed by X-ray diffraction. Apart from these, compounds (XLIX, n = 3, R = C_6H_5, or OC_6H_5)[151,152], (L, n = 3)[210], and (LII, Z–L = $CH_2CH_2OCH_2$–C≡CR)[219], as well as [4]ferrocenophanes[5,198] and [4]dibenzenechromophanes[226] contain a seven-membered chelate ring:

(LIV) (Ref.221)



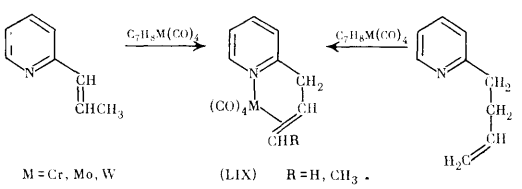
(LV) (Ref.222)

(LVI) (Ref.223)



Chelates with medium and large rings are of special interest[152,198,227,228]. For example, complexes (XLIX, n = 4, R = C_6H_5 or OC_6H_5) contain eight-membered rings, while complexes (XLIX, n = 5, R = C_6H_5 or OC_6H_5) contain nine-membered chelate rings. The ease of formation of medium sized rings can be explained in this case[152] by the decrease of the extent of transannullar interactions compared with hydrocarbon rings of the same size. Fairly large numbers of ferrocenophanes containing rings of medium size and macrorings have been synthesised[198] and [5]bisarenechromophanes have also been obtained[226,229]. However, the increase of the stability of such complexes as a result of the CE is apparently either small or zero. This is confirmed by the finding that the olefinic end of the ligand in complex (LVII) can be displaced by ethylene[228]:

(LVII)

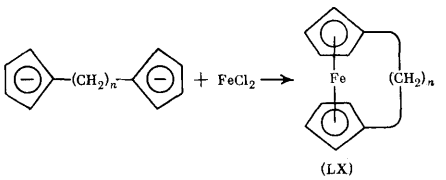


n = 1, 2, 4, 8.

Thus, despite the significant differences between the natures of the coordinating ligands, incorporating groups such as olefinic, allyl, cyclopentadienyl, etc., even a formal calculation of the number of units in the chelate ring reveals quite clearly a tendency towards the formation of the more stable five- and six-membered rings. Complexes (I) and (II) with three-membered rings are unique. Four-membered rings are also fairly rare with the exception of compounds with bicyclic dienes, which is due to the geometrical characteristic features of the latter. The lower stability of four-membered chelates compared with five-membered chelates is indicated by the fact that allyldiphenylphosphine forms chelate complexes neither with palladium(II) nor platinum(II), while butenyldiphenylphosphine forms them readily[117]. The use of divinyl ether was also unsuccessful, while hexa-1,5-diene gave a positive result[213]. The isomerisation of mesityl oxide under the influence of platinum(II) with formation of the mesityl iso-oxide complex (LVIII) containing a five-membered chelate ring is instructive. Even the loss of conjugation energy is compensated by the gain of chelate formation energy:

(LVIII).

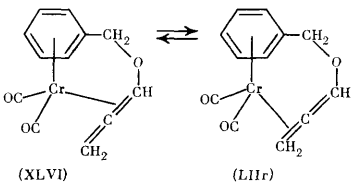
The greater stability of five-membered chelate rings compared not only with four-membered but also with six-membered rings can be demonstrated by the reaction of 2-alkenylpyridines with norbornadiene complexes of Group VI metals[230]:



M = Cr, Mo, W (LIX) R = H, CH_3.

Isomerisation results only in the formation of complexes (LIX) containing five-membered chelate rings. The isomerisation of cyclo-octa-1,3-diene and cyclo-octa-1,4-diene under the influence of transition metals with formation of cyclo-octa-1,5-diene complexes is also consistent with these ideas[231-233]. The greater stability of five-membered rings compared with six-membered rings is also indicated by the interactions of 4-pentenyl and 3-butenyl derivatives of sulphur, selenium, and phosphorus with palladium(II). Only the 3-butenyl derivatives react with formation of five-membered chelates. It is of interest to note that platinum(II) forms chelates with both series of the above compounds[113,114,117]. The same can be said also of dienes, in which the double bonds are separated by two or three atoms[213]. The isomerisation of *o*-allylphenyldiphenylphosphine to the propenyl derivative[125,126] can also serve as evidence in support of the greater stability

of five-membered rings. This is also evident from a comparison of the relative reactivities of five- and six-membered chelates (see, for example, Garrow and Hartwell[117]).



Yet another example illustrating the dependence of the CE on the size of the ring formed is provided by formation of ferrocenophanes in accordance with the following scheme:

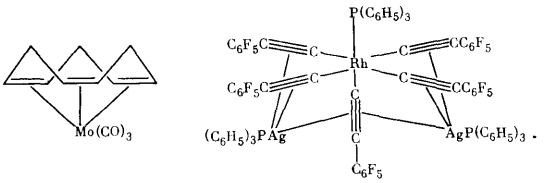
(LX)

Thus the yield of a compound of type (LX) is 50% for $n = 2$, 2.5% for $n = 3$, 0.053% for $n = 4$, and 0.025% for $n = 5$.[198] The amount of polymeric products increases in the same sequence.

At the same time, chelates have been discovered in which the differences between the stabilities of the five- and six-membered rings are small. The chromium dicarbonyl complex with an arene-allene ligand gives rise in solution to an equilibrium mixture of the two forms corresponding to five-membered [compound XLVI)] and six-membered [compound (LIId)] chelates[196]. Unfortunately, this new instance of metallotropy has not been investigated adequately:

(XLVI) (LIIr)

The geometry of the ligand sometimes imposes a particular size on the chelate ring. Thus, in the case of arene-acetylene chelates of type (LIIe), six- and seven-membered rings are formed readily, while complexes with five-membered rings could not be obtained[219].

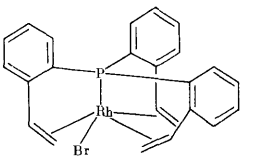


Quantitative data reflecting the dependence of thermodynamic stability on the size of the ring formed on chelation are available only for silver complexes[9,13-15,234], but they are satisfactorily correlated with qualitative data for other metals.

In conclusion of this Section one should note that approximately one-third of the known types of organometallic chelates have not been obtained as a result of specific synthesis but have been discovered accidentally as a result of the isomerisation of the ligand or its synthesis in the coordination sphere of the metal. In most cases this applies to five-membered chelates [compounds (XXIV), (XXV), (XXXI)–(XXXIV), (XL)–(XLIV), (XLVI), (XLVII), (LVIII), and (LIX)], but isolated examples of the synthesis of four-membered [compounds (XI), (XII), and (XVIII)], six-membered [compounds (XLVIII), and (LIId)], and seven-membered [compounds (LIV), and (LV)] complexes by this procedure are also known.

2. The Number of Rings

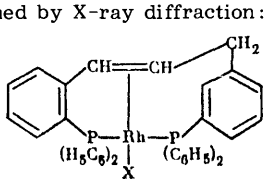
Studies on complexes with polydentate kn–$l\pi$- and $k\pi$-ligands were begun quite recently.



Complexes with polydentate $k\pi$-ligands ($k > 2$) have been little studied. Examples are provided by compounds (LXI)[235] and (LXII)[236] with ligands where three isolated double or triple bonds are coordinated to one metal atom. The structure of complex (LXII) has been established by X-ray diffraction:

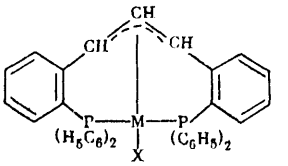
(LXI) (LXII)

Ferrocenophanes with two, three, and four bridges[5,198] as well as bisarenechromophanes with two bridges[237,238] can be assigned to compounds of this type.



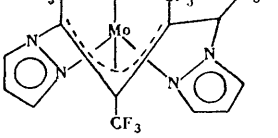
Complexes with kn–$l\pi$-ligands have been studied to a greater extent. Ligands potentially capable of forming five-membered rings have been synthesised for this purpose: tri(3-butenyl)phosphine[239], tri(4-pentenyl)phosphine[240], tri(*o*-vinylphenyl)phosphine[241,249], and tri(*o*-vinylphenyl)-arsine[242]. A rhodium(I) salt forms with these ligands penta-coordinate complexes of type (LXIII) whose structure, determined by X-ray diffraction[243,244], is trigonal-bipyramidal:

(LXIII)



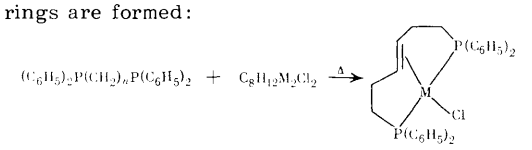
The double bonds are located approximately in the equatorial plane. Complexes with a similar structure have been obtained from phenyldi(*o*-vinylphenyl)phosphine[242] and dibutenyl-phenylphosphine[245]. On formation of complexes with Group VI metal[138,139], palladium(II)[246], and platinum(II)[246,247] carbonyls, these ligands react as bidentate species and in the case of palladium(II) and platinum(II) there is a rapid exchange of the coordinated and non-coordinated olefine groups according to ^{1}H NMR data. On the other hand, compounds containing two phosphorus atoms and one double bond [1,6-bis(diphenyl-phosphino)-*trans*-hexene and 1,6-bis(diphenylarsino)-*trans*-hexene] behave as tridentate ligands on formation of complexes with Group VI metal carbonyls[248].

Similar complexes with diphosphino-olefin ligands have been obtained also for other metals (see Bennett et al.[249] and the references therein and Clark[250]). The rhodium(I) complex (LXIV) has been quoted as an example[249]. Dehydrogenation of compounds (LXIV) leads to allyldiphosphinerhodium(I) complex of type (LXV). Other analogous derivatives (LXV) as well as complex (LXVI) with an allyl-dinitrogen ligand have also been obtained for other metals. The structures of compounds (LXV, M = Pd)[251] and (LXVI)[252] have been confirmed by X-ray diffraction:



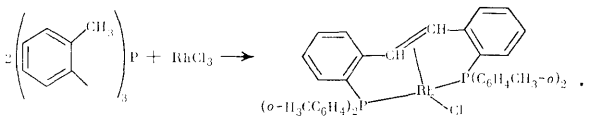
(LXIV)

X = Cl, Br



(LXV)

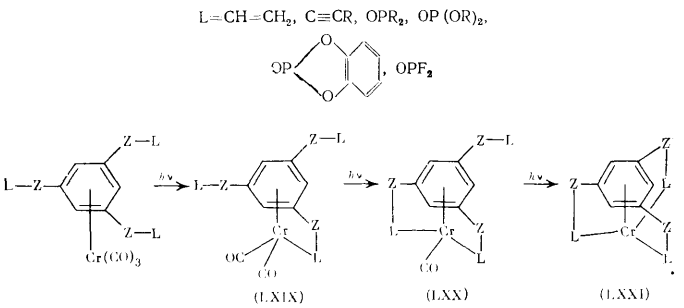
M = Pd; X = Cl; M = Rh, Ir, Ni; X = —



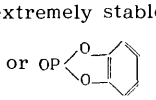
(LXVI)

It is noteworthy that, in the presence of a dehydrogenation catalyst, α,ω-bis(diphenylphosphino)alkanes form complexes (LXVII) with a tridentate diphosphino-olefin ligand only for $n = 6$,[250] i.e. only in the case where two five-membered chelate rings are formed:

M = Rh, Ir. (LXVII)



When $n = 5$, 7, or 8, complexes of type (LXVII) were not isolated. The tendency towards the formation of the analogous complex (LXVIII) with a conformationally more rigid chelating ligand [2,2′-bis(ditolylphosphino)stilbene] is so great that the ligand is generated in the coordination sphere of the metal from tri(*o*-tolyl)phosphine as a result of the dehydrogenation of the latter[253]:



(LXVIII)

Similar reactions involving the formation of complexes with polydentate ligands as a result of dehydrogenation, isomerisation, and dimerisation have been investigated by Bennett and co-workers[135,253-258].

The characteristics of chelation with polydentate ligands have been studied systematically by Nesmeyanov and co-workers[259] in relation to arenechromium tricarbonyl complexes containing in the ω-position and in the side chain groups capable of coordination to metals:

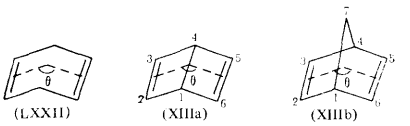
(LXIX) (LXX) (LXXI)

Z are bridges consisting of $(CH_2)_n$ or various combinations of CH_2 and O. As a result, it has been found that the reaction is arrested at the single-bridge chelates (LXIX) when L = CH = CH_2 or $OPPh_2$ and at the two-bridge chelates (LXX) when L = $OP(OPh_2)$; all the CO ligands are substituted in succession with formation of extremely stable three-bridge ligands (LXXI) when L = OPF_2 or  .

Whereas the electronic factors in chelation are determined by the nature of the group L, the steric factors are determined mainly by the size of the bridge Z. Thus single-bridge chelates of type (LXIX) are formed starting with a two-membered bridge, while the two- and three-bridge chelates (LXX) and (LXXI) are formed only starting with a three-membered bridge. The three-membered bridge (six-membered chelate ring) proved to be optimal in the synthesis of polycyclic chelates of this type. The structure of the three-bridge complex (LXXI, Z–L = $CH_2CH_2OPF_2$) has been established by X-ray diffraction[260].

Thus the nature of the ligand plays a significant role in the formation of polycyclic chelates.

3. The Conformation and Geometry of the Ligand



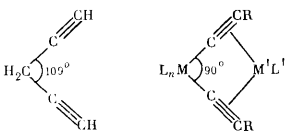
The question of the influence of the conformation of the ligand on the ease of formation of the chelates reduces to the elucidation of the number of possible conformations, their relative contributions, and, mainly, the conformation favourable for chelation. Apparently the greater the population of this favourable conformation, i.e. the conformation corresponding to the coordinated ligand, the greater the stability of the chelate complex. In the limiting case with a rigidly fixed conformation favourable for chelation, the contribution of this factor to the stability of the chelate complex should be a maximum. Indeed, a high stability has been observed in many cases for conformationally rigid ligands with a favourable disposition of the double bonds, such as, for example, norbornadiene and bicyclo[2.2.2]octa-2,5-diene[16] (Table 4).

Cyclo-octa-1,5-dienes[261] and cyclo-octatetraene[262], which have been shown to have the preferred boat conformation, form chelate complexes very readily; these have been obtained in large amounts with various metals. Cyclo-octadiene complexes are particularly stable (Tables 3 to 5).

The chair conformation of *cis*, *cis*-cyclodeca-1,6-diene is preferred to the boat conformation[263]. As a result, this ligand does not react with platinum(II) salts and its reaction with palladium(II) results in the formation of a polymeric complex[182]. On reaction with rhodium(I) derivatives at 80 °C, it gives rise to a chelate complex. This finding has been explained[32] by the fact that, at an elevated reaction temperature, the contribution of the boat conformation becomes considerable.

For linear ligands, the number of possible conformations is greater than for cyclic ligands and this number increases with increase in the length of the chain; the contribution of the favourable conformation therefore diminishes. Indeed, the stability of the complexes of linear ligands is lower (Tables 3 and 5). The decrease of the conformational mobility of the ligand results in an increase in the stability of the complexes formed. Thus *o*-allylphenyldimethylarsine and o-allylphenyldiphenylphosphine form chelate complexes with palladium(II) containing six-membered chelate rings[202], while pentenyldiphenylphosphine does not form such complexes[116]. This can be explained by the fact that, after the replacement of the C–C single bond in the chain by a multiple bond of the benzene ring, free rotation about this bond becomes impossible.

A significant change in geometry is observed in cyclic dienes, especially after the introduction of a bridge into the diene molecule. Only isolated examples of complexes have been described for cyclohexa-1,4-diene (LXXII) itself[65], but Dewar benzene[66,67] and norbornadiene[37-39,70-79] form complexes readily, which is probably due to the greater rigidity of the molecules owing to the presence of a bridge.



(LXXII) (XIIIa) (XIIIb)

The geometry of norbornadiene is particularly favourable for coordination to a metal, since in this compound the dihedral angle θ has the optimum value of approximately 115° and the

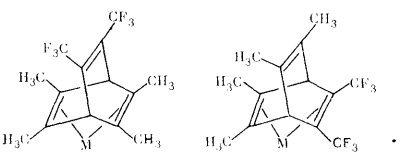
distance between C(1) and C(4) is increased to 2.24 Å, in contrast to Dewar benzene where it is approximately 1.55 Å; this reduces the extent of the non-bonding interactions of C(1) and C(4) with the metal atom on coordination[67]. It is interesting to note that an increase in the length of the bridge up to 2 and even 4 members causes little change in the geometry of the ligands[84,264] and the latter form stable complexes, like norbornadiene.

An important factor which diminishes the stability of chelate complexes with dienes is a non-parallel arrangement of the double bond. Such an arrangement is encountered in cyclic dienes with an odd number of atoms in the ring [the derivatives of cyclohepta-1,4-diene (XIV, a–f) and cyclonona-1,5-diene (XXXIX, a–c)], and also in dienes with an even number of atoms in the ring but with an asymmetric disposition of the double bonds (cyclo-octa-1,4-diene) or an asymmetric position of the bridge as in bicyclo[3.3.1]nona-2,6-diene (XXXVIIIe).

The geometry of the chelating ligand can depend on the nature of the atoms in the chain connecting two coordinating groups and also on their hybridisation. The replacement of a carbon atom in the chain of the diyne ligand (LXXIII) by the metal atom greatly reduces the angle between the acetylenic fragments which leads to a geometry of the ligand favourable for chelation. Complexes with ligands of type (LXXIV) are known[98–100], while no complexes have so far been obtained for the ligand (LXXIII). On the other hand, the formation of four-membered chelate rings by diolefin ligands requires an increase of the angle between the olefin fragments. This can be achieved by altering the hybridisation of the bridging carbon atom from sp^3 to sp^2, as shown in complex (XII)[64].

(LXXIII) (LXXIV)

4. The Nature of the Coordinating Groups

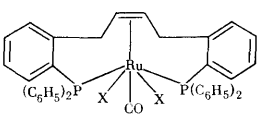


This problem has so far been little studied. In terms of the bond strength, the coordinating fragments can be arranged in the following sequence (for metals in a low oxidation state): P > As > N > unsaturated ligand > O; Se > S ≫ O (see also Table 4). Chelate complexes with a heteroatom can be arranged in the same sequence in terms of their stability. The data in Table 2 show that the stability of the selenium-containing chelate complexes of silver is higher than that of the corresponding sulphur-containing complexes. Chemical data are also consistent with this finding. Thus, in the case of alkenyl sulphide complexes of palladium(II) and platinum(II), *p*-toluidine fully substitutes the ligand, while in the alkenyl selenide derivatives only the double bond is displaced[113,114]. On the other hand, the substitution of the double bond C=C in the pentenylarsine complexes of platinum(II) by *p*-toluidine requires prolonged refluxing[200]. These complexes are as a rule more stable than the diene complexes. For example, diphenyl-*o*-styrylphosphine substitutes norbornadiene in Group VIB metal complexes with formation of complexes of type (XXX)[127].

The influence of substituents in the coordinating groups has not been studied systematically. It is evident from the available data that the introduction of even one alkyl substituent into a coordinating unsaturated group as a rule destabilises the chelate (Tables 1 and 3) and this is manifested even in the case of cationic silver complexes, the opposite behaviour being observed in the corresponding non-chelate mono-olefin complexes. Steric effects probably play a major role in organometallic chelates.

IV. THE INFLUENCE OF THE NATURE OF THE METAL ON THE STABILITY OF THE CHELATES

The stability of the chelate π–*n* and π–π complexes as a function of the nature of the metal varies as a rule in parallel with the stability of complexes of a similar structure containing non-chelating ligands. Thus the stability of the mono-olefin complexes of platinum(II) is greater than that of the analogous palladium(II) compounds. The same relative stabilities are observed also for chelate complexes with ligands containing a double bond. The CE does not as a rule alter the tendency in the variation of the stability but merely enhances it. The study of the dependence of the properties of the complexes on the metal is complicated by the fact that a sufficiently correct comparison is possible only for complexes containing the atoms of metals belonging to a single subgroup. Such a comparative study has been carried out by infrared and Raman spectroscopic methods for diene complexes of metals with the d^8 electron configuration and identical geometries of the compounds[30,34]. This led to the conclusion that the stability of the hexa-1,5-diene and cyclo-octadiene complexes of palladium(II), platinum(II), and rhodium(I) increases in the sequence indicated from palladium(II) to rhodium(I).



Depending on the nature of the metal, 2,3,5,6-tetramethyl-7,8-bis(trifluoromethyl)bicyclo[2.2.2]octa-2,5,7-triene can be coordinated in two ways: (LXXV) and (LXXVI):

(LXXV) (LXXVI)

A complex of type (LXXVI) is formed for M = $Mo(CO)_4$ or C_5H_5CO[80] and a complex of type (LXXV) for M = $[RhCl]_2$ or $Rh(Ph_3P)Cl$[16]; when M = $Fe(CO)_3$, complexes of both types are formed with the complex of type (LXXV) predominating[80].

It is noteworthy that in the case of chelates it is possible to obtain complexes with a metal–olefin bond in which the metal is in a higher oxidation state than is possible for non-chelate mono-olefin ligands. An example is provided by ruthenium(II) complexes of type (LXXVII)[156]:

(LXXVII)

X = Cl, Br.

The formation of such complexes is important primarily because the analogous compounds with monodentate and olefinic ligands occur as intermediates in catalytic processes and cannot be isolated because they are extremely unstable. Indeed, ruthenium(II) complexes of mono-olefins have not been isolated.

In contrast to inorganic chelates, the influence of metal atomic radius on chelate stability is low, since its variation for transition metals in Periods I–III in the zero oxidation state is insignificant (within the limits of 0.1 Å)[265]. The degree of oxidation exerts a major influence on the radius variation.

Specific valence angles α, which determine the geometry of the complex, are characteristic of each metal atom, depending on its nature, degree of oxidation, and ligand environment. It is interesting to examine this problem in relation to diene ligands used most frequently and forming the most stable complexes—norbornadiene and cyclo-octa-1,5-diene. Complexes of metals with square [for example, palladium(II), platinum(II), and rhodium(I)] and octahedral [for example, Group VI metals, ruthenium(II), etc.] configurations ($\alpha = 90°$) form somewhat more stable compounds with norbornadiene[37–39] (see also Table 4). The stability of tetrahedral norbornadiene complexes {for example, the complex Ni(O)-[(duroquinone)Ni(diene)]}, is lower than that of complexes containing less rigid ligands—cyclo-octadiene and bicyclopentadiene[18,19]. Group IB metals (valence angles $\alpha = 109°$, 120°, and 180°), characterised by a tendency towards linear hybridisation which increases from copper(I) to gold(I)[266], do not form cationic chelate complexes with norbornadiene§. Complexes in which norbornadiene behaves as a monodentate ligand were isolated later[267].

Not one chelate complex of the π–*n* or π–π type is known for gold(I). Only the powerful chelating ligand *o*-phenylenebisdimethylarsine forms a chelate complex with a tetrahedral configuration: $[(\text{diarsine})_2\text{Au}]^+\text{I}^-$.[266]

According to X-ray diffraction data, in complexes with a trigonal-bipyramidal configuration (valence angles 90° and 120°), ligands such as norbornadiene and cyclo-octadiene occupy one axial and one equatorial position ($\alpha = 90°$) and not two equatorial positions ($\alpha = 120°$), which also reflects the importance of the correspondence between the valence angles of the metal atoms and the geometry of the ligands.

---o0o---

Summarising this review, one may say that organometallic chelate complexes constitute a new rapidly developing field in the chemistry of organometallic compounds. A large number of various chelate complexes of this type, among which polycyclic chelates are of special interest, have now been obtained. At the same time, the properties of organometallic chelates have so far been inadequately studied and the information available on this topic is in the main qualitative. Nevertheless, one may conclude that, in terms of many of their properties, organometallic chelates resemble inorganic chelates. This similarity is manifested primarily by the fact that in complexes of both types the five- and six-membered rings are the most stable, that the stability of the complexes increases with increase of the number of chelate rings in the molecule and with increase of the rigidity of the ligand, and also that both the entropy and enthalpy factors make an important contribution to the CE. At the same time, organometallic chelates have a whole series of characteristics associated primarily with the geometry of the organic ligand and the nature of the metal–carbon bond. Whereas the M = L bond in inorganic chelates is of the donor–acceptor type (*n*-type) and an increase of electron density at the heteroatom in the group L stabilises this bond, in organometallic chelates (where L is an organic π-ligand) the type of the metal–ligand bond is different. It is a combination of donor–acceptor and dative bonds. The nature of this π-bond makes its impression also on the geometry of the molecules of organometallic chelates. The metal atom in such complexes is as a rule located in a plane perpendicular to that of the π-ligand and not on the axis of the bond between the metal and the coordinating atom, as happens in inorganic chelates. Whereas the latter involve mainly metal cations, among organometallic chelates complexes of metals in a low oxidation state occupy a major place, which not only greatly extends the region of existence of chelate complexes in general but also makes it possible to expect that they will manifest new useful properties. For example, organometallic chelates with an increased electron density at the metal atom may prove to be active reductants or electron transferring agents, preserving at the same time the structure of the complex. The increase of stability as a result of the CE makes it possible to synthesise and investigate new types of organometallic complexes, information about the structure of which can throw light on the mechanisms of many catalytic processes. Finally, these complexes can themselves prove to be active catalysts, which has been confirmed by the isolation of some of them in catalytic reactions.

§ The only exception is that of the relatively unstable copper(I) complex of 7-t-butylnorbornadiene to which a chelate structure has been attributed solely on the basis of the ^{1}H NMR spectrum[267].

Propargyl Compounds in the Synthesis of Carbocycles and Heterocycles

S.F.Karaev, Sh.V.Garaeva, and A.M.Sladkov (deceased)

Data on the conversion of propargyl compounds into carbocycles and heterocycles are surveyed. The bibliography includes 181 references.

I. Introduction 492
II. Cycloaddition 492
III. Cyclisation 497

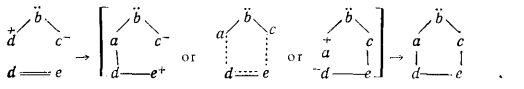
I. INTRODUCTION

The cyclisation reactions of propargyl compounds have been the object of a comprehensive study in view of their importance for theoretical and synthetic organic chemistry. The characteristic features of the cyclisation of propargyl compounds are in many respects determined by their tendency to undergo rearrangements, Michael addition reactions, and diene and carbene syntheses.

The increased interest in the cyclisation of propargyl compounds is caused, apart from the need to solve theoretical problems, by their enormous role in the synthesis of carbocycles and heterocycles otherwise difficult to obtain, which can serve as the starting materials for the preparation of natural products and medicinal drugs.

Derivatives of isoquinolines[1], pyrimidines[2], pyranoflavans[3], and pyranoacridones[4], which occur in natural condensed systems, many vitamins, and antibiotics, have been obtained from propargyl compounds. For example, we may note the synthesis of a natural antibiotic—the lactone of 4-hydroxy-2-vinyl-but-2-enoic acid—from propargyl vinyl ether[5], of hydroxypyrones with a broad spectrum of biological activity from propargylvinyl alcohols[6], of aryldihydroisoquinolines, which are intermediates in the synthesis of alkaloids, from propargylbenzylamines[1], and of oxazoles, which are intermediates in the synthesis of vitamins B_6, from *O*-propargyliminoesters[7]. The antihypertonic activity of *N*-(guanidinoalkyl)pyrrolidines, synthesised from tertiary homopropargyl alcohols[8], has been noted and synthetic lignan lactones have been obtained by the intramolecular diene synthesis from propargyl propiolates[9].

In view of the undoubted practical value of acetylenic compounds of this type, there has been a considerable growth in interest in their cyclisation reactions in recent years. A monograph[10] and a number of reviews[11-16] have been published on the chemistry of acetylenic compounds, but they do not deal with the problem under consideration in terms of the cyclisation of propargyl compounds. In the present review an attempt is made to arrange systematically the studies in the last ten years on the cyclisation of propargyl compounds. Data published before 1971 are considered in those cases where this is necessary for the purposes of exposition.

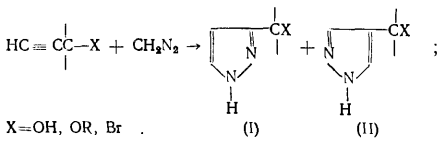


II. CYCLOADDITION

The cyclisation reactions of unsaturated systems in which rings are formed solely as a result of the rupture of π-bonds without the elimination of any fragment are known as cycloaddition reactions. These reactions constitute a universal method for the synthesis of various carbocyclic and heterocyclic systems. They include, for example, the widely familiar carbene and diene syntheses, 1,3-dipolar cycloaddition, and [2 + 2]cycloaddition.

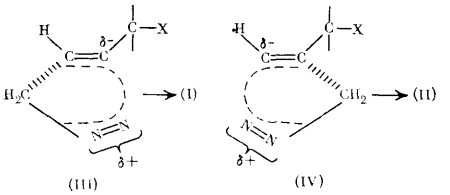
Cycloaddition reactions with participation of ethynyl compounds have been most fully examined in a monograph[10].

1. 1,3-Dipolar Cycloaddition



A clear-cut classification of 1,3-dipolar cycloadditions has been devised by Huisgen[17]. According to Huisgen's definition, any compound *a*–*b*–*c*, in which the atom *a* has an electron sextet and is a positive centre, the atom *c* has a free electron pair and carries a negative charge, and the atom *b* usually possesses an unshared electron pair, can constitute a 1,3-dipolar system. Problems of the mechanism of the 1,3-cycloaddition have been frequently discussed in the literature[18-20] and can be represented in a general form as follows:

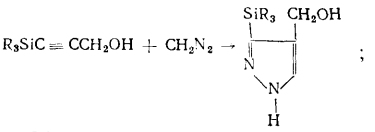
Diazoalkanes, azides, nitrile ylides, nitrile imines, and nitrile oxides are typical 1,3-dipoles.



(a) Cycloaddition of Diazoalkanes

When propargyl compounds interact with diazoalkanes, substituted pyrazoles are formed. Thus the cycloaddition of diazomethane to propargyl alcohols, propargyl ethers, or propargyl bromides leads to two pyrazole isomers[21-23]:

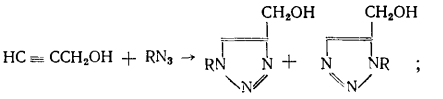
X=OH, OR, Br . (I) (II)



The ratio of the isomers depends on the nature of the substituents. Thus in the case of methylphenylethynylmethanol mainly the isomer (II) is formed; on the other hand, the main product of the reaction of propargyl bromide is the isomer (I). The reaction apparently proceeds via the transition states (III) and (IV):

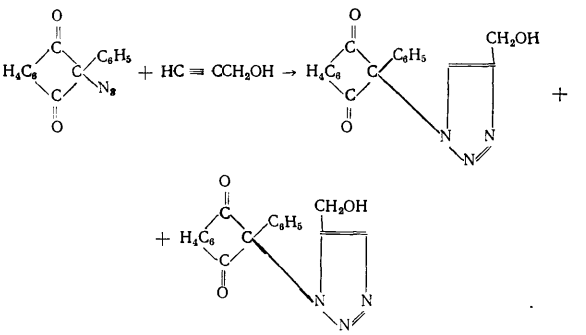
(III) (IV)

It has been established[24] that the mode of 1,3-cycloaddition of substituted propargyl compounds to diazomethane is independent of the steric effect of the substituents and the electrostatic effects and that the decisive factor is the nucleophilic and electrophilic properties of the atoms between which a bond is formed.



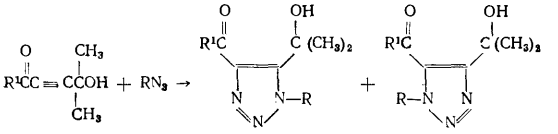
Pyrazoles are also produced in the interaction of propargyl compounds with substituted diazoalkanes. Propargyl alcohols and propargyl ethers react with methyl- or dialkyl-diazomethanes[21,25] to form exclusively an isomer of type (I), while an isomer of type (II) is obtained only from phenyl-substituted propargyl alcohols and ethers. Similar pyrazoles are also formed in the interaction of trifluorodiazoethane with propargyl bromide[26]. C_{sp}-trimethyl- or triphenylsilyl-substituted propargyl alcohols[27,28] are capable of entering into this reaction, an isomer of type (II) being mainly formed:

R=CH$_3$, C$_6$H$_5$.



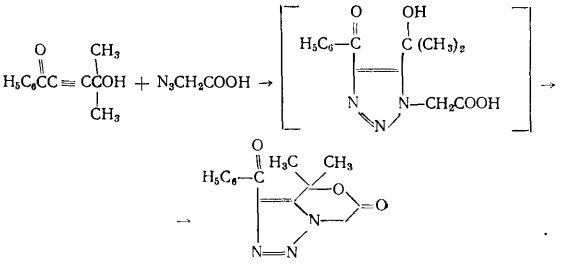
(b) Cycloaddition of Azides

The cycloaddition of azides to propargyl compounds leads to the corresponding triazoles, for example[29]:



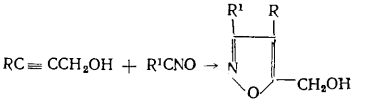
R=C$_6$H$_5$, C$_6$H$_5$CH$_2$.

2-(4-Hydroxymethyl-1,2,3-triazol-1-yl)- and 2-(5-hydroxymethyl-1,2,3-triazol-1-yl)-2-phenylindan-1,3-diones are formed from 2-azido-2-phenylindan-1,3-dione and propargyl alcohol[30]:



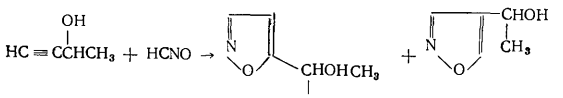
The ease of the cycloaddition of azides to propargyl compounds depends on the nature of the substituent at the triple bond and the structure of the azide. C_{sp}-bromo-substituted propargyl alcohols are less reactive than the unsubstituted alcohols[31]. Tertiary propargyl alcohols react with benzyl azide to form triazoles more readily than in the reaction with phenyl azide. The reactions of organic azides with the Iotsich reagent, obtained from propargyl alcohol, do not lead to cyclic compounds[32]. C_{sp}-acyl-substituted propargyl alcohols can also enter into the 1,3-cycloaddition reaction[33]:

Here the main factor determining the direction of the reaction is the high polarisation of the conjugated ketoethynyl system, which is responsible for the preferential formation of 1-R-4-acyl-substituted 1,2,3-triazoles. However, when aryl azides are introduced into the reaction, such regioselectivity is not observed. The ratio of the 4- and 5-acyl-substituted isomers changes in this instance towards an increase in the content of the latter.

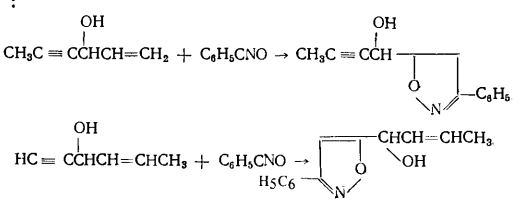


It is noteworthy that electron-donating (alkyl) substituents in the azide facilitate cycloaddition while electron-accepting substituents hinder it.

In certain cases the cycloaddition of azides to C_{sp}-acyl-substituted propargyl alcohol is accompanied by secondary processes involving the functional groups of the azide and the propargyl component. Thus azidoacetic acid reacts with benzoylethynyldimethylmethanol to form 4-benzoyl-1-methoxycarbonyl-5-(1-hydroxy-1-methylethyl)-1,2,3-triazole, which readily undergoes lactonisation:

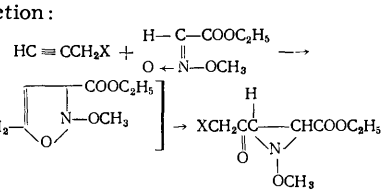


(c) Cycloaddition of Nitrile *N*-oxides



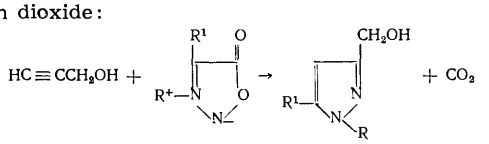
Propargyl alcohols readily react with nitrile oxides to form isoxazole derivatives[34,35]:

Secondary propargyl alcohols give rise to a mixture of isomeric isoxazoles[36]:



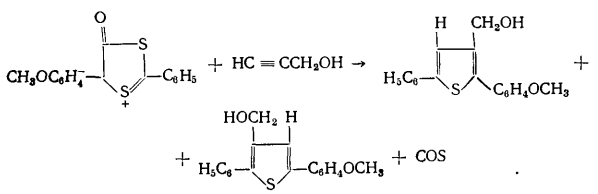
When benzonitrile oxide interacts with secondary vinylpropargyl alcohols, the addition can involve the double or triple bond depending on the structure of the initial compound[37]:

The 1,3-cycloaddition of nitrile oxides to propargylamines also leads to isoxazole derivatives[38].



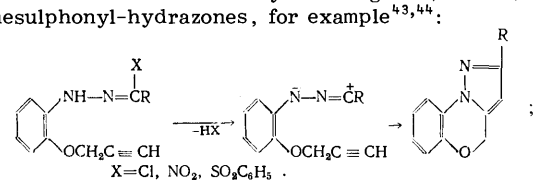
The mechanism of the formation of isoxazoles has been determined from the amount of incorporated deuterium[39]. It has been suggested that isomeric isoxazoles are obtained either directly via 1,3-dipolar cycloaddition or via the intermediate formation of the oxime $RC(=NOH)C\equiv CR^1$ with subsequent cyclisation. In the presence of D_2O isoxazoles free of deuterium are formed in the former case and [4-D]-isoxazoles are the products in the latter case.

Aziridine derivatives are formed in the reaction of propargyl alcohol and propargyl chloride with nitronic ester[40]. This is apparently associated with the rearrangement of the substituted 4-isoxazoline obtained in the first stage of the reaction:



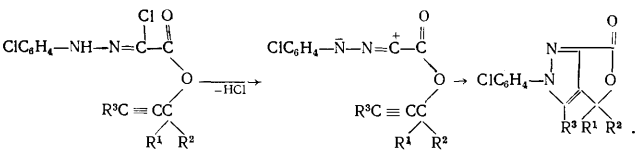
(d) Other Cycloaddition Reactions

Mesoionic compounds can also be regarded as 1,3-dipoles. They can form five-membered rings on reaction with propargyl compounds. Thus the interaction of 3-R-4-R^1-sydnone with propargyl alcohol leads to the formation of a pyrazole derivative[41]. Here the sydnone reacts via a [3 + 2]cycloaddition mechanism with simultaneous elimination of carbon dioxide:



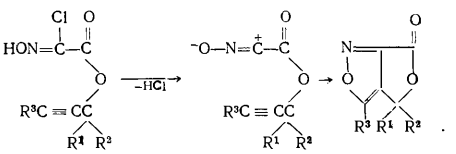
In the cycloaddition of mesoionic 1,3-dithiolones to propargyl alcohol, carbonyl sulphide is split off and a mixture of isomeric thiophens is formed[42]:

(e) Intramolecular Cycloadditions



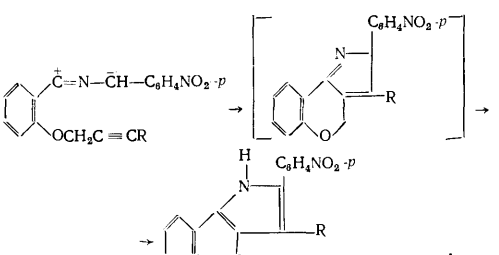
The reaction involving cycloaddition to propargyl compounds can occur not only intermolecularly but also intramolecularly. Such reactions involve molecules containing the necessary functional groups[17] (in a particular instance a 1,3-dipolar and a propargyl fragment).

The intramolecular cycloaddition of propargyl-substituted nitrile imines leads to the corresponding condensed pyrazoles. The sources of nitrile imines may be halogeno-, nitro-, and benzenesulphonyl-hydrazones, for example[43,44]:



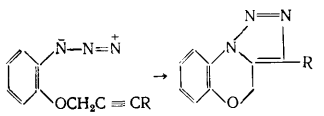
The ease of ring closure depends on the nature of the substituent R in the nitrile imine residue. In the case of the CH_2OH group, cyclisation does not occur.

The elimination of hydrogen chloride from "propargyl oxalate chlorohydrazone" leads to the formation of nitrile imines in which there is a possibility of intramolecular cycloaddition[45]. This results in the formation of furopyrazole derivatives:

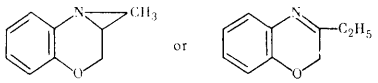


An analogous behaviour has been observed for "propargyl oxamide chlorohydrazone" but here the product is a mixture of isomeric pyrazoles[46].

Nitrile oxides with a propargyl fragment also readily undergo intramolecular cycloaddition. When "propargyl oxalate chloro-oximes" are heated in benzene in the presence of triethylamine, isoxazole derivatives are formed[45]:

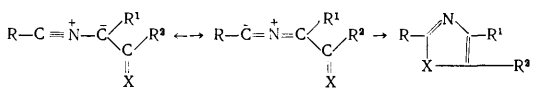


Benzopyranoisoxazole has been synthesised analogously[47]. It is noteworthy that the first reaction is structurally selective—only traces of the second isomeric adduct are formed, while both isomers are produced in the last reaction. Propargyl-substituted nitrile ylides are converted into benzopyranopyrrole derivatives as a result of intramolecular cycloaddition[48]:



C_{sp}-Phenyl-substituted propargyloxy-derivatives give rise to pyrrole in a low yield (6%) under these conditions, which can be accounted for by the steric hindrance due to the C_6H_5 group.

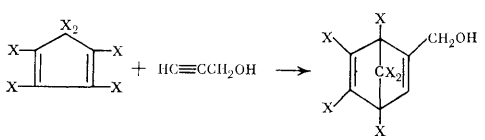
Aryl azides containing the propargyloxy-group are converted into triazolobenzoxazines on intramolecular cycloaddition[49]:



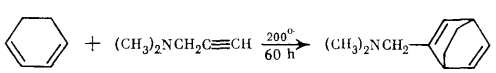
This is the first example of the intramolecular cycloaddition of the azide group to a triple bond. It is noteworthy that, in contrast to propargyl-substituted azides, azides with allyl groups form unstable Δ^2-1,2,3-triazolines, whose subsequent decomposition with elimination of molecular nitrogen gives rise to the reaction product:

2-Propargylthiophenyl azide undergoes analogous heterocyclisation to triazolobenzothiazine.

The intramolecular cycloaddition of nitrogen-containing analogues of propargyl-allenyl dipoles via the mechanism



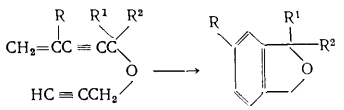
is of considerable interest. These reactions have already been surveyed and examined in a review[51].



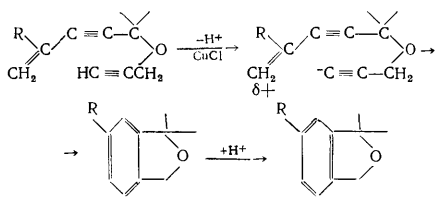
2. The Diene Synthesis

The Diels–Alder reaction belongs to the class of thermally allowed concerted processes[52], which means that unexcited molecules having 4π and 2π electrons respectively are combined. The diene synthesis has been discussed in detail in monographs[10,53,54] and in a review[19].

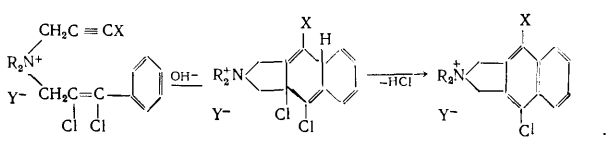
Propargyl compounds are active dienophiles. Thus propargyl alcohol reacts with hexachlorocyclopentadiene[55–57] and cyclopentadiene[58] at 130–150 °C to form the corresponding bicycloheptadienes:



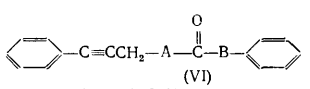
Propargyl chloroacetates[59,60] as well as the propargyl esters of trihalogenoacetic acids[61] react with the above dienes under analogous conditions. The yield of the adducts of the propargyl esters of trihalogenoacetic acids with hexachlorocyclopentadiene increases with increase of the atomic number of the halogen, while the opposite behaviour is observed for the adducts with cyclopentadiene. The reaction of dimethylpropargylamine with cyclohexadiene leads to cyclisation products in accordance with the mechanism[62]:



The reaction with the amine hydrochloride proceeds analogously. Allyldimethylamine does not react with cyclohexadiene under these conditions.



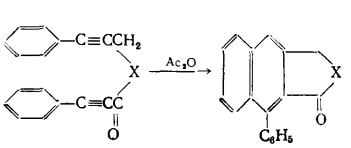
Propargyl compounds in which both reaction centres are located in the same molecule also enter into the diene synthesis. Thus intramolecular cyclisation with formation of phthalanes takes place on heat treatment of the propargyl ethers of vinyl- and isopropenyl-acetylenic alcohols[63]:



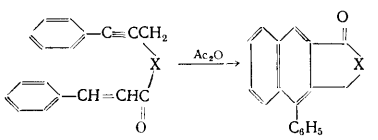
C_{sp}-Substituted propargyl ethers of vinylacetylenic alcohols also cyclise under analogous conditions[64]. The nature of the substituent in the acetylenic group has a significant influence on the reaction[65]. Electron-accepting groups facilitate cyclisation, while electron-donating groups greatly hinder it. Copper chloride has been used as a catalyst in order to accelerate the diene concentration[66]. The role of the catalyst apparently consists in the formation of the ethynyl carbanion:

It is noteworthy that the intramolecular condensation of the propargyl ethers of phenylacetylenic alcohols proceeds under more severe conditions than that of their vinylacetylenic analogues[67]. The diene synthesis involving β,γ-dichloro-γ-phenylallyl(propargyl)ammonium halide salts in the presence of alkalis proceeds with elimination of HCl and leads to benzoindolinium derivatives in high yields[68]:

Alkenylphenylallylammonium salts undergo the diene condensation also in the absence of alkalis. The intramolecular 1,4-cycloaddition of propargyl compounds of type (VI) in the presence of acetic anhydride opens a new pathway to synthetic lignan lactones[69–72]:

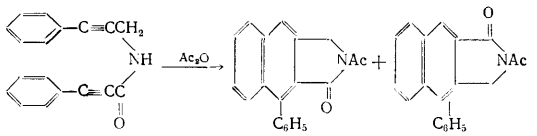


(VI)

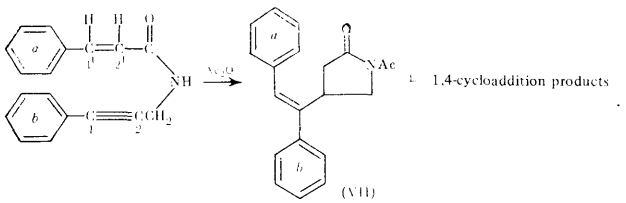


A=O, NH, $NCH_2C_6H_5$

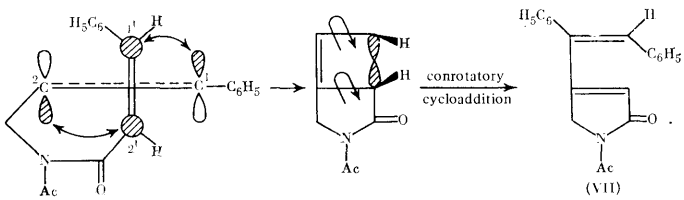
B= *cis*-CH=CH, *trans*-CH=CH, C≡C .



Here there is a possibility of the following pathways in the 1,4-cycloaddition: (1) electron-donating dienes interact with electron-accepting dienophiles (normal reaction); (2) electron-accepting dienes interact with electron-donating dienophiles (anomalous reaction). In the reaction of *N*-benzyldiynamide[70] and a diyne ester[69] the first pathway operates:

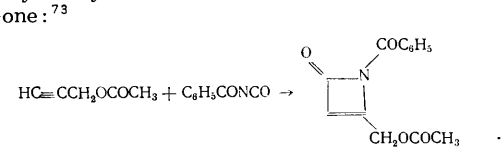


The intramolecular cycloaddition of *cis*- and *trans*-enynamides[71] and also of *N*-benzyl-*trans*-enynamide[70] proceeds via the second pathway:

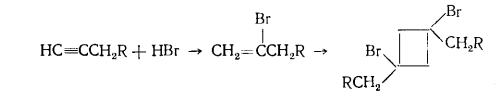


In the case of diynamides both pathways operate[71]:

There exist data[72] showing that, together with 1,4-cycloaddition products, yet another compound [compound (VII)] is formed in the intramolecular condensation of N-phenylpropargylamide of *cis*-cinnamic acid in the presence of acetic anhydride:

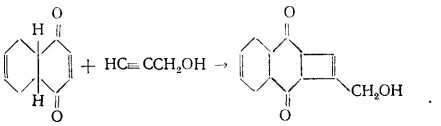


The use of deutero- and bromo-substituted analogues shows that compound (VII) is obtained as a result of the total rupture of the bond between the C(1′) and C(2′) atoms with formation of new C(1)–C(1′) and C(2)–C(2′) bonds. It has been suggested that this reaction takes place as a result of the thermally induced intramolecular concerted $[{}_{\pi}2_{s} + {}_{\pi}2_{a}]$-cycloaddition with formation of the sterically strained cyclobutene and subsequent conrotatory cyclodecomposition of the cyclobutene via the $[{}_{\sigma}2_{a} + {}_{\pi}2_{s}]$- or $[{}_{\sigma}2_{s} + {}_{\pi}2_{a}]$-mechanism. New bonds are formed in the suprafacial addition to the *cis*-C=C bond and the antarafacial addition to the C≡C bond. These bonds exhibit electron-donating and electron-accepting properties respectively:



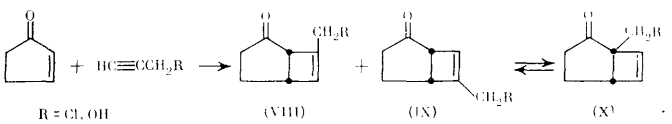
3. 1,2-Cycloaddition

The 1,2-cycloaddition to propargyl compounds has been studied inadequately. The interaction of propargyl acetate with benzoyl isocyanates leads to a substituted 1-benzoyl-2-azetin-4-one:[73]



The cycloaddition of methyl propargyl ether to trichloroacetyl and benzoyl isocyanate has been considered in reviews[74,75].

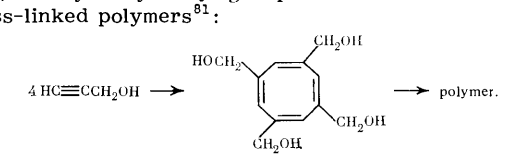
The formation of cyclobutane derivatives from compounds of the type $HC{\equiv}CCH_2R$ in the presence of anhydrous HBr has been observed recently[76]. Together with the usual addition products, *cis*- and *trans*-1,3-dialkyl-1,3-dibromocyclobutanes are formed under these conditions (as a result of cyclodimerisation):



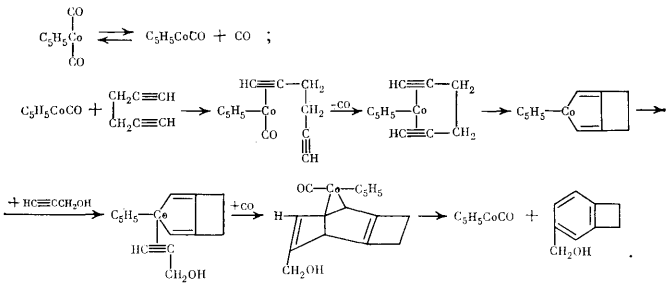
By varying the reaction conditions and the substituents R, it is possible to obtain cycloaddition products with maximum yields.

The photocycloaddition of a Δ^2-ene-1,4-dione to propargyl alcohol ($\lambda > 300$ nm) in benzene at room temperature leads to adducts of the tricyclo[6.4.0.$0^{3,6}$]dodecane series containing the cyclobutene ring[77]:

Under the same conditions, cyclopent-2-ene-1,4-diones do not form such rings owing to their extremely high tendency towards photopolymerisation. However, by altering the reaction conditions, it is possible to achieve the cycloaddition of propargyl alcohol in this case also[77].

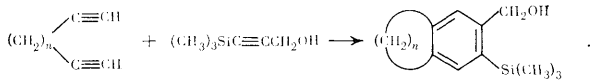


In order to elucidate the influence of the nature of the substituent in propargyl compounds on the ease and structural specificity of the cycloaddition, the photocycloaddition of cyclopent-2-en-1-one to propargyl chloride and propargyl alcohol has been investigated[78,79]:



The reaction of cyclopentenone with propargyl chloride in ether proceeds comparatively unambiguously. Only the "head-to-head" and "head-to-tail" adducts, compounds (VIII) and (IX) respectively, are formed at the beginning of the photolysis in proportions of 3:1, after which their photoisomerisation products (X) appear. At the end of the photolysis the product of the addition of the solvent to cyclopentenone also accumulates. The reaction of propargyl alcohol with cyclopentenone in benzene is slow and compounds (VIII) and (IX) obtained initially undergo photopolymerisation with formation of minor products having a labile structure. It has been established that the structural specificity of the cycloaddition of cyclopentenone to propargyl compounds depends greatly on steric factors.

Methoxymethyl-3,4-carbonyldioxycyclobutene is formed in 22% yield in the photocycloaddition of methyl propargyl ether to vinylene carbonate[75].

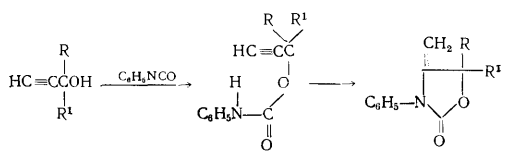


The cyclodimerisation, cyclotrimerisation, and cyclooligomerisation reactions also belong to the class of 1,2-cycloadditions. The direction of these reactions depends mainly on the type of catalyst employed. Thus cyclic trimers and tetramers have been synthesised from propargyl alcohols in the presence of di(π-allyl)nickel[80]. The cyclisation of propargyl alcohol catalysed by nickel acetylacetonate and its mixture with triphenylphosphine leads to 1,3,5,7-tetra-(hydroxymethyl)cyclo-octatetraenes. When the latter are heated, the hydroxymethyl groups condense with formation of cross-linked polymers[81]:

The most active catalysts in the intermolecular cycloaddition of propargyl compounds are transition metals[82,83]. The 1,2-cycloaddition process has been thoroughly investigated in relation to the interaction of propargyl alcohol with bipropargyl and its C_{sp}-substituted derivatives in the presence of Δ^5-cyclopentadienylcobalt dicarbonyl[84]. The results obtained[85,86] led to many well-founded hypotheses concerning the reaction mechanism which reduces, to the following scheme[84]:

The reaction of silicon-containing propargyl compounds with diacetylenes catalysed by $C_5H_5Co(CO)_2$ is an interesting type of cocyclisation[87–89]:

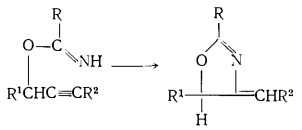
An increase in the length of the polymethylene chain favours cycloaddition.



III. CYCLISATION

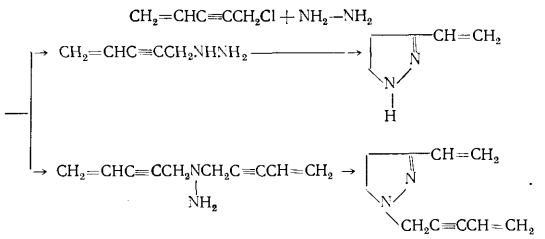
1. Intramolecular Addition to the Triple Bond

The cyclisation of propargyl compounds via intramolecular addition to the triple bond has found extensive applications in the synthesis of a wide variety of carbocyclic and heterocyclic systems. The rings are formed via the intramolecular addition of NH, OH, CH, SH, and ZH groups.



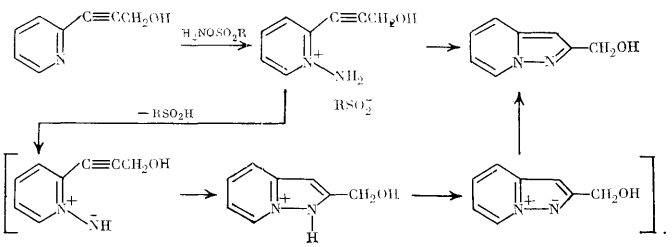
(a) NH-Addition

Five-membered heterocycles are synthesised by the intramolecular attack by the NH group on the C≡C bond. Thus the interaction of terminal propargyl alcohols with phenyl isocyanate leads initially to the corresponding carbamates, which readily undergo intramolecular cyclisation in the presence of bases and are converted into oxazolidinones[90–93]:

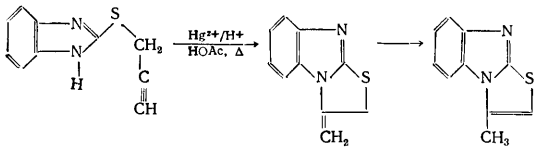


When the acetylenic hydrogen atom in the initial alcohol is replaced by bromine, bromo-oxazolidinones are formed, but, when the hydrogen is replaced by the aminomethyl group, the reaction cannot be carried out[93]. This difference in the behaviour of the aminoalcohol carbamates and their analogues can be explained by the polar influence of the C_{sp} substituent. Since heterocyclisation takes place as a result of the nucleophilic attack by the nitrogen atom of the carbamate group on the ethynyl carbon atom, the polarisation of the triple bond, generating a partial positive charge on the attacking atom, is essential for its successful occurrence.

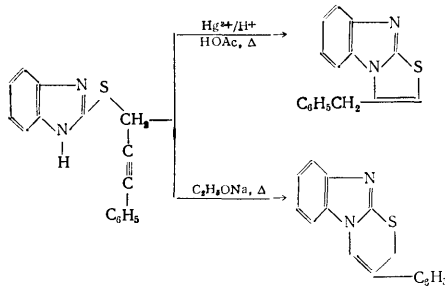
On heating in benzene in the presence of 1,5-diazabicyclo-[5.4.0]undec-5-ene, propargyl benzimidates are converted into methyleneoxazolines in 45–50% yield[7]:



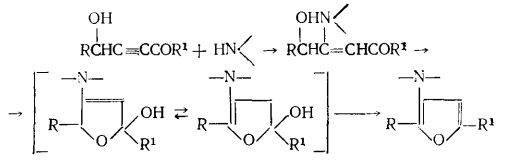
The latter are stable compounds. On treatment with t-C_4H_9OK, they are converted into oxazoles. The possibility of synthesising oxazole derivatives in the presence of Ag^+ or Hg^+ salts in 97.3% yield has been demonstrated recently[94].



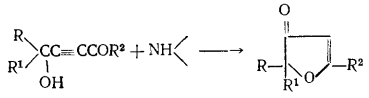
When hydrazine or phenylhydrazine reacts with primary vinylpropargyl halides in the presence of CuCl, substitution products are formed and then cyclise to vinylpyrazolines[95–98]:



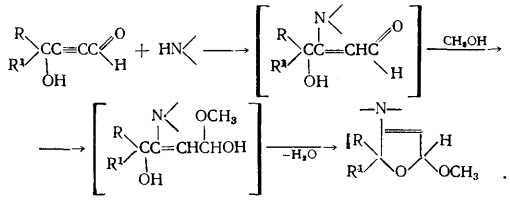
Tertiary vinylpropargyl halides and propargyl halides behave analogously in reactions with hydrazine. However, secondary vinylpropargyl halides do not give rise to pyrazolines, which are formed as a result of the direct attack by the nucleophile on the carbon atom linked to the halogen and subsequent cyclisation of the hydrazine formed. C_{sp}-pyridylpropargyl alcohol reacts with *O*-mesitylenesulphonylhydroxylamine to form the corresponding salt which is converted into pyrazolopyridine in 70–90% yield on treatment with potassium carbonate in dimethylformamide (DMF).[99] The similar transformation of propargylammonium compounds of the type $\diagdown\overset{+}{N}-CH_2C\equiv CH$ usually proceeds via a 2,3-sigmatropic rearrangement[100–102]. The explanation of the conversion of C_{sp}-pyridylpropargyl alcohol into pyrazolopyridine in terms of the formation of an allene intermediate is unconvincing, since it is difficult to assume the possibility of the formation of a strained five-membered cyclic compound with an allene group. It has been suggested[99] that the attack by NH on the electrophilic centre of the triple bond results in the formation of a dipolar ion which is stabilised as a consequence of the migration of hydrogen:



Terminal propargylthiobenzimidazoles give rise to satisfactory yields of 3-methylthiazolo[3,2-*a*]benzimidazoles in the presence of mercury ions[103]:

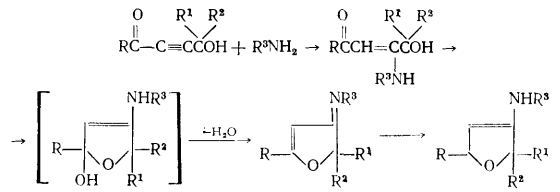


The cyclisation of C_{sp}-substituted propargylthiobenzimidazoles gives rise to 3-benzylthiazolo[3,2-*a*]benzimidazoles or 4-phenyldihydrothiazino[3,2-*a*]benzimidazoles depending on the reaction conditions[103]:

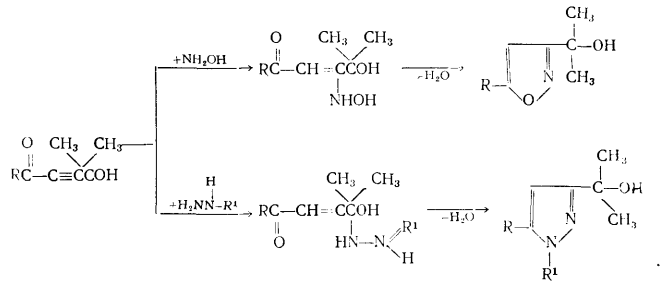


Certain reactions involving the addition of amines to propargyl compounds are accompanied by cyclisation. Thus the interaction of secondary propargyl ketols with primary and secondary amines leads to the formation of β-aminofurans[104,105]:

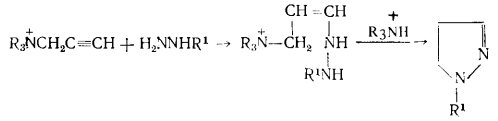
It has been suggested that nucleophilic addition of the amine to the triple bond takes place initially with subsequent cyclisation of the resulting aminovinylketol to β-aminofuran. Tertiary γ-ketols are converted into β-furanones on treatment with secondary amines and subsequent hydrolysis[106]:



Propargylaldols react with primary amines to form acyclic compounds[107]. The attempts to achieve the nucleophilic addition of diethylamine to propargylketols in anhydrous media [ether, tetrahydrofuran (THF), and benzene] lead to tarry products[108]. Propargylaldols combine with dialkylamines in anhydrous methanol and are converted into stable 4-dialkylamino-2-methoxydihydrofurans in 43–54% yield. The solvent as well as the dialkylamine apparently adds on in this instance[108]:

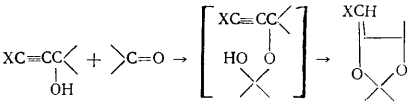


In absolute benzene or ether in an argon atmosphere the addition of diethylamine is accompanied by charring and an individual product cannot be isolated.

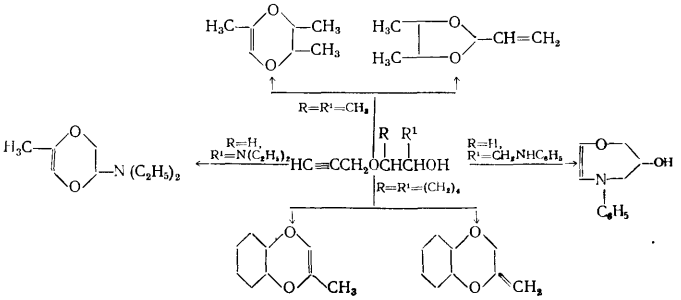


The addition of primary amines to propargylketols proceeds in accordance with the mechanism[109]:

The interaction of propargylketols with bifunctional nucleophiles (hydrazine, hydroxylamine) in a weakly alkaline medium involves the triple bond. The adducts formed initially cyclise to isoxazoles and pyrazoles[110]:

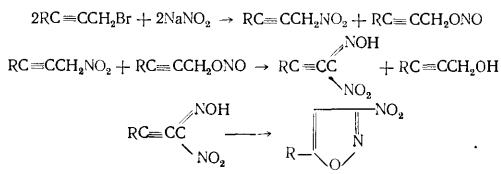


The reaction of hydrazine with trialkylpropargylammonium salts leads to the formation of pyrazolines[111]:

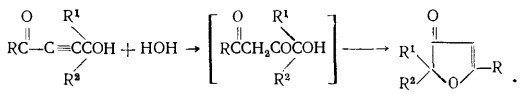


(b) OH-Addition

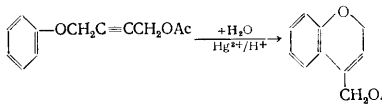
Among intramolecular cyclisations, the intramolecular addition of the OH group is of special interest. Thus it has been shown that, when propargyl alcohols interact with carbonyl compounds, substituted 1,3-dioxolans are formed[112–118]:



The extent and ease of cyclisation depend on the substituent X. The reaction proceeds readily when X = RC≡C, Br, RCOO, CN, or ROO.[117] On the other hand, the reaction does not occur at all when X = H, CH_2 = CH, C_6H_5O, CH_2OH, $CH(OC_2H_5)_2$, or CH_2OCH_3.[117,118] By comparing the spectroscopic characteristics of propargyl alcohols with their reactivities in the heterocyclisation reactions with carbonyl compounds, it has been established[117] that there is a qualitative relation between the reactivities of propargyl alcohols and the differences $\Delta\delta$ between the chemical shifts of the ≡CH group in the ^{1}H NMR spectra. Thus compounds for which $\Delta\delta$ is small are unreactive. Propargyl alcohols with functional group substituents which are actively involved in cyclisation have high values of $\Delta\delta$.



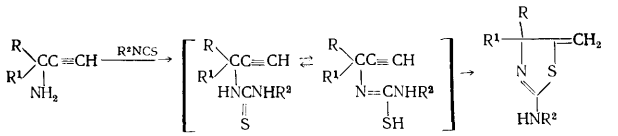
The cyclisation of alkyl-substituted propargyloxyethanols leads to rings of different size[119]:



The application of propargyl compounds in the synthesis of isoxazole derivatives has been described[120]. Thus 3-nitroisoxazole has been obtained from propargyl bromide and sodium nitrite in DMF. The cyclisation of C_{sp}-substituted propargyl bromides also leads to 3-nitroisoxazoles[121]:

This mechanism has been confirmed by the isolation from the reaction mixture of a C_{sp}-substituted propargyl alcohol. In some cases the hydration of propargyl compounds also leads to the formation of rings. Propargylketols are fairly readily hydrated in dilute sulphuric acid or in alcoholic alkali in the presence of mercury salts and also in the presence of amines in protic solvents[104,122,123], being converted under these conditions into β-furanones, apparently via a β-diketol stage. In aqueous dioxan the yield of furanones is ≤50%:

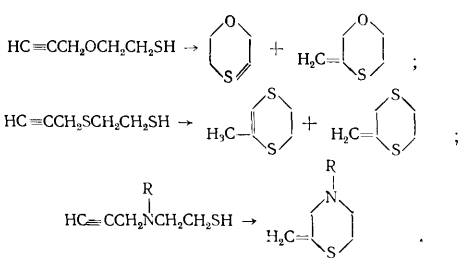
Under analogous conditions, the C_{sp}-acetoxymethylpropargyl ether of phenol gives rise to 4-acetoxymethyl-Δ^3-chromene[124]:



Under the same conditions, phenyl propargyl ether is converted into phenoxyacetone.

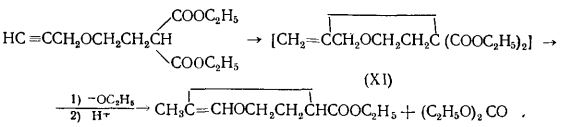
An interesting cyclisation of phenolic and enolic propargyl compounds has been discovered recently[125,126]. The monopropargyl ether of catechol is converted into 2,3-dihydro-2-methylene-1,4-benzodioxin in 65–90% yield on refluxing with mercury(II) oxide in DMF. In the absence of a catalyst and at temperatures below 110 °C, cyclisation does not occur. 2,3-Dihydro-2-methylenenaphtho[2,3-*b*]dioxin has been obtained under analogous conditions from the monopropargyl ether of 2,3-dihydroxynaphthalene.

(c) SH-Addition



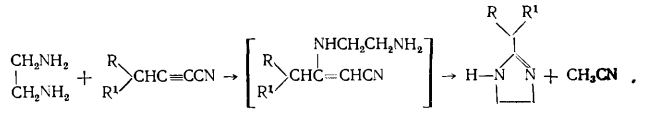
The intramolecular addition of the SH group to the C≡C bond is used to synthesise sulphur-containing heterocycles. There exists the view[127] that, when α,α-disubstituted propargylamines react with isothiocyanates, thiourea derivatives are formed initially and then give rise to the final reaction products under the influence of bases. However, Azerbaev et al.[128] believe that the intermediate thiourea derivatives are immediatley converted into thiazolines (via the thione–thiol tautomeric equilibrium):

Secondary α-propargylamines react with isothiocyanates to form thiazolidines. The reactions of isothiocyanates with secondary amines are slower than those with primary amines. It is noteworthy that cyclisation becomes more difficult with an increase in the bulk of the groups R^1 and R^2. The tendency towards cyclisation also diminishes with increase in the size of the group R. Similar features of the cyclisation had also been noted earlier[127,129] and the difficulties in the cyclisation reaction were accounted for by steric factors.



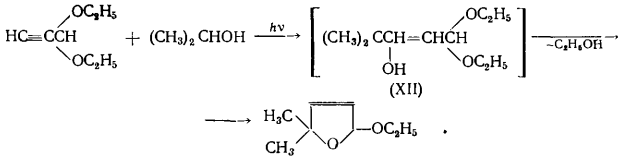
The interaction of α,α-disubstituted propargylamines with benzoyl isothiocyanate leads the formation of 2-benzamido-5-methylene-2-thiazoline[130]. It has recently been suggested[131] that the interaction of aryl isoselenocyanates with 2-alkynylamines proceeds analogously to the reaction with isothiocyanates, i.e. via the intermediate formation of seneloureas which undergo cyclisation during the reaction with formation of the corresponding selenazolines. The reactions of 2-propynylamines with isoselenocyanates proceed more vigorously than those with isothiocyanates.

Compounds containing heteroatoms between the thiol and propargyl groups can also be used to synthesise heterocycles. It has been established[132] that the structure of the products of the cyclisation of propargyl derivatives of hydroxy-, mercapto-, and amino-ethanethiols in the presence of bases depends on the nature of the heteroatom. Whereas a mixture of 2-methylene-1-thia-4-oxacyclohexane and 3-thia-6-oxacycloheptene is formed from propargyloxyethanethiol, in the reaction involving propargylthioethanethiol the main reaction products are 2-methylene-1,4-dithia-2-cyclohexene and 2-methylene-1,4-dithiacyclohexane. Only one cyclic product, namely 2-methylene-1-thia-4-azacyclohexane, is formed from propargylaminoethanethiol:

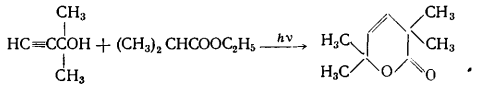


(d) CH-Addition

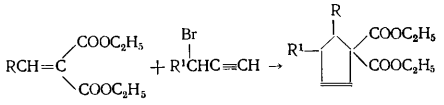
Propargyl compounds containing an active hydrogen atom undergo the Michael reaction with formation of cyclic compounds. Thus the intramolecular cyclisation of propargyloxyethylmalonic ester in the presence of sodium ethoxide in alcohol leads to derivatives of dihydropyran[133]:



It has been suggested that the intermediate compound (XI) interacts with the ethoxide anion, splits off diethyl carbonate, and is converted into the final product.

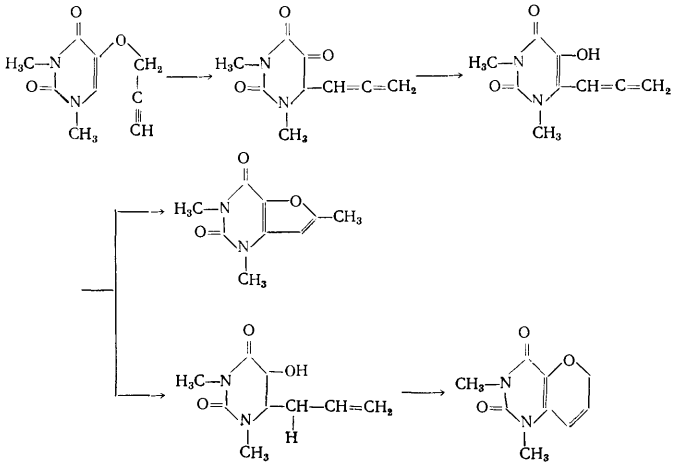


The Michael adducts of ethylenediamine and the "inverted" propargyl cyanides readily cyclise to imidazolines (yield 80%) with elimination of acetonitrile[134]:

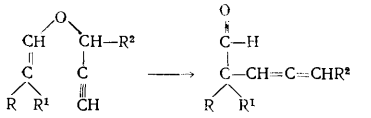


The photochemical reaction of the diethyl acetal of propiolaldehyde with isopropyl alcohol proceeds via the intermediate (XII) and gives rise to a dihydrofuran derivative as a result of the elimination of ethanol[135]:

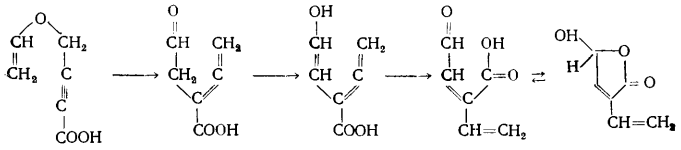
Under these conditions, propargyl alcohols are converted into acyclic compounds[136]. The interaction of ethynyldimethylmethanol with ethyl isobutyrate results in the formation of a pyrone derivative[137]:



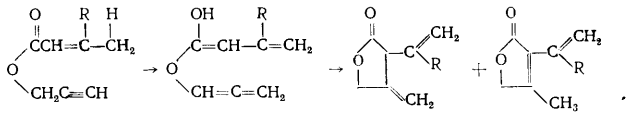
The addition of diethyl isobutylidenemalonate to secondary propargyl bromides in the presence of zinc or on heating in THF can be regarded as a new method of synthesis of cyclopentene derivatives[138]:



2. Cyclisation Involving the Claisen Rearrangement

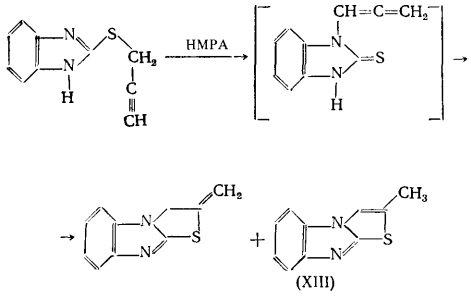


One of the commonest methods of synthesis of heterocycles involves the cyclisation of propargyl compounds via a sigmatropic rearrangement. Thus the thermal cyclisation of propargyl ethers of phenols leads to the formation of chromenes[75]. In contrast to this, the cyclisation of propargyloxyuracils results in the additional formation of furopyrimidine[2]:

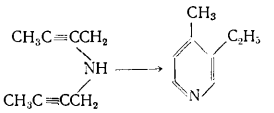


This can be explained by the fact that the electron-withdrawing effect of the uracil nucleus is greater than that of the phenyl group. This effect renders the central carbon atom of the allene fragment in the enol more electron deficient. As a consequence of this, the sensitivity of the enolic hydroxy-group to nucleophilic attack increases and ring closure results. The solvent exerts a decisive influence on the mode of cyclisation. Furopyrimidines (66%) are formed from substituted propargyloxyuracils in DMF at 130 °C. Pyrolysis in xylene at 130 °C leads to pyranopyrimidines (48%). The propargyl ethers of hydroxymethylacridone[4], substituted hydroxynapthalenes[3], coumarins[139–141], and hydroquinone[142] behave analogously in the intramolecular cyclisation reaction. Propargyl vinyl ethers react differently. Their thermal cyclisation with a vinyl fragment containing vinyl substituents leads to allenyl-substituted aldehydes[143]:

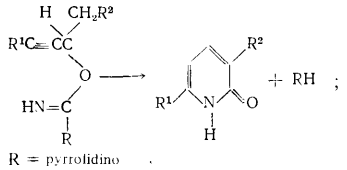
The cyclisation of the C_{sp}-carboxyether leads to the formation of a natural antibiotic—the lactone of dihydroxyvinylbutanoic acid[5]:



It has been suggested that the initial propargyl vinyl ether is converted via a cyclic transition state into an allene aldehyde, which undergoes a prototropic rearrangement with formation of a diene aldehyde which then cyclises to the final product. Alkenyl-γ-lactams and alkenyl-γ-lactones have been obtained from propargylamides or propargyl esters of alkanoic acids[144–146]. The reaction mechanism is as follows:

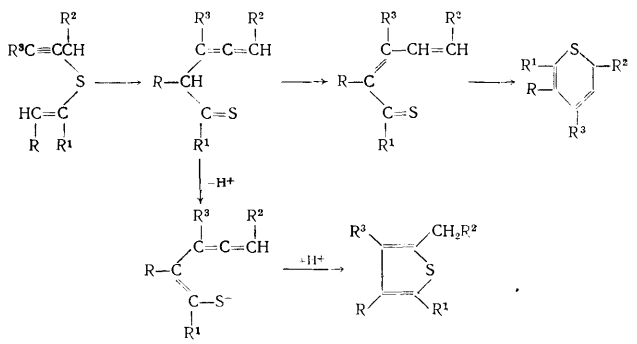


The unsaturated ester of the propargyl alcohol probably enolises with participation of an α-hydrogen atom as a result of 1,5-migration with formation of an intermediate, which is converted into the final product via the mechanism of the ene reaction involving the transfer of a hydrogen atom from the enol group.

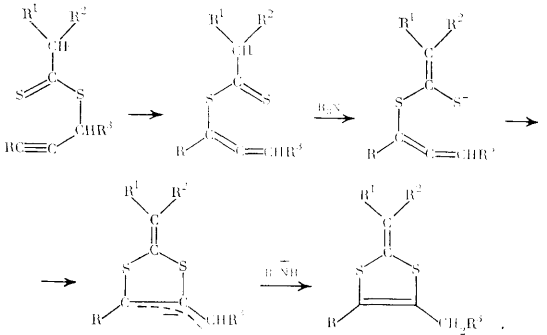


An instant rearrangement has been observed in the thermal cyclisation of propargylthiobenzimidazole in hexamethylphosphoramide (HMPA):[147,148]

Only compound (XIII) is formed in ethanol in the presence of sodium ethoxide. Under these conditions, dipropargyl sulphides do not cyclise. The thermal rearrangement of C_{sp}-alkyl-substituted dipropargylamines in the presence of potassium t-butoxide in butyl alcohol leads to alkylpyridines[149]:

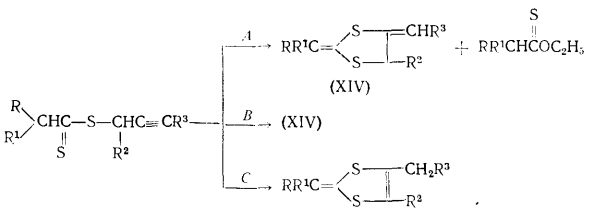


Under these conditions, the unsubstituted dipropargylamine is converted into the corresponding nitrile. A new method of synthesis of 2-pyridones by the thermolysis of *O*-propargyl derivatives of isoureas has been described[150,151]:



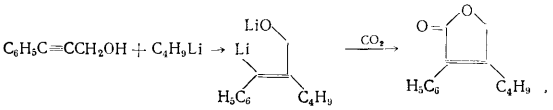
R = pyrrolidino

It has been suggested that the initial reaction stage is the thermal 3,3-sigmatropic rearrangement of the initial compound into an allene, whose tautomeric transformation gives rise to the corresponding diene. The elimination of pyrrolidine from the diene leads subsequently to an isocyanatodiene, which undergoes electrocyclic cyclisation to a pyridone.

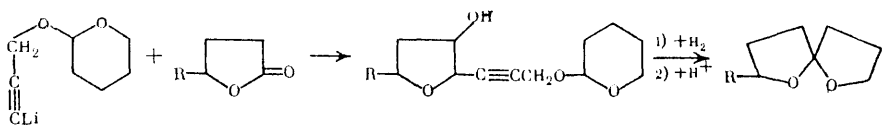


Sulphur-containing vinylpropargyl compounds also undergo the Claisen rearrangement[152,153]. An allene intermediate is formed in the initial stage. Its subsequent transformation can take place with formation of various substituted heterocycles:

The solvent and the presence of an amine exert the most significant influence on the direction of the reaction. The reaction in HMPA leads to the specific synthesis of 2*H*-thiopyrans. The basicity of HMPA apparently favours the 1,3-isomerisation of the allene intermediate to a conjugated diene, whose subsequent transformation leads to a thiopyran. When the reaction is carried out in HMPA or dimethyl sulphoxide (DMSO) in the presence of amines, mixtures of substituted thiopyrans and thiophens are formed. Amines probably catalyse the conversion of the allene intermediate into a thiophen. Propargyl vinyl sulphides containing the cyano-group in the vinyl fragment gives rise to thiopyrans on heating in silicone oil, while in DMSO in the presence of di-isopropylamine they produce a mixture of thiopyran and thiophens[154]. Propargylthiothiopyran cyclises like propargyl sulphides with formation of thiopyranothiopyran and thiopyranothiophen[155]. The thermal cyclisation of propargyl alkanedithioates in xylene proceeds via the mechanism[156]

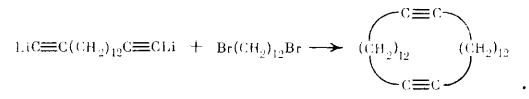


The base-catalysed cyclisation of propargyl alkanedithioates has been investigated[157]. The reaction can be carried out in the presence of sodium ethoxide in absolute alcohol (method *A*) or in the presence of potassium t-butoxide in a mixture of t-butyl alcohol and the dimethyl ether of ethylene glycol (method *B*) and also in the presence of sodium ethoxide or potassium t-butoxide in the dry dimethyl ether of ethylene glycol (method *C*):

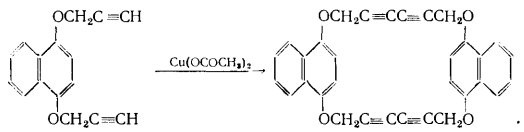


3. Other Cyclisation Reactions

Apart from the reactions described, a number of non-general cyclisation reactions have been described for propargyl compounds.

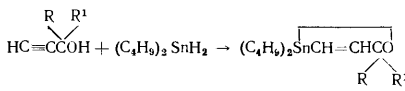


C_{sp}-phenyl-substituted propargyl alcohol readily reacts with butyl-lithium in ether in the presence of symmetrical *N*,*N*'-dimethylethylenediamine to form an intermediate whose reaction with carbon dioxide leads to the corresponding lactone in a yield up to 70%:[158]

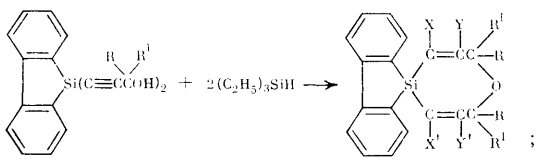


C_{sp}-Lithio-derivatives of propargyl ethers react with lactones in diethyl ether and give rise to hydroxylactones whose hydrogenation and subsequent acid hydrolysis afford the corresponding spiro-compounds[159]:

The dilithio-derivative of hexadeca-1,10-diyne is readily alkylated by 1,12-dibromododecane in a THF–HMPA mixture with formation of a 28-membered macrocycloalkadiyne[160]:

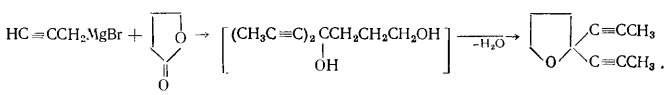


The intermolecular cyclisation of 1,4-dipropargyloxynaphthalene in the presence of copper acetate on heating in pyridine has been reported recently[161]. The reaction leads to the formation of a tetrayne crown-ether in 96% yield:



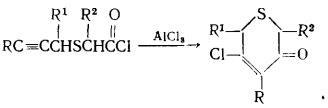
Other propargyl ethers have also been introduced into this reaction[162].

The interaction of dibutylstannane with propargyl alcohols leads to unsaturated cyclic organotin ethers[163]:

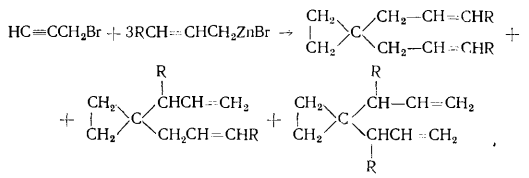


The addition of dialkylchlorohydrosilanes and the corresponding germanes and stannanes to substituted propargyl alcohols gives rise to the corresponding γ-hydroxyalkenyl analogues. The reduction of the latter with lithium tetrahydroaluminate and subsequent intramolecular dehydrocondensation led to the synthesis of 2-sila-, 2-germa, and 2-stanna-1-oxacyclopentanes[164]. The ease of cyclisation depends on the polarity of the metal–hydrogen bond.

Iotsich reagents derived from propargyl alcohols react with dichlorosilafluorene to form silicon-containing glycols whose hydrosilylation with triethylsilane is accompanied by cyclodehydration[165]:

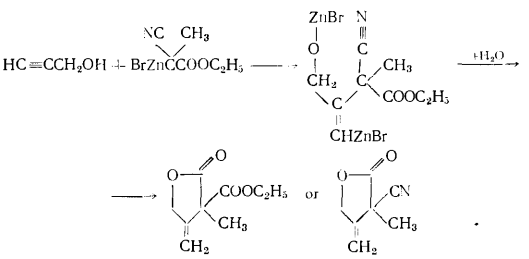


X, Y, X', Y' = $(C_2H_5)_3Si$ or H .



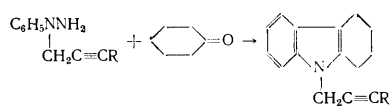
There exists the view that the final product of the interaction of the Grignard reagent derived from propargyl bromide with γ-butyrolactone, namely 2,2-dipropynyltetrahydrofuran, is also formed via the cyclodehydration of the intermediate 1,4-diol:[166]

The intramolecular cyclisation of chlorides of propargylthioalkanecarboxylic acids catalysed by $AlCl_3$ leads to derivatives of dihydrothiopyranones[167]:



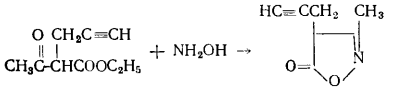
The addition of unsaturated organozinc compounds to the propargyl compounds $HC{\equiv}CCH_2X$ leads either to the normal adducts or to cyclic compounds[168–170]. The reactions of propargyl alcohols (X = OH), ethers (X = OR), and their nitrogen-containing analogues (X = NR_2) result in the formation of mono- or di-addition products. Only diaddition takes place in the reaction of propargyl bromide or chloride with subsequent 1,3-elimination and the formation of cyclopropane derivatives. When propargyl bromide is treated with substituted allyl derivatives of organozinc compounds, mixtures of three substituted cyclopropanes are produced:

The lotsich reagent derived from phenyl propargyl ether reacts with C_{sp}-ethyl-substituted propargylzinc bromide, also forming a cyclopropane derivative[171]. In contrast to this, the formation of acyclic compounds is observed in the reaction of propargyl alcohol with the lotsich reagent.

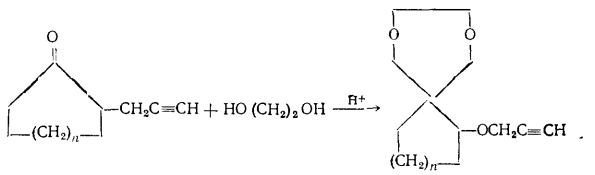


Treatment of propargyl bromide with organomagnesium compounds results in the formation of the products of the Wurtz exchange reaction and also the products of an intramolecular rearrangement[172–174].

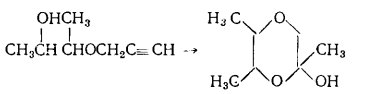
The reaction of propargyl alcohol with the zinc derivative of ethyl bromocyanopropionate leads to the formation of γ-lactones[175,176]:



Mixtures consisting of lactones, adducts, and transesterification products are formed from secondary propargyl alcohols. The reaction involving tertiary propargyl alcohols affords a complex mixture of products Under these conditions, C_{sp}-substituted propargyl alcohols do not react and diethylpropargylamine gives rise to addition products alone.



Certain cyclisation reactions of propargyl compounds proceed without involving the triple bond. This permits the specific use of the latter in subsequent reactions. Propargylphenylhydrazines are readily converted into *N*-propargyltetrahydrocarbazoles on interaction with cyclohexanone in acetic acid[177]:



The propargyl group is retained also in the intermolecular cyclisation of ethyl propargylacetoacetate with hydroxylamine[178]:

2-Propargylcycloanones react with glycol to form the corresponding propargyl spirodioxolans[179]:

The monopropargyl ether of butane-2,3-diol undergoes cyclohydration in an aqueous medium in the presence of mercury(II) oxide and sulphuric acid with formation of 2-hydroxy-2,5,6-trimethyl-1,4-dioxan[180]:

The interaction of propargyl alcohols with the β-chloroalkyl ethers of glycidol in the presence of $BF_3.(C_2H_5)_2O$ leads to the formation of derivatives of propargyloxymethyl-1,4-dioxan[181].

Dynamic Light Scattering and Thermal Motion of Macromolecules in Solutions

V.S.Skazka

The theory and practice of a new method of studying the translational and rotational mobility of macromolecules in solution by dynamic light scattering are briefly outlined. Experimental assemblies are described, and results obtained by this method for macromolecules of different chemical structure are reported. The possible applications of the method and its likely future developments are discussed.
The bibliography includes 47 references.

I. INTRODUCTION

In diffusion, sedimentation, and viscosity phenomena the organised translational and rotational motion of macromolecules in solutions takes place as a result of their interaction with an external field of force: in diffusion, the field of the chemical potential gradient, in sedimentation, the centrifugal force field, and in viscous flow, the field of the flow velocity gradient. The presence of these fields (external to the macromolecule) can perturb the results. Therefore in many experiments allowance must be made for these perturbing effects, usually by extrapolating the results to zero values of the fields or gradients.

However, we can approach the study of the mobility of macromolecules in a different way: by using the dynamic light scattering method. Macromolecules in solution are in a state of continuous thermal motion. The displacement of their centre of gravity, which characterises the "macro-Brownian" motion[1], can be described according to Einstein's theory in terms of the translational diffusion coefficient D. The "micro-Brownian" motion of the individual segments of the macromolecule is determined by the rotational diffusion coefficient D_r and by the spectrum of relaxation times for the small-scale intramolecular motions[2]. The Brownian motion causes fluctuations in the concentration of the macromolecules in solution, and these fluctuations can scatter the electromagnetic energy when a light wave is passed through the solution. Therefore the light scattered by a solution of a polymer must contain (in principle) information on the kinetic characteristics of the macromolecules.

II. THEORETICAL FOUNDATIONS

The classical theory[3] deals with the scattering of light on time-averaged fluctuations of the concentration of the solution $\overline{(\Delta c)^2}$. This treatment leads to formulae giving the molecular weight of the dissolved macromolecules, their size, and the thermodynamic parameters of the solution–solvent system from the intensity of the scattered light[3].

In practice, however, the fluctuations are time-dependent owing to the presence of thermal Brownian motion, and therefore the time dependence of the fluctuations is determined by the kinetic parameters of the macromolecules in solution. Concentration fluctuations arise, grow, and disappear with time: this produces a modulation of the frequency of the scattered light, i.e. a shift of its frequency with respect to the incident frequency. The frequency shift can be interpreted as the manifestation of the Doppler effect during light scattering by moving macromolecules whose velocity in the solution is determined by the intensity of the Brownian motion. The light scattered by the solution will have a distribution of frequency (of variable width) with a profile centred on frequency of the incident light. Thus the width of the scattering spectrum carries information on the statistical distribution of the kinetic parameters of the macromolecules in solution.

The molecular theory of the spectral distribution of the intensity of light scattered by liquids was formulated by Komarov and Fisher[4], who used the mathematical framework of space–time correlation functions proposed by van Hove[5]. For any system of N particles we can define the probability density G_1 of finding a given particle at time $t = 0$ at a point in the solution having the coordinate r_0, and at time $t > 0$ at the point r, irrespectively of the position of the other particles. Another characteristic quantity (G_2) defines the probability density of finding a particle at the point r in the solvent at time $t > 0$ when another particle is at the point r_0 at time $t = 0$.

The functions G_1 and G_2 are the internal and the external autocorrelation function respectively. The internal autocorrelation function G_1 describes the probability of displacements of a given particle in the solution, the external function G_2 describes the probability of the relative displacement in the solution of two particles whose motions are assumed to be mutually independent.

The time autocorrelation function $G(\tau)$ for any function $x(t)$ is given by the expression

$$G(\tau) = \lim_{T\to\infty} \frac{1}{2T} \int_{-T}^{T} x(t)\, x^*(t+\tau)\, \mathrm{d}t = \langle x(t)\, x^*(t+\tau) \rangle ,$$

where $x(t)$ is the value of the function at time t, and $x^*(t + \tau)$ is the complex conjugate value of this function at time $t + \tau$: the angle brackets denote averaging with respect to time. The autocorrelation function differs from other averages in being independent of the variable τ.

The spectral density of the intensity of scattered light is found by a Fourier transformation of the space–time function for the scattering system:

$$\mathcal{J}(\omega) = \int_{-\infty}^{\infty} G(\tau) \exp(i\omega\tau)\, d\tau .$$

The theory of dynamic light scattering by solutions of polymers was developed by Pecora[6–8]. The theory is too complex to be reviewed in detail, and we shall confine ourselves to describing the main physical postulates on which it is based. Pecora considers two independent correlation functions. The first [the autocorrelation functions for the centre of gravity of the macromolecule, $G_\phi(\tau, \mathbf{r})$] is defined as the probability of finding the centre of gravity of a molecule at the point r at time $t > 0$ if at time $t = 0$ the centre of gravity of the same molecule is at the origin of the coordinate system. The second correlation function is the space–time correlation function $G_A(\tau, \mathbf{r})$, which defines the probability of a second segment of a macrmolecule being found at the point r at time $t > 0$ if an arbitrarily chosen segment of the same macromolecule is at the origin at time $t = 0$. Thus the quantity $G_A(\tau, \mathbf{r})$ defines the correlation between the motions of the segments within the macromolecule.

The optical spectrum of the scattered light is found by Fourier transformation of the correlation functions $G_\phi(\tau, \mathbf{r})$ and $G_A(\tau, \mathbf{r})$:[9]

$$\mathcal{J}(\omega) = \frac{N}{2\pi} \int_{-\infty}^{\infty} G_A(\tau, \mathbf{r})\, G_\Phi(\tau, \mathbf{r}) \exp[i(\omega - \omega_0)\tau]\, d\tau ,$$

where

$$G_A(\tau, \mathbf{r}) = \langle A(t) A^*(t+\tau) \rangle$$
$$G_\Phi(\tau, \mathbf{r}) = \langle \exp\{-i[\mathbf{q}, \mathbf{r}(t)]\} \exp\{i[\mathbf{q}, \mathbf{r}(t+\tau)]\} \rangle .$$

The vector q is the difference between the wave vectors of the incident and the scattered wave. Its numerical value is

$$q = \frac{4\pi n_0}{\lambda_0} \sin\frac{\vartheta}{2} .$$

In this expression n_0 is the refractive index of the medium, λ_0 is the wavelength of the incident light in a vacuum, and ϑ is the scattering angle.

The physical meaning of the quantity $A(t)$ can be explained as follows. The light wave scattered by every jth particle (of a total number N of particles) is defined by the equation

$$E_j = A_j(t) \exp\{-i[\mathbf{q}, \mathbf{r}_j]\} \exp(i\omega_0 t) ,$$

where $A_j(t)$ is the amplitude of the wave scattered from the jth particle.

The aggregate field of the light wave from N scattering elements is

$$E_s = \sum_{j=1}^{N} E_j = \sum_{j=1}^{N} A_j(t) \exp\{-i[\mathbf{q}, \mathbf{r}_j(t)]\} \exp(i\omega t) . \qquad (1)$$

The intensity of the scattered light is proportional to the square of the amplitude of the light wave:

$$\mathcal{J}_s = \langle |E_s|^2 \rangle , \qquad (2)$$

On the assumption that the light scattering events from all the particles in solution are mutually independent, carrying out the summation of Eqn.(2) after inserting Eqn.(1) into it gives

$$\mathcal{J}_s = \left\langle \sum_{j=1}^{N} |A_j|^2 \right\rangle = N \langle |A|^2 \rangle .$$

Thus the parameter $A(t)$ is the average amplitude of the scattered light wave.

If we ignore the intramolecular thermal motion of the macromolecules, i.e. if we neglect the rotational motion and the mutual displacement of the segments, the autocorrelation function takes it simplest form:

$$G_A(\tau, \mathbf{r}) = N |A|^2 .$$

The optical spectrum is given by the equation

$$\mathcal{J}(\omega) = N |A|^2 \frac{1}{2\pi} \int_{-\infty}^{\infty} \exp[i(\omega - \omega_0)\tau]\, G_\Phi(\tau)\, d\tau .$$

The autocorrelation function $G_\phi(\tau)$ can be calculated by noting that it describes a time dependence analogous to that of a large concentration fluctuation artificially imposed on the system at time $t = 0$.[10] Concentration changes in such a fluctuation obey Fick's law, which for $G_\phi(\tau)$ can be written as

$$\partial G_\varphi(\tau)/\partial\tau = D\nabla^2 G_\varphi(\tau) , \qquad (3)$$

where D is the translational diffusion coefficient of the macromolecule. Solving Eqn.(3) by the method of Fourier transforms in space gives

$$G_\varphi(\tau) = \exp(-Dq^2\tau) . \qquad (3')$$

Hence

$$\mathcal{J}(\omega) = \frac{N|A|^2}{2\pi} \int_{-\infty}^{\infty} \exp[i(\omega - \omega_0)\tau] \exp(-Dq^2\tau)\, d\tau =$$
$$= \frac{N|A|^2}{2\pi} \frac{q^2 D}{(\omega - \omega_0)^2 + (q^2 D)^2} . \qquad (4)$$

The shape of the spectral line is Lorentzian, centred on the frequency ω_0. The half-width of the Lorentz outline, $(\Delta\omega)_{1/2} = (\omega - \omega_0)_{1/2}$, is simply related to the translational diffusion coefficient:

$$(\Delta\omega)_{1/2} = q^2 D . \qquad (5)$$

Usually in dynamic light scattering experiments the solution is irradiated with polarised light, with the electric vector of the light wave in a vertical plane, and the intensity of the scattered light with the same polarisation is measured. The intensity of this component can be denoted $\mathcal{J}_{VV}$, and identified with the the quantity given by Eqn.(4). It is also possible to determine the intensity of the component of the scattered light in which the polarisation of the light wave is horizontal ($\mathcal{J}_{HV}$).

Formula (4) applies if the size of the macromolecule $(\overline{h^2})^{1/2}$ is much less than the wavelength λ_0 of the incident light. The criterion of smallness for a molecule in dynamic light scattering is the same as the criterion adopted in the classical theory of light scattering[3]: $(\overline{h^2})^{1/2} \leq \frac{1}{20}\lambda_0$. Under these conditions the internal interference (Debye) function is $P(\theta) = 1$. For large molecules, when $P(\theta) < 1$, the intensity of the light scattered by isotropic spherical symmetrical molecules is obtained by multiplying the right-hand side of Eqn.(4) by $P(\theta)$.[8] In this case the $\mathcal{J}_{VV}(\omega)$ spectrum is unaffected by intramolecular motion.

On the other hand if the macromolecule is asymmetrical the scattering spectrum is affected by the internal thermal motion (molecular rotation). Assuming that the translational and the rotational motion of the macromolecule are mutually

independent we obtain the following equation for the spectrum of the scattered light:

$$\mathcal{I}_{vv}(\omega) = \frac{4NA}{\pi}\alpha^2\left\{\left|\frac{1}{n}\sum_{j=1}^{n/2}J_0(qb_j)\right|^2\frac{q^2D}{(\omega-\omega_0)^2+(q^2D)^2} + \right.$$
$$\left. + 5\left|\frac{1}{n}\sum_{j=1}^{n/2}J_2(qb_j)\right|^2\frac{q^2D+6D_r}{(\omega-\omega_0)^2+(q^2D+6D_r)^2} + \ldots\right\}. \qquad (6)$$

The scattered light spectrum is the sum of two Lorentzian curves whose relative statistical weight is determined by the squares of sums containing the spherical Bessel functions J_0 and J_2 (zero-order and second-order respectively). In Eqn.(6) n is the number of segments, b_j is the distance of the jth segment from the centre of gravity of the macromolecule, and α is the polarisability of the macromolecule.

The intramolecular Brownian thermal motion affects the spectral distribution of the intensity of scattered light. The micro-Brownian motion in a group of macromolecules has been calculated[11] by using the sub-chain model (see, for example, Ref.12), in which the macromolecule is assumed to contain a number of linearly arranged, freely interconnected segments, each of which acts as a flexible "sub-chain". The hydrodynamic interaction with the solvent is transmitted by beads at the ends of the sub-chains, which have a significant mass and a coefficient of friction ξ. Each bead experiences highly elastic forces from the neighbouring sub-chains. The action of these forces is similar to that of a spring with linear characteristics, and the distance between the ends of sub-chains is assumed to have a Gaussian distribution.

Thus by studying the dynamics of motion of the segments in real macromolecules we are studying the dynamics of motion of a set of beads interconnected by elastic springs and immersed in a viscous medium. The motion of the jth bead determines the jth mode of the intramolecular motion, and is characterised by a relaxation time (τ_j). Unfortunately the theory does not allow us to calculate τ_j for all j. Only τ_1 (which refers to the rotation of the macromolecule as a whole) is theoretically calculable. For the two extreme cases of negligibly small and of maximum possible hydrodynamic interaction (penetrable and impervious group of macromolecules respectively) the following formulae have been obtained[11] for τ_1:

$$\tau_1 = \frac{6M[\eta]\eta_0}{\pi^2RT} \text{ and } \tau_1 = \frac{0.422M[\eta]\eta_0}{\pi^2RT}.$$

The spectrum of the scattered light with allowance for the intramolecular thermal motion by the Rouse and Zimm theory is described by the equation[13]

$$\mathcal{I}_{vv} = P_0(x)\frac{q^2D}{(\omega-\omega_0)^2+(q^2D)^2} + \sum_{j=2}^{\infty}P_1(x)\frac{q^2D+1/\tau_j}{(\omega-\omega_0)^2+(q^2D+1/\tau_j)^2} +$$
$$+\sum_{j=1}^{\infty}P_2(x)\frac{q^2D+1/\tau_j}{(\omega-\omega_0)^2+(q^2D+1/\tau_j)^2}. \qquad (7)$$

The argument z of the scattered light amplitudes P_0, P_1, and P_2 depends on the size of the macromolecules: $x = q^2\bar{h}^2/6$. For $0 \leq x \leq 1$ the only contribution to $\mathcal{I}_{vv}(\omega)$ is that of the diffusional motion of the centre of gravity of the macrmolecules, given by the first term in the right-hand side of Eqn. (7). The contribution of the internal motion to the spectral distribution of the intensity of scattered light becomes significant only when $x \gg 1$. These values of x are reached only in macromolecules having a mass $>10^6$ and in measurements with large scattering angles θ.[14]

If the macromolecule has a significant optical anisotropy the spectral distribution of scattered light intensity shows contributions from the translational motion of the centre of gravity of the macromolecules (D) and from the rotation of the molecule as a whole, characterised by the rotational diffusion coefficient D_r. The rotation of the macromolecules modulates the intensity of the scattered light at a frequency equal to the rotation frequency of the group of macromolecules: this effect is directly observable in the spectrum of the scattered light. The intensities of the $\mathcal{I}_{vv}$ and $\mathcal{I}_{Hv}$ components in the scattered light are given by

$$\mathcal{I}_{vv}(\omega) = \frac{NA}{9\pi}(\alpha_\parallel + 2\alpha_\perp)^2\frac{q^2D}{(\omega-\omega_0)^2+(q^2D)^2} + \frac{4}{3}\mathcal{I}_{Hv} \qquad (8)$$

$$\mathcal{I}_{Hv}(\omega) = \frac{NA}{9\pi}(\alpha_\parallel - \alpha_\perp)^2\frac{q^2D+6D_r}{(\omega-\omega_0)^2+(q^2D+6D_r)^2}, \qquad (9)$$

where $\alpha_\parallel$ and $\alpha_\perp$ are the polarisabilities of the macromolecules in directions parallel and perpendicular to the molecular axis respectively.

Eqns.(4), (6), (8), and (9) form the basis of all methods of determining D, D_r, and τ for macromolecules in solution from experimental measurements of the dynamic scattering of light.

In its present state of development the theory of the dynamic scattering of light does not allow for concentration effects in the system, i.e. it is strictly applicable only to solutions at infinite dilution. However, some experimental studies of the concentration dependence of the shape of the scattered line have been reported[15,16]. It is assumed implicitly that the equations which relate the shape of the spectrum to the parameters of the molecular motion remain valid at finite concentrations, but this assumption has no theoretical justification.

III. MEASUREMENTS PRINCIPLES

When using the dynamic light scattering method in practice we should note that the frequency shift of the scattered light for polymer solutions is of the order of $\Delta\omega \cong 10^3$–10^4 Hz. Therefore in order to distinguish these frequencies in the optical spectrum ($\omega_0 \cong 10^{15}$ Hz) we need a spectroscopic equipment with a resolving power of $\omega_0/\Delta\omega \cong 10^{11}$ or better. The resolving power of ordinary optical methods is far from being adequate for this purpose. Furthermore the spectral width of the incident light should be less than $\Delta\omega$: this condition can be met by using laser light.

The spectral distribution of the intensity of scattered light is studied by optical mixing methods, which are an extension to the optical frequency range of methods commonly used at radio frequencies[9,17]. The wanted signal is transmitted by using waves having a carrier frequency $\omega_0 \cong 10^6$ Hz, modulated at the frequency of the signal ($\Delta\omega$). In the detector these waves are mixed with a reference signal of frequency comparable to that of the carrier wave: the interference between the reference and the carrier frequency reveals the wanted signal $\Delta\omega$. By using a laser as the light source in conjunction with an FEU photoelectric amplifier and a spectrum analyser the same procedure can be applied to waves in the optical frequency range.

The optical mixing used in these measurements consists in the destructive interference of two light waves (reference, and carrier) incident on the cathode of the FEU. The result is a modulation of the current taken from the FEU. The modulation frequencies correspond to the frequencies in the wanted signal, and the signal is centred on the frequency difference between the reference wave and the information-carrying wave. If the frequency of the reference wave is comparable to that of the wave carrying the information (i.e. the light scattered by the polymer solution) the current taken from the FEU will display the frequencies of the wanted

signal. The dependence of the photocurrent on $\Delta\omega$ will be determined by the shape of the spectral line of the incident light, with the important difference from the normal optical methods (for example, the Fabry–Pérot interferometer or other similar apparatus) that the changes in photocurrent are now in the audio frequency range, whereas the frequency changes which define the shape of the spectral line are centred on the optical frequency $\omega_0 \cong 10^{15}$–10^{16} Hz.

The procedure can be illustrated as follows. Let a light wave of amplitude E_0 and frequency ω_0 fall on the scattering particles 1 and 2 in a state of Brownian motion with velocities v_1 and v_2. The light scattered by these particles (observed at an angle θ) will contain the Doppler frequency shifts $\Delta\omega_1$ and $\Delta\omega_2$ with respect to the base frequency ω_0. To simplify the discussion we shall assume equal amplitudes E_1 and E_2 of the components scattered by particles 1 and 2 in the light wave incident on the FEU photocathode. Since the current at the output of the FEU is proportional to the square of the amplitude of the light wave, and the FEU cannot resolve frequencies above 10^9 Hz, we can express the current I by the formula

$$I = \text{const} + E^2 \cos(\Delta\omega_1 - \Delta\omega_2)t .$$

Since $\Delta\omega_1$ and $\Delta\omega_2$ are ~10^3–10^4 Hz it follows from this equation that the photocurrent at the FEU output is modulated by two audio frequencies. In practice, of course, the shifted frequencies of the light wave ($\Delta\omega$) form a complex spectrum which characterises the system and is reflected in the frequency dependence of the photocurrent. Since the beat frequencies of the photocurrent are in the audio region they can be analysed with standard spectral frequency analysers used in radio technology. Their resolving power is usually better than 10 Hz, which is several orders better than the resolving power of ordinary optical spectroscopy equipment.

Two experimental arrangements can be used[9] to extract from the scattered light spectrum the signal carrying information on the kinetic parameters of the scattering macromolecules. In the first (homodyne) assembly the beam of scattered light strikes the surface of the photocathode, where interference between the frequencies contained in the spectral line can take place. In this case the wave whose frequency corresponds to the maximum of the spectral line of the scattered light acts as the reference wave. A beat signal centred on the frequency 0 Hz appears at the output of the FEU. In the second (heterodyne) scheme a reference (base) beam of light of frequency ω_b, obtained from a separate source, is directed at the photocathode together with the experimental beam of scattered light. In this case the beat signal is centred on the frequency $\omega_0 - \omega_b$. If the same laser is used as the base source and for generating the signal, $\omega_0 - \omega_b = 0$, and the signal is centred on the frequency 0 Hz (as in the homodyne variant).

We note that the description "centred" is applied to the beat signal on the understanding that only frequencies $\omega > 0$ have a real significance, i.e. the beat signal has only one branch. We should also stress that so far no really ambiguous names have been proposed for the two variants described above. In particular, the homodyne method has been called the self-beat method[10].

At present the homodyne method of producing beat signals is the more widely used. In the homodyne scheme the photocurrent duplicates the outline of the scattered line (except for a d.c. component and the shot noise of the FEU), but with double the width:

$$I(\omega) = C_1 \frac{2q^2D}{(\Delta\omega)^2 + (2q^2D)^2} , \qquad (10)$$

In the heterodyne scheme the outline of the photocurrent line exactly duplicates that of the scattering line of the spectrum.

A typical homodyne assembly[19] for measuring $\mathcal{I}_{vv}$ at different scattering angles θ is shown in Fig. 1. It consists of a circular photoelectric nephelometer in which the intensity of scattered light can be measured for angles in the range $\theta = 30$–$150°$. The experimental solution is placed in the cylindrical cell K, on which the light of a He–Ne laser ($\lambda_0 = 632.8$ nm) is focussed by the diaphragms D_1 and D_2 and the lens L_1. To optimise the signal-to-noise ratio the scattering volume and its reflection on the photocathode should be as small as possible[9]. By focussing the laser radiation the beam diameter can be reduced to 0.2–0.3 mm. The scattered light is focussed on the photocathode of the FEU by the diaphragm D_3 and L_2, whose focal length is chosen to give an image on the photocathode smaller than the diameter of the light beam in the measuring cell K. The photocurrent from the output of the FEU is taken to the KP amplifier, which has linear frequency characteristics and a stable gain at audio frequencies. The d.c. component of the FEU output is eliminated by a capacitor and the current from the KP is led to the input of the spectrum analyser SA (standard radiotechnical model).

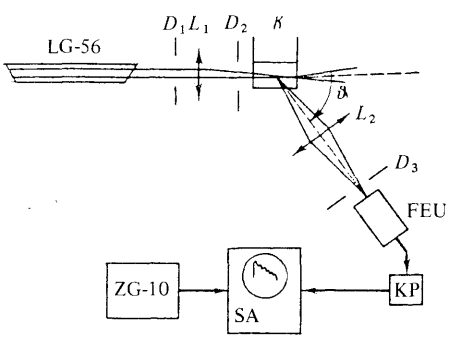

Figure 1. Homodyne variant of the apparatus for studying the dynamic scattering of light in polymer solutions[19]

The spectral distribution of the intensity of scattered light is displayed by analysing the frequency dependence of the photocurrent, $I(\omega)$, at the output of the SA. The photocurrent is characterised by comparing it with the mathematically expected signal and its frequency dependence. The audio frequency generator ZG-10 is used to calibrate the frequency scale of the scan of the SA oscilloscope. The frequency at which the signal is 3 dB down is measured for $\Delta\nu = (\Delta\omega)/2\pi \to 0$. This frequency $(\Delta\nu)_{1/2}$ is assumed to be equal to the half-width of the photocurrent line. In the

homodyne variant the parameter $(\Delta\nu)_{1/2}$ is related to the diffusion coefficient by the equation

$$2\pi(\Delta\nu)_{1/2}=(\Delta\omega)_{1/2}=2q^2D\ , \qquad (11)$$

measured at different values of θ and extrapolated to $\theta = 0$ the intercept on the vertical axis is

$$(\Delta\omega)_{1/2}=6D_r\ , \qquad (12)$$

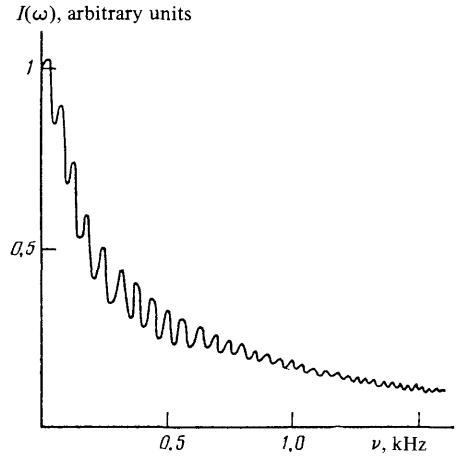

Figure 2. Outline of the photocurrent line on the screen of the spectrum analyser for a solution of the $M = 10^7$ fraction of polystyrene in toluene; $c = 0.05\%$, scattering angle $\theta = 60°$.[19]

A typical plot of the photocurrent against frequency at the FEU output, photographed from the screen of the spectrum analyser, is shown in Fig.2.

IV. SOME EXPERIMENTAL RESULTS

Measurements of $(\Delta\omega)_{1/2}$ as a function of θ are shown in Fig.3 for some polymer solutions. The D values calculated from the slope of the lines are given in Table 1 together with the D values obtained by an independent method (polarisation interferometry). The concentration of the solutions were the same in both sets of measurements (~0.05%). As Table 1 shows, the agreement between the D values obtained by the two methods is acceptable.

We note that the extrapolation of curve *2* in Fig.3 does not pass through the origin. This effect is due to the anisotropic component of the light scattered by polystyrene (PS) solutions. It follows that at the highest molecular weights the amplitude modulation of the light scattered by PS solutions is large enough to be experimentally detectable. Amplitude modulation of the scattered light results from the rotational motion of macromolecules showing optical anisotropy.

The $\mathcal{J}_{VV}$ spectrum of the scattered light for an anisotropic molecule is the sum of at least two Lorentzian curves according to Eqn.(8). The half-width is determined by the parameters D and D_r, and the contribution from the translational diffusion decreases as the scattering angle decreases. In principle this allows us to separate the component due to molecular rotation from the overall spectrum. If $(\Delta\omega)_{1/2}$ is

Table 1. Diffusion coefficients D for some polymers, determined by dynamic light scattering and by measurements of longitudinal diffusion in solutions[19].

Polymer	Solvent	$10^{-6}M$	$10^{11}D$, $m^2 s^{-1}$	
			light scattering	longitudinal diffusion
Polystyrene	toluene	1.0	1.3	1.4
Polystyrene	»	13.0	0.6	0.5
Styrene–methyl methacrylate block copolymer	butyl acetate	0.6	1.6	1.8
Polyvinyltrimethylsilane	cyclohexane	0.5	1.0	1.04

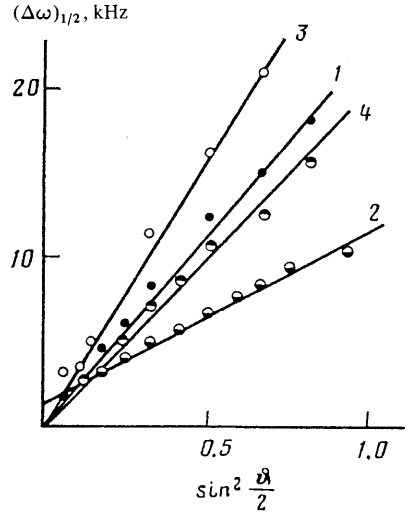

Figure 3. Plots of the half-width of the scattering angle $(\Delta\omega)_{1/2}$ against $\sin^2\theta/2$ for polystyrene (*1*, *2*), the styrene–methyl methacrylate block copolymer (*3*), and polyvinyltrimethylsilane (*4*).[19]

Experiments of this type for F-actin are reported in Ref. 20. The D_r values calculated by Eqn.(12) were close to the values given by other methods for this polymer.

An analysis of the frequency dependence of $\mathcal{J}_{VV}$ has been reported[21] for the PS fraction with $M = 10^7$ in benzene and decalin. An appropriately oriented Frank–Ritter prism was inserted into the scattered light path of the apparatus shown in Fig.1 to separate $\mathcal{J}_{VV}$ from the overall scattered intensity. The root mean square radius of inertia of the PS molecule in benzene was found to be $(\overline{R^2})^{1/2} = 140$ nm from the light scattering results. This value of $(\overline{R^2})^{1/2}$ accounted for a change from 6 to 1 in $x = q^2\overline{h^2}/6 = q^2\overline{R^2}$ for solutions in benzene over the working range of scattering angles. The range of x values for solutions of PS in decalin was calculated from the radius of inertia of the PS macromolecules

obtained by Flory's formula from the characteristic viscosity. The choice of these solvents was dictated by the difference in their thermodynamic properties in relation to PS and by the large difference in their viscosities.

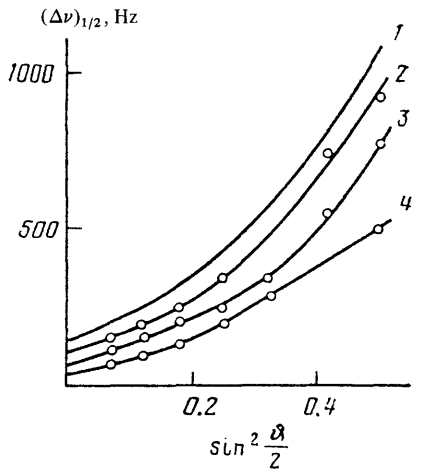

Figure 4. Plots of the half-width of the scattering line $(\Delta\nu)_{1/2}$ against $\sin^2\theta/2$ for solutions of the $M = 10^7$ fraction of polystyrene in toluene at different concentrations: *1*) 0; *2*) 0.06; *3*) 0.12; *4*) 0.18 g/100 cm^3.[21]

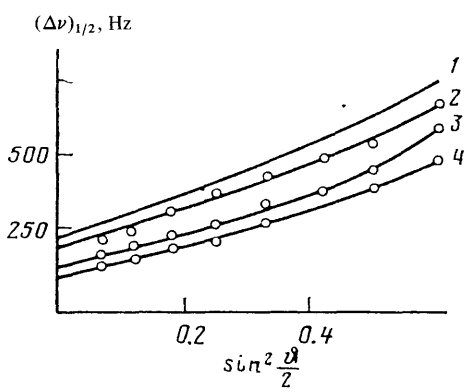

Figure 5. Plots of the half-width of the scattering line $(\Delta\nu)_{1/2}$ against $\sin^2\theta/2$ for a solution of the $M = 10^7$ fraction of polystyrene in decalin at different concentrations: *1*) 0, *2*) 0.05, *3*) 0.12, *4*) 0.17 g/100 cm^3.[21]

The dependence of $(\Delta\nu)_{1/2}$ on $\sin^2\theta/2$ for solutions of PS in benzene and in decalin at different concentrations is shown in Figs.4 and 5. The shape of the scattering line at all the concentrations can be described as the sum of at least two Lorentz curves, as indicated by the non-linearity of the plots in Figs.4 and 5. The width of the spectral distribution of the scattered light intensity increases as the concentration of the solution decreases. The results were therefore extrapolated to zero concentration. Fig.6 shows the dependence of $(\Delta\nu)_{1/2}$ on the concentration of the solution c for the scattering angle $\theta = 0$: the plot is linear within experimental error. Linear plots of $(\Delta\nu)_{1/2}$ against c were obtained also for other (non-zero) scattering angles. Plots of $(\Delta\nu)_{1/2}$ against $\sin^2\theta/2$ for $c = 0$ are shown as the upper lines in Figs.4 and 5. Extrapolation of the data in Fig.6 to $\theta = 0$ gave the $(\Delta\nu)^0_{1/2}$ values: the half-widths of the scattering spectra for $\theta = 0$ and $c = 0$. The $(\Delta\nu)^0_{1/2}$ values were used to calculate the rotational diffusion coefficients of the PS molecules in benzene and decalin by the equation

$$2\pi(\Delta\nu)^0_{1/2} = (\Delta\omega)^0_{1/2} = 2 \cdot 6D_r \,. \qquad (13)$$

The D_r values and some physical parameters of the PS solutions are given in Table 2.

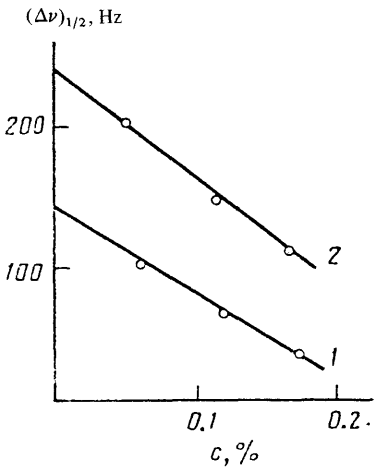

Figure 6. Dependence of $(\Delta\nu)_{1/2}$ at the scattering angle $\theta = 0$ on the concentration of the solution (c) for the $M = 10^7$ fraction of polystyrene in toluene (*1*) and in decalin (*2*).[21]

Table 2. Physical characteristics of solvents and of the solutions of the $M = 10^7$ fraction of polystyrene[21]

Solvent	$10^3\eta_0$, Pa s	x	D_r, s^{-1}	
			light scattering	FBR
Benzene	0.64	1—6	120	100
Decalin	2.07	0.6—3.4	80	—

At low values of the scattering angle θ the parameter $\mathcal{J}_{vv}$ is controlled by the first term of Eqn.(8). Under these conditions the dependence of $(\Delta\nu)_{1/2}$ on $\sin^2\theta/2$ is described by a straight line whose slope is proportional to the translational diffusion coefficient D. Using the homodyne method of detecting the scattered light we find, for small θ,

$$2\pi[(\Delta\nu)_{1/2} - (\Delta\nu)^2_{1/2}] = 2q^2D \,. \qquad (14)$$

The diffusion coefficients of the PS fraction calculated for $c = 0$ from the initial slope of the curves in Figs.4 and 5 are $D = 0.4 \times 10^{-11}$ m^2 s^{-1} in benzene and 0.2×10^{-11} m^2 s^{-1} in decalin.

It is interesting to compare the D_r values obtained in this way with data on the rotational diffusion coefficient of PS in benzene calculated from measurements[22] of flow birefringence (FBR). According to those measurements, $D_r = 100$ s^{-1} for the $M = 10^7$ fraction of PS. This is acceptably close to the value $D_r = 120$ s^{-1} given by the dynamic light scattering method (see Table 2). The difference between the two values is probably due partly to the difference between the methods of determining D_r and partly to the dependence of $\mathcal{I}_{VV}$ on the mode of dispersion of the sample. The effective spectral broadening (and therefore also the D_r value) for $x < 10$ is greater for polydispersed than for monodispersed samples[23].

The role of the second term in Eqn.(8), which according to Eqn.(9) is proportional to $(\alpha_\parallel - \alpha_\perp)^2$, increases markedly with the anisotropy of the macromolecules. In principle, the anisotropic component $\mathcal{I}_{HV}$ can be measured at the scattering angle $\theta = 0$. This allows complete elimination of the Doppler effects due to the translational motion of the macromolecules on the spectral distribution[24,25]. From Eqn. (9) for $\theta = 0$ we obtain

$$\mathcal{I}_{Hv} = \frac{NA}{9\pi}(\alpha_\parallel - \alpha_\perp)^2 \frac{6D_r}{(\Delta\omega)^2 + (6D_r)^2} .$$

Under these conditions the scattering spectrum has a simple Lorentz outline. The half-width of the spectrum is determined by Eqn.(12). Hence there are at least two possible ways of decoupling the component contributed by the rotation of an anisotropic molecule from the scattering spectrum: extrapolation of the data obtained from measurements of $\mathcal{I}_{VV}$ to zero angle of scattering and direct measurements of $\mathcal{I}_{HV}$ at $\theta = 0$.

Parallel measurements of the angular dependence of $\mathcal{I}_{VV}$ and of the parameter $\mathcal{I}_{HV}$ at $\theta = 0$ have been made on solutions of three samples of poly-γ-benzyl-*L*-glutamate (PBG) in dimethylformamide (DMFA).[21] Because of their rigidity the molecules of this polymer have a high segmental anisotropy: $(\alpha_\parallel - \alpha_\perp) = 400 \times 10^{-23}$.[26] This is almost two orders of magnitude higher than typical values for polymers with flexible chains. Hence in the case of solutions of PBG in DMFA we can extract the anisotropic component from the overall spectrum with confidence.

The parameter $\mathcal{I}_{VV}$ for solutions of PBG in DMFA was measured at different angles of scattering by the apparatus shown in Fig.1. On the other hand, for measurements of $\mathcal{I}_{HV}$ at $\theta = 0$ the following optical assembly was used. The experimental solution was placed in a glass cell in the shape of a tube 15 mm in diameter and 10 cm long in the path of the light beam. The cell was located between crossed Frank–Ritter prisms, one of which (at the point of entry of the beam into the cell) polarised the laser light in a vertical plane, while the other (following the cell) separated the $\mathcal{I}_{HV}$ component of the scattered light. Because the polarisation by the prisms was not perfect, part of the primary beam reached the photocathode of the FEU. The horizontal component of this primary beam, which had an elliptical polarisation, was used as the reference beam in the heterodyne detection method. The current from the FEU was taken to a specially designed amplifier, assembled from micro-modules, incorporating high- and low-frequency corrections and having a high gain at audio frequencies. The signal was then passed to the input of the spectrum analyser. The spectral distribution of the photocurrent observed on the SA screen had the same width as the scattering spectrum[9]. All the recorded spectrograms were similar to those shown in Fig.5.

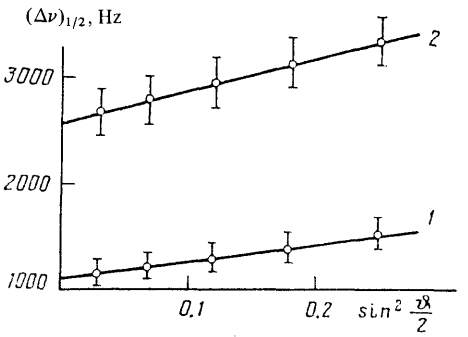

Figure 7. Dependence of $(\Delta\nu)_{1/2}$ on $\sin^2\theta/2$ for solutions of PBG samples 1 and 2 in DMFA.[21]

Table 3. Experimental data for solutions of PBG in DMFA.[21]

Sample	$10[\eta]$, m^3 kg^{-1}	$10^{13}s$, s	$10^{-3}M_\eta$	$10^{-3}M_{s\eta}$	$10^{11}D$, m^2 s^{-1}	$10^{-3}M_{sD}$	D_r, s^{-1} from $\mathcal{I}_{Hv}$	D_r, s^{-1} from $\mathcal{I}_{vv}$	D_r, s^{-1} from FBR
1	8.2	3.5	370	330	0.84	360	630	570	580
2	3.7	3.0	220	180	1.30	220	1160	1400	1350
3	0.8	2.2	83	70	—	—	5900	—	6600

Symbols: $[\eta]$ is the characteristic viscosity; s is the sedimentation coefficient; M_η is the molecular weight of PBG calculated from the $[\eta]$ value by the Mark–Koene equation; $M_{s\eta}$ is the molecular weight calculated from $[\eta]$ and s using the hydrodynamic constant A_0; M_{sD} is the molecular weight calculated from sedimentation and diffusion data.

Fig.7 shows the dependence of $(\Delta\nu)_{1/2}$ on $\sin^2\theta/2$ for PBG samples 1 and 2, plotted from measurements of the angular dependence of the $\mathcal{I}_{VV}$ spectrum. We note that the plots do not go through the origin. A corresponding plot for sample 3 could not be obtained because of the high noise level and the large width of the spectrum. The curves in Fig.7 were used to calculate the translational diffusion coefficients D of samples 1 and 2 by formulae (14). The results are given in Table 3 with the molecular weights of the PBG samples. The M values were determined in various ways: from characteristic viscosity $[\eta]$ data, inserted into the equations of Mark and Koene[26], from sedimentation and viscosimetric data, using the hydrodynamic constant $A_0 = 4.1 \times 10^{-17}$ J K^{-1}, and in the case of samples 1 and 2 from measurements of D and s, where s is the sedimentation coefficient[26]. The similarity between the M values obtained by different methods suggests that the PBG samples are not significantly polydispersed.

The rotational diffusion coefficient D_r is calculated from the intercept on the vertical axis of the plot of $(\Delta\nu)_{1/2}$ against $\sin^2\theta/2$ (Fig.7). In the homodyne variant of the detection system the quantities $(\Delta\nu)^0_{1/2}$ and D_r are related by Eqn.(13). It follows from Fig.7 that for the PBG samples

1 and 2 the $(\Delta\nu)^0_{1/2}$ values are (respectively) 1100 ± 100 and 2600 ± 200 Hz. The D_r values derived from these[21] by formula (13) are given in Table 3.

The second method of determining D_r consists in finding $(\Delta\nu)_{1/2}$ for the scattering angle $\theta = 0$ for the $\mathcal{J}_{H\nu}$ spectrum[24]. In the heterodyne detection variant the quantity $(\Delta\nu)_{1/2}$ is related to the rotational diffusion coefficient by the expression

$$2\pi(\Delta\nu)_{1/2} = (\Delta\omega)_{1/2} = 6D_r \ . \qquad (15)$$

The values of $(\Delta\nu)_{1/2}$ determined from the photocurrent spectra for the PBG samples 1, 2, and 3 were 600 ± 50, 1100 ± 100, and 5600 ± 500 Hz respectively at $\theta = 0$. These values were used to calculate the rotational diffusion coefficients D_r (also given in Table 3).[21] It is evident that the two methods of calculating D_r give similar results.

These values can be compared also with measurements[26] of the rotational diffusion coefficient of PBG in DMFA by the dynamic flow birefringence method. Values of D_r calculated from those measurements for PBG fractions of molecular weight corresponding to samples 1, 2, and 3 are also given in Table 3. We note that the D_r values calculated from the dynamic flow birefringence are close to those obtained by the dynamic light scattering method.

The measurement of D by the dynamic light scattering method has some important advantages over the conventional refractometric methods. Firstly, the principle of the measurement is more rational: we observe "self-diffusion" rather than diffusion across a boundary. Thus the creation of a solvent–solution diffusion boundary becomes unnecessary. The measurements of D are carried out under conditions of strict thermodynamic equilibrium. The measurement time is much shorter: a measurement of the angular dependence of $\mathcal{J}_{\nu\nu}$ and calculation of D can be completed in 15–20 min, whereas a refractometric determination of D usually requires at least 24 h. Because of the shorter experimental times the requirements on the temperature stability of the experimental cell are less demanding. On the other hand, like all light scattering experiments, the method requires painstaking purification of the solutions and cleaning of the cells[3].

V. FURTHER DEVELOPMENTS OF THE METHOD

The dynamic light scattering method has been used not only to determine the hydrodynamic characteristics of macromolecules (D,[27,28] D_r,[29] and the parameters of the intramolecular motion and of the relaxation processes in polymer chains[30,31]), but also to study cooperative diffusion in concentrated polymer solutions[32] and chain mobility in polymer gels[33], and to monitor the dynamics of the formation of critical fluctuations in polymer solutions[34] and molecular motion in polymer networks[16] and in polymer films adsorbed on a different polymer[35]. Attempts have been made to apply the dynamic light scattering method in studies of the kinetics of chemical reactions[8,17,18,36].

Dynamic light scattering assemblies incorporating minicomputers (correlometers) for direct calculation of the correlation function $G_\phi(\tau)$ are now widely used[9,37]. In the homodyne method of recording the photocurrent the autocorrelation function $G_\phi(\tau)$ is simply related to the autocorrelation function of the photocurrent $G_I(\tau)$ by the expression[37]

$$G_I(\tau) \approx 1 + f|G_\varphi(\tau)|^2 \ , \qquad (16)$$

where the constant $f \leq 1$ is a correction for incoherent effects and for the finite time of flight of electrons. Inserting the expression (3′) for $G_\phi(\tau)$ into Eqn.(16) gives

$$G_I(\tau) = 1 + f\exp(-2q^2D\tau) \ . \qquad (17)$$

This equation applies to small isotropic particles for $x < 1$. In the case of anisotropic molecules the spectrum of the scattered light ($\mathcal{J}_{\nu\nu}$) is given by Eqn.(8). The autocorrelation function of the photocurrent $G_I(\tau)$ in this case becomes, to a first approximation,

$$G_I(\tau) = 1 + C_1\exp(-2q^2D\tau) + C_2\exp[-(q^2D + 6D_r)\tau] \ , \qquad (18)$$

where C_1 and C_2 are constants. We note from formulae (17) and (18) that the autocorrelation function of the photocurrent is a simple exponential or the sum of two exponentials. This greatly simplifies the interpretation of the results and the calculation of D and D_r.

The most noteworthy of the assemblies developed for analysing the spectral distribution of the light it is the quadratic detection spectrometer described in Ref.38. It can be used to analyse the spectral distribution of light intensity in scattered light. A special attachment to this spectrometer for calculating the autocorrelation function $G_\phi(\tau)$ has also been developed[39].

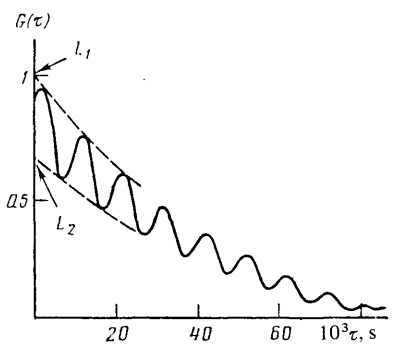

Figure 8. Autocorrelation function for the light scattered by a polystyrene suspension in a vibrating cell[40].

We should note a further potential application of dynamic light scattering. Japanese workers[40] have proposed a new method of determining the sedimentation coefficient of dissolved particles. Vibrational acceleration is applied to the polymer solution by setting the cell and the solution in vibrational motion with a frequency ω_V and amplitude a_V. The autocorrelation function of the photocurrent in this case is an exponential [given, for example, by Eqn.(17) with a superimposed sinusoidal oscillation of frequency ω_V produced by the sedimentation motion of the particles (Fig.8)]. The amplitude of these oscillations is proportional to the amplitudes a_i of the relative displacement of the particles in the solution. On the spectral distribution of the photocurrent this autocorrelation function corresponds to two maxima with a Lorentz outline and centred on the frequencies $\omega = 0$ and $\omega = \omega_V$. The parameter a_i can be evaluated from the ratio of the heights of these maxima. The average sedimentation coefficient is given by the expression

$$(\overline{s^2})^{1/2} = \frac{1}{a_V\omega_V}\left(\sum A_i a_i^2\right)^{1/2} \ , \qquad (19)$$

where A_i is the relative intensity of the light scattered by the *i*th particle. Formula (19) applies to the heterodyne variant of the method of light detection. The degree of polydispersion of the dissolved particles can also be obtained if the homodyne variant of the apparatus is used.

By solving the equation of motion for the *i*th particle of a solution in a vibrating cell in terms of the autocorrelation function $G_I(\tau)$ and averaging over all the particles the authors[40] converted Eqn.(19) into

$$s = \frac{1}{a_v \omega_v} \frac{L_1 - L_2}{L_1} \quad (20)$$

where L_1 and L_2 are the intercepts obtained by extrapolating to the ordinate axis the envelopes of the sinusoidal modulation of the autocorrelation function $G_I(\tau)$ shown in Fig.8. Formula (20) is valid for small vibration amplitudes a_v, and it offers a practical method of calculating *s* from dynamic light scattering data. The criterion for smallness of the vibration amplitude of the cell is a displacement a_i during one vibration period smaller than the wave length of the laser radiation.

As well as *s* we can determine the translational diffusion coefficient *D* from the upper envelope of the autocorrelation function $G_I(\tau)$, using (for example) Eqn.(17). Of course, this parameter can also be determined by studying light scattering without vibration of the cell.

The original paper[40] describes a study of the sedimentation of a suspension of polystyrene latex in water by this method. The sedimentation coefficient of the latex measured in an ultracentrifuge was $s = 2.81 \times 10^{-7}$ s, and the value calculated by Eqn.(20) from the autocorrelation function of the scattered light was 3.0×10^{-7} s. Thus the effectiveness of the proposed method of determining *s* from measurements of dynamic light scattering was convincingly demonstrated. There is no evidence that the method has been adopted in other laboratories so far, but any attempt to develop new methods of determining sedimentation coefficients without resorting to the traditional ultracentrifuge techniques cannot fail to attract interest.

To conclude this review we should mention one more method, developed during the past 2 or 3 years: the use of holography in studies of dynamic light scattering[41]. The holographic correlometer with phase modulation has been used successfully in studies of ultra-slow molecular motions in very viscous scattering media[41].

The dynamic light scattering method offers some important advantages over the traditional methods of studying the translational and rotational mobility of macromolecules. These advantages are discussed above. However, the apparatus which has to be used to analyse the frequency dependence of the photocurrent is fairly complex. The experimenter must have had some previous experience of working with a spectrum analyser, and he must be familiar with modern methods of correlation analysis, including the use of correlometers (a highly specialised form of digital computer).

New fields of application of dynamic light scattering have been identified in recent years. In addition to the existing studies of the mobility of polymeric molecules[42], the properties of polyelectrolyte solutions at different ionic strengths have been investigated[43,44]. Dynamic light scattering is being studied in concentrated solutions and in gels[45], and the transition temperature in macromolecular systems (polystyrene[46] and poly(methyl methacrylate)[47]) are being determined. Additions to this list in the near future are likely. Thus we may conclude that the dynamic light scattering method is being successfully developed.

The Photoelectron Spectra and Molecular-orbital Characteristics of Covalent Aromatic Organoelemental Compounds

V.F.Traven' and B.I.Stepanov

The effects of the interaction of various heteroatoms (and heteroatomic fragments) with carbon π-electron systems in covalent organoelemental compounds are discussed in the review in terms of molecular orbital theory. Particular attention is devoted to the analysis of the structure of the molecular orbitals, determined from photoelectron spectroscopic data and quantum-chemical calculations within the framework of the simple Hückel molecular orbital method parametrised on their basis. It is shown that the parameters characterising the mixing of the orbitals in model compounds can be used to obtain the molecular-orbital characteristics and to interpret the spectroscopic properties and reactivities of complex heteroaromatic compounds.

I. INTRODUCTION

The photoelectron spectra of aromatic organoelemental compounds, in which the heteroatoms are present in substituents or rings, together with the corresponding quantum-chemical calculations within the frameworth of the simple method make it possible to estimate the orbital mixing parameters of individual fragments in the molecules of these compounds and to obtain objective data for the molecular orbitals (MO), which determine the spectroscopic properties and reactivities of the compounds. Such information is important for the study of problems of chemical bonding within the framework of the molecular orbital theory and for the solution of practical problems—the establishment of new aromatic organoelemental systems[1], the synthesis of effective π-donors[2-5], the synthesis of phototropic compounds[6,7], etc. The interaction of the orbitals in aromatic organoelemental compounds has been analysed in reviews[8-11] concerned with the study of the influence of various substituents on the ionisation energies of substituted benzenes; the role of unoccupied *d* orbitals in certain organoelemental compounds has been discussed[12-16] and the ability of the atoms of heavy elements to form double bonds with carbon and with one another, etc. has been considered[17,18].

This review presents a survey of the quantitative estimates for the mixing of the orbitals of the π-electron systems of the carbon atoms and various non-carbon element-containing substituents and fragments incorporated in the rings. The estimates have been obtained from the analysis of the photoelectron spectra (PES) of the corresponding compounds and from quantum-chemical calculations within the framework of the simple method. We shall consider some aspects in greater detail.

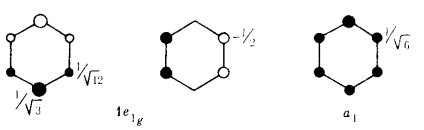
In both non-empirical and semiempirical quantum-chemical calculations the orbitals of whole groups or molecular fragments rather than the atomic orbitals (AO) are used as the basis orbitals. In non-empirical calculations this is the SAMO method (simulated *ab initio* technique)[19,20], while in semiempirical calculations it is the group orbital method[20-24], which explains successfully the spectroscopic properties of many organic and organoelemental compounds[25-27]. Following the development of PES, the corresponding computational schemes have been applied effectively also in the simple quantum-chemical approximations[28,29]. Within the framework of such calculations, the molecular orbital is treated as a linear combination of bond orbitals in the LCBO-MO method[30-32], for example, while in the LCFO-MO scheme[33] it is treated as a linear combination of fragment orbitals. Despite the differences between the names and in certain specific problems, the essential features of the above schemes are identical; instead of atomic orbitals, "effective" orbitals, for example those of the individual molecular fragments, are considered in the basis set. Such schemes make calculations significantly less laborious and yield a particularly large amount of information in the study of the electronic and molecular structures of complex organoelemental compounds and in the first place compounds containing the elements of high Periods for which there are frequently no parameters in semiempirical methods.

In the solution of the Roothaan equations

$$\sum_{\mu=1}^{N} c_{\mu i}\,(H_{\mu\nu} - \varepsilon_i \delta_{\mu\nu}) = 0\,,$$

where μ and ν are the indices of the basis fragment orbitals, i is the index of the molecular orbital, $c_{\mu i}$ and ε_i are the coefficients and energies of the molecular orbitals, and $\delta_{\mu\nu} = 1$ (for $\mu = \nu$) or 0 (for $\mu \neq \nu$) is the Kronecker delta, by the simple method (Hückel's π-approximation), the influence of the interelectron interaction is taken into account implicitly in the parametrisation of the skeletal integrals $H_{\mu\mu}$ and $H_{\mu\nu}$. In particular, compared with the rigorous semiempirical methods in which the skeletal integrals are parametrised on the basis of atomic spectroscopic data, in the simple method the parametrisation based on molecular electronic spectra is apparently more useful: it has been suggested that $H_{\mu\mu}$ and $H_{\mu\nu}$ be estimated from photoelectron spectroscopic data for "model" compounds in which the corresponding μth and νth orbitals of the fragments are characterised by unoverlapped ionisation bands[28-31]. The parameters $H_{\mu\mu}$ and $H_{\mu\nu}$ found from the molecular spectra include to some extent the interelectronic effects (see below).

In terms of the π-approximation, only those fragment orbitals which have π-symmetry (or are close to it) relative to the molecular plane are included in the basis set of the simple calculation. For example, within the framework of the method of fragment orbitals, the integral H_S, corresponding to the $3p_\pi$ orbital of the sulphur atom in heterocyclic and heteroaromatic compounds, is estimated from the PES of compounds in which the sulphur atom is linked to two carbon atoms, in particular, the spectra of dimethyl sulphide[35] and not from the atomic spectrum of sulphur (where the ionisation potential of the $3p$ orbital is 13.32 eV[34]) and not from the PES of hydrogen sulphide (the ionisation potential of the b_1 orbital formed by the $3p_\pi$ orbital of sulphur is 10.47 eV[30]). One should bear in mind that in a compound of this kind (C_{2v} symmetry group) not only the $3p_\pi$(S) atomic orbital but also the (+)-combination of the $2p_\pi$ orbitals of two carbon atoms belong to type b_1. For this reason, the highest occupied molecular orbital ($2b_1$ orbital) of dimethyl sulphide is not identical with the p orbital of the sulphur atom, although it is generated predominantly by this orbital†:

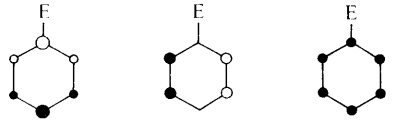


$$H_S = -I_{2b_1}^{SMe_2} = -8.67 \text{ eV}\,.$$

It is important to note that a further increase in the complexity of the molecule of the "model" compound alters little the parameter $H_{\mu\mu}$. For example, $H_S = -8.80$ eV, estimated in terms of the ionisation potential of the $3p_\pi$ orbitals of two sulphur atoms from the PES of 1,4-di(methylthio)benzene[30], differs only slightly from $H_S = -8.67$ eV found from the PES of dimethyl sulphide.

The parameters corresponding to the fragment orbitals localised predominantly at the atoms of other Group V–VII elements can be found analogously by simple quantum-chemical calculations in terms of the π-approximation; in this review these parameters are denoted respectively by H_O, H_{Se}, H_N, H_{Br}, etc.

The fragment orbitals involving the sp^3-hybridised orbitals of the atoms of Group IVA elements are taken into account in the calculations under consideration within the framework of the $\sigma-\pi$ conjugation scheme. The possibility of the overlap of the orbitals of the π- and σ-bonds located in a single plane but directed at an angle ϕ relative to one another has been discussed in detail in connection with the hyperconjugation model[36] and in another study[37] where this model was developed for organoelemental benzene derivatives. The integrals $H_{\mu\mu}$ corresponding to the σ(E–S) orbitals, are estimated from the first ionisation potentials of the compounds EMe_4: the orbitals of the four σ(E–C) bonds of the tetrahedral EC_4 fragment transform within the framework of the T_d symmetry group as $3t_2 + 1a_1$ and the triply degenerate t_2 orbital proves to be the highest occupied orbital. The corresponding diagonal matrix elements $H_{\mu\mu}$ will henceforth be designated by H_{EC}.



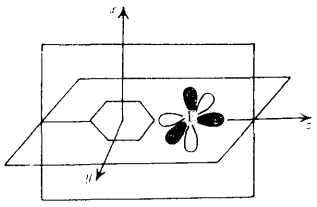
For the purpose of the present review, the π orbitals of aromatic hydrocarbons which can mix with the orbitals of the heteroatoms in heteroaromatic compounds are of special interest. The molecular orbitals of benzene have been studied in many investigations[38-45]. For example, according to the data of Dewar et al.[43] three π orbitals of benzene (the classification corresponds to the D_{6h} symmetry group) belong to types e_{1g} and a_{2u} and have the following coefficients (the filled circles correspond to positive coefficients and the open circles to negative coefficients; the size of the circles is proportional to the absolute magnitude of the coefficient):

It is known from the PES of benzene that the ionisation potential of the a_{2u} orbital is 12.23 eV[43] and the two degenerate e_{1g} orbitals have identical energies (their ionisation potential is 9.24 eV). Their degeneracy is removed after the introduction of a substituent E into the benzene molecule. In monosubstituted benzene derivatives C_6H_5E (C_{2v} symmetry) the benzene π orbitals transform as b_1, a_2, and b_1:

† According to a calculation by the extended Hückel method, the contribution of the $3p_\pi$ orbital of the sulphur atom is not less than 85% of the highest occupied molecular orbital (HOMO) of dimethyl sulphide.

they have come to be designated as the $\varphi_{\pi(sym)}$, $\varphi_{\pi(asym)}$, and φ_{π_1} orbitals respectively#:

$\varphi_{\pi(sym)}$, b_1 $\varphi_{\pi(asym)}$, a_2 φ_{π_1}, b_1



In conformity with the foregoing, in quantum-chemical calculations parametrised on the basis of PES data (simple method, π-approximation), the following diagonal elements $H_{\mu\mu}$ have been adopted for the benzene π orbitals as the fragment integrals:

$$H_{\pi(sym)} = H_{\pi(asym)} = -9.24 \text{ eV}; \; H_{\pi_1} = -12.23 \text{ eV}.$$

"Model" compounds in the PES of which an ionisation band corresponding to a linear combination of the μth and νth fragment orbitals is observed are used to estimate the non-diagonal integrals $H_{\mu\nu}$. By determining the corresponding ionisation potential I_i from the PES and setting $I_i = -\varepsilon_i$, one can find the parameter $H_{\mu\nu}$ from the secular equation

$$\begin{vmatrix} (H_\mu - \varepsilon_i) & H_{\mu\nu} \\ H_{\mu\nu} & (H_\nu - \varepsilon_i) \end{vmatrix} = 0 \; . \qquad (1)$$

The possibility of the involvement of particular fragment orbitals in the molecular orbitals is determined by their symmetry. For example, benzene derivatives PhE in which the substituents E contain the atoms of Group IV–VII elements (for example, $SiMe_3$, PMe_2, SMe, or Cl) have approximately C_{2v} symmetry. Under the influence of the symmetry operations, three π orbitals of the benzene ring and the p orbitals of the atom E transform as shown below:

C_{2v}	E	C_2^z	$\sigma_v^{(xz)}$	$\sigma_v^{(yz)}$	
φ_{π_1}	+1	−1	+1	−1	b_1
$\varphi_{\pi(sym)}$	+1	−1	+1	−1	b_1
$\varphi_{\pi(asym)}$	−1	+1	−1	−1	a_2
φ_{p_z}(E)	+1	+1	+1	+1	a_1
φ_{p_y}(E)	+1	−1	−1	+1	b_2
φ_{p_x}(E)	+1	−1	+1	−1	b_1

We shall assume that the HOMO of the compound PhE are produced as a result of the mixing of only the $\varphi_{\pi(sym)}$ orbital of benzene and the φ_{p_x} orbital of the heteroatom E. The parameter $H_{E\pi(sym)}$ characterising the degree of mixing of the above fragment orbitals, can then be found from Eqn.(1).

On the other hand, if account is taken of the fact that the HOMO of the substituted benzene is produced as a result of the mixing of not only the φ_{p_π}(E) and the $\varphi_{\pi(sym)}$ orbitals but also the φ_{π_1} orbitals (all these orbitals belong to the same irreducible representation b_1 of the C_{2v} group), then the parameter $H_{E\pi(sym)}$ must be found from the solution of the third-order secular equation

$$\begin{vmatrix} (H_{\pi(sym)} - \varepsilon) & H_{E\pi(sym)} & 0 \\ H_{E\pi(sym)} & (H_E - \varepsilon) & H_{E\pi_1} \\ 0 & H_{E\pi_1} & (H_{\pi_1} - \varepsilon) \end{vmatrix} = 0 \; . \qquad (2)$$

The relations between the non-diagonal elements $H_{\mu\nu}$, characterising the interactions of the benzene π orbitals and the p_π orbital of the heteroatom E, are then employed:

$$H_{E\pi(sym)} \times \sqrt{3} = H_{E\pi(asym)} \times 2 = H_{E\pi_1} \times \sqrt{6} = H_{EC}. \qquad (3)$$

These are selected in accordance with the coefficients of the benzene π orbitals indicated above.

The inclusion of the φ_{π_1} orbital in the basis set alters only slightly $H_{E\pi(sym)}$. For example, the values of $H_{S\pi(sym)}$, obtained by the two methods described above and characterising the mixing of the fragment π orbital localised mainly at the sulphur atom with the benzene $\varphi_{\pi(sym)}$ orbital, are virtually identical: 0.84 ± 0.04 eV and 0.78 ± 0.06 eV respectively.

It must be specially emphasised that Eqn.(3) makes it possible to estimate the parameter H_{EC}, which characterises directly the interaction of the p_π orbital of the heteroatom E with the $2p_\pi$ orbital of the carbon atom.

The effects of the interelectronic interactions are taken into account in the values of the ionisation potentials found from the PES of "model" compounds and hence in the corresponding parameters $H_{\mu\mu}$ and $H_{\mu\nu}$. The quantum-chemical calculations based on this parametrisation procedure can therefore be carried out in terms of the scheme of the simple method without adjustment for self consistency.

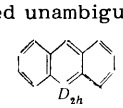
Furthermore, the parameters $H_{\mu\mu}$ and $H_{\mu\nu}$, estimated from the ionisation potential obtained from the PES, include the reorganisation energy and the changes in the correlation and relativistic energies accompanying photoionisation. Thus the parametrisation of the quantum-chemical models, based on the PES data, removes to a large extent the limitations of the Koopmans theorem, which are evident in a comparison of the ionisation potentials I_i determined from the PES with the eigenenergies ε_i^{SCF} calculated in terms of the one-electron approximation[46,47]: $I_i = -\varepsilon_i^{SCF}$. This is probably why the quantum-chemical calculations employing the above parametrisation procedure are fairly reliable for the estimation of the electronic and molecular structures of complex organic and organoelemental compounds and are frequently comparable, as regards the amount of information they provide, with the results of much more cumbersome calculations by the self-consistent field (SCF) method.

In the subsequent Sections of this review, PES data for aromatic hydrocarbons and the corresponding aromatic organoelemental compounds will be discussed. The ionisation potentials of the compounds which it is proposed to regard as "model" compounds are compiled in Tables 1–3 and 6. It is noteworthy that the PES of organic compounds of certain elements have been discussed in a number of reviews[48–50]. However, the use of different quantum-chemical models by different investigators for the purpose of interpretation precludes the comparison on the basis of the data in the above reviews of the capacities of the orbitals of different elements for mixing with the π orbitals of carbon atoms. In order to discover the trends in the variation of the molecular-orbital parameters of the corresponding compounds as a function of the atomic number of the element, we present in the same Tables the results of our quantum-chemical analysis of the molecular orbital structures on the basis of the scheme proposed above. The integrals $H_{E\pi}$ and H_{EC} are compared as parameters in terms of which the degree of mixing of the orbitals is to be estimated.

This designation of the orbitals enumerated has been generally adopted for unsubstituted benzene and also in the analysis of the molecular-orbital structures of polysubstituted benzene derivatives and polycyclic compounds involving heteroatoms[30,32,43].

The mixing of the carbon π orbitals with the orbitals of the heteroatom not only in the "model" compounds, where the atoms of the elements are present as substituents, but also in cyclic compounds—π-donors, benzenes incorporating a non-carbon element in the ring, and the corresponding heterocycles—is analysed in this review.

II. THE π-ORBITALS OF BENZENE AND POLYCYCLIC AROMATIC HYDROCARBONS



The molecular π orbitals of benzene have been thoroughly investigated and their structures were partly discussed above. The ionisation of degenerate $1e_{1g}$-π orbitals is observed at 9.24 eV, the ionisation of the highest-energy σ orbital is observed at 11.44 eV, and finally the ionisation of the lowest π orbital ($1a_{2u}$) is observed at 12.23 eV.[43] This assignment has been confirmed by the "perfluoro-effect"[44,45]: on passing from an unsaturated or aromatic compound to its perfluoroanalogue, the energies of the π orbitals change slightly, while the energies of the σ orbitals diminish appreciably, which can be seen from the ionisation potentials of hexafluorobenzene[45]: 10.12 eV (π_2, π_3); 12.73 eV (π_1); 14.02 eV (σ).

It has been shown for naphthalene[45] with the aid of the "perfluoro-effect" that a band in the PES beginning at 11 eV corresponds to the ionisation of its σ orbital; the bands in the region of lower energies refer to the ionisation of the π orbitals. This conclusion is in good agreement with the results of a non-empirical calculation according to which the four highest molecular orbitals of naphthalene are π orbitals and the fifth is a σ orbital. The same conclusion has been reached with the aid of calculations by the Hückel molecular orbital method using a parametrisation based on PES data[51-55]; the ionisation potentials (eV) and their assignments are listed below:

D_{2h} 8.12 ($1a_u$) 8.91 ($2b_{1u}$) 10.08 ($1b_{3g}$) 10.85 ($1b_{2g}$) 11.05 ($1b_{1u}$).

The dependence of the structure of the molecular orbitals of polycyclic aromatic hydrocarbons on the number of benzene rings has been investigated with the aid of various quantum-chemical methods and PES data[49,56-59]. It has been established that the energy of the σ orbital of benzene, corresponding to an ionisation energy of 11.44 eV in the PES, becomes 11.00 eV on passing to naphthalene and then does not change appreciably with increase of the number of condensed benzene rings. Therefore all the bands below 11.00 eV, for example in the PES of anthracene and phenanthrene, are assigned unambiguously to the ionisation of π orbitals:

D_{2h} 7.47 ($2b_{2g}$) 8.57 ($2b_{3g}$) 9.23 ($1a_u$) 10.26 ($1b_{2g}$) 10.40 ($2b_{1u}$).

The simple Hückel molecular orbital (HMO) method also yields satisfactory results for large polycyclic aromatic hydrocarbons: in particular, the vertical ionisation potentials I_i of polycyclic aromatic hydrocarbons determined from the PES correspond satisfactorily to the energies ε_i of the π orbitals calculated in units of β in terms of the HMO scheme:

$$I_i = -(\alpha_c + \varepsilon_i \beta_{cc}).$$

This makes it possible to determine the absolute values of the Coulombic integral α_C (within the framework of the simple method, the parameter α_C is identical with the diagonal element H_C) and the resonance integral β_{CC} (the integral β_{CC} is identical with the non-diagonal element H_{CC})[49]:

$$\alpha_c = H_c = -(6.55 \pm 0.34) \text{ eV},$$
$$\beta_{cc} = H_{cc} = -(2.73 \pm 0.33) \text{ eV}.$$

These values are convenient for simple quantum-chemical calculations of the energies of the π orbitals of aromatic hydrocarbons and their heterocyclic analogues[49,50,58,60].

III. CHARACTERISTIC FEATURES OF THE MIXING OF THE ORBITALS OF THE ATOMS OF GROUP II–VII ELEMENTS WITH THE π ORBITALS OF CARBON ATOMS

1. Halogen Atoms

The ionisation potentials of the *p* electrons of the halogen atoms are comparatively high. For example, the following values of *I* (eV) have been found from the PES of hydrogen halides: 16.03–16.06 for fluorine[61]; 12.74–12.82 for chlorine[62]; 11.64–11.98 for bromine[63]; 10.38–11.05 for iodine[62]. The ionisation energies of the unshared electrons of the halogens in halogenomethanes are somewhat lower and are listed in Table 1. This feature of the halogens is reflected in their higher electronegativity compared with carbon and hydrogen atoms[64].

Table 1. Estimation of the degrees of mixing of the *p* (halogen) and benzene π orbitals in the halogenobenzenes PhE.

E	*I*(E), eV	*I*(PhE), eV	$H_{E\pi(sym)}$, eV	Characteristics of the HOMO of PhE*					U.v. spectrum** (Ref.69)
				ε, eV	c_{ortho}	c_{meta}	c_{para}	c_E	
F	14.57 (Ref.52)	9.11 (b_1); 9.82 (a_2); 12.12 (b_1); 12.15 (Ref.67)	−0.84	−9.12	−0.311	0.269	0.566	0.150	210 (3.93); 261 (2.30)

I	9.54; 10.16 (Ref.66)	8.78 (b_1); 9.75 (a_2); 10.59; 11.70 (Ref.8)	−0.59	−8.80	−0.300	0.186	0.453	0.600	207 (3.86); 226 (4.12); 257 (2.85)

Note: *I*(E) are the ionisation potentials of the electrons of the *p*(E) orbital in the halogenomethanes MeE (according to PES data) and *I*(PhE) are the ionisation potentials of the halogenobenzenes (according to PES data).

* The characteristics of the HOMO of the halogenobenzenes (the energy ε and the coefficients c_μ) were obtained by ourselves as a result of calculation by the Hückel molecular orbital method with PES parametrisation (for the details of the calculation, see the Introduction): $H_C = -6.75$ eV; $H_{CC} = -2.5$ eV.[49].

** The positions of the absorption bands (in nm) are indicated (the logarithms of the molar extinction coefficients are shown in brackets).

Since the *p* orbitals of the fluorine atom ionise at the highest energy, the degree of their mixing with the more readily ionisable π orbitals of carbon in fluorobenzene molecules is not considerable, which constitutes the fundamental basis of the "perfluoro-effect" already mentioned, which

lowers significantly the energies of the σ orbitals and to a lesser extent those of the π orbitals. The *p* electrons of the chlorine, bromine, and iodine atoms ionise more readily, but this does not lead to more effective mixing of their orbitals with the π orbitals of the benzene ring, because the effectiveness of the mixing of the orbitals is determined not only by the difference between their energies and by their symmetry but also by their overlap[65]. Table 1 lists the ionisation potentials of the *p* electrons of the halogen atoms in halogenomethanes, the ionisation potentials of halogenobenzenes, and the positions of the intense long-wavelength absorption bands in the ultraviolet spectra of halogenobenzenes. It also lists the integrals $H_{E\pi(sym)}$ characterising the degree of mixing of the p_π orbitals of the halogens with the $\phi_{\pi(sym)}$ orbital of benzene.

The structure of the $\varphi_{\pi(asym)}$ orbital does not change but it has a lower energy, probably as a consequence of the inductive effect of the halogen.

In full agreement with numerous experimental data, it follows from a comparison of the coefficients of the HOMO of various halogenobenzenes that the halogen atoms are *ortho*, *para*-directing and that the directing effect is more marked for the fluorine atom. Comparison of the integrals $H_{E\pi}$ shows that the fluorine atoms are mixed to the greatest extent with the π orbitals of the benzene ring. However, in conformity with the coefficients c_E, the contribution of the unshared electrons of the halogen to the HOMO of the halogenobenzene increases in the sequence

$$F<Cl<Br<I .$$

The greatest bathochromic shifts are undergone by the absorption bands of benzene in the ultraviolet spectrum of fluorobenzene[69]: an intense long-wavelength absorption band is observed in the spectrum of fluorobenzene at 210 nm instead of 203 nm in the spectrum of benzene. In the ultraviolet spectrum of iodobenzene a new absorption band, compared with other halogenobenzenes, appears at 226 nm, which could be accounted for by the mixing of the $5p_x$ orbital of iodine and the π orbitals of benzene. However, the same band is observed also in the electronic spectrum of the iodide ion: apparently the absorption at 226 nm is a consequence of the local electronic transitions and is not related to the $p-\pi$ conjugation system. We may also note that the diphenyliodonium cation absorbs in the region of 226 nm[69,70] (the ultraviolet spectra of compounds in which the bromine and chlorine atoms are linked to two phenyl groups have been investigated[71-73]).

There exist also other estimates of the orbital interactions in halogenobenzenes[64,74-77]. In particular, the degree of mixing of the orbitals of the halogen atoms with the π orbitals of benzene has been estimated[75] in terms of a less rigorous criterion (compared with the integral $H_{E\pi}$ which we proposed), namely the splitting of the energies of the benzene b_1 and a_2 orbitals (the halogenobenzene and the splitting of the energies of these orbitals are indicated below in eV): fluorobenzene, 0.44; chlorobenzene, 0.57; bromobenzene, 0.64; iodobenzene, 0.71. According to this criterion, the 5*p* orbital of iodine is mixed with benzene orbitals to a greater extent than the 2*p*(F), 3*p*(Cl), and 4*p*(Br) orbitals[75].

2. Atoms of Oxygen Subgroup Elements

As in the fluorine subgroup, an increase of the atomic number of the element in the oxygen subgroup decreases its relative electronegativity. However, in aryl(alkyl) chalcogenides the influence of the steric structure on the conditions governing the mixing of the orbitals is significantly more appreciable (compared with halogenobenzenes). We shall examine as an example how the structure of compounds of the type R_2E varies for different E.

The valence angle in the hydrides H_2E diminishes on passing from oxygen to tellurium: 104.5° for O, 92.2° for S, 91.0° for Se, and 89.5° for Te.[78] In dimethyl chalcogenides Me_2E, the C–E–C valence angles are somewhat greater but the trend in their variation is the same: 111.5° for O,[78] 98.9° for S,[79] 98° for Se,[80] and 93° for Te.[81] The closeness of the C–E–C valence angle in the compounds R_2E to 90° can be used to characterise the deviation of the orbitals of the unshared electron pair from the *p* orbitals of the isolated atoms. Using this estimate, one can assume that in the series of dimethyl chalcogenides only the *p* orbitals of tellurium are hardly mixed with the orbitals of the methyl groups: the C–Te–C angle in dimethyl telluride differs insignificantly from 90°. The character of the unshared electrons of the chalcogen atoms in compounds of the type R_2E can be reliably determined within the framework of the molecular orbital method[30]. It has been found that, of the two pairs of unshared electrons formally not involved in the formation of bonds with the hydrogen atoms (for example in the water molecule), only one cannot mix with the *s* orbitals of the hydrogen atoms as a consequence of symmetry properties (b_1 for the C_{2v} symmetry group). The other orbital has the a_1 symmetry, i.e. the same as in the (+)-combination of the *s* orbitals of the hydrogen atoms and can mix with the latter.

In the dimethyl derivatives of the chalcogens Me_2E not only the $p_x(E)$ orbital but also certain combinations of the atomic orbitals of carbon can have the b_1 symmetry[35]. In these compounds the p_x orbital of the chalcogen is involved in the formation of the molecular orbital localised predominantly on the chalcogen: in the PES of dimethyl chalcogenides, the ionisation bands of the corresponding *p* orbitals of the chalcogens are comparatively narrow (although they are wider than in the PES of the hydrides[3]).

Evidently even wider possibilities for the mixing of the orbitals of the unshared electron pairs of the chalcogens with the orbitals of the substituents appear in the corresponding aromatic derivatives. This is probably why the C–E–C angle in compounds of the type PhEMe is even greater: 120° ± 2° for O,[82] 106° ± 2° for S,[83] 99.6° ± 2.5° for Se,[84] and 101° for Te[85]. The stereoelectronic factor exerts an even greater influence on the structure of the molecular orbitals of these compounds. For example, phenyl(alkyl) chalcogenides can exist in a conformation in which the alkyl group is oriented in the plane of the benzene ring and the p_x orbital exists under the most favourable conditions for mixing with the π orbitals of carbon (the dihedral angle $\phi = 0°$). For these compounds there is a possibility also of a different conformation which is sterically less hindered but is unfavourable from the standpoint of the energy of the $n-\pi$ conjugation. It is a perpendicular conformation in which the orbital of the unshared electrons is located in the plane of the benzene ring and can therefore mix only with the σ(CC) orbitals of the skeleton, while the E–C(H_3) bond is in a plane perpendicular to the benzene ring (the dihedral angle $\phi = 90°$).

The conformational properties of phenyl(alkyl) chalgogenides have been investigated by various methods. We shall note only some studies in which the PES method was used for this purpose. In a number of investigations intrinsic ionisation bands in the PES spectra of phenyl(methyl) chalcogenides were assigned to the "planar" ($\phi = 0°$) and "non-planar" ($\phi = 90°$) conformers[86-91]. On the other hand, the authors[85] assumed that the spectrum of telluroanisole reflects the planar conformation and the conformation with a dihedral angle $\phi \cong 60°$. However, the reliability of the

estimate based on PES data for non-planar conformations differing insignificantly in their energies has been questioned[92]. Overall, the data obtained show that the retention of free rotation of the substituents about the E–R bond in the compounds Ar–E–R does not prevent the mixing of the *p* orbitals of the chalcogens with the π orbitals of benzene.

The relative involvement of the *p*(E) orbitals and the π orbitals in the HOMO of anisole analogues is illustrated by the data in Table 2, which also lists the ionisation potentials of the unshared electron pairs of the chalcogens in the dimethyl chalcogenides Me_2E [they were used to estimate the energies of the p_π(E) orbitals which mix with the π orbitals] and the ionisation potentials of compounds of the type C_6H_5EMe. In order to estimate the integrals $H_{E\pi}$ within the framework of the LCFO-MO scheme, the first ionisation potentials of these compounds were employed.

Table 2. Estimation of the degrees of mixing of the *p* orbitals of Group VIA elements with the benzene π orbitals in the compounds PhEMe.

Note: *I*(E) are the ionisation potentials of the electrons of the *p*(E) orbital in the compounds Me_2E (according to PES data) and *I*(PhEMe) are the ionisation potentials of organoelemental derivatives of anisoles (according to PES data).

* The characteristics of the HOMO of the organoelemental derivatives of anisoles (the energies ε and the coefficients c_μ) were calculated by the Hückel molecular orbital method with PES parametrisation.

** The positions of the absorption bands (in nm) are indicated (the logarithms of the molar extinction coefficients are shown in brackets).

*** cf. Turner's data[96].

**** cf. the data of Bock et al.[42]

***** The absorption band of thioanisole at 200, 254, and 280 nm are indicated by Rodd[98].

Table 2 shows that in the series O, S, Se, Te the *p*(E) and π orbitals mix to the greatest extent for an element in a Second Period (as for the halogens). The most favourable combination of the above factors determining the degree of mixing of the orbitals is in fact encountered for oxygen. According to calculations by the Hückel molecular orbital method (PES parametrisation), the methoxy-group has the most powerful *ortho,para*-directing effect among other groups of the type EMe. With increase of the atomic number of the element, or with decrease of the ionisation potential of the electrons in the *p* orbital, and with the consequent increase of the difference between the energies of the interacting *p* and π(sym) orbitals, the contribution of the atomic orbitals of the chalcogen to the HOMO of the PhEMe molecule increases in the sequence

$$O<S<Se<Te.$$

On passing from anisole to thioanisole, selenoanisole, and telluroanisole, there is a bathochromic shift of the long-wavelength absorption in the ultraviolet spectra (Table 2). The maximum shift of the intense long-wavelength band is observed in the spectrum of thioanisole. These facts can be partly explained by the increased HOMO energy in the above series of compounds[97,99,100]. There is also a possibility of the involvement of unoccupied *d* orbitals for which the possibilities for mixing with the unoccupied π orbitals of benzene are in fact greatest in the case of the sulphur atom. The absorption bands at 223 and 231 nm, observed in the spectrum of telluroanisole, are apparently determined to a large extent by local effects.

We may also note that there exist other schemes for the parametrisation of the quantum-chemical calculations based on PES data[30,101–108]. In the method for the estimation of the parameters $H_{\mu\nu}$ adopted in this review the influence of the inductive effect of the substituent E on the energies of the benzene π orbitals and the difference between the inductive effects of the methyl and phenyl groups in the estimation of the energies of the atomic orbitals of the elements are not taken into account explicitly. In the parametrisation based on PES data for *p*-disubstituted benzenes, a correction has been made[30] for the alteration of the energy of the *n*(E) orbital as a consequence of the inductive influence of the benzene fragment but no account is taken of the difference between the sensitivities to the inductive effect of the benzene $\varphi\pi$(sym) and $\varphi\pi$(asym) orbitals.

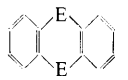
Quantum-chemical studies in terms of the π-approximation, parametrised on the basis of PES data, have been used successfully[109–119] for the analysis of the molecular orbitals also of aromatic organoelemental compounds—monocyclic and polycyclic aromatic compounds containing heteroatoms in the ring. In particular, calculations in terms of the π-approximation were carried out using the parameters (eV)

$$\alpha_S = -9.4;\ \alpha_{Se} = -8.5;\ \alpha_C = -7.0;\ \beta_{CS} = -1.8;\ \beta_{CSe} = -1.5;\ \beta_{CC} = -3.0\ .$$

These made it possible to interpret reliably the PES of furan and its analogues[109,110]. For example, the $3p_\pi$ orbital of the sulphur atom in the thiophen molecule is fully conjugated with the π orbitals of carbon, which results in the formation of delocalised molecular orbitals, and on photoionisation it is not manifested by a separate band in the spectrum: the first two ionisation potentials of 8.9 and 9.5 eV have been attributed to the two highest π-electronic levels: $a_2(\pi)$ and $b_1(\pi)$ respectively. The replacement of the S atom by O, Se, and Te atoms affects only slightly the $a_2(\pi)$ level but alters significantly the energy of the $b_1(\pi)$ level. This type of dependence of the energies of the above molecular orbitals on the nature of the heteroatom can be understood by analysing their symmetries: the energy of the $a_2(\pi)$ molecular orbital, which has a nodal plane passing through the heteroatom, varies less than the energy of the $b_1(\pi)$ orbital to which the orbital of the heteroatom makes a considerable contribution[109,110]. The ionisation potentials (eV) of the a_2 and b_1 orbitals of compounds (I) are presented below:

(I)

	O	S	Se	Te
a_2	8.90	8.87	8.80	8.81
b_1	10.32	9.52	8.95	8.27



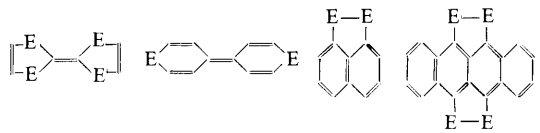
This contribution becomes a maximum for E = Te: the highest occupied orbital of tellurophen is a $b_1(\pi)$ orbital.

The character of the $p(E)-\pi$ mixing in tricyclic compounds is illustrated by the results of a study[119] in which the PES of dibenzofuran analogues were investigated and interpreted. The measured (PES) and calculated (Hückel molecular orbital method, PES parametrisation) ionisation potentials of, for example, dibenzoselenophen, are compared below:

I(exp.), eV	7.88	8.30	9.25	9.95	10.43	11.27	12.93
I(calc.), eV	8.07	8.51	9.25	9.81	10.07	11.47	12.58
Orbital	$5b_2$	$2a_2$	$4b_2$	$3b_2$	$2b_2$	$1a_2$	$1b_2$

Evidently the fragment π orbitals of the benzene nuclei and the p orbitals of the heteroatom are mixed in the molecule of this compound to the same extent as in the model compound: selenoanisole. An analogous conclusion applies also to other dibenzofuran analogues having planar molecules[120-123] and the maximum overlaps of the $p(E)$ and π orbitals. In the ultraviolet spectra of compounds of the dibenzofuran series, the greatest changes in the energies of the electronic transitions are observed on passing from dibenzofuran (absorption maxima at 249, 281, and 297 nm[124]) to dibenzothiophen (absorption maxima at 286, 313, and 323 nm[124]), while the spectra of dibenzoselenophen and dibenzotellurophen[125] are virtually identical with the spectrum of their thio-analogue.

In tricyclic compounds having the general structure



(II)

E = O, S, Se, Te

in the molecules of which the number of π electrons does not satisfy the Hückel rule for aromatic compounds, the p orbitals of the chalcogens and the carbon π orbitals are mixed less effectively. For example, the non-diagonal matrix element $H_{O\pi(asym)}$, found from the PES data for compound (II, E = O) is 0.94 eV, while 1.19 eV has been obtained from the PES of anisole. Although the molecule of dibenzo-p-dioxin is planar in the crystalline state[126], the discrepancies observed for compounds (II) between the measured and calculated ionisation potentials[127-129] can be due to the non-planarity of their molecules in the gas phase[130-132].

Among other compounds in which the chalcogen atoms are part of the composition of rings having more than six p electrons, mention should be made of derivatives of tetrathiafulvalene (III), dithiapyranylidene (IV), naphthalene (V), and tetracene (VI). The interest in the characteristics of the structure of the molecular orbitals of compounds (III)–(VI), in which E = O, S, Se, or Te, can be explained by the fact that the compounds exhibit electron-donating properties in highly conducting complexes with π acceptors[133-137]:

(III) (IV) (V) (VI)

In particular the PES of tetrathio-, dithiodiseleno-, and tetraseleno-fulvalenes, (IIIa), (IIIb), and (IIIc), respectively have been investigated[135]. In the region of low ionisation energies (below 11 eV), all three compounds have virtually identical PES: the replacement of the S atom by Se does not invert the sequence of the molecular orbitals. It is significant that the energies of all the π orbitals, except the HOMO, increase somewhat on successive replacement of the sulphur atoms by selenium. On the other hand, the energy of the HOMO, which is the most delocalised orbital, decreases somewhat [the first ionisation potentials of the compounds (IIIa), (IIIb), and (IIIc) are respectively 6.70, 6.75, and 6.90 eV].

Interesting results have been obtained by the LCFO-MO method in the analysis of the orbital interactions in naphthalene 1,8-disulphide (V).[136] The occupied molecular π orbitals of the compound are produced from the corresponding orbitals of two fragments—the naphthalene molecule and the disulphide bridge. The following molecular orbitals were taken into account for the naphthalene fragment (symmetry group approximately C_{2v})[45]: a_2 (−8.13 eV); b_1 (−8.88 eV); b_1 (−10.01 eV); a_2 (−11.37 eV); b_1 (−13.0 eV). The interaction between the p_π orbitals of two neighbouring sulphur atoms leads to two new energy levels [−8.1 (a_2) and −10.1 (b_1) eV] to which correspond wave function in the form of linear $p(-)$ and $p(+)$ combinations[138,139]. The determination of the energies of the molecular orbitals of naphthalene 1,8-disulphide reduces to the solution of two secular equations set up respectively for the a_2 and b_1 orbitals. The diagonal matrix elements $H_{\mu\mu}$ are set equal to the energies of the basis fragment orbitals (FO) and the non-diagonal matrix elements are found from the relation

$$H_{\mu\nu} = \sqrt{2} \cdot C_\mu \beta_{CS},$$

where C_μ is the coefficient of the molecular orbital of naphthalene at the site of the addition of the disulphide bridge (for the 1- and 8-positions, the values of C_μ are identical and for the four occupied molecular orbitals enumerated above they amount to 0.425, 0, 0.263, and 0.301 respectively) and β_{CS} is the integral characterising the interaction of the $2p(C)$ and $3p(S)$ orbitals; $\beta_{CS} = -1.8$ eV has been adopted[140]. The corresponding secular equations in the case under consideration have the following form:

$$\begin{vmatrix} (-8.13-\varepsilon) & 0.60\beta_{CS} & 0 \\ 0.60\beta_{CS} & (-8.10-\varepsilon) & 0.37\beta_{CS} \\ 0 & 0.37\beta_{CS} & (-11.37-\varepsilon) \end{vmatrix} = 0;$$

$$\begin{vmatrix} (-10.01-\varepsilon) & 0.57\beta_{CS} & 0 \\ 0.57\beta_{CS} & (-10.1-\varepsilon) & 0.43\beta_{CS} \\ 0 & 0.43\beta_{CS} & (-13.80-\varepsilon) \end{vmatrix} = 0.$$

Calculated data agree very well with experimental results.

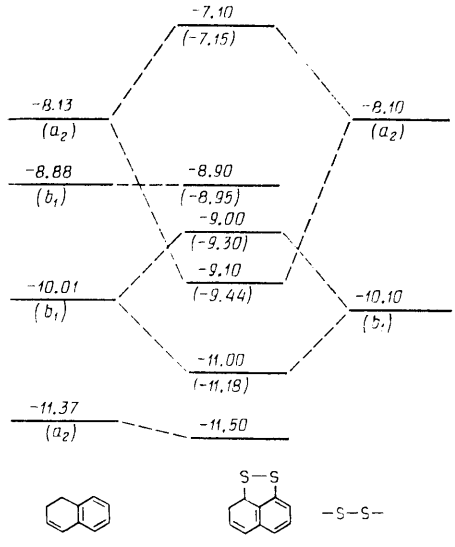


Figure 1. Schematic illustration of the formation of the π orbitals of 1,8-naphthylene disulphide[136] (the energies are indicated in electron-volts).

Fig. 1 illustrates a qualitative diagram describing the distribution of the π orbitals with respect of energy in the naphthalene 1,8-disulphide molecule (the estimated molecular orbital energies are indicated: the values based on PES data in brackets and the calculated values without brackets).

In conclusion of the discussion of the characteristics of the formation of the molecular orbitals from the fragment p(E) and π orbitals in compounds of Group VIA elements, we may note that, although the degree of mixing of the fragment orbitals decreases in the sequence O > S > Se > Te, selenium compounds and in certain cases also tellurium compounds have been found to be the most promising π donors in the corresponding complexes of organic metals[141,142].

3. The Atoms of Nitrogen-Subgroup Elements

In contrast to dimethyl chalcogenides Me_2E, in the series of compounds Me_3E (where E = N, P, As, or Sb) the increase of the atomic number and the decrease of the electronegativity of the element E never lead to a decrease of the ionisation potentials of its unshared electrons: the ionisation potentials of trimethylamine, trimethylphosphine, and trimethylarsine are almost identical (a slight increase is actually observed on passing from nitrogen to arsenic)[143]. The ionisation potentials of the unshared electron pairs of the heteroatoms in the hydrides H_3E differ to a greater extent[144]; The corresponding data are presented in Table 3.

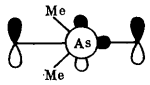
* The characteristics of the HOMO of the compounds $PhEMe_2$ (the energies ε and the coefficients c_μ) were calculated by the Hückel molecular orbital method with PES parametrisation (for the details of the calculations, see the Introduction).



** The positions of the absorption bands (in nm) are indicated (the logarithms of the molar extinction coefficients are shown in brackets).

In analysing this feature of compounds of Group VA elements, one must bear in mind the variation of the geometry, in particular in the series of compounds Me_3E and the corresponding variation of the hybridisation of the orbital of the unshared electrons of the heteroatom: for example, the C—E—C angle decreases from 108° for NMe_3 to 99° for PMe_3 and 96° for $SbMe_3$. According to Walsh[145], the increase of the deviation from the planar structure on passing from nitrogen to antimony corresponds to an appreciable alteration of the hybridisation of the orbital of the unshared electrons, to an increase of its s character, and to the corresponding decrease of its energy. Such hybrid orbitals of the unshared electrons of Group V elements would apparently be more correctly designated by the letter n rather than p.

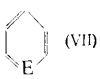
It appears that the mixing of the n orbital with the π orbitals of the corresponding benzene derivatives $PhEMe_2$ depends primarily on the degree of hybridisation of the n orbital[146,147]. In contrast to *N,N*-dimethylaniline, in the molecule of which the n orbitals of nitrogen and the orbitals of carbon are actively mixed, in *P,P*-dimethylphenylphosphine the degree of n(P)−π mixing is much lower[146] (Table 3):

The conformations and PES of dimethylvinyl- and dimethylphenyl-arsines have been investigated[148]. In these compounds the n(As) and π orbitals are not mixed; the first ionisation potentials of trimethylarsine and dimethylphenylarsine are almost identical, amounting to 8.65 and 8.67 eV respectively. It is of interest to note that the calculation by the CNDO/2 method for dimethylphenylarsine showed that the optimum conformation is one in which the n orbital of the arsenic atom, the bisector of the Me—As—Me angle, and the benzene ring are located in a single plane:

This conclusion is not unexpected: the same conformation had been observed earlier in solution for dialkyl(*p*-tolyl)-phosphines[150]. On the other hand, consistent with the assumption made, the *N,N*-dimethylaniline molecule has a conformation favourable for the n(N)−π conjugation: the $PhNC_2$ fragment is almost planar—the average C—N—C angle is 116°.[151] In this connection we may note that the effect of the n(P)−π conjugation in the series of compounds of tricoordinate phosphorus and its analogues have been investigated in detail also by other methods, in particular by potentiometric titration[152].

Table 4. The ionisation potentials (I, eV) of the compounds Ph_3E according to PES data[154].

E	I_1	I_2	I_3	I_4
N	7.00	8.81	9.25	10.29
P	7.85	9.02	9.18	9.68
As	8.03	—	9.10	9.58
Sb	8.08	—	9.06	—



The formation of the molecular orbitals of triphenylamine and its analogues of the type Ph_3E has been investigated[153,154]. Table 4 lists the vertical ionisation potentials of Ph_3E, which lie below 11 eV.[154] The ionisation potentials at 9 eV (I_2 and I_3) were attributed to orbitals localised preferentially in the

benzene rings; the ionisation potentials I_1 and I_4 were assigned to the orbitals formed by the mixing of the benzene π orbitals and the orbitals of the unshared electrons of the heteroatom. The maximum mixing of the n(E) and carbon π orbitals is observed in triphenylamine: the PES of this compound does not reveal the ionisation of isolated n(N) and π orbitals. The first band in the PES, characterising the n(E)$-\pi$ mixing, becomes narrower on passing from N to P and further to As and Sb.[153] As in the series of compounds $PhEMe_2$, in the present series of compounds the degree of n(E)$-\pi$ mixing diminishes sharply on passing from N to P and falls still further on transition to As and Sb:

$$N \gg P > As > Sb .$$

The PES data for p-disubstituted benzenes described by the formula p-$Me_2EC_6H_4EMe_2$ are fully consistent with the conclusion that the degrees of n(E)$-\pi$ mixing in the nitrogen and phosphorus compounds are significantly different[147].

However, it must be emphasised yet again that the weak capacity of the n orbital of the tricoordinate phosphorus atom (and also arsenic and antimony atoms) for mixing with the π orbitals is caused by the characteristics of its hybridisation. The alternative explanation of the above phenomenon, based on geometrical causes [the difference between the effective dimensions of the 3p(P) and 2p(C) orbitals, the greater E–C bond length compared with the N–C bond length, etc.], is hardly likely to be valid, because heteroaromatic compounds with dicoordinate atoms of Group VA elements, up to bismuthabenzene, are known:

(VII)

E=N, P, As, Sb, Bi .

The steric and electronic structures of organoelemental derivatives of benzene of type (VII) have been studied in detail and discussed in a number of reviews[48,155]. In the present review we shall confine ourselves to the principal conclusions reached in the investigations concerning the comparative estimates of the degrees of mixing of orbitals of different elements.

The molecules of compounds (VII) are planar and their bond lengths are characteristic of aromatic compounds. For example, according to the data of Bart and Dely[156], the phosphorus–carbon bond length in 2,6-dimethyl-4-phenylphosphabenzene is 1.74 Å, while the length of the P=C double bond in the $Ph_3P{=}CH_2$ is 1.65 Å and that of the P–C single bond in trimethylphosphine is 1.87 Å. The carbon–nitrogen, carbon–arsenic, and carbon–antimony bond lengths in the corresponding organoelemental derivative of benzene are 1.37 Å,[157] 1.85 Å,[158] and 2.05 Å.[159]

The principal spectroscopic characteristics of the organoelemental derivatives of benzene (VII) are listed in Table 5. The structure of the occupied molecular orbitals in these compounds can be naturally accounted for within the framework of the simple molecular orbital perturbation scheme (theory)[160]: the changes in the energy levels of the benzene π orbitals are determined by the coefficients of these orbitals referring to the position of the heteroatom. In conformity with the squares of these coefficients for the π orbitals of benzene (0.33 for $2b_1$, 0 for a_2, and 0.17 for $1b_1$), the greatest changes following the introduction of the heteroatom are undergone by the ionisation potential of the φ_π(sym) orbital (the $2b_1$ orbital); the energy of the π_1 orbital (the $1b_1$ orbital) changes less and finally the energy of the φ_π φ_π(asym) orbital (the a_2 orbital) hardly changes when the CH fragment is replaced by a heteroatom. We may note that there are linear relations between the ionisation potentials of the π orbitals of compounds (VII) and the ionisation potentials I_E of the p orbitals of the elements[160]:

$$I_{(2b_1)} = (5.24 + 0.36I_E), \text{ eV} \quad (r = 0.9998) ;$$
$$I_{(1b_1)} = (10.25 + 0.16I_E), \text{ eV} \quad (r = 0.9908).$$

(The values of I_E are 14.53 eV for N, 11.0 eV for P, 9.81 eV for As, and 8.64 eV for Sb.)

Table 5. The spectroscopic characteristics of organoelemental derivatives of benzenes PhE (E is a Group VA element).

E	I(PhE)*, eV (Ref.160)	U.v. spectrum** (Refs. 17, 161)
N	9.7–9.8 ($11a_1$, σ/n; $1a_2$, π), 10.5 ($2b_1$, π); 12.5 ($7b_2$, σ); 12.6 ($1b_1$, π)	175 (4.90); 192 (3.80); 250 (3.30) 270 (2.65)
P	9.2 ($3b_1$, π); 9.8–10.0 ($1a_2$, π; $13a_1$, σ/n); 11.5 ($8b_2$, σ); 12.1 ($2b_1$, π)	213 (4.28); 246 (3.93); 290 sm. (2.40)

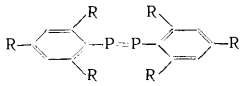
* The ionisation potentials of organoelemental derivatives of benzene (according to PES data).
** The positions of the absorption bands (in nm) are indicated (the logarithms of the molar extinction coefficients are shown in brackets); the solvent was cyclohexane.



The analysis of the structure of the occupied molecular orbitals of the organoelemental derivatives of benzene (VII) described above has been justified[160] with the aid of an *ab initio* calculation for phosphabenzene whereby it was found that none of the occupied molecular orbitals of this compound contains an appreciable contribution of the unoccupied 3d(P) orbitals (there exists also a different view concerning the role of these orbitals in the formation of the molecular orbitals of phosphabenzene[162]).

It is of interest to compare the fact of the active involvement of the p(E) orbitals in the formation of the π-type molecular orbitals of organoelemental benzene derivatives with data concerning the character of the orbitals of the unshared electrons of the heteroatoms in these heterocycles: the ionisation of the unshared electrons is manifested in the PES of both the hydrides H_3E and organoelemental benzene derivatives in the region of 10 eV, but the corresponding bands in the spectrum are overlapped by the band due to the ionisation of the benzene π orbitals[160,163–165]. The ionisation of the unshared electrons of the sp^2-hybridised phosphorus atom was first observed in the form of an individual band by Schäfer et al.[164]; the band half-width in the PES of 2-phosphanaphthalene proved to be only 20% smaller than the half-width of the band due to the ionisation of the unshared electrons of the sp^3-hybridised phosphorus atom. The n orbital of the phosphorus atom, located in the plane of the carbon fragment in the molecules of aromatic phosphorus compounds (phosphabenzene, phosphanaphthalene, and phospha-anthracene), is apparently mixed with the σ(CC) orbitals.

The capacity of the 3p(P) orbitals for appreciable overlapping with the 2p(C) orbitals had been observed earlier in linear compounds, in particular in coloured compounds of the type of cyanines and triarylmethanes[166–169]: X-ray diffraction studies showed, for example, that the phosphorus–carbon bond length in phosphamethinecyanines is

1.76 Å[168,169], i.e. is virtually the same as in phosphabenzene (1.74 Å).

The geometrical parameters of the *p* orbitals of the elements of high Periods do not prevent their overlap with both the π orbitals of the sp^2-hybridised carbon atom and with the *p*(E) orbital of another E atom. Bis(2,4,6-tri-t-butylphenyl)diphosphene, the first stable compound with a double bond between phosphorus atoms, has been recently isolated and characterised[170] (cf. the earlier communications[171-173]):

(VIII)

R = t-Bu .

The molecule of the diphosphene (VIII) is planar and the P=P bond length is 2.034 Å; its ultraviolet spectrum [284 (ε = 15660), 340 (ε = 7690), and 460 (ε = 1360)] resembles very closely that of its *N*-analogue—bis(2,4,6-tri-t-butylphenyl)diazene[174].

4. The Atoms of Carbon Subgroup Elements

We shall now discuss the behaviour of the benzene π orbitals under the influence of substituents incorporating atoms of the Group IVA elements. In the sp^3 valence state these elements form bonds assuming tetrahedral directions and have comparatively low ionisation potentials. In the corresponding non-planar compounds the σ and π orbitals of the individual fragments are therefore capable of mixing, although, for example, in compounds having the general structure $PhEMe_3$, the perturbation of the benzene π orbitals is slight: the first ionisation potential decreases by only 0.24 eV on passing from benzene to trimethylphenylsilane.

The interaction of the π orbitals of the benzene ring with the orbitals of the σ(E—C) bonds in the compound $PhEMe_3$ has been discussed in detail in many communications; certain questions concerning this problem were considered above (in the introduction).

In the series of compounds $PhEMe_3$, one is dealing with the possibility of the mixing of the benzene $\varphi\pi$(sym) and σ(E—Me) orbitals[37]. The ionisation potential of the electrons of the σ(E—C) orbitals in the series of compounds Me_4E varies in parallel with the variation of the electronegativity of the element E[175]. However, one should note that the first ionisation potentials of the compounds $PhEMe_3$ vary only slightly: the degree of mixing of the σ(E—C) and π orbitals in the phenyl derivatives of the elements of the carbon subgroup as well as the degree of mixing of the *n*(E) and π orbitals in the corresponding compounds of Group V—VII elements decrease with increasing atomic number of the element:

$$C > Si > Ge > Sn .$$

The corresponding data, including the results of quantum-chemical calculations for the compounds $PhEMe_3$ in terms of the π-approximation (parametrisation based on PES), are presented in Table 6.

It is noteworthy that the longest-wavelength absorption is observed in the ultraviolet spectra of phenylsilanes. The maximum shift of the absorption band has been observed in

Table 6. Estimation of the degrees of mixing of the σ(E—C) and σ(C—E) orbitals with the benzene π orbitals in the compounds $PhCH_2EMe_3$ and $PhEMe_3$.

the ultraviolet spectrum of *p*-bis(trimethylsilyl)benzene [absorption bands at 226 and 270 nm compared with the bands at 214 and 263 nm in the ultraviolet spectrum of *p*-bis(t-butyl)benzene].[178] This feature is probably due to the contribution of the unoccupied 3*d* orbitals of silicon to the unoccupied molecular orbitals of phenylsilanes, which reduces the energies of these molecular orbitals. The molecular orbital perturbation theory[43] and the CNDO/2 method (both with and without the inclusion of the 3*d* orbitals in the basis set)[179] have been used for quantitative estimates of the contributions of the 3*d*(Si) orbitals.

Since the unoccupied d_{xz} orbitals of silicon have b_1 symmetry (relative to the C_{2v} group, they can be mixed also with the occupied σ and π orbitals of benzene having the same symmetry, which decreases the energy levels of the corresponding HOMO and hence also the absolute value of the integral $H_{\sigma\pi}$ characterising the degree of σ–π mixing in the compounds $PhEMe_3$. Furthermore, the low degree of mixing of the π and σ(E–C) orbitals in the series of compounds (X)–(XII) can probably be explained also by the fact that the C_{ar}–E(Me) bond length increases on passing from Si to Sn, which hinders the mixing.

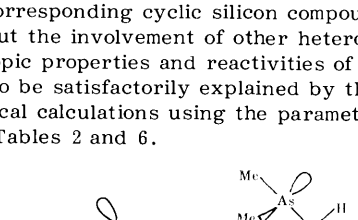
A more objective estimate of the capacity of various σ(C–E) orbitals for mixing is possible on comparing the corresponding spectroscopic characteristics of the benzyl derivatives $PhCH_2EMe_3$: in these compounds the C_{ar}–C(E) bond length is independent of E and the capacity for overlap of the *d* orbitals of the element with the benzene π orbitals is also significantly reduced. The ionisation potentials measured by the PES method[43,180], the results of quantum-chemical estimations, and the positions of the long-wavelength absorption bands in the ultraviolet spectra of the compounds $PhCH_2EMe_3$ are also presented in Table 6. As was to be expected, the degree of mixing of the σ(C–E) and π orbitals in these compounds is determined mainly by the difference between their energies and is therefore a maximum for the σ(C–Ge) and σ(C–Sn) orbitals.

The results presented in Table 6 agree well with the experimental data[37] and with the estimates[180] of other workers. Here it is appropriate to mention the results obtained when account is taken of contributions of different kinds to the observed changes in the energies of the highest occupied molecular orbitals. In particular, the results of such analysis have been obtained for the phenyl and benzyl derivatives of Group IVA elements $PhEMe_3$ and $PhCH_2EMe_3$.[43] Within the framework of molecular orbital perturbation theory, the changes in the energies of the benzene π_1 and $\pi_{2(sym)}$ orbitals δE_{π_1} and δE_{π_2} can be represented as the sums of the inductive ($q_{\mu i}.\delta W_i$) and hyperconjugation ($\beta^2 q_{\mu i}\Delta E^{-1}$) contributions:

$$\delta E_{\pi_1} = (1/6)\,\delta W + (1/6)\beta^2 (E_{\pi_1} - E_\sigma)^{-1},$$
$$\delta E_{\pi_2} = (1/3)\,\delta W + (1/3)\beta^2 (E_{\pi_2} - E_\sigma)^{-1},$$

while the change in the energy of the σ(E–C) orbital is defined by the formula

$$\delta E_\sigma = (1/3)\beta^2 (E_\sigma - E_{\pi_2})^{-1} + (1/6)\beta^2 (E_\sigma - E_{\pi_1})^{-1}.$$



In these expressions E_σ, E_{π_1}, and E_{π_2} are the energies of the corresponding unperturbed orbitals, $q_{\mu i}$ is the electron density of the φ_μ orbital at the *i*th centre, δW_i is the change of the effective ionisation potential of the *i*th carbon atom as a consequence of the inductive effect of the substituent, and β is the resonance integral between the 2*p*(C) orbital of the *i*th atom and the orbital of the substituent. The electron-accepting influence of the unoccupied *d* orbitals has been estimated by comparing the calculated and experimental estimates of δE_{π_2}. Table 7 summarises the results obtained. The determination of the contributions of the individual components enumerated in Table 7 is based on the experimental estimates of δE_{π_1}, δE_{π_2}, and δE_σ. The accuracy of such estimates is low and they must be regarded as extremely approximate; in particular, unstructured bands in the PES correspond to the ionisation of the σ orbitals. This is possibly why the hyperconjugation contributions by the carbon–element bonds in the benzyl compounds have been found to be clearly too low: they proved to be smaller even than the inductive contributions and also the corresponding contributions in compounds of the type $PhEMe_3$. Such results conflict with the estimates of other authors and the experimental data[37,180]. The effects of the mixing of the σ and π orbitals have also been investigated for the corresponding allyl compounds[180]. It is of interest that here the authors concluded that the resonance integrals β for the π and σ(C–E) orbitals are constant (for different E).

Table 7. Analysis of the causes of the changes in the orbital energies in the compounds $PhEMe_3$ and $PhCH_2EMe_3$ (according to the data of Dewar et al.[43]).

* Estimates of the hyperconjugation effect based on the data of Schweig et al.[180] are presented in brackets for comparison.

Among other types of organic compounds of Group IVA elements, in which the σ and π orbitals are mixed, one should mention arylpolysilanes[181–183]. Estimates of the degree of σ(Si–Si)–π mixing in their molecules have been obtained from PES data and the absorption spectra of charge-transfer complexes and the influence of the stereoelectronic factor has been revised[184]. The σ(Si–C) and π orbitals are also mixed in the corresponding cyclic silicon compounds both with and without the involvement of other heteroatoms[176,185]. The spectroscopic properties and reactivities of these compounds can also be satisfactorily explained by the results of quantum-chemical calculations using the parameters enumerated above in Tables 2 and 6.

The σ–π mixing is undoubtedly not a specific feature of organic compounds of Group IVA elements. For example, it also occurs in allyl sulphides[186]. The dependence of the degree of mixing of the σ(C–As) and π orbitals on the conformation has been studied[148]. It has been found that these orbitals are not mixed in benzyldimethylarsine, but their contribution to the HOMO of allyldimethylarsine, which has a different conformation, is extremely significant.

As for the atoms of Group VA elements, the 3*p* orbital of the silicon atom can be mixed with the carbon π orbitals to form molecular orbitals of the corresponding aromatic compounds. Among such compounds, mention should be made in the first place of silabenzene and silatoluene—compounds in which the silicon atom is in a tricoordinate state and which exhibit properties characteristic of aromatic compounds. Owing to their exceptionally high reactivity, it was for a long time not only impossible to isolate silabenzene and silatoluene in a pure state and to investigate them using appropriate chemical reactions but it was actually not possible to detect them by employing "trapping" reactions[17]. However, theoretical calculation showed that silabenzene should be thermodynamically very stable. In particular, it followed from the MINDO/3 calculation that the C—Si bond length of the cyclobenzene molecule should be 1.753 Å, which is ~ 5% less than the length of the C—Si single bond in methylsilane (1.837 Å).[187] According to the results of the *ab initio* calculation (in terms of the STO-3G basis set), the conjugation energy in the silabenzene molecule is −22 kcal mol^{-1} (for the benzene molecule the calculated conjugation energy is −32 kcal mol^{-1} and agrees fully with experimental data).[188]

The somewhat more stable silatoluene had been obtained earlier by the dehydrochlorination (at −77 °C) of 1-chloro-1-methyl-1-silacyclohexa-2,4-diene[189] and the pyrolysis (at 450 °C) of 1-allyl-1-methyl-1-silacyclohexa-2,4-diene[190]. Silabenzene was obtained in 1980 by the pyrolysis of 1-allyl- and 1-acetoxy-1-silacyclohexa-2,4-dienes[191,192].

The published PES of these aromatic organosilicon compounds are of interest. In conformity with the relations noted above and found in a study of the PES of phosphabenzene and its analogues, the ionisation potentials of silabenzene should vary linearly with the ionisation potential of the 3*p* electrons of the silicon atom. The calculated ionisation potential of silabenzene and its value determined from the PES are similar:

I(calc.), eV (Ref.1)	8.2 ($\varphi_{\pi(\mathrm{sym})}$)	9.2 ($\varphi_{\pi(\mathrm{asym})}$)	11.5 (φ_{π_1})
I(exp.), eV (Ref.191)	8.0	9.3	11.3

This shows that five 2*p* electrons of the carbon atoms and one 3*p* electron of the silicon atom in the molecule of this compound are delocalised, in full agreement with the characteristics of the formation of aromatic systems. An analogous situation has been observed also in the case of silatoluene[193]. Two ionisation bands in its PES have been assigned: at 7.7 eV to the $\varphi_{\pi(\mathrm{sym})}$ orbital and at 9.15 eV to the $\varphi_{\pi(\mathrm{asym})}$ orbital.

In conformity with the considerably higher energies of the highest occupied molecular orbitals of silabenzene and silatoluene compared with their carbon analogues, the ultraviolet spectra of these compounds exhibit a distinct bathochromic shift of all the absorption bands. As in the ultraviolet spectrum of benzene, three absorption bands are observed in that of silabenzene (at 10 K in an argon matrix): at 212 nm (instead of 180 nm in the benzene spectrum), at 272 nm (instead of 203 nm), and at 315—320 nm (instead of 255—265 nm). The long-wavelength absorption in the ultraviolet spectrum of silatoluene is observed at 315 nm instead of 255—265 nm in the ultraviolet spectrum of toluene[192].

The first compounds with an sp^2-hybridised germanium atom, namely 4-ethyl, and 4-(t-butyl)germatoluenes, have also been synthesised by the pyrolysis of the corresponding cyclohexadienes and investigated by the PES method[194].

Silabenzene and silatoluene proved to be the first compounds with an sp^2-hybridised silicon atom which was sufficiently stable for their study by the PES method. The first communications concerning the synthesis of stable disilenes—compounds with a double bond between two silicon atoms—appeared in 1981—1982.[195-197] For example, tetramesityldisilene[196] $(Me_3C_6H_2)_2Si{=}Si(C_6H_2Me_3)_2$ was obtained by the photolysis of 2,2-dimesitylhexamethyltrisilane[196], while the photolysis of hexakis(2,6-dimethylphenyl)cyclotrisilane yielded the disilene $(Me_2C_6H_3)_2Si{=}Si(C_6H_3Me_2)_2$.[197] It has been shown by X-ray diffraction that the bond length between the silicon atoms in the first of these disilenes is shorter than a single silicon—silicon bond in polysilanes by 10% and its ultraviolet spectrum showed an absorption at a longer wavelength, namely at 272 nm (3.85), 340 nm (3.44), and 422 nm (3.8), compared with the ethylene analogue.

5. The Atoms of the Boron Subgroup Elements

Organic compounds of the boron subgroup elements are distinguished by a high reactivity: they readily oxidise in air, react with electron donors, and tend to polymerise. The corresponding boron compounds are somewhat less reactive. Their PES and their orbital structure have been investigated in greater detail.

The BC_3 fragment in the trimethylborane molecule is planar and the boron atom has orbitals assuming trigonal directions. The first band in the PES of this compound refers to the ionisation of the σ(B—C) orbital and is observed at 10.7 eV; the ionisation of the σ(C—H) orbital is observed at 12.8—14.5 eV.[198]

In the study of the PES of boranes in which the boron atom is linked to unsaturated fragments, attention was concentrated on the estimation of the role of the unoccupied 2*p* orbitals of the boron atom in the formation of the occupied molecular orbitals. Since the boron atom has unoccupied *p* orbitals with the same principal quantum number $n = 2$ as the carbon atom, its corresponding compounds constitute a convenient model for the estimation of the role of the unoccupied orbitals in bonding, particularly in view of the ambiguity of the conclusions concerning the role of the unoccupied *d* orbitals in compounds of the elements in the Third and higher Periods[13-16].

The first attempt to estimate the involvement of the unoccupied *p* orbitals of boron in the interaction with the π orbitals of carbon was undertaken in connection with the comparison of the PES of trivinyl- and triethyl-boranes[199]. The first ionisation potentials of these compounds proved to be virtually identical, namely 9.7 and 9.6 eV respectively, and the ionisation of the π electrons in trivinylborane begins at 10.7 eV, as in ethylene. According to the authors[199], no appreciable mixing of the unoccupied 2*p*(B) orbitals with the π orbitals of the vinyl groups is observed in trivinylborane either as a consequence of the displacement of the orbitals from the plane (with conservation of the sp^2-hybridisation of the boron atom) or owing to the pyramidal structure of trivinylborane.

The involvement of the unoccupied 2*p* orbitals of the boron atom in the formation of the molecular orbitals of phenylboranes has been estimated by Ramsey and O'Neil[200]. As in the case of, for example, phenylsilanes $PhSiX_3$,[179] where the *d* orbitals play a significant role in the formation of the molecular orbitals, a dependence of the contribution of the unoccupied 2*p*(B) orbitals to the molecular π orbitals of the phenylboranes $PhBX_3$ on the character of the substituents X is observed. Fig.2 compares the energies of the π orbitals of various phenylboranes of the type $PhBX_2$. For example, in the PES of $PhBR_2$ the first ionisation potential refers to the ionisation of the a_2 orbital, whose energy increases as a consequence of the electron-donating influence of the group BR_2. It has been found from the results of a

quantum-chemical calculation that the contribution of the $2p$(B) orbital to the $\pi(b_1)$ orbital is considerable and the energy of the molecular orbital is therefore reduced.

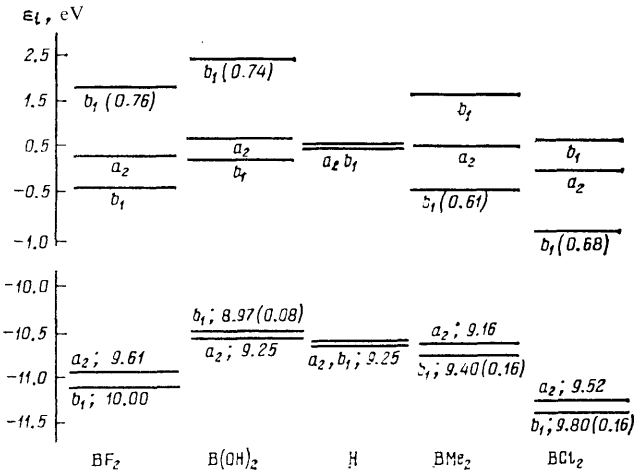

Figure 2. The influence of the substituents BX_2 on the energies of the π orbitals of the phenylboranes $C_6H_5BX_2$ according to PES data (the ionisation potentials are indicated in electron-volts) and CNDO/2 calculations [the energies of the molecular orbitals are indicated along the ordinate and the coefficients of the $2p$(B) orbitals in the corresponding molecular orbitals are indicated in brackets][200].

It was established in the same study[200] that the $2p$(B) orbital makes a considerable contribution to the occupied π orbitals also in dichlorophenylborane. As a consequence of the π-donor influence of the oxygen and fluorine atoms, the degree of involvement of the $2p$(B) orbital in the occupied $\pi(b_1)$ orbitals in the compounds with X=OR and F is reduced but becomes considerable in the unoccupied $\pi^*(b_1)$ orbitals.

6. The Atoms of the Zinc Subgroup Elements

Compounds in which the metal atom is bound to organic groups are known for virtually all the Group II metals. The reactivity of the organic compounds of the beryllium subgroup metals is, however, appreciably higher as a result of which their structure has been scarcely investigated by the PES method. On the other hand, although the zinc subgroup metal atoms have appreciably lower electronegativities than carbon, their organic, including aromatic, compounds are much less reactive; they have found wide applications in organometallic synthesis and are classical objects in theoretical chemistry[201,202]. The mixing of the orbitals in these compounds, in the first place in mercury compounds, has been studied in fair detail.

The C—E—C angles in dialkyl derivatives of Group IIB metals are ~ 180°[78] and the carbon–metal σ-bonds have low ionisation potentials[203–208]; the ionisation potentials of dimethylmercury, for example, are 9.3 and 11.6 eV[203,208]. Both properties specified above promote the mixing of the atomic orbitals of Group IIB metals with the carbon π orbitals in the corresponding organometallic compounds.

The role of the interaction of the σ and π orbitals in the benzyl and allyl compounds of mercury containing the

fragment was first noted by Nesmeyanov as early as 1948[209]; a molecular-orbital interpretation of the effect of the $\sigma-\pi$ conjugation was first achieved in a study of the absorption spectra of charge-transfer complexes[210]; quantitative estimates of the degree of mixing of the σ(C—Hg) and π orbitals in allyl and benzyl compounds of mercury were achieved only when PES was employed[211–218].

In particular, in a study of the PES of allylmercury chloride, Schmidt et al.[211] estimated the degree of mixing of the σ(C—Hg) and carbon π orbitals with the aid of the quantity δE determined from the formula

$$\delta E = (H_{\sigma\pi})^2/\Delta E ,$$

in which ΔE is the difference between the energies of the fragment orbitals and $H_{\sigma\pi}$ the resonance integral for the σ and π orbitals. The values of $H_{\sigma\pi}$ calculated from the PES data for allylmercury chloride and benzylmercury chloride proved to be virtually identical (0.98 and 0.99 eV respectively) and close to the corresponding values for the allyl and benzyl compounds of other metals[212].

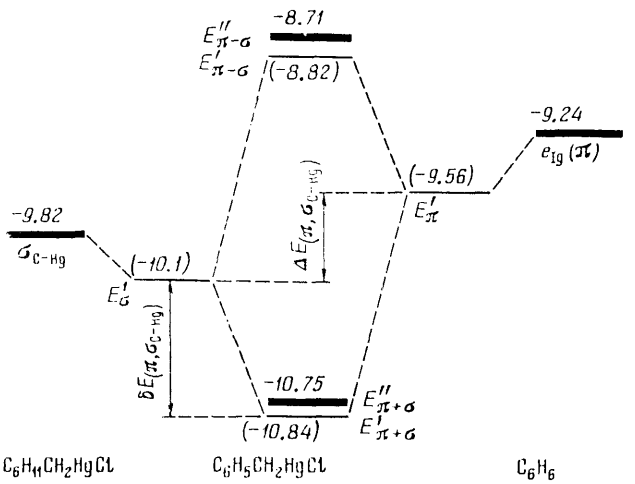

Figure 3. Schematic illustration of the formation of the molecular orbitals of benzylmercury chloride[213] (the energies are indicated in electron-volts).

An attempt has been made[213] to separate the contributions to the molecular orbital energy due to the σ(C—Hg)—π mixing, the inductive effect, and the mixing of the σ(C—Hg) and π orbitals with the σ(C—H) orbitals. Fig. 3 presents a qualitative diagram for the formation of the molecular orbitals of benzylmercury chloride. The value of E(C—Hg) shown in this diagram was found from the correlation between the ionisation potentials of the n(Cl) and σ(C—Hg) orbitals established on the basis of data referring solely to alkylmercury chlorides; the values of E'_{σ}(C—Hg) and E'_{π} were estimated taking into account the inductive effects of the Ph and CH_2HgCl groups respectively; the energies $E'_{\sigma-\pi}$ and $E'_{\sigma+\pi}$ were found from equations proposed[37] for a quantitative description of the $\sigma-\pi$ mixing; the energies $E''_{\sigma-\pi}$ and

$E''_{\sigma+\pi}$ were estimated with the aid of the corresponding ionisation potentials found from the PES of benzylmercury chloride. The difference between the values of $E'_{\sigma-\pi}$ and E'_{π} is equal to the absolute change in the energy of the benzene $b_1(\pi)$ orbital arising owing to its mixing with the σ(C—Hg) orbital and the value 0.74 eV was adopted for it. The differences between the $E''_{\sigma-\pi}$ and $E'_{\sigma-\pi}$ energy levels and also between $E''_{\sigma+\pi}$ and $E'_{\sigma+\pi}$ are associated with the additional destabilisation of the molecular orbitals on mixing of the initial σ(C—Hg) and π orbitals with σ(C—H) orbitals.

It is of interest to compare the values of the integral $H_{\sigma(C-H)\pi}$, characterising the degree of mixing of the σ(C—Hg) and π orbitals, obtained in two ways. One value was found from the data in the diagram (Fig.3):

$$H_{\sigma(C-Hg)\pi} = \sqrt{(-9.56+8.82)(-10.1+8.82)} = -1.0 \text{ eV}.$$

The other, amounting to −1.1 eV, was found from the scheme discussed in the Introduction, i.e. without including the additional effects noted in the diagram but with an appropriate selection of model compounds for the estimation of the energies of the fragment orbitals: the energy of the π orbital was estimated with the aid of the first ionisation potential of benzene, while the first ionisation potential of methylmercury chloride was used to estimate the energy of the σ(C—Hg) orbital[214]:

$$H_{\sigma(C-Hg)\pi} = \sqrt{(-9.24+8.71)(-10.8+8.71)} = -1.1 \text{ eV}.$$

Without overestimating the similarity of the above two estimates of the integral $H_{\sigma(C-H)\pi}$, we emphasise yet again that, with an apt selection of "model" compounds, it is as a rule possible not only to parametrise reliably the quantum-chemical calculations for the corresponding complex compounds on the basis of the PES of the "model" compounds[108] but also one can estimate fairly reliably the degree of mixing of particular atomic or fragment orbitals.

There are few data for the orbital interactions in compounds where the mercury atom is linked directly to carbon π-electron systems[213,218,219]. The ionisation potentials (eV) of phenylmercury chloride PhHgCl [9.40 ($b_1 + a_2$); 10.45 (σ_{C-Hg}); 10.84 (p_{Cl})] and phenylmercury bromide PhHgBr [9.33 ($b_1 + a_2$)] show that the occupied 5*d* and unoccupied 6*p* atomic orbitals of mercury are not effectively mixed with the benzene π orbitals. The same conclusion is valid also for diphenylmercury[219]. On the other hand, the mixing of the $e_{1g}-\pi$ orbitals of propynyl groups and the $e_{1g}(5d_{xz}$ and $5d_{yz})$ orbitals of mercury in mercurialkynes has been observed.

The PES method and the quantum-chemical calculations in the π-approximation parametrised on its basis make it possible to estimate quantitatively the degree of mixing of the orbitals of various elements with the carbon π orbitals in the corresponding organoelemental aromatic compounds. The estimates obtained show that the main factor determining the effectiveness of the mixing is the principal quantum number of the element, i.e. the number of the Period to which it belongs. The most effective π-type mixing with the π orbitals of carbon is that of the corresponding orbitals of the elements in the Second Period.

Nevertheless the atoms of elements having a principal quantum number greater than two are capable of $(p-p)\pi$ bonding both with carbon atoms and with one another contrary to the "classical double bond rule"[220-222]. The parameters $H_{E\pi(sym)}$ and $H_{(CE)\pi(sym)}$, characterising the mixing of the benzene $\phi_{\pi(sym)}$ orbital with the corresponding orbitals localised at the heteroatoms E, are fairly large, their values being listed below for certain Group IV—VII elements (see also Tables 1—3 and 6):

C	N	O	F
−1.03	−1.21	−1.37	−0.84
Si	P	S	Cl
−0.60	−0.34	−0.84	−0.63
Ge	As	Se	Br
−0.54	0.0	−0.72	−0.62

As shown in the present review, the parameters $H_{E\pi(sym)}$, determined from the analysis of the PES of "model" compounds (substituted benzene derivatives) determine unambiguously in their turn the parameters H_{EC} ($H_{EC} = \sqrt{3}H_{E\pi(sym)}$), which characterise the mixing of the orbitals of the element not with the benzene π orbital but with the $2p_{\pi}$ orbital of the carbon atom and are suitable for the estimation and parametrisation of the mixing of the orbitals also in calculations carried out in terms of an atomic basis set. The parameters H_{EC} have been used successfully in the analysis of the molecular orbital structure, particularly in the case of cyclic compounds where the atoms of the elements are present as part of the composition of rings and not as substituents[108-110,129].

The matrix elements $H_{\mu\mu}$ and $H_{\mu\nu}$, used in quantum-chemical calculations by the simple method, have a complex nature: they include also effects determined by the skeletal integrals and the effects of the interelectronic interactions. At the same time it is evident that the diagonal elements $H_{\mu\mu}$ and $H_{\nu\nu}$ depend mainly on the energy of the electron in the μth and νth fragment orbitals respectively, while the non-diagonal elements $H_{\mu\nu}$ depend mainly on the energy of the electron in the region of the mixing of the μth and νth fragment orbitals and thus characterise the degree of their interaction. The parameters $H_{\mu\nu}$, which have a perfectly definite quantum-chemical significance, can, in our view, provide a better understanding of the experimental results in many instances than the numerous constants estimating the conjugation effects. The molecular-orbital characteristics calculated on their basis have been used successfully in the interpretation of the spectra (in the first place photoelectron spectra) and reactivities of complex organoelemental aromatic compounds, including polycyclic compounds.

Transition Metal Complexes as Catalysts of the Synthesis of Hydrocarbons from Carbon Oxides and Hydrogen

A.L.Lapidus and N.M.Savel'ev

The results of studies on the synthesis of hydrocarbons from carbon oxides and hydrogen in the presence of metal complex catalysts are considered and the characteristic features of the activation of CO and CO_2 by transition metal complexes and the mechanisms of the reduction of carbon oxides by hydrogen are discussed.
The bibliography includes 114 references.

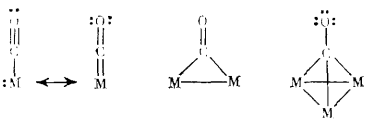
I. INTRODUCTION

The synthesis of hydrocarbons from carbon oxides and hydrogen has currently acquired renewed great practical importance as a method for the preparation of motor fuels and valuable chemical products based on coal[1-3]. The inadequate yield of the existing synthetic processes, the lack of catalysts for the specific synthesis of individual hydrocarbons and their narrow fractions, the considerable energy consumption, and also certain technological difficulties due to the need to remove considerable amounts of heat as a consequence of the highly exothermic nature of the reactions must be included among their deficiencies[4]. Both in our country and abroad, a vigorous search is being prosecuted for metal complex catalysts of the synthetic reactions, possessing high activity and selectivity under mild conditions[4,5].



The synthesis of hydrocarbons from carbon oxides and hydrogen in the presence of metal complex catalysts is a comparatively new branch of metal complex catalysis. The first studies in this field were published as late as 1976. The number of publications having a direct bearing on the synthesis of hydrocarbons from CO and H_2 in the presence of transition metal complexes is small —it does not exceed several tens of communications dealing with the modelling of individual stages of the process and proposing reaction mechanisms. A series of reviews have considered the activation of CO [6,7] and CO_2 [7-9] by transition metal complexes, the reduction of CO [6,7] and CO_2 [7,9] to organic compounds, and the synthesis of hydrocarbons from CO and H_2 in the presence of metal complex catalysts[6,7].

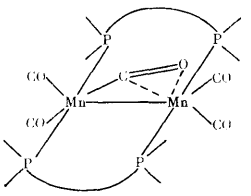
The present review deals with methods for the activation of carbon monoxide and with its reactions in the presence of transition metal complexes, including the synthesis of hydrocarbons from CO and H_2; it also discusses the problem of the activation of CO_2 by transition metal complexes. The activation of hydrogen by transition metal complexes has been considered in a monograph[10].

II. THE REDUCTION OF CARBON MONOXIDE IN THE PRESENCE OF TRANSITION METAL COMPLEXES

1. The Ways in which Carbon Monoxide is Coordination to Transition Metals

Examination of various ways in which the CO molecule is coordinated to transition metals makes it possible to infer the degree of activation of the carbonyl ligand and hence to outline procedures for the reduction of carbon monoxide to hydrocarbons or other organic compounds. These procedures are represented below[7]:

(Ia) (Ib) (II) (III)



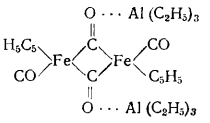
It is well known[11] that in metal carbonyls there is a simultaneous transfer of electrons from the σ orbital of the CO group to the metal atom and from the metal to the π orbital of CO. The transfer of electrons from the *d* orbitals of M to the π orbitals of CO entails a decrease of the C–O bond order and an increase of the metal–carbon bond order; this has been confirmed by infrared spectroscopic data. The stretching vibration frequency in free carbon monoxide is in the range 2146–2170 cm^{-1} and the corresponding vibration frequencies of the terminal CO group of metal carbonyls [structure (I)] have lower values (2000–2100 cm^{-1}).[11] With some approximation, the decrease of the stretching vibration frequency reflects the decrease of the C–O bond force constant and also the bond order. The increase of electron density at the transition metal atoms leads to an increase of the reverse supply of electrons to the π orbitals of CO and to a decrease of the C–O bond order. For example, the stretching vibration frequencies of the CO groups in the isoelectronic and isostructural complexes $[Mn(CO)_6]^+$, $Cr(CO)_6$, and $[V(CO)_6]^-$ are 2096, 2000, and 1859 cm^{-1} respectively[12]. Thus the contribution of the resonance structure (Ib) increases in the sequence Mn, Cr, V. However, the decrease of the bond order for the terminal CO groups of metal carbonyls is insignificant and an appreciable charge in the C–O bond length has not been observed[13].

The stretching vibration frequencies of the bridging carbonyl groups [structure (II)] are in the range 1700–1850 cm^{-1} and the C–O bond order is two and in some cases even less. Despite the outward analogy of the bridging carbonyl groups and organic carbonyl compounds (ketones, aldehydes, etc.), the character of the C–O bond in these compounds differs appreciably. Firstly, the transition metal atom is less electronegative than the carbon atom, which leads to a greater polarisation of the M–C bond compared with the C–C bond. Secondly, the MCM angle is much smaller than that at carbon in the sp^2-hybridised state and amounts to, for example, 83° for $Co_2(CO)_8$ and 77° for $Fe_2(CO)_9$.[14,15] Furthermore, the metal–metal bond shields the carbon atom of the bridging carbonyl ligand. For the reasons indicated above, the bridging carbonyl group is less reactive with

respect to nucleophilic attack on the carbon atom than the carbonyl groups in organic compounds.

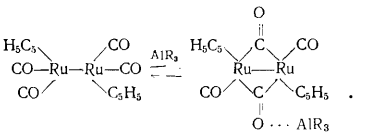
The bridging carbonyl groups bound to three metal atoms [structure (III)] are inadequately described by the valence bond method. However, it is evident that an appreciable decrease of the C–O bond order is attained in this case because the stretching vibration frequencies in μ^3-CO are in the region of 1600 cm^{-1}. At the same time the bridging carbonyl groups bounds to three metal atoms are characterised by longer C–O bonds. For example, the C–O distance in $Rh_6(CO)_{16}$ is 1.155 ± 0.015 Å for the terminal groups and 1.201 ± 0.022 Å for the bridging groups[16].

Thus, depending on the nature of the complex and on the mode of coordination of the carbonyl ligand, the latter exhibits different reactivities, which are determined by the redistribution of electron density in the M_nCO system. An extremely unusual mode of coordination of the CO group has been observed comparatively recently. The complex $Mn_2(CO)_5(dppe)_2$, where dppe = bis(diphenylphosphino)-ethane[17], coordinates the CO molecule in accordance with the scheme below:



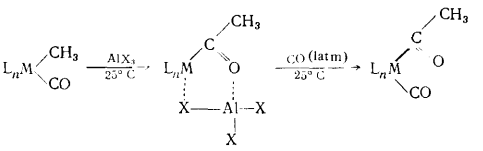
In this case the carbonyl ligand forms a σ-bond with one Mn atom and a π-bond with the other, which leads to an unexpectedly low stretching vibration frequency of CO (1645 cm^{-1}).

2. The Reactivity of the Carbonyl Ligand



When a CO molecule is coordinated to two or more transition metal atoms, as indicated above, the C–O bond order is appreciably reduced. Thus the bridging carbonyl groups are activated to a greater extent by the transition metal than the terminal groups[18]. This type of coordination of CO obtains in carbonyl clusters and has much in common with the dissociative adsorption of CO on metal surfaces, including metals forming part of the composition of heterogeneous catalysts. Presumably the bridging carbonyl ligands bound to three carbon atoms are activated to the greatest extent. However, convincing evidence confirming their enhanced reactivity has not so far been obtained.

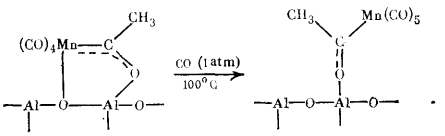
An appreciable increase of the reactivity of the carbon ligand is achieved when it interacts with Lewis acids[19,20]. Such interaction is characteristic of the strongest Lewis acids—derivatives of boron and aluminium. The possibility of adding a Lewis acid to the oxygen atom of the carbony ligand was observed for the first time by Schriver and co-workers[21,22] for the bridging CO groups in the complex $[(C_5H_5)Fe(CO)_2]_2$, which forms an adduct with two $Al(C_2H_5)_3$ molecules:



The structure of the adduct was established by X-ray diffraction[21]. Its formation reduces greatly the stretching vibration frequencies of the bridging CO groups involved in the interaction with the Al atom and some increase of the stretching vibration frequencies of the terminal carbonyl ligand. The decrease of the stretching vibration frequencies of the CO groups bound to Al is induced by the weakening of the C–O bonds as a consequence of the shift of electron density towards the electron acceptor molecule, which entails a decreased electron density at the transition metal atom and hence increased stretching vibration frequencies of the terminal CO groups.

The study of the interactions of complexes containing both bridging and terminal CO groups with Lewis acids has shown that the bridging CO groups are more basic. The basicity of the oxygen atom of the CO group increases in the sequence terminal groups < doubly bridging groups < triply bridging groups[19]. The differences between the basicities can be used to shift the equilibrium and to convert terminal groups into bridging groups; for example[23]:

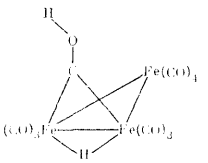
Thus the action of the Lewis acid alters the structural parameters of the carbonyl ligand and leads to a redistribution of electron density, which favours nucleophilic attack on the carbon atom of the coordinated CO molecule.



It has been shown[24,25] that the Lewis acids BX_3 (X = F, Cl, or Br) and AlX_3 (X = Cl, Br, CH_3, or iso-C_4H_9) catalyse the insertion of CO into the M–C bond:

$L_nM(CH_3)(CO)$ = $(CO)_5MnCH_3$, $(CO)_5MoCH_3$, $(C_5H_5)(CO)_3MoCH_3$ and $(C_5H_5)(CO)_2FeCH_3$.

The rate of insertion of CO increases by several orders of magnitude under these conditions. In certain cases, this reaction does not occur in the absence of the Lewis acid at a CO pressure of 1 atm and 25 °C. For example, the insertion of CO in the Fe–C bond of $(C_5H_5)(CO)_2FeCH_3$ occurs only at a CO pressure of 136 atm and 125 °C in the absence of AlX_3. The structure of the intermediate acyl complexes bound to the Lewis acid was established by X-ray diffraction[25].



It is of very great interest that the above reaction is catalysed also by Al_2O_3.[26] It was found that, when $(CO)_5MnCH_3$ is deposited from pentane onto an Al_2O_3 film which had been heated to 500° or 1000 °C, the CO is inserted to the Mn–C bond at 25 °C. On the basis of the analysis of the infrared spectra, the authors[26] propose the following structure of the adducts:

In contrast to the adducts with molecular Lewis acids (AlX_3 and BX_3), in this case the successive addition of CO molecules takes place at higher temperatures (100 °C).

Thus the data presented above permit the conclusion that the Lewis acid significantly activates the carbonyl ligand in relation to nucleophilic attack on the carbon atom. The insertion of CO in the Mn–C bond on the Al_2O_3 surface is of fundamental importance because it is directly related to the mechanisms of the Fischer–Tropsch reaction in the presence of heterogeneous catalysts.

Reports of the activation of the carbonyl ligand by protic acids have appeared recently. It has been shown[27] that treatment of $[HFe_3(CO)_{11}]^-$ with a solution of HSO_3F in anhydrous CD_2Cl_2 leads to the formation of the compound $H_2Fe_3(CO)_{11}$, which has an extremely unusual structure according to ^1H NMR data and contains a protonated carbonyl ligand:

The same group of investigators were then able to show[28,29] that the carbonyl ligand activated in this way is capable of being reduced to CH_4 under mild conditions:

$$[Fe_3(CO)_{13}]^{2-} + HSO_3CF_3 \xrightarrow{25^\circ C} CH_4 + H_2 + CO + Fe^{2+} + SO_3CF_3^- .$$

The yield of CH_4 was 0.56 mole per mole of the cluster in three days. The presence of even trace amounts of water greatly reduced the rate of reaction.

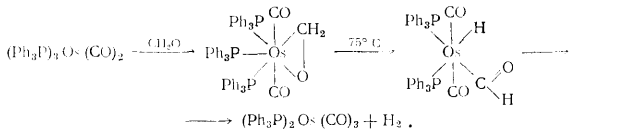
3. The Reduction of the Carbonyl Ligand

The possibility of reducing the carbonyl ligand to the formyl ligand was first demonstrated in 1976.[30] It was found that, when various carbonyl complexes in tetrahydrofuran (THF) are treated with $Na[HB(OCH_3)_3]$ at 25 °C, the formyl derivatives are formed:

$$M(CO)_n + [HB(OCH_3)_3]^- \rightarrow \left[(CO)_{n-1}M-C\begin{matrix}O\\H\end{matrix}\right]^- + B(OCH_3)_3 .$$

The formation of the formyl ligand was detected by ^1H NMR, ^{13}C NMR, and infrared spectroscopic methods. On reduction of $Fe(CO)_5$, the formyl ligand was activated in the form of $[(Ph_3P)_2N][(CO)_4FeCHO]$ in 39% yield. A series of communications[31–44] on the synthesis of formyl complexes were published in subsequent years. It was shown[31,32] that the reduction of $[(C_5H_5)Re(CO)_2(NO)]BF_4$ with $Li[HB(C_2H_5)_3]$ in THF at 0–25 °C leads to the formation of mono- and di-formyl complexes, while BH_3 reduces the formyl ligand to the methyl ligand under the same conditions:

$$[(C_5H_5)Re(CO)_2NO]^+ \xrightarrow{HB(C_2H_5)_3^-} (C_5H_5)Re(CO)(NO)(CHO) \rightarrow \begin{cases} \xrightarrow{BH_3\cdot THF} (C_5H_5)Re(CO)(NO)(CH_3) \\ \xrightarrow{HB(C_2H_5)_3^-} (C_5H_5)Re(NO)(CHO)_2 \end{cases} .$$

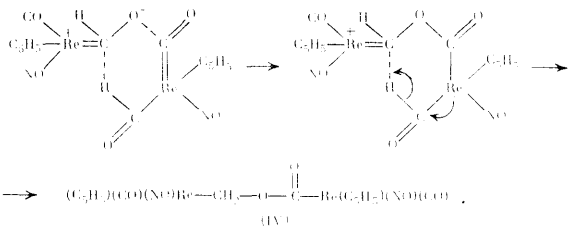


Another groups of investigators[33,34] were able to demonstrate the formation of the hydroxymethyl complex on reduction of the carbonyl ligand with $NaBH_4$ in THF at 0–25 °C:

$$[(C_5H_5)Re(CO)_2NO]^+ \xrightarrow{NaBH_4} (C_5H_5)Re(CO)(NO)X ;$$
$$X = CHO, CH_2OH, CH_3 .$$

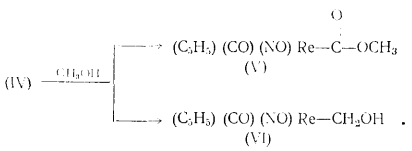
Depending on the reaction conditions, it is possible to isolate formyl, hydroxymethyl, or methyl complexes.

Treatment of $Os_3(CO)_{12}$ or $Ir_4(CO)_{12}$ with $Li[HB(C_2H_5)_3]$ leads to the reduction of one of the carbonyl ligands to the formyl ligand[35,36] and the formation of the cluster anions $[Os_3(CO)_{11}(CHO)]^-$ or $[Ir_4(CO)_{11}(CHO)]^-$. The latter anion decomposes with formation of the hydride complex $[Ir_4(CO)_{11}H]^-$.



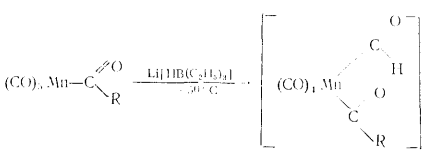
An osmium complex[27] containing coordinated formaldehyde, which is a tautomer of the hydroxymethylene ligand $-C\begin{matrix}H\\OH\end{matrix}$ has been synthesised:[37]

On heating, the complex decomposes with evolution of H_2 and formation of $(Ph_3P)_2Os(CO)_3$.

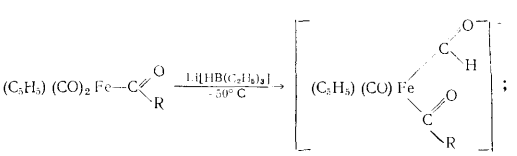


Studies have shown[38–40] that the formyl complexes behave as donors of the hydride ion. For example, when $[(C_2H_5)_4N]\cdot[(PhO)_3PFe(CO)_3(CHO)]$ reacts with $Re_2(CO)_{10}$, a formyl complex of rhenium is formed: in the case of acetone, isopropyl alcohol is produced and in the case of alkyl halides, the products are alkanes.

A hydride ion need not be transferred only to another transition metal complex. The disproportionation of formyl complexes with transfer of a hydride ion to the formyl ligand in accordance with the following scheme has been described[41,42]:



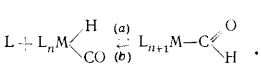
(IV)



The metalloester (IV) has been isolated and characterised by ^1H NMR and infrared spectroscopy. Its methanolysis leads to the formation of the methyl ester of the metalcarboxylic acid (V) and to the hydroxymethyl complex (VI):

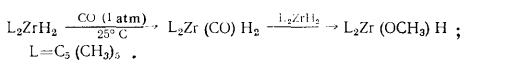
Dinuclear formyl complexes[43] of the type $Li[(CO)_5MM'(CO)_4\cdot(CHO)]$, where M = M' = Re or M = Re and M' = Mn, were first obtained from $Li[HB(C_2H_5)_3]$ and $ReMn(CO)_{10}$ or $Re_2(CO)_{10}$ at 25 °C.[43] Treatment of these complexes with an excess of $K[HB(t\text{-}C_4H_9)_3]$ leads to the formation of formaldehyde and methanol in yields of 21 and 38% respectively.

Formyl complexes of Mn and Fe containing an acyl ligand have been recently synthesised and characterised[45]:



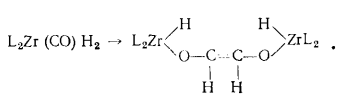
R = Ph, CH_2OCH_3, $COOCH_3$, CF_3, CH_3 .

These complexes decompose at room temperature in accordance with the scheme

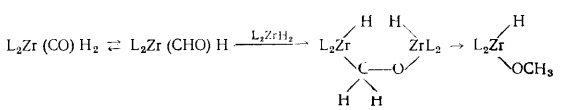


It has been suggested that the decomposition of these complexes entails a transfer of the hydride ion from the formyl to the acyl ligand[45].

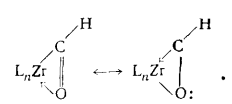
Thus it has now been reliably demonstrated that formyl complexes of transition metals exist. It has been established that the reduction of the carbonyl ligand by an active donor of the hydride ion leads to the formyl ligand and in certain cases the latter is reduced with formation of the hydroxymethyl or methyl groups. The study of the properties of the formyl complexes showed that they are capable of transferring the hydride ion to the carbonyl[38–40], formyl[41,42], or acyl[45] ligand and also to ketones and alkyl halides[38–40]. It is noteworthy that in the cases indicated above it is suggested that the formyl ligand is formed on treatment with a hydride ion donor, namely BH_3, $NaBH_4$, $Li[HB(C_2H_5)_3]$, etc., i.e. as a result of the nucleophilic attack by the hydride ion on the carbonyl ligand. There has been only one communication[46] on the synthesis of a formyl complex as a result of the insertion of the CO group in the Rh–H bond [reaction (*a*)]. Furthermore, all the formyl complexes synthesised hitherto are coordination-saturated and reaction (b) is therefore hindered, although at elevated temperatures the ligand is split off and a carbonyl hydride complex is formed[35]:



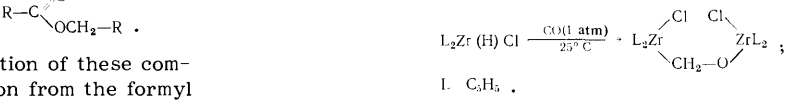
On the other hand, there exist many instances of the insertion of CO in a transition metal–carbon bond with formation of acyl complexes[47]. The formation of formyl complexes from hydrocarbonyls is thermodynamically less favourable than the formation of acyl complexes from alkyl carbonyls.



In 1976 the reduction of the carbonyl ligand to the methoxy-group was reported[48]:

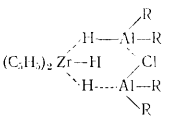


Hydrolysis of the resulting complex leads to the formation of methanol. In the absence of an excess of L_2ZrH_3, the carbonyl hydride complex $L_2Zr(CO)H_2$ dimerises according to the scheme

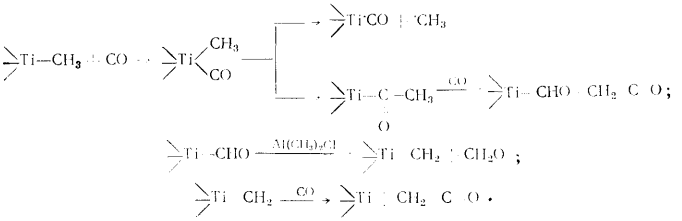


The authors[48] proposed a reaction mechanism with the intermediate formation of a formyl complex:

Subsequent investigations of this reaction led the authors[49] to the conclusion that the formyl complex formed on insertion of CO in the Zr–H bond can be stabilised as a consequence of the formation of a π-bond, as in the stabilisation of an acyl ligand[50]:

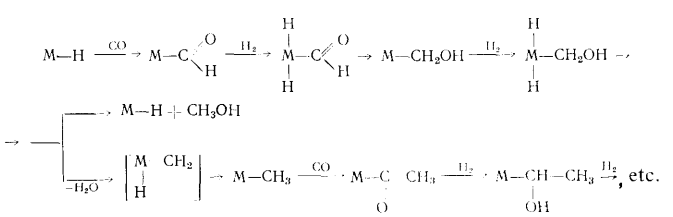


When CO interacts with zirconium halide hydride, a dinuclear complex is also formed and hydrolyses with formation of CH_3OH: [51]



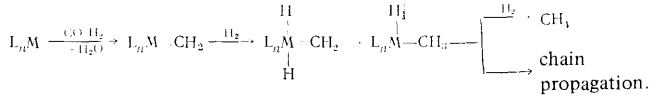
Thus zirconium hydride complexes reduce carbon monoxide under mild conditions. In this case the formation of the coordination-unsaturated formyl complex $L_2Zr(CHO)H$ as a result of the insertion of CO in the Zr–H bond has been postulated. The complex is stabilised by the additional π-binding of the formyl ligand.

In the presence of $HAlR_2$ (R = iso-C_4H_9) and $(C_5H_5)ZrCl_2$, it has been possible to reduce CO to linear alcohols[52]. The reaction proceeds at 25 °C and a carbon monoxide pressure of 1–4 atm in benzene. The formation of a zirconium hydride complex during the course of the reaction has been postulated:



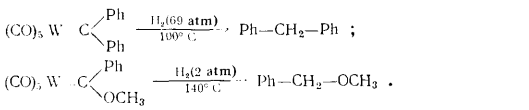
As a result of the interaction of this complex with CO and subsequent hydrolysis, a mixture of normal alcohols in the molar proportions $C_1 : C_2 : C_3 : C_4 = 1 : 0.12 : 0.15 : 0.03$ is formed. An excess of $HAlR_2$ inhibits the reaction but up to ten $HAlR_2$ addition cycles can be carried out without an appreciable decrease of activity. The use of ^{13}CO leads to the formation of $^{13}CH_3OH$.

Enikolopyan and co-workers observed that, in the presence of $Al(CH_3)_2Cl$, $(C_5H_5)_2TiCl_2$ catalyses the reduction of CO at 20–50 °C and atmospheric pressure to formaldehyde and keten. The introduction of $LiAlH_4$ into this catalytic system increases its activity (three moles of CH_2O per gramme-atom of Ti are formed in 1 h at 50 °C under 1 atm CO pressure). The authors[53] suggested the following reaction mechanism:

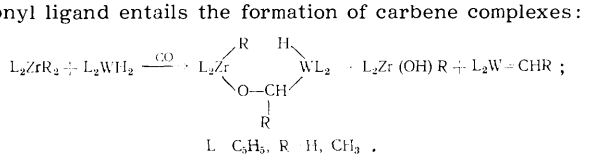


The study of model reactions involving the reduction of the carbonyl ligand and also the formation of complexes containing the formyl, hydroxymethyl, and methyl ligands on reduction of the coordinated CO molecule suggested a number of mechanisms of the CO hydrogenation reaction catalysed by transition metal complexes.

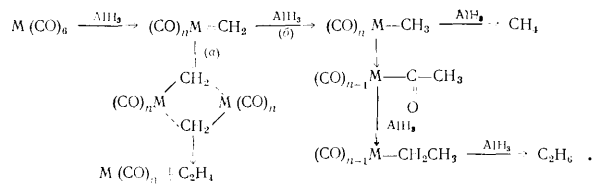
The following mechanism has been proposed for the process[54]:



The authors were unable to confirm it experimentally because most of the studies on the CO reduction reaction were published subsequently.

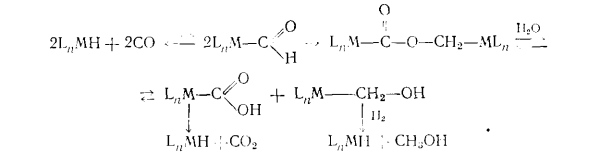


In 1976 it was suggested[30] that the reduction of the carbonyl ligand should lead to the formation of a carbene complex:



It has been shown that the carbene complexes are reduced with formation of alkanes:

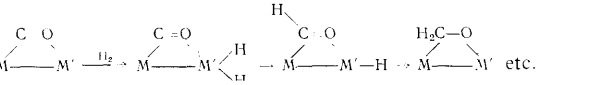
Subsequent studies[55,56] confirmed that the reduction of the carbonyl ligand entails the formation of carbene complexes:



Treatment of $Ru_3(CO)_{12}$, $Cr(CO)_6$, $Mo(CO)_6$, or $W(CO)_6$ with aluminium hydride in THF at 22 °C leads to a rapid evolution of C_1–C_3 hydrocarbons[57]. The ethylene content in the reaction product is 95% for chromium, molybdenum, and tungsten carbonyls. Not more than two carbonyl groups of the complex are reduced during the reaction and the solution remains homogeneous. The activity of $LiAlH_4$ is somewhat lower if BH_3 is inactive. A mechanism involving the formation of a carbene complex has been postulated[57]:

The selective formation of C_2H_4 has been explained by the preferential occurrence of the process via pathway (*a*). It may be that the carbonyl ligand is activated as a result of the binary coordination of the CO group: M–CO...AlH_3.

A mechanism for the reduction of CO involving a stage in which formyl complexes disproportionate has also been proposed[41]:



The authors observed[58] that the decomposition of the carbonyls $Ru_3(CO)_{12}$, $Os_3(CO)_{12}$, $Os_6(CO)_{16}$, $Rh_4(CO)_{12}$, and $Ir_4(CO)_{12}$ on the surfaces of Al_2O_3, SiO_2, or MgO at 250° to 400 °C in argon leads to the formation of C_1–C_3 alkanes and CO_2. The selectivity in the formation of CH_4 is 59–100%, depending on the nature of the complex. When the reaction is carried out in an atmosphere of CO, 5–13 moles of CH_4 and 40–90 moles of CO_2 are formed per mole of the complex. The authors suggest that the carbonyl ligand initially reacts with H_2O or surface OH groups of the oxide with formation of CO_2, after which the carbonyl ligand is reduced with hydrogen.

A more detailed study of this reaction showed[59] that hydrocarbons are formed from both polynuclear and mononuclear carbonyls and that in the case of the latter [$Cr(CO)_6$, $Mo(CO)_6$, $W(CO)_6$, and $Fe(CO)_5$] the maximum yield of CH_4 per gramme-atom of the metal is achieved. The authors[59] concluded that the synthesis of hydrocarbons in this instance does not require a catalyst of the cluster type and proposed a mechanism of the formation of methane in which H_2 plays an unusual role:

$$4OH(ads) + M(CO) \rightarrow MO_3 + 2O^-(ads) + CH_4 ;$$
$$3H_2 + MO_3 \rightarrow M + 3H_2O ;$$
$$\underline{2H_2O + 2O^-(ads) \rightarrow 4OH^-(ads)} \quad ;$$
$$CO + H_2 \rightarrow CH_4 + H_2O .$$

Inspection of the mechanisms presented above as well as the mechanisms of the model reactions involving the reduction of the carbonyl ligand permits the conclusion that the process can proceed with participation of a mononuclear complex rather than a cluster. On the other hand, it has been suggested[18,60] that carbon monoxide is reduced most readily in the presence of cluster catalysts because in the latter there is a possibility of the formation of active intermediates of the type M–CO–M', where M and M' are transition metal atoms:

Experimental confirmation of the existence of such structures has not so far been obtained, although they are known for transition metal complexes containing molecules with triple bonds (N_2 and C_2H_2).[60] It is believed[18,60] that the formation of intermediates of the type M–CO–M' and their hydrogenation may be energetically more favourable than the reduction of the CO molecule coordinated to one transition metal atom. Unfortunately both the possibility of the formation of such structures in carbonyl clusters and the possibility of the hydrogenation of CO with their intermediate formation have not so far been rigorously demonstrated[60–62].

We may note that, as stated above, the binary coordination of the carbon monoxide molecule (M–CO...M') is achieved in the adducts of metal carbonyls with Lewis acids. It has also been suggested that dinuclear complexes of the type L_nZr–CO–ZrL_n (L is the ligand) are formed on reduction of the carbonyl ligand to $-OCH_3$.

Thus examination of the above mechanisms of the reduction of CO with participation of transition metal complexes permits the conclusion that the most active catalytic system for the activation of CO is obtained on binary coordination of carbon monoxide of the type M–CO...M' or M–CO–M'.

4. The Synthesis of Hydrocarbons from CO and H_2

In 1976 Muetterties and co-workers[63] demonstrated for the first time that the synthesis of hydrocarbons from CO and H_2 can be catalysed by transition metal complexes. Methane is formed in the presence of $Ir_4(CO)_{12}$ or $Os_3(CO)_{12}$ in toluene at 140 °C and atmospheric pressure of the 1 : 4 CO–H_2 mixture. However, the rate of reaction is low and the degree of conversion of CO amounted to 1% after 3–5 days. The addition of Ph_3P or $(CH_3O)_3P$ increases slightly the activity of the catalyst.

The non-catalytic reduction of the carbonyl ligand occurs in the presence of niobium hydride complexes[64,65]. Treatment of $(C_5H_5)_2Nb(CO)H$ with hydrogen at 140 °C and a pressure of 1 atm in organic solvents leads to the formation of methane[64]. However, only the carbonyl ligand is then

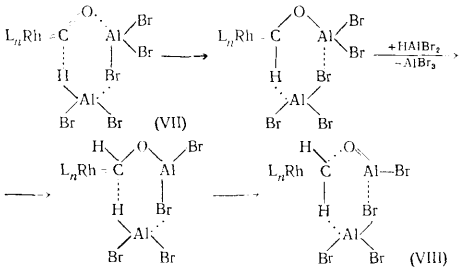
reduced, which was demonstrated using $(C_5H_5)_2Nb(^{13}CO)H$. The introduction of a mixture of CO and H_2 into the system did not increase the yield of CH_4. The hydride complex $(C_5H_5)_2NbH_3$ reduces the carbonyl ligand to $Cr(CO)_6$ at 45 °C in benzene and an H_2 pressure of 1 atm;[65] this involves the formation of CH_4 and C_2H_6 (10% per gramme-atom of niobium). The yield does not increase when CO is introduced into the system and Cr_2O_3 and $(C_5H_5)_2Nb(CO)H$ are formed at the end of the reaction.

Another example of the non-catalytic reduction of CO by hydrogen to CH_4 is the reaction of $(C_5H_5)_2Ti(CO)_2$ with H_2 at 150 °C in toluene[66]. When D_2 is employed, CD_4 is formed. The authors[66] do not present quantitative data for the yield of CH_4, but state that the reaction is non-catalytic and that the introduction of CO into the system does not increase that the introduction of CO into the system does not increase the yield of CH_4. At the end of the reaction, a cluster having the composition $Ti_6O_8(C_5H_5)_6$ was isolated and its structure was determined. Apparently the formation of $Ti_6O_8 \cdot (C_5H_5)_6$ is caused by the interaction of the titanium complex with water formed in the course of the synthesis of CH_4 from CO and H_2.

The most active catalytic system at atmospheric pressure has been proposed by Demitras and Muetterties[67]. It includes iridium, rhodium, or ruthenium carbonyls and the Lewis acids $AlCl_3$, $AlBr_3$, and BBr_3.[67,69] When the reaction is carried out in a Lewis acid melt without solvent with the ratio $CO : H_2 = 1 : 3$ at 180 °C and 1 atm, C_1–C_4 alkanes are formed. The complexes can then be arranged in the following activity series: $Ir_4(CO)_{12} \cong Rh_6(CO)_{16} \cong Rh_4(CO)_{12} > Ru_3(CO)_{12} \gg H_2PtCl_6 > PdCl_2$. The complexes $Cr(CO)_6$, $Mo(CO)_6$, $W(CO)_6$, $Re_2(CO)_{10}$, $Fe_2(CO)_9$, $Fe_3(CO)_{12}$, $Os_3(CO)_{12}$, $NiCl_2$, and $Co_4(CO)_{12}$ showed no activity. It is noteworthy that the activity series for the complex catalysts differs significantly from that for deposited heterogeneous catalysts in the methane formation reaction[70]. The catalytic activity of $Ir_4(CO)_{12}$ is such that 5 moles of CO enter into the reaction per mole of the complex in 1 h. During the reaction, the system remains homogeneous and the formation of metallic iridium is not observed. Furthermore, kinetic calculations based on the activity data for heterogeneous iridium catalysts showed that, even if the entire iridium from the initial $Ir_4(CO)_{12}$ catalyst were reduced to the metal and each metal atom functioned as an active centre for the methane formation reaction, then the calculated rate of reaction would have been lower by several orders of magnitude than the observed rate in the $Ir_4(CO)_{12}$–$AlCl_3$ system.[67] The introduction of metallic aluminium into the given catalytic system resulted in a sharp increase of the yield of hydrocarbons under the same conditions[71–73]. An appreciable alteration of the reaction products and an increase of the degree of conversion of CO are then observed[72].

Similarly the introduction of metallic aluminium into the "transition metal complex–$AlBr_3$" system led to a sharp increase of the yield of hydrocarbons when iridium, ruthenium, and particularly osmium and nickel carbonyls were employed under the same conditions[74]. The complex-forming metals used can be arranged in the following series in terms of their activities: Rh > Ir > Ru > Os > Ni (Table 1). This activity series differs from the analogous series for the M_nL_m–$AlCl_3$ systems presented above. The composition of the reaction products depends on the nature of the catalyst; in the presence of $Ir_4(CO)_{12}$ the main product is CH_4, while in the presence of $Rh_4(CO)_{12}$, $Ru_3(CO)_{12}$, and $Os_3(CO)_{12}$, appreciable amounts of C_4H_{10} and less C_2H_6 and C_3H_8 are formed together with CH_4. The degree of conversion of CO into hydrocarbons during the experiment then reaches 89% or 22 moles of CO per gramme-atom of rhodium. For the most active systems based on rhodium complexes, a study was made of the influence of the structure of the rhodium complex on the properties of the Rh_nL_m–$AlBr_3$–Al system[72] (Table 1). It was found that both mononuclear complexes and clusters exhibit virtually identical activities per gramme-atom of rhodium.

Table 1. The degrees of conversion of carbon monoxide (K_{CO}, mol CO/g-atom M) and the composition of the reaction products (vol.%) in the synthesis of alkanes from CO and H_2 in the presence of transition metal complexes.

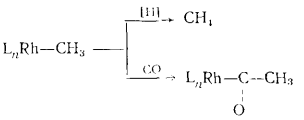


Complex	K_{CO}	CH_4	C_2H_6	C_3H_8	iso-C_4H_{10}	n-C_4H_{10}
$Rh_4(CO)_{12}$	22	47	8	14	30	1
$[Rh(CO)_2Cl]_2$	22	47	8	14	29	2
$Na_3[Rh_{12}(CO)_{30}]$	22	46	9	15	29	1
$(Ph_3P)_3RhCl$	21	50	6	13	30	1
$RhCl_3 \cdot 3H_2O$	3	37	13	12	35	3
$Ir_4(CO)_{12}$	12	73	9	8	9	1
$Ru_3(CO)_{12}$	7	50	5	9	35	1
$Os_3(CO)_{12}$	6	33	11	12	43	1
$NiCl_2$	3	33	16	13	36	2

Note: Conditions: 150°, 10 h, $CO : H_2 = 1 : 4$, molar ratios $M : AlBr_3 : Al : Co = 1 : 200 : 40 : 25$; the following catalysts showed no activity: $Fe(CO)_5$, $Co_2(CO)_8$, $(Ph_3P)_2PdCl_2$, $Mn_2(CO)_{10}$, $Mo(CO)_6$, $W(CO)_6$, and $TiCl_4$.

It was demonstrated by infrared spectroscopy[74] that in the course of the synthesis from CO and H_2 the initial rhodium complexes are converted into a mononuclear anion of the type $[Rh(CO)_2Br_2]^-$. Thus the data presented show that the synthesis of alkanes from CO and H_2 in the presence of the Rh_nL_m–$AlBr_3$–Al catalytic system proceeds on a mononuclear rhodium complex.

The study of the influence of the amount of metallic aluminium in the $Rh_4(CO)_{12}$–$AlBr_3$–Al system[72] showed that an increase of the ratio $Al : AlBr_3$ increases K_{CO} and the C_4H_{10} content in the products of the synthesis; at the same time there is a sharp decrease of the amount of CO_2. The authors[74] suggested the formation of $HAlBr_2$ from H_2, $AlBr_3$, and Al during the synthesis of alkanes from CO and H_2. The presence of $HAlBr_2$ was confirmed by the reduction of acetone to isopropyl alcohol. It was found that, when the $AlBr_3$–Al system was dissolved in THF and treated with a 1 : 4 CO–H_2 mixture at 150 °C, solutions capable of reducing acetone were formed. The reaction with solutions known beforehand to contain $HAlBr_2$, obtained from $LiAlH_4$ and $AlBr_3$, proceeded analogously. In addition, the amount of isopropyl alcohol formed and hence of $HAlBr_2$ was directly proportional to the aluminium content in the $Rh_4(CO)_{12}$–$AlBr_3$–Al system. Thus an increase of the content of aluminium in the $Rh_4(CO)_{12}$–$AlBr_3$–Al system entails an increase of K_{CO} and at the same time also an increase of the amount of $HAlBr_2$ formed during synthesis.

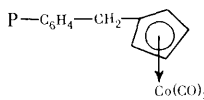


On the basis of the data obtained, the authors[74] proposed the following mechanism of the synthesis of hydrocarbons from CO and H_2 in the presence of the "rhodium complex–$AlBr_3$–Al" catalytic system:

The carbene complex formed and incorporated in the intermediate (VIII) can then be reduced to the methyl complex:

$$L_nRh{=}CH_2 \xrightarrow{[H]} L_nRh{-}CH_3 .$$

On further hydrogenation, this complex gives rise to an alkane or CO is inserted in the Rh–C bond and the resulting acyl complex is reduced in accordance with the mechanism presented above to the ethyl complex of rhodium:



It has been observed[75] that in the presence of the $W(CO)_6$–$AlCl_3$ catalytic system at 200 °C and a pressure of the CO–H_2 mixture of 120 atm, alkylbenzenes are formed from benzene:

$$C_6H_6 + CO + H_2 \rightarrow Ph{-}(CH_2)_n{-}H .$$

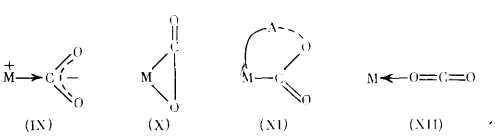
The length of the aliphatic chain of alkylbenzenes is consistent with the Schulz–Flory distribution characteristic of heterogeneous catalysts of the Fischer–Tropsch synthesis[76]. The molar ratios of the products were $PhCH_3 : PhC_2H_5 : PhC_3H_7 : PhC_4H_9 : PhC_5H_{11} = 25 : 39 : 1 : 0.1 : 0.1$.[75]

A catalyst containing the cobalt carbonyl complex grafted to a polymer (P) has been proposed for the synthesis of hydrocarbons from CO and H_2:[77]

At 190–200 °C and a pressure of the 1 : 3 CO–H_2 mixture of 30 atm and using n-octane as the solvent, a mixture of C_1–C_{20} hydrocarbons was obtained. The content of hydrocarbons in the products of the synthesis decreases uniformly with increase of their molecular weight. The catalyst exhibits a fairly low activity: 1×10^{-5} mole of CO is consumed per gramme-atom of cobalt in 1 h. The catalytic system containing $Al(C_2H_5)_3$ and the nickel salt of a carboxylic acid with 8–10 carbon atoms, dissolved in a hydrocarbon solvent, proved to be more active[78]. At 330 °C and a pressure of the mixture ($CO : H_2 = 1 : 4$) of 8 atm, the formation of C_1–C_4 hydrocarbons was observed (91% CH_4, 6% C_2H_6, 2% C_3H_8, and 1% C_4H_{10}). After 8 h, the degree of conversion of CO was 62%; a gaseous mixture containing 31 vol.% of the hydrocarbon was formed.

In the presence of cobalt acetylacetonate and $Al(C_2H_5)_3$ dissolved in alkylterphenyl, the formation of C_1–C_6 hydrocarbons from a 1 : 1 CO–H_2 mixture was observed at 190 °C and 1 atm.[79] The rate of formation of the hydrocarbons was 4.4×10^{-4} mole C/h g CO.

The use of $Ru_3(CO)_{12}$, $Os_3(CO)_{12}$, and $Ir_4(CO)_{12}$ as catalysts of the Fischer–Tropsch synthesis in THF or n-heptane as the solvent has been described[80]. At 300 °C and a pressure of the mixture ($CO : H_2 = 1 : 1$) of 200 atm, a mixture of C_1–C_{30} hydrocarbons was obtained after 20 h (1.9 moles of C_{10}–C_{20} and 0.6 mole of C_{20}–C_{30} per mole of the catalyst). However, the study of the kinetics of the reaction and the infrared spectra of the reaction mixture under the conditions of the synthesis showed[81,82] that the true catalyst of the synthesis of hydrocarbons in this case was metallic ruthenium formed from $Ru_3(CO)_{12}$. Apparently reports of the metal complex catalysis of the Fischer–Tropsch reaction at temperatures above 200 °C should be treated with some caution, because the majority of the transition metal complexes are unstable under these conditions.



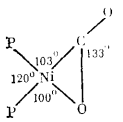
Layer compounds of graphite with transition metals occupy a position intermediate between homogeneous metal complex systems and heterogeneous catalysts of the Fischer–Tropsch reaction. It has been shown that at 300–350 °C the layer compounds of graphite with Group IV–VIII transition metals and potassium catalyse the synthesis of C_1–C_5 hydrocarbons from a mixture of CO and H_2 at 1 atm;[83,84] the main product of the synthesis is CH_4. The activity of layer compounds of graphite with $FeCl_2$ in the synthesis of hydrocarbons from CO and H_2 has been reported recently[85]. This catalyst is active in the synthesis of C_1–C_4 hydrocarbons from CO and H_2 at 300–500 °C and 1–20 atm; the main product of the synthesis is methane (70–90%).

Thus the survey of the literature dealing with the application of metal complex catalysts in the Fischer–Tropsch reaction permits the conclusion that homogeneous systems superior in their activity to traditional heterogeneous catalysts can be developed in principle. This problem has attracted many investigators both in our country and abroad as shown by the constant growth of the number of publications devoted to the application of metal complex catalysts in the reduction of CO to hydrocarbons. The development of studies in this field permits the hope that significant advances will be made in the immediate future.

III. THE REDUCTION OF CARBON DIOXIDE

1. The Ways in which Carbon Dioxide is Coordinated to Transition Metals

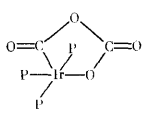
The activation of carbon dioxide by transition metals is directly related to the mode of formation of the bond between CO_2 and the transition metal. The coordination chemistry of CO_2 is a comparatively new field of the chemistry of organometallic compounds. The first complex containing the CO_2 molecule was synthesised by Vol'pin and Kolomnikov in 1969.[86] However, to date only a few complexes with CO_2 have been obtained when the structure has been established reliably. In principle the bond between CO_2 and the metal can be formed in accordance with the following schemes[8,9]:



(IX) (X) (XI) (XII)

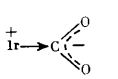
The interaction of the carbon atom of the CO_2 molecule, which exhibits Lewis acidity, with the transition metal [structure (IX)] is possible for metals in low oxidation states, which have an enhanced electron density. The adducts of transition metal complexes with Lewis acids containing the

"metal–Lewis acid" bond have a similar structure[20]. For example, the interaction of $(Ph_3P)_2Ir(CO)Cl$ with BF_3 leads to an adduct with a donor–acceptor Ir–BF_3 bond[87].



The complexes of transition metals in the lowest oxidation states, containing CO_2, can have the structure (X), which presupposes the interaction of the metal with the π-bond in CO_2. A third type of coordination is possible in the presence of a Lewis acidity centre in the coordination sphere or outside it [structure (XI)], where A is a Lewis acidity centre, which interacts with one of the oxygen atoms of the coordinated CO_2. Such interaction usually leads to the irreversible coordination of CO_2 in the form of carbonate, acetate, etc. Structure (XII) illustrates the interaction of the transition metal in the highest oxidation states, which is electron-deficient, with the weakly basic oxygen atom in CO_2. Such interaction between the transition metal and CO_2 is the least probable.

To date, X-ray diffraction studies have been carried out on only a few complexes containing CO_2 as the ligand. The structure of a complex containing CO_2 was first investigated by Aresta et al.[88] It was found that the P_2NiCO_2 fragment of the complex $[L_2Ni(CO_2)].0.75C_6H_5CH_3$, where $L = P(C_6H_{11})_3$, is located in a single plane:



while CO_2 is linked to the nickel atom by a π-bond [see structure (X)]. The non-coordinated C–O bond has a length of 1.17 Å, which differs little from the length of the C–O bond in the free CO_2 molecule (1.16 Å), while the coordinated C–O bond has a length of 1.22 Å, which is much less than the length of a single C–O bond (1.45 Å); the OCO angle is 133°. Carbon dioxide is weakly bound in this complex and can be readily removed on passing argon through a solution of the complex in toluene at 25 °C; the initial complex is reformed on saturation of the solution with CO_2.

The structure of the complex $L_3Ir(CO_2)_2Cl$, where $L = P(CH_3)_3$, has also been established by X-ray diffraction[89]. Iridium has an octahedral coordination and the Ir–C and Ir–O bonds as well as a five-membered chelate ring formed by two CO_2 molecule were identified in the complex:

Thus CO_2 is coordinated in the given instance to the transition metal and the Lewis acid centre [see structure (XI)]. It has been suggested[89] that the complex is formed following the electrophilic attack by the carbon of the CO_2 group on the iridium atom with the subsequent analogous electrophilic attack by a second CO_2 molecule on the oxygen atom of the coordinated CO_2 and the closure of the organometallic ring. The replacement of the $P(CH_3)_3$ ligands by the chelating ligands $(CH_3)_2PCH_2CH_2P(CH_3)_2$(dmpe) in the above complex hinders the coordination of two CO_2 molecules. This results in the formation of the complex $(dmpe)_2Ir(CO_2)Cl$, for which the following mode of coordination of CO_2 has been proposed [see structure (IX)]:[90]

The structure of the complex $[Co(pr\text{-}Salen)K(CO_2)THF]_n$, where pr-Salen is *N,N'*-di(7-propylsalicylidene)ethylenediamine, has been studied recently[91]. In this polymeric complex CO_2 is coordinated to Co via the carbon atom, and one oxygen atom is linked to two potassium atoms, the other oxygen atom being linked to one potassium atom. Thus, in this instance CO_2 is bound to the transition metal via the carbon atom and there is additional coordination to the Lewis acidity centre (K^+) via the oxygen atoms. The lengths of the C–O bonds in the coordinated CO_2 molecule are 1.22 and 1.24 Å, while the OCO angle is 135 °C.

CO_2 is coordinated in an unusual manner in the $[HOs_3.(CO)_{10}(\mu\text{-}CO_2)Os_6(CO)_{17}]^-$ cluster[92]. The carbon atom of the CO_2 ligand is bound to the Os_6 cluster and the two oxygen atoms are found to the Os_3 cluster. The lengths of the C–O bonds in the CO_2 bridging ligand are 1.28 and 1.36 Å. It has been suggested[92] that the Os_6–C fragment can be regarded as a coordinated carbene and the coordination of the two oxygen atoms of the CO_2 ligand with the Os_3 cluster resembles that of a carboxylate ligand.

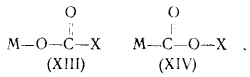
Thus the structures of only four complexes containing a coordinated CO_2 molecule have been reliably established by X-ray diffraction, CO_2 being coordinated in the complex in accordance with Schemes (IX)–(XI). The coordination of carbon dioxide to the transition metal alters its configuration. In all cases the OCO angle of the CO_2 ligand differs appreciably from 180° characteristic of the free CO_2 molecule. In certain cases the length of the C–O bond increases significantly. Evidently such marked changes in the structure of the CO_2 molecule as well as the redistribution of electron density induced by the interaction with the transition metal are associated with the activation of carbon dioxide. Since CO_2 is a fairly labile ligand, the preparation of the transition metal complexes of CO_2 must be based on initial coordination-unsaturated complexes.

2. The Reduction of Carbon Dioxide in the Presence of Transition Metal Complexes

The reactions involving the insertion of carbon dioxide in M–H or M–C bonds are apparently intermediate reactions in catalytic cycles leading to the reduction of CO_2. Unfortunately the mechanisms of these processes have not been investigated. The following schemes can therefore be proposed for the given reactions[8,9]:

$$LM{-}CO_2 \xrightarrow{X} LM{-}(CO_2){-}X\,, \qquad (1)$$

$$X{-}CO_2 \xrightarrow{LM} LM{-}(CO_2){-}X\,, \qquad (2)$$



$$LM{-}X \xrightarrow{CO_2} LM\begin{matrix}X\\ \diagdown\\ \diagup\\ CO_2\end{matrix} \rightarrow LM{-}(CO_2){-}X\,, \qquad (3)$$

$$LM{-}X \xrightarrow{CO_2} LM{-}X{-}CO_2 \rightarrow LM\ CO_2X^{\ominus} \rightarrow LM{-}(CO_2){-}X\,, \qquad (4)$$

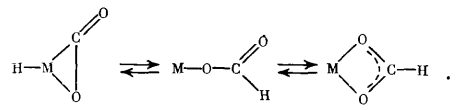
where LM is the transition metal complex and X = H or alkyl. The reaction involves three reactants: the transition metal complex, the ligand (H or R), and CO_2. Two of these can initially react with one another and then with a third reactant. Scheme (1) corresponds to attack by the free ligand on the coordinated carbon dioxide. Scheme (2) leads to an insertion product via the formation of an adduct of CO_2 with the ligand and its stabilisation on the transition metal. Both these schemes presuppose the presence of the free ligand in the reaction mixture. If the metal–ligand bond (M–H or M–R) is formed, the CO_2 molecule can be either coordinated to the coordination-unsaturated metal centre with subsequent migration of the ligand to the bound CO_2 [Scheme (3)] or can

attack directly the bound ligand with the intermediate formation of an ion pair [Scheme (4)].

There are two possible variants of the structure of the insertion product depending on the polarity of the M–X bond[8,9]:

(XIII) (XIV)

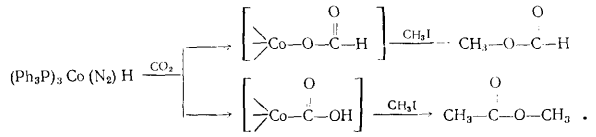
This entails the formation of a formate complex (XIII) or metal-carboxylic acids or their esters (XIV). The first of these reactions can serve as a basis for the catalytic reduction of CO_2 by hydrogen with formation of formic acid, methanol, and other products. In most of the known reactions involving the insertion of CO_2 in an M–H or M–C bond, formate complexes are formed. The insertion of CO_2 in a transition metal–hydrogen bond was observed for the first time in relation to the cobalt complex $(Ph_3P)_3Co(N_2)H$;[93] the cobalt formate complex $(Ph_3P)_nCoOOCH$ is formed in benzene at 25 °C and a CO_2 pressure of 1 atm. A similar formate complex has been obtained also from $(Ph_3P)_3CoH_3$.[94] The presence of the formate group in the complex has been confirmed by treatment with methyl iodide, which leads to the formation of methyl formate. In addition, treatment of the complexes with concentrated sulphuric acid leads to the evolution of CO; complexes of carbon dioxide evolve CO_2 under these conditions.



It is noteworthy that the reactions with sulphuric acid or methyl iodide constitute a kind of test and help to distinguish formate complexes from complexes with CO_2, which have very similar infrared spectra. As for the transition metal complexes with CO_2, the structure of the formate complexes has been established reliably by X-ray diffraction only in isolated cases. The structure of the ruthenium complex $(Ph_3P)_3$. .Ru(H)OOCH has been described[95]. In the crystalline form, the compound contains a formate group in which hydrogen is located in the *trans*-position relative to this group. This complex was obtained by the reaction of CO_2 with a solution of $(Ph_3P)_4RuH_2$ in toluene at 25 °C at 1 atm [96] or with solutions of $(Ph_3P)_3RuH_4$ and $(Ph_3P)_3Ru(N_2)H_2$.[97] The reactions of the above complex in solution are extremely unusual for formate complexes and are more consistent with the complex of ruthenium hydride and CO_2 of the type $(Ph_3P)_3Ru(CO_2)H_2$. For example, the reactions with Ph_3P, N_2, H_2, or CO are accompanied by the elimination of CO_2 under mild conditions[97]:

$$(Ph_3P)_3\,Ru\,(H)\,OOCH \xrightarrow{L} (Ph_3P)_3\,Ru\,(L)\,H_2 + CO_2\ ;$$
$$L = Ph_3P,\ N_2,\ H_2,\ CO\ .$$

The hypothesis of the formation of the ruthenium hydride complex with CO_2 has been confirmed by ^1H NMR study of a solution in the ruthenium formate complex $[Ph(CH_3)_2P]_4$. .Ru(OOCH)$^+$.[98]



The iron formate complex $L_2Fe(OOCH)_2$, where $L = Ph(C_2H_5)_2P$ or $Ph_2(C_2H_5)P$, is formed when the solid complexes L_3FeH_4 or $L_3Fe(N_2)H_2$ are irradiated with visible light in an atmosphere of CO_2;[99] the formation of the formate complex is not observed in the absence of irradiation. The authors[99] suggest that the reaction is induced by the photochemical dissociation of the H_2 or N_2 ligand.

In all cases of the formation of formate complexes, it has been suggested that the first stage of the reaction is coordination of CO_2 to the transition metal atom, which requires the presence of a coordination-unsaturated complex with an enhanced electron density at the transition metal atom. Like the complexes containing CO_2, formate complexes can therefore be obtained only when the molecule of the initial complex containing labile ligands (N_2, H_2, Ph_3P), whose dissociation leads to coordination-unsaturated complexes. The formate complexes are apparently formed from the hydride complex with CO_2 as a result of the migration of the hydride to the carbon atom of the CO_2 molecule:

This reaction is in most cases reversible. For example, the ruthenium complex $(Ph_3P)_3Ru(H)OOCH$ contains the formate ligand in the solid state[95], while on its dissolution in CH_2Cl_2 a complex containing carbon dioxide is formed: $(Ph_3P)_3Ru$. .$(H_2)CO_2$.[97,98]

Together with the formation of formate complexes following the insertion of CO_2 in an M–H bond, a metal-carboxylic acid can also be produced. The interaction of CO_2 with $(Ph_3P)_3Co(N_2)H$ and subsequent methylation of the reaction products with CH_3I entail the formation of both methyl formate and methyl acetate (approximately 17%):[100]

Thus the interaction of carbon dioxide with transition metal hydride complexes leads to its reduction. This reaction is apparently the key stage in the reduction of CO_2 by hydrogen to give organic compounds.

Instances of the conversion of the formate complexes into carbonyl hydride complexes are known. For example, $(Ph_3P)_3Rh(OOCH)H$ is converted into $(Ph_3P)_3Ru(CO)H_2$ on heating[95]. In the presence of silicon or aluminium hydrides and ruthenium and rhodium complexes, CO_2 is reduced in benzene to CO:[101]

$$(Ph_3P)_3\,MCl + HSi\,(OC_2H_5)_3 \xrightarrow{CO_2\,(1\,atm)} (Ph_3P)_2\,M\,(CO)\,Cl\ ;$$
$$M = Rh,\ Ru\ .$$

The yield of CO is one mole per mole of the complex. HSi. .$(C_2H_5)_3$, $H_2Si(C_3H_7)_2$, and $LiAlH_4$ can be used as the reductants. It has been suggested[8,101] that in the first stage the silane adds to the complex via the oxidative addition mechanism with formation of a metal–hydrogen bond, after which CO_2 is inserted in this bond with formation of a formate ligand, whose decomposition leads to the formation of carbonyl complexes. The interaction of CO_2 with transition metal hydrides complexes also leads to carbonyl complexes[97,102]. The ruthenium complex $(Ph_3P)_4RuH_2$ reacts with CO_2 at 130 °C and a pressure of 20 atm to form $(Ph_3P)_3Ru(CO)H_2$.[97] The reaction with $[Ph_2(CH_3)P]_4WH_4$ takes place under milder conditions. The refluxing of a solution of this complex in toluene in a CO_2 atmosphere results in the formation of $[Ph_2(CH_3)P]_3W(CO)_3$ (yield 60%).[102] The reduction of CO_2 to CO can be achieved using H_2 as the reductant,[103] i.e.

$$(Ph_3P)_3\,RhCl + CO_2 + H_2 \xrightarrow[100^\circ C]{(40\ atm)} (Ph_3P)_2\,Rh\,(CO)\,Cl + H_2O + Ph_3P\ ,$$

and hexamethylphosphoramide as the solvent. The reaction is appreciably accelerated by the addition of water. It has been suggested[103] that formic acid is formed initially and then decomposes to CO and H_2O.

The disproportionation and deoxygenation of CO_2 in the presence of titanium and zirconium complexes have been described[104]:

$$[(C_5H_5)_2\,TiCl]_2 + CO_2 \xrightarrow[90^\circ C]{10\ atm} [(C_5H_5)_2\,TiCl]_2O + CO\ ,$$

$$4\,(C_5H_5)_2\,Ti\,(CO)_2 + 4{}^{13}CO_2 \xrightarrow[50^\circ C]{1\ atm} [[(C_5H_5)_2\,Ti]_2\,(^{13}CO_3)]_2 + 2{}^{13}CO + 8CO\ ,$$

$$3\,(C_5H_5)_2\,Zr\,(CO)_2 + 3CO_2 \xrightarrow[70^\circ C]{1\ atm} [(C_5H_5)_2\,ZrO]_3 + 9CO\ .$$

The disproportionation of CO_2 in the presence of carbonylmetallate anions has been investigated[105]:

$$2Na[(C_5H_5)Fe(CO)_2] + CO_2 \rightarrow [(C_5H_5)Fe(CO)_2]_2 + Na_2CO_3 + CO .$$

The use of $^{13}CO_2$ made it possible to demonstrate that the disproportionation of CO_2 proceeds in accordance with the mechanism

$$2CO_2 + 2e \rightarrow CO_3^{2-} + CO .$$

The authors[105] suggest that two CO_2 molecules are coordinated to the initial complex $Na[(C_5H_5)Fe(CO)_2]$ in the first stage of the reaction with the subsequent formation of Na_2CO_3 and $[(C_5H_5)Fe(CO)_3]^+$; the latter reacts rapidly with the excess of $[(C_5H_5)Fe(CO)_2]^-$ anions to form a dimer.

The example of the non-catalytic reduction of CO_2 to a formate ligand or to CO presented above can be regarded as models of the individual stages of catalytic processes involving CO_2. It is noteworthy that the reduction of carbon dioxide to CO or HCOOH is thermodynamically unfavourable at low temperatures and pressures. It therefore occurs only when the product can bind strongly to the transition metal.

3. Catalytic Reduction of Carbon Dioxide

Catalytic reactions based on CO_2 constitute a field of organic chemistry which has been little studied. Several investigations have been devoted to the synthesis of alkyl formates or formamides from CO_2, H_2, an alcohol, or an amine[106,107]. It has been shown[100] that methyl formate is formed from CO_2, H_2, and CH_3OH at 60 atm and 100 °C:

$$CO_2 + H_2 + CH_3OH \rightarrow HCOOCH_3 + H_2O .$$

Since the reaction involving the formation of HCOOH from CO_2 and H_2 is thermodynamically unfavourable under mild conditions, the authors added alkylating agents (CH_3I and a solution of BF_3 in CH_3OH) to the reaction mixture in order to shift the equilibrium. $(Ph_3P)_3IrH_3$ and $(Ph_3P)_3Ru(H)Cl$ showed the highest catalytic activity. Subsequently Japanese investigators obtained alkyl formates from CO_2, H_2 and alcohols (CH_3OH, C_2H_5OH, and C_3H_7OH) at 50 atm and 140 °C in the presence of $(Ph_2PCH_2CH_2PPh_2)_2Pd$ and $(Ph_3P)_4RuH_2$ and added amines [$(C_2H_5)_3N$, etc.].[107] The yield of alkyl formate reached 50 moles per mole of the catalyst. At a pressure of the CO_2–H_2 mixture of 50 atm and at room temperature, the formation of HCOOH in an amount up to 40 moles per mole of the catalyst was observed in the presence of $(Ph_2PCH_2CH_2.PPh_2)_2Pd$ and $(C_2H_5)_3N$. The addition of water to the reaction mixture increases significantly the yield of formic acid[108]. It has been shown[109] that the carbonylmetallate anions $[HFe(CO)_4]^-$ and $[HFe_3(CO)_{11}]^-$ also catalyse the synthesis of alkyl formates from CO_2, H_2, and an alcohol.

Secondary amines interact with CO_2 and H_2 at 50–60 atm and 100–125 °C to form dialkylformamides[9]:

$$CO_2 + H_2 + R_2NH \rightarrow HCONR_2 + H_2O .$$

The most active catalysts are $(Ph_2PCH_2CH_2PPh_2)_2Pd$, $(Ph_3P)_2Ir(CO)Cl$, and $(Ph_3P)_3CuCl$, in the presence of which the yield reaches 800–1200 moles of dimethylformamide per mole of the catalyst.

In protic media, vanadium, titanium, molybdenum, and tungsten complexes catalyse the reduction of CO_2 by zinc and aluminium amalgams to HCOOH, HCOH, CH_3OH and in certain cases also to CH_4 at a CO_2 pressure of 1–5 atm and 20 °C;[110,111] the yields amount to several moles per mole of the catalyst.

At 150 °C and 1 atm the L_nRh_m–$AlBr_3$ system, where $L_nRh_m = Rh_4(CO)_{12}$, $[Rh(CO)_2Cl]_2$, or $(Ph_3P)_3RhCl$, catalyses the reduction of CO_2 by hydrogen to carbon monoxide[112]. The yield of CO ranged from 9 to 11 moles of CO per gramme-atom of rhodium. In addition, traces of C_1–C_3 alkanes were detected in the gas phase and the dissolution of the solid phase in THF led to solutions whose infrared spectra (absorption bands at 1981 and 2059 cm^{-1}) corresponded to the anions $[Rh(CO)_2X_2]^-$, where X = Cl or Br. In the absence of the rhodium complex or H_2, there was no reduction of CO_2. It has been suggested[112] that a hydride-containing rhodium complex with CO_2 is formed in the given instance and that $AlBr_3$ apparently activates the coordinated CO_2 molecule. The introduction of metallic aluminium into the given system has resulted in a sharp increase in the yields of hydrocarbons under the same conditions (see Table 2).[73]

An increased content of aluminium in the $Rh_4(CO)_{12}$–$AlBr_3$–Al system gives results analogous to those in the synthesis of alkanes from CO and H_2 in the presence of the same system[73]. In the range of Al : $AlBr_3$ ratios from 0 to 0.1, the content of C_1–C_4 alkanes increases and there is a sharp decrease of the CO concentrations in the products of the synthesis. In the absence of metallic aluminium, CO_2 is reduced only to CO and the yields of alkanes are low (Table 2). The introduction of aluminium accelerates the reduction of CO to alkanes[72], which leads in its turn to a decrease of the CO concentration in the products of the synthesis.

Table 2. The degrees of conversion of carbon dioxide (K_{CO_2}, mol CO_2/g-atom Rh) and the compositions of the reaction products (vol.%) in the synthesis of alkanes from CO_2 and H_2 in the presence of rhodium complexes.

L_nRh_m	K_{CO_2}	Reaction products, vol.%					
		CO	CH_4	C_2H_6	C_3H_8	iso-C_4H_{10}	n-C_4H_{10}
$Rh_4(CO)_{12}$	9	0	64	9	5	21	1
$[Rh(CO)_2Cl]_2$	8	0	68	7	4	20	1
$(Ph_3P)_2Rh(CO)Cl$	6	0	73	8	4	15	0
$(Ph_3P)_3RhCl$	6	0	73	11	4	12	0
$RhCl_3 \cdot 3H_2O$	2	14	60	9	5	12	0
$Rh_4(CO)_{12}$	8	98	1	0.5	0.5	0	0

Note: Reaction time 20 h; the remaining conditions were the same as in Table 1. The last row presents data obtained in the absence of metallic aluminium.

The catalytic properties of the L_nRh_m–$AlBr_3$–Al system are significantly influenced by the structure of the rhodium compound (Table 2).[73] The compositions of the reaction products are extremely similar for all the rhodium complexes investigated but they are different from those obtained in the presence of $RhCl_3$. Thus the presence of ligands (CO and Ph_3P) in the molecule of the initial complex results, as in the reduction of CO (Table 1), in the formation of systems exhibiting a higher catalytic activity in the reduction of CO_2 than that of the $RhCl_3$–$AlBr_3$–Al system.

The synthesis of C_1–C_2 hydrocarbons and dimethyl ether from CO_2 and H_2 at 1 atm and 300–400 °C in the presence of graphite layer compounds with a transition metal (Mo, W, Co, Ni, Pd, Pt, Fe) and an alkali metal (K, Na), has been described[113].

Methanol has been obtained from CO_2 and H_2 in the presence of $SnCl_4$ at 200 °C and a pressure of 100 atm (1 : 3 CO_2–H_2 mixture).[114] The yield of methanol was 8.2% for a degree of conversion of CO_2 of 8.8%. Together with the synthesis of methanol, the authors[114] observed the formation of small amounts of CO at 200–300 °C.

These few examples exhaust the number of catalytic reactions involving the reduction of CO_2 in the presence of transition metal complexes. In most cases the mechanisms of the reactions of CO_2 with a transition metal and of the activation of the coordinated carbon dioxide molecule have not so far been established.

The data examined permit the conclusion that the development of metal complex catalysts for the synthesis of hydrocarbons from carbon oxides and hydrogen is so far feasible on a purely laboratory scale. The systems obtained cannot serve as a basis for the creation of catalysts of practical importance. On the other hand, the mechanisms of processes involving transition metal complexes and those in the presence of heterogeneous catalysts have much in common in many instances. The study of metal complex catalysts for the reduction of carbon oxides can therefore prove useful both for the development of new industrial catalysts for the synthesis of hydrocarbons from mixtures of carbon oxides and hydrogen and for the improvement of the existing ones.

Solvation Effects and the Mechanism of the Heterolysis of t-Butyl Halides

G.F.Dvorko, E.A.Ponomareva, and N.I.Kulik

Data on the kinetics and mechanism of the heterolysis of t-BuX (X = Cl, Br, I) in the gas phase and in individual solvents are surveyed. The mechanism of the unimolecular heterolysis of t-BuX and the role of the solvent in this process are discussed. The bibliography includes 192 references.

CONTENTS

I. Introduction 547
II. The nature of the transition state 547
III. Kinetic parameters of the heterolysis of t-BuX in the gas phase and in individual solvents 552
IV. Solvation effects 554

I. INTRODUCTION

The reactions involving the unimolecular heterolysis of t-BuX (unimolecular solvolysis, S_N1, $E1$) have attracted the attention of chemists for more than 40 years[1-6]:

$$\text{t-BuX} \xrightarrow{\text{ROH}} \begin{cases} \text{t-BuOR} + \text{HX} \\ \text{Me}_2\text{C}{=}\text{CH}_2 + \text{HX} \end{cases}.$$

Both substitution and elimination products are formed in proton-donating solvents, while in the gas phase and in aprotic solvents only elimination products are obtained. These reactions have been widely used in the study of the mechanism of the heterolytic cleavage of a covalent bond and of the influence of the solvent on the process. The principal data on the mechanisms of these reactions can be found in any modern text-book or monograph on organic or physical organic chemistry (see, for example, Refs.7-13). More detailed data are available in reviews of the solvolysis of organic substrates[1,5,14-17] and of the influence of the solvent on heterolytic reactions[4,6,18-24]. The number of publications on this problem has rapidly increased recently, novel research techniques have appeared, and new approaches to the interpretation of the results have been devised; at the same time contradictions have also accumulated.

The aim of the present review is a critical survey of modern ideas concerning the mechanism of the heterolysis of t-BuX. Attention has been concentrated on the effect of the solvent. Virtually all the available experimental kinetic parameters for the heterolysis of t-BuX (X = Cl, Br, I, or F) and certain other t-butyl derivatives in the gas phase and in individual solvents have been compiled and tabulated in the present review. A correlation analysis of the influence of various solvent parameters (nucleophilicity, electrophilicity, polarity, polarisability, and the energy of the self-association of the solvent) on the rate of heterolysis of t-BuX (X = Cl, Br, or I) has been carried out. This permits a critical approach to the interpretation of the solvent effect and certain new conclusions about the reaction mechanism.

II. THE NATURE OF THE TRANSITION STATE

The very extensive data on the heterolytic reactions of t-BuX are usually surveyed on the basis of the same, at first sight simple, mechanism, according to which a cationoid intermediate (an ion pair or a carbonium ion) is formed in the rate-limiting stage from t-BuX and is then rapidly converted into the reaction products.

The rates of these reactions increase rapidly with increase of solvent polarity; in the case of t-BuCl, the increase is by ~15 orders of magnitude on passing from n-heptane to water (Table 1) (t-BuCl is used as a standard in the correlation of the rates of solvolysis of other substrates—see the Grunwald–Winstein equation[1-3,14,15,18,21,23,25]).

Marked charge separation takes place in the transition state of the heterolysis of t-BuX:[1-6,10,23,26,27] 0.8 of an electron[4,26,28], $\mu^{\neq} = 8.8$ D, $d^{\neq} = 2.3$ Å.[26] In hydroxyl-containing solvents $\mu^{\neq}$ increases markedly[4,23]. On passing from the initial to the transition state, the volume of t-BuCl increases from 111 to 116 $cm^3\ mol^{-1}$;[6] however, the volume of activation diminishes as a result of electrostriction: $\Delta V^{\neq} \cong -20$ $cm^3\ mol^{-1}$.[29] $Me_4N^+Cl^-$ is used as a model of the transition state[18]. The appreciable charge separation in the transition state is indicated by the reaction constant[30] for the heterolysis of $RCMe_2Cl$ in the Taft equation [$\rho = -3.3$ in 80% ethanol (EtOH) [31] and $\rho = -3.6$ in dimethylformamide (DMF) [32]]. The agreement between the experimental β-deuterium kinetic isotope effect in the solvolysis of t-BuCl [33] and the calculated H–D effect for the formation of t-Bu^+ ($k_{C_4H_9Cl}/k_{C_4D_9Cl} \cong 2.4$) [34] as well as the slope (~0.9) of the relation between the free energies of activation for the solvolytic reactions of alkyl chlorides and their heats of ionisation[35] are consistent with this finding.

The rate of solvolysis of t-BuCl depends on the nature of the solvent approximately in the same way as the rate of addition of Br_2 to styrene and phenylacetylene[36], which indicates a high polarity of the transition state in all cases. We may note that the calculations based on the ^{14}C and ^{37}Cl kinetic isotope effects lead to a less polar transition state[37-39], although it is believed[40] that the small isotope effect of chlorine (~1.01) in the solvolysis of t-BuCl is associated with the intense solvation of the anion formed and not with the low polarity of the transition state.

The effects of the solvent and salts[41,42] indicate the formation of a highly polar transition state[4,6,43], although in the case of Ph_2CHX these effects are more marked than for t-BuX.[16,44-46] The heterolysis of diphenylmethyl derivatives usually results in the formation of intermediate carbonium ions and solvent-separated ion pairs[16,45,47]. In the reaction involving t-BuX, less polar intermediates are apparently produced. Evidence has been adduced[6,18,19] in support of the view that the polarity of the transition state in the heterolysis of t-BuCl decreases with decrease of the polarity of the medium; however, other investigators believe[46,48] that the polarity of the transition state is independent of the nature of the medium. The possibility of the formation of a four-membered transition state in the heterolysis of t-BuCl in solvents of low polarity has been discussed[4,26,48,49].

Table 1. The logarithms of the rate constants for the heterolysis of t-BuX and solvent parameters.

Remarks. The main bulk of the values of ε, n, B, E, E_T, DN, AN, and δ^2 were taken from Refs. 6, 11, 21, 22, 90, and 91 (see Section IV).

[a] Calculated from the values of k at 230–680 °C. [b] Taken from Kanevskii and Zarubina[146]. [c] $\lg k^{25} = -7.26$ in the paper of Rudakov and Kozhevnikov[48]. [d] Taken from Makitra and Pirig[147]. [e] At 25 °C. [f] $\lg k^{25} = -7.43$ in the paper of Rudakov and Kozhevnikov[48]. [g] $\lg k^{25} = -7.52$ in the paper of Rudakov and Kozhevnikov[48]. [h] Calculation from the values of k at 40°, 50°, and 55 °C. [i] At 30 °C. [j] Calculation from the values at 24.8°, 39.2°, and 50.7 °C. [k] $\lg k^{25} = -5.66$ in the paper of Peters and Anteunis[32]. [l] Estimate from $k^{60} = 9.1 \times 10^{-8}$ s^{-1}, $\Delta H^{\neq} = 102.1$ kJ mol^{-1}.[16] [m] Calculation from the values of k at 20°, 40°, and 60 °C for [HBr] ≅ 0.0275 M. [n] $\lg k^{25} = -5.36$ in the paper of de la Mare et al.[118] [o] $\lg k^{24.5} = -5.92$ in Hoffman's paper[117]. [p] $\lg k^{25} = -9.9$ in Rudakov's paper[128]. [r] Calculation from the values of k at 20°. 40°, 44.4°, 50°, and 60 °C, taken from Winstein et al.[68], yields $\lg k^{25} = -7.16$. [s] Calculation from the values of k at 39°, 53°, and 70 °C.[140] [t] Calculation from the values of k at 27–60 °C, taken from Viana and Concalves[129], yields $\lg k^{25} = -5.3$. [u] Calculation from the values of k at 100° and 120 °C, taken from Koppel[145], yields $\lg k^{25} = -10.0$. [v] Taken from Gutman[90]. [w] Estimate in Abraham's paper[18] from data for 120 °C.[4] $\lg k^{25} = -10.4$ in the paper of Pocker and Buchholz[148] and $\lg k^{120} = -7.0$ in the paper of Koppel and Palm[4]. If $\lg k^{25} = -12.7$ is used, then $\Delta H^{\neq} = 132.3$ kJ mol^{-1} and $\Delta S^{\neq} = -52.8$ J mol^{-1} K^{-1} (realistic values). If one uses $\lg k^{25} = -10.4$, then $\Delta H^{\neq} = 77.9$ kJ mol^{-1} and $\Delta S^{\neq} = -191.3$ J mol^{-1} K^{-1} (improbable values). [x] Estimate in Abraham's paper[6]: $\lg k^{25} = -13.5$.

The interpretation of the solvent effect is complicated by the fact that the solvent influences both the initial state of the substrate and the transition state and a difference between these effects has been observed[6,10,15,48]. The separate effects of the medium on the solvation of the initial and transition states are taken into account using a thermodynamic approach to the analysis of kinetic data[6,48,50]. Unfortunately this method does not differentiate the ionic intermediates formed in the heterolysis of a covalent bond; the polarity of the transition state is usually assumed to be constant for all media.

Comparative analysis of the Henry coefficients for the ground state and the rate constants for the solvolysis of t-BuCl showed[48] that the change in the rate of reaction in a medium of low polarity depends greatly on the degree of solvation of the transition state, while in a polar medium it depends on the degree of solvation of the substrate in the initial state. The use of the solubility parameter δ in combination with the free energies of activation enabled Abraham[6] to determine the free energies of the transition state in the heterolysis of t-BuCl(Br) in various solvents. It was shown that the decrease of the free energies of activation with increase of the polarity of the medium is due both to the increase of the energy of the initial state and the decrease of the energy of the transition state, the latter making the main contribution.

The correlation between the relative free energies of the transition state and the free energies of the model compound $Me_4N^+Cl^-$ showed that the polarity of the transition state is much higher in polar solvents than in solvents of low polarity. However, after the determination of the contribution of the energy of formation of a cavity (cage) in the solvent, Abraham recently abandoned this conclusion; he now believes that the polarity of the transition state is independent of the nature of the medium. On the basis of the concept of S_N1 transition states as ternary species formed from $t\text{-}Bu^+X^-$ and solvent molecules ($R^+...X^-...Solv$) or metal ions ($R^+...X^-...M^+$), Rudakov[50,51] analysed the influence of the medium on the rate of heterolysis of t-BuX and, having separated the effects of the solvation proper and the Coulombic interaction in the transition state, showed that the solvent effect is due mainly to the solvation of the transition state.

It is noteworthy that the solvation of the substrate in the initial state can greatly influence $\Delta H^{\neq}$ and $\Delta S^{\neq}$.[15] The initial state is less polar than the transition state and its solvation therefore depends greatly on the solvent structure[52,53].

It is usually believed that the heterolysis of t-BuX, interpreted within the framework of Winstein's scheme, stops at the stage involving the formation of a contact ion pair[54–57]:

$$t\text{-}BuX \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} t\text{-}Bu^+X^- \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} t\text{-}Bu^+ \mid Solv \mid X^- \underset{k_{-3}}{\overset{k_3}{\rightleftarrows}} t\text{-}Bu^+ + X^-.$$

However, this is not always so. Since the solvolysis of t-BuX in proton-donating solvents proceeds via the S_N1 mechanism, t-BuOR should be formed from an intermediate carbonium ion or a solvent-separated ion pair (attack by the nucleophile on the contact ion pair would lead to S_N2 substitution)[14,16]. In water the yield of the olefin (~5%) is independent[58] of the nature of the departing group in t-BuX (X = Cl, Br, I, or SMe_2I), which indicates the formation of an intermediate carbonium ion; in acetic acid, ethanol[58], and methanol[59], the yield of the olefin increases with the basisity of the departing group, which indicates the formation of the olefin from intermediate ion pairs.

It is believed[60] that in solution in CF_3CH_2OH the contact ion pair is converted into a solvent-separated ion pair in the rate-limiting stage of the ionisation of t-butyl halide. The contact ion pairs were generated in solution in CF_3CH_2OH by the addition of HCl to isobutene[14,61]:

$$t\text{-}BuCl \underset{k_{-1}}{\overset{k_1}{\rightleftharpoons}} t\text{-}Bu^+Cl^- \overset{k_2}{\rightsquigarrow} t\text{-}Bu^+ \mid Solv \mid Cl^- \quad (\downarrow)$$
$$Me_2C{=}CH_2 + HCl \qquad t\text{-}BuOCH_2CF_3 .$$

The yield of the product of the reaction involving the reconversion of the ion pair (t-BuCl) was higher by a factor of two than the yield of the substitution product ($t\text{-}BuOCH_2CF_3$). Consequently $k_{-1} > k_2$ and the rate-limiting stage in the heterolysis of t-BuCl in CF_3CH_2OH should be the formation of a solvent-separated ion pair. The phenolysis of t-BuCl apparently proceeds partly via a carbonium ion—the rate of reaction diminishes in the presence of a salt with a common ion[62]. This is apparently a unique case, since the salt effect, associated with the operation of the Law of Mass Action, is not as a rule manifested in the solvolysis of t-BuX.[14,16] Possibly this effect may be important in methanol and dioxan[63].

The solvolysis of t-BuCl in formic acid proceeds at the same rate as the unimolecular exchange of the anion[64], which indicates the formation of an intermediate carbonium ion or a solvent-separated ion pair. The solvolysis of t-BuCl in *N*-methylpyrrolidinone in the presence of radioactive LiCl* is accompanied by the unimolecular exchange of the anion (~3%); the usual salt effect of the chloride observed under these conditions indicates the formation of an intermediate solvent-separated ion pair. The same intermediate is apparently formed in the solvolysis of 2-bromo-2-methylpentane in DMF.[32] The intermediate solvent-separated ion pair is apparently also formed in the methanolysis of 2,4-dimethylhex-4-yl phthalate, which proceeds with 54% retention of the configuration[66]. The exchange of the anion in t-BuCl, catlaysed by $FeCl_3$, apparently proceeds in benzene solution via a solvent-separated ion pair[67]. In acetone[68], $MeNO_2$,[69] and acetic acid[14], the anion derived from t-BuCl(Br) does not exchange; the specific salt effect of perchlorate is not manifested in acetic acid. Consequently in these and less polar solvents the main intermediates are contact ion pairs†.

Evidence showing that the reaction proceeds via a rate-limiting stage involving the formation of a contact ion pair in the heterolysis of t-BuBr in acetonitrile was obtained by a comparative study of the influence of added water and salts on the rates of the reactions of t-BuBr and Ph_2CHBr.[45] It is evident from the foregoing that in aprotic solvents the rate of reaction is as a rule limited by the stage involving the formation of a contact ion pair, while in proton-donating solvents the rate-limiting stage involves the conversion of the contact ion pair into a solvent-separated ion pair. The increase of the dipole moment of $[t\text{-}BuCl]^{\neq}$ on passing from aprotic to proton-donating solvents[4,23,26] and also Abraham's conclusion that the polarity of the transition state increases with increase of the polarity of the medium[6,18] are satisfactorily consistent with this finding.

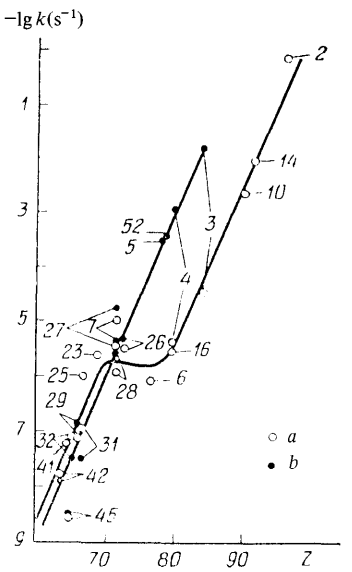
The above view has been confirmed in a study[70] where the logarithms of the rate constants for the heterolysis of t-BuBr and Ph_2CHBr in various solvents were compared with the Kosower solvent polarities, Z. It was shown that in aprotic solvents the rates of heterolysis of both substrates are similar, while in proton-donating solvents t-BuBr reacts at a rate lower by 2.5 orders of magnitude (see Figure).

---

†The heterolysis of t-BuCl(Br) in acetic acid apparently proceeds partly also via a solvent-separated ion pair, which is indicated by the formation of t-BuOAc in ~30% yield[58].

The Figure also shows that there is a linear relation between $\lg k_{Ph_2CHBr}$ and Z for the entire set of solvents, while the rate of heterolysis of t-BuBr deviates sharply from this relation in the region of the transition from aprotic to proton-donating solvents as a result of the decrease of the rate of reaction in isopropyl alcohol. The $\lg k_{Ph_2CHBr}$ are satisfactorily correlated with the values of Z (correlation coefficient 0.978), while in the case of t-BuBr the correlation is unsatisfactory[71]. This can be explained by a change of mechanism of the heterolysis of t-BuBr: in aprotic solvents the rate of the process is limited by the formation of a contact ion pair, while in proton-donating solvents it is limited by the formation of a solvent-separated pair. In the heterolysis of Ph_2CHBr the rate-limiting stage involves in all cases the formation of a solvent-separated ion pair[45,72]. Analogous features were manifested on comparing a more restricted set of data for t-BuCl and Ph_2CHCl: in proton-donating solvents Ph_2CHCl reacts faster by ~3 orders of magnitude than t-BuCl,[73] while in acetonitrile the rates are similar[74].

Thus the heterolysis of t-BuX proceeds via the formation of intermediate solvent-separated and contact ion pairs. The former predominate in proton-donating solvents, while the latter predominate in aprotic solvents. A contact ion pair is apparently formed in the gas phase[75,76]. In a few individual instances (in phenol and water) the reaction can proceed partly via a carbonium ion.



t-Butyl halides do not enter into a reaction via the S_N2 mechanism owing to the strong repulsion in the transition state between the nucleophile and the methyl groups[1,3,10,15]. In 1959 Winstein et al.[68] showed that the conclusion by Ingold[77] and other workers[78,79] according to which the substitution in t-BuCl(Br) in solution in acetone proceeds via the S_N2 mechanism must be treated merely as an unsuccessful hypothesis. However, when one of the methyl groups in t-BuX is substituted by a more electron-accepting group ($ArSO_2CH{=}CH{-}$) substitution via the S_N2 mechanism (more precisely via an S_N2 ion pair) at a tertiary carbon atom becomes possible[80]. Consequently the different reactivities of tertiary carbon in reactions involving the S_N1 and S_N2 mechanisms are due to both steric and electronic effects of the substituents.

The possibility of the operation of the $E2$ mechanism has been discussed[41,65,81,82]. The evidence against this reaction mechanism is that the yield of the olefin and the deuterium isotope effect in the solvolysis of t-BuCl are almost independent of the basicity of the mixed solvent[40], although in the presence of strong bases this reaction pathway is possible[59,83].

It is believed[84,85] that the smallness of the kinetic isotope effect and the deviation of the rate of heterolysis of t-BuCl in CF_3CH_2OH from the linear relation between $\lg k_{t\text{-}BuCl}$ and $\lg k_{1\text{-}AdBr}$ (where 1-AdBr is 1-adamantyl bromide) show that the elimination of HCl from the ion pair $t\text{-}Bu^+Cl^-$ is rate-limiting. However, comparison of the rates of heterolysis of t-BuCl, 1-AdCl, and 2-chloro-2-methyladamantane in various solvents, including fluorinated alcohols, shows[54,55] that all these substrates react via the same mechanism. This rules out the possibility of dehydrohalogenation as the rate-limiting stage.

According to Hammett[3], analysis of the kinetics of solvolysis of t-BuX is complicated by the reaction involving the internal return of the ion pair (with a rate constant k_{-1}). Harris[14] believes that the return reactions (k_{-1}, k_{-2}, and k_{-3}) are unimportant for t-BuX; elimination, dissociation of ion pairs, (k_2, k_3), or the interaction of the intermediates with the solvent predominate for these substrates. The absence of mixing of the oxygen in the solvolysis of t-BuOCAr[1,16] and
$$\text{t-BuO}\overset{\overset{\displaystyle{}^{18}O}{\|}}{C}\text{Ar}$$
2,4-dimethylhex-4-yl phthalate[86] is used as an argument against the occurrence of the internal ion pair return. However, it is believed[40] that, absence of the mixing of ^{18}O in t-alkyl derivatives can be caused by steric effects in the presence of which the reconversion takes place without mixing.

The occurrence of internal return is indicated by the formation of a sulphone on solvolysis of t-BuOSOAr.[87] The possibility of external return is indicated by the unimolecular exchange of the anion in t-BuX [26,32,64,65] and the salt effect based on the Law of Mass Action[62]. Analysis of the dependence of the heat capacities of activation on the composition of the medium (H_2O–EtOH) and on temperature led Blandamer et al.[88] to the conclusion that at ~20 °C the rates of internal return and of the elimination of HCl from $t\text{-}Bu^+Cl^-$ are approximately the same. Bentley and co-workers[54,55] and Harris et al.[85] believe that the observed deviations in weakly nucleophilic solvents such as CF_3CH_2OH and $(CF_3)_2CHOH$ are due to reactions involving the ion pair return and are not caused by the rate-limiting dehydrochlorination. As mentioned above, the proportions of the products following the addition of HCl to isobutene in CF_3CH_2OH clearly indicate the occurrence of the stage involving internal ion pair return[14,16,60].

Dependence of $\lg k_{t\text{-}BuBr}$ (*a*) and $\lg k_{Ph_2CHBr}$ (*b*) on Z (data from Table 1 and Refs. 70 and 71). The numbering of the solvents is the same as in Table 1; 52 = n-PrOH.

The influence of the solvent on the rate of reaction is attributed to its electrostatic and acid–base properties[2-5,20,22-89,90,91]. When the reaction is carried out in solution, it is always necessary to take into account the effect of non-specific solvation[4,20,23], although recently attempts have been made frequently to reduce the influence of the solvent on the kinetic parameters solely to its acid–base properties[22,90,92,93]. It is believed[94] that the high rate of solvolysis in water is caused by the presence of a small amount of OH groups not bound by a hydrogen bond and of unshared electron pairs (~6%).

The rate of heterolysis of t-BuX is known to depend strongly on the electron-accepting properties of the solvent[4,23]. This is indicated by the increase of the rate of reaction owing to the formation of hydrogen-bonded complexes with the departing group[1,4,5,15,95] and also by the catalysis by metal ions[5,96–99], which is described by an equation analogous to the Brønsted equation[5,100]. The great importance of electrophilic solvation in the heterolysis of t-BuX is indicated by the comparison of the rates of elimination of HBr from t-BuBr in a weakly polar ($\varepsilon = 15$) but electrophilic solvent such as SO_2 and in propylene carbonate, which is a strongly polar solvent ($\varepsilon = 70$). In the former case[101] at −15 °C we have $k = 5.2 \times 10^{-5}$ s^{-1}, while in the latter case[102] $k = 9.4 \times 10^{-7}$ s^{-1} (calculated from the temperature variation of k).

The question of the nucleophilic cooperation of the solvent in the heterolysis of t-BuX is still controversial[55,92,93,103]. On the basis of data for Ph_3CCl, Swain suggested in 1948 a push-pull character of the effect of the solvent on the heterolysis of t-BuCl.[104] Thornton[40] developed this hypothesis into the concept of a continuous spectrum of S_N1–S_N2 mechanisms. In 1970 Schleyer and co-workers[105] compared the rates of solvolysis of t-BuCl and 1-AdBr in various solvents and concluded on the basis of the observed deviations in a weakly nucleophilic medium ($CF_3CH_2OH + H_2O$) that the heterolysis of t-BuCl in other solvents proceeds with the nucleophilic cooperation of the sovlent. However, the same deviations are observed on comparing the rates of heterolysis of 1-AdBr and 1-AdOTos [106] and the rates of heterolysis of t-BuCl and 1-AdCl are poorly correlated with one another[15], although the correlation observed on comparing 1-AdBr and t-BuBr was on the whole satisfactory[54] and the deviations were the same as in the comparison of t-BuCl and 1-AdBr.

Other examples of the correlation between the rates of solvolysis of t-BuCl with the rates of solvolysis of various substrates can be found in the literature[15,107]; some of these lead to the conclusion that nucleophilic cooperation by the solvent takes place, while others indicated their absence. All this demonstrates the unreliability of the conclusions based on such comparisons. One of the causes may be the formation of different intermediates depending on the nature of the substrate and the solvent[108]. Thus it follows from a comparison of the rates of solvolysis[109] that the stability of the cations decreases in the sequence $Ph_3C^+ > t\text{-}Bu^+ > 1\text{-}Ad^+$, although it has been shown[110,111] that $1\text{-}Ad^+$ is more stable than $t\text{-}Bu^+$. The cause of the observed differences between the rates may consist in the fact that the rate of heterolysis of t-BuX is limited by the stage involving the formation of a contact ion pair, while in other instances more polar intermediates are produced[16,112,113]. However, to a first approximation, the rate of solvolysis reflects the stability of the cationic intermediate[35].

Evidence in support of the nucleophilic involvement of the solvent has been obtained in the case of DMF.[32,114] It has been shown[115] that the heterolysis of the bond at a tertiary carbon atom can proceed with the nucleophilic cooperation of a neighbouring group [the solvolysis of $PhSO-(CH_2)_nCR_2Cl$]. The conclusion that the cation formed in the solvolysis of t-BuBr undergoes nucleophilic solvation was based on the analysis of the dependence of $\Delta C_p^{\neq}$ on m (where $\Delta C_p^{\neq}$ is the heat capacity of activation and m is the sensitivity of the solvolysis to the influence of the solvent in the Grunwald–Winstein equation) for certain substrates in different media[116]. It is believed[32] that the higher value of $\Delta S^{\neq}$ in the heterolysis of t-BuBr in acetonitrile (amounting to −42 J mol^{-1} K^{-1}) [117] compared with that in $MeNO_2$ (−67 J mol^{-1} K^{-1}) [118] is due to the fact that the tendency towards nucleophilic solvation, of the charges separated in the transition state, by acetonitrile is smaller. Comparison of the nucleophilicity parameters of these solvents (see Table) shows that acetonitrile is more nucleophilic. In addition it has been shown[119,120] that $\Delta S^{\neq} = -84$ J mol^{-1} K^{-1} in acetonitrile. It is believed[14] that the heterolysis of t-alkyl substrates proceeds without the nucleophilic cooperation of the solvent. Fairly convincing evidence has been adduced[10] against the nucleophilic involvement of the solvent in the heterolysis of t-BuX. Indeed a solvent molecule can hardly attack the carbonium ion formed "from the rear" if even a charged nucleophile is incapable of it.

In 1972 Koppel and Palm[20] carried out a correlation analysis of the solvation effects in the heterolysis of t-BuCl and showed that the rate of reaction is independent of the nucleophilic properties of the medium. Later Fawcett and Krygowski[93] concluded that the basicity of the solvent influences the rate of heterolysis of t-BuCl—its influence on the rate constant is to the extent of ~20%. Other workers[22,92], who used the donor (DN) and acceptor (AN) numbers of the solvents, arrived at an analogous conclusion.

Bentley and Carter[121] recently summarised the available evidence in support of nucleophilic cooperation of the solvent in the heterolysis of t-BuX. They believe that this reaction proceeds via the mechanism involving an S_N2-intermediate (its rate is limited by the stage in which an ion pair is formed on treatment of the covalent substrate with a nucleophile[15]). The main evidence adduced by the above workers[121] reduces to the fact that in weakly nucleophilic solvents [acetic acid, formic acid, trifluoroacetic acid, CF_3CH_2OH, and $(CF_3)_2CHOH$] the rate of heterolysis of 1-AdCl(Br) is higher than would follow from the linear relation between $\lg k_{t\text{-BuX}}$ and $\lg k_{1\text{-AdX}}$ and that the rates of heterolysis of 1-AdX and t-BuX in these solvents are similar, while in a nucleophilic medium (80% ethanol) t-BuX reacts faster by ~3 orders of magnitude than 1-AdX. Bearing in mind that the $1\text{-}Ad^+$ cation is more stable in the gas phase than $t\text{-}Bu^+$,[110,111] the authors[121] conclude that the observed differences between the rates of reaction in 80% ethanol can be explained by the nucleophilic cooperation of the solvent in the heterolysis of t-BuX. The authors[121] ignore the fact that the weakly nucleophilic solvents which they enumerated are at the same time comparatively strong acids; the cause of the observed differences can therefore be the fact that the adamantyl substrates are more susceptible to electrophilic catalysis than the t-butyl substrates[15,16].

We may note that, when $\lg k_{1\text{-AdBr}}$ is plotted against $\lg k_{1\text{-AdCl}}$ on the basis of the values quoted by Bentley and Carter[121], deviations from linearity are also observed in the weakly nucleophilic (strongly electrophilic) medium owing to the increase of the rate of heterolysis of 1-AdCl. If one follows the reasoning of Bentley and Carter[121], one must conclude that the heterolysis of 1-AdBr proceeds with nucleophilic cooperation by the solvent, while the heterolysis of 1-AdCl takes place without such cooperation, which is absurd. As in the comparison of the rates of heterolysis of t-BuX and 1-AdX, here the differences between the reactivities of the substrate decrease with increase of the electrophilicity (or with decrease of the nucleophilicity) of the medium). From our point of view, the natural explanation is that the chlorides, forming more stable hydrogen-bonded complexes with proton-donating solvents than the bromides, are more sensitive to electrophilic catalysis. In addition, one must bear in mind that in the heterolysis of 1-AdX and t-BuX different intermediates can be formed in the rate-limiting stage and, even when the same intermediate is formed in both cases, for example, a solvent-separated ion pair, the energies of the solvation of the cation and anion by the internal ligand in $1\text{-}Ad^+|Solv|X^-$ and $t\text{-}Bu^+|Solv|X^-$ can vary greatly as a function of the nature of the solvent.

As a second argument in support of S_N2-substitution in t-BuX, Bentley and Carter[121] point to the formation, noted by Bunton and Nayak[122], of radioactive t-BuCl* in the solvolysis of t-BuCl in aqueous methanol (the authors erroneously state that aqueous acetone was used) in the presence of NaCl*. This example cannot serve as evidence in support of the S_N2 mechanism since in aqueous methanol there is a possibility of the formation of solvent-separated ion pairs and a carbonium ion, which leads to the exchange of the anion via the S_N1 mechanism involving the external return of the ion (k_{-3}) or the ion pair (k_{-2}).

Thus, the examination of the entire set of data, including the publications of recent years, shows that the question of the nucleophilic involvement of the solvent in the heterolysis of t-BuX still remains controversial.

In the interpretation of the solvent effects, one must bear in mind that the time required for t-BuX to pass from the initial to the transition state is usually shorter than the orientational relaxation time of the solvent molecules (the lifetime of the transition state is 10^{-13} s and the orientational relaxation time of the dipole is 10^{-10}–10^{-11} s).[23] Evidence has been presented[50] in support of the view that the maximum stabilisation of the transition state and the highest rate of the process are attained only under the conditions of equilibrium solvation of the transition state.

III. KINETIC PARAMETERS OF THE HETEROLYSIS OF t-BuX IN THE GAS PHASE AND IN INDIVIDUAL SOLVENTS

Table 1 presents the logarithms of the rate constants for the heterolysis of t-BuCl(Br, I) at 25 °C and the parameters of the solvents which we used for the correlation analysis. The heterolysis rate constants have been determined for all three alkyl halides in only 8 of the 50 solvents and in the gas phase; t-BuCl was investigated mainly in proton-donating solvents (21 out of 35), t-BuI in aprotic solvents (21 out of 23), and t-BuBr approximately to equal extents in both groups of solvents (9 out of 13). This restricts the scope of comparative analysis.

Table 2. The activation parameters of the heterolytic reactions of t-BuX.

Remarks. [a]Calculated from the values of k at 230–680 °C; $\Delta H^{\neq} = 188.8$ kJ mol^{-1} and $\lg A = 19.93$ have been obtained by Hegtman et al.[158] for t-BuCl. [b]At 27 °C; $\Delta H^{\neq}$ and $\Delta S^{\neq}$ depend greatly on temperature; $\Delta H^{\neq}_{60°} = 19.7$ kJ mol^{-1} and $\Delta S^{\neq}_{60°} = -268.0$ J mol^{-1} K^{-1}. [c]Calculation from the values of k at 45°, 50°, and 55 °C. [d]Calculation from the values of k at 24.8°, 39.2° and 50.7 °C. [e]Calculation from the values of k at 100° and 120 °C [145] yields $\Delta H^{\neq} = 89.2$ kJ mol^{-1} and $\Delta S^{\neq} = -145.7$ J mol^{-1} K^{-1}. [f]Calculation from the values of k at 39°, 53°, and 70 °C.[140] [g]At 20°, 40°, and 60 °C; [HBr] ≅ 0.0275 M. [h]$\Delta H^{\neq} = 93.8$ kJ mol^{-1} and $\Delta S^{\neq} = -41.9$ J mol^{-1} K^{-1} are quoted by Hoffman[117]. [i]Calculation from the values of k at 20°, 40°, 44.4°, 50°, and 60 °C [68] yields $\Delta H^{\neq} = 78.7$ kJ mol^{-1} and $\Delta S^{\neq} = -126.4$ J mol^{-1} K^{-1}. [j]Calculation from the values of k at 315–370 °C; $\lg k^{25} = -22.9$. [k]$\lg k^{25} = -6.49$. [l]$\lg k^{25} = -25.6$. [m]$\lg k^{25} = -5.16$. [n]$\lg k^{25} = -2.20$. [o]$\lg k^{25} = -5.00$. [p]$\lg k^{25} = -6.71$.

Simple comparison of the rate constants shows that the sensitivity of t-BuX to changes in the nature of the solvent on passing from one proton-donating solvent to another (H_2O–MeOH) or from a proton-donating solvent to another solvent (MeOH–propylene carbonate) decreases in the sequence Cl > Br > I, which can be explained by the fact that in the series of departing groups indicated the capacity of the solvent for electrophilic cooperation in the heterolysis diminishes. Indeed the sensitivity of t-BuX to the change of the aprotic solvent depends comparatively little on the nature of the halogen.

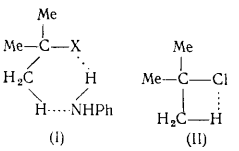
The rate of heterolysis of t-BuX decreases in the leaving-group order (Table 2):

$$OTos > I > ONO_2 > Br > Cl > OAc \approx OPOEtH \approx OPO(OH)_2 > F > SMe_2I.$$

The differences between the rates diminish with increase of the acidity of the proton-donating solvent; for example, $\lg(k_{t\text{-BuBr}}/k_{t\text{-BuCl}})$ decreases monotonically from 1.6 to 1.0 in the series MeOH–H_2O–HOAc–HCO_2H (the increasing influence of the formation of hydrogen-bonded complexes abolishes the effect of the departing group). In the gas phase and in aprotic solvents the above ratio is higher ($\lg k^{Br}/k^{Cl} \cong 2.7$; $\lg k^{I}/k^{Cl} \cong 4.3$) and depends little on the nature of the solvent. In CH_2Cl_2 these quantities are lower (2.3 and 3.4 respectively)—here the influence of the formation of hydrogen-bonded complexes is also manifested[142].

Table 2 presents a compilation of the activation parameters for the heterolytic reactions of t-BuCl, t-BuBr, and t-BuI and presents certain data for the heterolysis of t-BuF, t-$BuONO_2$, t-BuOTos, t-BuOAc, t-BuOEt, t-BuOP(O)EtH, t-$BuOP(O)(OH)_2$, and t-$BuS^+Me_2I^-$.

Analysis of the relations between $\Delta H^{\neq}$ and $\Delta S^{\neq}$, $\Delta H^{\neq}$ and $\Delta G^{\neq}$, and $\lg k^{25}$ and $\lg k^{50}$ for t-BuCl(Br, I) in various solvents[159] indicates the non-uniformity of the interaction[11] in the series considered, as shown by the failure of the isokinetic relation and the absence of the compensation effect. This may be due to the different degrees of charge separation in the transition state in various media, in agreement with the earlier conclusion that the rate-limiting stage is the formation of a contact ion pair in aprotic solvents and of the solvent-separated ion pair in proton-donating solvents.



The values of $\Delta H^{\neq}$ and $\Delta S^{\neq}$ vary marketdly as a function of the nature of the solvent—from 164.1 kJ mol^{-1} (n-heptane, t-BuCl) to 49.8 kJ mol^{-1} (dioxan, t-BuI) and from −207.7 kJ mol^{-1} (dioxan, t-BuI) to 58.6 kJ mol^{-1} K^{-1} (water, t-BuBr); therefore the conclusions that $\Delta S^{\neq} \geqslant 0$ [160,161] or that $\Delta H^{\neq}_{S_N1} > \Delta H^{\neq}_{S_N2}$ and $\Delta S^{\neq}_{S_N1} > \Delta S^{\neq}_{S_N2}$ [2,12,13] for reactions involving the S_N1 mechanism have little justification. The $\Delta S^{\neq}$ as a rule decreases in the series of solvents H_2O > proton-donating solvents > aprotic solvents; in the first case $\Delta S^{\neq} > 0$, in the second case $\Delta S^{\neq} \cong 0$, and in the third case $\Delta S^{\neq} < 0$. This can be explained by the fact that on formation of the transition state in water the effect of structure breaking in the solvent[162] predominates over the ordering of the latter as a result of the solvation of the ion pair produced; in other proton-donating solvents these effects are approximately identical, while in polar aprotic solvents the decrease of $\Delta S^{\neq}$ is due mainly to structure formation in the solvent around the ion pair formed.

The disruption of the structure of a proton-donating solvent with the aid of ultrasound increases the rate of solvolysis of t-BuCl.[103] The addition of small amounts of H_2O_2, ROH, tetrahydrofuran (THF), or acetonitrile also leads to the destabilisation of the water structure and hence to an increase of the rate of solvolysis of t-BuX.[163,164] The increase of the stability of the water structure on passing from H_2O to D_2O entails a decrease of the rate of solvolysis of t-BuCl ($k_{H_2O}/k_{D_2O} = 1.3$ was obtained at 25 °C [165]) with a simultaneous increase of $\Delta S^{\neq}$.[166] The negative value of $\Delta S^{\neq}$ for t-BuF in H_2O is associated with the formation of strong hydrogen bonds in the transition state, while $\Delta S^{\neq} \cong 0$ in n-heptane indicates an insignificant solvation of the transition state. Indeed, in the gas phase $\Delta S^{\neq}$ is also close to zero. $\Delta S^{\neq} = 33.1$ J mol^{-1} K^{-1} for t-BuI in $PhCF_3$ can be explained by the preferential solvation of the initial state as a result of the dipole–dipole interaction

$$(C^{\delta+}—F^{\delta-},\ C^{\delta+}—I^{\delta-}).$$

On formation of the transition state the dimensions of the $C^{\delta+}$–$I^{\delta-}$ dipole greatly increase, which leads to desolvation (disruption of the quadrupole).

The values $\Delta S^{\neq} \cong -80$ J mol^{-1} K^{-1} in certain proton-donating solvents (aniline, phenol) can be explained by the formation of a cyclic solvate complex of type (I) in the transition state[48,136]:

In aprotic solvents containing groups with a high dipole moment (CN, NO_2, CO), the formation of a quadrupole between the substrate and the solvent molecule is to be expected[3,4,141,167], which should reduce $\Delta S^{\neq}$ by ~80 J mol^{-1} K^{-1}; [12,120] the lower values of $\Delta S^{\neq}$ (from −125 to −210 J mol^{-1} K^{-1}) [dioxan, $(CO_2Et)_2$, CH_2Cl_2, RCO_2Et)] are apparently associated with the formation of complex cyclic associated species in the transition state[142,144]. This also applies to t-BuCl in propylene carbonate and acetone. The low value of $\Delta S^{\neq}$ in benzene is probably caused by the interaction of the substrate with the induced dipole of the C_6H_6 molecule[168].

In the gas phase and in non-polar aprotic solvents, $\Delta S^{\neq}$ is close to zero or has a low positive value. This conflicts with the hypothesis of the formation of a four-membered transition state of type (II) [6,18,48,49,142] in a medium of low polarity, since an appreciable decrease of $\Delta S^{\neq}$ is in fact to be expected precisely under the given conditions on formation of a cyclic transition state; this occurs, for example, on decomposition of t-BuOEt (Table 2). The increase of $\Delta S^{\neq}$ in acetonitrile in the sequence t-BuX < t-$BuONO_2$ < t-BuOTos can be explained by the decrease of the steric requirements in the dipolar solvation of the transition state, while the increase of $\Delta S^{\neq}$ in water in the sequence t-BuF < t-BuOAc < t-BuCl < t-BuBr is probably caused by the decrease of the solvation energy of the departing group.

It is noteworthy that $\Delta H^{\neq}$ and $\Delta S^{\neq}$ can vary markedly with temperature; for example, in the solvolysis of t-BuCl in t-BuOH, $\Delta H^{\neq}$ decreases by ~84 kJ mol^{-1} and $\Delta S^{\neq}$ by ~290 J mol^{-1} K^{-1} on raising the temperature from 27° to 60 °C (Table 2).[129,169] In this case the heat capacity of activation is $\Delta C_p^{\neq} = -2760$ J mol^{-1} K^{-1}; in water $\Delta C_p^{\neq} = -347$ J mol^{-1} K^{-1}.[170] The values of $\Delta C_p^{\neq}$ ranging from −125 to −625 J mol^{-1} K^{-1} for S_N1 reactions are usually accounted for by the necessity for the reorganisation of the solvation shell when the substrate passes to the activated state[170,171] or more precisely by the temperature variation of the solvation of the anion formed[172,173]. Indeed $\Delta C_p^{\neq}$ can depend greatly not only on the solvent but also on the nature of the departing group ($\Delta C_p^{\neq} = -255$ J mol^{-1} K^{-1} for t-BuBr in t-BuOH [129]). $\Delta C_p^{\neq} < -650$ J mol^{-1} K^{-1} and its marked decrease on passing from t-BuBr to t-BuCl cannot be explained either by the influence of temperature on the solvation of the anion generated[173], or by the presence

of a stage involving ion pair return[165,174,175], or by large errors in the determination of the temperature variation of the rate constant[176]. The above effects are apparently associated with the structure of the solvent and its temperature variation[173,177]. This may be confirmed to some extent by the fact that in the hydrolysis of the compound RX the quantity $\Delta C_p^{\neq}$ in D_2O is always lower than in H_2O.[166] The significant role of the solvent structure is indicated by the fact that the rate of solvolysis of t-BuCl in the $(CF_3)_2CHOH-H_2O$ mixture passes through a minimum when the solvent composition corresponds to the dihydrate $(CF_3)_2CHOH.2H_2O$,[178] while the rate of hydrolysis of $PhCH_2Cl$ passes through a minimum at the temperature of the maximum density of water[179].

IV. SOLVATION EFFECTS

We carried out a correlation analysis of the influence of solvent parameters on $\lg k$ [71,180] on the basis of the equation

$$\lg k = a_0 + a_1 DN + a_2 AN + a_3\delta^2 \qquad (1)$$

and the Koppell–Palm equation[11,20] with inclusion of the Hildebrand parameter[6] δ^2:

$$\lg k = a_0 + a_1\frac{n^2-1}{n^2+2} + a_2\frac{\varepsilon-1}{2\varepsilon+1} + a_3\delta^2 + a_4 B + a_5 E\ , \qquad (2)$$

where DN is the donor number[21,90], AN the acceptor number[22,90], n the refractive index, ε the dielectric constant, B an empirical parameter of the basicity (nucleophilicity)[11,20], E empirical parameter of the electrophilicity calculated[11,20] from the Dimroth–Reichardt polarity parameter[91] E_T by the formula $E = E_T - 25.10 - 14.84f(\varepsilon) + 9.59f(n)$, and $\delta^2 = (\Delta H_M - RT)/V_M$ the Hildebrand parameter which characterises the energy of interaction of solvent molecules with one another; ΔH_M is the molar heat of evaporation and V_M is the molar volume. The solvent parameters are listed in Table 1. The Hildebrand parameter has been used in a number of studies for the interpretation of kinetic data[6,22,46,181], although it is frequently employed in the relatively unsuitable form of the solubility parameter δ.[6,46] For comparison with the data of Fawcett and Krygowski[93], we also carried out a calculation by Eqn.(2) with E replaced by E_T. In order to determine the influence of each parameter, the calculation was performed with successive inclusion of the parameters in accordance with the procedure of Chapman et al.[182] (the solvents for which the error exceeded the average error by a factor greater than or equal to 2.5 were rejected). The calculation was carried out on a Mir-2 computer.

The application of Eqn.(2) to t-BuCl in 28 solvents (solvents 2–9, 11, 13, 16–21, 23–31, 41, 45, 47) # yields the expression:

$$\lg k = -18.2 + 16.6f(n) + 7.06f(\varepsilon) + 4.77\delta^2 + 0.293E \quad (r=0.960,\ S=0.664).$$

When account is taken of B, we obtain $r = 0.961$. When the parameters δ^2, $f(n)$, $f(\varepsilon)$, and E are excluded, the values of r decrease respectively to 0.946, 0.945, 0.928, and 0.749. Thus the rate of hydrolysis of t-BuCl depends mainly on the electrophilicity of the solvent, to a lesser extent on its polarity, and depends little on the polarisability and self-association energy of the solvent. The nucleophilicity of the solvent does not influence the rate of reaction. These conclusions are consistent with the results of the calculations for t-BuCl by the Koppel–Palm equation[20,159].

In order to deduce the specific features of the solvation effects in proton-donating and aprotic solvents, we carried out calculations by Eqn.(2) separately for each group of solvents. In 15 proton-donating solvents (solvents 2–8, 11, 13, and 16–21), we obtained the equation

$$\lg k = -15.4 + 19.7f(n) + 5.10\delta^2 + 0.263E \quad (r=0.962,\ S=0.554).$$

When account is taken of B and $f(\varepsilon)$, we obtain $r = 0.964$; without taking into account δ^2, $f(n)$, and E, the values of r are respectively 0.934, 0.878, and 0.877. Thus in proton-donating solvents the rate of solvolysis of t-BuCl depends equally on the electrophilicity and polarisability of the solvent and to a lesser extent on its self-association energy; the basicity and polarity of the solvent do not affect the rate of reaction.

The rate of decomposition of t-BuCl in 13 aprotic solvents (solvents 23–31, 41, 45, 47, and 51) is described by the equation

$$\lg k = -20.8 + 14.1f(n) + 14.2f(\varepsilon) + 0.523E \quad (r=0.956,\ S=0.754).$$

When account is taken of B and δ^2, we obtain $r = 0.961$; when $f(n)$, $f(\varepsilon)$, and E are disregarded, the values of r are respectively 0.941, 0.743, and 0.856. Thus the ionisation of t-BuCl in aprotic solvents depends most on the polarity of the solvent, greatly on its electrophilicity, and depends only slightly on its polarisability.

When E is replaced by E_T in Eqn.(2),[20] we obtain the following equation for t-BuCl in 28 solvents (solvents 2–9, 11, 13, 14, 16, 17, 19, 21, 23–31, 41, 45, and 47):

$$\lg k = -21.5 + 3.67\delta^2 - 0.00351B + 0.289E_T \quad (r=0.960,\ S=0.697). \qquad (3)$$

Taking into account $f(n)$ and $f(\varepsilon)$, we have $r = 0.961$; when δ^2, B, and E_T are disregarded, the values of r are respectively ~0.952, 0.949, and 0.730. Consequently the rate of heterolysis of t-BuCl actually depends on E_T (the nucleophilicity actually decreases somewhat the rate of reaction in this case). Our results conflict with the conclusion[93] that the rate of heterolysis of t-BuCl increases with increase of both the electrophilicity (E_T) and basicity (DN) of solvents. We may note that Fawcett and Krygowski[93] used only five solvents ($r = 0.909$), while we used 28 solvents.

The application of Eqn.(1) to the description of the rate of heterolysis of t-BuCl in 15 solvents (solvents 2–4, 6, 16, 19, 23, 24, 27–29, 31, 41, 45, and 47) yields the expression

$$\lg k = -12.4 + 0.0917AN + 10.6\delta^2 \quad (r=0.980,\ S=0.606). \qquad (4)$$

When account is taken of DN, we have $r = 0.800$; when AN and δ^2 are disregarded, the values of r are 0.897 and 0.899 respectively. Thus the rate of heterolysis of t-BuCl depends equally on AN and δ^2. The basicity of the solvent does not affect the rate of reaction, which conflicts with the conclusions[22,92] that the rate of reaction increases appreciably with increase of DN.

Following the replacement of δ^2 by δ in Eqn.(1), the correlation becomes appreciably worse[180].

The application of Eqn.(2) to t-BuBr leads to the following relation in 14 solvents (solvents 2, 4, 14, 16, 23, 25–29, 31, 32, and 41):

$$\lg k = -8.00 + 10.3\delta^2 + 0.0883E \quad (r=0.972,\ S=0.481).$$

When account is taken of $f(n)$, $f(\varepsilon)$, and B, we have $r = 0.984$; when δ^2 and E are disregarded, the values of r are respectively 0.871 and 0.960. Consequently the rate of heterolysis of t-BuBr is determined fairly completely by δ^2; the electrophilicity of the solvent promotes the reaction to a slight extent, while the polarisability, polarity, and nucleophilicity of the solvent have no importance.

#Here and henceforth the solvents are numbered as in Table 1.

When E is replaced by E_T in Eqn.(2), we obtain the following expression for t-BuBr in 14 solvents (solvents 2–4, 16, 23, 25–29, 31, 32, 41, and 42):

$$\lg k = -11.8 + 9.68\delta^2 + 0.0954E_T \quad (r = 0.969,\ S = 0.502). \qquad (5)$$

When account is taken of f(n), f(ε), and B, we have $r = 0.981$. When δ^2 and E_T are disregarded, the values of r are 0.900 and 0.960. Thus the rate of heterolysis of t-BuBr depends mainly on δ^2; allowance for E_T improves the correlation slightly.

The application of Eqn.(1) to t-BuBr yields the following relation for 12 points (solvents 2, 4, 16, 23, 26–29, 31, 32, 41):

$$\lg k = -8.53 + 0.0137DN + 0.0252AN + 11.7\delta^2 \quad (r = 0.976,\ S = 0.488). \qquad (6)$$

The exclusion of AN or DN has comparatively little influence on the correlation coefficient (r = 0.975 and 0.964 respectively), while the exclusion of δ^2 lowers r to 0.770. Thus the rate of heterolysis of t-BuBr depends virtually only on δ^2. The correlation of the rates taking into account only DN and AN (or E_T and B) leads to poor results.

The application of Eqn.(2) to t-BuI in 19 solvents (solvents 2, 3, 26, 28, 29, 31, 32, 34–42, 45, 46, and 49) yields the expression

$$\lg k = -9.69 + 6.32f(\varepsilon) + 11.8\delta^2 \quad (r = 0.965,\ S = 0.491).$$

When account is taken of f(n), B, and E, we have $r = 0.975$; when f(ε) is disregarded, r = 0.952. Consequently the rate of heterolysis of t-BuI depends mainly on δ^2.

Following the replacement of E by E_T, we obtain the following equation for the same 19 solvents:

$$\lg k = -12.5 + 5.72\delta^2 + 0.147E_T \quad (r = 0.973,\ S = 0.437).$$

Taking into account f(n), f(ε), and B, we obtain $r = 0.976$; when δ^2 and E_T are disregarded, the values of r are 0.953 and 0.952. Thus the rate of heterolysis of t-BuI is equally well correlated with both δ^2 and E_T. The nucleophilicity of the solvent does not affect the rate of reaction.

Application of Eqn.(1) to t-BuI in 11 solvents (solvents 2, 3, 26, 29, 31, 32, 34, 41, 45, and 46) leads to the relation

$$\lg k = -7.38 + 0.0455AN + 8.77\delta^2 \quad (r = 0.966,\ S = 0.668). \qquad (7)$$

Our correlation analysis showed that the rate of heterolysis of t-BuX is independent of the nucleophilic properties of the medium. In all cases the contribution of the parameters B or DN was close to or equal to zero with the exception of Eqn.(3), where B actually reduces slightly the rate of reaction. Consequently we conclude that the heterolysis of t-BuX proceeds without the nucleophilic cooperation by the solvent. This agrees with the conclusions of Koppel and Palm[20] and also Kulik[159] and conflicts with the conclusions of the authors of a number of studies[15,22,32,40,54,55,85,92–94,104,105,114,116,118], who believe that the formation of the transition state requires nucleophilic attack by the solvent. Our Eqns.(4), (6), and (7) showed that the conclusions[22,90,92–94] concerning the influence of the acid–base properties of the solvent on the rate of heterolysis of t-BuX are only half justified—only as regards the acid properties of the solvent.

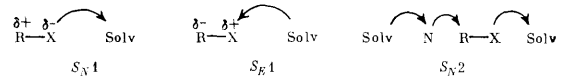
Recently Abraham et al.[183] correlated the values of lg k for t-BuCl(Br, I) in 15 specially selected solvents (solvents 2–4, 7, 16, 23–26, 28, 29, 45, 47, 50, and 51) in terms of the Koppel–Palm equation and the equation

$$\lg k = a_0 + a_1\pi^* + a_2\alpha + a_3\beta, \qquad (8)$$

where π^* is the dipolarity parameter and α and β are the parameters of the electrophilicity and nucleophilicity of the solvents respectively[183]. In the former case the rate of reaction is described by a three-parameter equation including f(ε), f(n), and E with correlation coefficients of 0.975 (t-BuCl), 0.963 (t-BuBr), 0.934 (t-BuI), while in the latter case it is described by a two-parameter equation (the parameters π^* and α) with $r \cong 0.995$. This provided the authors[183] with grounds for the conclusion that Eqn.(8) describes the solvent effect better than the Koppel–Palm equation. Naturally a two-parameter equation is always better than a three-parameter equation, since the latter suffers from an uncertainty in its derivation[185,186], but the conclusions of Abraham et al.[183] provide only for the set of solvents indicated from which aromatic and organic polychloro-solvents have been excluded. Furthermore, out of the 45 values of lg K quoted by Abraham et al.[183], 14 had been calculated and four (t-BuBr in isopropyl alcohol, t-butyl alcohol, diethyl ether, and dioxan) had been taken from an unknown source—the values indicated are missing from Refs.6, 18, and 128 to which Abraham et al. refer[183]. Recently published data[129] on the solvolysis of t-BuBr in t-BuOH show that the value quoted by Abraham et al.[183] ($\lg k_1^{25} = -6.50$) is lower by 1.5 orders of magnitude than the experimental value (Table 1). It has been shown[159] that the correlation of the lg k for t-BuCl(Br, I) carried out for the entire set of solvents leads to better results. Consequently the set of solvents employed by Abraham et al.[183] on the one hand improved the correlation in terms of Eqn.(10) and on the other impaired the correlation in terms of the Koppel–Palm equation. In essence, the data obtained by Eqn.(10) agree well with the results of the correlation in terms of the Koppel–Palm equation, since it has been shown recently[187] that the parameter π^* is correlated with f(ε) and f(n). The main conclusion reduces in both cases to the rejection of the nucleophilic involvement of the solvent.

Nucleophilic attack by the solvent "from the rear" can actually hinder the unimolecular heterolytic reaction. Indeed the nucleophilic solvation of the carbonium ion generated leads to the stabilisation of the intermediates formed and hence can retard their subsequent migration along the reaction coordinate. It has been shown[32] that the nucleophilic involvement of a DMF molecule in the heterolysis of 2-bromo-2-methylpentane leads to the establishment of the dead-end equilibrium

$$\mathrm{DMF} \cdot \mathrm{R^+Br^-} \underset{-\mathrm{DMF}}{\overset{+\mathrm{DMF}}{\rightleftharpoons}} \underset{\mathrm{RBr}}{\mathrm{R^+Br^-}} \rightleftarrows \mathrm{R^+ \mid Solv \mid Br^-} \rightarrow \text{products}.$$



Consequently the intuitive hypothesis of Bentley and Schleyer[15] that the substrate should "make use" of the nucleophilic cooperation by the solvent does not occur on the main reaction pathway if it obtains at all.

In contrast to the nucleophilicity factor, other solvent parameters influence the rate of heterolysis of t-BuX and, depending on the nature of the leaving group or the set of solvents, any one of them can predominate.

The rate of heterolysis of t-BuCl in the entire set of proton-donating and aprotic solvents is determined mainly by the electrophilicity. The solvent polarity and polarisability promote the reaction to an appreciable extent. Calculation by the Koppel–Palm equation[129] shows that the solvent electrophilicity is also of decisive importance for t-BuBr and t-BuI.

It is possible to put forward the following picture of the mechanism of the unimolecular heterolysis of t-BuX: as a result of the action of the internal nucleophile (the t-butyl group), an electron is transferred to the departing group and this is sufficient for the rapid subsequent elimination of HX in the gas phase. In the condensed phase the reaction is to a large extent promoted by the delocalisation of the charge of the anion generated over the solvent molecule, i.e. by the electrophilic cooperation in the heterolysis. The positive charge generated does not require the nucleophilic cooperation by the solvent since it is sufficiently delocalised over the three methyl groups. Furthermore, the action of

the nucleophile is hindered by the pronounced steric hindrance. For reactions via the S_E1 mechanism, one can outline the opposite picture: in this case the nucleophilic cooperation in the heterolysis becomes decisive[188]. Reactions of the S_N2 type require both the nucleophilic and electrophilic cooperation by the solvent[93,189]. Hence follows a simple generalisation concerning the role of the solvent in substitution reactions:

S_N1 S_E1 S_N2

Analysis carried out separately in proton-donating and aprotic solvents[180] makes it possible to define and specify in greater detail the mechanism of the heterolysis of t-BuCl.

In proton-donating solvents the rate of reaction depends equally on the electrophilicity and polarisability of the solvent and is described by the two-parameter equation

$$\lg k = -(15.7\pm1.4) + (19.3\pm2.0)f(n) + (0.383\pm0.026)E \quad (r=0.934).$$

In aprotic solvents the decisive factor is the polarity and to a lesser extent the electrophilicity:

$$\lg k = -(17.7\pm1.7) + (15.5\pm1.4)f(\varepsilon) + (0.441\pm0.051)E \quad (r=0.941).$$

The dependence of the rate of heterolysis of t-BuCl in proton-donating solvents on the electrophilicity and polarisability factors can be explained by the fact that, as a result of the formation of hydrogen-bonded complexes by the anion generated, the negative charge is strongly delocalised over the solvent molecule, which leads to the formation of a readily polarisable transition state. In an aprotic medium the dependence of the rate of reaction mainly on the solvent polarity can be accounted for by the fact that in this instance the heterolysis occurs as a result of the dipole–dipole interaction of the t-BuCl molecules with solvent molecules[3,4,23,120,141]. If this is so, the rate of reaction should increase with increase of the dipole moment of the solvent. Indeed a satisfactory correlation has been observed between ε and μ (for solvents 23, 24, 26–32, 35–39, 41, 42, 45–47):

$$\mu = -13.0 + 13.4\varepsilon \quad (r=0.969,\ S=1.30).$$

The solvation of the anion generated should play a smaller role in this instance, which is in fact observed.

The differences between the rates of heterolysis of t-BuX in proton-donating and aprotic solvents are associated to some extent with the fact that in the former case a solvent-separated ion pair is formed in the rate-limiting stage, while in the latter case a contact ion pair is produced. It has been shown[44] that the formation of a solvent-separated ion pair depends much more on the formation of hydrogen-bonded complexes than the formation of a contact ion pair.

If *AN* is employed as the electrophilicity parmeter, the rate of heterolysis of t-BuCl is described satisfactorily by the two-parameter Eqn.(4), which also includes δ^2.

In contrast to t-BuCl, the rate of heterolysis of t-BuBr and t-BuI depends mainly on the self-association energy of the solvent, which is determined by the cohesive energy density and polarity of the solvent. We have

$$\lg k = -(8.06\pm0.28) + (13.9\pm1.2)\delta^2 \quad (r=0.963)$$

for t-BuBr and

$$\lg k = -(7.11\pm0.32) + (12.8\pm1.5)\delta^2 \quad (r=0.952)$$

for t-BuI.

One should note that δ^2 is an independent parameter. Indeed δ^2 is hardly correlated with the four parameters of Eqn.(2)—r = 0.72 for 41 solvents (solvents 2–9, 11, 13, 16–21, 23–32, 34–42, 45–47, 50, and 51). The maximum correlation coefficient among the one-parameter relations is observed for the δ^2–E relation (r = 0.70); allowance for the polarity parameter increases r to 0.72, while nucleophilicity and polarisability do not affect r. In proton-donating solvents (17 solvents) the multiple correlation coefficient is 0.83, while in aprotic solvents (24 solvents) it is 0.40.

The influence of the factor δ^2 on the rate of heterolysis of t-BuX can be explained by the fact that the residence time of the substrate in the solvent cage (10^{-8}–10^{-11} s) [23] and hence the probability of its ionisation increase with increase of the cohesion energy of the solvent. The migration of t-BuX relative to the solvent molecules leads to the dissipation of the energy required for the attainment of the transition state. If the influence of δ^2 is reduced solely to the energy required for the formation of the cage in the solvent, as is usually done[6,22,46], then it becomes incomprehensible why δ^2 should affect the rate of reaction if the process proceeds in the solution already formed. At the same time it is difficult to achieve a clear-cut interpretation of the dependence of the influence of δ^2 on the nature of the leaving group, since a different set of solvents has been used for each substrate.

In conformity with the rule of Richardson and Soper[190], the increase of the rate of heterolysis of t-BuBr with increase of the cohesion of the solvent shows that the products of the above reactions, or more correctly the transition state, have a greater cohesion than the initial reactants. The observed difference for t-BuCl can be hardly explained by the fact that in this case the cohesions of the reactants and reaction products, or more correctly $[t\text{-BuCl}]^{\neq}$, become equalised either due to the increase of the cohesion of t-BuCl or as a result of the decrease of the cohesion of the transition state. The explanation should apparently be sought in an increase of order in the solution[24] on passing from t-BuBr to t-BuCl. This conclusion is in good agreement with the latest interpretation of the low values of $\Delta C_p^{\neq}$ in S_N1 reactions[173], based on the concept that the solvent structure influences the solvation of the anion generated.

It is believed[129] that the marked decrease of $\Delta C_p^{\neq}$ in t-BuOH on passing from t-BuBr to t-BuCl is associated with the fact that the molecules of t-BuCl can enter freely into structural cavities or into the middle of the polymeric associated solvent species, while the molecules of t-BuBr are incapable of this. Cohesion therefore has apparently little influence on the heterolysis of t-BuCl, while a change in the solvent structure can lead to intense thermodynamic and kinetic effects[129,162,178]. It has been shown[191] that the stability of the solvation sphere around t-BuX depends on the nature of the halogen.

---o0o---

Thus, the correlation analysis of the influence of solvent parameters shows that the rate of heterolysis of t-butyl halides depends mainly on the electrophilicity of the solvent and increases with its self-association energy. In all cases the heterolysis of t-BuX proceeds without the nucleophilic cooperation by the solvent.

In conclusion we may note that t-butyl halides are relatively unsuitable as standards for the comparative analysis of the influence of the solvent on solvolytic and other heterolytic reactions. Non-uniformity of the mechanism is characteristic of these substrates: a contact ion pair is formed in the rate-limiting stage in aprotic solvents, while a solvate-separated ion pair is formed in proton-donating solvents; in isolated instances (H_2O, phenol) carbonium ions are formed. Diphenylmethyl halides are more promising standards for the analysis of solvation effects.

During the preparation of the manuscript for the press, the paper of Swain et al.[192] was published and in it a correlation analysis has been carried out for 77 reactions in 61 solvents using the solvent electrophilicity (A) and nucleophilicity (B) parameters. The authors conclude that all the solvolytic reactions (26 systems) require both the nucleophilic and electrophilic cooperation of the solvent and that the influence of the nucleophilicity increases in the sequence Ph_2CHCl < t-BuCl < MeBr < 1-AdBr < t-BuBr. The series which they present[192] conflicts with modern ideas[14-16], according to which there should be no nucleophilic cooperation in 1-AdBr and such cooperation should be a maximum in MeBr. The reason for this discrepancy is that the parameters A and B of the solvents were calculated from the entire set of data on the basis of critical conditions arbitrarily selected by the authors[192]: $A = B = 1$ in water, $A = B = 0$ in hexane, and $A = 0$ in hexamethylphosphoramide and $B = 0$ in CF_3COOH. The parameters A and B obtained for other solvents as a result of the calculation[192] conflict with widely familiar experimental data. Thus, according to Swain et al.[192], acetic acid is less nucleophilic than formic acid and is less electrophilic than water. The lack of validity of the conclusions of Swain et al. [192] is associated also with the fact that they employed only an insignificant proportion of the experimental data. For example, out of the 35 known values of $\lg k$ for the heterolysis of t-BuCl in individual solvents only 6 were employed, while in the case of t-BuBr only 4 out of 21 were employed.

Advances in the Chemistry of β-Aminoketones

G.A.Gevorgyan, A.G.Agababyan, and O.L.Mndzhoyan

Data on the aminomethylation reaction (the Mannich reaction) for the period 1970-1980 are examined and a systematic account is given. The synthesis of β-aminoketones from various ketones (dialkyl ketones, alkyl aryl ketones, heterocyclic alkyl ketones, and cyclic ketones, as well as diketones) is discussed.
The bibliography includes 229 references.

I. Introduction 561
II. Aminomethylation of ketones 561
III. The Mannich reactions with aldehydes 576

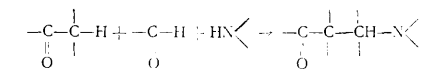
I. INTRODUCTION

The interest in β-aminoketones (Mannich bases) has been stimulated recently by the following factors: (a) β-aminoketones are intermediates in the synthesis of α,β-unsaturated ketones, β-aminoalcohols, and heterocyclic compounds; (b) β-aminoketones are potentially biologically active compounds.

The main method of synthesis of β-aminoketones is based on the aminomethylation of ketones. The extensive literature on the aminomethylation reaction, called the Mannich reaction, has been systematically represented throughout in review articles[1-13], and monographs[14,15]. A review[16] is devoted to advances in the study of the Mannich reaction during the period 1960–1970.

In our own review article[17], we considered the aminomethylation reaction using α-aminoacids as the amino-components.

It is known that β-aminoacids possess a broad spectrum of biological activity. Many of them have found applications in medical practice. Thus the hydrochlorides of 4-(n-propoxy)- and 4-(n-butoxy)-β-piperidinopropiophenones (falicaine and dyclonine) as well as the hydrochloride of 4-(n-propoxy)-β-hexamethyleneiminopropiophenone (hexacaine) are used in medical practice as local anaesthetics[18-21], the hydrochloride of 4-methyl-α-methyl-β-piperidinopropiophenone (mydocalm) is used as an anticonvulsant[22], and the hydrochloride of 6-[β-(3-phenylpyrrolidino)propionyl]-1,4-benzodioxan (pyrroxan) is an α-adrenoblocking agent[23,24].



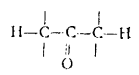
Furthermore, antibacterial[25-29], anti-inflammatory[30,31], antitumour[26,32-37], analgesic[37,38], psychotropic[39] and other properties[40-47] have been discovered in a large number of β-aminoketones.

The present review is devoted to the available literature data on the aminomethylation reactions of various ketones accumulated during 1970–1980 (and for diketones also up to 1970).

For clarity and to ensure brevity of exposition, we thought it useful to quote the biological activities of β-aminoketones in a separate column in the Tables.

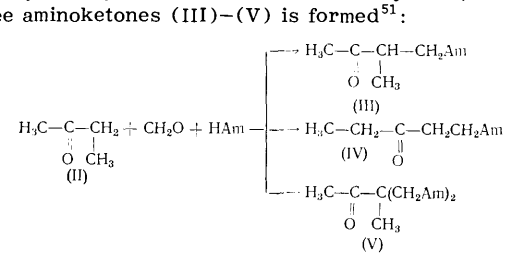
II. AMINOMETHYLATION OF KETONES

One of the convenient methods of synthesis of β-aminoketones is the Mannich reaction, which consists of the condensation of a ketone containing at least one hydrogen atom in the α-position with an aldehyde (usually formaldehyde) and an amine:



Numerous communications have been devoted to the study of the mechanism of this reaction[1,6-8,10,38,48].

1. Dialkyl Ketones

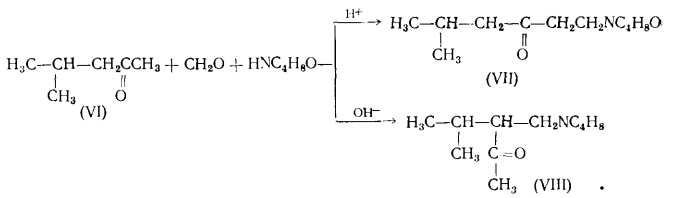


A number of studies have been made of the aminomethylation of asymmetric dialkyl ketones[49-63]. Despite the fact that the Mannich reaction has been studied for a long time, the problem of selectivity for asymmetric ketones has still not been fully solved. Some data[49] are now recognised as erroneous.

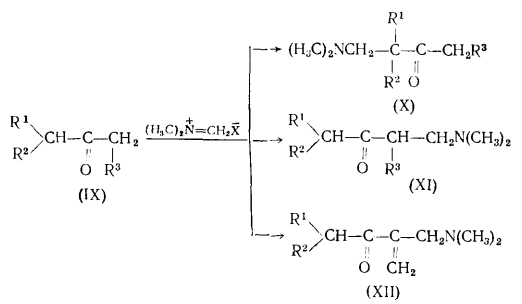
There are mobile hydrogen atoms in the α- and α'-positions in the molecules of dialkyl ketones of type (I), which suggests different modes of aminomethylation:

(I)

When ethyl methyl ketone (II) is aminomethylated, a mixture of three aminoketones (III)–(V) is formed[51]:



Am = $N(C_2H_5)_2$, NC_5H_{10}.



It has been shown that, with decrease of the pH of the medium, the yields increase: on heating ethyl methyl ketone, paraformaldehyde, and diethylamine in ethanol at pH 8–9 for 6 h, the overall yield of the mixture of aminoketones is 28.6%, while at pH 1 it is 43%. The formation of compound (IV) has been demonstrated by specific synthesis and also mass-spectrometrically[52].

The relation between the yields of the final products and the pH of the medium has also been considered[53].

The aminomethylation of 4-methyl-2-pentanone (VI) in ethanol in an acid medium leads to a mixture of 1-morpholino-5-methylhexanone (VII) and 1-morpholino-2-isopropyl-3-butanone (VIII) (in proportions of 69:31) with an overall yield of 81%, while in a basic medium a mixture of compounds (VII) and (VIII) is obtained with the latter predominating [(VII):(VIII) = 8:92]; the overall yield is 43%:

It has now become possible to direct aminomethylation to a particular α-carbon atom in an asymmetric ketone using immonium salts as the reagents. Thus the aminomethylation of the ketone (IX) [54–57] using the immonium salt $(CH_3)_2\overset{+}{N}=CH_2X^-$ (0.05 M, X = CF_3CO_2 or ClO_4) in trifluoroacetic acid at 72 °C leads to selective attack on the more substituted α-carbon atom with formation of compound (X):[56]

$R^1 = R^3 = H, CH_3$; $R^2 = CH_3, C_2H_5, n\text{-}C_4H_9$

$R^1 + R^2 = (CH_2)_n$, $n = 3–5$.

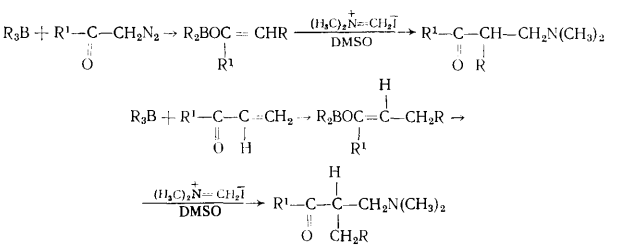


Table 1. The regioselective synthesis of the β-aminoketones (X) and (XI) from asymmetric ketones $RCOCH_3$ and immonium salts[55].

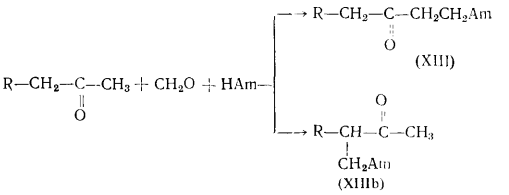
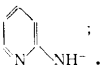
Immonium salt	R	Overall yield, %	(X):(XI)
Solvent F_3C-COOH			
$(CH_3)_2\overset{+}{N}=CH_2CF_3COO^-$	$C_6H_5CH_2$	95	85:15
ditto	CH_3CH_2	85	80:20
»	$(CH_3)_2CH$	90	85:15
»	cyclopentyl	90	95:5
»	cyclohexyl	70	69:31
Solvent CH_3CN			
$(C_3H_7)_2\overset{+}{N}=CH_2ClO_4^-$	cyclopentyl	80	0:100
ditto	$(CH_3)_2CH$	95	0:100
»	cyclohexyl	90	0:100

On increase of the concentration of the immonium ion to 2 M, the reaction product is compound (XI), which is formed, according to the authors, as a result of the isomerisation of the aminoketone (X).† In acetonitrile at 72 °C and in the presence of a 2 M concentration of the immonium ion, the reaction product is compound (XI), whose formation is accompanied by that of the aminoketone (XII), which contains the vinyl group. The sterically hindered dipropyl(methylene)ammonium salt reacts specifically with the methyl group in alkyl methyl ketones in acetonitrile (Table 1).



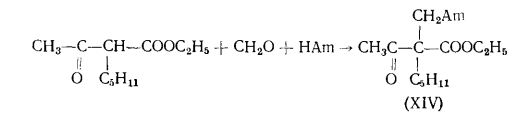
From the experimental data, the authors conclude that the regioselectivity is greatly influenced by the size of the group at the nitrogen atom, the solvent, the concentration of the immonium salts, and the counterion.

Enol borinates also react regiospecifically with dimethyl(methylene)ammonium iodide in dimethyl sulphoxide (DMSO).[54] The reaction constitutes an effective method of synthesis of Mannich bases from α-diazoketones or α,β-unsaturated ketones and aldehydes:



$R = C_2H_5, C_6H_{13}, C_7H_{15}$; $R^1 = C_6H_5$ $(CH_3)_2CH$.

Despite the possibility of aminomethylation at both methylene groups of the substituted acetone molecule[58–63], the products of aminomethylation at the methyl group have been characterised[58] [compound (XIIIa)], while other workers[59–61] characterised the products of aminomethylation at the methylene group [compound (XIIIb)]:



(a) $R = CH_2CH_2COOC_2H_5$, CH_2CH_2CN, $CH_2CH{=}C(Cl){-}CH_3$, $CH_2CH_2C_6H_4OCH_3$-*m*;

$CH_2CH_2{-}C(C_7H_4{-}OH\text{-}o)_2CH_3$; Am = $N(C_2H_5)_2$, NC_5H_{10}, $N(C_3H_7)_2$

(b) $R = C_6H_5$,  ; Am = $N(CH_3)_2$, $N(C_2H_5)_2$ NC_4H_8O

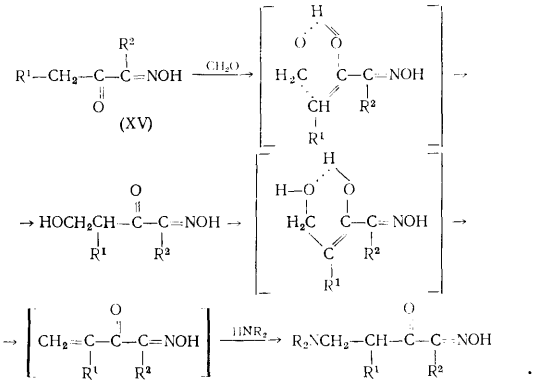
Optically active Mannich bases (XIV) have been obtained in 36–50% yield by the reaction of (+)-ethyl 2-methylbutylacetoacetate with paraformaldehyde and secondary amines[62]:

Am = $N(CH_3)_2$, $N(C_2H_5)_2$, $N(C_3H_7)_2$, $N(n\text{-}C_5H_{11})_2$, NC_5H_{10}, NC_4H_8O, $N(CH_2CH_2OH)_2$.

The above justifies the conclusion that, regardless of the pH of the medium, the aminomethylation of asymmetric dialkyl ketones leads to the formation of the α- and α′-aminomethyl derivatives and that in an acid medium the reaction involves

†In our view, the direct formation of compound (XI) cannot be excluded.

preferentially the less substituted α-carbon atom, while in an alkaline medium it involves the more substituted α-carbon atom. It has been suggested that the observed relation between the regioselectivity of the aminomethylation and the reaction conditions reflects the change in the relative rates of the enolisation and addition stages.



2. Isonitrosoketones

A number of studies have been made of the aminomethylation of α-isonitrosoketones[64-67]. It has been shown that the products of the aminomethylation of α-isonitrosoketones (XV) are mono-, di-, and tri-substituted derivatives (Table 2).

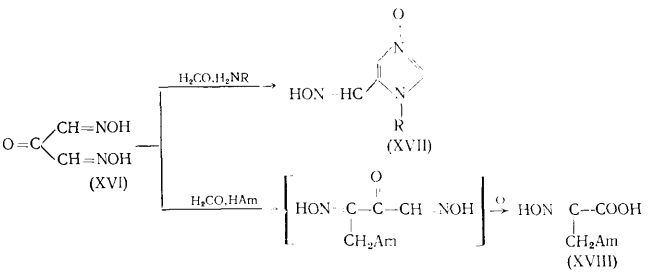


Table 2. The Mannich reaction involving substituted isonitrosoketones.

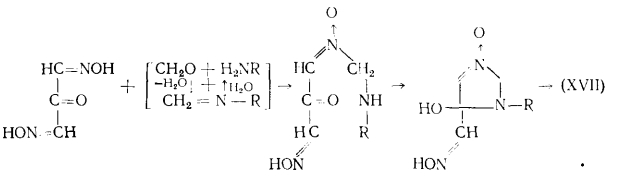
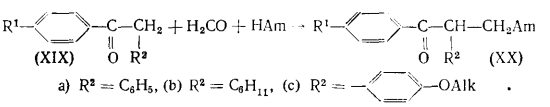
$CH_3CH_2-C(=O)-C(=NOH)-CH_3$	$CH_3-CH(CH_2Am)-C(=O)-C(=N-OH)-CH_3$; Am = $N(CH_3)_2$, NC_4H_8, NC_5H_{10}	47—75	[64]
$CH_3-C(=O)-C(=NOH)-R^1$; R^1 = CH_3, C_6H_5, $COOC_2H_5$	$AmCH_2-CH(AmCH_2)-C(=O)-C(=NOH)-R^1$; Am = $N(CH_3)_2$, $N(C_2H_5)_2$, NC_4H_8, NC_4H_8O, NC_5H_{10}	31—90	[64]
$CH_3-C(=O)-CH(-NOH)$	$AmCH_2-CH(AmCH_2)-C(=O)-CH=NOH$; Am = $N(C_2H_5)_2$, NC_4H_8O, NC_5H_{10}	26—70	[65]
$C_5H_{10}NCH_2-CH(C_5H_{10}NCH_2)-C(=O)-CH=NOH$	$C_5H_{10}NCH_2-CH(C_5H_{10}NCH_2)-C(=O)-C(=NOH)-CH_2Am$; Am = $N(C_2H_5)_2$, NC_5H_{10}	35, 51	[65]

Hahn and Bartnik[64] proposed a probable reaction mechanism consisting of the following stages: (1) condensation of the formaldehyde with the CH acid component in which the amine behaves as a basic catalyst; (2) dehydration of the hydroxymethyl derivative formed; (3) nucleophilic addition of the amine to the double bond facilitated by the vicinity of the carbonyl group.



The mode of reaction of di-isonitrosoacetone (XVI) with formaldehyde and primary and secondary amines has been investigated. The reaction products are respectively derivatives of 5-(hydroxyiminomethyl)imidazole 3-*N*-oxide (XVII) and the oxime of aminopyruvic acid (XVIII):[67]

R = CH_3, C_2H_5, C_6H_{11}, $C_6H_5CH_2$, *p*-$CH_3OC_6H_4$, *p*-$C_2H_5OC_6H_4$
Am = NC_4H_8O, NC_5H_{10}.



The authors explain the formation of compound (XVII) in the following way:

This is consistent with the data obtained by Lettau[68-72] for the condensation of isonitrosoketones with aldehydes and primary amines.

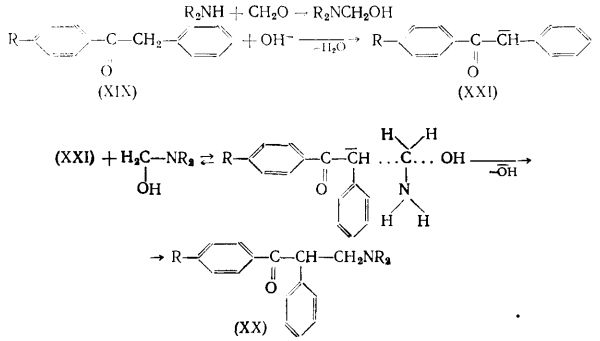
3. Alkyl Aryl Ketones

In order to investigate the problem of structure–reactivity relation, a large group of β-aminoketones (XX) have been synthesised by the Mannich reaction from substituted benzyl phenyl and cyclohexylmethyl phenyl ketones (XIX) (Table 3):[38,73-80]

a) $R^2 = C_6H_5$, (b) $R^2 = C_6H_{11}$, (c) R^2 = —OAlk.

It is known that the course of the Mannich reaction and the yields of products are significantly influenced by the pH of the medium[3,81]. The results of studies in recent years fully confirm this hypothesis[38,51,73-77]. Thus the yield does not exceed 28% in the condensation of the ketone (XIXa), paraformaldehyde, and pyrrolidine in an acid medium (pH 1–2) on heating for 30 h. On the other hand, in a

basic medium (pH 8–9) heating in the course of 4 h ensures a 70–90% yield of the aminoketone (XX):



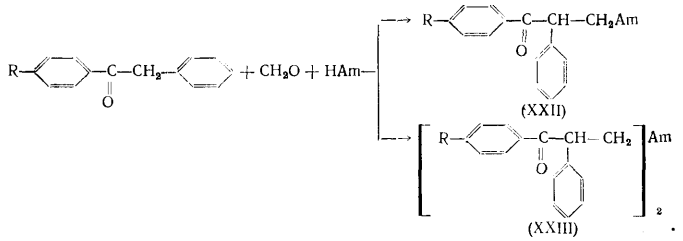


Table 3. Aminomethylation of benzyl phenyl and cyclohexylmethyl phenyl ketones.

			Yield, %	Biological activity	Refs.
R^1	R^2	Am			
H, HO, n-alkoxy-(C_1–C_7), iso-C_3H_7O, iso-$C_5H_{11}O$	C_6H_5	NC_5H_{10}	38–92	analgesic, anaesthetic	[73]
H, HO, n-alkoxy-(C_1–C_5), iso-$C_5H_{11}O$	C_6H_5	NC_4H_8O	46–89	—	[73]

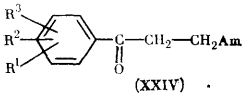
H	 R^3 = H, HO, n-alkoxy-(C_1–C_5), iso-C_3H_7O, iso-C_4H_9O, iso-$C_5H_{11}O$	NC_4H_8	32–62	ditto	[75]
H, n-alkoxy-(C_1–C_5)	C_6H_5	NC_6H_{12}	61–75	anti-inflammatory, antipyretic	[76]
H, HO, F, C_4H_9O, iso-C_3H_7O		NC_5H_{10}, NC_6H_{12}, HN—$CH(CH_3)_2$	43–91	ditto	[77]
H, n-alkoxy-(C_1–C_5), iso-C_3H_7O, iso-$C_5H_{11}O$	C_6H_5	$HNCH_3$, HNC_4H_9	47–80	loss of analgesic activity	[78]

In all probability the reaction proceeds via the S_N2 mechanism[38]. Presumably, with increase of the pH of the medium, the concentration of the carbanion (XXI) increases, which tends to increase the rate of reaction.

The opposite relation is observed in the aminomethylation of the ketones (XIXb).[77] Thus, when a reaction mixture consisting of equimolar amounts of cyclohexylmethyl phenyl ketone, paraformaldehyde, and hexamethyleneimine is heated for 15 h at pH 1.0 in dioxan, the yield is 83%, while at pH 7.0–8.0 it does not exceed 25–30%. In this case the reaction apparently proceeds via the electrophilic substitution mechanism (S_E).

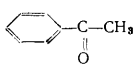
When primary amines are used, the disubstituted derivative (XXIII) is formed together with the monosubstituted products (XXII):[75]

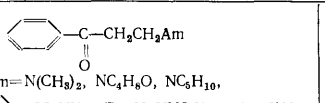


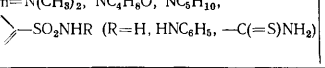
It is known that the biological activity of β-aminoketones is significantly influenced by the presence and position of an alkoxy-group in the benzene ring, the structure of the amino-group, and also the substituent in the α-position[18].

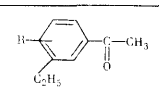
Pharmacological studies of the salts of the aminoketones (XXa, Am = NC_5H_{10}) showed that the methoxy- and ethoxy-derivatives completely lack a surface-anaesthetic activity. An increase of the length of the alkoxy-group to four carbon atoms results in the appearance of a moderate activity, which weakens as the length of the hydrocarbon chain is increased further to six atoms[45]. The hypotensive activity of these compounds increases with increase of the length of the alkoxy-group from methoxy- to pentoxy, after which it falls. The replacement of piperidine by pyrrolidine in the molecule of compounds (XXa) results in the appearance of both terminal and conductor anaesthesia. Some of them approach dicain as regards their anaesthetic activity and morphine as regards their analgesic activity[73].

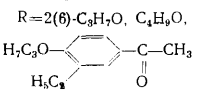
The anti-inflammatory activity of the aminoketones (XX) has been investigated as a function of their capacity to arrest the haemolysis of rat erythrocytes. It has been shown that *in vitro* they all suppress the haemolysis of erythrocytes at a concentration of 10^{-3}–10^{-4} M and, after an increase in the length of the chain of the alkoxy-group, at 10^{-5}–10^{-9} M.[31]

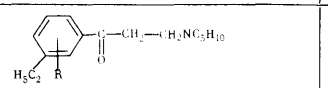


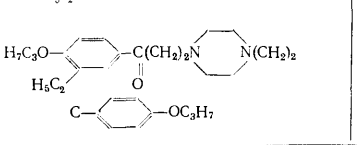


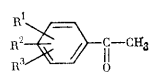


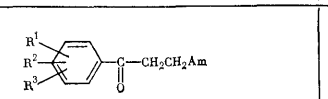


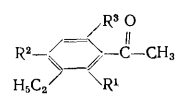


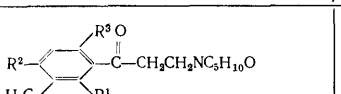












A change in the position of the alkoxy-group, as in compound (XXc, Am = pyrrolidine), and also the replacement of the cyclic amine by a primary amine (methylamine, butylamine) lead to the loss of analgesic activity[75,78]. The replacement of the phenyl group in the α-position by the cyclohexyl group, as in compound (XXb), is not reflected in the anti-inflammatory activity of the compounds, but some of them acquire antipyretic properties[77].

In order to investigate the relation between the chemical structure and biochemical activity, Schrotter and co-workers also synthesised a large group of β-aminoketones (XXIV) (Table 4):[82–87]

Piperidino-derivatives are the most active among the aminoketones (XXIV, R^1 = H, R^2 = 4-alkoxy-, R^3 = C_2H_5) and the intensity of the anaesthesia increases up to $R^2 = n\text{-}C_3H_7O$, remains constant up to $R^2 = n\text{-}C_6H_{13}O$, and then falls[83]. On the other hand, the maximum duration of the activity of the compound has been noted for the *n*-heptoxy-derivative. Compounds with iso-groups are inferior to the *n*-alkoxy-derivatives both as regards the intensity of the anaesthesia and the duration of the activity. It has been noted that, when the methyl or ethyl group is introduced into the 4-position of the piperidine residue, the strength and duration of the activity increase. The replacement of the 4-alkoxy-group in aminoketones (XXIV) by an alkoxy-group

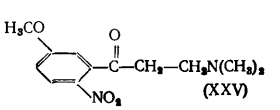


Table 4. Aminomethylation of acetophenones.

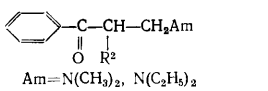
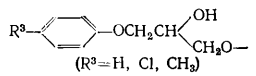
*The yields are given in grams.

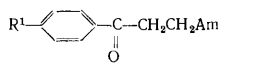
[R^2 = 4-Alko-$(CH_2)_nO$; n = 2, 4] made it possible to obtain substances with the same activity but a greater duration of the latter[84]. Antiparasitic and antibacterial properties have been found in some aminoketones of the (XXIV) series[85,87].

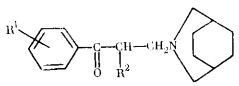
The aminomethylation of substituted acetophenones has also been studied[43,88—116] (Tables 4—6). It has been shown that, when 5-methoxy-2-nitroacetophenone reacts with formaldehyde and dimethylamine hydrochloride in 1-butanol, β-dimethylaminomethyl-5-methoxy-2-nitropropiophenone (XXV) is formed[95,96]:

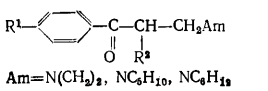
(XXV)

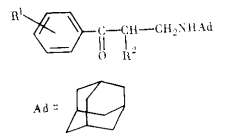


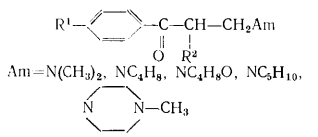


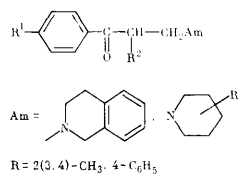












Subsequently, Back established that the aminomethylation of 2-nitro- and 2-ethoxycarbonyl-aminoacetophenones leads to the formation of 2-nitro- and 2-ethoxycarbonylamino-α-dimethylaminomethylacrylophenones (XXVI) in addition to the expected propiophenone derivatives[92,94]:

(XXVI)

The authors explained the formation of compound (XXVI) by the fact that, under the conditions of the Mannich reaction,

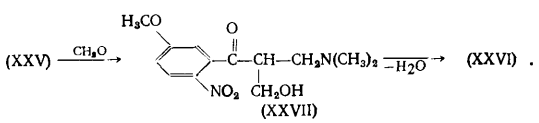


Table 5. Aminomethylation of α-substituted acetophenones.

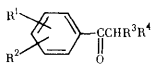
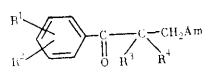
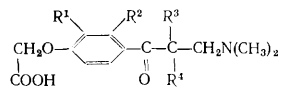
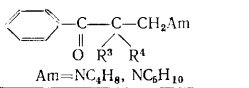
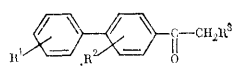
the *C*-hydroxymethyl compound (XXVII) is formed from compound (XXV) and its dehydration leads to compound (XXVI):

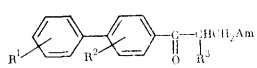


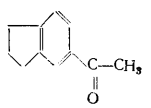


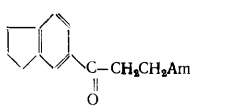




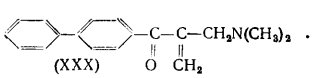








This has been confirmed by both physicochemical analytical methods and by various reactions of compound (XXVI).[92,94] Thus catalytic hydrogenation of compound (XXVI) and acetylation of the reduction product (XXVIII) lead to the formation of 2-acetamido-5-methoxy-α-methyl-β-dimethylaminopropiophenone (XXIX):



The formation of an acrylophenone derivative has been described also by Mann et al.[97] in relation to compound (XXX) as an example:

Table 6. Aminomethylation of substituted acetophenones.

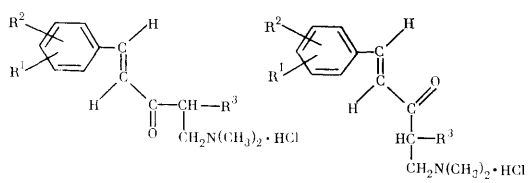
(XXX)

3,4,5-Trisubstituted acetophenones containing nitro-groups in the 3- and 5-positions are aminomethylated with difficulty (with a yield of 8—12%).[98]



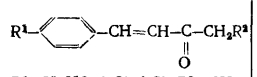
In the case of resacetophenone, the aminomethyl group enters the ring of compound (XXXI):[109]

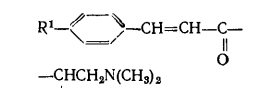
(XXXI)

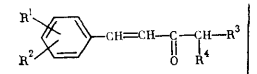
The aminoketones (XXXII) have been obtained by the condensation of substituted styryl ketones, paraformaldehyde, and amine hydrochlorides[26,34,36,60,107,117—128] (Table 7):

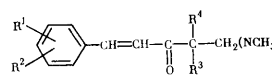
(XXXII)

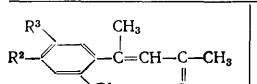
According to infrared spectroscopic data, 4-dimethylaminomethyl-1-phenyl-1-ionen-3-ones (XXXII, $R^3 = C_5H_{11}$) exist in the *S-cis*- and *S-trans*-forms[118]:

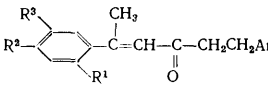


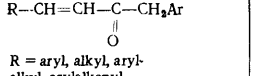


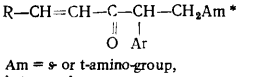


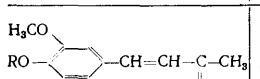


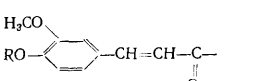


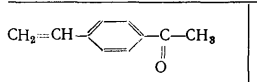


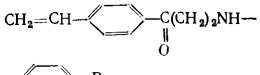












S-trans-(XXXII) *S-cis*-(XXXII)

Compounds (XXXII) possess various biological properties[26,34,36,60,107,120,122,123]. In particular, many hydrochlorides of derivatives of 5-dimethylamino-1-substituted phenylpent-1-en-3-ones [XXXII, R^1 = H or 2(3)-Cl; R^2 = H or 4(6)-Cl; $R^3 = (CH_2)_4CH_3$] exhibit pronounced cytotoxic properties[34,36,122].

Their antimitochondrial properties have been investigated[120,122]. It has been shown that their hydrochlorides manifest a high inhibiting activity, while the methiodides lack these properties. The antimitochondrial properties of the products of the deamination of the aminoketones (XXXII)

have also been studied and it has been shown that the unsaturated ketones are inactive in this respect[120].

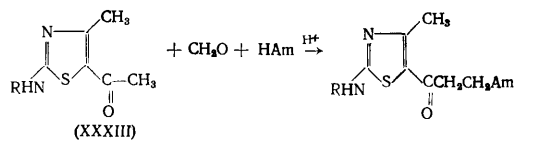


Table 7. Aminomethylation of styryl ketones.

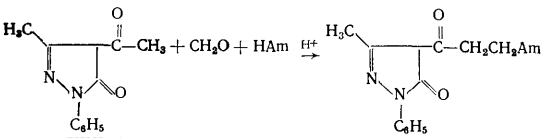
*Possess antimicrobial and antimitotic activity.
**The yields are given in grams.

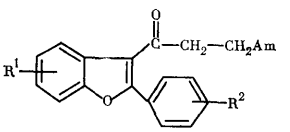
4. Heterocyclic Methyl Ketones



A number of studies have been made on the aminomethylation of heterocyclic methyl ketones[41,101,129—134]. It has been shown[130] that 2-substituted 5-acetyl-4-methylthiazoles (XXXIII) can be aminomethylated in concentrated hydrochloric acid or in a 2:1 acetic acid–dioxan mixture with a yield of 40–90%. The aminomethylation in ethanol, acetic acid, and dimethylformamide was unsuccessful:

(XXXIII)

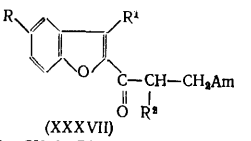
R = H, $CH_3C(=O)$—, $C_6H_5C(=O)$—, m-$NO_2C_6H_4C(=O)$—, $ClCH_2C(=O)$—, Cl_3CH—$C(=O)$—, CH_3CH=CH—; Am = $N(CH_3)_2$, $N(C_2H_5)_2$, $N(iso\text{-}C_3H_7)_2$, NC_4H_8O, NC_5H_{10}



The aminoketones (XXXV) have been obtained in 60% yield by the aminomethylation of 4-acetyl-3-methyl-1-phenyl-2-pyrazolin-5-one (XXXIV) in ethanol in the presence of hydrochloric acid[131]:

(XXXIV) (XXXV)

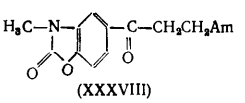
Am = $N(C_2H_5)_2$, $N(C_6H_5)_2$, NC_4H_8O



A method of synthesis of pharmacologically active aminomethyl derivatives of 3-acetylbenzofuran (XXXVI) has been patented[132]:

(XXXVI)

R^1 = H, a halogen, or lower alkyls: R^2 = H, a halogen, lower alkyls, or an alkoxy-group; Am = lower alkylamines, pyrrolidine, morpholine, piperidine, hexamethyleneimine, piperazine, or *N*-methylpiperazine.

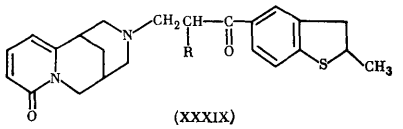


The aminoketones (XXXVII) have been synthesised by the condensation of substituted 2-acetylbenzofurans with formaldehyde and amines[134]:

(XXXVII)

R = Cl, Br, CH_3O; R^1 = H, CH_3; R^2 = H, CH_3, C_2H_5; Am = $N(CH_3)_2$, $N(C_2H_5)_2$, NC_5H_{11}

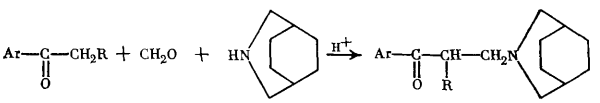
β-Aminoketones of the benzoxazolinone series (XXXVIII), which exhibit an analgesic activity, have been obtained in 60–80% yield[41]:



(XXXVIII)

Am = $N(CH_3)_2$, NC_4H_8O, NC_5H_{10}, 

Aminoketones derived from cytisine (XXXIX), whose cholinolytic activity exceeds that of cytisine itself, have



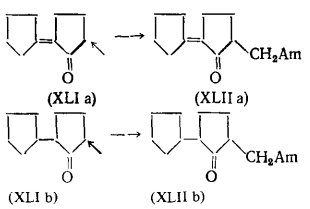
been obtained from substituted acetylthioindanones[133]:

(XXXIX)

R = H, CH_3 .

The aminoketones (XL), obtained by the interaction of substituted acetophenones or propiophenones with paraformaldehyde and the hydrochloride of 3-azabicyclo[3.2.2]-nonane in ethanol with added hydrochloric acid, possess an anticough activity[101]:

(XL)



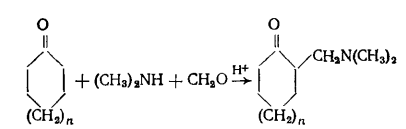
Ar = 3-pyridyl, 2-thienyl, 3-indolyl, or 1-(*N*-methyl-4-piperidinyl)-5-methyl-4-pyrazolyl; R = H or CH_3.

The aminomethylation of certain acetyl derivatives of steroids has been described[135–137].

5. Cyclic Ketones

A large number of publications have been devoted to the aminomethylation of cycloalkanones and their various derivatives[30,56,138–164], on the one hand, and heterocyclic ketones[167–204], on the other. Table 8 lists the substituted cyclopentanones and the corresponding Mannich bases.

Roth and Thassler showed that the aminomethylation of 2-cyclopentylidene and 2-cyclopentyl-cyclopentanones (XLI, a and b) in isopropyl alcohol results in the formation of the aminoketones (XLII, a and b) as the sole products[138]:



(XLI a) (XLII a)

(XLI b) (XLII b)

Am = $N(CH_3)_2$, NC_4H_8, NC_4H_8O, NC_5H_{10}, NHC_6H_{11}, $NHCH_2C_6H_5$.

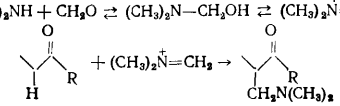


Table 9 lists the cyclohexanone derivatives and their aminomethylation products.

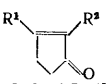
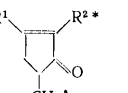
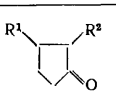
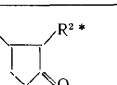
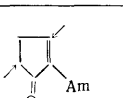
The aminomethylation of cyclohexanone and cyclopentanone involving the direct use of an immonium ion[143,144] generated in the reaction mixture has been studied:

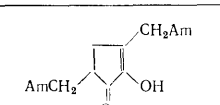


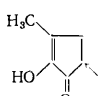


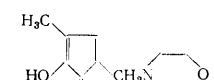


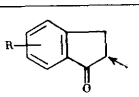


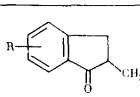






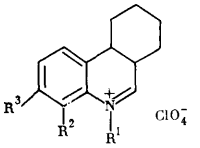






$n = 0, 1$

$$(CH_3)_2NH + CH_2O \rightleftarrows (CH_3)_2N{-}CH_2OH \rightleftarrows (CH_3)_2\overset{+}{N}{=}CH_2 \qquad (1)$$



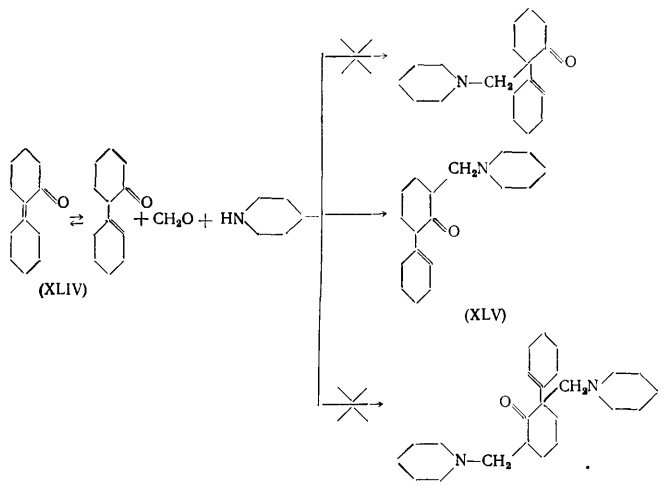
According to the authors, this method has the following advantages: (1) the concentration of the immonium ion is higher than that resulting from equilibrium (1) and the reaction is thus faster; (2) lower temperatures can be used; (3) an aprotic medium can be employed.

Table 8. Aminomethylation of cyclopentenones and cyclopentanones.

Initial ketone	Aminomethylation product	Yield, %	Refs.
 R^1=CH_3, C_6H_5, 4-FC_6H_4, $C_6H_5CH_2$, $CH_2CO_2C_2H_5$, *N,N*-diethylacetamido, acetylmorpholino-	 Am=$N(C_2H_5)_2$, NC_4H_8O, NC_4H_8, HNC_3H_7, HNC_6H_5, 	**	[30]
 R^1=CH_3, C_6H_5; R^2= alkyl (C_1—C_8)	 Am=$N(CH_3)_2$, HNC_4H_9, NC_4H_8O, NC_5H_{10}	**	[30]
	 Am=NC_4H_8, NC_4H_8O, NC_5H_{10}	61—73	[139]
		34.0	[140]
 R = CH_3, C_2H_5, iso-C_3H_7, Cl, Br, CH_3O	 Am=$N(CH_3)_2$, NC_4H_8, NC_5H_{10}, NC_4H_8O	60—75	[151]

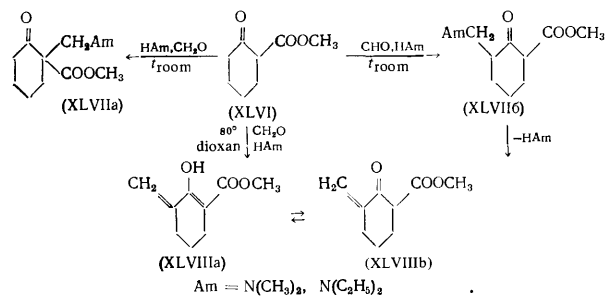
*Exhibits analgesic and anti-inflammatory activity.
**The yields are given in grams.

The condensation of cyclohexanone with paraformaldehyde and secondary amines in the presence of an inorganic acid in 1-butanol leads to quaternary substituted tetrahydrophenanthridinium salts (XLIII):[145,146]



(XLIII)

R^1 = CH_3, C_2H_5, C_6H_5, $C_6H_5CH_2$; R^2 = R^3 = H; R^2 + R^3 = C_6H_5 .

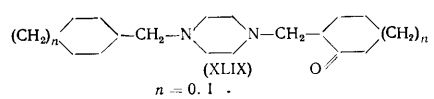


Although the aminomethylation of the 2-(cyclohex-1-enyl)-cyclohexanone (XLIV) molecule is possible in both the 2- and 6-position, the authors[147] showed that in benzene the only

product is the aminoketone (XLV):

(XLIV) (XLV)

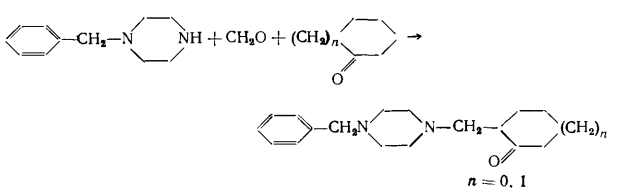
Depending on the temperature and the duration of heating, the aminomethylation of 2-methoxycarbonylcyclohexanone (XLVI) proceeds via two different pathways[148]:



(XLVIIa) (XLVI) (XLVIIб) (XLVIIIa) (XLVIIIb)

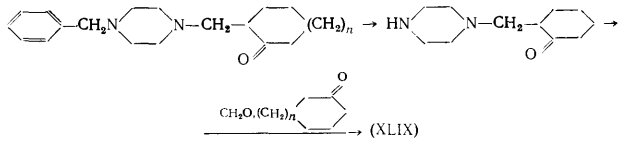
Am = $N(CH_3)_2$, $N(C_2H_5)_2$

The above scheme shows that, at room temperature in dioxan, a mixture of compounds (XLVIIa) and (XLVIIb) in proportions of 55 : 45 is formed, while at 80 °C in dioxan compound (XLVIIIa), which is the enolic form of the deamination product of the Mannich base (XLVIIIb), is produced.



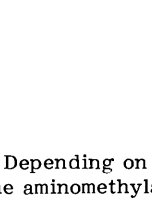
The synthesis of symmetrical Mannich bisbases (XLIX) has been studied[149]:

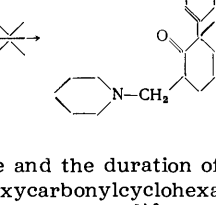
(XLIX)

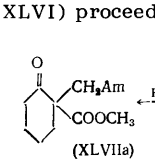


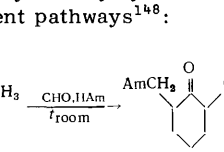
$n = 0, 1$.

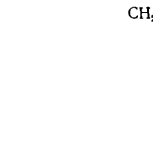
Data have also been published on the synthesis of asymmetric Mannich bisbases. Having first protected one of the nitrogen atoms in the piperazine molecule by a benzyl group, the authors obtained a monosubstituted product:

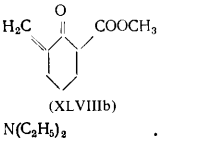


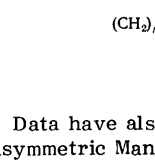


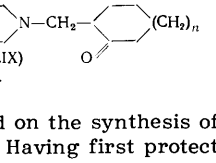






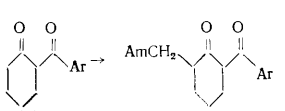






$n = 0, 1$

Having then removed the protecting group, the product was reintroduced into the Mannich reaction and the expected bisbase (XLIX) was obtained:



(XLIX)

Table 9. Aminomethylation of cyclohexanone and its derivatives.

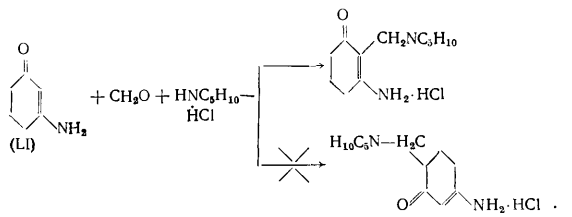
*The yields are given in grams.

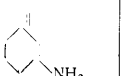
2-Aroylcyclohexan-1-ones (L) react under the conditions of the Mannich reaction with certain amines to form 6-aminomethyl-2-aroylcyclohexan-1-ones:[150]

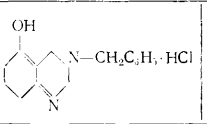
(L)

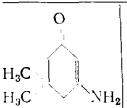
Ar = C_6H_5, $C_6H_4OCH_3$-p, $C_6H_2(OCH_3)_3$-3, 4, 5; Am = NC_5H_{10}, $N(CH_3)_2$.

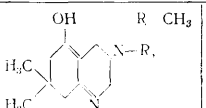
The aminomethylation of 3-aminocyclohex-2-en-1-one (LI) by piperidine hydrochloride and formaldehyde proceeds in accordance with the scheme[153]

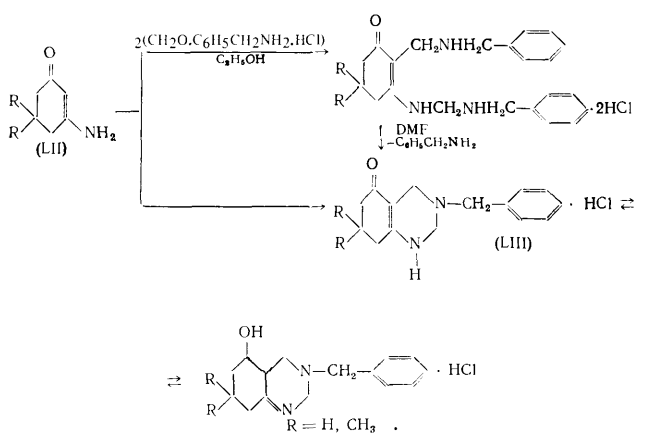












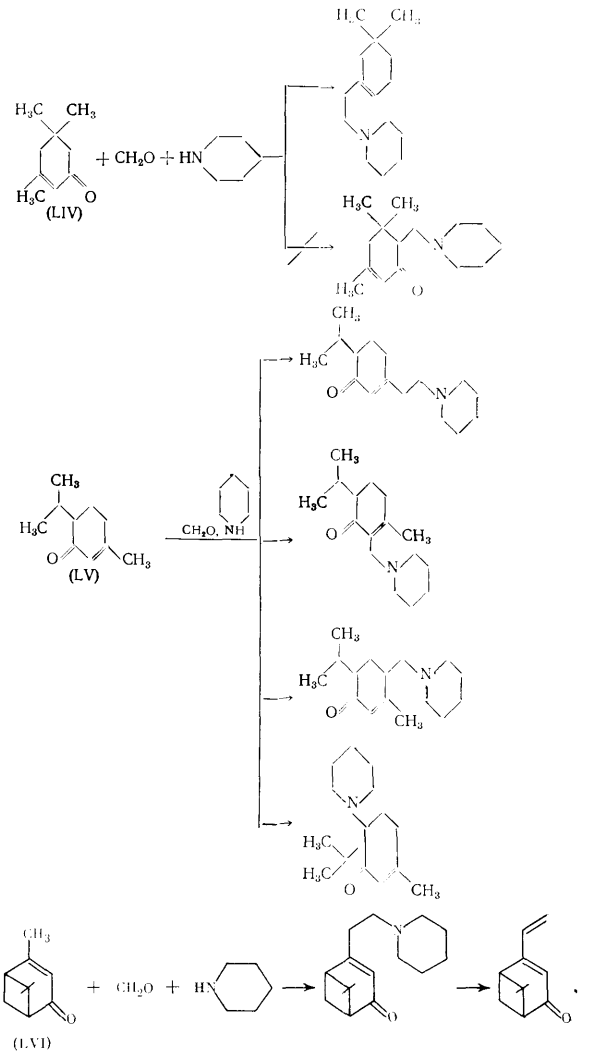


Table 10. Aminomethylation of substituted cyclohex-2-en-1-ones.

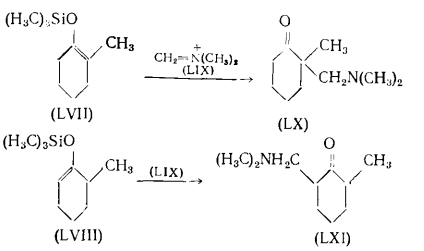
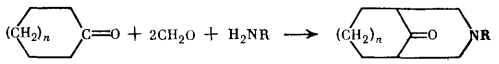
Enamine	Amine hydrochloride	Quinazoline derivatives	Yield, %
	$H_2NCH_2C_6H_5$		55,0
	H_2N-CH_3		42,0
		ditto, R = 	46,0
	$H_2N-CH_2-C_6H_5$	» , $R = CH_2C_6H_5$	64,0

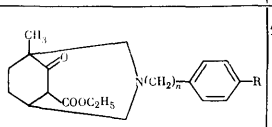


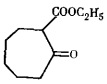
It has been shown that the product of the reaction of substituted cyclohex-2-enones (LII) with benzylamine hydrochloride (and other primary amines) and formaldehyde is a quinazoline derivative (LIII) (Table 10):[153]

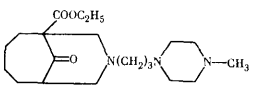
The formation of vinylogues on aminomethylation of isophorone (LIV), piperitone (LV), and 2-pinen-4-one (LVI):

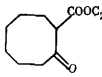


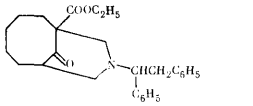
The regioselectivity of the reactions of the trimethylsilyl ethers of the enolic forms of cyclohexenone (LVII) and (LVIII) with the carbonium-immonium ion $[CH_2=\overset{+}{N}(CH_3)_2]$ (LIX) to form the Mannich bases (LX) and (LXI) in 65 and 78% yields respectively has been investigated and the authors established that compound (LXI) consists of a 2 : 1 mixture of stereoisomers[157].

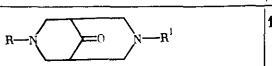






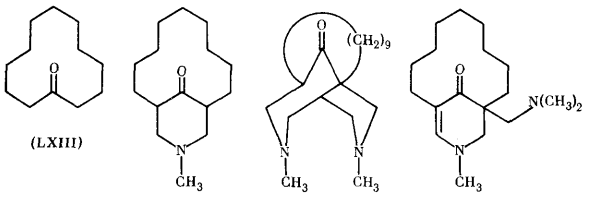






The condensation of substituted cyclic ketones with two moles of paraformaldehyde and one mole of a primary amine in acetic acid[158–160,162] or methanol[161] leads to the bicyclic

compound (LXII) (Table 11).



(LXII)

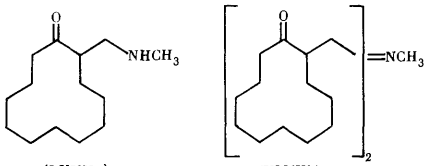


Table 11. The formation of bispidines on aminomethylation.

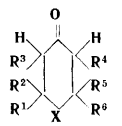
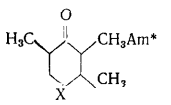
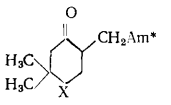
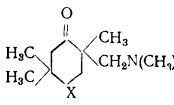
Interesting data have been published on the aminomethylation of the cyclododecanone (LXIII).[163] Refluxing with formaldehyde and methylamine for two days resulting in the formation of a mixture of substances whose separation led to the isolation of the azabicyclopentadecanone (LXIV), the bispyridinediazatricyclopentadecanone (LXV), and the dihydropyridin-4-one (LXVI). On heating for less than two days, the products are the aminoketones (LXVIIa) and (LXVIIb):

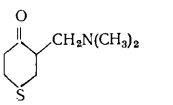


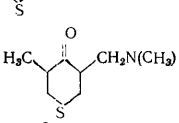
(LXIII) (LXIV) (LXV) (LXVI)

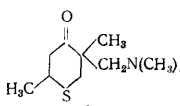


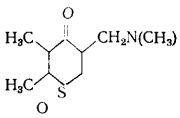








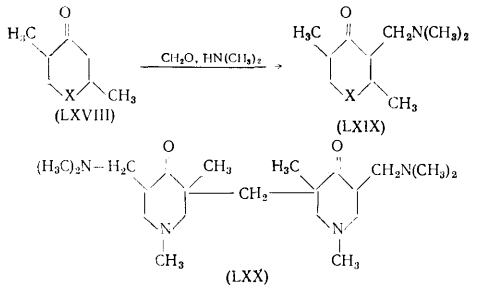




(LXVIIa) (XLVIIb)

Golovin and co-workers carried out a major study of the aminomethylation of saturated cyclic γ-ketones by formaldehyde and various amines as a function of the number and positions of the alkyl substituents relative to the carbonyl group and also the character of the heteroatom X in the ring (X = O, S, or N) [167-169,172-178] (Table 12).

Table 12. Aminomethylation of γ-ketones.



R^1	R^2	R^3	R^4	R^5	R^6	X	Aminomethylation product	Yield, %	Refs.

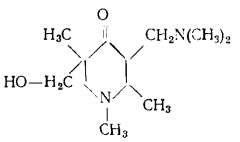
H	H	H	CH_3	H	CH_3	S		10—21	[177]

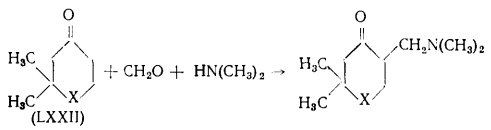
*Am = $N(CH_3)_2$, $N(C_2H_5)_2$, $N(C_3H_7)_2$, $N(C_4H_9)_2$, NC_4H_8, NC_4H_8O, NC_5H_{10}, NC_6H_{12}.

In the aminomethylation of 1,2,5-trimethylpiperidin-4-one (LXVIII, X = NCH_3), bis(1,2,5-trimethyl-3-dimethylaminomethyl-4-oxopiperidinyl)methane (LXX) was isolated together



with the main reaction product (LXIX):[167-169]

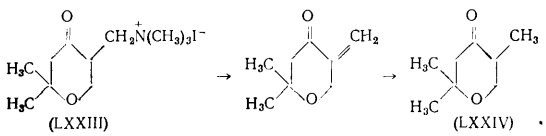
(LXVIII) (LXIX) (LXX)



X = O, S ,

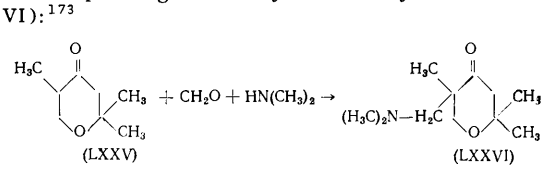
When the above reaction is carried out with a twofold excess of paraformaldehyde, 3-dimethylaminomethyl-5-hydroxymethyl-1,2,5-trimethyl-4-piperidinone (LXXI) is mainly formed:

(LXXI) .



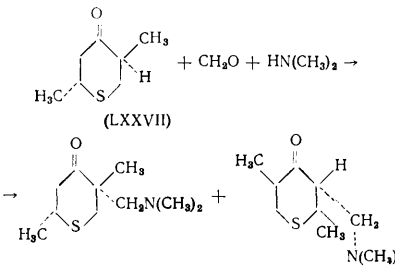
In order to elucidate the influence of two methyl groups in the β-position relative to the carbonyl group on the regioselectivity of the Mannich reaction, it was shown later[169] that, regardless of the nature of the entering aminomethyl group, the aminomethylation of compound (LXXII) proceeds with participation of only the methylene group located on the opposite side of the heterocycle relative to the methyl substituents:

(LXXII)



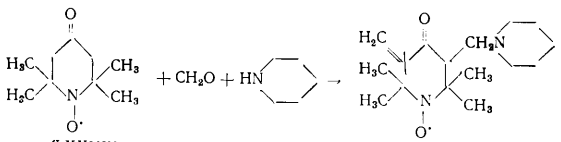
X = O, S, NCH_3 ,

Additional proof of the structure of the Mannich bases has been obtained[170] by exhaustive Hofmann methylation. For example, the methiodide of the aminoketone (LXXIII) has been converted by reductive deamination into the known 2,2,5-trimethyl-4-oxotetrahydropyran (LXXIV):[171]



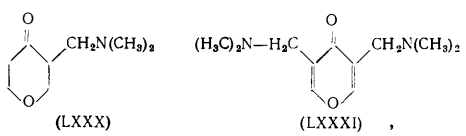
(LXXIII) (LXXIV) .

The study of the structural specificity of the aminomethylation of 2,2,5-trimethyl-4-oxotetrahydropyran (LXXV) showed that the reaction is directed exclusively to the tertiary carbon atom adjoining the carbonyl group and leads to the formation of the corresponding 5-dimethylaminomethyl derivatives (LXXVI):[173]



(LXXV) (LXXVI) .

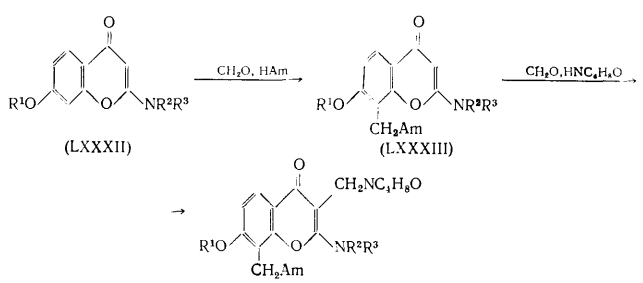
The study of the products of the aminomethylation of *trans*-2e, 5e-dimethyl- and *cis*-3e, 5e-dimethyl-tetrahydro-1-thiopyran-4-ones (LXXVII) showed that only monoaminoketones with an axial orientation of the aminomethyl group are formed. The absence of bisaminomethyl bases from the reaction products in this instance can be explained by the impossibility of the entry of a second axial aminomethyl group next to the carbonyl group as a consequence of the *meta*-axial interaction[176]. It has been shown that the orientation of the aminomethylation depends exclusively on the structure of the initial ketone, namely on the number and positions of the alkyl substituents in the ring:



(LXXVII) .

It is of interest that the aminomethylation of 2,2,6,6-tetramethyl-4-oxopiperidine-1-oxide (LXXVIII) results in the formation of compound (LXXIX) in 94% yield[179,180]:

(LXXVIII) (LXXIX) ,

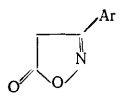


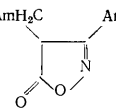
As early as 1952, Wiley[181] described the condensation of 4-pyrone with dimethylamine hydrochloride and formaldehyde in ethanol; the reaction product was identified as the monoaminoketone (LXXX). It was shown subsequently that both mono- and bis-dimethylaminomethylpyrones (LXXX) and (LXXXI) are formed[182]:

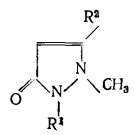
(LXXX) (LXXXI) ,

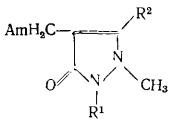
Table 13 lists the products of the aminomethylation of isoxazoles[183,184], pyrazoles[185], uracils[186], coumaranones[187], and other heterocyclic ketones[188-192]. A number of studies have been made on the aminomethylation of chromans, isochromans, and pyrans[193-204].

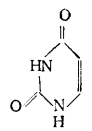
It has been shown[195] that the aminomethylation of chromans takes place in the 3-position. However, according to other data[196], in the case of 2-dialkyl-amino-7-hydroxychroman (LXXXII, R = H) substitution takes place in the 8-position with formation of compound (LXXXIII) and only the subsequent aminomethylation is in the 3-position with formation of compound (LXXXIV):

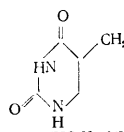


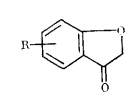


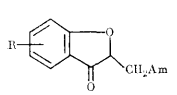


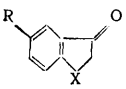


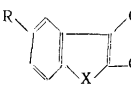


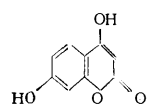


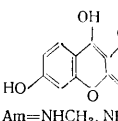


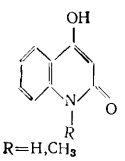


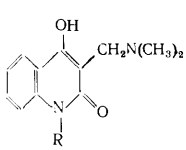


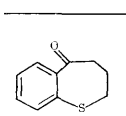


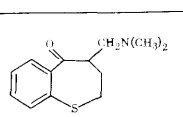


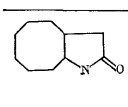


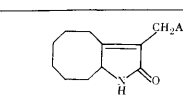












(LXXXII) (LXXXIII) (LXXXIV)

R^1 = H; Am = NC_4H_8O, NC_5H_{10},  NR^2R^3 = $N(CH_3)_2$, $N(C_2H_5)_2$, NC_5H_{10}, $N(CH_3)C_2H_5$, $N(C_2H_5)C_6H_5$;

R^1 = CH_3, Am = NC_4H_8O; NR^2R^3 = $N(C_2H_5)_2$, NC_4H_8, NC_5H_{10} .

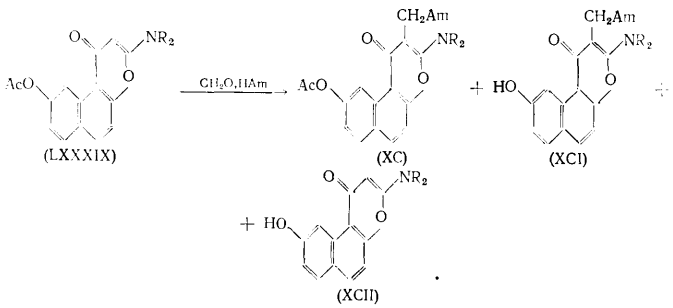
 NR_2=$N(CH_3)_2$, $N(C_2H_5)_2$, $N(CH_2)C_2H_5$	 Am=NC_4H_8O,NC_5H_{10},	21—54	neuro-tropic	[202]
 X=O, CH_2		70;88	—	[204]

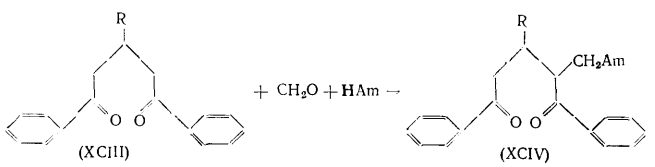
The aminomethylation of 3-dialkylamino-1-oxo-1*H*-napntho-[2,1-*b*]pyrans (LXXXVI) in acetic acid leads to 2-dialkyl-aminomethylamino-1-oxo-1*H*-naphtho[2,1-*b*]pyrans (LXXXVII), which exhibit an anticonvulsant activity[198,199] (Table 14).



(LXXXVI) (LXXXVII) (LXXXVIII)

NR_2 = $N(CH_3)_2$, $N(C_2H_5)_2$, N (iso-C_3H_7)$_2$, NC_4H_8, NC_5H_{10}, $N(CH_2CH{=}CH_2)_2$, $N(CH_3)CH_2C_6H_5$, $N(C_2H_5)CH_2C_6H_5$;
Am = NC_4H_8O, NC_5H_{10} .

In the presence of an excess of acetic acid, 3-dialkylamino-2-{1-hydroxy-3-oxo-3*H*-naphtho[2,1-*b*]pyran-2-ylmethyl}-1-oxo-1*H*-naphtho[2,1-*b*]pyran (LXXXVIII) is formed as a side product. Its structure has been demonstrated by specific synthesis:



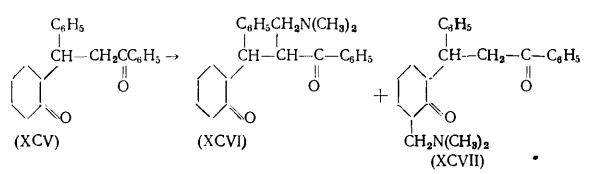
The aminomethylation of compound (LXXXIX) yielded a mixture of the three compounds (XC), (XCI), and (XCII):

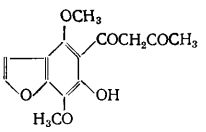
6. Diketones

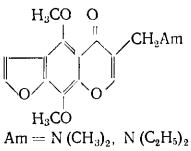
Comparatively few studies have been devoted to the aminomethylation of diketones[205–221] (Table 15).

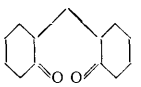
Thus Tilichenko and co-workers showed that the aminomethylation of the diketones (XCIII) yields only the monoaminomethyl derivatives (XCIV):[205–212]

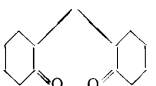
The condensation of 1-(2-oxocyclohexyl)-1,3-diphenyl-3-propanone (XCV) with formaldehyde and dimethylamine hydrochloride results in the formation of a mixture of 2-dimethylaminomethyl-1-(2-oxocyclohexyl)-1,3-diphenyl-3-propanone (XCVI) and 1-(3-dimethylaminomethyl-2-oxocyclohexyl)-1,3-diphenyl-3-propanone (XCVII):[209]

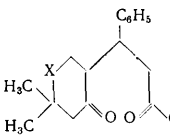


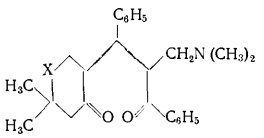


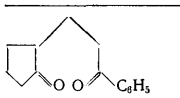


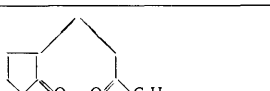


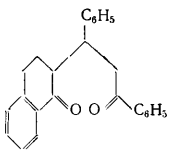


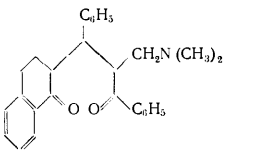


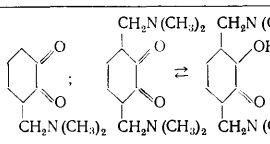












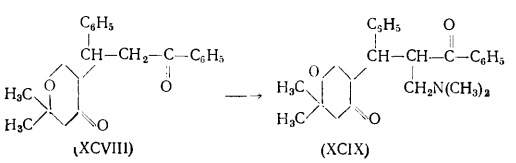


Table 15. The Mannich reaction involving diketones.

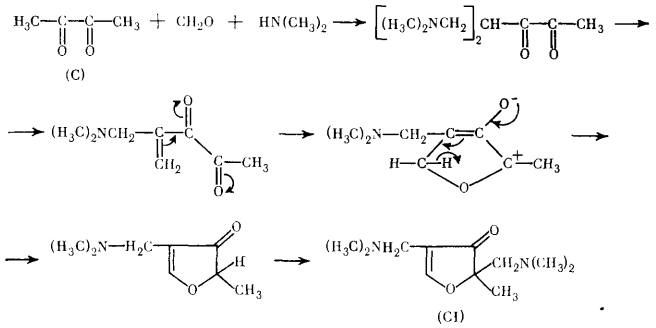
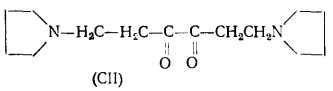
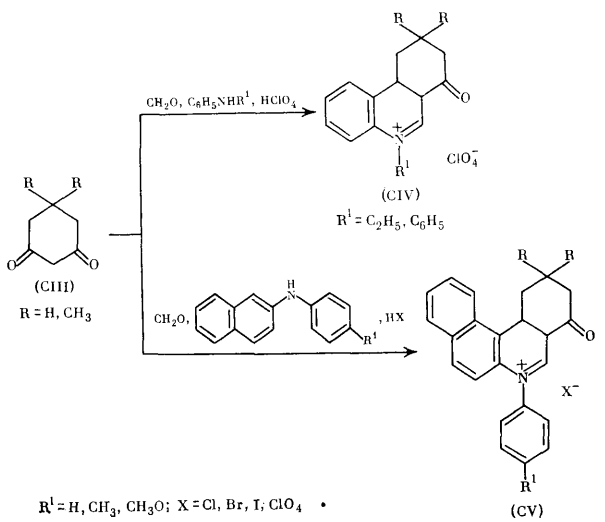


Initial ketone	Aminomethylation product	Yield, %	Refs.
	 Am = N $(CH_3)_2$, N $(C_2H_5)_2$, NC_5H_{10}		[219]
	 Am = N $(CH_3)_2$, N $(C_2H_5)_2$	48—100	[212]
 X = O, S, CH_2		70—83	[210, 211]
	 Am = N $(CH_3)_2$, NC_4H_8O	50; 70	[211]
		59	[211]
		24	[213]

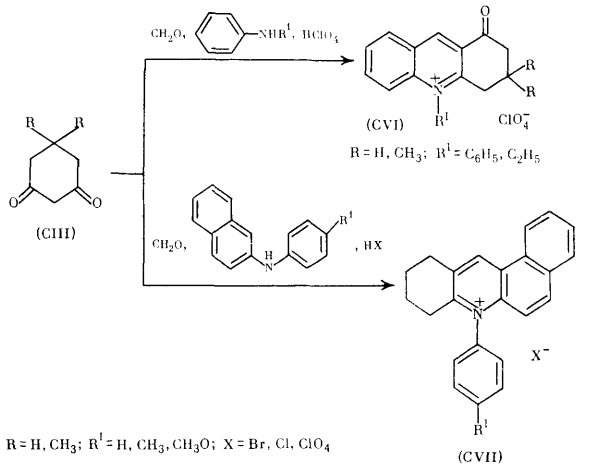
On the other hand, the aminomethylation of 1-(α,α-dimethyltetrahydro-γ-pyron-β′-yl)-1,3-diphenyl-3-propanone (XCVIII) in the ring is not observed; only 2-dimethylaminomethyl-1-(α,α-dimethyltetrahydro-γ-pyron-β′-yl)-1,3-diphenyl-3-propanone (XCIV) is produced[210,212]:



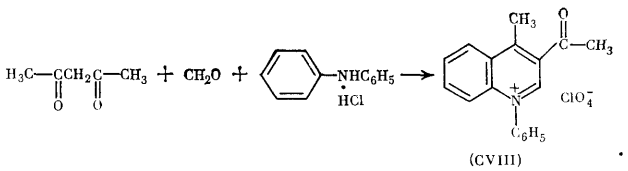
When the Mannich reaction is carried out with butane-2,3-dione (C), the character of the product obtained depends on the nature of the amino-component[213]. Thus the product



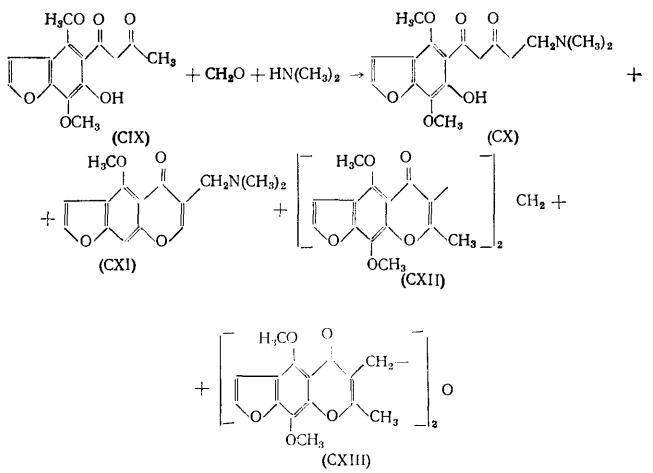
of the condensation of butane-2,3-dione with paraformaldehyde and dimethylamine is 2-methyl-2,4-bis(dimethylaminomethyl)-3-furanone (CI) in 18% yield, whose formation can be represented as follows:



When compound (C) reacts with pyrrolidine, the diaminoketone (CII) is formed in 44% yield:

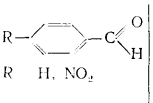


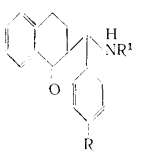
Secondary aromatic amines of the benzene series cyclise with paraformaldehyde and dimedone (CIII, R = CH_3) in the presence of perchloric acid to form the *N*-substituted quaternary 9,9-dimethyl-7-oxo-7,8,9,10-tetrahydrophenanthridinium salts (CIV). Phenyl(*p*-X-phenyl)-2-naphthylamines cyclise in the presence of hydrochloric, hydrobromic, and perchloric acids to form *N*-aryl-substituted 2,2-dimethyl-4-oxo-1,2,3,4-tetrahydrobenzo[*a*]phenanthridinium salts (CV):

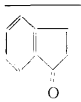


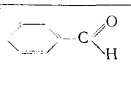
The condensation of diphenylamine and *N*-ethylaniline with formaldehyde and cyclic β-diketones (CIII) leads to the formation of *N*-substituted 1-oxo-1,2,3,4-tetrahydroacridinium salts (CVI). The authors' more detailed studies of the products of the reaction with 2-arylaminonaphthalenes showed that the cyclisation involves the most reactive α-position of the naphthalene ring, which leads to the formation of quaternary 11-oxo-8,9,10,11-tetrahydrobenzo[*a*]acridinium salts (CVII):[215]

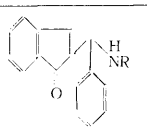
Acetylacetone reacts with formaldehyde and diphenylamine in the presence of perchloric acid to form 3-acetyl-1-phenyllepidinium perchlorate (CVIII):[216]

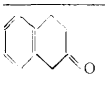


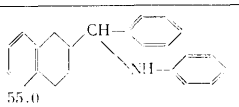


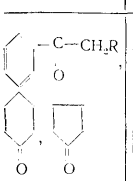


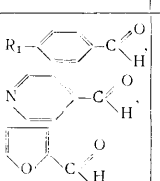


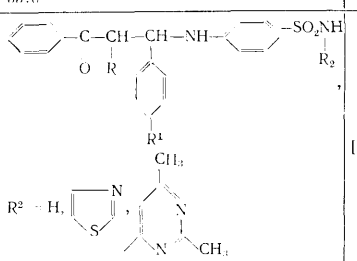


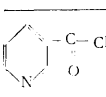


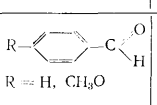


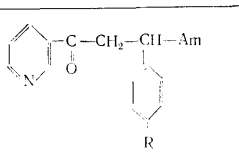


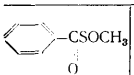


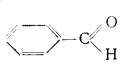


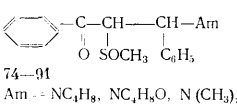






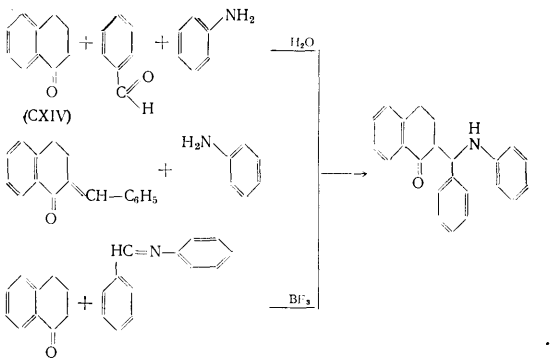






The aminomethylation of ω-acetylkhellinone (CIX) leads to the formation of the cyclisation product (CXI) and the dimerisation products (CXII) and (CXIII) in addition to the main product (CX):[217–219]

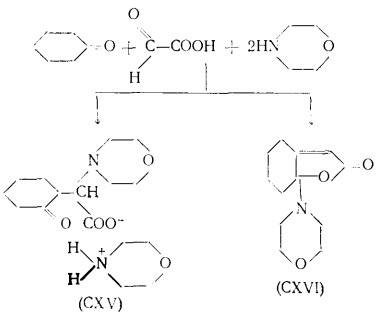
III. THE MANNICH REACTIONS WITH ALDEHYDES



A number of studies have been devoted to the aminomethylation of ketones by various aldehydes[111,166,222–226] (Table 16).

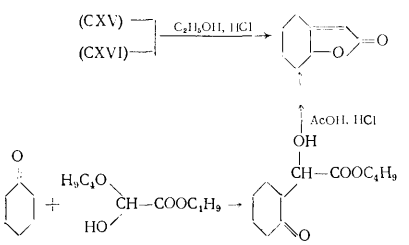
Table 16. The Mannich reaction involving various aldehydes.

Initial ketone	Initial aldehyde	Aminomethylation product [yield, %]	Refs.
	 R = H, NO_2	 52–100* R^1 = C_6H_5, $C_6H_5OCH_2$-*p*	[222]
		 93, 97* R = C_6H_5, $C_6H_4OCH_3$-*n*	[222]
	ditto	 55.0	[166]
 R = H, CH_3	 R^1 = H, CH_3O, NO_2	 R^2 = H, 31–94	[111]
	 R = H, CH_3O	 20–100 Am = NHC_3H_5, NHC_5H_{11}, NC_5H_{10}, NC_4H_8O, $NHCH_2C_6H_5$, $NH(CH_2)_2C_6H_5$	[223]
		 74–91 Am = NC_4H_8, NC_4H_8O, $N(CH_3)_2$	[224]



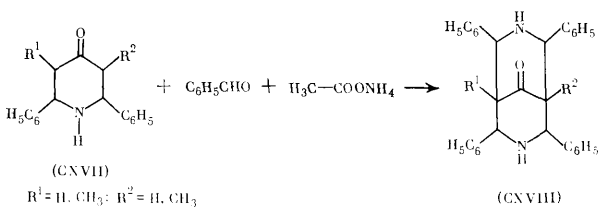
*The reaction was carried out in the presence of a catalyst (BF_3).

In particular, when the α-tetralone (CXIV) is condensed with benzaldehyde and amines, substitution takes place in the 2-position, which has been demonstrated by specific synthesis[218]:



(CXIV)

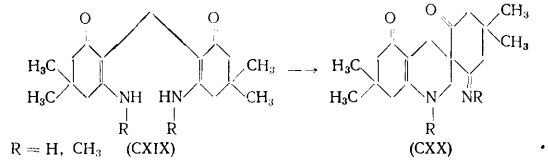
On the other hand, the condensation of cyclohexanone, morpholine, and glyoxalic aldehyde results in the formation of a mixture of products (CXV) and (CXVI):[214]



(CXV) (CXVI)

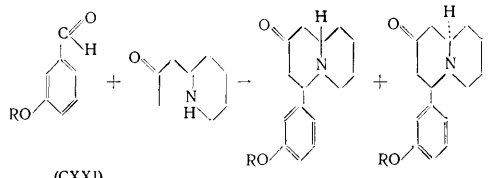
The formation of compounds (CXV) and (CXVI) has been demonstrated as follows:

When benzaldehyde is used in the Mannich reaction instead of formaldehyde, the substituted piperidinones (CXVII) are converted into aza- and diaza-bicyclo[3.3.1]nonan-9-ones (CXVIII):[226]



(CXVII) R^1 = H, CH_3; R^2 = H, CH_3 (CXVIII)

It has been shown[226] that compound (CXVII, $R^1 = R^2 = CH_3$) does not form a bicyclic product despite the presence of two axial α-hydrogen atoms. Steric hindrance generated by the tertiary carbon atoms C(3) and C(5) operates in this instance.



Not three but only two components, one of which plays the role of both the amino- and the CH-acid component, can enter into the Mannich reaction. Similar condensations,

i.e. intramolecular Mannich reactions, have been investigated in other studies[227–229]. In particular, it has been shown that methylenebisenaminoketones (CXIX) condense with formaldehyde to form the spiro-compounds (CXX):[227]

R = H, CH_3 (CXIX) (CXX)

The condensation of isopelletierine (CXXXI) with 3-methoxybenzaldehyde in an aqueous medium leads to the formation of *trans*- and *cis*-quinolizidines (CXXII) and (CXXIII) in proportions of 1:6, while the reaction with 3-hydroxybenzaldehyde leads almost exclusively to *trans*-quinolizidine (CXXIV).[229] On the other hand, in methanol the reaction proceeds with formation of compounds (CXXII) and (CXXIII) in proportions of 5:1. It has been shown that the interaction of compound (CXXI) with an arylaldehyde in an alkaline medium leads to the formation of *cis*-4-aryl-quinolizidin-2-one, which then isomerises to the corresponding *trans*-form:

(CXXI) (CXXII), R = CH_3 (CXXIII)
R = H, CH_3 (CXXIV), R = H

The data presented in this review on the synthesis of β-aminoketones show that more detailed studies of the Mannich reaction would be useful. This is due to the extensive possibilities for its application in organic synthesis and in particular in the specific synthesis of compounds with a potential biological activity.

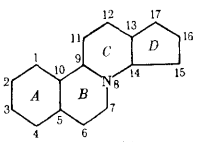
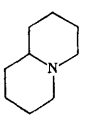
Total Synthesis of 8-Azasteroids

F.A.Lakhvich, L.G.Lis, and A.A.Akhrem



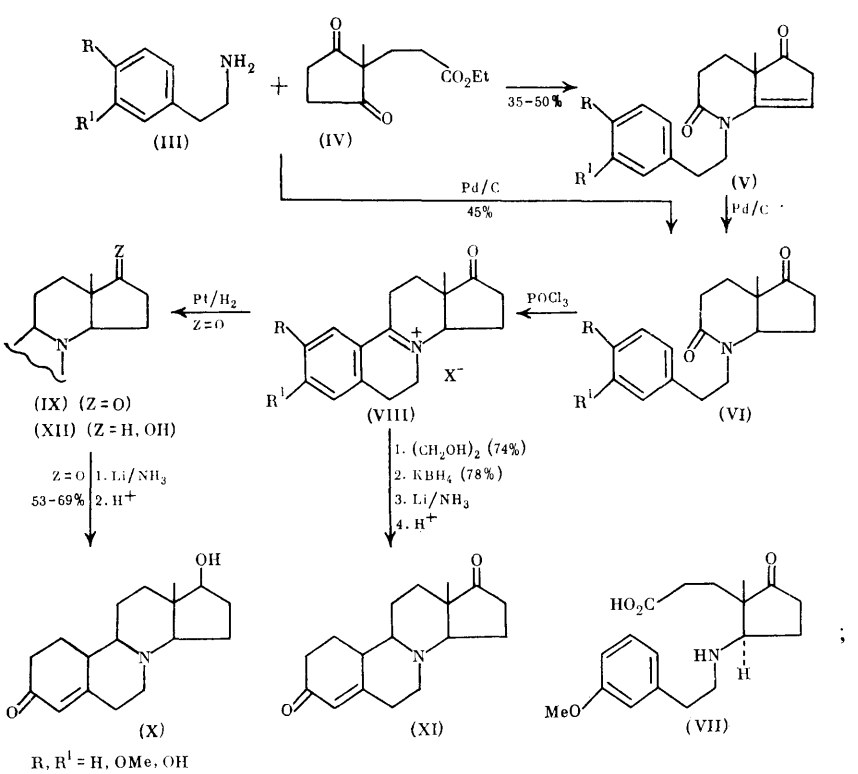
Studies on the total synthesis of 8-azasteroids from the start of investigations in this field (1963) up to 1983 are examined. Earlier studies on the synthesis of compounds formally containing the 8-azasteroid skeleton and those on the synthesis of 8-azasteroids with an additional heteroatom are also analysed. Data are presented on the stereochemistry and biological activity of these compounds.
The bibliography includes 148 references.



CONTENTS

I. Introduction 582
II. Compounds with one heteroatom 583
III. Compounds with two and more aromatic rings 590
IV. Compounds with an additional heteroatom 594
V. Biological activity of 8-azasteroids 601

I. INTRODUCTION



8-Azasteroids include compounds with a partly or fully hydrogenated cyclopentanophenanthrene skeleton (I) in which the carbon atom in the 8-position has been replaced by nitrogen:

(I)

(II)

Compounds of this type have not been found in nature and all the known derivatives of this class are synthetic products. The development of studies on the synthesis of 8-azasteroids is due to a number of factors. It was postulated that the introduction of a heteroatom, entailing significant changes in the geometry of the molecule, would make it possible to obtain new hormonal preparations. However, in general this hypothesis was not confirmed and the compounds obtained possessed only a weak hormonal activity or lacked it altogether and the main efforts of investigators were then directed to the search, among compounds of this series, for those possessing a biological activity resembling that of steroids in

Scheme 1

the absence of hormonal activity. This would make it possible to replace in clinical practice many steroid preparations whose application is complicated by their hormonal activity. Significant advances have been made on these lines. This stage of the development of the chemistry of heterosteroids is therefore characterised by the abandonment of the synthesis of structurally closest heteroanalogues of natural steroids and an increase of the number of studies on the synthesis of 8-azasteroids with an additional heteroatom, additional rings, and other derivatives with substituents and stereochemistry unusual for natural steroids.

On the other hand, 8-azasteroids can be regarded as derivatives of the heterocyclic compound quinolizidine (II), whose fragment is incorporated in the main structural unit in many structural compounds. The structural similarity of formula (I) to heterocycles of the quinolizidine series makes it possible to employ earlier data on both the synthesis and stereochemistry of the latter in studies on 8-azasteroids. On the other hand, certain investigations of the synthesis of heterocyclic systems, formally leading to the formation of the 8-azasteroid skeleton, did not deal with the latter as such and have therefore escaped the notice of investigators. Only isolated studies on 8-azasteroids have been briefly considered in the existing reviews on heterocyclic steroids[1-4].

This review is the first attempt at a survey of studies devoted to the direct synthesis, stereochemistry, and biological activity of 8-azasteroid compounds. It presents data both on the synthesis of close 8-aza-analogues of natural steroids (Section II) and on the formal construction of the 8-azasteroid skeleton, including derivatives with two and more aromatic rings (Section III) or with an additional heteroatom (Section IV).

II. COMPOUNDS WITH ONE HETEROATOM

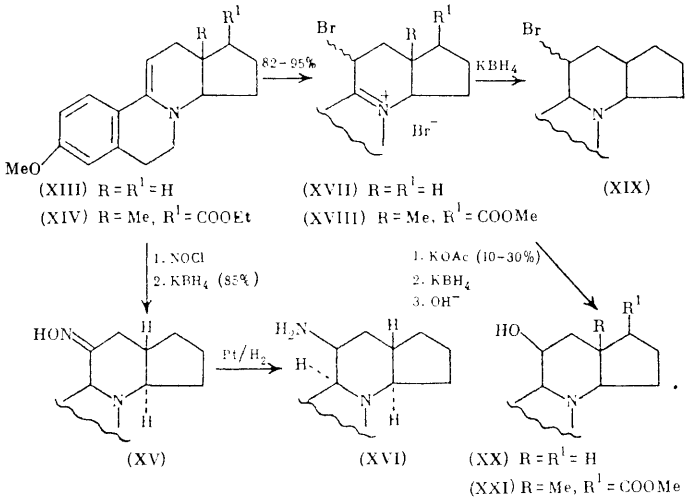
The first studies on the total synthesis of 8-azasteroids were published in 1963. Meltzer's group was able to obtain *dl*-8-azaoestrone and its stereoisomers[5] (Scheme 1). A key failure of this scheme is the condensation of β-phenylethylamines (III) with a diketone (IV), which leads to the unsaturated lactam (V). Catalytic hydrogenation of the latter takes place sterospecifically, giving rise to a high yield of the lactam (VI) with a *cis*-C/D-junction. The same product has been obtained in a single stage by the reductive condensation of the amine (III) and the diketoester (IV). The aminoacid (VII) was obtained as a side product of the condensation and was converted at the melting point into the *trans*-C/D-lactam (VI). The Bischler–Napieralski cyclisation of both isomeric lactams made it possible to obtain the quaternary salts (VIII), which have been isolated as the corresponding *cis*- and *trans*-perchlorates. Catalytic hydrogenation of the *cis*-perchlorate leads to a mixture of the *syn*- and *anti*-H(9)/CH_3(13)-isomeric bases (IX) with a *cis*-C/D-junction. Under the same conditions, the *trans*-perchlorate gives rise to the *trans*-C/D-isomer (IX) with the *anti*-orientation of H(9) and CH_3(13).

Treatment of each isomer of the 3-methoxy-derivative (IX) with 48% HBr leads to the corresponding stereoisomers of 8-azaoestrone, which have been isolated in the form of the hydrobromides. Among the compounds obtained the *anti, trans, trans*-isomer† is *dl*-8-azaoestrone. The configurational assignments were based on the study of molecular models, infrared spectra, rates of oxidation, and subsequently the study of ^{1}H NMR spectra[6]. X-Ray diffraction data for the hydrobromide of *dl*-8-azaoestrone confirmed the validity of the assignments for each isomer[7]. Detailed studies of the stereochemistry of the compounds obtained by ^{1}H NMR[6] led the authors to an erroneous alteration of the assignments for the *cis*-C/D-isomers, but subsequently[8], after the synthesis of the fourth isomer, these assignments were corrected. In particular, it was found that the Bhacca–Williams correlations[9], which established the position of the angular substituent from the change of its chemical shift on passing from chloroform to benzene, are inapplicable to the 8-azasteroid series.

In the synthesis of the isomer with the *trans*-C/D-junction[6], the lactam (V) was reduced with potassium tetrahydroborate and subsequent catalytic hydrogenation to form the saturated 17β-alcohol which gives rise to the *trans*-C/D-lactam (VI) as a result of the Jones oxidation in 27% yield relative to the initial diketoester (IV).

The Birch reduction of the methyl ether of 8-azaoestrone (IX) (*trans*-C/D) followed by acid hydrolysis yielded compounds of the 8-aza-19-nortestosterone (X) series. 8-Aza-19-norandrostenedione (XI) was obtained analogously from the quaternary salt (VIII). In compounds (XI) and (X) the β-orientation was attributed to the hydrogen at C(10) on the basis of the known fact that acid treatment of the Birch reduction products results in the formation of more stable isomers having this configuration.

The reduction of each of the three stereoisomers of 8-azaoestrone with lithium tetrahydroaluminate proceeds stereospecifically to form the corresponding isomeric 8-azaoestradiols (XII). The α-orientation has been attributed to the 17-hydroxy-group in the compounds obtained from the *cis*-C/D-isomers and the β-orientation was attributed to the corresponding group in the compounds obtained from the *trans*-C/D-isomer, and the structure of the latter was confirmed by X-ray diffraction[10].



The scheme for the total synthesis of 8-azaoestrone examined above was also used to synthesise 17-deoxy-compounds[11].

In the course of further studies on the modification of 8-azasteroids, a method was developed for the introduction of the 11-hydroxy- and 11-amino-groups[12] (Scheme 2). When the tetracyclic enamine (XIII) is treated with nitrosyl chloride, the 11-nitroso-adduct is formed and its reduction leads to the oxime (XV). Catalytic hydrogenation of both the nitroso-derivative and of the oxime gives rise to the diamine (XVI) with a *trans*-quinolizidine junction and an axial amino-group. The attempts to hydrolyse compound (XV) under various conditions for the subsequent introduction of the 11-hydroxy-group were unsuccessful. A method was therefore developed involving the low-temperature bromination of the enamines (XIII) and (XIV) to give a mixture of the quaternary salts (XVII) and (XVIII) respectively, epimeric with respect to C(11). The reduction of the salt (XVII) with tetrahydroborate leads to the bromide (XIX), which, however, was resistant to nucleophilic substitution reactions. It was found that treatment of the quaternary salts (XVII) and (XVIII) with potassium acetate followed by reduction and hydrolysis leads to the aminoalcohols (XX) and (XXI), the former being obtained in the form of a mixture of three of the four possible isomers with respect to C(9) and C(11) (two *trans*-B/C and one cis-B/C), while the latter was obtained as the sole isomer with a *trans*-quinolizidine junction and an axial 11-hydroxy-group. Another pathway leading to analogous results but with a higher yield consists in the treatment of the quaternary salts (XVII) and (XVIII) with silver nitrate to form the corresponding 11-oxo-derivatives, whose subsequent reduction leads to a mixture of two isomeric bases (XX)

† Here and henceforth the terms *anti(syn)*-, *trans(cis)*-, and *trans(cis)*- refer to the orientation of H(9) and CH_3(13) [or H(13)] in the first case, to the B/C-junction in the second, and to the C/D-junction in the third.

in the former case and of a single base (XXI) in the latter. The stereochemistry of the compounds obtained was deduced from infrared and ^{1}H NMR spectroscopic data.

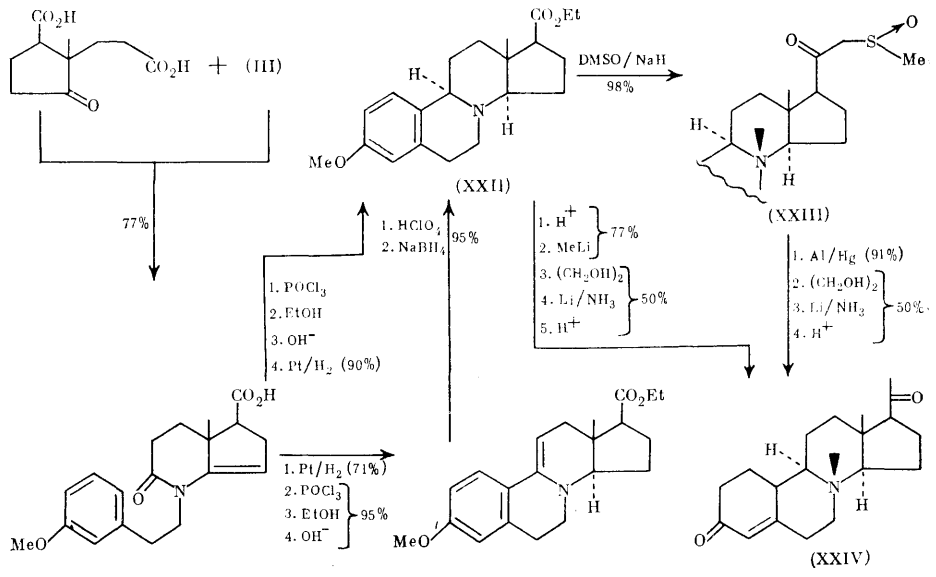
(XX) R = R^1 = H
(XXI) R = Me, R^1 = COOMe

8-Aza-analogues of 19-norprogesterone have been synthesised by a method[13] analogous to that for the synthesis of 8-azaoestranes and 8-aza-androstanes[5,6], as shown in Scheme 3. The introduction of the pregnane side chain was achieved by the Arens–Van Dorp method or the Corey method. In the first procedure the aminoester (XXII) is subjected to acid hydrolysis followed by treatment with methyl-lithium. The Birch reduction of the resulting ketone in the form of the ethylene ketal yields two 8-aza-19-norprogesterones (XXIV) epimeric with respect to C(17).

In the second method, the ketosulphoxide (XXIII) is obtained by the reaction of the ester (XXII) and the anion of dimethyl sulphoxide and its subsequent cleavage gives rise to 8-aza-19-norprogesterone (XXIV) with a 17β-acetyl group.

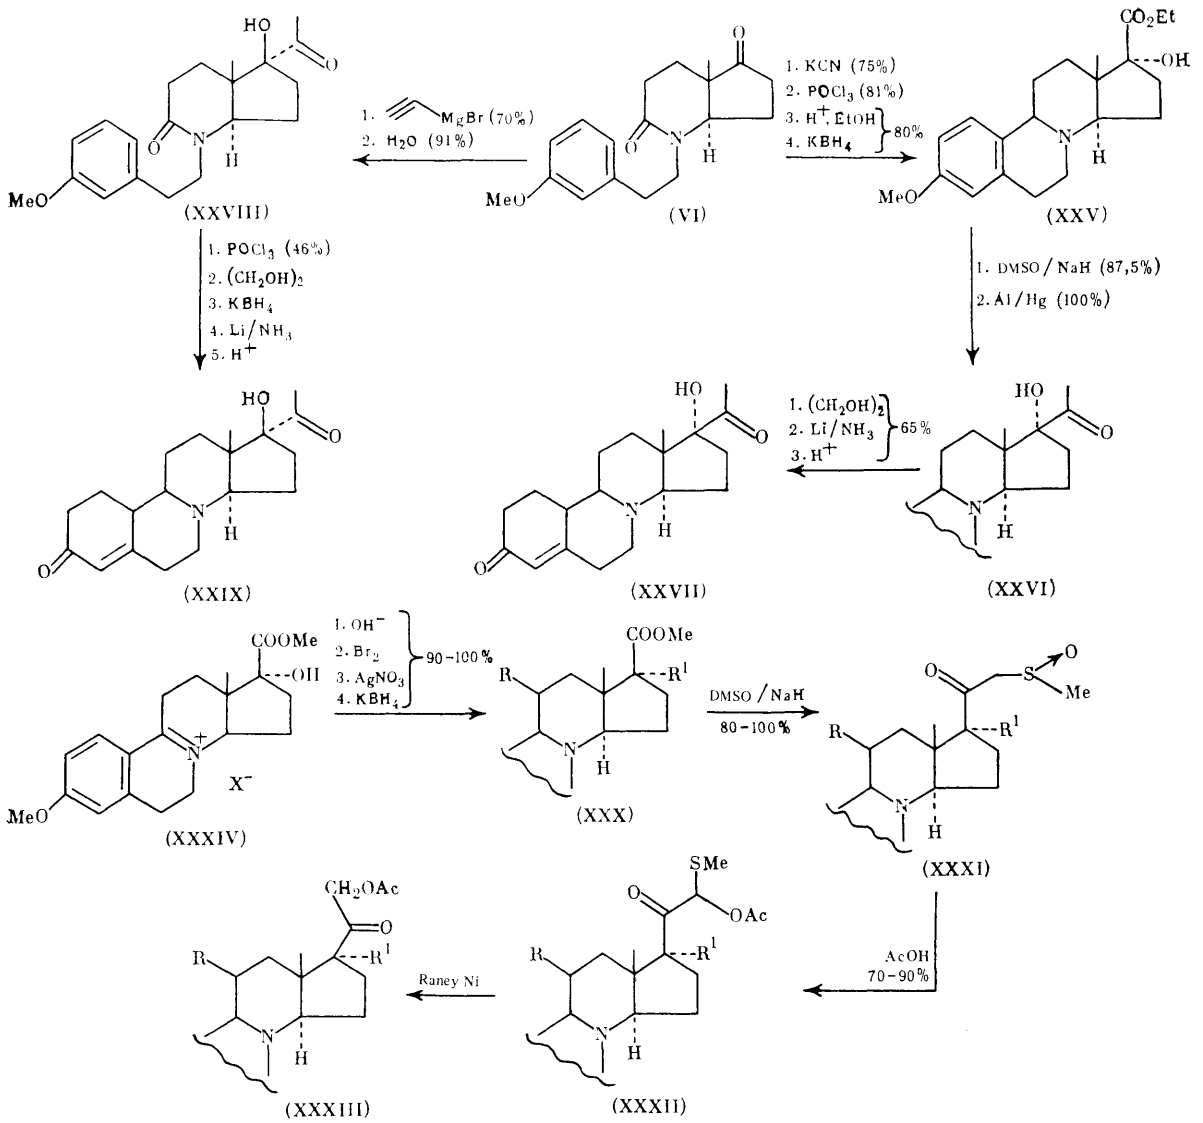


Two alternative methods have been used for the introduction of the 17-hydroxy-group, making it possible to obtain selectively either the 17α- or the 17β-hydroxy-derivative[13]. In the first procedure the ketolactam (XXVI) was converted into the aminoester (XXV), as shown in Scheme 4. Treatment of the latter with the anion of dimethyl sulphoxide yields a β-ketosulphoxide, whose cleavage with aluminium amalgam results in the formation of the ketoalcohol (XXVI). Protection of the 20-oxo-group with subsequent Birch reduction and acid hydrolysis gives rise to 17α-hydroxy-8-aza-19-norprogesterone (XXVII).

The synthesis of the 17β-hydroxy-compounds consists of the following steps. The reaction of the ketolactam (VI) with ethynylmagnesium bromide and subsequent hydration give rise to the ketone (XXVIII), from which 17β-hydroxy-8-aza-19-norprogesterone (XXIX) was obtained by the sequence of reactions presented in the Scheme.

In order to introduce the 21-hydroxy-group, a method was developed for the modification of the corticoid side chain using the Pummerer rearrangement[14]. Treatment of the esters (XXX) with the anion of dimethyl sulphoxide by Corey's method yields the 17β-ketosulphoxide (XXXI), whose rearrangement takes place on heating in acetic acid to form the acetate of the hemimercaptal (XXXII). Desulphurisation of the latter leads to the 21-acetoxy-derivative (XXXIII). Compound (XXXd), used in this Scheme, has been obtained from the quaternary salt of the ester (XXXIV) by the method described previously[12].

The method of synthesis of 17-deoxy-12-oxo-8-azasteroids by the *AB* + *D* → *ABCD* scheme was proposed by Meyers' group[15] (Scheme 5). Condensation of the aminoesters (XXXV) with the cycloalkanones (XXXVI) leads to the tetracyclic enaminoketones (XXXVII),[16] whose reduction gives rise to the aminoketone (XXXVIII). Treatment of the enaminoketone (XXXVII) with an excess of methyl iodide leads to a mixture of the *C*- and *O*-alkylated salts (XXXIX) and (XL) in proportions of 9 : 1. Catalytic hydrogenation of the quaternary salt (XXXIX) yields the methyl ether of 17-deoxy-12-oxo-8-azaoestrone (XLI) in the form of a mixture of two isomers, whose configuration was established by X-ray diffraction and infrared and ^{1}H NMR spectroscopy#.



Scheme 3

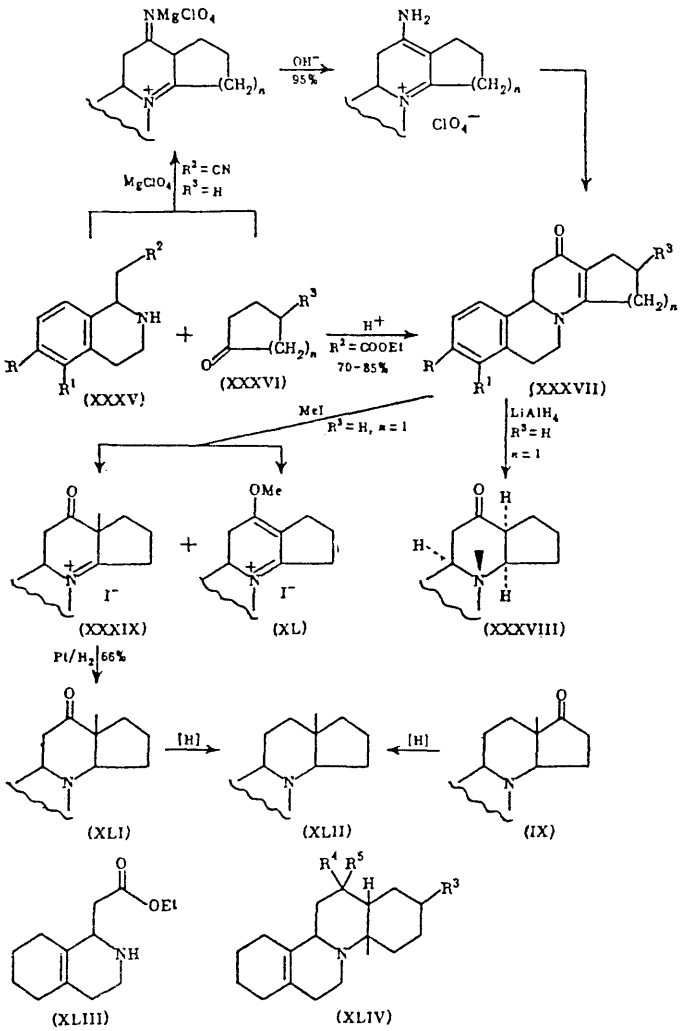
(XXII)
(XXIII)
(XXIV)

Initially incorrect configurations were erroneously attributed to these compounds[17,18], but these were corrected after X-ray diffraction studies[8,19].

Scheme 4

(a) $R = R^1 = H$; (b) $R = H$, $R^1 = OH$; (c) $R = OH$, $R^1 = H$; (d) $R = R^1 = OH$.

The stereochemistries of the bases (XLI) and (IX) were compared by the specific reduction of these compounds to the deoxy-derivatives (XLII). The replacement of the β-aminoester (XXXV) by the β-aminonitrile also makes it possible to obtain the enaminoketone (XXXVII). Under these conditions, the yields were somewhat lower at all stages for $n = 1$ and 3 than for $n = 2$.[25]



Using the octahydroisoquinoline ester (XLIII) as the *AB* fragment in the condensation with cycloalkanones, compounds of type (XXXVII) with a $\Delta^{5(10)}$-bond were obtained and their modification at C(12) and addition of a Grignard reagent to the $\Delta^{13(14)}$-bond give rise to the derivative (XLIV).[20] Analogous studies have been carried out using different ketones (XXXVI) with rings containing between 5 and 15 atoms[21].

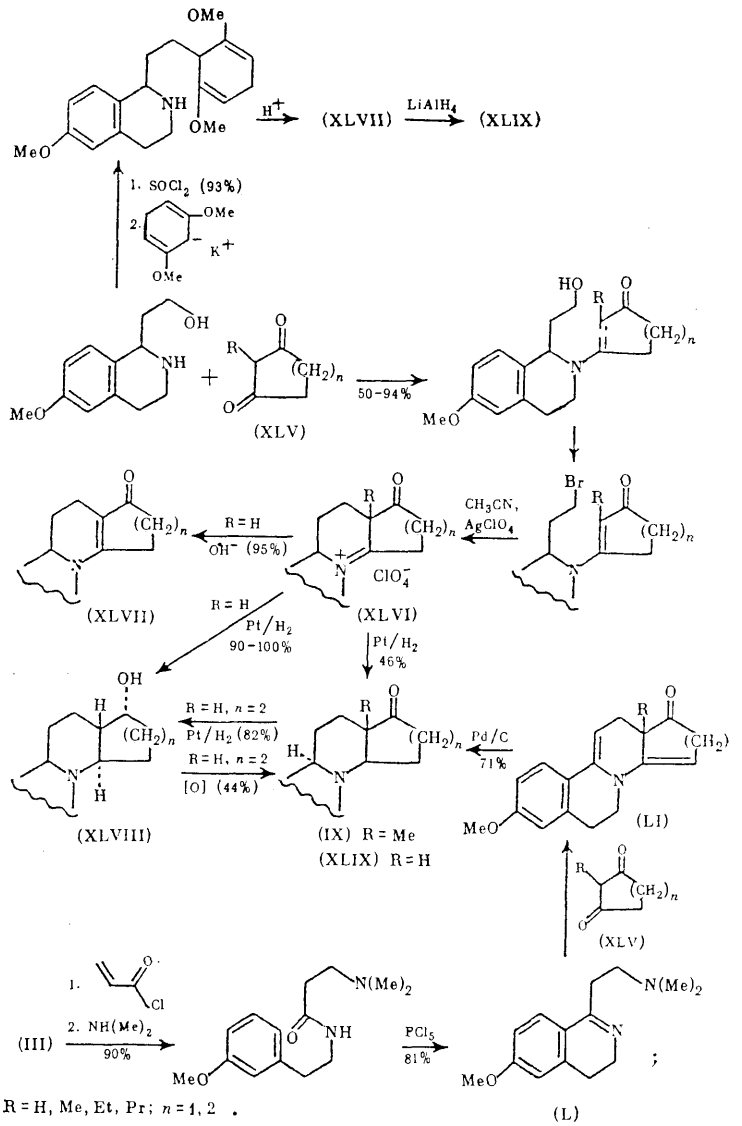
The condensation of β-aminoesters of type (XXXV) with cycloalkanones was investigated on model compounds[22] and the dependence of the rate of reaction and of the yield of the product on the nature of the departing group (the ester residue) was established. The conditions for the angular alkylation of cisoid enaminoketones were investigated on tricyclic *BCD* model compounds[23,24].

The synthesis of the methyl ether of 8-azaoestrone and its analogues was developed by the same workers using the method presented in Scheme 6.[26] The unstable immonium salt (XLVI) is hydrogenated over the Adams catalyst to form a mixture of the methyl ether of 8-azaoestrone (IX) and its stereoisomer, to which the *syn,trans.cis*-configuration was subsequently assigned[8]§.

§ The *anti,trans,cis*-configuration was initially attributed to this compound[26].

Scheme 5

When $n = 2$ and R = H, the transoid enaminoketones (XLVII), obtained previously by Nelson and Tamura[27], is formed. The hydrogenation of its immonium salt (XLVI) gives rise to the aminoalcohol (XLVIII), whose Jones oxidation leads to the methyl ether of 18-nor-D-homo-8-azaoestrone (XLIX).



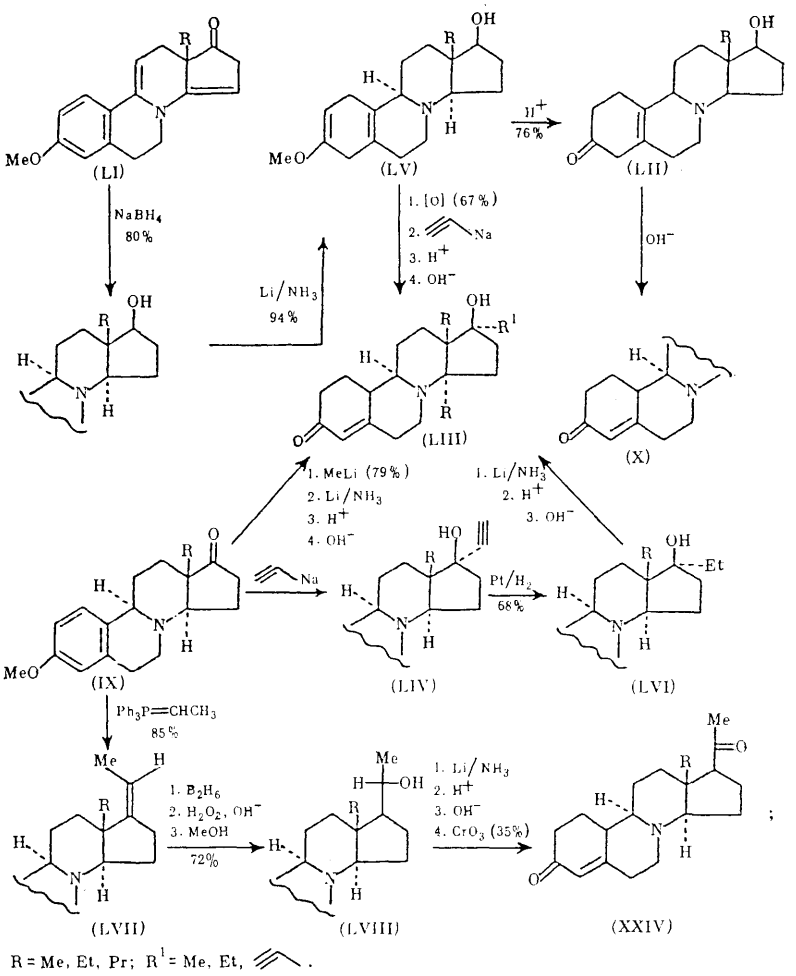
Clarkson's synthesis of 8-azaoestrone and its D-homo-analogue was based on the Michael reaction between the diamine (L) and the β-diketones (XLV) [28] (Scheme 6). The reaction proceeds with simultaneous cyclisation to form the enamines (LI), whose catalytic hydrogenation leads to the aminoketones (IX) and (XLIX). When the latter are fused with pyridine hydrochloride, 8-azaoestrone or its D-homo-analogue are formed. A *cis*-C/D-junction with β-orientation of the benzyl proton was attributed, on the basis of the results of the oxidation with mercury acetate, to the second isomeric ketone obtained on reduction of the enamine (LI) ($n = 2$).

The methyl ether of 8-aza-D-homo-18-noroestrone was synthesised by the method presented in Scheme 6.[27] The reduction of the enaminoketone (XLVII) with lithium tetrahydroaluminate leads to a mixture of two isomeric ketones (XLIX) with a *trans*-B/C-junction, which are epimers with respect to C(13), since one of the isomers is converted into the other on treatment with a base. However, the configurations of the isomers were not established.

Subsequently various details of 8-aza-19-nortestosterone, (X) and (LIII), were obtained[29] from the enamine (LI) and the methyl ether of 8-azaoestrone (IX) (Scheme 7). In order to investigate the biological activity, various substituents were introduced into the 17-position of the 8-aza-19-nortestosterone molecule. 17α-Substituted derivatives of 8-aza-19-nortestosterone (LIII) were then obtained from compound (IX). The above methods are inapplicable to the synthesis of 17α-ethynyl derivatives (LIII). They were synthesised by the Oppenauer oxidation of the aminoalcohol (LV) with subsequent ethynylation and hydrolysis.

8-Aza-19-norprogesterone (XXIV) and its analogues were obtained from the aminoketone (IX) via stages involving the formation of the ethylidene derivative (LVII) and the methylmethanol (LVIII).[30] The 13-ethyl derivatives were synthesised in accordance with the same scheme.

Scheme 6

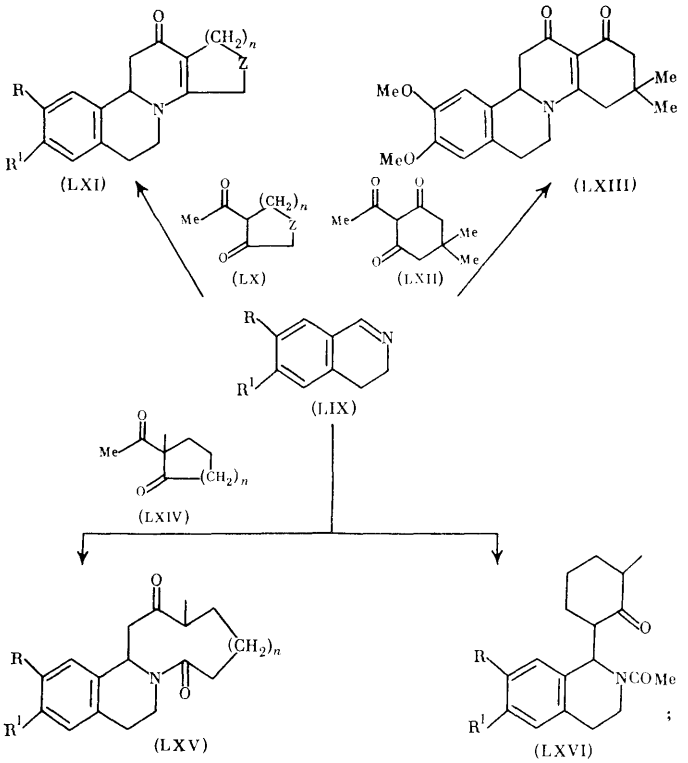


A simple scheme for the synthesis of 12-oxo-derivatives of 8-azasteroids consists in the condensation of 3,4-dihydroisoquinolines (LIX) with 2-acetylcycloalkanones (LX) (Scheme 8).[31] The enaminoketones (LXI) are then formed in yields ranging from 7 to 85%. Some of them had been obtained earlier (Z = CH_2).[16] The condensation of 6,7-dimethoxy-3,4-dihydroisoquinoline (LIX) with 2-acetyldimedone (LXII) yielded the enaminodiketone (LXIII). The attempt to condense the non-enolysable β-diketones (LXIV) with an angular substituent leads to the opening of the β-diketone ring and subsequent alkylation and acylation of the dihydroisoquinoline at C(1) and N respectively. This entails the formation of azecinotetrahydroisoquinolines (LXV) and *N*-acetyl-1-(2-oxocycloalkyl)tetrahydroisoquinolines (LXVI).[32]

Synthesis of 18-nor-8-azasteroids[33], which differs from Meltzer's method[5] by the procedure used to obtain the unsaturated lactams (LXVII) (Scheme 9), was proposed in 1975. The cyclisation of these lactams under the influence of polyphosphoric acid (PPA) is accompanied by oxidative-reductive disproportionation and takes place quantitatively to give an equimolar mixture of the immonium salts (LXVIII) and the pyridinium salts (LXIX). Treatment of the salt (LXVIII) with a base gives rise to the enaminoketone (XLVII), which is reduced with lithium tetrahydroaluminate (when $R=R^1=OCH_3$) to a derivative of 18-nor-8-azaoestrone (XLIX) having the *syn,trans,cis*-configuration. The attempts to introduce an angular substituent in the 13-position of the enaminoketone (XLVII) were unsuccessful and only the *O*-alkylation product was isolated in the form of the immonium salt. Its reduction with tetrahydroborate yielded a mixture of the bases (LXX) and (LXXI).

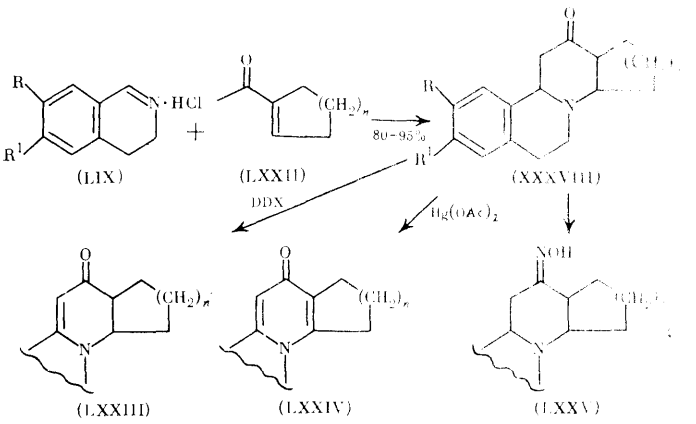
The synthesis of 12-oxo-derivatives of 8-azasteroids (XXXVIII) by the reaction of the hydrochloride of 3,4-dihydroisoquinoline (LIX) with αβ-unsaturated ketones (LXXII)

Scheme 7



was achieved independently by two groups of investigators (Scheme 10).[34-41] The compounds are formed in the form of a mixture of two or three isomers with respect to C(9) and C(13) and the isomeric composition depends on the reaction conditions and the size of the ring in the αβ-unsaturated ketones (LXXII).[36-38] The configuration of the compounds obtained was investigated chemically by the interconversion of various epimers and oxidation to the enaminoketone (LXXIII) by 2,3-dichloro-5,6-dicyano-1,4-benzoquinone (DDQ) and to the γ-pyridone (LXXIV) in the presence of mercury diacetate[36,39]. 12-Hydroxyimino-derivatives of type (LXXV) with different substituents in the 2-, 3-, 4-, 7-, and 11-positions[34] were obtained and a study was made of the elimination of the 12-carbonyl group by various reducing agents[40]. The stereochemistry of the resulting compounds with a six-membered D ring was partly confirmed by ^1H and ^{13}C NMR data[41].

The first study of the synthesis of 8-azasteroids in the USSR was published in 1969 [42] (Scheme 11). The key stage is the reaction of triacylmethanes (LXII) with 3,4-dihydroisoquinolines (LIX). This leads to the formation of the enaminodiketones (LXIII), which have the 8-azasteroid skeleton[42-44]. The enaminodiketone group in compound (LXIII) proved to be chemically extremely inert. The attempts to introduce the angular methyl group in the 13-position were unsuccessful: under the severe conditions of the anionoid *C*-methylation, it was possible to isolate only the 16-methyl derivative in an insignificant yield[44]. We were able to achieve the selective removal of the 12-oxo-group from the enaminodiketones (LXIII) under the conditions of the ionic hydrogenation reaction. The reaction proceeds with total regiospecificity giving rise to products having the general formula (XLVII) in a high yield[45]. It was found that the Baeyer–Villiger oxidation of the enaminodiketones (LXIII, $Z=CH_3$) leads to the formation of the ε-lactones (LXXVI), whose methanolysis results in the formation of the diketoesters (LXXVII), which exist in equilibrium with the keto-enol form.



The cyclodehydrogenation of the diketoester (LXXVII) proceeds with simultaneous dehydrogenation to give the benzopyrrocolines (LXXVIII).[46,47] The dehydrogenation of the enaminodiketones (LXIII) leads to the formation of the γ-pyridones (LXXIX),[48] the polyfunctional group of which proved to be more reactive. Thus the ionic hydrogenation of the pyridones (LXXIX) proceeds with hydrogenolysis of the keto-group in the D ring to form the 17(17a)-deoxo-compounds (LXXIV) with a satisfactory yield[49]. A method was therefore developed for the direct synthesis of γ-pyridones by the condensation of 3,4-dihydroisoquinoline *N*-oxide (LXXX) with triacylmethanes (LXII).[47,48,50] The condensation proceeds via the 1,3-addition with subsequent cyclodehydration of the intermediate β-triketone. The presence

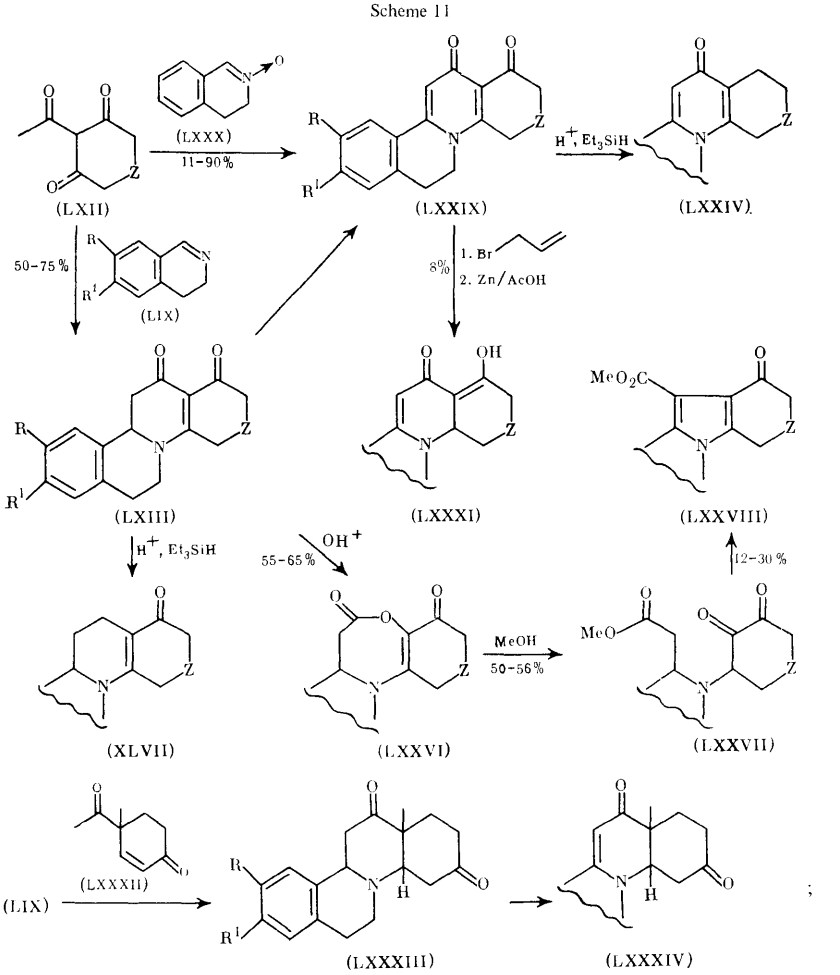
of the $\Delta^{9(11)}$-bond destabilises the enaminodiketone group and the pyridone (LXXIX) reacts with allyl bromide to form a pyridonium salt, which is reduced, without further purification, to the dihydropyridone (LXXXI) with zinc and acetic acid.



The condensation of 3,4-dihydroisoquinolines (LIX) with the diketone (LXXXII) results in the formation of the 8-aza steroid compounds (LXXXIII) with a *cis*-C/D-junction[51,52]. The dehydrogenation of the latter by chloranil leads to the formation of the enaminoketones (LXXXIV). The reduction of compounds (LXXXIII) and (LXXXIV) as well as their tosylhydrazones by sodium tetrahydroborate has been studied[53].

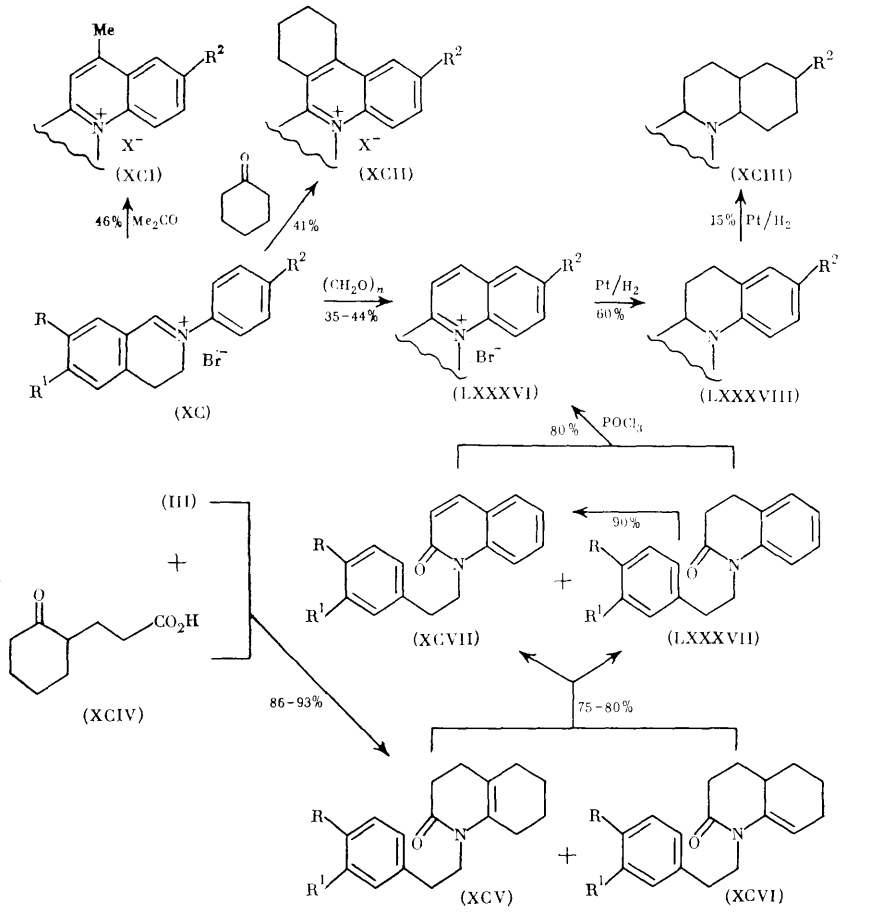
III. COMPOUNDS WITH TWO AND MORE AROMATIC RINGS

Polycyclic compounds with two and more aromatic rings, which formally have the 8-azasteroid skeleton, were obtained even before the initiation of studies on the total synthesis of 8-azasteroids. Various modern reduction methods make it possible to convert these compounds into compounds with saturated B, C, and D rings. Brown's studies[54] on the synthesis of dibenzo[*a*,*f*]quinolizines, in which the incorrect conclusions concerning the structure reached in analogous investigations by Japanese workers[55] were corrected, are characteristic in this respect. Thus the cyclisation of the amide (LXXXV) yielded a mixture of quaternary salts having various structures, from which dibenzo[*a*,*f*]quinolizinium iodide (LXXXVI) was isolated (Scheme 12).

The same product is formed on cyclisation of the dihydroquinoline (LXXXVII).[56] The reduction of the tetracyclic salt (LXXXVI) with tetrahydroborate gives rise to the dibenzo[*a*,*f*]quinolizine (LXXXVIII). Analogous data were obtained for the cyclisation of the dihydroquinolone (LXXXVII) [56] or the tetrahydroisoquinoline (LXXXIX) [57] with subsequent *O*-methylation. The synthesis of angularly substituted dibenzo[*a*,*f*]quinolizines has been achieved in accordance with Scheme 13:[58–60]

Scheme 13



R, R^1, R^2, R^3 = H, OAlk, OH, —O—CH_2—O—, Alk .

Salsmans and Van Binst[61] developed a method of synthesis of compounds containing the tetracyclic 8-azasteroid skeleton (Scheme 14) on the basis of the reaction of 2-phenyl-3,4-dihydroisoquinolinium salts (XC) with carbonyl compounds. The proposed mechanism of the formation of compounds (LXXXVI), (XCI), and (XCII) involves the Michael addition of CH-active compounds to the C=N bond with subsequent stages involving the intramolecular electrophilic attack by the carbonium ion on the activated *ortho*-position of the *N*-aryl substituent, the elimination of water, and intramolecular hydride transfer. The catalytic hydrogenation of the isoquinolinium salts (LXXXVI) yields dibenzo[*a*,*f*]quinolizines (LXXXVIII), which are converted by more far-reaching reduction into the D-homo-8-azasteroid derivatives (XCIII), whose configuration has not been established.

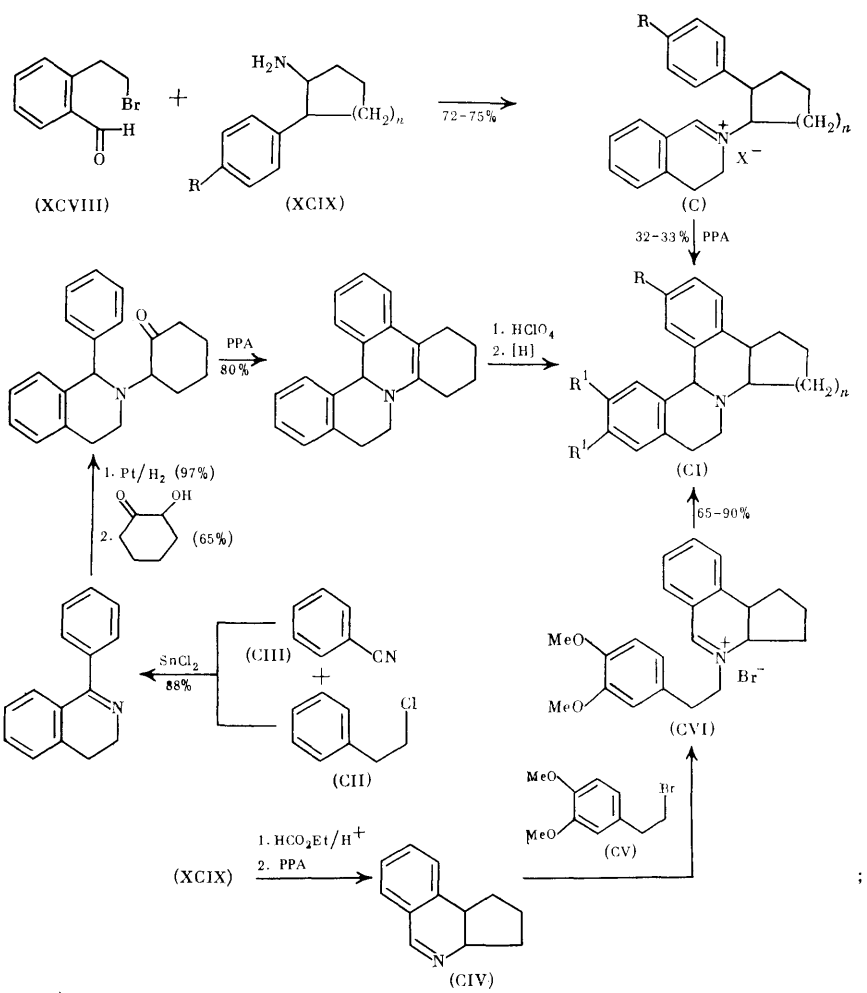
Later an improved synthesis of dibenzo[*a*,*f*]quinolizines (LXXXVIII) was described[62]. A mixture of enamides (XCV) and (XCVI), with the former predominating, was obtained by the condensation of β-phenylethylamines with the acids (XCIV) (Scheme 14). The dehydrogenation of this mixture yielded compounds (XCVII) and (LXXXVII), whose cyclisation gave rise to the quinolizinium salt (LXXXVI, R=R^1=OCH_3). Derivatives unsubstituted in the A ring are not cyclised.

The synthesis of 8-azasteroid compounds with an 11-12-condensed E ring has been achieved by the same group of investigators[63] (Scheme 15). The interaction of the aldehyde

Scheme 14

R, R^1, R^2 = H, OMe; X = Cl, Br, ClO_4 .

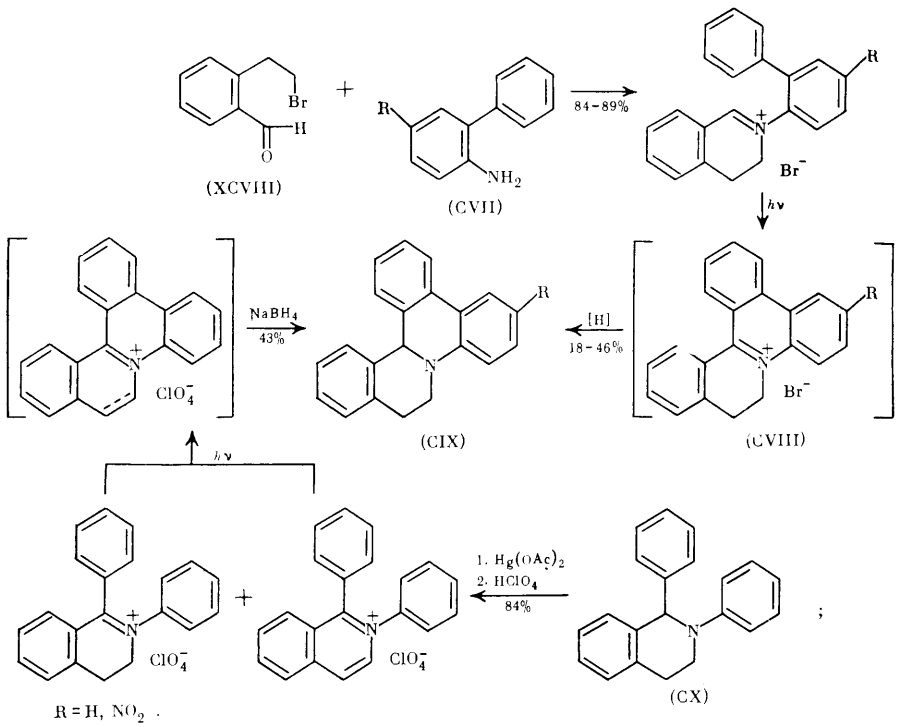
(XCVIII) with 2-phenylcyclohexylamine (XCIX, $n = 2$) yielded the *trans*- or *cis*-dihydroisoquinolinium salt (C), depending on the stereochemistry of the initial phenylcyclohexylamine. The cyclisation of this salt under the influence of polyphosphoric acid gives rise to the corresponding *trans*-C/D- and *cis*-C/D-dibenzo[*a*,*f*]-quinolizines (CI). Other stereoisomeric bases (CI) have been obtained from β-phenylethylchloride (CII) and benzonitrile (CIII), as shown in the Scheme. The stereochemistry of all the bases (CI) obtained was established on the basis on ^1H and ^{13}C NMR data[64] and by comparison with the spectroscopic characteristics of model compounds[65,66].



The use of 2-phenylcyclopentylamines (XCIX, $n = 1$) in the reaction with the aldehyde (XCVIII) makes it possible to obtain 8-azasteroid compounds (CI, $n = 1$) with a five-membered D ring[67]. An alternative pathway leading to the formation of compounds (CI, $n = 1$) was proposed by the same workers. Refluxing of the amine (XCIX) in ethyl formate with subsequent cyclisation of the formamide results in the formation of the dihydroisoquinoline (CIV), which leads to the immonium derivative (CVI) on heating with the bromide (CV). Cyclisation of the immonium derivative gives rise to the pentacyclic product (CI). The pathways leading to the cyclisation of compounds (CVI) to (CI) and the causes of the formation of various isomers as a function of the stereochemistry of the initial amine (XCIX) and the selected synthetic scheme have been investigated.

The tribenzoquinolizine analogues of 8-azasteroids (CIX) have been obtained by condensing the aldehyde (XCVIII) with 2-aminobiphenyl (CVII) (Scheme 16)[68] and subsequent acid or photochemical cyclisation to the phenanthridizinium salt (CVIII) and its reduction without isolation in a pure form. Analogous products have been obtained from tetrahydroisoquinolines (CX):[69]

In the course of studies of the methods of synthesis of compounds containing the dibenzoquinolizinium cation in order to obtain precursors of 8-azasteroids, a method has been developed for the synthesis of dibenzo[*a*,*f*]quinolizinium perchlorates (CXIII) (Scheme 17) by the condensation of the isoquinolines (CXI) with the aldehydes (CXII) and subsequent intramolecular cyclisation[70]. The application of this method to the synthesis of 17-nitro-substituted precursors of D-homo-8-azasteroids made it possible to synthesise various tetracyclic compounds (CXIII) containing the OH, OAc, and OMe groups in the A ring and the NO_2 group in the D ring[71]. The use of the dihydroisoquinolines (CXIV) in this sequence of reactions leads initially to the heterocyclic diene (CXV), which subsequently cyclises quantitatively to the tetracyclic 17-nitro-derivative (CXVI):



In 1975 Chapman[72] obtained the quinolizinium perchlorates (CXVIII) and (CXX) (Scheme 18) by the condensation of 3,4-dihydroisoquinolinium perchlorate (LIX) with the cyclic αβ-unsaturated ketones (CXVII) and (CXIX) containing a methyl substituent in the β-position.

IV. COMPOUNDS WITH AN ADDITIONAL HETEROATOM

The synthesis of 8-azasteroid compounds with an additional heteroatom can be achieved with the aid of the approaches described in Section II and also by special methods. Thus Scheme 19 illustrates different ways of constructing the 8,13-diazasteroid molecule from β-phenylethylamines (III). Thus the interaction of compounds (III) and the acid chloride (CXXI) gives rise to the amide (CXXII), which cyclises to the dihydroisoquinoline (CXXIII).[73] Its subsequent reductive cyclisation results in the formation of 8,13-diazaoestrane derivatives (CXXIV). It was found that the failure of the attempt at reductive cyclisation described by Burckhalter and Abramson[74] was associated with the use of the dihydroisoquinoline (CXXIII) in the form of the hydrochloride, as pointed out by Taylor and Lenard[73]. This entails reductive cleavage, leading to the diamine (CXXV) whose interaction with the hydrochloride (CXXVI) leads to a derivative of 8,13-diazagonane (CXXVII).[74] The reduction of the immonium linkage with various reagents results in the

Scheme 19

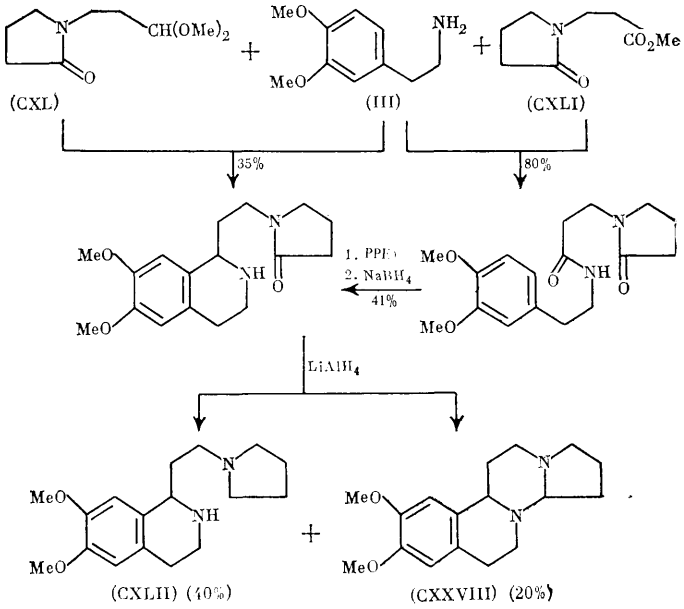
R, R^1, R^2 = H, OMe .

formation of the diazasteroid (CXXIV),[75] which give rise to the diamines (CXXVIII) on treatment with lithium tetrahydroaluminate. X-Ray diffraction studies of the amide (CXXIV)[75] and also infrared and ^{1}H NMR spectroscopic data[79] showed that compounds (CXXIV) and (CXXVIII) have the 9α,14α-configuration with the *trans*-B/C- and *trans*-C/D-junctions.

The fragmentation and possible pathways leading to the decomposition of compounds (CXXIII) and (CXXVIII) under mass-spectrometric conditions have been studied[77].

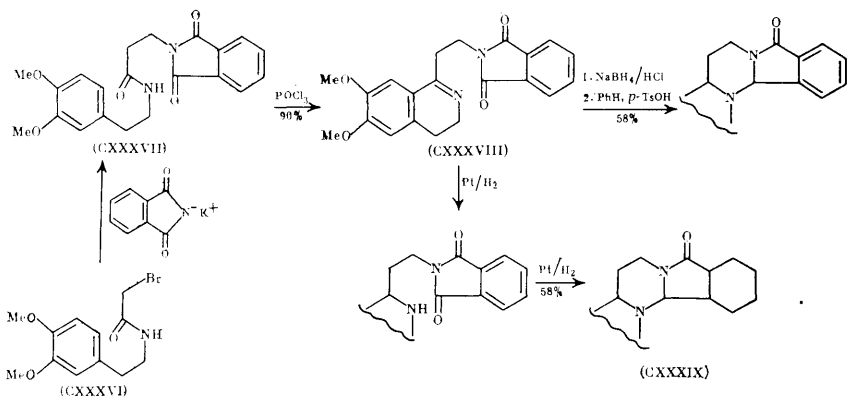
Another version of the synthesis of the amide (CXXII) consists in the condensation of the β-phenylethylamines (III) with 3-bromopropionyl bromide and the reaction of the resulting bromamide with the potassium derivative of succinimide[78]. The tetrahydroisoquinoline (CXXIX), which gives rise to the 8,13-diazasteroid (CXXIV) after the azeotropic distillation of the alcohol, has been obtained in the study of the reductive cyclisation of the dihydroisoquinoline (CXXIII) under the influence of sodium tetrahydroborate[79]. The removal of the keto-group followed by oxidation with mercury acetate leads to the immonium salt (CXXX), in which the presence of the $\Delta^{13(14)}$-bond has been demonstrated by ultraviolet spectroscopy.

The Birch reduction of 8,13-diazasteroids (CXXVIII) has been investigated. The main reduction product is the diene (CXXXI), which is converted either into the non-conjugated enone (CXXXIV) or into 8,13-diaza-19-norandrost-4-en-3-one (CXXXIII) depending on the conditions used in the treatment. The enolic ether (CXXXII), formed in the course of their reduction, gives rise to 8,13-diaza-19-norandrostan-3-one (CXXXV) as a result of appropriate treatment. ^{13}C NMR data have been published for compounds (CXXXI) and (CXXXII)[80] and also for compounds (CXXIII), (CXXIV), and (CXXVIII).[81]



The attempts at the synthesis of C-nor-, C-homo-, and D-homo-8,13-diazaoestranes in accordance with the scheme examined above with the appropriate replacement of the starting compound were unsuccesful[76].

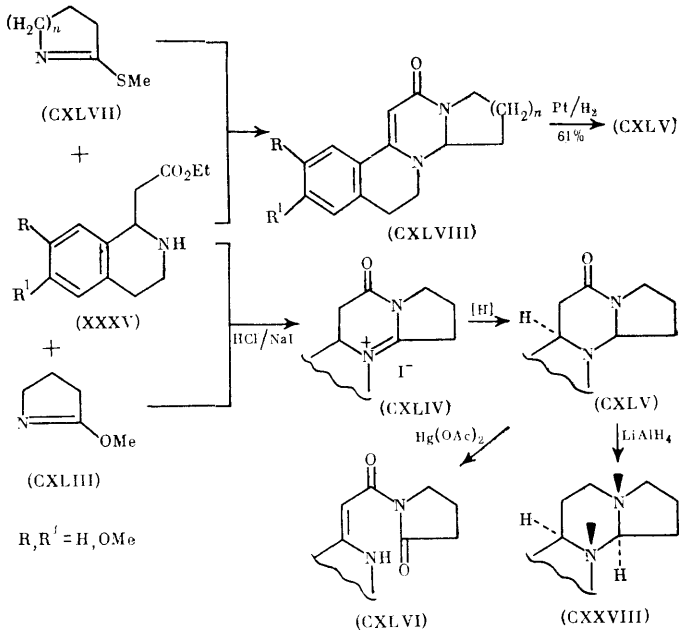
The use of potassium phthalimide in condensation with the bromamide (CXXXVI) leads to the formation of the amide (CXXXVII),[82] whose cyclisation produces the dihydroisoquinoline (CXXXVIII) (Scheme 20). The reductive cyclisation of the latter proceeds via an intermediate tetrahydroisoquinoline to form the diazasteroid (CXXXIX) containing the additional saturated E ring. In order to retain the aromtic E ring, the reductive cyclisation is carried out with sodium tetrahydroborate. In the study of the configuration of compound (CXXXIX) considerable difficulties arose as a consequence of the presence of the additional D/E-junction.



Infrared and ^{1}H NMR spectroscopic data make it possible to postulate the *trans*-C/D-junction and the *syn*-H(9)/H(14)-configuration. However, the constant $J_{H(14)/H(15)} = 4$ Hz precludes a choice between the *trans*- and *cis*-D/E junctions. X-Ray diffraction analysis demonstrated the α-orientation of the H(14), H(15), and H(16) protons, which indicate a *cis*-D/E-junction.

The synthesis of 8,13-diazasteroids was undertaken on the basis of the condensation of homoveratrylamine (III) with the acetal-lactam (CXL) or with the ether-lactam (CXLI), the closure of the C ring being achieved by reductive annelation under the influence of lithium tetrahydroaluminate[83] (Scheme 21). The 8,13-*seco*-diazasteroid (CXLII) is then formed as a side product. From infrared and ^{1}H NMR spectroscopic data a *trans*-B/C-junction and the *syn*-orientation of the H(9) and H(14) protons were attributed to the 8,13-diazasteroid (CXXVIII).

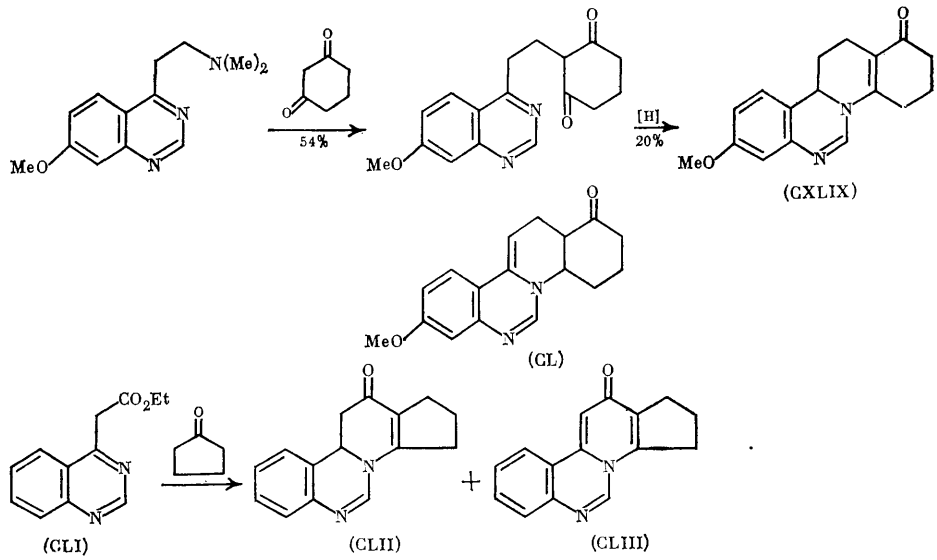
Scheme 21



Scheme 20

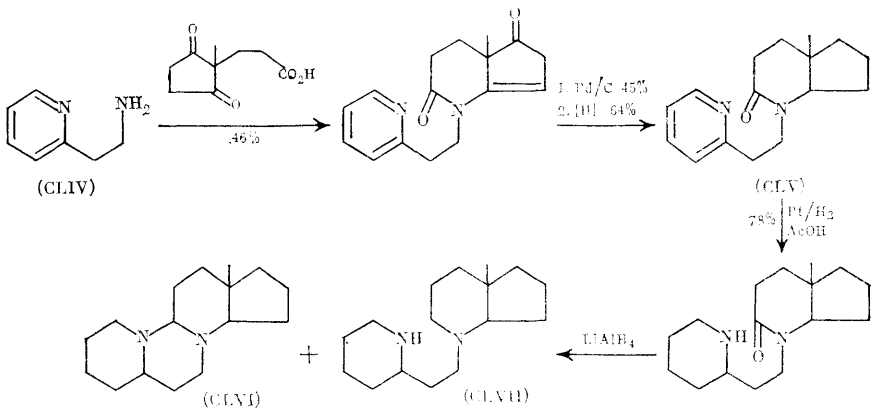
Japanese chemists proposed[84,85] another approach to the synthesis of 8,13-diazasteroids (Scheme 22) on the basis of the reaction of the tetrahydroisoquinoline ester (XXXV) with the butyrolactam (CXLIII), which proceeds with formation of an unstable tetracyclic compound, which gives rise to the salt (CXLIV) on treatment with HCl/NaI. On reduction, this salt is converted into a mixture of the two isomeric bases (CXLV). The *trans*-B/C-junction with the *syn*-orientation of H(9) and H(14) and the *cis*-B/C-junction with the *anti*-orientation of these protons were attributed to the bases[85]. The reduction of the aminoketones (CXLV) or of the salt (CXLIV) with lithium tetrahydroaluminate leads to a 70% yield [relative to compound (XXXV)] of the diamine (CXXVIII), which has the same configuration as the compound obtained earlier[74]. The attempt to oxidise the base (CXLV) with mercury acetate to the corresponding $\Delta^{9(11)}$-derivative gives rise to the cleavage product (CXLVI) only.

Scheme 22



Using the lactim thioethers (CXLVII) in the condensation with the ester (XXXV), 8,13-diazasteroids (CXLVIII) were also obtained in yields of 63% ($n = 1$), 81% ($n = 2$), and 7.8% ($n = 3$).[86] The reduction of compound (CXLVIII, $n = 1$) over the Adams catalyst yields the 8,13-diazasteroid (CXLV).

The synthesis of 6,8-diazasteroid systems was undertaken in 1964 [87] by a method analogous to that of Clarkson[28], as shown in Scheme 23. The ^{1}H NMR spectrum of compound (CXLIX) in trifluoroacetic acid contains a signal at 4.86 p.p.m., which the author attributed to the olefinic protons, which he believes to arise as a consequence of the isomerisation of the initial compound in an acid medium to the enamine (CL). Such isomerisation is unlikely, particularly since, according to our data[44], the signal at 4.86 p.p.m. in trifluoroacetic acid can be quite legitimately assigned to the benzyl H(9) proton of the base (CXLIX).



The attempt to synthesise 6,8-diazasteroid systems by the condensation of ethyl 3,4-dihydro-4-quinazolinylacetate (CLI) with cyclopentanone was unsuccessful[88] (Scheme 23). The authors were able to isolate only traces of compounds to which the structures (CLII) and (CLIII) were attributed on the basis of infrared spectroscopic and mass-spectrometric data.

The synthesis of 8,10-diazasteroids was undertaken by a group of Japanese chemists by a method[89] (Scheme 24) analogous to that of Brown et al.[6] The use of the pyridine derivative (CLIV) made it possible to obtain a ketolactam, which was reduced to the amide (CLV) via a thioketal with subsequent desulphurisation. The saturation of the pyridine ring and subsequent reductive cyclisation give rise to a mixture of two isomers of the 8,10-diazasteriod (CLVI) and the non-cyclised product (CLVII) in yields of 16, 21, and 32% respectively. Compounds (CLVI) are stereoisomers with respect to the C/D-junction. The stereochemistry of the final product was established on the basis of the postulated mechanism with reductive cyclisation and also infrared and ^{1}H NMR spectroscopic data. The physicochemical criteria of the stereochemistry of the compounds presented by Takahata et al.[89] are not unduly convincing, since the stereochemistry of the proton at C(9) is assessed from the presence of the Boltzmann bands in the infrared spectrum, which in the given instance can be accounted for also by a *trans*-diaxial disposition of the hydrogen atom at C(5) and the free electron pair of the N(10) nitrogen atom, while the ^{1}H NMR criteria, in

Scheme 23

Scheme 24

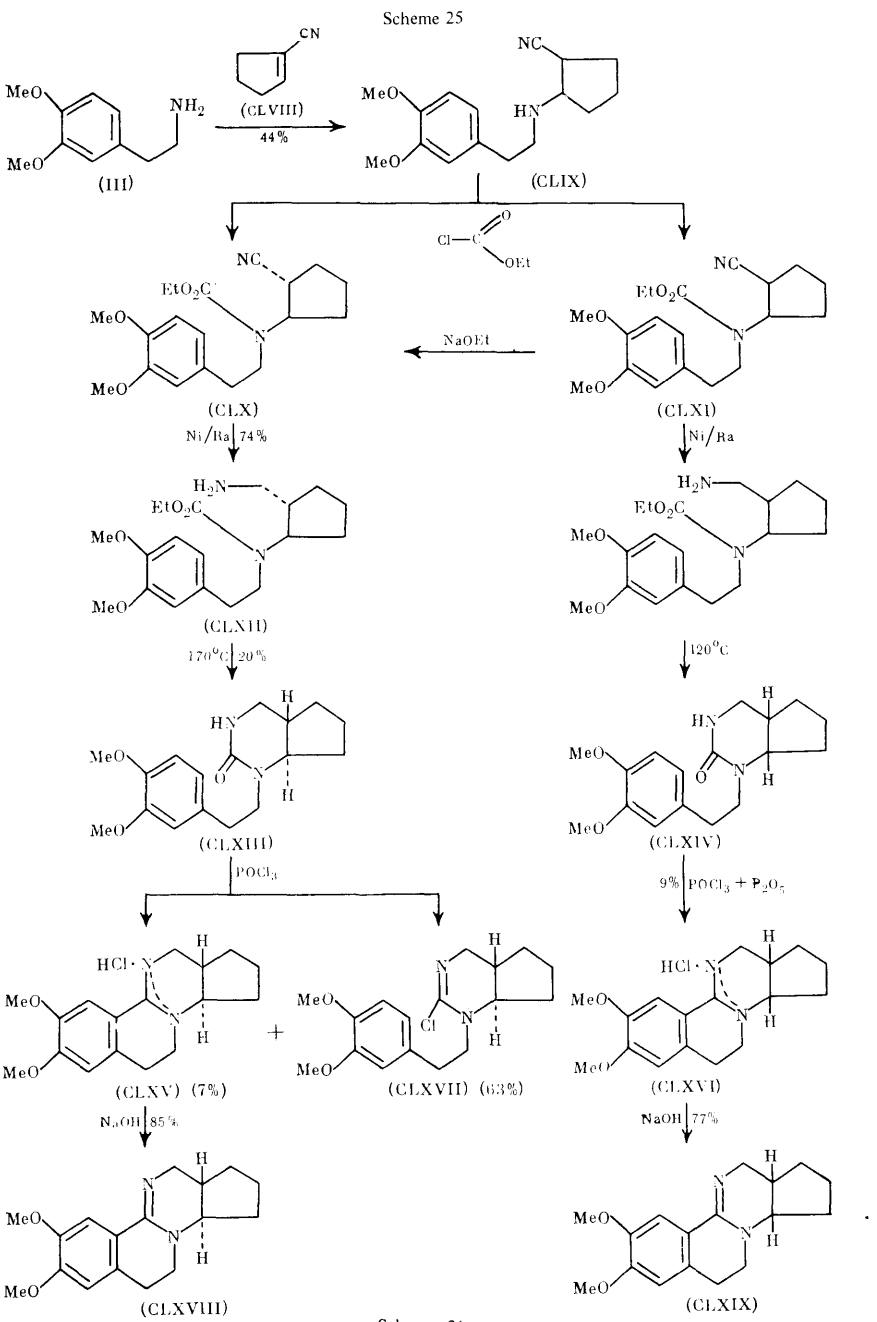
terms of which the stereochemistry of the proton at C(9) is usually deduced from its chemical shift, refer to the tetrahydroisoquinoline fragments and their *a priori* employment in the given instance is unjustified.

8,11-Diazasteroid compounds have been synthesised in accordance with Scheme 25.[90] The addition of homoveratrylamine to 1-cyanocyclopentene (CLVIII) yields the aminonitrile (CLIX) in the form of a mixture of the *cis*- and *trans*-isomers. Their interaction with chloroformic ester results in the formation of a mixture of the urethanes (CLX) and (CLXI) in proportions of 5 : 1, the latter isomerising to the former on treatment with sodium ethoxide. The *cis*- and *trans*-configurations were attributed to the compounds on the basis of the hypothesis that the *trans*-isomer is thermodynamically more stable. The hydrogenation of the *trans*-nitrile (CLX) over Raney nickel leads to the corresponding amine (CLXII), whose heating at 170 °C in ethylene glycol gives rise to the pyrimidinone derivatives (CLXIII) with a *trans*-C/D-junction. The cyclisation of compounds (CLXIII) and (CLXIV) leads to the hydrochlorides of the 8,11-diazasteroids (CLXV) and (CLXVI) respectively. In the case of the derivative (CLXIII), the main reaction product is then the chloro-compound (CLXVII). Treatment of the salts (CLXV) and (CLXVI) with alkali gives rise to the free bases (CLXVIII) and (CLXIX) with a low overall yield.

Meyers' method (see Scheme 5) has been used to synthesise 8,16- and 8,17-diazasteroids[91] (Scheme 26). The initial compounds in this Scheme are trimethylpyrrolidinone (CLXX) and *N*-acetylpyrrolidinone (CLXXI), which were condensed with the ester (XXXV). This led to the formation of the enaminoketones (CLXXII) in the former case and the isomeric *N*-acetyl derivatives (CLXXIII) and (CLXXIV) in the latter case. The structures of the diazasteroids (CLXXIII) and (CLXXIV) were established on the basis of the ultraviolet and ^{1}H NMR spectra and also by a comparative study of their fragmentation in the mass spectra.

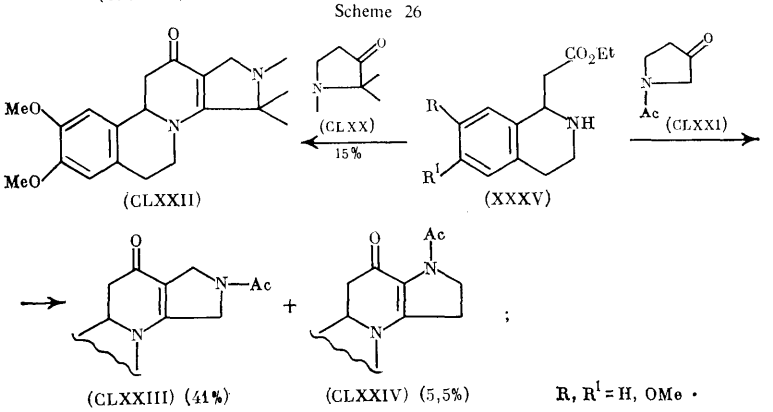
A novel scheme has been proposed for the synthesis of 8,14-diazasteroids[92] (Scheme 27). Compound (CLXXV) was obtained by the sequence of reactions presented in the Scheme. The subsequent synthesis is carried out via two equally important pathways. The first postulates the cyclisation of compound (CLXXV) and the catalytic hydrogenation of the intermediate salt (CLXXVI). The tricyclic ester (CLXXVII) formed under these conditions is converted into the 8,14-diazasteroid (CLXXVIII) on refluxing in ethylene glycol. In the second method the D ring is formed initially by refluxing the ester (CLXXV) in ethylene glycol and the resulting amide (CLXXIX) is cyclised to the $\Delta^{9(11)}$-8,14-diazasteroid (CLXXX). Its conversion into the iodonium salt and reduction with sodium tetrahydroborate or catalytically give rise to the diazasteroid (CLXXVIII), to which the *cis*-quinolizidine structure was attributed from infrared and ^{1}H NMR spectroscopic data and the results of the selective deuteration in the 9-position, and also bearing in mind its resistance to oxidation to the dehydro-derivative (CLXXX) on treatment with mercury acetate. The mutual orientation of the H(9) and H(13) protons was not established.

The synthesis of 8,15-diazasteroids was undertaken by the method of Yamazaki et al.[93] (Scheme 28), which is analogous to the method of Meltzer et al.[5] The condensation of homoveratrylamine with the pyrrolidinone derivatives (CLXXXI) yielded the amide (CLXXXII), whose cyclisation under the influence of ethyl polyphosphate (PPE) gives rise to the dihydroisoquinoline (CLXXXIII). The reductive cyclisation of the latter leads to a mixture of the non-cyclised product (CLXXXIV) and the 8,15-diazasteroid (CLXXXV). The *anti*,*trans*,*trans*-configuration has been attributed to compound (CLXXXV).



In the search for new biologically active compounds in the series of 8-azasteroid derivatives with an additional heteroatom, the synthesis of D-homo-8-aza-17-thia- and D-homo-8,17-diaza-steroids was undertaken[94] (Scheme 29). For this purpose, the ester (XXXV) was condensed with the heterocyclic ketones (CLXXXVI) and (CLXXXVII) to form the tetracyclic enaminoketones (CLXXXVIII) and (CLXXXIX). The introduction of the 3-tetralone (CXC) into this condensation gives rise to the D-homo-8-azasteroid (CXCI) with the additional aromatic E ring.

The synthesis of 8,12-diaza-D-homosteroids was undertaken by a group of Japanese investigators[95] (Scheme 29) in order to study their biological activity. The tetracyclic diene (CXCIII) was obtained by the condensation of the amine (CXXV) with cyclohexane-1,2-dione (CXCII) and was converted by reduction over the Adams catalyst and subsequent acylation into the 8,12-diaza-D-homosteroid (CXCIV) as a mixture of two isomers with respect to C(9), the *trans*-B/C-isomer being isolated in 22% yield and the *cis*-B/C-isomer in 9% yield. The stereochemistry of the compounds obtained was established from infrared and ^{1}H NMR spectroscopic data and was confirmed by studying the rates of oxidation to the corresponding $\Delta^{9(11)}$-derivatives.



4,8-Diazasteroids (CXCV) were obtained in 1979 by the method illustrated in Scheme 30.[96]

The synthesis of D-homo-8-aza-17-oxasteroids was undertaken (Scheme 31)[97,98] by the method described in Scheme 11.

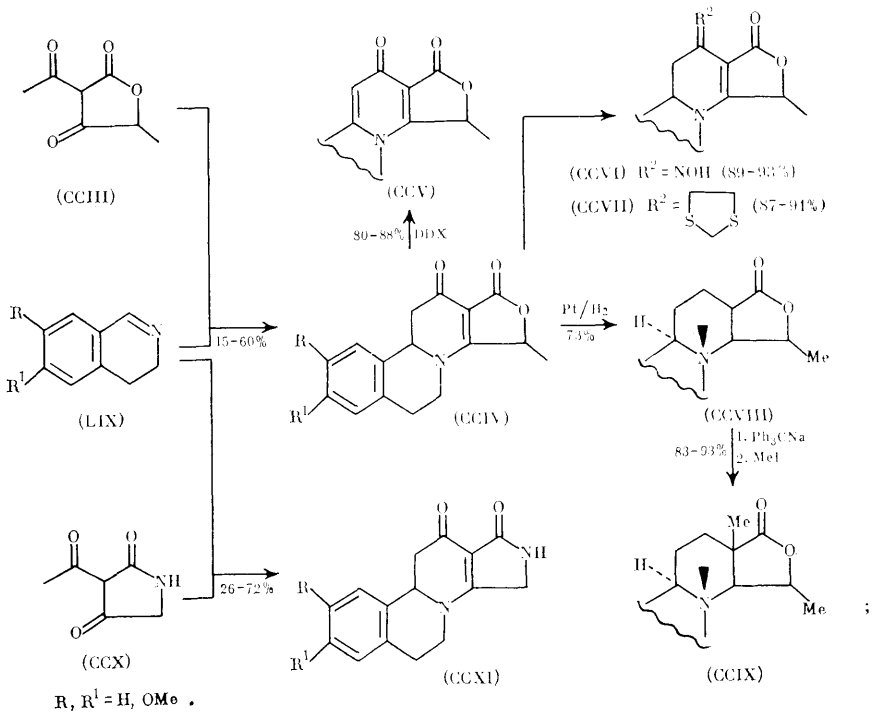
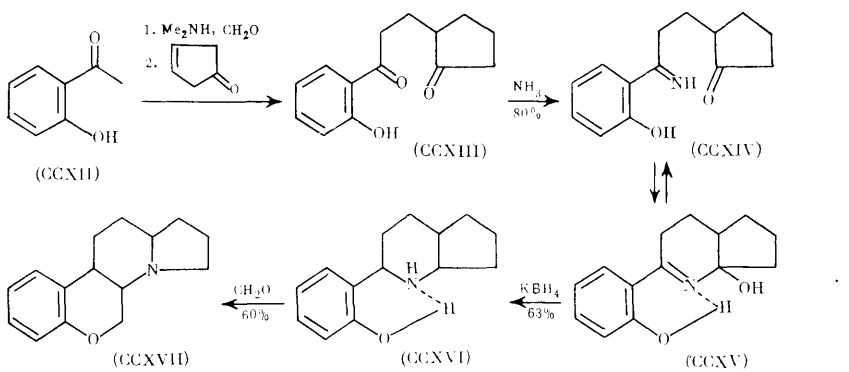
The use of the dihydrodehydroacetic acid derivative (CXCVI) in condensation with 3,4-dihydroisoquinolines (LIX) made it possible to obtain the tetracyclic enaminoketolactones (CXCVII). Like the enaminodiketones (LXIII), these compounds undergo dehydrogenation to form the γ-pyridones (CXCVIII) which are oxidised by monoperphthalic acid to the ε-lactones (CXCIX). Compounds (CXCVIII) have also been obtained by the condensation of 3,4-dihydroisoquinoline *N*-oxide (LXXX) with the acid (CXCVI).[48] The enaminoketolactones (CXCVII) showed a tendency to undergo certain reactions which are uncharacteristic of carbocyclic vinylogul lactams (LXIII). Thus, treatment with alkali in aqueous methanol gives rise to the aminoacetal (CC) whose content in the equilibrium mixture reaches 60%. Treatment of this mixture with methyl iodide in the presence of potassium carbonate in acetone produces the diester (CCI). Reduction of the enaminoketolactone (CXCVII) with tetrahydroborate gives rise to the hydroxypyrone (CCII).

When 3-acetyl-5-methyltetronic acid (CCIII) was condensed with the 3,4-dihydroisoquinolines (LIX), the enaminoketolactones (CCIV) of the 8-aza-16-oxasteroid series were obtained (Scheme 32).[99,100] These compounds are readily dehydrogenated to γ-pyridones (CCV) and give rise to the oximes (CCVI)[100] and thioketals (CCVII)[101] derived from the 12-oxo-group. Under the conditions of catalytic hydrogenation over the Adams catalyst, a mixture of three aminolactones (CCVIII), isomeric with respect to C(13) and C(15), was obtained[102,103] and their stereochemistry was established from infrared and ^{1}H NMR spectroscopic and mass-spectrometric data. Angular alkylation of the resulting aminolactones proceeds with total stereospecificity, producing two derivatives of 8-aza-16-oxaoestrone (CCIX) isomeric with respect to C(15) and having a *cis*-C/D-junction[102]. The 13- and 15-deutero-derivatives of compounds (CCVIII) and the 15-deutero-analogue of compound (CCIX) have been obtained and a mass-spectrometric study has been made of the dependence of the fragmentation and the peak ratios in the mass spectrum on the stereochemistry of the C/D-joined compounds (CCVIII) and (CCIX).[104]



When 3-acetyltetramic acids (CCX) were condensed with the 3,4-dihydroisoquinolines (LIX), 8,16-diazasteroids (CCXI) were obtained (Scheme 32).[105]

6-Oxa-8-azasteroid (CCXVII) was synthesised in 1971 (Scheme 33).[106] For this purpose, the Mannich base obtained by the reaction of acetophenone (CCXII) with dimethylamine



Scheme 31

Scheme 32

Scheme 33

and formaldehyde is condensed with cyclopent-3-enone. The resulting 1,5-diketone (CCXIII) gives rise to the iminoketone (CCXIV) on treatment with ammonia. The solid iminoketone exists in the cyclol form (CCXV). The reduction of the latter with tetrahydroborate results in the formation of the quasisteroid chelate (CCXVI), which gives rise to 6-oxa-8-azasteroid on treatment with formaldehyde.

V. BIOLOGICAL ACTIVITY OF 8-AZASTEROIDS

A common biological activity is not observed for different azasteroids, including 8-azasteroids and in this sense the term "azasteroid" indicates only that these heterocyclic compounds are structurally related. It has been observed that

many 8-azasteroids possess useful therapeutic properties characteristic of natural steroids or absent from the latter. Some 8-azasteroids showed a hormonal activity, but it is usually much lower than that of their carbocyclic analogues. Thus 8-azasteroids are a new class of biologically active compounds which are promising for the creation on their basis of new therapeutic preparations, exhibiting, in contrast to natural steroids, a selective action on the functions of the organism.

Thus compounds of type (XXIV) with an aromatic A ring[107], compounds (LIV),[108] compounds (VIII), compound (IX) and its 17-deoxy-derivatives, as well as their analogues containing double bonds in the 13-, 14-, and 16-positions[109,110] can be useful in the treatment of vascular collapse and serve as anti-shock agents. The hormonal activity of these compounds is insignificant. In particular the 3-methoxy-derivative (LIV, R=Me) exhibits 1/20 of the oestrogenic activity of mestranol,[29] while the oestrogenic activity of 8-azaquinoestrol (LIV), where the 3-methoxy-group has been replaced by the cyclopentoxy-group, does not exceed 1/20 of the oestrogenic activity of oestrone[111,112].

Semi-quantitative estimates of the anti-shock activities of a series of 17-deoxy-derivatives of 8-azasteroids (IX) and their quaternary salts of type (VIII) have been made and certain conclusions have been reached concerning the relation between the structure and activity[11]. Thus, in the case of free bases, phenols (containing OH groups in the 2- and 3-positions) proved to be less active than their methyl ethers, while the opposite relation has been observed for the quaternary salt. In the absence of the angular 13-methyl group, the activity of the methyl ethers of quaternary salts of type (VIII) remains unchanged but it diminishes in the phenolic quaternary salts and increases in the methyl ethers of the corresponding bases.

The 8-azasteroids (XVII) and (XVIII) as well as their analogues containing the 11-acetoxy-group and compound (XIX) can be useful in the treatment of vascular diseases and in endocrinology[113].

The 21-acyloxy-derivatives (XXXIII) exhibit a cardiotonic activity together with a weak hormonal activity[114]. The sulphur-containing 8-azasteroid (XXXII) and quaternary salts have analogous properties[115]. Compounds of types (XX) and (XXI) as well as their quaternary salts exhibit an anti-inflammatory activity in addition to the types of activity indicated above[116].

The sulphoxides of type (XXXI) and their 9(11)-dehydro-analogues possess cardiotonic and anti-fertility activities[117]. The 11-ketoximes of the 8-azasteroids (IX) can be used as anabolic preparations and the 17-amino-derivatives obtained from them are effective in the treatment of vascular collapse[118].

The oximes (XV) as well as their quaternary salts manifest cardiotonic and anti-inflammatory activities together with a hormonal activity, the extent of which has not been indicated[119].

The Δ^4-3-oxo-derivatives of the 8-azasteroids (X), (XI), and (XXIV) as well as their synthetic precursors, formed as a result of the Birch reduction of the aromatic ring, can be used as hypotensive preparations and in the treatment of vascular collapse and other cardiovascular diseases[120]. A hypotensive activity has been observed in the dienamines (LI).[121]

Compounds of type (XXIV) exhibit a gestogenic activity and in the case of compounds with the 13-methyl group this activity amounts to 1/40 of the gestogenic activity of progesterone, while the introduction of the 13-ethyl group increases this activity to 1/2–1.[13,30] A weak oestrogenic activity has been found in the 8-azaoestrone derivatives (IX) and (XLIX).[122]

Derivatives of 8-aza-19-nortestosterone (LIII)[123] and their synthetic precursors with a $\Delta^{5(10)}$-bond[124] exhibit gestogenic, androgenic, and anabolic activities. Thus the 17-ethynyl-13-methyl derivative (LIII) has 1/5 of the gestogenic activity of its carbocyclic analogue norethisterone. The introduction of the 13-ethyl group increases the gestogenic activity and approximately compensates for the decrease of this activity as a result of the introduction of the heteroatom. A weak antiandrogenic activity has been observed in the 17-ethyl derivative (LIII).[29]

The 12-oxo-derivatives of 8-azasteroids (XXXVIII) and their oximes (LXXV) exhibit a psychosedative activity[34]. They are also antidepressants and have been suggested as agents effective against Parkinson's disease[35].

Analgesic activity has been observed in the 8,13-diaza-steroids (CXXIV).[74,125]

The study of the biological activity of 8-azasteroid enaminodiketones of type (LXIII) showed that these compounds exhibit various types of pharmacological activity in the absence of hormonal activity[126]. Among compounds of this type, substances with anti-inflammatory, membrane-stabilising, and antifibrinolytic activities have been discovered[127–129]. Some of them manifest either immunostimulating or immunodepressing activities.

In the series of 8,16-diazasteroids of type (CCXI) and compounds based on them, substances have been found which stabilise the membranes of erythrocytes, the Erlich cells, and lysosomes and exhibit anti-inflammatory, anaphylactic, and cardiotonic activities[105,130].

Among 8-aza-16-oxasteroids of type (CCIV) and their derivatives and D-homo-analogues, compounds with anti-inflammatory, membrane-stabilising, and antifibrinolytic activities have been found[127,131].

During the preparation of the review for the press, new publications on the synthesis and properties of 8-azasteroids appeared. Thus a mass-spectrometric study has been made of the fragmentation and peak intensity ratios in the spectrum as a function of the stereochemistry of the B/C- and C/D-junctions in 12-oxo-derivatives of 8-azasteroids (XXXVIII) (Scheme 10).

The configuration of 12,16-dioxo-derivatives of D-homo-8-azasteroids (LXXXIII) has been studied by NMR (Scheme 11).[133] The signals corresponding to all the protons of the 8-azasteroid skeleton have been assigned and their spin–spin coupling constants have been found. The authors were unable to observe any kind of relation between the stereochemistry of the B/C-junction and the fragmentation in the mass-spectra of the compounds indicated. The deutero-analogues with respect to the C(11), C(15), and C(17) atoms were used.

An unsuccessful attempt at the synthesis of 8-aza-11-thia- and 8,13-diaza-11-thia-steroids has been described[134]. In the course of this investigation, compounds having the C-nor-D-homo-8-aza-11-thiasteroid skeleton were obtained.

A review of the syntheses and biological activities of 8-aza-, 8,16-diaza-, and 8-aza-16-oxa-steroids of types (LXIII) and (LXVII) (Scheme 11) and (CCIV) and (CCXI) (Scheme 32) was published in 1982.[135] The syntheses and biological activities of 8-aza-16-oxa- and D-homo-8-aza-17-oxasteroid enaminolactones, obtained from compounds (CXCVII) (Scheme 31) and (CCVII) (Scheme 32), have been described. It has been shown that these compounds exhibit anti-inflammatory, membrane-stabilising, and antifibrinolytic activities and, in terms of their effectiveness, they are superior to prednisolone without exhibiting a hormonal activity.

Anti-inflammatory, antiallergic, and immunotropic activities have been found in the series of 8-aza-, 8,16-diaza-, and

8-aza-16-oxa-steroids. Some of the data on their biological activity have already been published[141-146].

It has been shown[147] that 8-azasteroids interact with cytochrome P-450, certain kinetic parameters of the oxidation of these compounds by cytochrome P-450 have been investigated, and the characteristics obtained have been compared with the analogous characteristics of natural steroids.

A simple stereospecific synthesis of 8-aza-12-oxasteroids has been proposed[148].

The Oxidation of Haemoglobin

A.E.Myshkin

The literature data on the oxidation of human haemoglobin and the haemoglobin of other vertebrates in the form of complexes with ligands and in the free state are surveyed. The relation between conformational changes in oxyhaemoglobin and the rate of its autoxidation as well as the role of the chemical factors influencing the conformation of the protein, the active centre, and the rate of oxidation of haemoglobin are emphasised.
The bibliography includes 122 references.

CONTENTS

I. Introduction 606

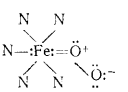
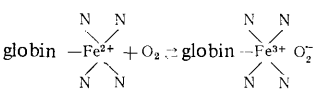
V. The oxidation of haemoglobin under the influence of radiation 620



I. INTRODUCTION

Approximately 3% of the circulating haemoglobin (Hb) is oxidised daily in the blood of the adult human being[1]. The reductase systems in the erythrocyte reduce most of the oxidised haemoglobin. However, under these conditions, the blood contains permanently 1–2% of the oxidised form—methaemoglobin (Hb^+) relative to the total amount of the unoxidised and oxidised forms. The small amount of methaemoglobin in the blood plays a definite physiological role: in particular, methaemoglobin actively binds certain anions (CN^-, OCN^-, SCN^-, N_3^-, etc.) which have a high affinity for iron(III) and are capable of binding the iron in cytochromes and of blocking the respiratory chain of the mitochondria[2,3]. An increase of the concentration of methaemoglobin above 1–2% lowers the oxygen transport function of blood. This state, referred to in clinical practice as methaemoglobinemia, belongs to the class of dangerous pathological conditions and requires treatment when it is sufficiently acute. The causes of methaemoglobinemia can be various: hereditary breakdown of the primary globin structure, the breakdown of the functioning of the methaemoglobin reductase systems in the erythrocyte, and the entry into erythrocytes of methaemoglobin-forming substances of endogenic or exogenic origins. In all these cases, uselessly circulating methaemoglobin accumulates in the blood. The understanding of the mechanism of the oxidation of haemoglobin or more precisely of the oxidation of the haem iron of haemoglobin and the conditions promoting or hindering this process ultimately helps physicians to find ways of preventing or reducing methaemoglobinemia. The aim of the present review is to survey the existing literature concerning various pathways leading to the oxidation of haemoglobin with emphasis on the purely chemical aspects of this process.

In discussing the data, preference is given to human oxyhaemoglobin (if the origin of haemoglobin is not otherwise stipulated, human haemoglobin may be assumed). However, when interesting data of chemical importance are available, the haemoglobins of other vertebrate species are also considered. In a number of instances, deoxyhaemoglobin has been considered (in other words oxidation under anaerobic conditions) as well as other ligand derivatives of haemoglobin. The one-stranded haemoprotein myoglobin (Mb)—the oxygen-accumulating system in the muscle which has many properties in common with haemoglobin—is also considered in certain cases in the present review. Anomalous haemoglobins have not been dealt with because their wide variety and in many instances their unusual properties require their consideration in a special review. The fundamental ideas concerning the structure and functions of haemoglobin are also not described because such data have been frequently dealt with in various reviews, monographs, and textbooks. Sufficiently complete information about these questions in the Russian language can be found, in particular, in the review of Sharonov and Sharonova[4].



II. THE BOND BETWEEN THE HAEM IRON AND OXYGEN

Oxyhaemoglobin (HbO_2) is a diamagnetic complex of haemoglobin with molecular oxygen in which the haem iron formally retains the +2 oxidation state. The diamagnetism and geometry of this complex still constitute a topic which is attracting the attention of investigators. Among many of the models proposed, those of Pauling[5] and Weiss[6] have been most widely adopted. Pauling assumes that the bond between Fe(II) and O_2 is formed with participation of two *d* electrons of Fe(II) and two *p* electrons of the positively charged oxygen atom in the diamagnetic dipole $^+O-O^-$. The remaining four *d* electrons of the iron are located in its two t_{2g} orbitals, iron also being diamagnetic under these conditions. The structure of Pauling's complex can be represented as follows:

where N denotes the four pyrrole porphyrin atoms and one imidazole nitrogen atom of the histidine protein. The use of the isotope hybrid $^{16}O^{18}O$ in a complex with haemoglobin in the study of Raman spectra[17] has confirmed Pauling's model in which the Fe–O–O group forms an angle of 120°.

Weiss[6] assumes that, when the haem iron interacts with molecular oxygen, an electron is transferred from iron to oxygen:

The single unpaired electron of the iron atom in the $(Fe)^5_{1/2}$ state is then paired with the lone electron of the superoxide radical-anion $\dot{O}_2^-$ (henceforth designated simply by O_2^-) imparting diamagnetic properties to the complex. In support of his model, Weiss points out the known similarity

of the absorption spectra of HbO_2 and alkaline methaemoglobin HbOH. The structure of the complex of Hb with O_2 in which the charges are separated was subsequently supported by means of various methods[8-14]. It has been shown[15] that the length of the O–O bond and the frequency of its stretching vibrations in free O_2^- are the same as the analogous parameters of the O_2 ligand in HbO_2. The Raman spectra of HbO_2 and HbCO at 4 °C in the range 200 to 1700 cm^{-1}, obtained on excitation with a laser at a wavelength of 441.6 nm, agreed with the Raman spectra of the low-spin iron(III) complexes in Hb^+.[12] This justified the claim that the iron in HbCO, like that in HbO_2, is in the +3 oxidation state and is bound to the CO^- anion. However, within the framework of Pauling's model, a partial shift of electron density from iron to oxygen is also permissible. Calculations by various workers yielded different negative charges on oxygen: from 0.1 (Olafson and Goddard[16]) to −0.56 (Kirshner and Loew[17]). The calculated temperature dependence of the quadrupole splitting ΔE_Q in the Mössbauer spectrum of HbO_2 constitutes a satisfactory confirmation of Pauling's model[18]. The concept of the decisive role of the rotation of the O_2 bound to iron was used in the calculations. In the chosen model at a low temperature HbO_2 may exist in one of four potential wells of identical depth due to the interaction of the π^* orbitals of O_2 with the d_{xz} and d_{yz} orbitals of iron and the p_z orbitals of the four nitrogen atoms of the porphyrin. According to the calculation, the height of the barriers between the potential wells is 200 cm^{-1}. The calculated temperature variation of ΔE_Q, determined by the rotation of O_2, agrees exactly with the experimental value within the framework of Pauling's model.

An attractive model of the Fe–O_2 bond in HbO_2, having the electronic configuration of ozone, has also been proposed[19]. The formation of the O_2–O bond in ozone takes place without a marked influence on the O–O bond in the initial O_2 molecule. The singlet ground state of O_3 is stabilised by a three-centre four-electron π-bond. The deviation of the angle between the bonds in O–O–O from 90° (117°) can be explained mainly by the repulsion by the doubly occupied p orbitals of the extreme atoms. The following requirements must be met by Fe(II) for the formation of an analogous bond between the latter and O_2: (1) the presence of the d_z orbital with one electron for the formation of a σ-bond with the analogous p_z orbital of O_2; (2) the presence of the d_{xz} orbital with one electron for the formation of a bond with the π-electron system of O_2; (3) the absence of electrons from the d_{xy} orbital, since the latter is strongly antibonding in relation to the nitrogen atoms of the porphyrin (Fe–O_2 is located in the yz plane passing between the two nitrogen atoms of the porphyrin); (4) the location of the four remaining electrons in the $d_{x^2-y^2}$ and d_{yz} orbitals of iron. Finally the electronic configuration of iron in the proposed model of HbO_2 can be expressed as follows:

$$(d_{x^2-y^2})^2\,(d_{yz})^2\,(d_{xz})^1\,(d_{z^2})^1 \quad \text{or} \quad (t_{2g})^5\,(e_g)^1$$

Ab initio calculation for this model leads to a fully unpolarised Fe–O_2 system.

Thus the survey of the literature on the Fe–O_2 bond in HbO_2 leads to the conclusion that there exist sufficiently well-founded data in support of both ionic and covalent models. Since the main haemoglobin–oxygen dissociation process under normal conditions involves the elimination of the neutral O_2 molecule [Eqn.(1)], i.e.

$$HbO_2 \rightleftarrows Hb + O_2\,, \qquad (1)$$

$$HbO_2 \rightleftarrows Hb^+ + O_2^-\,, \qquad (2)$$

but at the same time there is always at least slight autoxidation of HbO_2 which can be formally described by Eqn.(2), it is reasonable to adopt the covalent bond between O_2 and Hb as the most probable, in conformity with Pauling's model or another similar model, where there is a partial transfer of electron density from iron to oxygen. In other words, it is logical to assume that under normal conditions the contribution of the $Fe^{3+}O_2^-$ structure to the bond between the haem iron and O_2 is fully realistic. However, the concept of a non-polar but effectively polarisable Fe–O bond, in which a negative charge is readily transferred to oxygen under conditions promoting the oxidation of the haem iron is also permissible.

It is likewise essential to note that, if there is an integral negative charge on the oxygen of HbO_2, this does not imply that the iron is in the +3 oxidation state, since the porphyrin system has a considerable capacity for compensating the electron deficiency at the central metal ion. It is difficult to infer the true oxidation state of iron in HbO_2 on the basis of all the available data. Therefore, designations such as Fe^{2+} and Fe^{3+} are in this instance extremely arbitrary and are more in the nature of descriptive symbols[20].

III. THE AUTOXIDATION OF OXYHAEMOGLOBIN

In conformity with the Eqn.(2) presented in the preceding Section, the simplest pathway leading to the oxidation of the haem iron is the dissociation of HbO_2 with the heterolytic rupture of the Fe–O bond. If the medium contains no oxidants other than oxygen molecules under these conditions, then such HbO_2 oxidation is referred to as autoxidation. The autoxidation can be facilitated by agents capable of interacting with O_2 and HbO_2 (reductants of all kinds) or of abstracting O_2^- (protons). Depending on the pH of the medium, the mechanism of the autoxidation of HbO_2 can vary significantly. It is therefore useful to consider this process separately in neutral, acid, and alkaline media.

1. The Autoxidation of HbO_2 in a Neutral Medium

It is known that HbO_2 is gradually modified on storage in neutral aqueous solutions and that one of the main characteristics of this process is the oxidation of HbO_2 to methaemoglobin. However, the low rate of oxidation of HbO_2 at temperatures $\leq$40 °C, where the thermal denaturation of the protein promoting the autoxidation does not play a significant role, hinders the systematic study of the autoxidation of HbO_2 in neutral media. It has been noted[20] that, in the autoxidation of HbO_2 in a neutral buffer, the maximum on the Soret band shifts from 412 to 405 nm, the intensity of the 541 and 575 nm band falls, and a band at 500 nm, characteristic of Hb^+, appears. It has been noted further that the oxidation of HbO_2 is accompanied by its degradation: the band at 280 nm is smoothed out. All these changes are accelerated in a more dilute HbO_2 solution (1.3×10^{-5} M) in which part of the HbO_2 is dissociated into dimers. It has been suggested[20] that the autoxidation of HbO_2 is accelerated by the hydrogen peroxide formed in the reaction, which has been confirmed by special experiments with added catalase, capable of decomposing H_2O_2, which inhibited the autoxidation of HbO_2.

The study of the kinetics of the autoxidation of HbO_2 in 0.1 M phosphate buffer at pH 7.2 showed that the reaction consists of two stages in which the rate constants for the individual stages are 0.032 h^{-1} (degree of reaction ~50%) and 0.0037 h^{-1}. Measurements were also made for the kinetics of the autoxidation of isolated chains under

analogous conditions at 25 °C. The rate constants for the autoxidation of the α- and β-chains proved to be 0.025 and 0.009 h^{-1}, which served as a basis for the assumption that the α- and β-subunits of HbO_2 are oxidised preferentially in the rapid and slow stages respectively. The latter was confirmed by the separation into the individual chains of ~30% oxidised HbO_2 after its treatment with CO and KCN: the isolated α-chains contained 53% of the cyanomet-form, while the β-chains contained only 5% of this form. The different tendencies of the α- and β-subunits of HbO_2 towards autoxidation enabled the authors to suggest that the transition $\alpha_2\beta_2 \rightarrow \alpha_2^+\beta_2^+$ proceeds via the intermediate semi-oxidised form $\alpha_2^+\beta_2$. The reduction of the partial pressure in the system from 57 to 40.5 mmHg increased the rate of autoxidation of mainly the β-chains.

The influence of the Cl^-, F^-, and N_3^- anions on the rate of autoxidation of HbO_2 has been studied at pH 7.4 and 37 °C.[22] The authors suggest that the mechanism of the autoxidation involves in this case the nucleophilic substitution of O_2^- by the corresponding anion. In contrast to the data of Shtamm et al.[20], single-stage oxidation kinetics were observed in this case. At a concentration of the anions of 0.1 M and an ionic strength of 0.5 (in the presence of added sulphate), the rate constants in the presence of Cl^-, F^-, and N_3^- were respectively 0.0229, 0.0348, and 0.175 litre $mole^{-1}$ h^{-1}. At the same time the E_{act} were found to be 32 kcal $mole^{-1}$ for the chloride anion and 26.8 kcal $mole^{-1}$ for the azide anion. Analogous studies by the same workers were carried out in the pH range from 5 to 9.3.[23] The activity sequence was established for a wider range of anions: $N_3^- > SCN^- > OCN^- > F^- > Cl^- > Br^-$. A mechanism was proposed in which the nucleophilic substitution by the superoxide anion by other anions is promoted by the attack of the proton on the oxygen bound to the iron. The low rate of the process compared with the rate of substitution at the haem iron of ligands such as N_3^-, OCN^-, and F^- is explained by the relatively low polarity of the Fe–O_2 bond and the necessity for additional energy to achieve its polarisation. The authors explained the decrease of the rate of autoxidation on passing from an acid to a neutral medium by the decrease of the concentration of the protons interacting with FeO_2.

The mechanism proposed[22,23] for the nucleophilic substitution of O_2^- by other anions is fairly convincing only for the azide anion, whose effect is greatly superior to those of the other anions. The virtual absence of this effect for HbCO (in this case nucleophilic substitution would have involved the unlikely elimination of CO^-) constitutes confirmation of this mechanism for the azide. The linear dependence of the pseudo-first order rate constant on the azide concentration is quoted as another piece of evidence. The absence of a similar linearity for the chloride anion throws doubt on the mechanism of the nucleophilic substitution of O_2^- by the chloride anion as well as other halide anions. According to the above data[22,23], the activity of the halide anions increases from bromide to fluoride in order of decreasing nucleophilicity of these anions in an aqueous medium (contrary to the authors' claim). However, the main objection is the possibility of non-specific and specific interactions of the anions with the protein, in particular in the region of the fixation of DPG, as a result of which the conformational equilibrium $R \rightleftharpoons T$ for HbO_2 is displaced to a greater or lesser extent towards the T-conformation, which can significantly increase the tendency of HbO_2 towards autoxidation. The influence of anions on HbO_2 has been discussed in detail[24].

Whereas the possibility of the nucleophilic substitution of the superoxide anion by salt anions as the sole pathway leading to the autoxidation of HbO_2 in the presence of salts is doubtful, the formation of O_2^- in the reaction medium in the autoxidation of HbO_2 has been quite reliably established. In particular, it has been observed that in the autoxidation of HbO_2 [25] the rate of reaction is inhibited to one-third by catalase. On the other hand, superoxide dismutase, which disproportionates O_2^-, inhibits the autoxidation only slightly. This has led to the conclusion that the O_2^- formed in the system is rapidly converted into H_2O_2, which is actively involved in the oxidation of HbO_2, ensuring its conversion into the oxidised form to the extent of one-third. An analogous effect has been observed also in the autoxidation of human HbO_2.[26]. In this case the reaction was carried out in 0.067 M phosphate buffer at pH 7.4 with added EDTA (to bind traces of Cu^{2+}) at 37 °C. A mechanism involving the following stages has been proposed:

$$\text{Fe (II) } O_2 \rightarrow \text{Fe (III)} + O_2^-,$$
$$\text{Fe (II) } O_2 + O_2^- + 2H^+ \rightarrow \text{Fe (III)} + O_2 + H_2O_2,$$
$$\underline{2\text{Fe (II) } O_2 + H_2O_2 + 2H^+ \rightarrow 2\text{Fe (III)} + 2O_2 + 2H_2O},$$
$$4\text{Fe (II) } O_2 + 4H^+ \rightarrow 4\text{Fe (III)} + 3O_2 + 2H_2O.$$

It follows from the above scheme that O_2^- participates actively in the autoxidation of HbO_2. This has been confirmed by the results of another study[27], whose authors suggest that O_2^- gives up one electron to the oxygen in HbO_2, after which the partially reduced oxygen [the superoxide anion bound to Fe(II)] abstracts a second electron from Fe(II) and binds two protons to form H_2O_2. In the native erythrocyte this process does not apparently play an appreciable role, since the concentration of superoxide dismutase in the native erythrocyte is ten times higher, according to the authors' estimate[27], than the concentrations sufficient for the complete suppression of the oxidative effect of O_2^-. The direct involvement of O_2^- in the oxidation of HbO_2 has also been confirmed for a system where O_2^- was generated by the oxidation of xanthine catalysed by xanthine oxidase[28]. The following reactions are postulated in this instance:

$$2H^+ + O_2^- + \text{Fe (II) } O_2 \rightarrow \text{Fe (III)} + H_2O_2 + O_2,$$
$$O_2^- + \text{Fe (III)} \rightarrow \text{Fe (II) } O_2,$$
$$2O_2^- + 2H^+ \rightarrow H_2O_2 + O_2.$$

It has been established that in a neutral medium the first of the above reactions is suppressed by the third after the attainment of an O_2^- concentration $>10^{-5}$ M. In a study with isolated chains[21] a higher rate of the autoxidation of the α-chains (0.025 h^{-1} at 25 °C) compared with the β-chains (0.009 h^{-1}) was observed. It was suggested that the valence hybrids $\alpha_2^+\beta_2$ are formed as intermediates in the autoxidation of HbO_2. This implies that, for example, in the observed 20% oxidation of HbO_2, 40% of the HbO_2 molecules are actually involved in the oxidation process. According to Tomoda et al.[29], in the autoxidation in 0.01 M phosphate buffer at pH 6.6–7.8 the rate constants for the formation of $\alpha_2^+\beta_2$ and $\alpha_2\beta_2^+$ are respectively 2.2×10^{-2} h^{-1} and 1.88×10^{-2} h^{-1}. The addition of inositol hexaphosphate (IHP) accelerated the oxidation of both subunits approximately by a factor of two in this instance.

The formation of valence hybrids in the autoxidation of haemoglobin can have serious physiological consequences. Analytic isoelectrofocussing in a polyacrylamide gel of the haemolysates of the blood of patients suffering from methaemoglobinemia with a more than 20% Hb^+ content revealed the presence of three fractions: HbO_2, Hb^+, and partly oxidised Hb.[30] The amount of the last fraction was 35–50% of the total amount of the haemoprotein. Thus the determination of the oxidised haemoglobin by the generally accepted Drabkin method yields the concentration of the oxidised haem, but not the amount of the haemoglobin tetramers involved in the oxidation. The increased affinity for oxygen and the almost total absence of cooperative

behaviour are characteristic of the valence hybrids (analogous data have also been obtained in another study[31]). The last two factors significantly impair the oxygen transporting capacity of the blood in patients suffering from methaemoglobinemia.

There are data[32] for the autoxidation of HbO_2 in the blood plasma at pH 7.5 and 37 °C. The results of the study of Mansouri and Winterhalter[21] have been confirmed: the decrease of the oxygen partial pressure in the blood plasma from 126 to 23 mmHg increased severalfold the rate of autoxidation of HbO_2.

The study using the HbO_2 from the frog *Rana esculenta*[33], chosen because of its high lability with respect to autoxidation, established that the rate of oxidation of this oxyhaemoglobin in 0.01 M phosphate buffer at pH 7.0 is significantly influenced by the heavy metal ions present in the buffer. The addition of EDTA greatly decreased the rate of autoxidation in this instance. In the absence of heavy metal ions, 7% of HbO_2 was found to be oxidised after 1 h at 2 °C and at an initial HbO_2 concentration of 1.5×10^{-5} M, whereas in the presence of added 10^{-4} M metals, the following amounts of oxidised HbO_2 were found: 28% for Cu, 16% for Zn, 5% for Sn, 11% for Fe, 14% for Cr, 18% for Mn, 16% for Hg, 11% for Pb, 17% for Co, 13% for Cd, and 20% for Ni. In particular, it was established that copper forms complexes with the imidazole groups of histidine and causes the denaturation of the protein, which is reversible in the presence of EDTA. The catalytic effect of heavy metals was also noted in the autoxidation of sperm whale or ox oxymyoglobin (MbO_2) in various buffers[34]. An equimolecular amount of Cu(II) accelerated in this case the oxidation by a factor of 25. The accelerating effect of Cu(II) on the autoxidation of the sperm whale MbO_2 at pH 5.0 [35] is explained by the binding of Cu(II) by the GH1 histidine, which interacts with haem and accelerates the delocalisation of the valence electron of the iron. According to the authors, this electron may fall into the potential well of the acceptor (the O_2 in the medium or Cu^{2+}) when the latter forms a complex in the region of His GH1.

It has been noted[36] that at pH 7 (0.05 M tris buffer) the addition of $ZnCl_2$, $PdCl_2$, and $CdCl_2$ did not entail spectroscopic changes in the HbO_2 solution, whereas the addition of $FeCl_2$, $FeCl_3$, $CuCl_2$, and $HgCl_2$ did lead to spectroscopic changes and the formation of a precipitate. It is remarkable that the presence of EDTA, which suppresses the effect of Cu(II), does not interfere with the oxidative activity of Fe(II) and Fe(III).

Apart from the study[35] quoted above, there exists a fairly extensive literature on the autoxidation of MbO_2. The exact determination of the amount of free O_2 evolved on formation of Mb^+ is important for the understanding of the mechanism of the autoxidation of MbO_2.[37] It has been shown that only 20% of the O_2 bound in MbO_2 (in the ox and sperm whale) is converted into water, while 75% is evolved in a free state. This suggested the following simple mechanism:

$$MbO_2 \rightleftarrows Mb + O_2 ,$$
$$Mb + H^+ + {}^1/_4 O_2 \rightarrow Mb^+ + {}^1/_2 H_2O .$$

This mechanism was confirmed by the dependence of the rate of autoxidation of MbO_2 on the O_2 concentration and the pH observed by the authors[37]: at pH 7 the autoxidation rate constants were found to be inversely proportional to $[O_2]$ and their logarithms increased linearly as the pH was reduced from 7 to 5. More detailed studies made it possible to elaborate further the above mechanism by including in the latter the intermediate O_2^- and H_2O_2 as oxidants[26]:

$$MbO_2 \rightarrow Mb^+ + O_2^- ,$$
$$MbO_2 + O_2^- + 2H^+ \rightarrow Mb^+ + O_2 + H_2O_2 ,$$
$$2MbO_2 + H_2O_2 + 2H^+ \rightarrow Mb^+ + 2O_2 + 2H_2O .$$

An unusual point of view concerning the possible mechanism of the autoxidation of HbO_2 has been put forward by Banerjee and Stetzkowski[38], who induced the autoxidation of HbO_2 by adding high-molecular-weight polypeptides obtained by the decomposition of horse heart Mb. In this case the transfer of haem from the haem pocket to the peptide was observed with formation of haemochrome. Peptides which readily bind ferrohaem, while the binding of ferrihaem is poor, are the most effective in the autoxidation of HbO_2. The following chain of transformations takes place in this case: the emergence of ferrohaem from the haem pocket, the binding of ferrohaem to the new ligand, the oxidation of ferrohaem, and the return of ferrihaem to the haem pocket. The process proceeds at the maximum rate when the haemoglobin is half-saturated by oxygen and is suppressed when its saturation is complete. Thus the autoxidation of HbO_2 in a neutral medium can be due to the oxidation of partly dissociated deoxyferrohaems derived from Hb in equilibrium with HbO_2. The initial ideas about the mechanism of the autoxidation of HbO_2 have been described in a monograph by Blyumenfel'd[39], who investigated the transfer of haem from haemoglobin to gelatin (the haem transfer reaction). However, in the absence of external ligands promoting the emergence of haem from the haem pocket, the haem dissociation mechanism of autoxidation gives rise to certain doubts bearing in mind that the α-subunits in HbO_2 are oxidised more readily than the β-subunits, while the bond between haem and the globin is stronger in the former than in the latter[21].

An approach to the understanding of the intimate mechanism of the autoxidation of HbO_2 in a neutral medium can be achieved by comparing this process with the autoxidation of protein-free iron(II) complexes. The principal possible mechanisms have been discussed in a review[40]. The simple bimolecular interaction

$$Fe(II) + O_2 \rightarrow Fe(III) + O_2^-$$

is an endothermic process and can hardly serve as a model of the main pathway in the autoxidation of HbO_2. The following scheme is more likely on energy grounds:

$$Fe(II) + O_2 \rightleftarrows Fe(II)O_2 ,$$
$$Fe(II)O_2 + Fe(II) \rightleftarrows Fe(II)O_2Fe(II) ,$$
$$Fe(II)O_2Fe(II) \rightarrow 2Fe(III) + O_2^{2-} \text{ etc.}$$

However, whereas this scheme is suitable for the porphyrin complexes of iron(II), in the presence of a protein environment the formation of a dimer is improbable. Finally, the process involving the transfer of an electron from the medium to the oxygen bound to iron(II) may play a definite role. This can be represented in the following scheme:

$$Fe(II)O_2 + H \rightarrow Fe(II)O_2H ,$$
$$Fe(II)O_2H \rightarrow Fe(III) + HOO^- .$$

However, this process too is relatively ineffective for HbO_2, since the O_2 in the haem pocket is protected from reductants by the distal histidine. There exists the view that the high oxidation-reduction potential of haemoglobin (+0.2 V at pH 7.0) is in fact largely due to this histidine[41].

2. The Autoxidation of HbO_2 in an Acid Medium

In a neutral HbO_2 solution there is a tetramer–dimer equilibrium [Eqn.(3)] which is largely displaced towards the tetrameric form of HbO_2 ($\alpha_2\beta_2$):

$$\alpha_2\beta_2 \rightleftarrows 2\alpha\beta \qquad (3)$$

A deviation of the pH of the solution from neutrality shifts the equilibrium towards the dimers. Even in a weakly acid medium (pH < 6) the concentration of the dimers is appreciable[42]. At pH < 4 considerable structural changes take place and are normalised by the prototropic groups masked in the protein. These include 18 of the 38 imidazole groups present in haemoglobin[43]. Dilatometric studies[42] have shown that at relatively high pH in the acid medium the volume of HbO_2 is somewhat increased, which is characteristic of globular proteins capable of being protonated. However, the protonation of HbO_2, starting from pH 4.5, results in a sharp decrease of the volume, which the authors explain by the intensified dissociation of HbO_2 into dimers.

The structural changes in carboxyhaemoglobin[45], whose conformation and properties are very close to those of HbO_2, have been investigated in detail in the pH range 3.3–1.8. It was noted that at pH > 3 the protein is uncoiled, while the haem remains bound to the native sections of the protein, although its environment is altered. At pH < 3, the structural changes in the protein are more significant: the uncoiling of the protein is accompanied by a considerable decrease of absorption in the region of the Soret band (there is a change in the character of the binding of haem) and also by the disappearance of the anomalous dispersion of the optical rotation and a change in absorption at 269 nm, both associated with the uncoiling of the protein globule. At pH < 2.1 almost all the haem is dissociated. In this case, the kinetics of the spectroscopic changes are independent of pH. It has been noted[46] that the absorption spectrum of the product of the denaturation of HbCO at pH 1.95 depends on the denaturation temperature (from 0° to 25 °C). The authors explain this by the splitting off of haem from the denatured product and its addition to another site in the protein, whose position depends on the process temperature. When the denaturation is carried out at pH 3.2, this type of temperature dependence of the process is not observed, which indicates the stability of the native bond between haem and globin at this pH.

The autoxidation of HbO_2 at a concentration of $\sim 3 \times 10^{-5}$ M has been investigated[47,48] in an acid medium at pH from 5.6 to 4.0 in the presence of various amounts of alkali metal salts. In all cases 0.1 M sodium acetate buffer solution was employed. The reaction rate constants, determined spectrophotometrically (at 576 nm), were mainly satisfactorily calculated in terms of a first-order process up to a considerable extent of reaction. The decrease of pH from 5.6 to 4.0 was accompanied by a linear increase of the logarithm of the rate constant. This justifies the attribution of the change in the activity of the protons of the medium in the above pH range to the same linearly varying factor. The observed linearity indicates a qualitative constancy of this factor as the activity of the proton is increased down to pH 4.0. This factor may be the conformational changes in the protein of HbO_2, which increases the lability of HbO_2 with respect to autoxidation. At the same time, these changes increase the degree of dissociation of HbO_2 into dimers and monomers. In the general case the dissociative-associative equilibrium for HbO_2 in various aqueous media is expressed by Eqn.(4), which supplements Eqn.(3), given above, by allowing for the possibility of the formation of monomers in the system:

$$\alpha_2\beta_2 \rightleftarrows 2\alpha\beta \rightleftarrows 2\alpha + 2\beta \,. \qquad (4)$$

Close to physiological conditions, reliable data concerning any kind of appreciable dissociation of haemoglobin into monomers are lacking, but monomers are detected when the deviation from neutral pH is considerable[49]. On the other hand, it is known that in a neutral medium chlorides increase the tendency of the monomeric subunits towards self-association[50,51] and the formation of the $\alpha\beta$ dimers[52]. Neglecting the possible difference between the rates of autoxidation of the α- and β-subunits, one can formulate a more general expression for the rate of oxidation of HbO_2:

$$\omega = -\frac{d[HbO_2]}{dt} = k_{obs}[HbO_2] = k_4[\alpha_2\beta_2] + k_2[\alpha\beta] + k_1[\alpha + \beta] \,, \qquad (5)$$

where k_4, k_2, and k_1 are the rate constants for the autoxidation of the tetramers, dimers, and monomers respectively and $[\alpha_2\beta_2]$, $[\alpha\beta]$, and $[\alpha + \beta]$ are the concentrations of the tetramers, dimers, and monomers respectively in terms of haem.

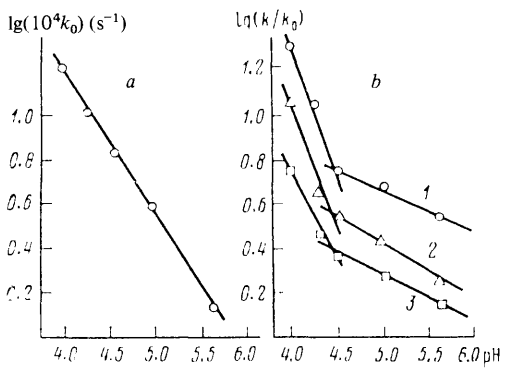


Figure 1. The pH dependence of the logarithm of the rate constant k_0 for the autoxidation of HbO_2 in the absence of chlorides (*a*) and the logarithms of the relative rates in the presence of KCl (*b*); $[HbO_2]_0 = 3 \times 10^{-5}$ M, 40 °C:[48] *1*) 0.333 M; *2*) 0.166 M; *3*) 0.083 M.

While the dependence of the rate of autoxidation of HbO_2 on the pH in the pH range 5.6–4.0 has no characteristic points[48], in the presence of alkali metal chlorides at concentrations up to 0.33 M, the pH dependen e of the logarithm of the rate constant has a sharp break at pH 4.5 (Fig.1). Presumably, there is a break in the curve for the pH dependence of the degree of tetramer–dimer dissociation at this pH in the presence of chlorides. The significant role of the chloride ion can be explained in this instance in the following manner. In the absence or at a low concentration of anions, the gradual increase of the activity of protons increases the number of protonated prototropic groups mainly in the imidazole and carboxylate residues. The accumulation of positive charges in the region of the α^1–β^2 contact increases the Coulombic repulsion of the dimers and gradually shifts the tetramer–dimer equilibrium to the right. In the presence of an electrolyte, the ionic strength of the medium at relatively high pH in the acid region intensifies the hydrophobic interactions between the dimers in the tetramers and to a certain extent prevents the dissociation of the latter (entropy factor). However, after the attainment of a certain level of protonation of the protein (tentatively in the region of pH 4.5), the region of the α^1–β^2 contact becomes readily accessible to the salt anions

as a result of the Coulombic repulsion of the dimers, the anions being directed to the positive charges on the protein mainly without loss of the hydration shell. Furthermore, as the protein is protonated its hydrophobic character diminishes. As a result of all these features, the role of the salt as a factor intensifying the hydrophobic interactions in the protein diminishes in a certain pH range, and the hydrated anions of the medium actually acquire the ability to enter the region of the contact between the $\alpha^1\beta^1$ dimers, destabilising the tetrameric structure. The simultaneous operation of these factors is apparently actually responsible for the appearance of a distinct break in the dependence of the rate of reaction on the pH in the presence of alkali metal chlorides. The dissociation of the $\alpha^1\beta^1$ dimers into monomers, which is possible at pH < 4.5 sharpens the break at pH 4.5. Speaking of the possible dissociation into monomers, the present author and Chundinova[47] emphasised that it is not obligatory to assume the formation of monomers separated by the medium when the "dissociative" influence of the pH on the autoxidation of HbO_2 is discussed: the cause of the strong effects on the autoxidation of HbO_2 can be also the weakening of the $\alpha^1-\beta^1$ contact as a consequence of the conformational changes in the monomers forming part of the dimers, preceding and determining the dissociation of the latter into monomers.

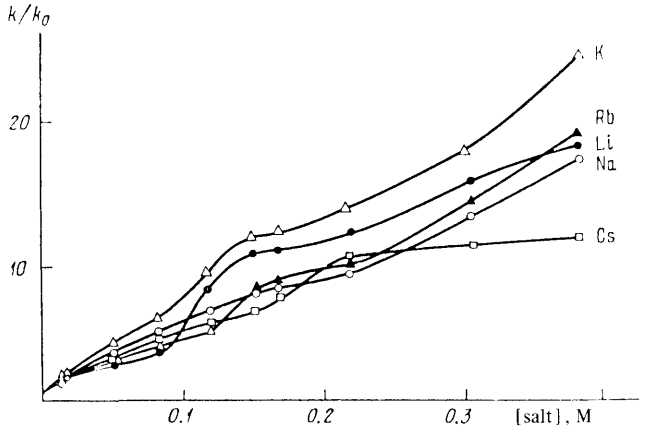

Figure 2. Dependence of the rate of autoxidation of HbO_2 on the concentration of alkali metal chlorides at pH 4.0 and 40 °C; $[HbO_2]_0 \cong 3 \times 10^{-5}$ M (in terms of haem).[47]

It has been established[47,48] that salt cations in an acid medium exert a very distinct influence on the rate of autoxidation of HbO_2. Fig.2 illustrates the curves for the dependence of k/k_0 (where k_0 is the rate constant in the absence of added salt) on the salt concentration for alkali metal chlorides at pH 4.0. The potassium cation is the most active and the caesium cation is the least active at concentrations above 0.25 M. At pH 5.6 the difference between the effects of the individual cations is more appreciable and in this case caesium is also the most passive. At pH 4.0 differences were also demonstrated between the effects of a series of anions. Fig.3 shows that the anions form the following sequence in terms of their accelerating effect on the autoxidation of HbO_2: $F^- < Cl^- < Br^- < I^- < ClO_4^-$.

This sequence is almost identical with Hofmeister's classical lyotropic series. The arrangement of the anions in conformity with the lyotropic series had been observed earlier for the dissociation of HbCO into dimers in a neutral medium under the influence of different sodium and potassium salts[54]. The closeness of the dissociation series to the series of anions in terms of their accelerating effect on the autoxidation of HbO_2 confirms the hypothesis[47,48] that there is a definite similarity between the mechanisms of the processes leading to the dissociation of HbO_2 into dimers and monomers and to its autoxidation.

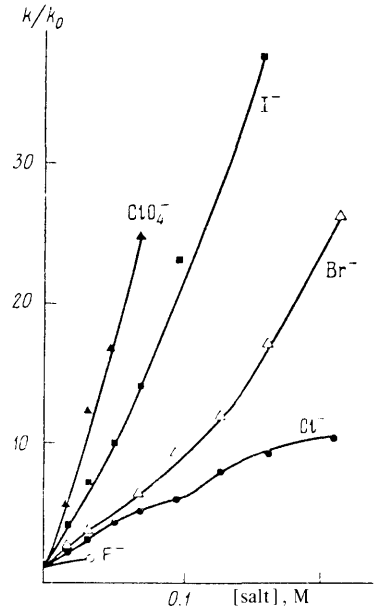

Figure 3. The influence of the sodium salt concentrations on the autoxidation of HbO_2 at pH 4.0 and 40 °C; $[HbO_2]_0 \cong 3 \times 10^{-5}$ M, $k_0 = (11.9-15.6) \times 10^{-4}$ s^{-1}.[47]

The influence of the nature and concentration of a series of carboxylate buffer anions on the autoxidation of HbO_2 has been investigated[55]. It has been observed that at pH 5.6, where HbO_2 is mainly tetrameric, and at pH 4.0, where HbO_2 exists preferentially in the form of dimers, the character of the influence of different carboxylate ions is significantly different. Fig.4 presents a plot of the logarithms of the rate constants for the autoxidation of HbO_2 at 40 °C against the molarity of the buffer. At pH 5.6 carboxylates can be clearly divided into three groups: alkanoates, chloroacetate (in the presence of which the reaction is 4–8 times slower than in the presence of alkanoates), and citrate, which gives rise to a complex concentration dependence. It is seen that small amounts of added alkanoates (up to ~0.2 M) have the most appreciable effect on the autoxidation of HbO_2. The chain length of the alkanoic acid has almost no influence on the effect under these conditions. At pH 4.0 the picture is different. If account is taken of the degree of dissociation of the alkanoic acids at this pH, then the alkanoates give rise to an almost linear dependence of the logarithm of the rate constant in the sequence formate < acetate <

propionate < butyrate, the rate in the presence of the butyrate, when the molarity of the buffers is 0.2 M, exceeding approximately by a factor of 15 the rate in the presence of the acetate. Hence it follows that, under conditions where HbO_2 is almost fully dissociated into dimers, non-polar agents modify extremely effectively the structure of HbO_2, rendering it significantly less resistant to autoxidation, which is not observed for the tetrameric structure of HbO_2 (pH 5.6). Consequently, the tetrameric HbO_2, whose outer surface is mainly hydrophilic, is relatively insensitive to non-polar agents, while the dimeric HbO_2, which has an open $\alpha^1-\beta^2$ contact surface with large hydrophobic sections, is extremely sensitive to non-polar agents.

Parameters of the Arrhenius equation for the oxidation of the sperm whale MbO_2 in 0.015 M tris–phosphate buffer[57].

pH	$t = 10-20°$			$t = 25-35°$		
	$\Delta G^{\neq}_{20}$	$\Delta H^{\neq}$	$\Delta S^{\neq}$, e.u.	$\Delta G^{\neq}_{29}$	$\Delta H^{\neq}$	$\Delta S^{\neq}$, e.u.
5.0	3.59	6.4	9.6	3.48	20.8	59.1
5.4	3.72	6.8	10.5	3.63	22.0	62.7
5.8	3.66	9.2	18.9	4.05	26.0	74.9
6.0	3.98	11.6	26.0	4.20	29.6	86.7
6.4	4.49	19.2	50.2	4.65	37.2	111.1
6.8	5.33	28.8	80.1	5.06	44.0	132.9

Measurements have been made for the kinetics of the denaturation of horse HbO_2 in the pH range 3.6–2.4 at 0 °C.[56] With decrease of pH in the above range, the first-order rate constant increased exponentially. Comparing this finding with the data of the present author and Chudinova[48], one can assume that, in the absence of an excess of salts, the denaturation and autoxidation processes (stimulated in all probability by the same factors), involving HbO_2 from different species, are proportional to the activity of the protons over a fairly wide pH range in the acid region.

Data on the autoxidation of ox MbO_2 at pH 7.0–5.0 [37] provide some justification for extending this pH range to 7.0. At the same time, it must be emphasised yet again that the "dissociative" mechanism of the autoxidation of HbO_2 formulated above presupposes conformational changes in the protein preceding the dissociation of the haemoglobin into subunits and not the dissociation itself. The character of these changes is apparently mainly the same as for the one-stranded myoglobin, which is confirmed by the linear dependence of the rate constant for the autoxidation of MbO_2 on the activity of protons[37].

The main parameters for the oxidation of the sperm whale MbO_2 have been determined in the pH range 7–5 in 0.015 M tris–phosphate buffer[57]. A linear dependence of the quantity $\lg [V/(1 - V)]$, where V is the Mb^+ concentration at a specific instant during the initial period of the reaction, on the pH was observed at 35 °C. Bearing in mind that the slope of this relation is two, the authors suggested that the autoxidation of MbO_2 is catalysed by the protonation of two histidine residues. The curve for the temperature variation of the rate of reaction has a break between 20° and 25 °C. The parameters of the Arrhenius equation observed at different pH are listed in the Table. The difference between these parameters for the temperature ranges 10–20° and 25–35 °C provided the authors with the grounds for the claim that there are two mechanisms of the autoxidation of MbO_2. It has been observed that the dependence of $\ln k$ on $\sqrt{I}$ (I is the ionic strength of the solution) at different temperatures is a minimum at $\sqrt{I} \cong 0.2$. The decrease of the rate of autoxidation of MbO_2 with increase of the ionic strength of the solution up to $I = 0.04$ is explained by the authors by the shielding of the positively charged groups of the protein, which are important for the autoxidation of MbO_2.

In conclusion of this Section, one can briefly formulate the principal possible causes of the acceleration of the autoxidation of HbO_2 in acid media. These may be (1) the conformational changes induced by the protonation of the weakly basic centres of the protein accompanied by the tetramer–dimer and dimer–monomer dissociation; (2) the protonation of the distal histidine, which enhances the hydrophilic properties of the haem cavitity, which can

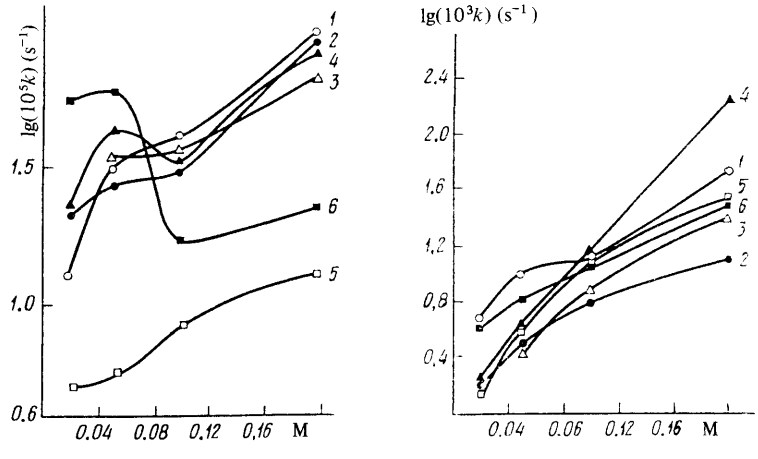

Figure 4. Dependence of $\lg k$ for the autoxidation of HbO_2 on the molarity of the buffer systems at 40 °C and $[HbO_2]_0 \cong 3 \times 10^{-5}$ M: *a*) pH 5.6; *b*) pH 4.0; *1*) formate buffer; *2*) acetate buffer; *3*) propionate buffer; *4*) butyrate buffer; *5*) chloroacetate buffer; *6*) citrate buffer[55].

facilitate the approach of the anions from the external medium to the iron and the emergence of O_2^-; (3) the protonation of the O_2 bound to the iron which promotes the electron transfer from Fe(II) to O_2 with subsequent elimination of HOO$^{\cdot}$.

3. The Autoxidation of HbO_2 (and the Oxidation of HbCO)

The mechanism of the action of alkali on haemoglobin has been most fully investigated by Perutz[58]. The main ideas reduce to the following. The free energy of the spherical polyelectrolyte is proportional to the square of its purely surface charge, as a consequence of which the stability of the polyelectrolyte diminishes on either side of the isoelectric point during the discharge of the cationic or anionic groups. Titration with acid or alkali can ionise the weak acids or bases concealed in the non-polar nucleus. After ionisation, these groups attract the hydration shell, which alters the native structure of the protein and shifts the equilibrium towards the uncoiled form. Three haemoglobins have been compared: human haemoglobin A, foetal haemoglobin (F), and ox haemoglobin. In 0.1 M NaOH at 20 °C, HbCO(A) is denatured in 20 s and HbCO(F) is denatured after 12 min, while the denaturation of the ox HbCO in 0.5 M NaOH has a 3 h half-decomposition period. Furthermore, it is known that all three haemoglobins dissociate into dimers at pH > 10. Hence follows the conclusion that the dissociation into dimers is reversible and does not constitute denaturation in the strict sense of the term. After the attainment of pH 11.6, the HbCO(A) dimers are cleaved and denatured, while the dimers of the two remaining HbCO are denatured only under more severe conditions. It has been suggested that this stage is in fact rate-limiting. Detailed analysis of the aminoacid composition of the three haemoglobins and comparison of the pK_a of various aminoacid residues led Perutz to the following conclusion: the cause of the instability of HbA in alkali is the presence in the latter in the region of the $\alpha^1-\beta^1$ contact of two Cys (G11α and G14β) units and also of Tyr H8β. In water the pK_a of the sulphhydryl groups of cysteine is 9.1–9.5 and that of the tyrosine hydroxyl is 9.5–10.0. Since these groups are strongly masked in haemoglobin, their true pK_a's are higher, but all these groups are undoubtedly ionised at pH > 12. Foetal haemoglobin has only one of the three residues specified (Cys in the γ-chain), while ox haemoglobin contain no such groups at all, which is the cause of its extremely high stability in alkali. Fig.5 illustrates schematically the dissociation of the dimer and the uncoiling of the monomeric chains under the influence of alkali. The author notes in this connection that there is no reliable information showing whether the dissociation into monomers or denaturation is the primary process.

The influence of the pH of the solution on the rate of autoxidation of human HbO_2 in the NaOH–glycine buffer in the pH range 9.0–12.0 at 40 °C has been studied in detail[59]. The observed relation is illustrated in Fig.6, which shows that the rate of autoxidation, which increases monotonically with increase of pH over the entire range investigated, gives rise to a pH dependence consisting of four clearly distinct sections. In the pH range 9–10 the rate constant increases linearly from 0.75 to 1.6×10^{-5} s^{-1}, i.e. approximately by a factor of 2. According to the available data for HbCO,[60] the concentration of the dimers increases approximately by a factor of 2 in the same pH range—from ~12 to ~24%. This agreement suggests that the rate of autoxidation of HbO_2 in the pH range 9–10 is determined mainly by the degree of tetramer–dimer dissociation. In the pH range 10–10.6 the rate constant increases linearly almost by an order of magnitude. Presumably the sharp break in the relation at pH 10.0 is caused not only by the rapid increase of the concentration of dimers (approximately by a factor of 3) but also by the conformational changes in the dimers formed. Next, the curve for the relation exhibits a further two breaks: at pH 10.6 and 11.6. The temperature variations of the rate of autoxidation have been determined for all three pH values and the following activation parameters have been calculated:

pH 10.7 $E_{act} = 60.3$ kcal mol^{-1}, $\Delta S^{\neq} = +116$ e.u., $\Delta G^{\neq} = 25.2$ kcal mol^{-1};
pH 11.45 $E_{act} = 18.7$ kcal mol^{-1}, $\Delta S^{\neq} = +15.7$ e.u., $\Delta G^{\neq} = 21.4$ kcal mol^{-1};
pH 12.0 $E_{act} = 10.9$ kcal mol^{-1}, $\Delta S^{\neq} = -36.7$ e.u., $\Delta G^{\neq} = 19.9$ kcal mol^{-1}.

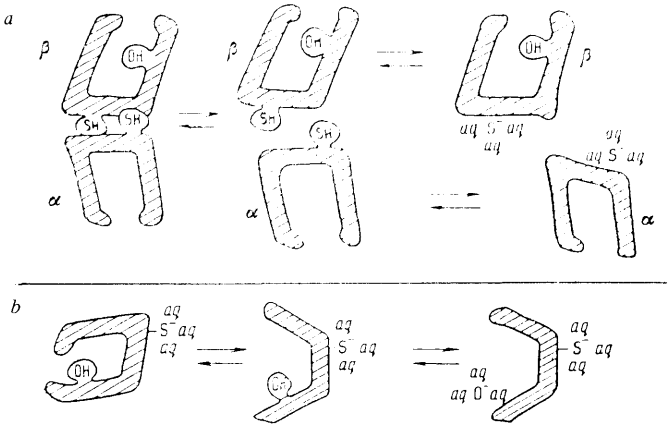

Figure 5. Schematic representation of the alkaline denaturation of haemoglobin according to Perutz[58]: *a*) dissociation of the dimer and ionisation of cysteine; *b*) uncoiling of the monomer and ionisation of tyrosine.

High enthalpies and entropies of activation are characteristic of the denaturation of proteins, in particular at pH 8, $E_{act} = 77.3$ kcal mol^{-1} and $\Delta S^{\neq} = 153$ e.u. for the thermal denaturation of human HbA.[61] On the other hand, the activation energy for the transition Fe(II) → Fe(III), involving simple iron complexes in the reaction with O_2, is of the order of 12–15 kcal mol^{-1}.[62,63] A negative entropy of activation for the oxidation reaction is also characteristic of all simple complexes. All these factors suggest that at relatively low pH values (9–10.5) the rate of autoxidation of HbO_2 is limited by conformational changes in the protein; on the other hand, with increase of pH their rate increases and the rate-limiting stage becomes the oxidation of iron in the already denatured haemoglobin (possibly in the dissociated haem). An attempt has been made at the interpretation of the kinetic results by comparing them with the absorption spectra in the range 245–320 nm at 10 °C (in order to detect only rapid conformational changes in HbO_2 under the influence of alkali). As was to be expected, an increase of pH from 9 to 10 hardly affects the spectrum. At pH 11, there is an appreciable increase of the absorption in the range 250–260 nm (normalisation of phenylalanine) and a shoulder appears in the range 285–295 nm (tryptophan, tyrosine). At pH 12 and 13 the spectral changes become more distinct. Thus one can assume that at pH 11 appreciable conformational

changes in HbO_2 already occur and these can cause, in particular, the unmasking of the tyrosine and the unreactive cysteine residues, whose ionisation, in conformity with the ideas of Perutz[58] and the present author and his co-workers,[59] leads to accelerated denaturation and autoxidation of HbO_2.

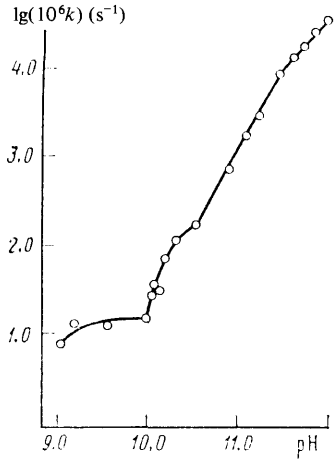

Figure 6. Dependence of $\lg k$ on the pH in the alkaline region for the autoxidation of HbO_2 at 40 °C; $[HbO_2]_0 \cong 3 \times 10^{-5}$ M.[59]

The kinetics of the oxidation of HbCO at pH 11.0–11.9 at 39 °C have been investigated[64] in the absence of molecular oxygen. In contrast to the data obtained in the study by Wallace et al.[23], where HbCO was oxidised at neutral pH in the presence of azide anions more slowly by 6–8 orders of magnitude than HbO_2, the rate of oxidation of HbCO in an alkaline medium proved to be comparable to the rate of autoxidation of HbO_2. Furthermore, the break observed in the dependence of $\lg k$ on pH for HbO_2 [59] was reproduced also for HbCO, although at a somewhat lower pH (11.4). This permitted the conclusion that, in the pH range 11–12, the mechanism of the oxidation of HbO_2 is the same as that of the oxidation of HbCO. In all probability at pH ranging from 11 to 11.4–11.6 the rate of oxidation of both HbO_2 and HbCO is limited by the protein denaturation stage, while at higher pH the rate-limiting stage is the oxidation of the denatured haemoprotein. The activation energy for the oxidation of HbCO at pH 11.65 (15.3 kcal mol^{-1}) is virtually identical with the corresponding value for HbO_2. At pH close to 12 the rate constants for HbO_2 and HbCO are very similar, whence follows the conclusion that in both cases the rate-limiting stage at high pH involves the transformation of the same substrate. Presumably the substrate is deoxyferrohaem. The nature of the direct oxidant of iron in HbCO was not elucidated in the present author's study[64]. Oxidation under aerobic conditions hardly altered the rate constant. In contrast to the first-order oxidation of HbO_2 which proceeds smoothly, the oxidation of HbCO takes place as a two-stage process—the first, faster stage continues up to ~50% degree of reaction.

The autoxidation of HbO_2 has been investigated in the presence of 0.01 M KCN without a buffer (pH ~10.4) with the addition of various amounts of primary normal aliphatic C_1–C_8 alcohols[65]. The comparative catalytic activity of the alcohols varies in this sequence as follows: 1; 2.2; 7.2; 17.5; 47.1; 893; 4010; 7500. The sharp increase of the activity of the alcohol on passing from 1-pentanol to 1-hexanol is noteworthy. This is probably associated with the greater capacity of 1-hexanol and higher-molecular-weight alcohols with a straight chain for insertion via the chain into the internal and mainly hydrophobic regions of haemoglobin.

The greater importance of non-polar effects compared with polar effects was manifested even more distinctly in the oxidation of HbCO in an alkaline buffer (pH 11.35) in the presence of tetra-alkylammonium bromides[66]. Tetramethylammonium bromide at concentrations up to 0.04 M (HbCO concentration 3×10^{-5} M) hardly influenced the rate of oxidation of HbCO. Its tetraethyl homologue showed a significant accelerating effect, while 0.01 M tetrabutylammonium bromide approximately doubled the rate of oxidation of HbCO.

Measurements have been made of the rate of autoxidation of HbO_2 in an alkaline medium in the presence of several stable nitroxy-radicals of the piperidine series[67]. The kinetic data made it possible to estimate the ability of these compounds to interact with HbO_2. The acceleration of the autoxidation of HbO_2 was determined as a measure of the conformational changes in the globin in the presence of different amounts of stable radicals up to the molar ratio radical : haem = 10 : 1. At pH 10.75 it was established that the 2,2,6,6-tetramethylpiperidin-1-yloxy-radical and its 4-oxo and 4-hydroxy-derivatives, which are widely used in the spin probe method, increase the rate of autoxidation of HbO_2 by a factor of 1.5–2 at the maximum concentrations employed. A somewhat greater effect (acceleration by a factor of three) is shown by the 2,2,6,6-tetramethyl-4,4-dinitropiperidin-1-yloxy-radical, which had not been used earlier in practice. Its 4-chloro-4-nitro-analogue proved to be still more active (acceleration by a factor of five). The geminal chloro- and nitro-groups apparently enable this nitroxy-radical to be bound specifically to particular polar centres of the HbO_2 molecule. At lower pH the influence of the nitroxy-radicals on the kinetics of the autoxidation of HbO_2 is less pronounced.

4. The Influence of Sulphydryl Reagents on the Autoxidation of HbO_2 (and the Oxidation of HbCO)

It is known that the blocking of the sulphydryl groups of haemoglobin by organomercury compounds, in particular by *p*-chloromercury benzoate (PCMB) promotes the dissociation of haemoglobin into dimers and monomers, which can be used to prepare isolated haemoglobin subunits[68]. It has been established that in the presence of an excess of PCMB the degree of dissociation of human haemoglobin into subunits depends on the concentration of the added NaCl, the degree of dissociation being a maximum in the presence of 0.1–0.2 M NaCl.[69] At a constant NaCl concentration (0.2 M) in the pH range 5.5–7.5 the degree of dissociation increases with decrease of pH and becomes complete already at pH 6 (at lower pH a precipitate is deposited). At pH 9–11, the dissociation of HbCO is incomplete and its extent decreases with increase of pH. Electrophoretic analysis showed that at low PCMB concentrations isolated subunits do not appear. Small amounts of the subunits are present when the PCMB : Hb ratio is 4 : 1 and a complete separation into subunits is achieved with the ratio 6 : 1. On the basis of these data and comparative data on foetal haemoglobin, the following conclusions have been reached: the reaction of PCMB with reactive SH groups (β-93) leads to the dissociation of HbCO into dimers; the reaction with β-112 SH-groups begins before the completion of the dissociation into dimers

and competes with the reaction of PCMB with the β-93 SH-groups. The dissociation into dimers is completed after both β-SH groups have reacted. The α-104 SH groups react with PCMB only after the completion of the reaction of the latter with the β-112 SH groups. The latter limitation is not obligatory at low pH, for example, at pH 4.7.

It has been noted[70] that, although the β-93 SH groups are not involved directly in cooperative interactions, the position of these groups in the mechanically important region of the protein makes their modification important for the state and functioning of HbO_2. Directly next to the β-93 SH groups on the surface of the $\alpha^1-\beta^2$ contact, there is histidine β-92 (the proximal histidine) and aspartyl β-94—the residue stabilising the deoxy-conformation of the C-end and of the β-chain as a result of the formation of a salt bridge with the His β-146 side chain. This interaction is directly associated with the Bohr effect and involves a cooperative mechanism. There are data showing[71] that the modification of the β-93 SH groups by a number of phenylmercury chloride derivatives increases the affinity of Hb for O_2. An analogous conclusion has been reached also for haemoglobin modified by cystamine and the dimethyl ester of cystine in acid and neutral media[72]. The Bohr effect then diminished and the shape of the oxygen equilibrium curves remained almost unaltered.

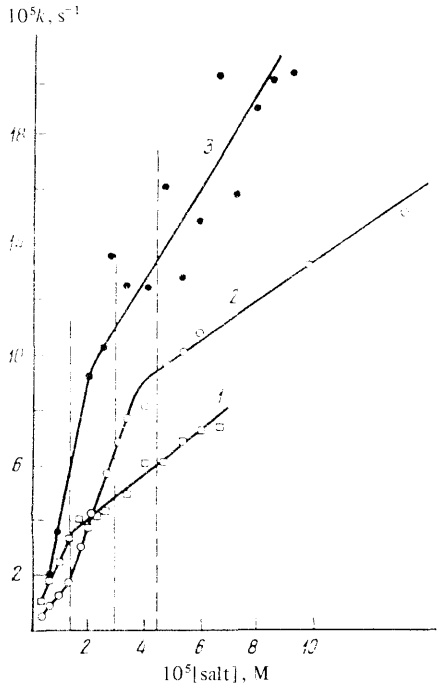

Figure 7. Dependence of the rate constant for the oxidation of HbCO in acetate buffer at pH 4.0, 30 °C, and $[HbCO]_0 = 3 \times 10^{-5}$ M on the concentrations of phenylmercury acetate (curve *1*), benzylmercury acetate (curve *2*), and mercury acetate (curve *3*).[74]

It has been observed[73] that the absorption spectra of Hb at pH 5.5–5.8 with added mercury(II) chloride resemble the spectra in the early stage of the acid denaturation of Hb (at pH 3, the Soret peak is reversely displaced to the region 370–390 nm and suffers an appreciable loss of intensity). Hence follows the conclusion that $HgCl_2$ interacts both with SH groups and with the imidazole residues of the protein.

The rates of oxidation of HbCO at pH 4.0 in the presence of phenylmercury acetate, benzylmercury acetate, methoxycarbonylmercury chloride, and mercury acetate have been measured spectrophotometrically at 30 °C and at a wavelength of 574 nm.[74] Fig.7 presents the curves for the dependence of the rate constant for the oxidation of HbCO on the concentrations of phenylmercury acetate, benzylmercury acetate, and mercury acetate. For the first two substances, an almost linear increase of the constant is observed up to reactant concentrations corresponding to the concentration of the reactive sulphydryl groups. Next, for phenylmercury acetate, the slope of the curve diminishes, while for benzylmercury acetate it actually increases. The results of the study have been interpreted taking into account the almost complete dissociation of HbCO into dimers at pH 4.0.[42] In the presence of benzylmercury acetate, the acceleration of the oxidation of HbCO after the binding of the reactive SH groups is due to the stronger effect of the reaction leading to the dissociation of the dimers into the monomers. The second break in the curve occurs in the region where the reaction of the reagent with the four SH groups of HbCO is completed. Hence one may conclude that the β-122 SH groups interact stoichiometrically and fairly rapidly with benzylmercury acetate. On the other hand, a further increase of the concentration of the latter is accompanied by a slower increase of the rate constant: in all probability the blocking of the β-112 SH groups does not entail the complete dissociation of the dimers and this process is completed only after the binding of the least accessible α-104 SH groups. A similar curve but with more distinct breaks has been obtained also for methoxycarbonylmercury chloride. In the case of phenylmercury acetate the first break in the curve also indicates the stoichiometric binding of the β-93 SH groups. On the other hand, the subsequent decrease of the slope of the curve and the absence of a break in the region corresponding to the four SH groups suggest the absence of the selective interaction of phenylmercury acetate with the β-112 SH groups. Despite the considerable scatter of the results the curve for mercury acetate (Fig.7) makes it possible to assert that, when account is taken of the "bivalence" of this salt, its effect is comparable in magnitude to that of the "univalent" benzylmercury acetate. On passing from the acetate buffer to the phosphate–citrate buffer, the chelating effect of the citrate in relation to the mercury compounds, inhibiting their activity, was observed. The important role of the reaction temperature, which influences the selectivity of the interaction of the mercury reagent with SH groups of different types has been demonstrated in relation to the oxidation of HbCO in the presence of added benzylmercury acetate[75]. Thus, following an increase of the reaction temperature from 30° to 39 °C at pH 4.0, the break characterising the stoichiometric selective binding of the reactive SH groups disappears, while the break in the region corresponding to the four SH groups is retained. An increase of temperature probably unmasks the β-112 SH groups at pH 4.0 and makes them just as accessible as the β-93 SH groups. Furthermore, it has been observed that at 39 °C the decrease of the pH in the range 4.85–4.0 (acetate buffer) also leads to a decrease of the selectivity of the interaction of benzylmercury acetate with SH groups of different types.

In the study quoted above[67], it was shown by the kinetic method described here that the new stable 4-bromo-2,2,6,6-tetramethyl-4-nitropiperidin-1-yloxy-radical is selectively

bound in alkaline media to the reactive SH groups of HbO_2, hardly altering the rate of autoxidation of HbO_2 but inducing a significant acceleration when it is bound to the unreactive SH groups of HbO_2. A procedure can be proposed for the estimation of the degree of binding and the denaturing effect of the new spin labels.

5. The Autoxidation of HbO_2 in the Presence of Reductants

It is known that the autoxidation of HbO_2 can be accelerated in the presence of reductants. Phenols, hydroquinone[76], phenylhydrazine[77,78], and aniline[78] have been most frequently tried as the latter. The role of the reductants in the oxidation of HbO_2 is usually explained[76] by assuming that the reductant transfers an electron bound by the haem iron to the oxygen, which simultaneously receives an electron from the iron and is reduced (after the binding of two protons) to H_2O_2. It is then also assumed that there is a posibility of two main mechanisms. Firstly, the reductant can interact with O_2^- after its formation, i.e. after the electron transfer from iron to oxygen. In this case the acceleration of the autoxidation of HbO_2 is comparatively slight. The other mechanism presupposes the interaction of the reductant with O_2^- in its formation stage, which is in this case rate-limiting. The reductant then accelerates precisely this stage, which results in an appreciably greater increase of the rate of autoxidation.

It has been observed[80] that the autoxidation of HbO_2 is accelerated also by a biological accelerator—glutathione (G). It has been shown that the formation of Hb^+ in its presence is due to hydrogen peroxide. The latter oxidises HbO_2 much more effectively than glutathione at the same concentration. The rate of formation of Hb^+ is proportional to the square of the concentration of glutathione, which made it possible to put forward the following simplified scheme for the process:

$$2G{-}SH + O_2 \rightarrow G{-}S{-}S{-}G + H_2O_2 ,$$
$$Hb \xrightarrow{H_2O_2} Hb^+ .$$

The influence of hydroquinone and catechol was studied in relation to the autoxidation of sheep and ox HbO_2 [76] in 0.05 M phosphate buffer at pH 6.8 with added EDTA at 37 °C. It was established that both dihydric phenols act catalytically, i.e. can be quantitatively isolated after the completion of the oxidation of HbO_2. In the presence of a tenfold excess of hydroquinone the arrest of the reaction was observed in the first ten or more seconds, which could be eliminated by adding a small amount of *p*-benzoquinone. Next it was observed that, in the absence of hydroquinone, benzoquinone reacts stoichiometrically with HbO_2. Thus in the proposed mechanism the benzoquinone formed initially as a result of the oxidation of hydroquinone oxidises HbO_2 with elimination of oxygen. The semiquinone formed oxidises in its turn a second HbO_2 molecule, which regenerates the benzoquinone. It has been established[81] that the oxidation of HbO_2 by benzoquinone in a phosphate buffer at pH 6.8 proceeds as a second-order reaction. There exists the view[82] that the hydroquinone participating in the oxidation of HbO_2 is first incorporated in the ligand environment of haem, after which two-electron reduction of O_2 takes place with the simultaneous oxidation of the haem iron and the exogenic ligand. The formation of O_2^- in the analogous HbO_2 oxidation reaction in the presence of phenylhydrazine has been demonstrated indirectly: by the reduction of ferricytochrome in the presence of HbO_2 and phenylhydrazine and by the oxidation of epinephrine.

There exist also data for the acceleration of the oxidation of haemoglobin in the presence of ascorbic acid[83], imidazole[83], hydroxylamine[81], and different amines and amides[79].

IV. THE OXIDATION OF HAEMOGLOBIN BY REAGENTS

1. The Oxidation of Haemoglobin in the Presence of Copper(II)

As already mentioned above, bivalent copper ions have an accelerating effect on the autoxidation of HbO_2, which greatly exceeds the effect of other metal ions[33]. The natural question arises whether Cu(II) is involved directly in the oxidation of the iron of HbO_2 in the presence of O_2 [Eqn.(6)] or whether it influences the structure of the protein [Eqn.(7)]:

$$Cu(II) \cdots HbO_2 \rightleftarrows Cu(I) \cdots Hb^+ + O_2 , \quad (6)$$
$$Cu(II) \cdots HbO_2 \rightleftarrows Cu(II) \cdots Hb^+ + O_2^- . \quad (7)$$

The mechanism of the action of Cu(II) has been studied in detail[84] using horse haemoglobin. It has been shown that the autoxidation of the purified HbO_2 at the normal pH is due mainly to traces of Cu(II) in solution. The addition of 10^{-4} M EDTA to 7.2×10^{-5} M HbO_2 sharply inhibits the autoxidation reaction. It has been shown by calculation that, in the absence of EDTA, an appreciable acceleration of the autoxidation is ensured by even 1–2 Cu(II) ions per 1000 haem species [the haemolysate contains 1.7 Cu(II) ions per 1000 haems]. The removal of O_2 from the system simplifies the situation: the entire copper is rapidly reduced quantitatively by the haemoglobin, after which the oxidation of Hb no longer takes place (Fig.8). In the presence of O_2, rapid initial oxidation of HbO_2 also takes place, after which comes the stage in which the oxidation is appreciably slower. The author suggests that the rapid oxidation of HbO_2 is caused by the direct transfer of an electron from Fe(II) in HbO_2 to Cu(II). In the slow stage the same process takes place, but the rate of the stage is limited by the regeneration of Cu(II) and Cu(I) in accordance with the equation

$$4Cu(I) + O_2 + 4H^+ \rightarrow 4Cu(II) + 2H_2O .$$

Comparison of the curves in Fig.8 shows that the rate of the rapid HbO_2 oxidation stage is lower than the rate of oxidation of Hb. This is an argument in support of the preliminary dissociation reaction $HbO_2 \rightleftharpoons Hb + O_2$ with conversion of the *R* form of haemoglobin into the *T* form, which, judging from all the evidence, shows a greater tendency towards oxidation by copper. The virtually complete absence of the oxidation of the weakly dissociated HbCO under these conditions constitutes a satisfactory confirmation of this finding. The question arises why Cu(II) oxidises Hb more effectively than other metal ions having a higher oxidation potential. This might be accounted for by the specific binding of Cu(II) to Hb, which facilitates the electron transfer. The equilibrium dialysis in 0.05 M tris buffer at pH 7.2 with the ratio Cu:haem = 1:2 showed that Cu(II) is bound to Hb, but only to 2 of the 4 subunits. This explains naturally why the degree of oxidation of HbO_2 or Hb presented in Fig.8 does not exceed 50%.

The latter conclusion was confirmed in relation to human haemoglobin[85]. It follows from Fig.9 that, when between two and four Cu(II) ions are transferred to the HbO_2 tetramer, there is a sharp jump in the rate of the rapid oxidation stage. On the other hand, this stage is fully inhibited by the blocking of the β-93 SH groups by iodoacetamides. Thus Cu(II) oxidises only the β-chains of human Hb and HbO_2.

This has been confirmed by the observed inertness of Cu(II) with respect to isolated α-chains, while isolated β-chains (the β_4 tetramer) were oxidised very rapidly. Superoxide dismutase and catalase inhibit the slow stage involving the oxidation of HbO_2 but do not affect the rapid stage. This confirms the direct oxidation of HbO_2 by copper in the rapid stage and the catalytic autoxidation of HbO_2 in the slow stage accompanied by the formation of O_2^- and H_2O_2 in the system.

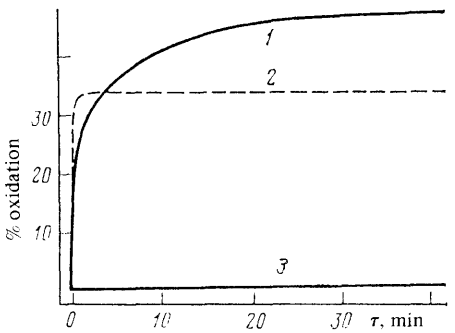

Figure 8. Time variation of the percentage oxidation of 1.42×10^{-4} M solutions of haem derived from horse HbO_2 (curve *1*), Hb (curve *2*), and HbCO (curve *3*) (in the absence of O_2) in a bis–tris buffer (pH 7.0) at 24 °C with added 5×10^{-5} M Cu(II);[84] τ is the time.

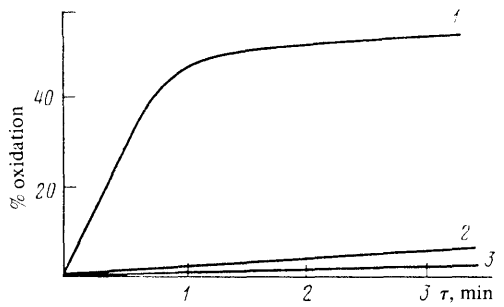

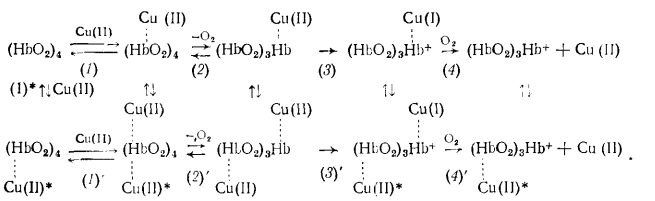

Figure 9. Kinetic curves for the oxidation of HbO_2 by four Cu(II) ions per tetramer (curve *1*), two Cu(II) ions per tetramer (curve *2*), and an excess of Cu(II) in the presence of iodoacetamide (curve *3*);[85] τ is the time.

Dialysis showed that human HbO_2 has four centres for the strong binding of Cu(II). In addition, there are also several (probably two) centres for the weak binding of Cu(II). It has been suggested that the first pair of Cu(II) ions are bound to the β-93 SH groups; the second pair, which ensures the rapid oxidation of HbO_2, is bound to centres located in the vicinity of haem, which ensures the transfer of an electron from Fe(II) to Cu(II) and the formation of haemochrome. The oxidation of the iron in the haem species is followed by the oxidation of the β-93 SH groups with formation of β-dimers containing the disulphide linkage. The presence of these dimers in the reaction product has been observed by gel electrophoresis. The third pair of bound Cu(II) ions are the cause, in the authors' view, of the experimentally observed precipitation of the haemoprotein.

Rifkind et al.[86] failed to confirm the binding of Cu(II) to the β-93 SH groups and also the formation of β-dimers by a procedure involving the modification of HbO_2 by *N*-ethylmaleimide and the comparison of the degrees of binding of Cu(II) to various haemoglobins (human, rabbit, horse, sheep, and bovine haemoglobins). Instead, it was suggested that in the case of human HbO_2 the first two Cu(II) ions are strongly bound to His β-2 or β-116 located on the proximal side in relation to haem and at a fairly long distance from it. At the same time, these residues are located close to the β-93 SH groups and the modification of the latter influences the binding of Cu(II) to His β-2 or β-116. Fig. 10 presents for comparison curves for the oxidation of horse and human HbO_2 as a function of the Cu(II) concentration. The indistinct break in the curve for human HbO_2 in the presence of 0.5 of a Cu(II) ion per haem moiety indicates the competitive binding of Cu(II) to the first and second pairs of centres for the binding of Cu(II). A scheme incorporating individual stages in which Cu(II) is bound and HbO_2 oxidised has been proposed:

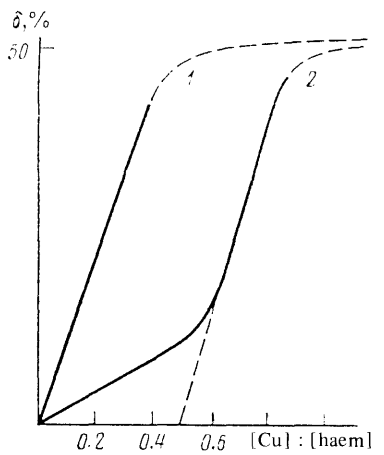

Figure 10. Dependence of the percentage of HbO_2 oxidised in the rapid stage (δ) on the amount of added Cu(II):[86] *1*) horse HbO_2; *2*) human HbO_2.

Stages (1)–(4) obtain in the case of horse HbO_2. For human HbO_2, stages (*1'*)–(*4'*) compete with the above stages. It follows from the scheme that in the latter case HbO_2 without a strongly bound Cu(II) ion can also participate in the haem iron oxidation step (stages marked by an asterisk).

It has been observed[87] that, in contrast to human and horse HbO_2 and Hb, in the sheep haemoglobins Cu(II) rapidly oxidises the haem moieties not only in the β-subunits

but also in the α-subunits. The experiments were performed at pH 6.9 in the absence of buffer in order to prevent the formation of Cu(II) complexes which might influence the mechanism of the action of this ion. The activation energies have been calculated as 53 kJ mol^{-1} for HbO_2 and 113 kJ mol^{-1} for Hb.

We shall consider in greater detail the study already mentioned, where the mechanism of the oxidation of sperm whale myoglobin by copper(II) was investigated[34]. The initial rate of oxidation of MbO_2 was determined spectrophotometrically (at $\lambda = 542$ nm) from the decrease of its concentration. It was shown that in an acid medium the kinetics of the oxidation of MbO_2 are more sensitive to the presence of Cu(II). Thus a change in the MbO_2:Cu(II) ratio from 1:0.125 to 1:12 increases the rate of reaction by a factor of ~45 at pH 5 and only by a factor of ~15 at pH 7. The steepness of the relations between the logarithm of the rate of reaction and $1/T$ in the temperature range 10–30 °C increases with decrease of pH. The authors explained this by the fact that the interaction of Cu(II) with the His GH1 centre for the binding of Cu(II), which is charged at low pH, leads to local changes unfavourable for electron transfer from haem to this centre, while an increase of temperature eliminates these difficulties. The sharp break in the relation at 30 °C (at temperatures in the range 30–40 °C the relation has much lower slopes, particularly at pH 6 and 7) is explained by a change in the hydration shell of the protein at this temperature. The authors compared the mechanisms of the autoxidation of MbO_2 and the oxidation of MbO_2 by copper(II). In the former case electron transfer via the protein to the O_2 dissolved in the medium as the final acceptor is postulated together with the simple splitting off of O_2^-. In the oxidation by Cu(II) the Cu(II) itself acts as such an acceptor. The electron transfer to copper requires the delocalisation of the electron of haem iron involving the tentative centre for the binding of Cu(II), namely His GH1. The probability of finding an electron in this centre depends on the degree of its protonation. The Cu(II) cation acts analogously—by being bound to His GH1 it increases the positive charge on the histidine, which increases the probability that an electron enters this region. The authors also postulate a mechanism in which Cu(II) is a centre for the binding of the dissolved O_2 acceptor. In this case the Fe(II)...Cu(II)... O_2 electron transfer chain with increasing redox potential may arise, as a result of which the electron transfer becomes thermodynamically spontaneous.

2. The Oxidation of Haemoglobin by Potassium Hexacyanoferrate(III)

The oxidation of haemoglobin and myoglobin by potassium hexacyanoferrate(III) constitutes the usual method of obtaining the oxidised forms of both haemoproteins. Despite this, almost no systematic studies of the kinetics and mechanisms of these reactions have been described in the chemical literature. It is therefore useful to consider only one study, by Antonini et al.[88], in which both of the above human haemoproteins were investigated. It was shown that the simpler system (Mb) reacts with potassium hexacyanoferrate(III) strictly in accordance with a second-order mechanism. $\Delta H^{\neq} = 4$ at pH 6 (0.1 M phosphate buffer) and $\Delta H^{\neq} = 0$ at pH 9.2 (borate buffer). It has been suggested that MbO_2 interacts with hexacyanoferrate(III) only after the dissociation reaction $MbO_2 \rightleftharpoons Mb + O_2$. In this case the rate of oxidation of MbO_2 should be determined either by the rate of its dissociation into Mb and O_2 or by the rate of reaction of Mb with O_2 and hexacyanoferrate(III). A linear relation between the reciprocal of the rate constant and the O_2 concentration in solution was observed at pH 6, which shows that the rate-limiting stage in the process is the dissociation of MbO_2. However, at pH 9.2 the linearity of the above relation no longer holds, which indicates deviations of the process mechanism at pH 9.2 from the simple dissociative scheme. The authors explained the influence of pH on the reaction by its effect not on MbO_2 but on hexacyanoferrate on the grounds that the influence of pH had not been observed in ligand substitution reactions involving MbO_2 (for example, reactions with CO), which have much in common with the reaction involving hexacyanoferrate(III).

When an excess of hexacyanoferrate(III) was allowed to interact with Hb, the first-order rate constant varied linearly during the reaction: it increased by a factor of 1.5 at pH 9.2 and decreased by a factor of 2 at pH 6.45, which was explained by the non-equivalence of the α- and β-chains in Hb. An increase of pH from 6.0 to 9.2 reduced by an order of magnitude the initial rate of reaction. In all cases the rate of oxidation of Hb remained ~100 times lower than the rate of oxidation of Mb under these conditions. The observation that hexacyanoferrate(III) does not oxidise the sulphydryl groups in Hb is significant: the addition of EDTA, which inhibits the oxidation of these groups, did not alter the rate of reaction.

The necessity for the preliminary dissociation into Hb and O_2 is postulated for the reaction of hexacyanoferrate(III) with HbO_2 as well as MbO_2, which was also confirmed by the increase of the rate of oxidation of HbO_2 as the partial pressure of O_2 in the mixture is reduced at pH 6.1 and 9.1 {18 °C, $[HbO_2]_0 = 10^{-5}$ M, and $[K_3Fe(CN)_6]_0 = 5 \times 10^{-3}$ M}.

There exist data concerning the products of the oxidation of horse Hb by hexacyanoferrate(III).[89] It was established by the method of isoelectric focussing that the β-chains are oxidised preferentially. However, a decrease of the ionic strength of the solution (to 0.001 M phosphate) accelerates the oxidation of the α-chains. On the other hand, the addition of inositol hexaphosphate, Cl^-, and the phosphate anion intensifies the oxidation of the β-chains.

3. The Oxidation of Haemoglobin by Nitrite

A much greater number of special investigations have been devoted to the oxidation of haemoglobin by nitrite than to its oxidation by hexacyanoferrate(III). This is apparently because poisoning by nitrite is not rare under modern hygienic conditions. Nitrite contaminates food particularly frequently by being present in water, the sources of which it enters in its turn from the soil[90].

While the mechanism of the reactions of haemoproteins with potassium hexacyanoferrate(III) is relatively simple and at least remains constant during a particular reaction, this cannot be said of the reactions of haemoproteins with nitrite. The most significant characteristic feature of the reaction HbO_2 with nitrite in its autocatalytic character: the kinetic curve is S-shaped (Fig.11). It has been observed[91] that the rate of oxidation of human HbO_2 by nitrite is proportional to $[NaNO_2]^{1.4}$. This reaction order is determined wholly by the structure of the protein, since in the case of rat HbO_2 the order with respect to nitrite is 3–4. Bearing in mind that a decrease of pH from 7.5 to 5.5 entails a linear decrease of the logarithm of the reaction half-life, i.e. that the rate of reaction increases with increase of the activity protons, the authors suggest that the reaction rate depends on the concentration of undissociated HNO_2. At the same time they do not take into account the fact that an increase of the

acidity of the medium always promotes denaturation processes, which have a particularly accelerating effect on the oxidation of HbO_2. Nevertheless, the reality of the increase of the HNO_2 concentration as the pH is reduced to 5.5 must be taken into account and the possible process mechanisms must be considered (HNO_2 can serve, for example, as a source of NO). Next the authors[91] discussed in detail the probability of the involvement of particular system components in the autocatalysis. Special experiments showed that Hb^+ does not influence the rate of reaction and it cannot therefore be the autocatalyst. The same was also established for the possible decomposition products of nitrous acid and also for nitrate. It may be that the autocatalytic character of the reaction is due to the accumulation of hydrogen peroxide in the system, which has been found to shorten the induction period. However, the inertness of H_2O_2 in the subsequent stages of the reaction led the authors to doubt its autocatalytic effect.

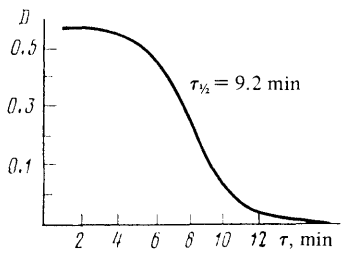

Figure 11. Kinetic curve for the oxidation of HbO_2 by nitrite; $[HbO_2]_0 = 1.8 \times 10^{-5}$ M, $[NaNO_2]_0 = 1.45 \times 10^{-3}$ M; 0.05 M bis–tris buffer at pH 7.0 with 0.1 M NaCl at 25 °C;[100] *D* is the optical density at 578 nm.

The above study[91] was continued by the investigation of the formation of methaemoglobin *in vivo* by administering sublethal amounts of $NaNO_2$ to dogs and rats[90]. After dogs had been administered perorally up to 20 mg of $NaNO_2$ per kilogram of body weight, an increase of the Hb^+ concentration in the blood of the animals was observed in the course of ~30 min up to a concentration of 25%, followed by a slow fall. At the same time EPR showed that in the initial stage of the intoxication process the HbNO concentration rises rapidly and reaches 2% after 10 min and then falls relatively fast. The authors explained the appearance of HbNO by the reduction of the unstable complex Hb^+NO, formed during intoxication, by reductase systems. The possibility of the formation of Hb^+NO enabled the authors to put forward the following mechanism of the oxidation of haemoglobin by nitrite:

$$Fe_p^{2+} + NO_2^- \rightarrow Fe_p^{2+} - NO_2^- ,$$
$$Fe_p^{2+} - NO_2^- + 2H^+ \rightarrow Fe_p^{3+} - NO^+ + H_2O ,$$
$$Fe_p^{2+} - NO^+ \rightleftarrows Fe^{3+} - NO ,$$
$$Fe_p^{2+} - NO + H_2O \rightleftarrows Fe_p^{3+} - H_2O + NO .$$

The second stage explains the observed[91] pH dependence of the oxidation of HbO_2 by nitrite. Stage 3, which is generally speaking fictitious, since it actually indicates only the presence of two resonance structures with Fe(II) and Fe(III), formally demonstrates the mechanism of the oxidation of iron, such oxidation being observed after the substitution of the NO ligand in Fe_p^{3+}–NO by water.

A more elaborate mechanism of the oxidation of HbO_2 by nitrite has been postulated by Tomoda et al.[92]. Bearing in mind that nitrite (like dithionite) is a reductant for O_2, the authors suggested that it interacts with the O_2 bound to iron and generates O_2^-. Experiment confirmed this hypothesis: the introduction of exogenic O_2^- into the system shortened the induction period of the oxidation reaction and the addition of superoxide dismutase lengthened it. The presence of $(\alpha^{O_2}\beta^+)_2$ and $(\alpha^+\beta^{O_2})_2$ was detected by the method involving the isoelectrofocussing of the partly oxidised HbO_2. Taking these two species into account, the process mechanism assumes the following form [Int $Hb(O_2)_2$ represents different half-oxidisied HbO_2 species]:

$$Hb(O_2)_4 + 2NO_2^- \rightarrow Int\,Hb(O_2)_2 + 2NO_3^- + O_2^- ,$$
$$2NO_2^- + 2O_2^- + 6H^+ \rightarrow 2NO + H_2O_2 + 2H_2O + O_2 ,$$
$$Hb(O_2)_4 + 2NO \rightarrow Int Hb(O_2)_2 + 2NO_2^- + O_2^- ,$$
$$Int Hb(O_2)_2 + 2NO_2^- \rightarrow Hb^+ + 2NO_3^- + O_2^- ,$$
$$2NO_2^- + 2O_2^- + 6H^+ \rightarrow 2NO + H_2O_2 + 2H_2O + O_2 ,$$
$$Int\,Hb(O_2)_2 + 2NO \rightarrow Hb^+ + 2NO_2^- + O_2^- .$$

Thus

$$Hb(O_2)_2 + 2NO_2^- + 6H^+ \rightarrow Hb^+ + 2NO_3^- + H_2O_2 + 2H_2O + O_2 ,$$
$$2O_2^- + H_2O_2 \rightarrow 2H^+ + 2NO_3^- ,$$

or ultimately

$$Hb(O_2)_4 + 4NO_2^- + 4H^+ \rightarrow Hb^+ + 4NO_3^- + 2H_2O + O_2 .$$

The final product of the oxidation of haemoglobin by nitrite has aroused particular interest among investigators. It has been noted[93] that, although the absorption spectra of the Hb^+ solutions formed on oxidation of HbO_2 by nitrite and hexacyanoferrate(III) have the same maximum at 630 nm, in other regions the spectra differ appreciably. The main difference between the nitrite Hb^+ is the presence of a distinct maximum at 540 nm. The hexacyanoferrate(III) Hb^+ has a maximum at 504 nm. The specific spectroscopic characteristics of the nitrite Hb^+ made it necesssary to assume[94] that nitrite oxidises the haem iron and at the same time reacts irreversibly with the protein or with the porphyrin. It was then claimed that the above reactions do not entail significant changes in the Hb^+ structure. The following experiment was carried out to demonstrate the irreversibility of the reaction of HbO_2 with nitrite: Hb^+ which had not been treated with nitrite beforehand was made to react with $NaNO_2$, whereupon NO_2^- was bound to Hb^+ in accordance with a sigmoidal relation; after the dialysis of the product combined with the ligand, it was again treated with nitrite and in this instance the NO_2^- was bound in accordance with a hyperbolic relation. The application of the EPR method[95] demonstrated the paramagnetic nature of the intermediate products of the oxidation of HbO_2 by nitrite. The formation of paramagnetic centres with $g = 2.005$ as well as the oxidation itself were characterised by an induction period and were accelerated with increase of the concentration of nitrite and with decrease of pH. The maximum of the EPR signal corresponded to a break in the Hb^+ formation curve. The EPR signal detected characterises the paramagnetic centres which exhibit autocatalytic activity and are not bound directly to NO. However, in a recently published study[96] it is claimed that prolonged dialysis of the Hb^+ solutions obtained by oxidising HbO_2 and Hb by nitrite and hexacyanoferrate(III) leads to the disappearance of spectroscopic differences betwee Hb^+ of different origin. This enabled the authors to assume that the conformations of Hb^+ are identical in the two cases, which rules out the hypothesis of the oxidation of the protein or the porphyrin fragment in

either procedure for the oxidation of haemoglobin. It is remarkable that the idea of the non-identity of the nitrite and hexacyanoferrate(III) Hb^+, allegedly associated with the different rates of their reduction by ascorbic acid[97], was disproved as early as 1943 [98] after experiments involving 24 h dialysis of the hexacyanoferrate(III) Hb^+ containing, before dialysis, residual potassium hexacyanoferrate(II), which accelerates the reduction of Hb^+.

As noted above[88], whereas hexacyanoferrate(III) oxidises Hb faster than HbO_2, the opposite behaviour obtains in the reaction with nitrite: Hb is not oxidised by nitrite at all[99]. The idea naturally arose that the allosteric effectors which reduce the affinity of Hb for O_2 should inhibit the oxidation of HbO_2 by nitrite. This hypothesis was confirmed in experiments with added inositol hexaphosphate[100]. The latter eliminated almost completely the rapid stage of the process, which follows the induction period. The mechanism of the action of inositol hexaphosphate, which presuposes the conversion of the *R* conformation of haemoglobin into the *T* conformation, has been satisfactorily confirmed by the accelerating influence of this effector on the oxidation of HbO_2 by hexacyanoferrate(III). However, later data[101] showed that other powerful allosteric effectors (DPG, NADP, and ADP) present in 2 and 5 molar excess do not affect the rate of oxidation of Hb by nitrite. It was concluded that the effect of inositol hexaphosphate observed previously is due to some factor other than the $R \rightarrow T$ transition.

The reactive SH groups play a special role in the oxidation of HbO_2 by nitrite[101]. It has been established that the blocking of these groups by iodoacetamide eliminates the inhibiting effect of inositol hexaphosphate for HbO_2 but causes no changes in the case of Hb.

V. THE OXIDATION OF HAEMOGLOBIN UNDER THE INFLUENCE OF RADIATION

In 1927 Fricke and Peterson[102] showed that, in the radiolysis of solutions of HbO_2, the latter undergoes partial oxidation. Manoilov devoted a number of studies to the action of ionising radiation on haemoproteins. He is the author of a review[103] which discusses, in particular, his work and that of other investigators on the oxidation of haemoglobin under the influence of radiation. In view of the existence of this review and also that of Starodub et al.[104], we shall consider only briefly certain studies, which give an idea about this research field and the main results achieved.

In order to understand the causes of the oxidation of haemoglobin, it is important to know the different characteristic changes occurring when solutions are irradiated. In particular a decrease of the redox potential of human haemoglobin has been observed in the course of γ-irradiation[105]. For a dose of 10–100 krad, the changes in the redox potential are slight. The potential falls by 10 mV at 500 krad and by 45 mV at 4.75 krad. The oxidation of HbO_2 on γ-irradiation of its solutions with doses in excess of 1 Mrad is accompanied by a change in the sedimentation coefficient and in the viscosity of the solution[106]. For doses greater than 4–5 Mrad, the appearance of haemochromogen was noted. During irradiation, the affinity of some of the haemoglobin molecules for O_2 increases and the haem–haem interactions are weakened. As stated above[30], these facts characterise the appearance in the solution of partly oxidised forms of haemoglobin.

γ-Irradiation can change from a factor promoting the oxidation of haem iron to one which causes reduction when Hb^+ solutions are irradiated. The solvated electron has been postulated as the primary reducing agent[107,108]:

$$Hb(Fe^{3+})_4 + e^-_{aq} \rightarrow Hb(Fe^{3+})_3(Fe^{2+}).$$

Hb^+ is also reduced on γ-irradiation of its frozen solutions at 77 K.[109] The difference between the optical spectra of the reduced Hb^+ and that of the usual Hb justifies the hypothesis of the formation during the reduction process of an active centre in a low-spin state, the centre being atypical for Hb.

The effects observed in the γ-irradiation of haemoglobin solutions are to a large extent characteristic also of irradiation by X-rays. It has been noted[110] that the stage of the haemoglobin oxidation proper is preceded by a stage in which O_2 is abstracted from HbO_2. The deoxy-form formed resembles the known product of the photodissociation of HbO_2. The Hb^+ arising during irradiation is in a high-spin state. For an irradiation dose of 10–100 krad, a decrease of the redox potential has been noted[111].

Haemoglobin is also oxidised during photoirradiation. During the exposure of an aqueous solution of mouse HbO_2 at 20–50 °C and pH 6.0 to the ultraviolet light of the PRK-4 lamp, the degree of oxidation of haemoglobin increases with the irradiation dose[112]. Under anaerobic conditions there is no oxidation. It has been suggested that the oxidation is preceded by the rupture of the haem–haemoglobin bond.

The damage to haemoglobin during irradiation can therefore be one of the links in the general radiation pathology of the animal organism[103].

---o0o---

During the preparation of this review for the press, studies on the autoxidation of haemoglobins and myoglobins[113–115], on the oxidation of HbO_2 by phenylhydrazine[116] and nitrofurantoin[117], on the oxidation of haemoglobins by nitrites[118–121], and on the oxidation of sulphhaemoglobin by hexacyanoferrate(III) [122] were published.

Kinetics of the Recombination of Radicals and Radical-ions in the Liquid Phase

Kh.S.Bagdasar'yan

The present state of the theory of the recombination of radicals and radical-ions is described on the basis of the diffusion gradient approach and in terms of the approximation of homogeneous chemical kinetics. The experimental data on the cage effect and on the kinetics of the geminate and volume recombination of radicals and radical-ions are discussed within the framework of the methods indicated. Particular attention is devoted to the influence of the viscosity of the medium on these processes. Spin effects in radical and radical-ion pairs and their influence on the recombination kinetics in the absence and presence of an external magnetic field are considered.

I. INTRODUCTION

The recombination of radicals (radical-ions) in the liquid phase is a complex reaction of a special type. The rate of recombination and the composition of the products are determined by the competition between several elementary processes. The complexity of this reaction follows directly from the significant difference between the reactions in the gas and liquid phases. In gases the reaction proceeds on collisions between the molecules; after each collision, the molecules either react or move apart to distances greatly exceeding the molecular diameters, after which collisions take place with other molecules. In the liquid phase chemical reactions proceed on encounters between molecules, which leads to the formation of a "pair" surrounded on all sides by the molecules of the liquid. The pair is characterised by an intrinsic lifetime or a dissociation rate constant. If there is no specific interaction between the molecules of the pair, then its lifetime is determined solely by the molecular movement and is of the order of R^2/D, where R is the sum of the molecular radii and D the sum of the diffusion coefficients. For the usual liquids ($D \cong 2 \times 10^{-5}$ cm^2 s^{-1} and $R \cong 5 \times 10^{-8}$ cm), the lifetime of the pair is $\sim 10^{-10}$ s. In viscous media or in a specific interaction between the molecules of the pair, its lifetime can be much greater.

If a potential barrier of the usual magnitude ($\geq$25 kJ mol^{-1}) exists for the given reaction and there is no specific interaction between the members of the pair, then during the lifetime of the latter the probability of the reaction is very low. In this case the kinetics of the liquid-phase reactions can be considered employing the usual methods of homogeneous chemical kinetics and the concept or pairs becomes superfluous. If there is no potential barrier for the reaction or it is very small, then the rate of such a reaction in the liquid phase can

be represented by the product of the rate of formation of the pairs and the probability of the reaction within the pair. The recombination of radicals (radical-ions) belongs to this class of reactions, which will be the subject of the present review.

Radical pairs are formed not only in the encounters of radicals but they also arise in the primary chemical step. The thermal or photochemical decomposition of molecules into atoms or radicals leads to the formation of a primary or geminate radical pair. Electron transfer from one molecule to another leads to the formation of a geminate radical-ion pair. The photo-ionisation of a molecule with ejection of an electron into the liquid medium results in the formation of a geminate radical-cation–electron pair. The geminate pairs either recombine (geminate recombination) or dissociate with liberation of the two species involved into space. Competition between these processes has come to be called the "cage effect". The radicals released into space react with radical acceptors or solvent molecules, forming secondary radicals. Ultimately all the radicals recombine via the formation of pairs in encounters.

An important characteristic of radical pairs is their spin state. The radical pair undergoes a periodic evolution of its spin state. In the simplest case there is a transition from a purely singlet state (the spins of the unpaired electrons of the radicals pair are antiparallel) to a purely triplet state (the spins of the unpaired electrons are parallel) and conversely via a continuous sequence of mixed states†. A radical pair can recombine only in the singlet state while a radical-ion pair can recombine (reverse electron transfer) also in the triplet state with formation of an electron donor or acceptor molecule in the triplet state. The spin evolution can take place under the influence of an external magnetic field, but is also possible without such a field as a result of the interaction of the unpaired electron with the paramagnetic nuclei of the radical, for example, with protons. The spin evolution and the factors influencing it lead to interesting phenomena such as the chemically induced nuclear polarisation, the influence of the magnetic field on chemical reactions, the magnetic isotope effect, and chemical radioemission. All these phenomena as well as the macroscopic recombination kinetics, the composition of the recombination products, the effectiveness of the initiation of radical chain reactions, and the effectiveness of photochemical systems for the transformation of light (solar) energy are determined by elementary processes involving a radical (radical-ion) pair, i.e. the recombination, dissociation, and spin transformations of the pair.

The difficulty of the theoretical analysis of barrier-free chemical reactions in the liquid phase is associated with the need of a detailed knowledge of the rules governding the molecular movement in liquids and solutions. The simplest version of this approach is the method of molecular pairs (Noyes[1]), according to which the molecules (radicals) of the pair are involved in a series of successive encounters as a consequence of molecular movement. The time between the encounters is defined by a semiempirical formula proposed by Noyes.[1] In each encounter the reaction takes place with a certain probability. The method based on the familiar relation between the disordered character of the molecular movement and diffusion—the macroscopic manifestation of this movement—has come to be widely used. This approach has been called the method of the diffusion gradient or diffusion kinetics. Subsequently we shall make use of the simplest versions of the method of diffusion kinetics. We may also note that the Noyes method has no advantages over the diffusion gradient method, as can be seen from their comparison,[1,2] and futhermore it is inconvenient for the consideration of complex kinetics. In this case the diffusion gradient method can be used in terms of the approximation of chemical kinetics, as will be described in the present review.

II. RADICAL PAIRS

1. Kinetics of the Formation and Dissociation of Radical Pairs

A radical pair is an intermediate short-lived species in radical reactions and its behaviour determines both the kinetics and the chemistry of radical reactions. We shall consider the kinetics of the formation of radical pairs in the encounters of radicals.

In 1918 Smoluchowski[3] considered the kinetics of fast coagulation on the basis of the following model. Small particles are linked to a large particle with a radius R, the size of the former being negligible compared with that of the large particle. The small particles do not interact with one another but disappear following each contact with the large particle. The rate of disappearance (adhesion) of the small particles is determined by the diffusion flux Φ of the small particles to the surface of the large particle:

$$\Phi = 4\pi R^2 D \left| \frac{\mathrm{d}c}{\mathrm{d}x} \right|_R , \qquad (1)$$

where D is the diffusion coefficient of the small particles and $|\mathrm{d}c/\mathrm{d}x|_R$ the concentration gradient of the small particles at the surface of the large particle. The concentration gradient is found by solving the diffusion equation

$$\frac{\partial c}{\partial t} = \frac{D}{x} \frac{\partial^2 (cx)}{\partial x^2} \qquad (2)$$

subject to the initial condition $c(0, x) = c_\infty$ (a uniform distribution of the small particles throughout the entire volume in the initial instant) and the boundary conditions $c(t, R) = 0$ (adhesion following each contact, so that $c = 0$ on the surface of the particle with a radius R) and $c(t, \infty) = c_\infty$ (constant concentration in the region remote from the surface). Expressions for the concentration gradient at the boundary of the large particle,

$$\left| \frac{\mathrm{d}c}{\mathrm{d}x} \right|_R = \frac{c_\infty}{R} [1 + R (\pi D t)^{-1/2}] , \qquad (3)$$

and for the diffusion flux,

$$\Phi = 4\pi R D [1 + R (\pi D t)^{-1/2}] c_\infty , \qquad (4)$$

which determines the rate of adhesion of the small particles to the large particle, follow from the solution of the diffusion equation. It follows from Eqn.(3) that the concentration gradient of the small particles diminishes continuously as those nearest to the surface adhere to it and, after a time of the order of R^2/D, it reaches the constant value c_∞/R. Correspondingly the diffusion flux also reaches a constant value:

$$\Phi = 4\pi R D c_\infty . \qquad (5)$$

In the studies of Vavilov and co-workers,[4] starting from 1928, the diffusion kinetics were first used to describe a molecular process—the quenching of fluorescence. The application of the method of diffusion kinetics to molecular

---

†The concept of the parallel and antiparallel arrangement of spins in the triplet and singlet states is simplified. Strictly speaking, in the triplet state the electron spins are added together, while in the singlet state they are subtracted.

processes is possible on the basis of the following clear model corresponding to Smoluchowski's theory for the coagulation of colloids.[5] One considers the diffusion of non-interacting point particles in the direction towards a sphere (or away from the sphere) with a radius R (the sum of the molecular radii). The sum of the diffusion coefficients of real molecules is adopted as the diffusion coefficient of the point particles. Depending on the character of the problem, the initial and boundary conditions for the point particles are established. The diffusion flux Φ of the point particles to a sphere with a radius R, subject to the boundary conditions indicated above, is identical with the number of encounters per unit time of real molecules A with a single molecule B and Eqns.(4) and (5) correspond to the non-stationary and stationary cases#. The quantity Φ/c_∞ has the dimensions of a bimolecular rate constant and has been called the "time-dependent rate constant". When a stationary regime is established, this quantity represents the bimolecular rate constant for the formation of pairs. If the two radicals are identical, then the multiplier 1/2 must be introduced into Eqns.(5).

An expression for the rate constant for the dissociation of a contact radical pair can be obtained analogously.[6] For this purpose, it is necessary to solve the diffusion equation subject to the initial condition $c(0, x) = 0$ (at the initial instant the point particles are absent from the given volume) and the boundary condition $c(t, R) = c_0$ (a constant concentration of the point particles is maintained at the boundary of a sphere with a radius R). The solution is

$$k_d = \frac{\Phi}{c_0} = \frac{D}{R^2}\left[1 + R(\pi Dt)^{-1/2}\right], \qquad (6)$$

where Φ is the diffusion flux of the point particles away from the surface of a sphere with a radius R into space.

Up to a time of the order of R^2/D, a constant flux is established with a stationary rate constant for the dissociation of the pairs $k_d = D/R^2$.

Stationary expressions for the rate constant for the formation of pairs ($4\pi RD$) and the rate constant for the dissociation of pairs (D/R^2) lead to the kinetic condition for the diffusion equilibrium:

$$4\pi RD[A][B] = \frac{D}{R^2}[AB]_{eq}. \qquad (7)$$

The equilibrium concentration of pairs $[AB]_{eq}$ is determined by the probability that the molecule B enters a spherical layer with a volume $4\pi R_A^2 R_B$. Assuming that the radii of the molecules A and B are identical, we obtain

$$[AB]_{eq} = 4\pi R^3[A][B], \qquad (8)$$

which agrees with the kinetic Eqn.(7) for the diffusion equilibrium.

2. Kinetics of the Recombination in Space

The kinetics of the recombination of radicals without taking into account explicitly the spin state of the radical pair arising following the encounter of the radicals in space are considered in this Section. The kinetic consequences of the spin state of the radical pair will be considered below.

If the reaction takes place in each encounter of the molecules A and B, then the rate of reaction is equal to the rate of formation of the pairs. Having divided Eqn.(5) by c_∞, we obtain an expression for the bimolecular rate constant at the stationary state:

$$k_{diff} = 4\pi RD. \qquad (9)$$

The Stokes–Einstein formula makes it possible to express RD in terms of T/η, where T is the temperature and η the viscosity of the medium; the ratio T/η is called the fluidity of the medium. If the molecular radii are equal, then

$$RD = \frac{4kT}{6\pi f\eta}, \qquad (10)$$

where k is the Boltzmann constant and f a correction factor of the order of unity§. Having substituted Eqn.(10) in Eqn.(9), we obtain an expression for k_{diff} known in the literature as the Smoluchowski–Debye formula:[7]

$$k_{diff} = \frac{8kT}{3f\eta}. \qquad (11)$$

Eqn.(11) had been derived earlier by Vavilov.[8]

We shall now consider a more general case of diffusion kinetics, where not every encounter of the radicals leads to reaction. In this case the concentration of the point particles on the surface of a sphere with a radius R is not zero but has a finite value, which varies during the reaction, tending to a constant. The solution of the diffusion Eqn.(2) leads in this case to the equation (see, for example, Noyes[1])

$$\Phi = \frac{4\pi RDc_\infty}{1 + 4\pi RD/k_2}\left(1 + \frac{k_2}{4\pi RD}e^{z^2}\operatorname{erfc} z\right), \qquad (12)$$

where k_2 is the bimolecular recombination constant not limited by diffusion (see below) and

$$z = \frac{(Dt)^{1/2}}{R}\left(1 + \frac{k_2}{4\pi RD}\right); \quad \operatorname{erfc} z = \frac{2}{\pi^{1/2}}\int_z^\infty e^{-u^2}du.$$

Different special solutions can be obtained from Eqn.(12). If the rate of reaction is limited by diffusion, i.e. $k_2 \gg 4\pi RD$, then $z \to [(Dt)^{1/2}/R](k_2/4\pi RD) \gg 1$ and $e^{z^2}\operatorname{erfc} z \cong 1/\pi^{1/2}z$ (the first term of the expansion of the expression $e^{z^2}\operatorname{erfc} z$ in series for large values of z). We obtain as a result Eqn.(4). It follows from Eqn.(12) that, after a time greater than R^2/D, a stationary flux and a stationary reaction rate are established. In this case [$t \to \infty$, $z \to \infty$, and the expression in brackets in Eqn.(12) tends to unity], we obtain for the experimental bimolecular rate constant k_{exp} the following expression:

$$k_{exp} = \frac{\Phi}{c_\infty} = \frac{4\pi RDk_2}{k_2 + 4\pi RD}. \qquad (13)$$

This important equation can be obtained immediately by formulating an equation for the diffusion flux Φ of point particles through any spherical surface $4\pi x^2$. This stationary flux is independent of x, i.e. Φ is a constant quantity and is found by solving the following equation:

$$\Phi = 4\pi x^2 D\frac{dc}{dx}. \qquad (14)$$

#In theoretical studies by the diffusion gradient method, the term "probability density" of the observation of molecules at a given site and at a given time is employed. The concentration of point particles is a clear expression of the "probability density".

§For simplicity we shall henceforth use Eqn.(10). If the molecular radii are not equal, then an additional multiplier enters Eqn.(10). For example, if the molecular radii differ by a factor of 2, the multiplier is 1.125; it enters into the correction factor f, which effectively characterises the deviation of the behaviour of real molecules from the Stokes–Einstein formula.

(Boundary conditions:

$$x\to\infty,\ c\to c_\infty;\ x\to R,\ c\to c_0,$$

where c_0 is the stationary concentration of the point particles at the surface of a sphere with a radius R). The integration of Eqn.(14) yields the following expression for the diffusion flux at the boundary of a sphere with a radius R:

$$\Phi = 4\pi RD(c_\infty - c_0) \quad . \tag{15}$$

The flux represents the rate of reaction of all the particles A with a single particle B; consequently $\Phi = k_2 c_0$. Thus it is possible to eliminate c_0 from Eqn.(15) and obtain Eqn.(13).

Two limiting cases follow from Eqn.(13).

1. The diffusion flux limits the rate of reaction, i.e. $4\pi RD \ll k_2$; then $k_{exp} = 4\pi RD = k_{diff}$, which agrees with Eqn.(9). For the usual liquids, k_{diff} is a quantity of the order of 10^{10} litre mol^{-1} s^{-1}.

2. The diffusion flux does not limit the rate of reaction, i.e. $4\pi RD \gg k_2$. Then k_2 is identical with the experimental constant k_{exp}. The constant k_2 is sometimes identified with the bimolecular rate constant for the reaction of the same radicals in the gas phase (see below).

It must be emphasised that, regardless of the reason why not every encounter between the radicals leads to reaction (steric hindrance, spin restrictions, or other causes), the diffusion gradient method leads to Eqn.(13) and all the factors hindering reaction determine the constant k_2. We may also note that Eqn.(9) has a limited range of applicability (see Section 6). However, as a consequence of a certain indefiniteness of the concept of the "sum of radii" and also as a consequence of the application of Eqn.(11) instead of Eqn.(9), it is frequently impossible to decide on the basis of experimental data which equation is valid—Eqn.(13) or (9). If the bimolecular recombination rate constant is measured over a wide range of fluidities of the medium, then Eqn.(13) makes it possible to obtain important information about the elementary processes determining the diffusion recombination kinetics (see below).

The concept of pairs was not used in the derivation of Eqn.(13). The experimental recombination constant k_{exp} can be represented as the product of the rate constant for the formation of pairs and the probability ϕ of reaction in the pair:

$$k_{exp} = 4\pi RD\varphi \quad . \tag{16}$$

One should bear in mind that ϕ is not simply a number less than unity but is a dimensional function of a series of kinetic parameters. It follows from Eqns.(13) and (16) that

$$\varphi = k_2/(k_2 + 4\pi RD).$$

On the other hand, ϕ can be expressed in terms of unimolecular constants for the recombination of the pair (k_1) and its dissociation (k_d). We thus obtain the expression

$$\varphi = k_2/(k_2 + 4\pi RD) = k_1/(k_1 + k_d). \tag{17}$$

The stationary rate constant for the dissociation of the pair is equal to D/R^2, which leads to a relation between the bimolecular constant k_2 and the unimolecular pair recombination constant k_1:

$$k_2 = 4\pi R^3 k_1 \quad . \tag{18}$$

In the general case the constant k_1 has a simpler physical significance than the constant k_2.

3. The "Cage Effect" (Stationary Recombination of Geminate Pairs)

One of the manifestations of the diffusion kinetics of the recombination of radicals is the "cage effect". Frank and Rabinovich[9] observed that the quantum yield of the dissociation of a molecule into atoms or radicals in a liquid medium is smaller than in a gaseous medium. This was explained by the fact that the radicals formed on dissociation are surrounded by solvent molecules which hinders their escape into space and facilitates the reverse reaction. The latter has been called geminate recombination. The proposed explanation has been confirmed by numerous experiments, in particular by the decrease of the quantum yield of the dissociation of molecules with increase of the viscosity of the medium.[1] According to modern terminology, the "cage effect" involves the recombination of geminate pairs in competition with the escape of radicals into space.

The "cage effect" has been studied experimentally by the photolysis or thermolysis in the liquid phase of compounds which readily decompose into radicals (peroxides, azo-compounds, etc.). The reaction is carried out in the presence of effective radical acceptors. The radicals which have escaped into space react with the acceptor to form a product other than the products of the reaction of the radicals in the cage. Thus, in the photolysis of azoethane in n-heptane in the presence of large amounts of styrene, some of the ethyl radicals formed emerge from the cage and add to styrene. In the cage the ethyl radicals either combined to form butane or disproportionate to form ethylene and ethane. The ratio $(C_4H_{10} + C_2H_4)/N_2$ represents the fraction of radicals which have reacted in the cage. This quantity increases from 46 to 84% with decrease of temperature from +99° to −75 °C. The decrease of temperature increases the viscosity of the medium, which hinders the emergence of the radicals from the cage. The photolysis and thermolysis of many compounds in various solvents have been studied at different temperatures and viscosities of the medium; the dimensions of the radicals formed have also been varied.[10,11]

The "cage effect" also determines the effectiveness of initiators of chain radical processes. The effectiveness of the initiators of the polymerisation of vinyl monomers, which determines the fraction of the radicals emerging into space on decomposition of the initiator, has been studied in particular detail. Thus the effectiveness of initiation by azobisisobutyronitrile is 0.5–0.7, while for benzoyl peroxide it amounts to 0.7–1.0.[12]

Numerous experiments have shown that even active radical acceptors, reacting with all the radicals which have emerged into space, cannot compete with the recombination in the cage. The decomposition of azobisisobutyronitrile in liquid bromine may be an exception; in this case products of the recombination in the cage were not detected.[13] It is not clear whether it is possible to reach an unambiguous conclusion from this not altogether usual experiment.

A quantitative theory of the "cage effect" was formulated on the basis of the diffusion gradient method[5] and also the Noyes' method of molecular pairs.[1] Both methods yield identical expressions for the "cage effect" but use different parameters. We shall consider the diffusion gradient method, which makes it possible to formulate the problem exactly. Suppose that the distance between the radicals at the instant of the generation of the pair is l. Under the conditions of the experiments examined above, there is continuous generation and destruction of the radical pairs. As a result of this, after a time of the order of R^2/D (much shorter than the duration of the experiment), a stationary concentration of the pairs is established in the system. According to the

clear model of the diffusion gradient method which we adopted, point particles are continuously generated on the surface of a sphere with a radius l and diffuse "outwards" (dissociation of the pair) and "inwards", where they are destroyed with a certain probability on the inner surface of a sphere with a radius R (geminate recombination). The fraction of the recombination ϕ is determined by the ratio of the diffusion fluxes:

$$\varphi = \frac{4\pi R^2 D \left| \frac{\overleftarrow{dc}}{dx} \right|_R}{4\pi l^2 D \left(\left| \frac{\overleftarrow{dc}}{dx} \right|_l + \left| \frac{\overrightarrow{dc}}{dx} \right|_l \right)} , \qquad (19)$$

where c is the concentration of the point particles and the arrows $\leftarrow$ and $\rightarrow$ indicate the directions of the diffusion fluxes "within" and "outside" a sphere with a radius l. The concentration gradients in Eqn.(19) are found by solving the stationary diffusion equation for the case of spherical symmetry with allowance for the reaction of the radicals with the acceptor¶:

$$\frac{D}{x} \frac{d^2(cx)}{dx^2} - k_a c[\mathrm{Ac}] = 0 , \qquad (20)$$

where [Ac] is the acceptor concentration and k_a the rate constant for the reaction of the acceptor with the radicals; the boundary conditions are $x \to \infty$, $c \to 0$; $x = R$, $c = c_0$. The rate of recombination is determined by the diffusion flux through a surface $4\pi R^2$. The rate of recombination can also be represented in the form $k_2 c_0$ (see above). We thus obtain the expression

$$\Phi = 4\pi R^2 D \left| \frac{dc}{dx} \right|_R = k_2 c_0 . \qquad (21)$$

This equation makes it possible to eliminate the unknown quantity c_0. As a result, we obtain the following expression for ϕ:

$$\varphi = \frac{R \exp[-b(l-R)]}{l[1 + 4\pi RD(1 + bR)/k_2]} , \qquad (22)$$

where

$$b \equiv (k_a[\mathrm{Ac}]/D)^{1/2} .$$

In the first place it is necessary to estimate bR. The rate constant for the addition of the reactive radical such as the methyl radical or the polymeric vinyl acetate radical to a typical radical acceptor (styrene) at 60 °C is of the order of 10^5 litre mol^{-1} s^{-1} [12] or 0.17×10^{-15} cm^3 s^{-1}. For the usual values $D = 2 \times 10^{-5}$ cm^2 s^{-1} and $R = 5 \times 10^{-8}$ cm and for [Ac] = 10 M, we obtain k_a[Ac] = 10^6 s^{-1} and $bR \leq 0.01$. Then Eqn.(22) becomes

$$\varphi = \frac{R}{l} \frac{k_2}{k_2 + 4\pi RD} . \qquad (23)$$

It was found that the quantum yield γ of the photodissociation of iodine decreases with increase of the wavelength of light from 0.83 at $\lambda = 4047$ Å to 0.11 at $\lambda = 7350$ Å.[14] This dependence can be explained by the fact that, with decreased energy of the quantum, the kinetic energy of the translational movement of the iodine atoms moving apart, given by $h\nu - E_{\mathrm{diss}}$, diminishes, which leads to a decrease of l and hence of γ, since $\gamma = 1 - \phi$. This type of dependence has not been observed in he photodissociation of azo-compounds, which leads to the formation of the CH_3 or CF_3 radicals.[15] Evidently in these cases the $h\nu - E_{\mathrm{diss}}$ excess energy is converted into the vibrational energy of the radicals formed and does not lead to their separation, i.e. contact or "almost" contact pairs arise. The results of a study[16] in which it was shown that the "cage effects" are the same in the thermolysis and photolysis of azo-compounds also agree with this conclusion. Since the radicals formed on thermolysis do not possess an excess translational kinetic energy, it is evident that the photolysis also does not lead to the separation of the radicals.

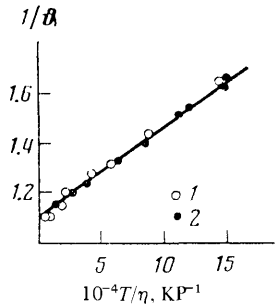

Figure 1. Dependence of $1/\phi$ on T/η; ϕ is the probability of the formation of C_2H_6—the product of geminate recombination in the photodecomposition of azomethane at temperatures from +98° to −72 °C: 1) ethyl acetate; 2) hexane.[5]

If RD is expressed in terms of T/η in accordance with the Stokes–Einstein formula, we obtain from Eqn.(23)

$$\frac{1}{\varphi} = \frac{l}{R} + \frac{l}{R} \frac{8kT}{3k_2 f\eta} . \qquad (24)$$

Figs.1 and 2 present the dependence of $1/\phi$ on T/η according to Eqn.(24) (see also Dobis et al.[15] and Chakravorty et al.[18]). A number of conclusions can be drawn from these data.

1. The ratio $l/R \cong 1$ when the radicals are formed simultaneously with ejection of the N_2 molecule (for example, in the photolysis of CH_3–N=N–CH_3) or $l/R \cong 2$ when the formation of the radicals is accompanied by the ejection of two CO_2 molecules [for example, in the photolysis of

$$(CH_3)_3COOC{-}\overset{O}{\overset{\|}{C}}{-}\overset{O}{\overset{\|}{C}}OO(CH_3)_3 .$$

Evidently a contact radical pair is formed in the former case, which agrees with the considerations expressed above, while in the latter case one CO_2 molecule separates the $(CH_3)_3CO$ radicals at the instant of formation of the pair, so that $l/R \cong 2$.

2. The slope of the linear $1/\phi - T/\eta$ plots makes it possible to calculate the quantity $k_2 f$. This feature requires a more detailed discussion. The geminate recombination of the $\dot{C}H_3$ and $\dot{C}F_3$ radical depends little on the nature of the solvent and ϕ is determined solely by the quantity T/η, while the recombination of t-butoxy-radicals exhibits a definite dependence on the solvent.[17] The straight line in Fig.2 corresponds to aliphatic solvents. For olefins and aromatic solvents with the same fluidities of the medium, the quantities $1/\phi$ are much greater, which indicates smaller values of the

¶ In Denisov's review,[10] this method of analysis of the "cage effect" has been erroneously called the method of "one-dimensional translational diffusion".

constant k_2. For alcohols, the values of k_2 are even smaller, since only traces of geminate recombination products have been detected in such media. The deviation from the straight line must be explained by the specific interaction of the butoxy-radicals with the solvents indicated, which hinders the recombination and facilitates the emergence of the radical into space.[17]

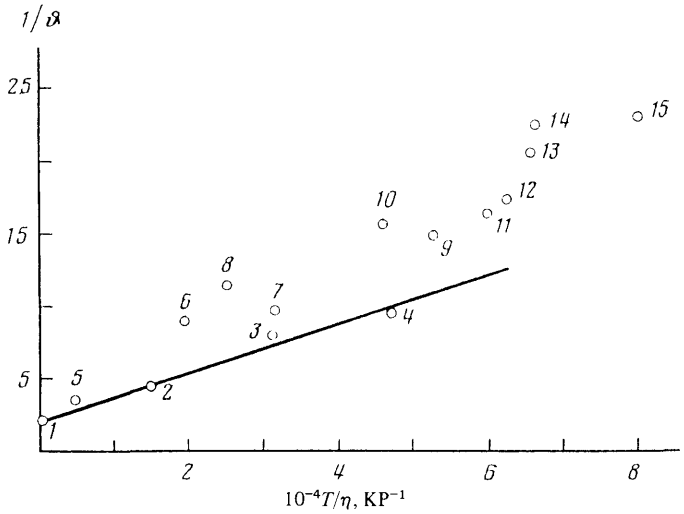

Figure 2. Dependence of $1/\phi$ on T/η; ϕ is the probability of the geminate recombination of t-butoxy radicals in various media: 1) liquid paraffin; 2) hexadecane; 3) dodecane; 4) decane; 5) dimethyl phthalate; 6) tetralin; 7) *o*-dichlorobenzene; 8) acetophenone; 9) cumene; 10) α-methylstyrene; 11) ethylbenzene; 12) cyclohexane; 13) toluene; 14) benzene; 15) oct-1-ene. The plot has been constructed on the basis of the data of Niki and Kamiya.[17]

Table 1. Kinetic constants for the recombination of radicals.

Constant, litre mol^{-1}s^{-1}	$\dot{C}H_3 + \dot{C}H_3$	$\dot{C}F_3 + \dot{C}F_3$	$(CH_3)_3\dot{C}O + O\dot{C}(CH_3)_3$
$10^{-10}\,k_2$	6.0 [5]; 11.7 [15]	1.4 [18]	0.41 [17]
$10^{-10}\,k^{gas}$	2.0 [19]	2.3 [19]	0.43±0.05 [20]
$10^{-10}\,Z^{gas}$	8.2	6.8	6.6

The constants k_2, determined from the slopes of the plots of $1/\phi$ against T/η (the multiplier f was assumed to be 0.65), are compared in Table 1 with the experimental recombination constants for the same radicals in the gas phase k_{gas} and with the calculated number of collisions Z in gases. The recombination constants in the gas phase for the methyl and trifluoromethyl radicals are ~1/4 of the number of collisions. This ratio corresponds to the probability that the spins of the colliding radicals are antiparallel. The recombination constant for the butoxy-radicals in the gas phase is much smaller than the number of collisions. For the methyl and butoxy-radicals, the rate constant k_2 is greater by a factor of 3–4 than the recombination constant in the gas phase. This can be explained by the fact that the geminate pair of radicals formed on photolysis is in a singlet state.[5] A difference between the constants has not been observed for the trifluoromethyl radical. However, one should treat all these conclusions with caution bearing in mind the experimental accuracy. There is only one reliable conclusion: the constants k_2 differ from the recombination constants in gases k_{gas} by a factor not greater than 2–3.

If a contact radical pair is formed, i.e. $R = l$, then the probability of recombination can be represented by Eqn.(17):

$$\varphi = k_1/(k_1 + k_d). \qquad (17)$$

Since the lifetime of the radical pair formed on photolysis or thermolysis is of the order of R^2/D, presumably a nonstationary value corresponding to Eqn.(6) must be adopted for k_d. If, however, the duration of the photolysis (thermolysis) greatly exceeds the lifetime of the pair, then a stationary value of D/R^2 enters into Eqn.(17). This can be demonstrated by the following calculation. Suppose that the pairs are formed at a rate I, whereupon $I\mathrm{d}\tau$ pairs are formed during the period $\mathrm{d}\tau$. The number of recombined pairs $\Delta(RR)$ during time t is defined by the expression

$$\Delta(RR) = k_1 I \int_0^t \left\{k_1 + \frac{D}{R^2}\left[1 + \left(\frac{R^2}{\pi D(t-\tau)}\right)^{1/2}\right]\right\}^{-1} \mathrm{d}\tau\,, \qquad (25)$$

After integration, it can be shown that, for $t \gg R^2/D$, the fraction of the recombined pairs is given by the expression

$$\varphi = \frac{\Delta(RR)}{It} = \frac{k_1}{k_1 + D/R^2}\,. \qquad (26)$$

In pulsed laser photolysis, where $t_{pulse} \cong R^2/D$, a nonstationary expression must be used for k_d (see below).

If the existence of very effective radical acceptors, for which $k_a[\mathrm{Ac}] > 10^6\ \mathrm{s}^{-1}$ is assumed, then there is a possibility of competition between the acceptors and geminate recombination. Having put $l = R$, Eqn.(22) can be expressed in the form

$$\varphi = \frac{\varphi_0}{1 + (1-\varphi_0)(k_a[\mathrm{Ac}]R^2/D)^{1/2}} \simeq \varphi_0\{1 - (1-\varphi_0)(k_a[\mathrm{Ac}]R^2/D)^{1/2}\}\,, \qquad (27)$$

where

$$\varphi_0 = k_2/(k_2 + 4\pi RD) = k_1/(k_1 + D/R^2)$$

is the fraction of geminate recombination in the absence of radical acceptors. It follows from Eqn.(27) that, in the presence of effective acceptors, ϕ should diminish as a linear function of $[\mathrm{Ac}]^{1/2}$. The influence of acceptors on recombination in the cage has also been represented in other forms,[1,21] but the linear dependence of ϕ on $[\mathrm{Ac}]^{1/2}$ remains.

4. Kinetics of the Recombination of Geminate Radical Pairs

The kinetics of geminate recombination can be investigated only by pulse methods. In the first study of this type,[22] the dissociation of the iodine molecule into atoms and their subsequent recombination in hexadecane and in carbon tetrachloride were followed by the method of picosecond photolysis. After 300–500 ps, geminate recombination reaches completion and an appreciable fraction of the iodine atoms emerge into space. An analogous study has been carried out in liquid xenon.[23] The kinetics of the geminate recombination in these studies have been discussed on the basis of the Noyes method of molecular pairs.[1] In this procedure use is made of the function $h(t)$, which expresses the probability that, after the first encounter between the molecules (radicals), a

second encounter takes place at a time between t and $t + dt$. Noyes proposed an approximate expression for the function $h(t)$:

$$[h(t) = pt^{-3/2}e^{-qt}] \quad , \qquad (28)$$

where p and q are constants. In this case the first encounter involves the formation of the geminate pair and the second encounter leads to reaction with a certain degree of probability. [The exact expression for the function $h(t)$ obtained by the diffusion gradient method[2] differs greatly from Eqn.(28).] Only an approximate agreement between Eqn.(28) and experiment has been noted.[22] In another study the[23] agreement with experiment was achieved by selecting three parameters. There is reason to believe that the picosecond dissociation of I_2 is complicated by phenomena which have no bearing on the geminate recombination.[24]

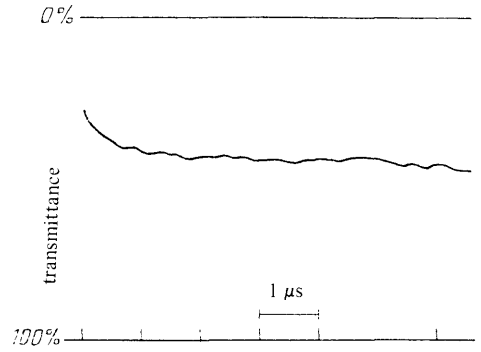

Figure 3. Kinetics of the geminate recombination of indandionyl radicals in liquid paraffin at 0 °C; T/η = 40 K P^{-1}.[26] For explanation, see text.

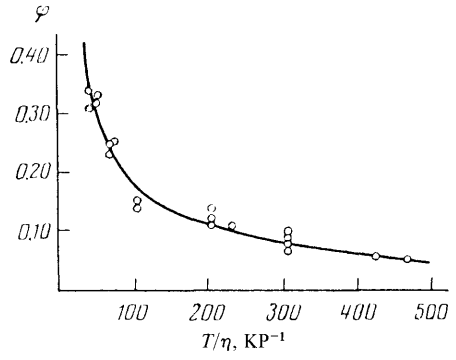

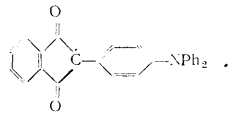

Figure 4. The fraction of the geminate recombination ϕ of indandionyl radicals as a function of the fluidity of the medium.[25]

The kinetics of the geminate recombination of indandionyl radicals, arising in the nanosecond photolysis of the corresponding dimer, have been studied:[25,26]

The geminate recombination has been observed only in viscous media (mixtures of hexane with liquid paraffin) in the region of fluidities below 500 K P^{-1}. Fig.3 illustrates typical kinetics of geminate recombination. The initial passage of the probing beam is determined by radical pairs and the plateau is due to the radicals which have escaped into space. Fig.4 shows the dependence of the fraction of geminate recombination ϕ on T/η. Analysis of the data on the "cage effect" leads to the conclusion that contact (or "almost" contact) radical pairs are formed on photolysis and thermolysis even in a mobile medium. Only on photodissociation of I_2 do I atoms move apart to distances exceeding the sum of their radii.[14]

We shall consider the kinetics of the geminate recombination of the contact radical pairs in terms of the "approximation of chemical kinetics".[6,26,27] The essential feature of this approximation consists in the fact that the rate of destruction of the given species is formulated in terms of the kinetic equations of homogeneous chemical kinetics, i.e. as the sum of the rates of formation and destruction of the given species via different pathways, including both chemical and diffusion processes. The rate constant for diffusion process, which in the general case depend on time, is found by solving the corresponding diffusion equation for point particles. For example, the rate constants for the formation and dissociation of pairs are determined by Eqns.(4) and (6). In terms of this approximation, the destruction of the contact radical pairs, which have arisen after the completion of the pulse, is determined by the equation

$$-\frac{dn}{dt} = k_1 n + \frac{D}{R^2}[1 + R(\pi D t)^{-1/2}]n \, . \qquad (29)$$

The first term represents the destruction of the pairs as a result of geminate recombination and the second as a result of the dissociation of the pairs [see Eqn.(6)]. The integration of Eqn.(29) yields

$$\frac{n}{n_0} = \exp\{-[(1 + a^2)k_1 t + 2a(\pi k_1 t)^{1/2}]\} \, , \qquad (30)$$

where $a^2 = D/R^2 k_1$ is the ratio of the stationary rate constant for the dissociation of the pair to the geminate recombination constant and n_0 is the initial concentration of the pairs. The fraction of pairs which have recombined during time t is

$$\varphi(t) = k_1 \int_0^t \frac{n}{n_0} dt = [1 - \exp(A^2 - z^2) - \sqrt{\pi} A \, e^{A^2}(\mathrm{erf}\, z - \mathrm{erf}\, A)]/(1 + a^2), \qquad (31)$$

where

$$A = a/[\pi(1 + a^2)]^{1/2} \text{ and } z = A + [(1 + a^2)k_1 t]^{1/2}.$$

When $t \to \infty$, Eqn.(31) becomes

$$\varphi = [1 - \sqrt{\pi} A \, e^{A^2} \mathrm{erfc}\, A]/(1 + a^2) \, . \qquad (32)$$

Eqn.(32) represents the fraction of recombined radical pairs under the conditions of non-stationary recombination kinetics. In terms of the approximation of chemical kinetics, this quantity is smaller than the fraction of the recombined radical pairs under stationary conditions, which is $(1 + a^2)^{-1}$.

5. The Multiplicity of the Radical Pair

For a more rigorous description of the kinetics of the recombination of a radical pair, it is necessary to take account of its multiplicity. The radical pair can exist in two extreme states: singlet or triplet. It follows from the quantum theory that the multiplicity of the pair varies continuously through a sequence of mixed states (see, for example, Buchachenko[28]). This phenomenon has come to be called spin evolution. The probability of the recombination of the radical pair is higher the greater the contribution of the singlet state to the multiplicity of the pair. The radical pair existing in a purely triplet state cannot recombine.

There are various mechanisms of the changes in the multiplicity of the radical pair. The following are of real importance.

1. The Δg-mechanism. This mechanism is manifested following the imposition of an external magnetic field. According to this mechanism, the rate of spin evolution is determined by the difference between the magnetic energies of the unpaired electrons of the radical pair. The energy of an electron in a magnetic field H is $\frac{1}{2}g\beta H$, where β is the Bohr magneton (0.927×10^{-20} erg G^{-1}) and g a proportionality coefficient—the so-called g-factor, which is determined from the EPR spectrum. For a free electron, $g = 2.0023$; for the unpaired electron in the radical, the g-factor differs from this value as a consequence of the spin–orbital coupling and depends on the type of the radical. In a magnetic field the triplet state of the radical pair is split into three sublevels T_-, T_0, and T_+, among which only the energy of the T_0 sublevel coincides with that of the pair in a singlet state (subject to the condition that there is no exchange interaction in the pair). Only T_0–S transitions, whose probability vary with time as $\sin^2(\frac{1}{2}\Delta g\beta Ht/h)$,[29] where $h = h/2\pi$ (h is the Planck constant), therefore occur in a magnetic field. In this expression

$$\left(\frac{1}{2}\right)\Delta g\beta H/\hbar = \left(\frac{1}{2}\right)2\pi\Delta g\beta H/h$$

represents the difference between the magnetic energies of the unpaired electrons expressed in units of rad s^{-1}. [This unit of measurement of the energy is obtained by dividing the magnetic energy of the electron $\frac{1}{2}g\beta H$ (ergs) by h (erg s), which yields the energy in s^{-1}, and by multiplying by 2π, which yields the energy in units of rad s^{-1}.]

If in the initial instant the pair exists in a purely singlet state, then after a time t_S, whereupon $\frac{1}{2}2\pi\Delta g\beta Ht_S/h = \pi/2$, the pair passes to a purely triplet state. The quantity $k_S = 1/t_S$ can be adopted, with some approximation, as the constant of the T_0–S transition, i.e. $k_S = 2\Delta g\beta H/h$. Since the quantities Δg are usually in the range 10^{-2}–10^{-3}, it follows that we obtain $k_S = 2.8 \times 10^8$–2.8×10^7 s^{-1} for $H = 10^4$ G.

2. The HFI-mechanism. Another mechanism leading to spin evolution is a consequence of the magnetic interaction of the unpaired electron with paramagnetic nuclei (usually with protons, but also with ^{13}C, ^{17}O, ^{19}F, ^{31}P, etc. nuclei). Since this interaction leads to splitting of the EPR line into a series of components, i.e. to a hyperfine structure of the spectrum, it has come to be called the hyperfine interaction (HFI). Quantitatively the HFI interaction is characterised by an HFI constant, which is determined from the EPR spectrum and is usually expressed in gauss. The HFI-mechanism of spin evolution also depends on the external magnetic field, but this dependence is of a type different from that in the case of the Δg-mechanism. In the absence of the magnetic field, all three sublevels of the triplet state of the pair are degenerate and their energies coincide with the energy of the singlet state. Under these conditions, the transition from the singlet state is to all three sublevels of the triplet state. When an external magnetic field is imposed, only the T_0–S transition takes place as a consequence of the splitting of the triplet level, which usually leads to a decrease of the probability of the transition. We may note that the necessary splitting of the triplet level is achieved in magnetic fields amounting to several tens or hundreds of gauss.

A quantitative analysis of the HFI-mechanism is difficult, particularly because the radical pair usually contains several paramagnetic nuclei, for example, protons, which are in the general case characterised by different HFI constants and this leads to a complex picture of spin evolution. Expressions have been published[29] for the probabilities of the S–T transitions for certain simple model radical pairs. For example, for the radical pair

$$\dot{R}^1 \cdots \dot{R}^2 \begin{matrix} \nearrow H \\ \searrow H \end{matrix}$$

in the absence of an external field, the probability of the S–T transition varies with time as $^2/_3 \sin^2(^3/_4At)$. The parameter A (rad s^{-1}) is related to the HFI energy, equal to $a\beta$, by the expression $A = 2\pi a\beta/h$, where a is the HFI constant (G) and β the Bohr magneton (erg G^{-1}). As in the case of the Δg-mechanism, for the time t_S corresponding to a change in the multiplicity of the pair we shall adopt the condition $^3/_4At_S = \pi/2$, whence it follows that $1/t_S = k_S = 3a\beta/h$. If $a = 100$ G, then $k_S = 0.4 \times 10^9$ s^{-1}. For other radical pairs, one should expect values of k_S of the same order of magnitude for the same values of a. If one radical contains m protons and the other n protons, then the extent of the HFI in the pair can be approximately calculated with a single effective HFI constant a_{eff}, which is defined by the formula

$$a_{eff} = \left(\sum_m a_m^2 + \sum_n a_n^2\right)^{1/2} . \qquad (33)$$

The periodic evolution of the spin state of the pair was observed experimentally for the first time by Anisimov et al.[30] A solution of tetramethylethylene (D) and perdeutero-*p*-terphenyl (A) in a non-polar solvent proved to be a convenient object for investigation. The ionisation of the solvent under the influence of ^{90}Sr radiation generates pairs of radical-ions ($D^+.A^-$) as a result of electron capture by the molecule of A and electron transfer from D to the solvent radical-cation. In the radical-ion D^+ all the protons are equivalent, while the HFI constants for A^- are small. In this case the picture of spin evolution simplifies and can be observed from the periodic maxima of the recombination fluorescence arising on recombination of the pair (electron transfer from A^- to D^+) with formation of a fluorescent molecule A*. These maxima are observed particularly clearly following the imposition of a magnetic field (3300 G), which leads to a further simplification of the picture of spin evolution as a consequence of the "disconnection" of the T_+ and T_- states. The recombination fluorescence maxima continued in succession over a period of 22 ns, which corresponded, according to a theoretical calculation,[31] to the maximum in the contribution of the singlet state of the pair.

An important feature of the HFI-mechanism is that a change in the multiplicity of the radical pair is accompanied by selection with respect to the orientations or reorientations of the spins of the paramagnetic nuclei. Since the relaxation of the nuclear spins is slow (minutes), the ratio of the molecules with the orientation of the nuclear spin along the magnetic field and in opposition to the field in the radical pair recombination products differs from the Boltzmann ratio. This phenomenon, which has come to be called chemically induced nuclear polarisation, has been described in detail in

a monograph[28] and in a review.[32] The phenomenon of chemically induced radioemission is also associated with the polarisation of nuclear spins on recombination of radical pairs.[33] If the radical pair contains a paramagnetic isotope, for example ^{13}C, then, as a consequence of the influence of the paramagnetic nucleus on the spin evolution, certain recombination products are enriched in the paramagnetic isotope—the magnetic isotope effect.[32,34,35] For all these phenomena, the observed effect is determined by competing processes involving spin evolution, recombination, and diffusion separation of the pair. The discussion of these interesting phenomena is outside the framework of the present review.

It is also necessary to consider the influence of the exchange interaction of unpaired electrons on the spin evolution. If this interaction is intense, then the spin evolution is hindered as a consequence of the appearance of an energy difference between the T_0 and S states. It is usually assumed, following the Noyes theory, that the radicals of the pair execute a series of repeating encounters as a consequence of molecular movement. In the intervals between these encounters the exchange energy is small and spin evolution reaches completion. However, spin evolution can be completed also in contact (or "almost" contact) pairs. As a result of the diffusional rotation of the radicals of the pair, the wave functions of the unpaired electrons do not overlap for a considerable proportion of the lifetime of the pair and the exchange interaction is therefore weak. The characteristic time of rotational diffusion is of the same order of magnitude as the characteristic time of translational diffusion[36] and spin evolution can therefore compete with the diffusional separation in the pair and also with the recombination of the radicals of the pair.

6. The Probability of the Recombination of the Radical Pair taking into account Spin Evolution

Theoretical consideration of the recombination of radical pairs taking into account spin evolution and the influence of the magnetic field is a complex task. It was shown in the previous Section that spin evolution can be approximately characterised as unimolecular $T-S$ transitions. In terms of the approximation of the methods of chemical kinetics, the behaviour of the radical pairs can then be described by the following scheme of elementary processes,[26] different variants of which have been used in many experimental studies:

$$\begin{array}{ccc} R{-}R & \underset{k_1}{\overset{}{\leftarrow}} & {}^1(R\cdot R) \underset{k_S}{\overset{3k_S}{\rightleftarrows}} {}^3(R\cdot R) \\ & & \downarrow k_d \qquad \downarrow k_d \\ & & R + R \qquad R + R \end{array} .$$

We shall carry out a kinetic analysis of this scheme.[26] The rate constant for the transition from the triplet to the singlet state is designated by k_S, whereupon the rate constant for the reverse transition (in the absence of a magnetic field) is $3k_S$ as a consequence of the triple degeneracy of the triplet state of the pair. Suppose that at a certain instant there are [P] pairs, among which there are [S] singlet pairs and [T] triplet pairs. The fraction of pairs which have recombined during time t is

$$\varphi(t) = \frac{k_1}{[P]} \int_0^t [S]\, dt \quad . \qquad (34)$$

The concentration of the singlet pairs can be found in terms of the approximation of chemical kientics by solving a system of kinetic equations for the singlet and triplet pairs:

$$\frac{d[S]}{dt} = k_S[T] - k_1[S] - k_d[S] - 3k_S[S] \; ; \qquad (35)$$

$$\frac{d[T]}{dt} = -k_S[T] - k_d[T] + 3k_S[S] \; . \qquad (36)$$

In the general case the constant k_d depends on time in accordance with Eqn.(6). We shall consider the application of Eqns.(34)–(36) in the description of geminate and volume recombination.

Geminate recombination. Geminate pairs arise either in the singlet or triplet state depending on the spin state of the initial molecule at the instant of dissociation. In the general case the characteristic time of geminate recombination is of the same order of magnitude as the lifetime of the pair. Consequently the following non-stationary quantity must be adopted for k_d:

$$k_d = \frac{D}{R^2}\left[1 + R(\pi D t)^{-1/2}\right] .$$

We shall consider special cases.

(a) The pairs arise in the triplet state and the time of transition to the singlet state is much greater than the dissociation time of the pair, i.e. $k_d \gg k_S$. In this case geminate recombination does not occur and all the pairs dissociate.

(b) The pairs arise in the triplet state, the transition to the singlet state is slow, and the recombination in the singlet state is rapid, i.e. $k_1 \gg k_S$. The rate of recombination is then determined by the rate of the process $T \to S$, which is equal to $k_S[T]$. Since in this case $[T] \gg [S]$, then neglecting the term $3k_S[S]$ in Eqn.(36), we arrive at Eqns.(29) and (32), in which k_S replaces k_1, i.e. the probability of the recombination is determined by the rate of transition of the pair to the singlet state in competition with the diffusional separation of the pair.

(c) The pairs arise in the singlet state and the transition to the triplet state is slow, i.e. $k_d \gg k_S$. The first two terms of Eqn.(35) can then be rejected, leading to Eqns.(29) and (32). In this case the probability of recombination is independent of the rate of spin evolution.

(d) If the spin evolution is very rapid, i.e. $k_S \gg k_d$ and $k_S \gg k_1$, then, regardless of the initial spin state of the pair, a spin equilibrium is established in which $[T] = 3[S]$. Having added together Eqns.(35) and (36), we again arrive at Eqn.(29), in which $k_1/4$ replaces k_1. This special case obtains in a viscous medium at a very high rate of spin evolution.

Thus, for all the special cases considered, the kinetics of the geminate recombination are described by Eqn.(29) and we obtain Eqn.(32) for the probability of recombination, in which the constant k_1 is modified for different special cases, as shown above.

In order to obtain a general expression for the kinetics of geminate recombination, it is necessary to solve Eqns.(35) and (36). An approximate solution can be obtained if the average value of k_d during the lifetime of the pair τ is adopted:

$$\bar{k}_d = \frac{D}{R^2\tau}\int_0^\tau \left[1 + R(\pi D t)^{-1/2}\right] dt \simeq 2.13D/R^2 \; . \qquad (37)$$

The coefficient 2.13 is obtained if one puts $\tau = R^2/D$. We then obtain for the probability of geminate recombination the same equations as for the volume recombination (see below), in which the average value $\bar{k}_d$ should be substituted for k_d.

Volume recombination. The geminate pairs which have dissociated with liberation of the radicals into space give rise to a volume concentration of radicals. The recombination takes place in space following the encounter of the radicals which have emerged from different pairs and produced secondary

pairs. Since the characteristic time of the volume recombination greatly exceeds the lifetime of the pair and the time of attainment of the stationary value of k_d, it follows that $k_d = D/R^2$ (see above). In this case Eqns.(35) and (36) are easily solved under specified initial conditions and expressions are obtained for [S] and [T] as functions of time. Integration of Eqn.(34) from 0 to ∞ yield expressions for ϕ for pairs arising in the singlet state:

$$\varphi_S = \frac{k_S k_1 + k_d k_1}{k_S k_1 + 4k_S k_d + k_1 k_d + k_d^2} \quad (38)$$

and for those arising in the triplet state:

$$\varphi_T = \frac{k_S k_1}{k_S k_1 + 4k_S k_d + k_1 k_d + k_d^2} \quad . \quad (39)$$

Since one-quarter of the pairs are formed in the singlet state and three-quarters are formed in the triplet state in an encounter between radicals in space, the overall probability of the recombination is defined by the expression

$$\varphi = \frac{1}{4}\varphi_S + \frac{3}{4}\varphi_T \quad (40)$$

or

$$\varphi = \frac{k_S k_1 + \frac{1}{4}k_1 k_d}{k_S k_1 + 4k_S k_d + k_1 k_d + k_d^2} \quad . \quad (41)$$

Certain special cases are of interest.

1. During the lifetime of the pair there is insufficient time for spin evolution, i.e. $k_d \gg k_S$. It then follows from Eqn.(41) that

$$\varphi = \frac{1}{4}k_1/(k_1 + k_d) \quad . \quad (42)$$

If in addition we have under these conditions $k_1 \gg k_d$, then $\phi = {}^1/_4$. In this case the bimolecular recombination constant $k_{exp} = 4\pi RD/4$. This case can obtain in a fluid medium and also for a low rate of spin evolution.

2. The spin transformation times are much shorter than the lifetime of the pair, i.e. $k_S \gg k_d$. We then have

$$\varphi = k_1/(k_1 + 4k_d). \quad (43)$$

If in addition $k_1 \gg k_d$, then $\phi = 1$ and $k_{exp} = 4\pi RD = k_{diff}$. This case can obtain in viscous media and for high rates of spin evolution.

It is seen from the above analysis that the expressions for the radical recombination rate constant in the form $k_{exp} = 4\pi RD/4$ or $k_{exp} = 4\pi RD$, which are frequently encountered in the literature, in reality obtain only in special cases, while Eqn.(41) and special cases of the latter [Eqns.(42) and (43)] correspond to more realistic conditions and constitute a generalisation of Eqn.(17) obtained without taking into account spin transformations.

7. Determination of the Kinetic Constants for Radical Pairs from Experimental Data

A method has been proposed[26] for the determination of the kinetic constants k_1 and k_S from experimental data for the kinetics of the volume and geminate recombination over a wide range of fluidities of the medium T/η.

Volume recombination. The probability of the recombination of the pair ϕ_{exp}, formed in an encounter between radicals, can be determined experimentally from the equality

$$\varphi_{exp} = \frac{k_{exp}}{4\pi RD} \quad , \quad (44)$$

where k_{exp} is the bimolecular recombination constant. Having expressed RD in terms of T/η by means of the Stokes–Einstein formula [Eqn.(10)], we obtain

$$\varphi_{exp} = \frac{3k_{exp}f\eta}{8kT} \quad . \quad (45)$$

We set ϕ_{exp} equal to the theoretical quantity ϕ (see above). It is then possible to determine from the experimental data the constants k_1 and k_S; for this purpose, it is necessary to measure k_{exp} over a wide range of fluidities of the medium. We shall explain the method for the determination of the kinetic constants in relation to the recombination of indandionyl radicals arising in the nanosecond photolysis of the corresponding dimer.[26] In the above study the bimolecular recombination constant k_{exp} was measured in mixtures of toluene and liquid paraffin over a wide range of fluidities of the medium—from 50500 to 41 K P^{-1}. In the region of low fluidities ϕ_{exp} reaches a constant value, which is evidently unity. It follows from this normalisation that $f = 0.65$. With increase of the fluidity of the medium to 500 K P^{-1}, all the singlet pairs recombine with a probability of unity; the rate of recombination of triplet pairs is determined by the rate of their conversion into singlet pairs in competition with the dissociation of the pair. Consequently in this range of fluidities we have $k_1 \gg k_S$ and $k_1 \gg k_d$. It then follows from Eqns.(39) and (40) that

$$\varphi_{exp} = \frac{1}{4} + \frac{3}{4}\frac{k_S}{k_S + k_d} \quad , \quad (46)$$

where $k_d = D/R^2$. Application of the Stokes–Einstein formula leads to the expression

$$(1 - \varphi_{exp})/(\varphi_{exp} - 0.25) = \frac{4kT}{6\pi f\eta R^3 k_S} \quad . \quad (47)$$

A plot of $(1 - \phi_{exp})/(\phi_{exp} - 0.25)$ against T/η is presented in Fig.5. $R^3k_S = 0.3 \times 10^{-13}$ cm^3 s^{-1} can be obtained from the slope of the straight line†. For a fluidity of the medium in excess of 3000 K P^{-1}, the experimental points deviate from the straight line. Consequently in this range of values of T/η not all the singlet pairs recombine and some of them dissociate.

In the region of high fluidities of the medium, it has been found that $\phi_{exp} < 0.25$. Evidently under these conditions not only all the triplet pairs but also some of the singlet pairs dissociate. Consequently $\phi_T = 0$ and $k_d \gg k_S$ for the singlet pairs, while k_1 and k_d are of the same order of magnitude. For this range of values of T/η, it follows from Eqns.(38) and (40) that

$$\varphi_{exp} = \frac{1}{4}k_1/(k_1 + k_d) \quad . \quad (48)$$

Having set Eqns.(45) and (48) equal to each other, we obtain

$$\frac{1}{k_{exp}} = \frac{3f\eta}{2kT} + \frac{1}{\pi R^3 k_1} \quad . \quad (49)$$

Fig.6 illustrates the dependence of $1/k_{exp}$ on η/T in the region of high fluidities and it follows from the plot that $f = 0.33$ and $R^3k_1 = 9.1 \times 10^{-13}$ cm^3 s^{-1}. The absolute values of the constant k_1 and k_S can be determined if reasonable

---

†The quantity $\bar{k}_d = 2.13\ D/R^2$ has been used.[26] As shown above, $k_d = D/R^2$ should be employed for the volume recombination. The constants k_1 and k_S quoted by Bagdasar'yan and co-workers[26,37] should be reduced by a factor of 2.13.

values are assumed for R. The study of the kinetics of the geminate recombination makes it possible to determine R directly from the experimental data (see below). Thus the following values of the constants have been obtained:

$$R=14.5 \text{ Å}, \ k_1=2.7\cdot10^8 \text{ s}^{-1}, \ k_S=9.0\cdot10^6 \text{ s}^{-1}.$$

For these values of the kinetic constants, Table 2 lists the recombination probabilities for singlet and triplet pairs calculated by Eqns.(38) and (39) and also the overall probability of recombination in the encounters between radicals in accordance with Eqn.(40).

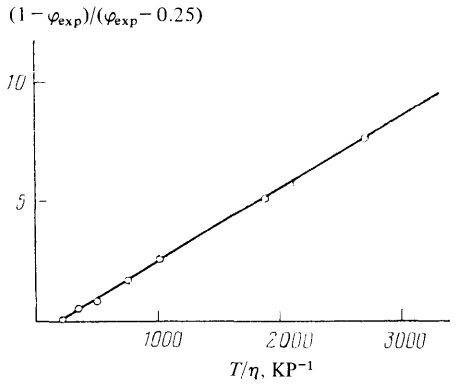

Figure 5. Dependence of $(1-\phi_{exp})/(\phi_{exp}-0.25)$ on T/η according to Eqn.(47) in the region of low fluidities.[26]

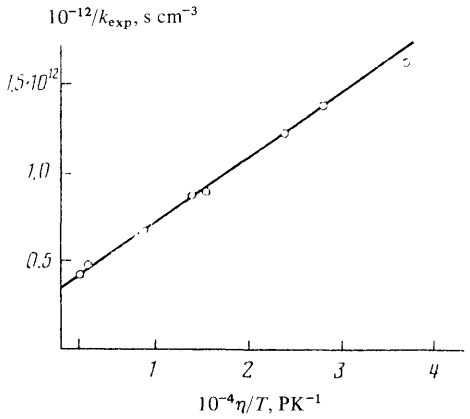

Figure 6. Dependence of $1/k_{exp}$ on η/T according to Eqn.(49) in the region of high fluidities.[26]

Geminate recombination. The kinetics of the geminate recombination of the indandionyl radicals, which have been observed only in a viscous medium (see Fig.4), obey Eqn.(31).[26] In this equation k_1 should be replaced by the constant k^*, which can have the significance of k_1^* or k_S^* depending on the state in which the geminate pair was generated: singlet or triplet (the asterisk denotes constants referring to the geminate pair). In the latter case the recombination takes place only after the conversion of the triplet pair into the singlet pair. Using Eqn.(32), $a^2=D/R^2k^*$ is found from experimental ϕ_{exp}, after which a value of k^* satisfying Eqn.(31) is selected. For this purpose, it is convenient to employ a programmable microcalculator. Since

$$a^2=D/R^2k^*=4kT/R^3k^*6\pi\eta,$$

the plot of a^2 against T/η makes it possible to determine R^3k^*. Thus $k^* = 0.9\times10^6$ s^{-1} and $R = 14.5$ Å were obtained for the indandionyl radicals. The value of R found makes it possible to determine the volume recombination constants k_1 and k_S, which were quoted above.

Table 2. Probability of recombination in the encounters of the indandionyl radicals forming pairs in the singlet and triplet states (according to the data of Bagdasar'yan et al.[26]) ($R = 14.5$ Å, $k_1 = 2.7\times10^8$ s^{-1}, $k_S = 9.0\times10^6$ s^{-1}).

T/η, K P^{-1}	D/R^2, s^{-1}	Recombination probabilities		
		Φ_S	Φ_T	Φ
5	$2.2\cdot10^5$	1	1	1
50	$2.2\cdot10^6$	0.96	0.79	0.83
500	$2.2\cdot10^7$	0.88	0.25	0.41
5000	$2.2\cdot10^8$	0.52	0.03	0.15
50000	$2.2\cdot10^9$	0.12	0	0.03

If the geminate pair arises in the singlet state, i.e. $k^* = k_1^* = 0.9\times10^6$ s^{-1}, then the constant k_1^* is 300 times smaller than k_1. If the geminate pair arises in the triplet state, then $k^* = k_S^*$ and the constant k_S^* is 10 times smaller than k_S. It may be that the cause of the difference between the constants is that the geminate pair has an excess energy of ~3 eV at the instant of formation and is in a highly vibrationally excited state, in contrast to the pair formed in the encounter between radicals.

The volume recombination of ketyl radical,[37] obtained by the photolysis of benzopinacone in mixtures of hexane with liquid paraffin having different fluidities (from 94400 to 410 K P^{-1}), has been investigated. Treatment of the experimental data by the method described above yielded the following constants: $k_S = 3\times10^8$ s^{-1} and $k_1 = 0.4\times10^{10}$ s^{-1}. In contrast to the indandionyl radicals, the geminate recombination of the ketyl radicals was not observed. Over the entire range of fluidities of the medium investigated, the pairs dissociate and the radicals are released into space. Evidently the pairs of ketyl radicals arise in the triplet state and their lifetime is not long enough for conversion into the singlet state. If the rate constants for the geminate and volume recombinations were identical, then geminate recombination might have been observed. Thus, as in the case of indandionyl radicals, the kinetic constants of the geminate and volume recombinations differ (or at least one of them is different).

8. The Influence of a Magnetic Field

Brocklehurst[38] was the first to put forward the idea that the influence of the magnetic field on the recombination of radicals is associated with the spin transformations in the radical pair. Later studies showed that the influence of the magnetic field is due to the Δg- and HFI-mechanisms of

the spin transformations. Certain examples of the influence of magnetic field on the recombination kinetics have been presented in reviews.[29,32] Systems for which the geminate pair constants have been determined and the influence of a magnetic field on the recombination of radicals has been observed will be considered below.

Under pulsed illumination (N_2 laser, duration of pulse 3 ns) of benzophenone (B) in solution in hexane, a hydrogen atom is transferred from hexane to a benzophenone molecule in the triplet state (^{3}B) with formation of a geminate pair in a triplet state consisting of the ketyl radical $\dot{B}H$ and the hexyl radical $\dot{R}$:[39]

$$^3B + RH \rightarrow {}^3(\dot{B}H\dot{R}) .$$

The second light pulse, emitted 38 ns after the first, induces the fluorescence of the ketyl radical. When a magnetic field whose strength is up to 8 kG is applied, the Δg interaction induces the $T_0 \rightarrow S$ transition and rapid recombination (reverse transfer of a hydrogen atom) of the singlet pair formed, which is accompanied by a decrease of the fluorescence intensity of the ketyl radical. If the HFI interaction were stronger than the Δg interaction, the opposite effect would have been obtained.

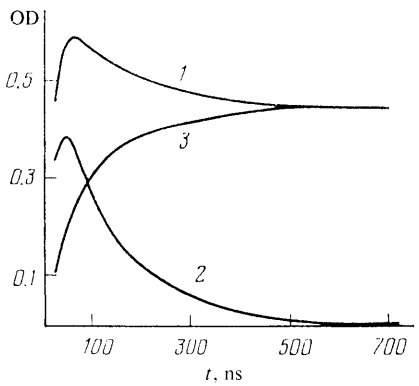

Figure 7. Kinetics of the variation of the optical density (OD) at 545 nm in the benzophenone–liquid paraffin system (η = 140 cP): 1) OD at λ = 545 nm; 2) ditto at λ = 620 nm multiplied by 3 (this is equal to the ratio $\varepsilon^{545}/\varepsilon^{620}$ for triplet benzophenone molecules); 3) difference between curves *1* and *2*.[40]

The analogous benzophenone–liquid paraffin system was investigated by nanosecond flash photolysis.[40] Fig.7 presents the kinetics of the variation of the optical density at λ = 545 nm (curve *1*) and λ = 620 nm (curve *2*) for η = 140 cP. The initial section of curve *1* is determined by the overall absorption by triplet benzophenone molecules and ketyl radicals, while the plateau on this curve corresponds to the absorption by ketyl radicals which have been released into space. Curve *2* corresponds to the absorption only by the triplet benzophenone molecules. It is seen that the triplets disappear at the instant when curve *1* reaches the plateau. Hence it follows that the destruction of the pairs $^3(\dot{B}H\dot{R})$ takes place immediately after their formation. Analysis of the experimental data leads to the conclusion that the ratio $k_d/(k_d + k_1) = 0.56$ and is independent of the viscosity of the medium. Consequently not only the dissociation of the pairs but also the transfer of a hydrogen atom from the ketyl radical to $\dot{R}$ depends on the viscosity of the medium. In the benzophenone–hexane system[39] the conversion of a triplet pair into a singlet pair competes with the dissociation of the pair. When hexane is replaced by liquid paraffin, the rate of dissociation of the pair diminishes by a factor of hundreds. Under these conditions, all the triplet pairs are converted into singlet pairs, which dissociate and recombine at approximately equal rates.

The $T-S$ transition can proceed also via the HFI-mechanism. In this case the application of a weak magnetic field decreases the probability of the $T-S$ transition as a consequence of the splitting of the triplet level and the disconnection of the T_+ and T_- states and hence decreases the fraction of the recombination process and increases the release of radicals into space. Studies of this type have been carried out in micellar solutions in which diffusional separation of the pairs is difficult, which favours spin transformations. Thus the nanosecond photolysis of various anthraquinones in a sodium dodecylsulphate solution has been studied.[41] A laser pulse results in the formation of the triplet radical pair $^3(Q\dot{R})$, where $\dot{R}$ is the radical formed from a solvent molecule and $\dot{Q}$ is a semiquinone radical. The application of a magnetic field up to 790 G slows down the destruction of the triplet pair and increases the release of the radicals into space. For anthraquinone, the constant k_S diminishes from 2.5×10^6 s^{-1} for $H = 0$ to 1×10^6 s^{-1} for H = 790 G; the constant k_d remains invariant at 1×10^6 s^{-1}.

The nanosecond photolysis of micellar solutions of benzophenone has been studied[42] in the presence of cyclohexadiene RH. A triplet pair $^3(\dot{B}H.\dot{R})$ arises under these conditions. The kinetics of the destruction of the triplet pair (it has been assumed that the destruction proceeds in accordance with a first-order reaction) and the fraction of the radicals released into space make it possible to determine the constants k_S and k_1. In a micellar solution of cetyltrimethylammonium bromide these constants are respectively 1.6×10^6 s^{-1} and 1.7×10^6 s^{-1}. The values obtained for sodium dodecylsulphate micelles are respectively 4.4×10^6 s^{-1} and 5.8×10^6 s^{-1}. When a magnetic field is applied, the release of radicals into space increases from 58% for $H = 0$ to 80% for H = 2000 G regardless of the nature of the micelles.

The spin effects and the influence of the magnetic field have been observed in the photoinitiation of emulsion polymerisation by triplet sensitisers.[43] For other methods of initiation of the emulsion polymerisation of the same monomers, the influence of a magnetic field has not been observed. The explanation is based on the considerations described above.

III. RADICAL-ION PAIRS

1. The Rehm–Weller Scheme

The behaviour of the radical-ion pairs arising as a result of the electron phototransfer will be considered in this section. The overall scheme of the phototransfer has been proposed by Rehm and Weller:[44]

$$A^* + D \underset{k_{21}}{\overset{k_{12}}{\rightleftarrows}} (A \cdot D)^* \underset{k_{32}}{\overset{k_{23}}{\rightleftarrows}} (A^{\cdot-} \cdot D^{\cdot+}) \begin{cases} \xrightarrow{k_d} A^{\cdot-} + D^{\cdot+} \\ \xrightarrow{k_1} A + D \end{cases} ,$$

where A* is an excited molecule of an electron acceptor, D an electron donor, (A.D)* an exciplex, i.e. an excited molecule with partial electron transfer or an excited unrelaxed acceptor–donor complex, and $(A^{\cdot-}.D^{\cdot+})$ a radical-ion pair

which can either recombine (reverse electron transfer) or can dissociate with formation of "free ions". The electron donor can also behave as an excited molecule. In order to complete this scheme, it is necessary to take into account the spin state of both the excited molecule and the radical-ion pair and also the possibility of the spin evolution of the pair. Thus in the phototransfer of an electron from dimethylaniline to an excited pyrene molecule in the singlet state, a radical-ion pair is produced in the excited singlet state, while the phototransfer of an electron with participation of a triplet benzophenone molecule leads to the formation of a pair in the triplet state. The energetic conditions necessary for the electron phototransfer and also the properties of the exciplexes have been examined in detail in a series of reviews and monographs[45,46] and will not be discussed in this paper. Here it is sufficient to note that, with increased dielectric constant of the medium ε, the lifetime of the exciplexes τ diminishes and there is a sharp increase of the rate constant k_e for the conversion of exciplexes into radical-ion pairs, as can be seen from Table 3.[47]

Table 3. Kinetic constants for the dimethylaniline–pyrene exciplex.[47]

Solvent	ε	τ, ns	$10^{-6}k_e$, s^{-1}
Acetonitrile	38	2.0	490
Methanol	33	9.4	95
Ethanol	24.5	19.8	41
Isopropyl alcohol	15.7	72.5	5
Tetrahydrofuran	4.6	102	~1
Diethyl ether	4.3	134.5	~1

On the basis of the Rehm–Weller scheme, we can obtain expressions for the phenomenological fluorescence quenching constant k_Q (or the constant for the destruction of the triplet state) and for the liberation of free ions. We shall assume that the process involving k_{32} can be neglected, i.e. that the vibrational relaxation is fairly rapid after the electron transfer (the process involving k_{23}). Under the conditions of steady-state illumination, stationary concentrations of the A*, (A.D)*, and ($A^{\bar{}}.D^{+}$) species are established in the solution. Having formulated the equations for the stationary state for the short-lived species indicated, in accordance with the above scheme, we arrive at the following expression for the quenching of the fluorescence (or the destruction of triplet states):

$$\frac{L_0}{L} = 1 + \frac{k_{12}\tau[D]}{1 + k_{21}/k_{23}} , \qquad (50)$$

where L_0 and L are the fluorescence intensities in the absence and presence of a quenching agent respectively and τ is the lifetime of the molecule A*. The empirical Stern–Volmer constant is expressed in terms of the constants for elementary processes in the following manner:

$$k_Q = \frac{k_{12}}{1 + k_{21}/k_{23}} . \qquad (51)$$

An expression for the quantum yield in the formation of free ions γ_{fi} can be obtained analogously:

$$\gamma_{fi} = \frac{\alpha_{fi}k_{12}\tau[D]}{1 + k_{12}\tau[D] + k_{21}/k_{23}} , \qquad (52)$$

where $\alpha_{fi} = k_d/(k_d + k_1)$ is the probability of the formation of free ions from the radical-ion pair. Two extreme cases must be considered.

1. The electron transfer is slow, i.e. $k_{21}/k_{23} \gg 1$. We then obtain

$$L_0/L = 1 + k_{12}k_{23}\tau[D]/k_{21} , \qquad (53)$$

$$\gamma_{fi} = \alpha_{fi}k_{12}k_{23}\tau[D]/k_{21} . \qquad (54)$$

2. The electron transfer is rapid, i.e. $k_{21}/k_{23} \ll 1$. We then have

$$L_0/L = 1 + k_{12}\tau[D] , \qquad (55)$$

$$\gamma_{fi} = \frac{\alpha_{fi}k_{12}\tau[D]}{1 + k_{12}\tau[D]} . \qquad (56)$$

We may note that for long lifetimes of A* ($\tau > 10^{-7}$ s) and for high values of the product $k_{12}[D] \geq 10^8$ s^{-1}, we have $k_{12}\tau[D] \gg 1$ and $\gamma_{fi} = \alpha_{fi} = k_d/(k_d + k_1)$, i.e. the quantum yield in the formation of free ions is equal to the probability of the formation of such ions from the radical-ion pair. This is the highest possible value of γ_{fi}.

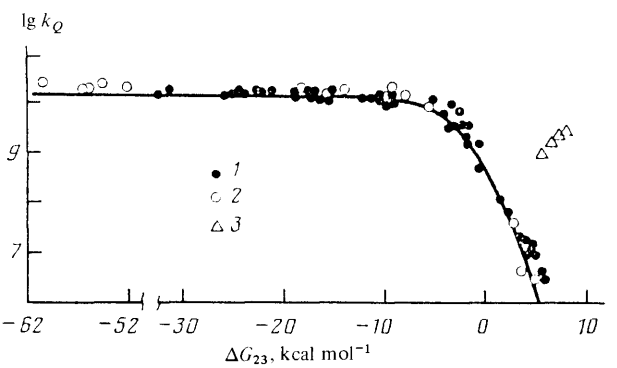

Figure 8. Dependence of the fluorescence quenching constant on ΔG_{23}: 1) electron acceptor in an excited state; 2) electron donor in an excited state; 3) transfer of a hydrogen atom.[48]

There is an interesting relation between the free energy of the electron transfer ΔG_{23} and the logarithm of the quenching constant $\lg k_Q$. The electron transfer rate constant k_{23} can be formulated in the usual form:

$$k_{23} = B_{23}\exp(-\Delta G_{23}^{\neq}/RT) , \qquad (57)$$

where B_{23} is a constant. According to Eqn.(44), $\Delta G_{23}^{\neq}$ is related to the free energy of electron transfer ΔG_{23}. The relation between these quantities can be most simply represented in the form of the linear Brønsted–Polanyi relation:

$$\Delta G_{23}^{\neq} = b + \beta\Delta G_{23} \qquad (58)$$

where b and β are constants for the given series of isotypical reactions. Thus Eqn.(57) can be written in the form

$$k_{23} = B\exp(-\beta\Delta G_{23}/RT) , \qquad (59)$$

where B is a new constant. Together with Eqn.(51), we obtain

$$k_Q = \frac{k_{12}B}{B + k_{21}\exp(\beta\Delta G_{23}/RT)} . \qquad (60)$$

For high negative values of ΔG_{23}, namely $\Delta G_{23} \leqslant -32$ kJ mol^{-1}, $k_Q = k_{12}$ follows from Eqn.(60). For positive values of ΔG_{23}, when the second term in the denominator is much greater than B, we obtain

$$\lg k_Q = \text{const} - 0.434\beta\Delta G_{23}/RT. \quad (61)$$

Fig.8 presents the dependence of $\lg k_Q$ on ΔG_{23},[48] where $\beta = 0.63$ (Bagdasar'yan[49]) and $k_{12} = 2 \times 10^{10}$ litre mol^{-1} s^{-1} (diffusion constant). The relation illustrated in Fig.8 is very general and has been established for many systems with electron transfer.[45]

2. The Absolute Rate Constants for the Formation and Dissociation of Radical-ion Pairs

In the previous Section we considered conditions determining the kinetics of the formation of geminate radical-ion pairs. The rate constant for the formation of radical-ion pairs in an encounter in space is defined by the Debye formula,[7] which is obtained from Eqn.(14) for the diffusion flux by adding to the right-hand side the term which defines the flux of point particles to a spherical surface $4\pi x^2$ under the influence of Coulombic attraction (or repulsion) to the central ion. For unlike charges e_1 and e_2 in a medium with a dielectric constant ε, this flux is

$$(De_1e_2/kT\varepsilon x^2) \cdot 4\pi x^2,$$

where $e_1e_2/\varepsilon x^2$ is the Coulombic interaction force and D/kT the mobility of the ions expressed in terms of the diffusion coefficient by the Einstein formula. Thus, instead of Eqn.(14), we obtain

$$\Phi = 4\pi x^2 D \frac{dc}{dx} - 4\pi Dqc \ , \quad (62)$$

where $q = e_1e_2/\varepsilon kT$ and Φ is independent of x. Integration of this equation subject to the boundary conditions $c = 0$ when $x = R$ and $c = c_\infty$ when $x \to \infty$ leads to the expression

$$\Phi = \frac{4\pi RDqc_\infty}{(e^{q/R} - 1)R} = 4\pi RDpc_\infty \ , \quad (63)$$

where

$$p = q[R(e^{q/R} - 1)]^{-1}$$

is the correction to Smoluchowski's formula for the number of encounters. The quantity q/R is the ratio of the Coulombic and thermal energies and Φ/c_∞ represents the rate constant for the encounters of radical-ions.

Eigen[50] obtained an expression for the rate of diffusional dissociation from the condition for the diffusional equilibrium of radical-ion pairs:

$$4\pi RDp[A][D] = k_d[A \cdot D]_{eq} \quad (64)$$

The equilibrium concentration of the pairs is obtained from Eqn.(8) by introducing the Boltzmann multiplier $e^{-q/R}$, which leads to the equation

$$k_d = \frac{D}{R^2}\left(\frac{q/R}{1 - e^{-q/R}}\right) \ , \quad (65)$$

where the multiplier in brackets represents the correction to the diffusion dissociation constant D/R^2 of uncharged species. It is noteworthy that Eqns.(63) and (65) presuppose that the ions are separated by at least one solvent molecule.

3. Geminate Radical-ion Pairs

The behaviour of the geminate radical-ion pairs arising as a result of electron phototransfer has recently attracted much attention. The influence of magnetic field on the yield of particular final recombination products has been studied in a number of investigations. However, the kinetic constants of the elementary processes determining the behaviour of the radical-ion pairs have been found in only a few studies. We shall consider in greater detail some of the systems investigated.

1. Pyrene–aromatic amines.[47,51–55] On excitation of pyrene (Py) with a laser pulse in the presence of a high concentration (0.1 M) of dimethylaniline (D) in a polar medium (CH_3OH or CH_3CN), an exciplex in a singlet state $^1(Py.D)^*$ is formed. The subsequent processes in this system are indicated schematically below:

$$\begin{array}{l} Py + D \rightarrow {}^1(Py \cdot D)^* \longrightarrow Py + D \\ \quad\quad\quad\

yield of the free ions on the viscosity of the medium was established:[55] with increase of the viscosity by a factor of 25 (from 5.8 to 142 cP), the constant k_d decreased only by a factor of 4 (from 2.6×10^7 to 0.6×10^7 s^{-1}). Experimental data were anlaysed in the above study without taking into account the spin transitions.

2. Anthracene–dimethylaniline (D).[56] The anthracene in solution in acetonitrile was excited with light at $\lambda = 337$ nm (N_2 laser, duration of pulse 2.5 ns). At a dimethylaniline concentration of 0.1 M, the fluorescence of anthracene is fully quenched after only 1 ns, which leads to the formation of a radical-ion pair in the singlet state. The kinetics of formation of the triplet anthracene molecule ^3A were determined by probing the solution at $\lambda = 425$ nm (the absorption maximum of ^3A). The probing beam from a dye-based laser followed the exciting beam at different time intervals. In the absence of a magnetic field, the yields of the anthracene triplets were 4.8, 8.2, and 10.5% after 5, 7, and 15 ns respectively. After the application of a magnetic field, the yield of the triplets diminished and reached a limiting value in fields stronger than 150 G. Subject to certain assumptions, agreement was achieved between the experimental data and the theory of spin evolution induced by hyperfine interaction.[53]

3. Fluorenone–diazabicyclo-octane in propylene carbonate.[57] Under the influence of light at $\lambda = 347$ nm (ruby laser), a triplet fluorenone molecule and then a radical-ion pair in the triplet state are formed. Optical absorption by the fluorenone triplets at 425 nm was measured immediately after the laser pulse and when 2 μs had elapsed, measurements were also made of the absorption by the fluorenone radical-anions at 540 nm. The fraction of the triplet radical-ion pairs which have dissociated into ions was determined from these data. The viscosity of propylene carbonate was varied from 1 to 100 cP by varying the temperature from 213 to 343 K. In this range of viscosities the yield of free ions α_{fi} changed from 0.13 to 0.89. It was assumed that the free ions are formed on dissociation of the triplet pair and that the recombination (reverse electron transfer) takes place in the singlet pair after the change in the spin state of the pair. Thus $\alpha_{fi} = k_d/(k_d + k_S)$ and, after the application of a magnetic field, $\alpha^H_{fi} = k_d/(k_d + k^H_S)$. The influence of the magnetic field can be represented in the form $(\alpha^H_{fi} - \alpha_{fi})/\alpha_{fi}$. This ratio increases from 1.5% to 23% with increase of the viscosity of the medium from 1 to 45 cP ($H = 270$ G). After the application of the magnetic field, the T_+ and T_- sublevels are disconnected, which decreases the probability of the transition from the triplet to the singlet pair and increases the probability of the competing process—the dissociation of the triplet pair into free ions.

The dependence of the probability of recombination $\phi = 1 - \alpha_{fi}$ on the viscosity of the medium has also been examined by the Noyes method.[57] The application of the diffusion gradient method makes it possible to estimate the constant k_S. Fig.9 illustrates the dependence of $1/\alpha_{fi}$ on η/T according to the data of Periasamy and Linschitz:[57] $k_S = 3 \times 10^8$ s^{-1} follows from the slope.

4. Pyrene–dicyanobenzene (A) in various solvents.[58] Excitation with a laser pulse at $\lambda = 347$ nm results in the formation of the radical-ion pairs ($Py^+.A^-$). The kinetics of the formation and destruction of the radical-ion pairs and the free Py^+ ions were followed spectrophotometrically at 445 nm (the absorption maximum of Py^+), while the kinetics of the formation and destruction of the free ions alone were followed conductimetrically (for several hundreds of nanoseconds). In solutions in acetonitrile ($\varepsilon = 38$) the maximum photocurrent is obtained immediately after the termination of the pulse and then diminishes slowly as a consequence of volume recombination. With decrease of ε of the solvent, the maximum photocurrent is attained after a longer time as a consequence of the decreased rate of dissociation of the radical-ion pairs. For liquids of average polarity ($\varepsilon = 9$–12), the experimental rate of formation of free ions approximately agrees with the rate of dissociation of the radical-ion pairs calculated by Eqn.(65).

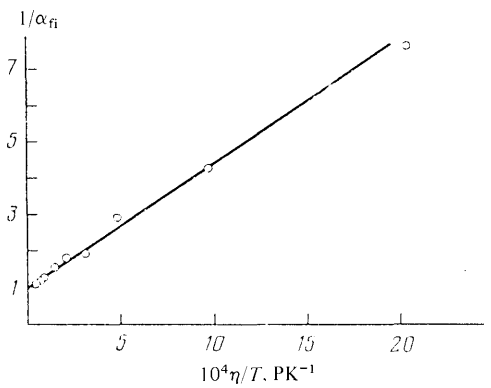

Figure 9. Dependence of $1/\alpha_{fi}$ on η/T according to the data of Periasamy and Linschitz.[57]

5. The

$Ru^{2+}(bpy)_3$ – methylviologen $\left(CH_3-\overset{+}{N}\!\!\bigcirc\!\!-\!\!\bigcirc\!\!\overset{+}{N}-CH_3\right)$.

system. This system has been the subject of numerous investigations in connection with the problem of the photochemical utilisation of solar energy, since, on illumination with visible light, it is thermodynamically feasible for the system to allow the decomposition of water into hydrogen and oxygen.[49] The primary reaction leads to the formation of a radical-ion pair (MV^{2+} = methylviologen):

$$Ru^{2+}(bpy)_3^* + MV^{2+} \rightarrow [Ru^{3+}(bpy)_3 \cdot MV^+] \begin{cases} \xrightarrow{k_1} Ru^{2+}(bpy)_3 + MV^{2+} \\ \xrightarrow{k_d} Ru^{3+}(bpy)_3 + MV^+ \end{cases}.$$

The radical-ion pair either recombines or dissociates with formation of the free ions MV^+ and $Ru^{3+}(bpy)_3$, which, in the presence of catalysts, are capable of inducing the evolution of hydrogen and oxygen respectively from water.

The yield of free ions from the radical-ion pairs, i.e. the quantity $k_d/(k_d + k_1)$, has been determined[59] by the method of nanosecond photolysis ($\lambda = 530$ nm). A characteristic feature of this system is the long lifetime of the excited $Ru^{2+}(bpy)_3^*$ molecules (several hundreds of nanoseconds), during which pairs are continuously generated and destroyed. The concentration of the radical-ions MV^+ released into space is related to the concentration of $Ru^{2+}(bpy)_3^*$ formed during the pulse in the following manner:

$$[MV^+]_\infty = [Ru^{2+}(bpy)_3^*] \frac{k_2[MV^{2+}]}{k_0 + k_2[MV^{2+}]} \frac{k_d}{k_d + k_1}, \qquad (66)$$

where the first fraction represents the probability of the reaction of $Ru^{2+}(bpy)_3^*$ with MV^{2+} [k_0 is the rate constant for the spontaneous deactivation of $Ru^{2+}(bpy)_3^*$]. All the necessary quantities were determined experimentally. Thus the

probability of the relase of the radical-ions into space from the radical-ion pairs was determined from Eqn.(66); it amounts to 0.22 for an aqueous solution and to 0.17 for an aqueous glycerol solution (η = 3.3 cP).

---o0o---

The application of diffusion kinetics to the description of homogeneous molecular processes began with the studies of Vavilov and co-workers (1928–1929), who based their treatment on the diffusion theory of the rapid coagulation of colloids proposed by Smoluchowski (1918). These studies led to the development of the diffusion gradient method for the description of the recombination of radicals and other barrier-free processes. Franck and Ravinowitch (1934) put forward the concept of the "cage" in which a "pair" of radicals arising in the photochemical or thermal dissociation of the molecules is enclosed. In Noyes' studies (1955–1961) the pair was regarded as a dynamic system whose behaviour is described by the microscopic parameters of molecular movement. Subsequently a quantitative description of the cage effect based on phenomenological kinetic parameters was achieved using the gradient diffusion method. This led subsequently to the concept of contact or "almost" contact pairs as intermediate species in radical-barrier free reactions.

The discovery of the spin and magnetic effects in radical pairs is a new important stage in a development of our ideas about the recombination of radicals. Soviet scientists have made a considerable contribution to the development of these ideas. The creation of a rigorous quantitative theory of the recombination of radicals taking into account the spin and magnetic effects and the molecular movements of radicals constitutes a very complex problem. An important step in this direction was made as a result of studies published recently.[60,61]

An approximate method, which the author of the present review called the approximation of chemical kinetics, has been widely used in experimental studies on the recombination of radicals. The phenomenological rate constants for various elementary processes, including diffusion and spin processes, which together determine the behaviour of the radical pairs, are used in this method. These constants can be found from experimental data.

The theory of radical recombination is still far from being complete. The experimental data considered in this review indicate an appreciable difference between the kinetic constants for geminate pairs and the pairs formed in the enounters of the same radicals in space. The discrepancy is apparently associated with the characteristic features of the formation and behaviour of the geminate pairs. It is undoubtedly essential to take into account the rotational diffusion of the radicals forming the contact or "almost" contact pairs, to which attention has been drawn in the present review. The recombination and dissociation of the radical-ion pairs and their dependence on the viscosity of the medium have been inadequately studied. The Debye–Smoluchowski [Eqn.(63)] and Eigen [Eqn.(65)] equations have received little experimental confirmation for organic radical-ions. Thus this field of chemical kinetics requires further studies—both experimental and theoretical.

The behaviour of geminate electron–radical-cation pairs, which were mentioned in the Introduction, is of considerable interest. The properties of these pairs to a large extent determine the chemical reactions occurring under the influence of ionising radiation on liquid media. A convenient method for the study of these pairs is two-quantum photoionisation (see the present author's earlier review[62]). The high mobility of electrons in the liquid medium results in a significant difference between an electron–radical-cation pair and a radical ion pair. The properties of geminate electron–radical-cation pairs therefore require separate consideration.

The Structural Chemistry of Crystalline Carbon: Geometry, Stability, and Electronic Spectrum

I.V.Stankevich, M.V.Nikerov, and D.A.Bochvar

The crystalline modifications of carbon described in the literature are briefly reviewed. The publications in which new types of structures, differing from the diamond and graphite lattices, are proposed and discussed are analysed in detail. The geometrical-topological characteristics of the hypothetical modifications of carbon, their relative stabilities, the nature of the chemical bonds, and the structure of the electronic spectra are discussed.
The bibliography includes 129 references.

II. Crystalline modifications of carbon described in the literature 641
III. Hypothetical crystalline modifications of carbon 644

I. INTRODUCTION

The carbon atoms forming part of the composition of hydrocarbon molecules stable under normal conditions can form chemical bonds with two, three, or four neighbours. As a rule in the first case the carbon atom and two of its partners are located on a single straight line, in the second case they form a planar molecular fragment with valence angles close to 120°, and in the third case a nearly tetrahedral disposition of the bonds is achieved. These features can be described in terms of the hybridisation theory, according to which carbon atoms tend to form directed two-centre σ-bonds with participation of sp-, sp^2-, and sp^3-hybrid orbitals; in the first two cases there is a possibility that additional bonds of the π-type may arise.

The numerous structural data for saturated and unsaturated hydrocarbons can be interpreted fairly reliably within the framework of the terms described above. Extended molecular systems in which carbon–carbon bonds are formed preferentially are of special interest. In the limit such systems can be regarded as infinite and consisting of carbon atoms only and can be divided into two groups: (1) systems made up of carbon atoms or small clusters of the latter having a regular structure in which the positions of the atoms or the clusters can be random; (2) systems in which the atoms are distributed regularly in three dimensions and form a complex bonded system with translational invariance. For example, carbon black, vitreous carbon, and various amorphous carbon films belong to the first, non-crystalline type, while crystals such as those of diamonds (cubic and hexagonal) and graphite (hexagonal and rhombohedral) belong to the second type.

Diamond and graphite are examples of extended systems in each of which sp^3 and sp^2 hybridisation obtains respectively; sp hybridisation arises in carbyne, which consists of linear macromolecules according to the investigators[1,2] who discovered this new allotropic form of carbon.

Together with diamond and graphite, whose structures have been thoroughly investigated, several other crystalline modifications of carbon have been described in the literature: up to eight carbyne forms, metallic carbon, C_8 carbon, etc., whose structures have not so far been established or have not been demonstrated sufficiently reliably.[3–6] The hypothesis has been put forward[7] that certain metastable carbon phases of unknown structure can arise in the growth of carbon layers on various crystalline modifications of boron nitride.

The modelling of the structure of amorphous carbon is an extremely complex problem and is extremely important for the interpretation of the physicochemical properties of the substance and for the creation of carbon materials with specified properties. In setting up a model of amorphous carbon, one usually employs the structural fragments of known crystalline modifications of carbon. For example, a model has been proposed[8] for the interpretation of the structure of sputtered amorphous carbon films according to which the structure of such a film can be represented as a bonded formation consisting of fragments of diamond-like and graphite-like types. The deficiencies of this model have been noted[9] and it has been emphasised that the earlier investigation[8] did not take into account the possibility of the formation of non-diamond-like and non-graphite-like fragments. Apparently the unsuitability of this model for the description of the structure of low-density carbon films is associated with this factor. The data quoted[9] also show that the most probable interatomic distance in the specimens obtained is intermediate between the lengths of single and double bonds; furthermore, the presence of multiple bonds is emphasised. A detailed analysis of experimental studies and model ideas used at the present time for the description of the structure of polymeric carbon has been carried out in a review.[10]

The existence of crystalline modifications of carbon of unknown structure, the difficulties arising in the modelling of the structure of amorphous carbon, and also the search for new carbon materials with a specified set of properties have led to the formulation of several theoretical problems which we believe to be extremely acute for the physical chemistry of carbon. It is necessary to discover whether the entire family of crystalline modifications of carbon is exhausted by the three forms described above—diamond, graphite, and carbyne, and, if not, what are the possible structures of these other hypothetical forms of carbon. It is also necessary to consider what evidence can be adduced in support of the possibility of the existence of such forms and what could be the physicochemical properties of these systems. This paper has been devoted to the analysis of the present state of these problems, which have been hardly discussed in the review mentioned above.[10]

II. CRYSTALLINE MODIFICATIONS OF CARBON DESCRIBED IN THE LITERATURE

There are two polytypical modifications of diamond: cubic diamond (D_c), which belongs to the $Fd3m$ symmetry space group and whose unit cell contains eight carbon atoms, and hexagonal diamond (D_h)—lonsdaleite, which belongs to the $P6_3/mmc$ symmetry space group and whose unit cell contains four carbon atoms.[11,12] The physical properties (density, hardness, electrical resistivity, and optical properties) of D_c and D_h are very similar, which is due to the identity of the first layer around each carbon atom in these diamond modifications; the valence angles are 109°28′16″ in both, the bond lengths are close to 1.545 Å, and the coordination number of each carbon atom is four. The difference between the second layers surrounding the carbon atoms in cubic diamond and in lonsdaleite is due to the fact that in cubic diamond all the layers made up of coordination tetrahedra are oriented in the same manner, while in lonsdaleite each succeeding tetrahedral layer is rotated by 60° relative to the previous layer.[13] Fragments of the crystal structures of D_c and D_h are presented, for example, in a monograph.[12]

The cubic modification of diamond is thermodynamically stable, being more stable than graphite at sufficiently high pressures, but it also exists at low pressures in a metastable state. The transformation of diamond into graphite takes place with a change in the first coordination sphere and in the type of chemical bond, which is the reason for the high energy barrier to the transformation and the low rate of the process. Lonsdaleite is a metastable modification of carbon; at high pressures it is transformed into cubic diamond and at low pressures into graphite. The phase transformations in carbon have been described in detail.[11,14]

Each carbon atom in diamond forms four stable covalent bonds with neighbouring carbon atoms and all the bonds are equivalent. The equivalence of the bonds in diamond makes it possible to employ the approximation of equivalent orbitals in the calculation of its band structure. The equivalent orbitals are linear combinations of atomic wave functions which are interconverted under the influence of the operations of the symmetry group of the crystal; this reduces the number of independent matrix elements and makes it possible to obtain the dependence of the energy of the molecular orbitals on the wave vector along symmetrical directions in the inverse space in an analytical form. The methods for the calculation of the electronic structure of crystals with the diamond structure have been considered in detail in a monograph.[15] The applicability of the method of equivalent orbitals to the description of the band structure of diamond indicates the localised character of the bonds in diamond, since the method of equivalent orbitals is particularly successful in a description of structures with localised bonds.

The second allotropic modification of carbon is graphite, which also exists in the form of two polytypic forms: hexagonal graphite (G_h) with a $P6_3/mmc$ symmetry group and four carbon atoms in the unit cell and rhombohedral graphite (G_r) which has a $R\bar{3}m$ symmetry space group and six carbon atoms in the unit cell.[11,12] Graphite has a layer structure and consists of hexagonal carbon layers linked by van der Waals forces. The structures of the layers in G_h and G_r are almost identical (the coordination number of carbon is three, the bond lengths are close to 1.42 Å, and the valence angles are 120°). However, the arrangements of the layers in these two modifications are different, which also leads to a difference between their crystal structures.[11,16] In hexagonal graphite each third layer repeats the first and each second layer is displaced relative to the first in such a way that half the atoms of each layer are located respectively above and below the centres of the hexagons of the neighbouring layers. The sequence of identical layers in G_h can be represented conventionally by the symbol ...ABABAB.... In rhombohedral graphite each fourth layer repeats the first. The sequence of the layers in G_r can be represented by the symbol ...ABCABC.... In several processes rhombohedral graphite always occurs in specimens of natural origin and in the products of the mechanical treatment of graphite.[16] The high degree of anisotropy of the physical properties of graphite (electrical conductivity and optical and thermal properties) is associated with the fact that the interaction between the hexagonal layers in graphite is much weaker than the interaction within each layer (the distance between the graphite layer is 3.35 Å); the physical properties of G_h and G_r are similar.

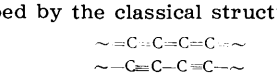
Of the four valence electrons of each carbon atom in graphite, three are involved in the formation of localised σ-bonds with neighbouring atoms. The fourth valence electron is located in the $2p$ orbital whose symmetry axis is at right angles to the plane of the hexagonal layer and participates in the formation of bonds of the π-type, which make up an extended delocalised π-electron system. The orthogonality of the orbitals of the electrons in the σ- and π-systems makes it possible to obtain the principal qualitative characteristics of the bands in the spectra of graphite in terms of the π-electron approximation, where only one $2p$ electron of each atom is taken into account and it is assumed that these mobile π-electrons migrate in the field of a rigid σ-skeleton.

Since the interaction between the layers of graphite, which is of the van der Waals type, is fairly weak, a two-dimensional model is frequently employed in the calculation of the band structure of graphite. The two-dimensional model leads to a zero width of the energy gap between the valence and conductivity bands and to a marked anisotropy of the properties of graphite, which agrees with experiment and the results obtained for the three-dimensional model. In order to achieve a quantitative agreement between theory and experiment, it is necessary to take into account also the interlayer interaction. The properties of graphite have been described by Ubbelohde and Lewis[16] and the methods for the calculation of its band structure have been described, for example, by Slonczewski and Weiss[17] and Ovchinnikov and Belyi.[18]

The principal properties of graphite and diamond have so far been adequately described in theoretical terms and the main efforts in this field are therefore nowadays directed to the study of diamond-like and graphite-like systems with less perfect and more indefinite structures (the influence of defects, the formation of layer compounds of graphite with various metals, the description of the band structure and properties of non-graphitised carbon, etc.), as well as the interconversions of the modifications of carbon and the conditions governing their formation.[11,16,19,20] Furthermore, diamond and graphite can be regarded as model systems on which it is possible to test various new methods and approximations of solid state physics and quantum chemistry.

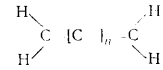
As mentioned above, apart from diamond and graphite, there exist also other crystalline modifications of carbon whose structure is so far unknown or has been studied with inadequate reliability. In 1979 the synthesis of new cubic modifications of carbon with the $Im3$ symmetry space group and containing sixteen carbon atoms in the unit cell was reported.[5] The new crystalline modification of carbon, called by the authors C_8, was obtained by condensing fluxes of carbon plasma on cooled supports; C_8 is formed in the form of single crystal inclusions, whose size is up

to 3000 Å, in a carbon film. The theoretical density of the new modification $\rho = 4.1$ g cm^{-3}, i.e. is greater than the density of diamond (3.51 g cm^{-3}); the microhardness of C_8 exceeds that of diamond, the coordination number is 4, and the period of the body-centred lattice is 4.28 Å. This modification of carbon consists of coordination tetrahedra[21] of the same kind as in D_c and D_h but somewhat deformed and more closely packed. The valence angles in the C_8 modification differ from the tetrahedral values (90° and 125°16′), while the bond lengths are also different and greatly reduced (1.42 and 1.23 Å).



The structure of C_8 can be represented as a result of the polycondensation of cubane C_8H_8,[22] in which hydrogen is competely removed and the vertices of the carbon cubes are linked by chemical bonds. The bond lengths between the vertices of individual cubes are 1.23 Å, which is close to the lengths of the triple bond in acetylene; however, the C–C bond length in cubane is 1.55 Å.[23] The combination of a coordination number of 4 and bond lengths of 1.42 and 1.23 Å in C_8 is not altogether usual and conflicts with the empirical rules established for bond lengths in molecules,[24] according to which bond lengths of approximately 1.54 Å are characteristic of a carbon atom forming four bonds. Certain diffraction lines in the X-ray diffraction patterns, close to those found[5] for C_8, have been observed for the carbon particles obtained as a result of the exposure of octane, decane, and iso-octane drops to a laser beam.[25] Nevertheless the deviation of the bond length in C_8 from the classical values shows that the crystal structure of C_8 requires additional experimental confirmation.

The report[6] of the preparation (as a result of the impact compression of a graphite single crystal up to pressures in excess of 150 kbar) of a modification of carbon, which is metastable at atmospheric pressure and which has a cubic lattice with a period of 5.545 Å and 24 atoms in the unit cell, has also not been finally confirmed. The individual interplanar spacings, determined in the above study,[6] are encountered in carbon powders obtained on crystallisation of carbon from the gas phase and also in the same powders subjected to high pressures and temperatures corresponding to the region of stability of diamond.[26] The symmetry space group of this modification has not been established. The authors[6] merely quote a set of space groups compatible with the observed diffraction lines. The density of the modification is 2.8 g cm^{-3}, i.e. is intermediate between the densities of diamond and graphite (2.265 g cm^{-3}).[16]



The phase diagram of carbon, in which a region of the thermodynamic stability of solid metallic carbon (carbon III) had been noted at high pressures ($p > 600$ kbar), was published in 1963.[27] The preparation of metallic carbon has been reported in another study,[4] but its structure had not been determined. The present ideas concerning the phase diagram of carbon have been described in detail by Bundy.[28]

Apart from the communications enumerated above concerning new crystalline modifications of carbon, there have been numerous studies devoted to crystalline modifications of carbon of the carbyne type. Up to eight modifications of carbyne are now known[3] (α-carbyne, β-carbyne, etc.), but the crystal structures of none of them have so far been established.

According to some investigations,[1–3,29,30] carbyne is a crystalline modification of carbon consisting of fairly long (number of carbon atoms approximately 10^3) linear carbon chains weakly interacting with one another. In the ideal case, there is a possibility of two carbyne forms, which can be described by the classical structural formulae

The end groups are not represented in these systems, although in fact such groups are extremely important for the understanding of the structural differences between these compounds. In the first case the macromolecule has the form

(I)

and is of the cumulene type. In the second case the macromolecule is of the poly-yne type:

(II)

In the case of purely carbon macromolecules, a structure of an intermediate type should obtain.

Raman spectroscopic data[31] indicate the presence in the spectrum of the mineral chaoite[32] of a band at 2140 cm^{-1} corresponding to the stretching vibrations of the triple bond $-C\equiv C-$; however, this fact alone is insufficient to conclude that the molecules of chaoite let alone those of all the carbyne modifications of carbon are linear. Henceforth carbyne will be understood as a modification of carbon with a linear structure of its constituent macromolecules and as crystalline modifications of carbon whose structure has not been established and which have been classified as carbyne forms of carbon; however, in the future it may turn out that certain carbyne modifications of carbon known at present do not consist of linear molecules. The proposed agreement concerning terminology is justified by the fact that the term "carbyne" has penetrated the literature extensively and is used both in relation to model systems consisting of linear carbon macromolecules[33–36] and in relation to crystalline modifications of carbon whose structure has not been established with adequate reliability or is unknown.[1–3,25,26,29,37,38]

The methods used to prepare carbyne are extremely varied: synthesis from acetylene;[30,39] deposition of carbon vapour, obtained on sublimation of graphite by a laser beam, onto a glass or other support;[40] the formation of a white film of carbyne when an electric current is passed through a graphite rod;[41] plasma-chemical methods;[42,43] etc.[44,45] Unfortunately a single crystal of carbyne sufficiently large for the elucidation of its crystal structure cannot be obtained by any of these methods. Single crystals of carbyne (chaoite), discovered in a meteorite crater,[32] in natural graphite deposits,[37] and in a meteorite[46] are also too small to determine their crystal structure.

The data obtained in the study of carbyne modifications of carbon lead to the following ideas about its structure and properties. Carbyne is a white substance[32,37,41,47] with an almost 100% content of carbon, whose density is intermediate between those of diamond and graphite, and which is chemically resistant to oxidants and other reagents.[48] Carbyne single crystals with dimensions up to 10^4 Å have hexagonal symmetry[1,2,32,38] and the unit cell contains a large number of carbon atoms (for example 144 for α-carbyne and 72 for β-carbyne[1,29]), which hinders the determination of its crystal structure from diffraction data. According to Whittaker,[3] the region of thermodynamic stability of carbynes is at temperatures from 2600 to 3800 K. On heating (by an electric current in an atmosphere of argon), graphite is slowly converted into linear forms of carbon, the reverse process occurring rapidly on cooling.[49] At pressures greater than 60 kbar, the carbyne forms of carbon are converted into diamond-like structures and, on reducing the pressure to 0 2 atm and less, carbyne sublimes.

According to some data,[26,50,51] the β-modification of carbyne is more stable at high pressures, while the α-modification is more stable at lower pressures. Some

data on the heat capacity of carbyne[52] indicate the quasi-one-dimensionality of its molecules but at the same time there have been reports[1,54] that, as a consequence of the high reactivity of the carbon chains, it is very difficult to avoid the formation of chemical bonds between them (with increase of their length) during the preparation of carbyne chemically. It may be that, as a consequence of this, in the synthesis of carbyne the final product always contains a definite number of bonds between the chains whose positions cannot be determined by X-ray and electron diffraction.

Overall, the available information about the physical properties of carbyne is fairly scanty, which leads to arbitrary theoretical constructions and estimates concerning carbyne, since the present state of the methods for the calculation of the electronic and crystal structures of solids precludes a reliable prediction of any one property of the solid without resorting to experimental data. At the same time, it is essential to note that most investigators have no doubt about the existence of crystalline modifications of carbon of the carbyne type because X-ray and electron diffraction methods lead to structural parameters of carbyne which are definitely different from those of diamond and graphite.[1,29,47,54,56] Furthermore, photoelectron spectroscopic data[55] also indicate significant differences between the spectra of diamond, graphite, and carbyne. Apparently carbyne has a characteristic ionic spectrum (the ratio of the concentrations of the C_2^- and C_6^- ions),[49,57] which makes it possible to employ ionic spectrometry for the detection of microinclusions of carbyne in carbon specimens of natural and artificial origins.

We may note that, in the literature devoted to theoretical studies of the electronic structure of carbyne, for example, in the communication of Misurkin and Ovchinnikov,[58] the activation energy for electrical conduction in carbyne, obtained from the measurement of the temperature variation of the electrical conductivity, is quoted as $\Delta E = 1-2$ eV and this value is identified with the width of the forbidden gap in carbyne $\Delta\varepsilon$. However, in another investigation[59] the conductimetric measurements were performed on a specimen consisting of a black insoluble powder containing 98% of carbon and obtained by the polycondensation of acetylene. At the same time it is known that in other methods of synthesis the carbyne forms of carbon are white and contain almost 100% of carbon. The activation energy for electrical conduction in the black specimen must have been influenced by admixtures and the boundaries between the grains, so that these data[59] concerning ΔE can hardly be correctly attributed to carbyne forms of carbon. The white colour of the carbon films is more probably an indication that the width of the forbidden gap in the electronic spectrum of carbyne is greater than the maximum energy of the photon in the optical range, which is 3.3 eV.

The carbyne macromolecules have been investigated by various quantum-chemical methods: in the π-electron approximation, in the valence approximation, and taking into account all the electrons. Special interest in this branch of the quantum chemistry of polymers arose in the second half of the 1960's [30] when it was suggested that carbyne consists of linear carbon chains or of fairly long hydrocarbon molecules of types I and II. The real differences between systems I and II are manifested primarily in the geometry, which in the case of system (I) depends on the parity of the number n. The carbon skeletons of the molecules of (I) and (II) are linear. In the former case the C–C bond lengths are identical and close to 1.3 Å, while in the latter case they alternate and the extent of this alternation apparently depends little on n.

The electronic spectra of systems (I) and (II) are also different. The energy of the first transition for the molecule of the cumulene type tends to zero, while in the case of the poly-yne system there is a forbidden gap whose width is non-zero.[60–63] For small values of n, the influence of the end groups on the C–C bond length is extremely significant. Calculations for a series of compounds C_4, C_4H_2, C_4H_4 and C_6, C_6H_2, C_6H_4 have been carried out[64] in terms of the valence approximation by the extended Hückel method (EHM) using Cusachs' parametrisation[65] with partial optimisation of the geometry; in the case of the C_4H_2, C_4H_4, and C_6H_2 molecules the calculations led to results close to the experimental data. Qualitative estimates of the C–C bond length in the linear C_4 and C_6 molecules have been made on the basis of these calculations.

Results indicating an appreciable influence of the end effects on the geometrical characteristics of the inner parts of the molecules of the given type, containing a fairly large number of carbon atoms, have been obtained.[66] The same communication[66] presents results of quantum-chemical calculations for molecules of the types C_nH_2, C_nH_4, and C_n (linear configuration) with $n \leq 18$ in the valence approximation of the EHM. A model was used in which it was assumed that the distance r between the carbon atoms is related to the corresponding bond population (Mulliken population) p by the expression

$$r = 1.860297 - 0.54869p + 0.109747p^2$$

found on the basis of calculated data for acetylene, benzene, ethylene, and ethane.

The calculation in the above study[66] was iterative. Hoffmann[66] analysed in detail the disadvantages of this model and noted in particular that the agreement in terms of the bond orders may not correspond to the total energy minimum. However, the bond lengths found for a small value of n proved to be close to the experimental lengths (allene, butatriene, diacetylene, triacetylene) and this factor served to some extent as justification of the possibility of employing this approach for high values of n. The results of Hoffmann's calculations[66] led to the conclusion that the influence of the end groups on the bond lengths in the C_n, C_nH_2, and C_nH_4 molecules is extremely significant, at any rate for $n < 20$.

In order to solve the question of the possible existence of fairly long molecules of the type C_nH_2, C_nH_4, and C_n, a whole series of quantum-chemical calculations were performed for model linear systems of the C_n type consisting of a large number of carbon atoms. These calculations were performed in terms of different approximations: at the π-electron level taking into account the influence of the σ-skeleton by an additive scheme, taking into account all the valence electrons (EHM, CNDO/2, and the method of a three-dimensional electron gas), and by non-empirical methods.[34–36,67–73] In some of these studies[67–72] Bloch's cyclic model was used. The possibility of the alternation of the lengths of neighbouring C–C bonds (r_1 and r_2) was assumed. The average total energy per elementary fragment (in the given case the elementary fragment consists of two carbon atoms) was regarded as a function of two independent parameters and was optimised. All these calculations led to the same qualitative conclusions regardless of the approximation employed: the minimum average potential energy of the $^\sim C_n$ system in the limit at $n \to \infty$ is reached when $r_1 \neq r_2$ and the C_∞ system is stable in relation to dissociation into diatomic fragments.

On the one hand, the conclusion of the alternation of the bond lengths is satisfactorily consistent with the Peierls theorem, which states that one-dimensional systems with

an energy spectrum of the metallic type are unstable, since the alternation of the bond lengths automatically leads to the appearance of a gap in the spectrum, which is manifested even in the Hückel π-electron approximation. On the other hand, it has been shown in a number of studies that, in terms of the π-electron approximation, when account is taken of the correlation effects, the width of the gap is not zero also when the bond lengths are equal ($r_1 = r_2$, see, for example, the relevant reviews[58,74]). It has been concluded[58] that in cumulene chains with a sufficiently large number of carbon atoms an antiferromagnetic state obtains and for this reason the bond lengths may be identical in long cumulene molecules far from the ends. However, we may note that this conclusion has been reached in terms of the π-electron approximation.

In conclusion one should note that, from our point of view, the use of the average value of the total energy for the estimation of the local geometrical properties of the molecule is an unduly rough approximation: the model leads *a priori* to an average bond length and for this reason the average total energies of the C_n, C_nH_2, and C_nH_4 systems with the same geometry of the carbon skeleton tend to the same limit and caution must be exercised in interpreting the results obtained within the framework of this model However, the conclusions reached in a number of studies[67-72] do not conflict with the possibility of the existence of fairly long molecules of the type C_n, C_nH_2, and C_nH_4. At the same time, the high reactivity of such systems can lead to the presence of intermolecular cross-links and, in order to avoid them, it is necessary to isolate the molecules from one another in some way. One of such procedures, associated with the synthesis of carbyne forms of carbon from tetrafluoroethylene, has been discussed.[75]

III. HYPOTHETICAL CRYSTALLINE MODIFICATIONS OF CARBON

1. The Geometrical-Topological Properties of Crystalline Carbon and Certain Energy Estimates

Diamond and graphite are two allotropic crystalline modifications of carbon which differ from one another both in the type of structure and in the coordination numbers of the atoms.[12] The structures of diamond and graphite are free from strain, since their valence angles agree with the classical angles for tetracoordinate and tricoordinate carbon atoms respectively. All the bonds in diamond are equivalent and the carbon atoms are located in structurally equivalent positions. To within fairly weak interlayer interactions, the positions of the atoms in graphite are also equivalent; the bonds in the graphite layer are equivalent to one another also when account is taken of the interlayer interactions. The characteristic features of the diamond and graphite structures enumerated above (the equivalence of the bonds and of the positions of the atoms, the absence of strain) distinguish them from the multiplicity of the remaining modifications of carbon listed above; apparently these features are responsible for the stability of diamond and graphite and their wide occurrence in nature.

If the macromolecules of carbyne have a linear structure, then its valence angles should be 180°, which also leads to the absence of strain, because an angle of 180° is characteristic of the dicoordinate carbon atom. In a structure of the cumulene type, the C–C bonds are equivalent and all the atoms occupy equivalent positions, provided that, as in graphite, one neglects their intermolecular interaction. In a structure of the poly-yne type, the equivalence of the bonds breaks down, but a linear chain of the poly-yne type is also free of strain. The deviations of the structural type of carbyne and of the coordination number of atoms in it from the corresponding characteristics of diamond and graphite make it possible to regard carbyne as the third allotropic crystalline modification of carbon.

We shall now consider the question whether there is a possibility of further crystalline modifications of carbons free from strain. Such a possibility will be considered in a purely geometrical sense and the identity of the valence angles with the classical values (109°28′16″, 120°, and 180° for tetracoordinate, tricoordinate, and dicoordinate carbon atoms respectively) will be regarded by convention as the criterion of the absence of strain.

The presence of chemical bonds between the carbon atoms in diamond and graphite makes it possible to describe naturally the structures of these compounds in terms of regular networks. The term "net" is used in this review as a non-oriented graph with an infinite number of vertices located in a three-dimensional space at the points corresponding to the positions of the lattice atoms. The vertices are assumed to be adjacent when the interatomic distances do not exceed 1.6 Å. In diamond the corresponding graph is connected and homogeneous and the degree of each of its vertices is 4. In graphite the graph is subdivided into an infinite number of subgraphs corresponding to individual layers. Carbyne can also be described in terms of an infinite number of subgraphs, each subgraph being linear. From the standpoint of the graph theory, the positions of the vertices and the lengths of the edges as well as their form are not significant. The problem of describing the possible crystalline modifications of carbon (CMC) is therefore a special case of the problem of describing infinite graphs satisfying the following properties: a graph must permit a geometrical construction in which the angles between the edges (in the given instance we consider the sections connecting the vertices) are identical with or close to the classical valence angles in the C–C bonds. Furthermore, the geometrical graph must have the property of periodicity and the number of atoms in the elementary fragment should not be very large.

Thus graph theory may be used for the description of structures which satisfy the essential requirements of valence theory for the carbon atom. We shall discuss initially the structures of the graphite-like type described by a system of unconnected graphs with a degree of 3, each of which can be represented in the plane as a periodic structure.

In connection with the problem of the existence of new crystalline modifications of carbon, this approach has already been used.[76] The authors of that investigation discussed mainly geometrical graphs with a mosaic structure made up of a combination of different carbon rings: four-membered and eight-membered, three-membered and twelve-membered, and also five-membered and seven-membered. Some of these planar systems are illustrated in Fig. 1. In all the structures there are extended π-electron systems. The valence angles deviate from 120°; the degree of each vertex of the graph is 3. For example, in the graph $(3:4,8^2)$ (Fig. 1*b*) two valence angles are 135° and the third is 90°. Here we have made use of a notation which is convenient for certain homogeneous graphs; the number 3 denotes the degree of the vertex and the numerals 4 and 8 represent the size of the rings to which each vertex belongs. In the graph $(3:4,8^2)$ each vertex belongs to one four-membered and two eight-membered rings, which is denoted

by the superscript 2 to the numeral 8. $(3:6^3)$ corresponds to a graphite layer (Fig. 1*a*) in terms of the same notation. Fig. 1*c* represents also a (3:5,7) net made up of five- and seven-membered rings. The deviation of the valence angles in the $(3:4,8^2)$ net from 120° leads to an energy gain compared with graphite, where the valence angles are 120°, The energy of the steric strain (E_{SS}) has been estimated[76] from the empirical formula $E_{SS} = 17.5\Delta\theta^2$ cal mol^{-1}, where $\Delta\theta$ is the deviation of the valence angles from the ideal value (120° or 109°28′16″ in the case of sp^2- or sp^3-hybridisation respectively). In estimating the relative stabilities of planar nets, account was also taken of the conjugation energy (E_{conj}) calculated in terms of the Hückel approximation.

Among the three-dimensional nets considered by Balaban et al.,[76] the net whose fragment is illustrated in Fig. 1*e* is of greatest interest. It is described in terms of truncated octahedra and the valence angles (90° and 120°) differ fairly appreciably from the tetrahedral values (the steric strain energy is 12 kcal mol^{-1}). The relative stability of this system was determined in relation to diamond (cubic) and the relative stabilities of graphite and diamond were estimated from the difference between the enthalpies of formation. The energies of the other (planar) forms shown in Fig. 1 were estimated in the way described above and were assumed to be $E_{SS} + E_{conj}$. This analysis resulted in the following stability series (in kcal mol^{-1}): graphite (0.0), cubic diamond (0.5), hexagonal diamond (3.0), system (*c*) (7.5), system (*e*) (12.0), and system (*b*) (17.0). A higher energy corresponds to the other nets considered in the above study.[76]

It is seen from the above analysis that the estimates obtained[76] are extremely approximate. In particular, the authors[76] in essence restricted their treatment to a purely topological approximation and did not attempt to estimate the bond lengths in the carbon structures which they considered. Apparently, the assumption of the planar character of the systems and in particular of the net made up of four- and eight-membered rings is insufficiently justified. For example, it is known that the eight-membered carbon ring in cyclo-octatetraene and its octamethyl derivatives is non-planar; a doubt therefore arises about the reality of system (b) which can hardly be planar.

Planar regular nets are the limiting case of finite nets which can be produced on a sphere with a sufficiently large radius. In this case a convex polyhedron can be associated with each such net. The possibility of the existence and methods of synthesis of some of the hydrocarbon systems whose carbon atoms are located at the vertices of the simplest polyhedra (the cube, the trihedral prism, the tetrahedron, and the dodecahedron) has been discussed in a number of studies.[77–82]

The possibility of the occurrence of the analogous unsaturated purely carbon systems—molecules whose atoms are located at the vertices of polygons or polyhedra has been considered in a number of studies.[83–89] Certain results obtained for small carbon clusters, including planar clusters, are of interest in this connection. For example, the potential energy surface for the C_3 triatomic molecule has been investigated[83] by the non-empirical LCAO-MO method. It was established that a linear configuration is most stable

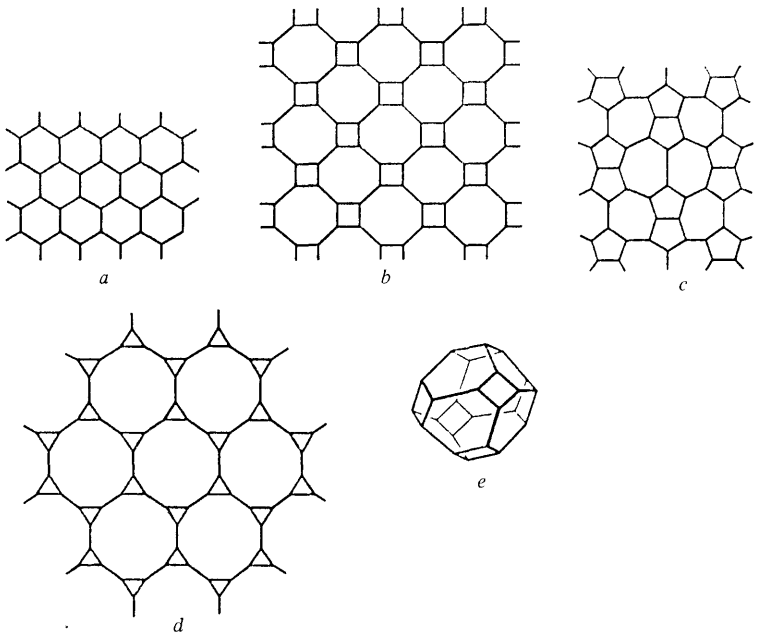


Figure 1. Some of the carbon systems considered by Balaban et al.[76]: *a*) $(3:6^3)$ graphite layer; *b*) $(3:4,8^2)$ system; *c*) (3:5,7) system; *d*) $(3:3,12^2)$ system; *e*) fragment of three-dimensional net.

for this molecule. Furthermore, a local minimum, corresponding to a trigonal configuration of the nuclei in the form of an isosceles triangle, was noted on the potential energy surface. The molecule has a triplet ground state.

A recent calculation for the C_4 cluster led to an unexpected result. It was found that the cyclic system in the form of a rhombus is energetically more favourable than the linear system.[84] The relative stabilities of various symmetrical configurations of clusters having the composition C_p ($p = 3-7$) have been discussed[85] within the framework of the semi-empirical MINDO/2 approximation. In particular, it was established that, for each of the C_3-C_7 clusters, there exist at least two isomers and that the absolute energy minimum corresponds to a non-linear configuration. For example, in the case of C_4 the most stable configuration is the rhombus (D_{2h} symmetry), which is consistent with the conclusions reached[84] by a non-empirical method. A distorted octahedral configuration obtains for C_6. In the case of C_4 a linear configuration proved to be unstable, but for other clusters (C_5, C_6 and C_7) local minima on the potential energy surface correspond to linear configurations. The relative stabilities of small carbon clusters have also been discussed by Beran et al.[86]

The electronic structures and relative stabilities of the carbopolyhedra with a large number of carbon atoms have been investigated.[87-89] The authors of these studies carried out calculations by various quantum-chemical methods for the carbododecahedron (C_{20}), the carbo-*s*-octahedron (C_{24}), which is a polyhedral fragment of the three-dimensional net (*e*) (Fig. 1), and carbo-*s*-eicosahedron (C_{60}) (Fig. 2).

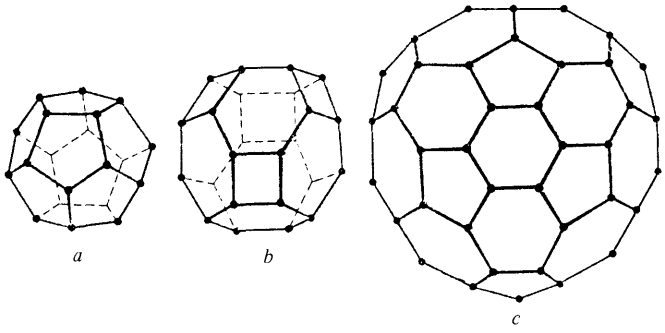

Figure 2. Carbopolyhedra: *a*) carbododecahedron; *b*) carbo-*s*-octahedron; *c*) carbo-*s*-eicosahedron.[87]

In the simplest case an approximation analogous to the Hückel approximation for planar unsaturated conjugated systems, which has been called[87-89] the ρ-approximation, was used. It was assumed that the σ-skeleton of the carbopolyhedra is made up of two-centre two-electron banana bonds in which the 2*s* and 2*p* orbitals of the carbon atoms participate. The remaining *p* orbitals are directed along the radius of the sphere described and the electrons associated with these orbitals are involved in the formation of the ρ-system on the sphere analogous to the π-system in the limiting case of the sphere—the plane.

The calculations performed in terms of the ρ-approximation[83] showed that the ρ-electron shell of the carbododecahedron is not closed (in the highest quadruply degenerate level there are two electrons), while the carbo-*s*-octahedron and the carbo-*s*-eicosahedron have a closed electron shell. The calculations performed with the aid of the EHM confirmed the conclusion concerning the character of the electron shells of the ground states of the carbododecahedron, the carbo-*s*-octahedron, and the carbo-*s*-eicosahedron. By varying the C–C bond lengths in C_{20}, C_{24}, and C_{60} while retaining the ideal symmetry for these systems, an equivalent value close to the length of a single bond was attained. In the case of the C_{20} system the above calculation shows that such a molecule, if it exists, should have the form of a distorted dodecahedron. Naturally, the symmetry of the carbododecahedron can be reduced by replacing two carbon atoms by boron atoms and by reducing thereby the total number of ρ-electrons by two. Such systems have a closed electron shell (EHM, ρ-approximation) and it is believed[87-89] that no obstacle to the possibility of their existence has so far been found.

The results described above have been confirmed by calculations carried out by the CNDO-2 method.[88,89]

We shall now proceed to the description of certain connected three-dimensional infinite regular nets, which can be achieved in three-dimensional space in such a way that the valence angles are equal to or close to the classical values. Apparently, one of the first studies on these lines[90] was published as early as 1946; its authors describe the structure of carbon made up of six-membered rings notated relative to one another. A net formed in three-dimensional space as a result of regular cross-links between the carbon skeletons of *o*-tetraphenylene, whose molecules are non-planar, corresponds to this crystalline modification of carbon. A net of this type has been used[91] to construct one of the possible models of amorphous carbon.

In relation to structural problems of crystal chemistry and crystallography, three-dimensional nets have been investigated systematically by Wells, who described a number of three-dimensional nets, suitable for the understanding of the topology of crystals with a complex structure, in a series of articles[92-103] about the geometrical principles of crystal chemistry, which were summarised in a monograph.[104]

In principle, any three-dimensional nets, including those with a regular structure, can be readily obtained with the aid of the operations involving the addition of new vertices or edges, for example, to a graph consisting of an infinite number of unconnected linear graphs. The problem consists in selecting those graphs which can be realised in the form satisfying the requirements formulated above.

A natural method of obtaining some of these nets (homogeneous graphs of degree 3), in which the valence angles, equal to 120°, are combined with a non-planar structure, has been described;[105,106] this is a type of coordination structure, as in diamond.

We may note that the planar layer of graphite can be regarded as a result of the formation of chemical bonds, i.e. regular cross links between zig-zag chains made up of carbon atoms located in a single plane. The valence angles are assumed to be 120° and each chain has two neighbouring chains. One can form analogously a chain made up of carbon atoms and having an *n*th order screw symmetry axis, in which the angles between the bonds along the chain are 120°, by distributing the carbon atoms along the edges of a regular straight *n*-hedral prism ($3 \leq n \leq 6$). Having arranged such prisms parallel to the *z* axis in such a way that each has *n* neighbours (Fig. 3), it is possible to form a system of cross links between the carbon chains which is periodic along the *z* axis. The periodic arrangement of the chains in space leads in this case to the formation of a crystal structure.

In fact, if it is assumed that the atomic orbitals are sp^2-hybridised, then the symmetry axis of the third hybrid orbital lies in a horizontal plane. Having arranged the set of chain macromolecules with parallel axes in space in a regular manner in such a way that in the direction of the horizontal hybrid atomic orbital (AO) of each atom there is an atom of a neighbouring chain (also having a hybrid atomic orbital directly at right angles to the z axis), it is possible to obtain a crystal structure in which each atom has three neighbours (two in its own chain and one in a neighbouring chain) and the valence angles are 120°. (When there is physical interaction between the atoms, there is a possibility of a distortion of the valence angles in certain structures.)

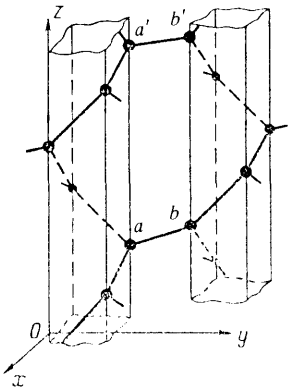

Figure 3. The principle of the construction of three-dimensional nets: the cross links between two adjacent chain systems having the 4_1 symmetry axis; the sections ab and $a'b'$ are parallel to the $z = 0$ plane.

Since fifth order [five-fold?] symmetry axes are impossible in crystals, it follows that $n \neq 5$. When $n = 6$, the chain degenerates into a planar regular hexagon and the cross-linking of such hexagons leads to the formation of a planar graphite layer. There remain two possible versions: with $n = 3$ and $n = 4$. When $n = 3$, the angles between the bonds along the chain are 120°, provided that the selected length of the side of the base of the trihedral prism is $r_1\sqrt{3}$ and the pitch of the helical chain (i.e. the difference between the z coordinates of the neighbouring atoms) is $r_1\sqrt{2/3}$, where r_1 is the distance between the neighbouring atoms along the chain. The distance r_2 between the nearest atoms of neighbouring chains is not related to r_1 and the choice of r_2 does not influence the symmetry of the crystal structure when $n = 3$. When $n = 4$, the valence angles are 120° when the side of the base of the tetrahedral prism and the pitch of the helical chain are $r_1\sqrt{2}$, where r_1 is also the distance between the neighbouring atoms along the chain.

Since the chains can have different chiralities, then for a given n there is a possibility of different versions of cross links leading to the formation of crystal structures. If the chiralities of the cross-linked chains are identical, then for a given n there is a possibility of only one method of cross-linking in which each chain with an nth order [n-fold?] screw symmetry axis is surrounded by n chains with the same chirality. The structures formed by the cross-linking of chain macromolecules of the same chirality will be designated by $C_1(n_j)$, where n_j characterises the screw symmetry axis of the chain macromolecule. The symbol $C_2(n)$ designates the crystalline carbon structures in which each chain with an nth order [n-fold?] screw symmetry axis is surrounded by n chains of the opposite chirality. In this case there is also a possibility of only one version of cross-linking. All the remaining structures formed by the cross-linking of chains of different chirality will be designated by the symbol $C_3^i(n)$, where i is an additional index. In structures of this type there are chains which have neighbours of different chirality.

Some of the other methods of cross-linking chain macromolecules described above, which lead to the formation of the $C_1(n_j)$, $C_2(n)$, and $C_3^i(n)$ structures, are shown in Fig. 4. Evidently it is possible to construct an infinite set of structures of the type $C_3^i(n)$; however, in modifications of this type the unit cells would contain too large a number of atoms.

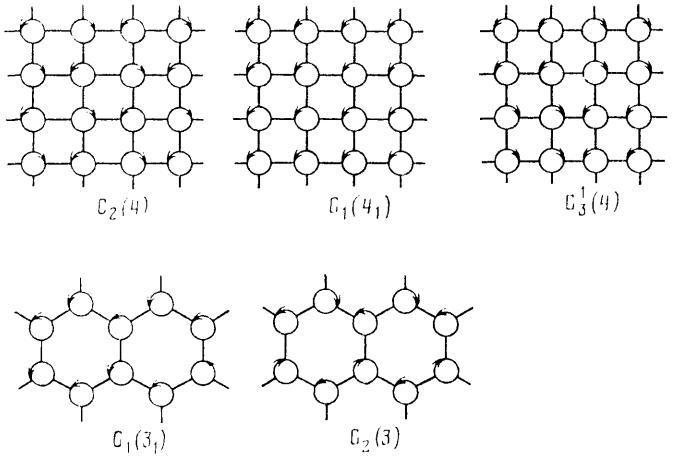

Figure 4. Classification of some of the three-dimensional crystalline modifications of carbon formed by cross links between chain macromolecules having symmetry screw axes of different orientations:[123] the orientations of the axes are indicated by arrows.

We shall consider in greater detail the crystal structures of certain modifications.

(a) *The $C_1(4_1)$ modification.* This modification is formed by the cross-linking of carbon chain molecules having 4_1 screw symmetry axes. Each of the chains has four neighbours of the same chirality. All the bonds are equivalent, so that one can assume that $r_1 = r_2 = r$. In the two directions perpendicular to one another and the 4_1 axis of each chain, there are helical chains of the same chirality as the initial chains.

The symmetry space group of the structure formed is $I4_132$ (see Bokii,[107] pp. 90, 104, No. 220). There is a body-centred cubic (BCC) Bravais lattice, in the unit cell there are eight carbon atoms, and the lattice parameter is $a = 2\sqrt{2}r$. The density of this modification ρ(g cm^{-3}) depends on the parameter r(Å) characterising the distance between the neighbouring carbon atoms: $\rho = 7.04/r^3$. For

example, $\rho = 2.46$ g cm^{-3} for $r = 1.42$ Å and $\rho = 1.93$ g cm^{-3} for $r = 1.54$ Å.

Each carbon atom in the $C_1(4_1)$ modification is located in one place with its neighbours, but the planes corresponding to sets of three terminal atoms in the C_6 fragments of the ethylene-like type intersect at an angle of 70°32′. By virtue of the total symmetry of the structure, when account is taken of the interaction between the atoms, significant distortions of the valence angles could not take place.

The enantiomorphic modification $C_1(4_3)$, formed by the cross-linking of chain carbon macromolecules having screw symmetry axes 4_3, has the $I4_332$ symmetry group. The scalar physical properties of the two enantiomers should be identical.

(b) *The $C_2(4)$ modification.* The structure of $C_2(4)$ and its projection on to the (001) plane are shown in Fig. 5. The $C_2(4)$ modification can be regarded as a result of the formation of regular cross links between chain carbon molecules having screw symmetry axes 4_1 and 4_3. Each chain has four neighbours of opposite chirality. All the valence angles can be chosen equal to 120°, provided that one disregards the possible distortions of the angles under the influence of interatomic interactions.

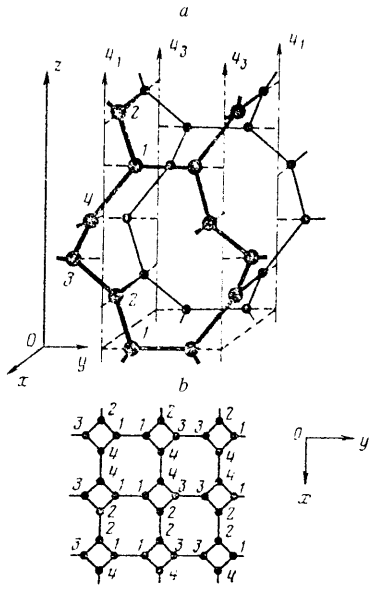

Figure 5. The crystal structure of the $C_2(4)$ modification:[112] *a*) structural fragment; *b*) view from above; identical numerals correspond to atoms whose *z* coordinates are equal or differ by amounts which are multiples of the period of translation along the *z* axis.

In contrast to the $C_1(4_1)$ modification, the bonds within the chain and between the chains are not equivalent. This is associated with the fact that the planes containing the carbon atom and the first layer around it are identical for the nearest atoms of neighbouring chains (the C_6 planar fragment), while non-planar C_6 fragments, with an angle of rotation of the corresponding planes of 70°32′ [the same as in $C_1(4_1)$], arise along the chain. The symmetry space group of this modification is $I\bar{4}m2$,[107] (pp. 80 and 96, No. 119). The Bravais lattice is hexagonal body-centred; the unit cell contains sixteen carbon atoms and the primitive cell contains eight carbon atoms. The unit cell parameters are $a = b = 2(r_1 + r_2)$ and $c = 2\sqrt{2}r_1$ The basis of the lattice consists of eight atoms; the volume of the unit cell is $v = 8\sqrt{2}r_1(r_1 + r_2)^2$. The density of this modification ρ depends on the two parameters r_1 and r_2: $\rho = 28.16/r_1 \cdot (r_1 + r_2)^2$. When $r_1 = 1.48$ Å and $r_2 = 1.34$ Å, we find $\rho = 2.39$ g cm^{-3}.

(c) *The $C_1(3)$ and $C_2(3)$ modifications.* The $C_1(3_1)$ modification and the enantiomorphic $C_1(3_2)$ modification have the symmetry space groups $P6_222$ and $P6_422$ respectively[107] (pp. 85 and 100, Nos. 183 and 184). The $C_1(3_1)$ modification, formed by the cross-linking of chain carbon macromolecules having symmetry screw axes 3_1, has a primitive hexagonal Bravais lattice containing six carbon atoms in the unit cell. The unit cell parameters are $\alpha = \beta = 90°$, $\gamma = 120°$, $a = b = (2r_1 + 3r_2)/\sqrt{3}$, and $c = r_1\sqrt{6}$, where r_1 is the distance between neighbouring atoms along the chains and r_2 is the distance between the nearest atoms in neighbouring chains.[106] The angles of rotation of the planes containing the atom and its immediate environment, corresponding to the transition to a neighbouring atom along the chain and to a neighbouring atom in a neighbouring chain, are 70°32′ and 38°56′ respectively. The density of the $C_1(3_1)$ modification with $r_1 = r_2 = r$ is defined by the expression $\rho = 6.76/r^3$; for $r = 1.48$ Å, we obtain $\rho = 2.08$ g cm^{-3}.

The $C_2(3)$ modification is made up by the cross-linking of chain carbon macromolecules having symmetry screw axes 3_1 or 3_2. Each chain has three neighbouring chains of opposite chirality. The Bravais chain is hexagonal and doubly body-centred, the unit cell contains eighteen carbon atoms, and the symmetry space group is $R\bar{3}m$,[107] (pp. 84 and 98, No. 166). The lattice parameters are $\alpha = \beta = 90°$, $\gamma = 120°$, $a = b = 2r_1 + 3r_2$, and $c = r_1\sqrt{6}$, where r_1 and r_2 have the same significance as for the $C_1(3_1)$ modification. The angles of rotation of the planes containing the atom and its first shell, corresponding to the transition from the atom to its neighbours along or between the chains, are 70°32′ and 0° respectively.

It is noteworthy that the projections of the structures described onto the (001) plane are of the same type as some of the planar carbon nets discussed[76] in connection with the assessment of the possibility of the existence of hypothetical planar carbon structures (Figs. 1 and 5).

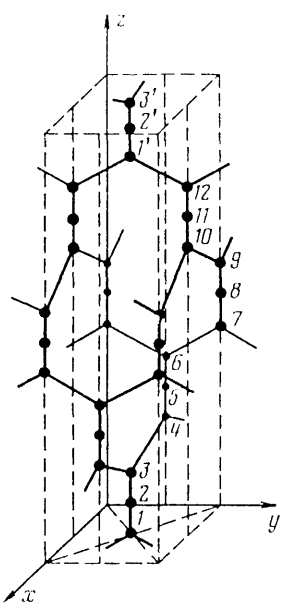
We may also note that new crystal structures can be obtained from the crystalline modifications of carbon of the type $C_1(n_i)$, $C_2(n)$, and $C_3^i(n)$ by the formal replacement of the C–C bonds by the $-C\equiv C-$ fragments. Hybridisations of two kinds are formally obtained in crystalline modifications of carbon of this type: sp^2 and sp. According to Kasatochkin's classification,[53] these modifications refer to transitional forms of carbon.

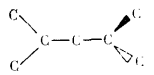
As a result of the cross-linking of chain carbon macromolecules, it is possible to construct yet another homogeneous C_5 net. We shall consider a planar linear chain macromolecule consisting of an infinite number of carbon atoms and having the *trans*-configuration. Suppose that the lengths of all the bonds are identical and equal to r_1 and that all the valence angles are 120°. With the aid of the translational operation in a direction perpendicular to the molecular plane with a translation vector having a length $r_1\sqrt{3}$, we shall construct from the initial chain macromolecule an infinite family of its images, which are located in parallel equidistant planes. It follows from this method

of construction that the centres of all the bonds of the family of molecules obtained in this way are located in the same plane, which we shall designate by $\tilde{S}_0$. The set of all the macromolecules forms the layer S_0, consisting of chain macromolecules located in parallel planes and separated from one another by a distance $r_1\sqrt{3}$. We shall direct the z axis at right angles to the $\tilde{S}_0$ plane and the origin of coordinates will be placed in this plane. Then each atom of the $\tilde{S}_0$ layer has a z coordinate equal to either $r_1/4$ or $-r_1/4$.

We shall construct yet another layer S_1 of this kind. We shall rotate it relative to the initial layer by 90° and, having retained the previous orientation of the z axis, we shall place it above the S_0 layer at a distance r_2 in such a way that an atom of the S_1 layer with the z coordinate equal to $-r_1/4$ relative to the $\tilde{S}_1$ plane corresponds to each atom of the S_0 layer with a coordinate $r_1/4$ relative to the $\tilde{S}_0$ plane and both atoms are located on a single line perpendicular to the $\tilde{S}_0$ plane. It is easy to show that this procedure is feasible.

We construct analogously an S_{-1} layer and place it below the S_0 layer at a distance r_2. Continuing this process without limit, we obtain an infinite system of layers in which each even layer is rotated relative to the odd layer by 90° and an atom of the S_{n+1} layer with a relative z coordinate $-r_1/4$ corresponds to each atom in the S_n layer with a relative z coordinate $r_1/4$ and both atoms are located on a single straight line parallel to the z axis.





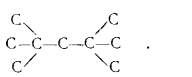


Figure 6. The crystal structure of allenocarbon; atoms *1–12* form the basis of the structure.

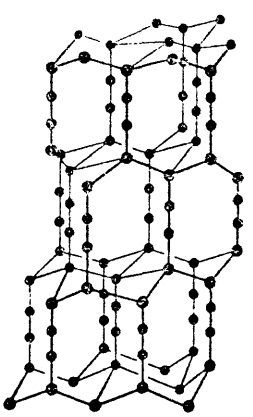
In the resulting structure all the valence angles are 120° and C_6 fragments of the ethylene type, with C_3 groups rotated relative to one another by 90°, are present. The C_8 net described with $r_2 = r_1$ coincides with one of the nets discussed in a monograph[104] (see also Hoffmann et al.[108]). It has a symmetry group $I4_1/amd$, a tetragonal lattice with the parameters $a = b = r_1\sqrt{3}$ and $c = r_1 + 4r_2$, contains eight atoms in the unit cell, and can be used to construct new structures. For example, we place along the sections connecting the atoms of two neighbouring layers an odd number (identical for all pairs of neighbouring atoms) n' of atoms. For $n' = 1$, the bond lengths can be chosen such that one obtains as a result a regular structure made up of fragments of the type

with two end groups rotated by 90° relative to one another. Such geometry is characteristic of compounds of the allene type[109] and we shall refer to this crystalline modification of carbon as allenocarbon (Fig. 6).

The same principle of construction has been applied by Mel'nichenko et al.[110] who used the diamond lattice for this purpose. If cubic or hexagonal diamond is represented as a structure made up of cross-linked carbon layers consisting of polycondensed carbon rings with a geometry close to that of the carbon skeleton of the cyclohexane ring, then several atoms can be placed at each cross link (the case of only one atom was considered by Mel'nichenko et al.[110]). As a result of this procedure, the layers move apart owing to the increase of the length of the interlayer cross links. However, in the case considered by Mel'nichenko et al.[110] somewhat unusual combinations of chemical bonds, made up of two tetracoordinate and one dicoordinate carbon atom, arise.



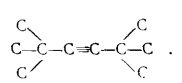


Figure 7. The crystal structure of poly-ynodiamond.[110]

It would be more useful to distribute an odd number of atoms at the interlayer cross links, whereupon more natural structural elements of the poly-yne type would arise:

The modification obtained in this way on the basis of cubic diamond is illustrated in Fig. 7 (poly-ynodiamond).

A number of studies have been devoted to the relative stabilities of crystalline modifications of carbon. Data for the relative stabilities of planar hypothetic carbon systems of the mosaic type were presented above. It was noted that in these structures there are unusual combinations of bonds, which hinders the estimation of their lengths. On the other hand, in the $C_1(4_1)$ and $C_2(4)$ structures described in two investigations[105,106] the bond lengths can be estimated[111,112] using for this purpose the empirical relations between the internuclear distance separating chemically bound atoms and the bond type as well as data for the geometry of the carbon skeleton of hydrocarbon molecules, which are comparable to individual fragments of the crystalline modifications of carbon considered.

In structure $C_2(4)$ there are bonds of two types:

According to the data of Tatevskii and Spiridonov,[24] $r_1 = 1.48 \pm 0.02$ Å and $r_2 = 1.34 \pm 0.02$ Å. The structure $C_2(4)$ can also be described in terms of eight-membered rings (in the boat form). The geometry of these rings should be close to that of the carbon skeleton of the cyclooctatetraene molecule in which the C–C bond lengths alternate and amount to 1.462 and 1.334 Å.[113] In graphite the C–C bond length has inreased by approximately 0.02 Å compared with benzene. Similarly the C–C bond length in diamond has also increased by approximately 0.02 Å compared with cyclohexane (1.52 Å). These estimates show that in the $C_2(4)$ crystalline modification of carbon there should be bonds whose lengths are close to 1.48 and 1.35 Å.

In the $C_1(4_1)$ modification all the bonds are equivalent (in the geometrical sense). The inner bond of the C_6 fragment of the ethylene-like type, in terms of which it is possible to describe the $C_1(4_1)$ crystal structure, should be similar in its character to the C–C bond between the rings in biphenyl, i.e. its length should be close to 1.48 Å. Bearing in mind that the immediate environment of this bond persists on passing to the crystal, the C–C bond length in the $C_1(4_1)$ modification was assumed to be 1.48 Å.

Using the C–C bond lengths quoted above in the $C_1(4_1)$ and $C_2(4)$ modifications, the relative stabilities of these systems have been estimated[111,112] in relation to diamond, graphite, and two carbyne modifications: α- and β-carbyne. The relative stabilities were estimated in the following way: with the aid of three empirical relations between the bond energy and bond length or bond type:

A. From the Dewar–Schmeising formula:[114]

$$\varepsilon(r) = -\frac{1140.593}{r} + \frac{3252.755}{r^2} - \frac{1199.129}{r^3},$$

B. From the linear relation obtained on the basis of Popov and Kogan's data.[62]

C. From the dependence of the bond energy on the bond type according to Popov and Kogan's data.[62]

D. By the virial-statistical method.[115]

The bond energies in the crystalline modifications considered were calculated in the first three instances from the formula

$$E = \frac{1}{2}\sum_i n_i \varepsilon(r_i),$$

where the summation extends over all the bonds of the given atoms and n_i is the number of bonds of the given type per carbon atom.

We shall consider in greater detail the estimation of the bond energy of the crystal by the virial-statistical method, which is based on the representation of the energy of the ground state of the quantum system in the form of a functional of the electron density.[116] The electron density of the molecule (crystal) is represented approximately by the sum of the electron densities of the atoms, which were evaluated on the basis of the calculations for the atoms carried out by Clementi and co-workers.[117,118] Next it is assumed that the virial theorem holds and that the total energy can be calculated as half the potential energy.

The potential energy is calculated in terms of the approximation within the framework of the statistical theory taking into account the Coulombic, exchange, and correlation contributions.[115]

The Table presents the relative bond energies for graphite, diamond, $C_2(4)$, $C_1(4_1)$, α-carbyne, β-carbyne, and allenocarbon calculated by the four methods A, B, C, and D indicated above. It follows from the tabulated data that, for all the methods used in estimates, the $C_2(4)$ modifications should be more stable than the $C_1(4_1)$ modification and also more stable than the α- and β-forms of carbyne.

Interatomic distances and the calculated* bond energies E(C–C) for certain crystalline modifications of carbon.

Structure	r_1, Å	r_2, Å	$-E$(C–C), kcal mole^{-1}			
			A	B	C	D
Graphite	1.42	—	0.0	0.0	0.0	0.0
Diamond	1.54	—	0.3	1.0	0.9	1.5
$C_2(4)$	1.34	1.48	5.3	4.8	6.0	7.4
$C_2(4_1)$	1.48	—	14.4	14.6	23.3	32.5
β-Carbyne	1.28	—	27.0	23.1	20.9	33.6
α-Carbyne	1.38	1.20	31.8	25.6	24.0	32.8
Allenocarbon	1.31	1.51	18.4	16.4	9.1	8.0

*Methods of calculation: A) from the formula for $\varepsilon(r)$ quoted by Dewar and Schmeising;[114] B) from the formula for $\varepsilon(r)$ quoted by Popov and Kogan;[62] C) from the average bond energies;[62] D) by the method of the electron density functional.[115]

In conclusion of this Section, we shall mention a study[119] in which the relative stabilities of certain skeletal hydrocarbon oligoradicals are discussed in connection with the problem of the existence of three-dimensional carbon structures with sp^2 hybridisation of the carbon atoms.

2. The Nature of the Chemical Bonds and the Structure of the Band Spectra of Certain Hypothetical Crystalline Modifications of Carbon

It is known that diamond is a dielectric and that the width of the forbidden gap at 295 K is 5.49 eV for indirect transitions.[120] The width of the forbidden gap in the graphite spectrum is close to zero and graphite is a semi-metal. The resistivity of the graphite single crystals in the plane of the aromatic ring is smaller by several orders of magnitude than in the direction of the translational c axis. The electronic spectrum of graphite has been discussed in a number of studies[17,18,121,122] in which an extensive bibliography on graphite has also been given.

It is of interest to analyse the possible electrophysical properties of the hypothetical crystalline modifications of carbon which were discussed above. This problem has been discussed in a number of communications for modifications of the type $C_2(4)$, $C_1(4_1)$, $C_1(3_1)$, etc. We shall consider initially in greater detail the results of the study of the band spectra of the $C_1(4_1)$ and $C_2(4_1)$ structures. In estimating the band spectra of these modifications, the authors[123-125] used a model according to which the $2p$ electrons (one from each atom) located in the $2p$ orbitals (the symmetry axis of each orbital is perpendicular to the plane passing through the corresponding atoms and its three nearest neighbours) and moves in the field of the σ-skeleton of the system; the remaining three valence electrons from each atom participate in the establishment of this field. This mathematical model is analogous to that employed in the calculations for non-planar conjugated systems of the type of biphenyl in terms of the π-electron approximation. The total energy of the crystal in this model depends only on the crystal orbitals made up of the $2p$ orbitals which are not involved in the formation of the σ-skeleton. Each crystal orbital is referred to a definite wave vector **k** and is sought in the form of linear combinations of Bloch functions.

In the version of this method without adjustment for self-consistency the absolute values of the diagonal elements of the Hamiltonian were assumed to be equal to the valence ionisation potential I_p of the carbon atom. The non-diagonal elements of the Hamiltonian $H\mu\nu$ were estimated from the Wolfsberg–Helmholtz formula $H\mu\nu = -1.75\, I_p S\mu\nu$, where $S_{\mu\nu}$ is the overlap integral of $2p$ atomic orbitals of the neighbouring carbon atoms. The interaction between non-neighbouring atoms was disregarded.

For the main symmetrical directions in the first Brillouin band of the $C_1(4_1)$ modification, analytical formulae have been obtained whereby one can find the one-electron energy levels as a function of the wave vector **k**. The dispersion laws for the main symmetrical directions in the first Brillouin band corresponding to a bond length of 1.48 Å are presented in Fig. 8. The valence ionisation potential I_p was assumed to be 11.4 eV. Fig. 8 shows that the $C_1(4_1)$ modification (within the framework of the model adopted) has a band spectrum characteristic of metals. The Fermi energy is $-I_p$.

Calculation of the band spectrum of the $C_1(4_1)$ modification within the framework of the method of crystal orbitals adjusted for self-consistency in terms of the Pariser–Parr–Pople (PPP) approximation (taking into account the two-electron interaction integral γ_0 at only one centre) did not alter the conclusion that the spectrum of the $C_1(4_1)$ modification has a metallic character in the case of the restricted Hartree–Fock method; the Fermi energy increases by $\gamma_0/2$ (approximately 5 eV) when account is taken of the inter-electron interaction.

In order to estimate the influence of the non-orthogonality of the $2p$ atomic orbitals with respect to the orbitals of the σ-skeleton on the band spectrum, the one-electron energies of the $C_1(4_1)$ modification were calculated[126] in terms of the valence approximation (at the centre of the first Brillouin band). The calculation showed that the model adopted reproduces fairly correctly the qualitative features of the spectrum, because, in terms of the valence approximation, the $C_1(4_1)$ modification also has a spectrum with a metallic character.

Within the framework of the same model, the band spectrum of the $C_2(4)$ modification has been estimated.[125] The calculation was performed using bond lengths of 1.48 and 1.34 Å for bonds along and between the chains respectively. In the spectrum of the $C_2(4)$ modification there is a forbidden gap and the maximum one-electron energy in the valence band and the minimum energy in the conductivity band are attained at the centre of the first Brillouin band, i.e. when $k = 0$. It follows from the calculation that the $C_2(4)$ modification should have semiconducting properties. The width of the forbidden gap in the spectrum is 2.2 eV for the parameters selected by Nikerov et al.[124]

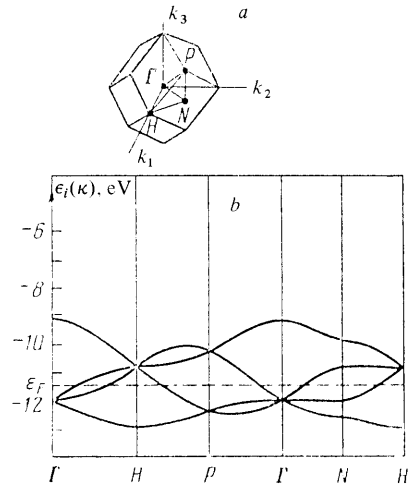

Figure 8. The band structure of the spectrum of the $C_1(4_1)$ crystalline modification of carbon: *a*) first Brillouin band (Γ—centre of band, *N*—centre of face, *H* and *P*—vertices); *b*) dependence of the one-electron energy levels $\varepsilon_i(\mathbf{k})$ on the wave vector $\mathbf{k} = (k_1, k_2, k_3)$ along the ΓH, HP, $P\Gamma$, ΓN, and NH directions; the dashed line indicates the position of the Fermi level ε_F.[123]

The spectrum of the crystalline modification constructed on the basis of the C_8 net and described above has been discussed.[108] Although in this net all the valence angles are 120°, the conjugation between the chains in different layers breaks down completely, in contrast to the $C_2(4)$ and $C_1(4_1)$ modifications considered above. The authors[108] estimated the C–C bond length for the polyene chain as 1.44 Å and obtained 2.494 Å for the distance between the polyene chains. With these values of the geometrical parameters, this modification has a density of 3 g cm^{-3}, i.e. intermediate between those of graphite and diamond. In terms of the EHM approximation, the modification has an energy spectrum of the metallic type with fairly broad bands and the energy of the Fermi level is approximately −10 eV (one should bear in mind that, in terms of the EHM approximation, this value is usually too low by 3–5 eV). Allowance for the possible alternation of the bond lengths in the polyene fragment does not introduce qualitative changes into the character of the spectrum, in contrast to the one-dimensional case.

Calculations for model macromolecular hydrocarbon systems, carried out in order to elucidate the factors influencing the band width in the three-dimensional structure, showed that the influence of the interchain interaction should be fairly strong. The authors[108] note that the Mulliken bond orders, found for the atoms located in adjacent polyene chains of the three-dimensional structure, proved to be positive, which

showed that there is an overall predominance of the bonding interaction between the chains.

3. Certain Considerations Concerning the Possibility of the Existence of New Crystalline Modifications of Carbon

In this Section of the review we shall attempt to draw certain structural analogies between the known crystalline modifications of carbon and hydrocarbons. Such analogies can be used as additional evidence in support of the possibility of the existence of new crystalline modifications of carbon.

Different hydrocarbon systems correspond to diamond and graphite, the structures of their carbon skeletons being close to the local structures of diamond and graphite. For graphite, these are benzene, naphthalene and other polyacene systems, coronene, and polycondensed aromatic hydrocarbons, while for diamond these are cyclohexane, adamantane, etc.

As mentioned above, the $C_2(4)$ structure can be described in terms of eight-membered rings characteristic of cyclo-octatetraene. The structures of cyclo-octatetraene and its octamethyl and octaphenyl derivatives have been thoroughly investigated. In all three molecules the ring has the boat conformation. The average length of a single bond in cyclo-octatetraene (1.462 Å) increases somewhat on passing to the methyl and phenyl derivatives (1.487 and 1.493 Å respectively). The length of the double bond is in the range 1.33–1.35 Å.

The synthesis of octalene—an unsaturated hydrocarbon formed by the condensation of two eight-membered rings—has been reported.[127] An interesting class of unsaturated hydrocarbons—cyclophane compounds—is known.[128] Some of these "multidecker" systems consist of two or more unsaturated six-membered rings linked by $-C_2H_2-$ bridging groups. The molecules have an interesting geometry: the planarity of the rings breaks down, the valence angles deviate from the standard values, and the system becomes strained.

If the six-membered fragments are now "replaced" by eight-membered fragments, no significant distortions of the valence angles should occur. Hypothetical systems of the type $C_{24}H_{16}$ with valence angles close to the ideal values arise. On the other hand, the carbon skeleton of the $C_{24}H_{16}$ molecule constitutes a polyhedral fragment of the $C_2(4)$ modification (Fig. 5). The synthesis of the molecule described above, which is itself of interest, might serve as additional proof of the possible existence of the $C_2(4)$ crystalline modification of carbon.

Next the crystalline modifications of carbon formed by tricoordinate carbon atoms can be described in terms of hexa-atomic fragments of the ethylene type:

In order to assess the possibility of the formation of carbon fragments of the ethylene type with rotated C_3 groups, calculations have been made[126] of the energy of the C_6 clusters of the form described above (the valence angles were assumed to be 120°) by the CNDO/2 and INDO methods as a function of the angle of rotation (the C–C bond lengths were assumed to be equal and were optimised). It was established[126] that the total energy, expressed as a function of ψ, is a minimum for $\psi = 90°$ and a maximum for $\psi = 0°$. This property of the energy is determined in the first place by the behaviour of the interaction energy of the nuclei, which is a minimum for $\psi = 90°$. On the other hand, the interelectron interaction energy is a maximum for $\psi = 90°$, but its increase is compensated by the energy of repulsion of nuclei, which decreases fairly rapidly. The equilibrium C–C bond length is close to 1.33 Å.

This calculation permits the conclusion that in the gas phase there is a possibility of the formation of C_6 clusters of the type considered; this supports the possibility of the existence in polymeric carbon of C_6 structural fragments with end groups rotated relative to one another. This possibility is also indicated by the non-planar structure of the biphenyl molecule in the gas phase: the angle of the relative rotation of the six-membered rings is approximately 42°.[129]

Thus one may conclude that diamond, graphite, and carbyne do not exhaust the possible crystalline structures which do not conflict with the ideas established at the present time concerning the ability of carbon atoms to participate in the formation of chemical bonds. Problems associated with a more detailed description of the geometry, energy relations, and spectroscopic and other physico-chemical properties of the hypothetical structures naturally remain open. All these problems can be solved, in principle, for each specific instance.

In particular, it follows from the above analysis that under normal conditions a metastable form of carbon with metallic properties can exist. It may be that some of the structures discussed above are realised among the wide variety of the existing crystalline modifications of carbon whose structure has not been established.

The Preparation of Labelled Organic Compounds by Treatment with Atomic Tritium

A.V.Shishkov, L.A.Neiman, and V.S.Smolyakov

The methods for the atomisation of gaseous tritium by thermal dissociation or under the influence of a high-frequency discharge, the reactions of atomic tritium, and its use for the preparation of labelled organic compounds are considered. Special attention is devoted to labelled biologically active compounds.
The bibliography includes 114 references.

CONTENTS

I. INTRODUCTION

The use of isotopic methods has exerted an extremely significant influence on the development of a whole series of branches of science and technology and in chemistry, biology, and fields located at the junction between these two sciences, namely biochemistry, molecular biology, and bio-organic chemistry, the application of isotopes has undoubtedly proved particularly fruitful.

Although compounds labelled by isotopes of organogenic elements are used in the isotopic method in both organic chemistry and in biological disciplines. the requirements which they must meet differ greatly in most cases. In the study of the mechanisms of organic reactions, one is interested primarily in the position of the label in the molecules of the starting materials and products; on the other hand, the concentrations of these substances are as a rule fairly large. For this reason, one uses here specifically labelled compounds (i.e. compounds labelled at a particular atom) whose molar radioactivity is not too great.

In biochemistry, molecular biology, and bio-organic chemistry, the isotopic method has come to be most widely used as a procedure for qualitative and quantitative analysis, its high sensitivity being particularly important because it makes it possible to determine reliably substances at concentrations close to those at which their biological activity is manifested. Since the sensitivity of the method is unambiguously related to the molar radioactivity (a) of the labelled compound, a tendency has clearly arisen recently towards using tritium-containing compounds instead of their analogues labelled with carbon-14 (when a single T atom is introduced into a molecule, $a \cong 30$ Ci mmol^{-1} compared with 0.064 Ci mmol^{-1} for ^{14}C) and also towards the use, together with compounds labelled specifically with tritium, also of multiply labelled compounds (labelled in more than one position in the molecule), of non-specifically labelled compounds (i.e. those in which the exact distribution of T atoms in the molecule is unknown), and generally labelled compounds (those labelled in all possible positions). All these features make it possible to increase a to 100–200 (and sometimes more (Ci mmol^{-1}. Using certain other radioactive isotopes of organogenic elements (^{32}P, ^{33}P, ^{35}S, and ^{125}I), it is possible to achieve even higher values of a; however, in contrast to tritium and ^{14}C, these isotopes are not universal for organic compounds, which naturally narrows the region of their applicability.

Other advantages of tritium over ^{14}C are its weaker β-emission, the possibility of introducing the tritium label by exchange methods, and also the much lower cost of tritium-labelled compounds.

Thus the importance of tritium-containing compounds as research tools is particularly great in biology and related disciplines and the development of methods for the introduction of the tritium label into organic compounds (in the first place into complex molecules of biopolymers) is required very urgently. In order to obtain compounds labelled with tritium, chemical (synthesis), biological (biosynthesis, and enzymic reactions), and exchange (isotope exchange) methods are used.[1,2] However, one should bear in mind that, for a whole series of complex organic compounds, chemical synthesis has so far been either not described at all or its achievement in the isotopically labelled version is virtually impossible. Biosynthesis is also by no means possible in all cases and frequently it does not allow the attainment of the required values of a and involves considerable difficulties in the isolation and purification of the products.

The important advantages of exchange methods are their universality, the presence of only one stage in the process ("high speed"), and the fact that they do not require the presence of the corresponding precursors and permit the introduction of tritium directly into the "finished" molecule. The exchange methods can be divided into catalytic (see Neiman's review[3]) and methods which can be called physical. The latter are understood to involve the substitution of hydrogen by tritium as a result of the interaction of organic compounds with tritium ions or atoms possessing an excess energy (hot tritium atoms, atomic beams, activation of gaseous tritium by its intrinsic β-emission or external factors—ultraviolet light, high-voltage electric discharge, high-frequency microwave discharge, and thermal dissociation).

In all probability the first method of this kind is that of Wilzbach,[4] which consists of the maintenance of the given substance in an atmosphere of gaseous tritium. The exposures required for the appreciable incorporation of the label were fairly long: ranging from several days to months. The Wilzbach method is universal, but its application entails vigorous decomposition reactions of the test substance, the formation of a large amount of labelled side products, and a low coefficient of utilisation of tritium. In subsequent years a whole series of improved versions of the Wilzbach method were proposed, but fundamental improvements—a decrease of

the degree of decomposition of the test substance and an increase of α—were achieved only using activated tritium atoms as the main reactive species.

The present review is devoted precisely to these methods for the activation of gaseous tritium—the thermal dissociation method and the discharge method (particularly the microwave discharge in the high-frequency and ultrahigh frequency ranges), which will be designated below as TAM (the thermal activation method) and HFAM (the high-frequency activation method). Both procedures have been investigated very vigorously and improved during recent years, but the data referring to them are being surveyed for the first time. Their advantages include true rapidity (the duration of exposure is 0.25–60 min), universality, and the possibility in many instances (this applies particularly to the TAM) to reduce the consumption of tritium in a single experiment to several tens of millicuries. The latter factor is extremely important, since it permits experiments in radioisotope laboratories of class III where special protective equipment is not required.

On the other hand, the trend which has arisen in the employment of radioisotopic methods in biological disciplines can be formulated thus: increasing numbers of a wide variety of labelled compounds with an increasingly complex structure are needed; it is required to reduce their amounts as much as possible but to maintain at the same time a high molar radioactivity. For this reason, the commercial manufacture of such compounds, which involves the development of individual methods of purification, storage, and analysis, has become increasingly complex and expensive. The most attractive solution to this problem evidently involves the creation of a cheap, reliable, universal, and rapid laboratory method for the introduction of the label†; we believe that the HFAM and particularly the TAM are suitable candidates as laboratory methods of this kind.

The mechanisms of the processes leading to the incorporation of the label in the compound on treatment with atomic tritium and the methodological problems associated with the practical application of the TAM and the HFAM are examined below. The Wilzbach method and its modifications are not included in this review, because, firstly, they have already been considered in detail (see, for example, the relevant reviews[1,5]) and, secondly, in most cases the involvement of tritium atoms in these reactions has not been reliably demonstrated. However, these procedures as well as the results of experiments with atomic beams[6] and data on the chemistry of hot tritium atoms[1,7] will be employed so far as it is necessary for the comparison of the results and the analysis of the theoretical principles of the TAM and the HFAM.

II. THE PREPARATION OF ATOMIC TRITIUM BY THE HIGH-FREQUENCY ACTIVATION METHOD

The fact that the microwave discharge plasma contains high concentrations of atomic hydrogen in various excited and ionised states has been known for a fairly long time and this is the basis for the employment of discharges in the high-frequency and ultrahigh-frequency ranges as sources of hydrogen atoms and ions in the acceleration technology and as sources of resonance ultraviolet radiation.

The first report[8] of the use of a high-frequency discharge for the preparation of labelled compounds apparently appeared in 1960. It was shown later[9,10] that the introduction of the label is due to the tritium–hydrogen exchange occurring with participation of tritium atoms. Best results are achieved when the discharge is initiated in hydrogen diluted with helium and not in pure hydrogen: the intensity of the molecular bands in the emission spectrum diminishes and the intensity of the atomic hydogen line at 121.6 nm increases and at a frequency of 40 MHz the line becomes the only one present in the spectrum of a mixture containing 99% of helium.[11] The introduction of metallic electrodes into the discharge contaminates the plasma as a consequence of the atomisation of the material of the electrodes and in addition there is an appreciable reduction of the yield of hydrogen atoms owing to their recombination on metallic surfaces. Sources with an electrodeless discharge, i.e. apparatus in which the discharge tube containing the working gas (tritium or its mixture with an inert gas) is placed in a high-frequency field generated by external electrodes, are free from this disadvantage.

Sources of two types are usually employed—with initiation of the discharge in the region of high frequencies (tens and hundreds of MHz) and ultrahigh frequencies (thousands of MHz). The two discharges differ both as regards the conditions for the existence of a stable plasma and the apparatus used. In the high-frequency range the discharge is initiated at relatively low pressures (10^{-2}–10^{-3} mmHg) and its characteristics depend significantly on the frequency of the gases employed and the entire apparatus, particularly the components located in the discharge zone; the intensity of the resulting atomic beam in a high-frequency discharge is usually lower by two–three orders of magnitude than in the ultrahigh-frequency range. A discharge at a frequency of 2450 MHz is initiated at a pressure of the working gas of 1–5 mmHg and the beam obtained has an intensity of $\sim 10^{14}$–10^{15} atoms cm^{-2} s^{-1}; the characteristics of the discharge depend less on the presence of impurities, but the design of the apparatus is in this case more complex. Fig. 1 illustrates schematically the apparatus for the preparation of hydrogen (tritium) atoms with the excitation source in the region of 40 MHz. It has been shown on apparatus of this kind[12] that the yield of the principal labelled product—the parent compound—is almost independent (for an infinitely thick target) of the energy of the incident species in the range 0.5–5.0 keV.

The introduction of the label is possible not only by means of a neutral atomic beam but also with the aid of tritium ions T^+. Here charge transfer takes place in the first stage: $T^+ + RH \rightarrow T^* + RH^*$ (the asterisk denotes the excited state) and the label incorporation process itself takes place with participation of a neutral atom. The formation of excited states is due to the fact that the charge transfer conditions differ from resonance conditions. Processes leading to the thermalisation of a fast ion and to charge transfer are accompanied by the excitation of the molecules of the medium, whose character resembles that occurring under the influence of radiation. This can lead to the degradation of the test substance, which is not observed in the case of neutral species, as demonstrated fairly convincingly by comparing the effects on the target of beams of helium atoms and ions with the same kinetic energies.[12] For the preparation of labelled compounds, the apparatus can be significantly simplified:[13] instead of a system of beam focussing electrodes and the charge transfer chamber, one uses a narrow withdrawing channel at the Earth's potential, which is located at the end-face of the source and is shielded from the effects

†When the label is to be introduced into complex biological substances, it is important to ensure direct contact between the user and an investigator familiar with the procedures involved in experiments with the given specific compounds; this can be readily achieved if the labelled preparation is obtained in the laboratory where it is to be employed.

of the plasma. The form of the withdrawing electrode-channel is chosen empirically so as to ensure the best focussing of the beam; charge transfer involving atomic ions is achieved mainly in the source itself and in the channel of the electrode. The target is located at a short distance from the source and the intensity of the beam of particles is fairly high.

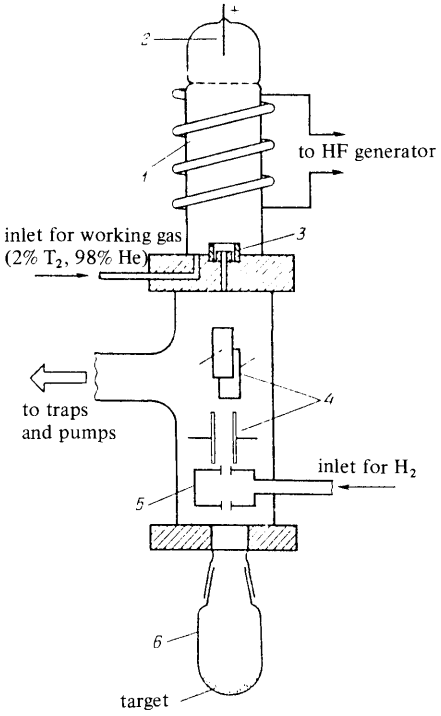

Figure 1. Apparatus for the preparation of fast tritium atoms by charge transfer involving atomic ions: 1) ion source with an electrodeless ring discharge (40 MHz); 2) accelerating electrode; 3) focussing electrode; 4) deflecting plates; 5) charge transfer chamber; 6) removable vessel for the target.

A source of atomic hydrogen with ultrahigh-frequency excitation has been used to synthesise tritium-labelled preparations.[10] The high pressure in the system and the large distance between the source and the target resulted in a low energy of the interacting atoms, which corresponded to the temperature of the walls. The apparatus is shown schematically in Fig. 2: a standard 2450 MHz generator and a standard microwave cell were used. The apparatus was connected to a pump which ensured continuous circulation of the working gas through the discharge and target zones at a controlled rate. The power evolved in the discharge is fairly high and the discharge is accompanied by an intense emission in the visible and ultraviolet regions, which may cause the photochemical decomposition of the test substance; for the protection from the latter, the target was placed outside the field of "vision" of the source. In apparatus with a high-frequency discharge, the intensity of the emission in the visible region is low and in addition only a small fraction of the emission can reach the target after passing through the narrow aperture (1–2 mm in diameter) of the withdrawing electrode. As already mentioned, in order to ensure the stability of an ultrahigh-frequency discharge, a fairly high gas pressure (~4 mmHg) is necessary, which corresponds to 1 Ci of tritium for apparatus whose volume is 500 cm^3.[10] An advantage of the high-frequency discharge is the low pressure (10^{-2}–10^{-3} mmHg), which corresponds to the consumption of 1–10 mc for the same volume. The high coefficient of the incorporation of tritium in the target makes it possible to employ the apparatus with a high-frequency discharge under conditions where the working gas flows through the discharge zone and beyond the pump it is sufficient to place a device for the oxidation of tritium and a trap. On the other hand, in apparatus with a UHF discharge, it is necessary to employ repeated gas circulation as a consequence of the low coefficient of the incorporation of tritium in the target due to the low energy of the atoms, which requires the inclusion of an additional pump and a more effective geometry of the apparatus. Furthermore, as the reaction proceeds, the working gas is enriched in protium.

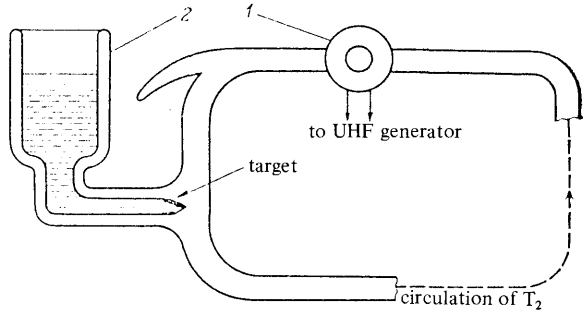

Figure 2. Schematic illustration of the apparatus for the introduction of the label with the aid of tritium atoms generated in an ultrahigh-frequency discharge (2450 MHz): 1) microwave cell; 2) trap with liquid nitrogen for the cooling of the target. The pump for the circulation of tritium and the system of pressure sensors are not shown in the diagram.

As regards the influence of various parameters on a, it has been found that the value of a for the labelled product increases with decrease of the thickness of the target or with increase of the duration of exposure to 5 min and is independent of the power of the discharge.[10] An increase of the distance from the source to the target reduces the yield of the labelled product. Low energies of tritium atoms are responsible for the dependence of the degree of incorporation of the label on the target temperature—on passing from 77 to 300 K, the activity a increases by a factor of ~5, but the degree of degradation of the test substance increases at the same time.

III. THE PREPARATION OF TRITIUM ATOMS BY THE THERMAL DISSOCIATION OF T_2

High temperatures in the range ~2000–3000 K are necessary in order to dissociate molecular hydrogen into atoms at an appreciable rate. On the other hand, the so-called furnace

sources employed in the molecular beam technique make it possible to heat the gas only to several hundreds of degrees and are naturally unsuitable for the preparation of atomic hydrogen. A novel and extremely simple technical solution has been found on the basis of the phenomenon of the catalytic dissociation of hydrogen on heated metallic filaments, which had been observed a long time ago by Langmuir.[14] The sources based on this principle have been used fairly extensively in studies of the reactions of atomic hydrogen with solid organic substances.[15,16] In order to improve the sensitivity, a number of workers have used a radioactive isotope (tritium) in their experiments.

The results of these studies are the basis of the method of synthesis of labelled preparations. The first experiments were performed with saccharides,[17] but the high yield of degradation products cast doubt on the practical value of the method. The main cause of the first failures was the use of thick targets which prevented the removal of heat from the reaction zone. The surface of the target was heated significantly both as a result of the absorption of the light emission from the filament and heat transfer through the molecular gas and as a result of the reactions of tritium atoms with the test substance. If effective removal of heat is ensured, the degree to which the test substance is preserved reaches 100% in some cases.[18]

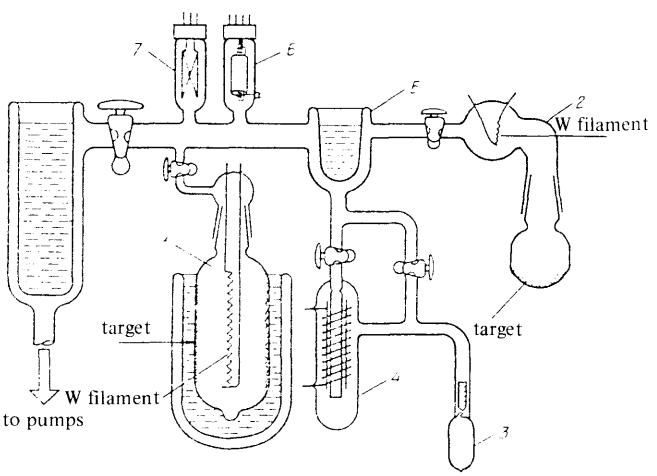

Figure 3. Apparatus for the preparation of labelled compounds with the aid of thermally activated tritium atoms: 1) vessel for the target used when the label is introduced under the conditions of direct light; 2) ditto for the introduction of the label into substances sensitive to light; 3) bulb with tritium opened by means of a metallic striker; 4) palladium leak valve for admitting measured amounts of tritium; 5) liquid nitrogen trap for freezing out condensable impurities; 6) and 7) pressure measuring sensors (thermocouple and ionisation sensors).

The apparatus used in such experiments is extremely simple (Fig.3) and consists of a glass cylinder with electrodes sealed into it between which is stretched a metallic (tungsten) filament heated electrically. A high vacuum is created in the cylinder, after which it is filled with tritium to the required pressure. The target substance is deposited on the inner walls of the cylinder cooled with liquid nitrogen or other cooling agents, which is necessary to prevent the access of the vapour of the test substance to the filament. The target film can be obtained by evaporating solutions or, what is more convenient for biopolymers, by lyophilisation. It is also possible to obtain frozen films of solutions, but it is then necessary to take into account the possible decomposition of the specimen as a consequence of the crystallisation of water during freezing. The undesirable effects can be avoided by employing rapid cooling of the target (for this purpose, it is best to use cooling agents other than liquid nitrogen) or by atomising the solution onto precooled walls. Satisfactory results are obtained when porous supports (filter or chromatographic paper, etc.) are used. The formation of a homogeneous film is then greatly simplified and the chemical and radiochemical yields are improved.[19]

In most cases reaction vessels with a comparatively small volume are used, since the establishment of the required pressure (10^{-2}–10^{-3} mmHg) then requires only a small amount of tritium. In such vessels the distance between the filament and the target is 3–4 cm. In larger vessels experiments with solid targets can be performed at room temperature. To prevent the incidence of direct light onto the specimen, the filament and the target are placed at an angle relative to one another.

Tritium is admitted into the reactor through capillaries, fine control high-vacuum valves, etc. It is best to use the so-called palladium leak valves in which molecular hydrogen diffuses through a palladium foil at an elevated temperature. This type of valve is extremely convenient for metering specified amounts and, furthermore, permits additional purification of the tritium. In the presence of a buffer reservoir it is possible to do without a leak valve altogether.

The conditions used in the introduction of the label differ little for different substances. The optimum results obtained when the temperature of the tungsten filament is 2000 K and heating is switched on for short periods (~15 s) with intervening cooling intervals (20–30 s). The tritium pressure is chosen to ensure that the atoms move from the filament to the target without colliding with molecules. This is associated with the dependence of the rate of the substitution reaction on the energy of the interacting particles. At a filament temperature of 2000 K, about 25% of the atoms formed have sufficient energy to react. The free path conditions for a distance between the filament and the target of ~3 cm are fulfilled at a pressure of ~5×10^{-3} mmHg. In the collisions between tritium atoms and target molecules unaccompanied by reaction the tritium atoms are also "cooled", as a result of which the label is localised in a thin surface layer whose thickness is ~5 Å,[20] and the attainment of high values of a requires the use of thin films of substance or the process must be frequently repeated, preparing anew a film of the substance already treated.

An increase of the temperature of the tungsten filament increases the fraction of the reactive species in the atomic beam. It can be shown that

$$n_{\varepsilon>\varepsilon_0} = \frac{2n\sqrt{\varepsilon_0}}{\sqrt{\pi(kT)^3}} \int_{\varepsilon_0}^{\infty} e^{-\varepsilon/kT} d\varepsilon = \frac{2n\sqrt{\varepsilon_0}}{\sqrt{\pi kT}} e^{-\varepsilon_0/kT}$$

where $n_{\varepsilon>\varepsilon_0}$ is the number of atoms in the beam with an energy greater than the specified limited ε_0 (activation energy) and n is the total number of atoms in the beam.

On the other hand, the rate of formation of tritium atoms itself increases ($T_2 \rightarrow 2T$); the activation energy for this process has been determined (see, for example, Brennan and Fletcher[21]) as 51.8 ± 1.0 kcal mol^{-1}, i.e. half the bond dissociation energy in the hydrogen molecule. For practical

purposes, one can employ the expression for the rate of atomisation

$$v_{at} = A\,(p)^{1/2} \exp(-\varepsilon/RT)$$

where $A = (1.5 \pm 0.5) \times 10^{2.5}$ atom cm^2 s^{-1} (mmHg)$^{-1/2}$ for tungsten, $\varepsilon = 51.8$ kcal mol^{-1}, and p is the hydrogen (tritium) pressure (mmHg).

For more rigorous calculations, the roughness coefficient, which according to most estimates is 1.4 for tungsten,[22] must be applied to the area of the filament calculated from its geometrical dimensions. Under the conditions described above at $T_{fil} \cong 2000$ K and a pressure of 5×10^{-3} mmHg, the quantity $v_{at} = 2.9 \times 10^{19}$ atom cm^{-2} s^{-1} and the beam of atoms onto the target is determined by the corresponding solid angle.

In apparatus of the type described it is usually possible to obtain, as a result of a single admission of tritium, preparations with an overall activity of 5–10 mCi; i.e. with $a = 10^3$–10^4 mCi g^{-1} for milligram amounts of the test substance. For biopolymers, for example, for proteins, this is an extremely high value (~10 Ci mmol^{-1}), which satisfies the majority of requirements. A great advantage of the method is the small consumption of tritium, which makes it possible to carry out experiments in radioisotope laboratories of any class.

IV. REACTIONS OF ATOMIC HYDROGEN

The main chemical reaction occurring when hydrogen atoms interact with saturated hydrocarbons is the abstraction of a hydrogen atom with formation of a free radical:

$$H + RH \rightarrow \dot{R} + H_2 \quad . \qquad (1)$$

The activation energy for this process is 6–8 kcal mol^{-1}.[23] For unsaturated compounds, hydrogen atoms should add to the multiple bond with a high efficiency, which also leads to the formation of a radical:

$$H + R{-}CH{=}CH{-}R' \rightarrow R{-}\dot{C}H{-}CH_2{-}R'. \qquad (2)$$

The activation energy for this reaction is 1–2 kcal mol^{-1}. Since the reaction results in the evolution of an amount of energy of ~40 kcal mol^{-1}, the radical formed is excited and can undergo various transformations, for example, can isomerise or decompose with dissociation of C–C or C–H bonds. In the case of functional derivatives of hydrocarbons, the spectrum of possible reactions is significantly broadened.

Not only primary processes but also subsequent reactions, leading to the formation of a labelled product, are evidently important for the synthesis of labelled compounds. The fate of the radicals formed via reactions (1) and (2) depends to a large extent on the experimental conditions: the phase state of the test substance, the temperature, and the chemical nature of the molecules of the medium. Thus the radical can enter into addition reactions with unsaturated compounds:

$$\dot{R} + R'{-}CH{=}CH_2 \rightarrow R'{-}CHR{-}\dot{C}H_2 \; . \qquad (3)$$

In chain reactions of this type, high-molecular-weight products are formed. When this is allowed by energy relations, the radical can abstract hydrogen or other atoms and groups of atoms from the molecules of the medium.

All the above reactions take place in both gas and liquid phases, but in the latter case account must be taken of the so-called cage effect, which limits the interaction of the radicals with one another and increases the probability of the stabilisation of the excited radicals but has little effect on the rates of reactions involving light hydrogen atoms.

In the reactions in the solid phase the differences become fundamental: the radicals formed are incorporated in the matrix and their subsequent fate depends on the properties of the latter. In a "soft" matrix, the diffusion of the radicals frequently limits the kinetic parameters of the entire reaction. In a "hard" matrix the translational movements and in many instances also the rotational movements of the radicals are hindered. This determines not only the quantitative characteristics of the rates of the processes but also the spectrum of the possible solid-phase reactions. Thus in a "hard" matrix there is relatively high probability of the stabilisation of the excited species as a result of the scattering of the energy, the intramolecular rearrangements of the type of *cis–trans*-isomerisation are hindered, etc. The lifetime of the radicals and hence their stationary concentration in a "hard" matrix are as a rule higher by several orders of magnitude than in the liquid and gas phases.

At the low temperatures usually employed for the synthesis of labelled preparations, the secondary reactions of the stable radicals with hydrogen atoms, whose mobility is fairly high even at ~100 K, assume an important role. As in the interaction of the radicals with one another, two processes are possible in this case:

$$RCH_2\dot{C}H_2 + H \rightarrow RCH_2CH_3 \text{ (recombination);} \qquad (4)$$

$$RCH_2\dot{C}H_2 + H \rightarrow RCH{=}CH_2 + H_2 \text{ (disproportionation).} \qquad (5)$$

However, the probabilities of these processes differ from those observed for the quadratic destruction of radicals—in many cases the rate of disproportionation is equal to or greater than the rate of recombination.[24]

In experiments involving the introduction of the label into organic substances, the target is usually thermostatted and the temperature (energy) of the tritium atoms is determined by the conditions of their generation. As a rule, the energy spectrum of the beam incident on the target corresponds to relatively high temperatures (ranging from room temperature to several thousands or tens of thousands of degrees) and this is responsible for their high reactivity. A decrease of temperature from 300 to 77 K should reduce the rate of reaction by a factor of ~10^{18}, i.e. almost to zero. However, it has been found that, even at temperatures close to 4 K, the rate of reaction is extremely high.[25] A detailed study showed that there are two mechanisms of the substitution of hydrogen by tritium, one of which obtains at relatively high temperatures (100–300 K) and is characterised by an activation energy of ~8 kcal mol^{-1}. At low temperatures (<100 K) the reaction with zero (0.3 kcal mol^{-1}) activation energy predominates, proceeding in all probability via a tunnel mechanism,[26] i.e. there is a possibility of completely different features of this reaction and other products may be formed. However, in the usual experiments the contribution of the tunnel reactions is small and can be disregarded.

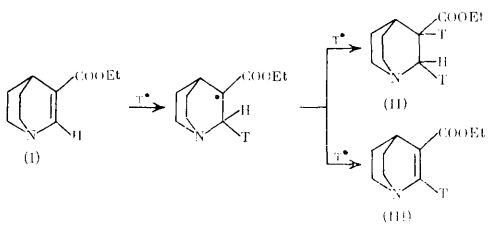
In the region of high (≥1 eV) energies, direct substitution of hydrogen, first observed for recoil tritium atoms[27] and subsequently studied in detail,[6,28,29] proceeds together with reactions of types (1) and (2):

$$H^h + RH \rightarrow RH^h + H, \qquad (6)$$

where H^h is a hot atom. The process cross-section increases rapidly with increase of the energy and reaches a maximum at 10 eV. The use of reaction (6) for the preparation of labelled compounds is prevented by the lack of sources of hydrogen atoms with a suitable energy spectrum and intensity. Atoms capable of substituting hydrogen via mechanism (6) can be obtained by the photolysis of certain hydrogen-containing compounds (for example, HI and H_2S) or by exposure to radiation. It is also possible to use high-energy (~10^6 eV)

recoil atoms obtained as a result of nuclear transformations [for example, $^{6}Li(n\alpha)T$, $^{3}He(np)T$] and also special apparatus for the generation of beams of accelerated atoms and ions.

However, all these methods are in essence inapplicable to the introduction of a label into biologically active substances: exposure to radiation and recoil atoms is known to entail a considerable degradation of the initial compound, while apparatus with beams is extremely complex and the actual beam intensities are insufficient for the attainment of a high activity. Thus experimenters have at their disposal mainly sources of atoms with moderate energies, where the main primary process is reaction (1) and (or) (2).



The reactions of hydrogen atoms with organic compounds have been described in detail in reviews.[30,31] Here we shall confine ourselves to the process, which plays an important role in the preparation of labelled compounds and which leads to the localisation of tritium in exchangeable groups of the type COOH, NH, NH_2, OH, SH, etc. Most of the tritium (90–99%) exists in this form and this fraction is independent of the chemical nature of the compound. Naturally such preparations cannot be used in practice without preliminary frequently fairly laborious purification. The mechanism of the reactions leading to the stabilisation of tritium atoms in the exchangeable groups is at present obscure. It may be that, as a result of stabilisation on the surface of a solid, the hydrogen atoms are polarised and interact in the form of a polar species predominantly with polar groups in the molecules of the medium. Such polarisation of hydrogen atoms has been demonstrated on the basis of EPR spectra.[31] The proposed mechanism is supported also by the finding that the coefficient of the introduction of the label into the polar groups depends little on the energy of the atoms.

V. PREPARATIVE SYNTHESIS OF LABELLED COMPOUNDS BY METHODS INVOLVING THE THERMAL AND HIGH-FREQUENCY ACTIVATION OF GASEOUS TRITIUM

As already stated, TAM and HFAM are universal methods for the introduction of the tritium label and are used to prepare labelled compounds belonging to a wide variety of classes. However, proteins (and also their fragments—peptides and aminoacids) have mainly attracted the attention of investigators and most of the studies in this field are devoted to such substances.

It was already stated above that, when organic compounds interact with tritium atoms generated under TAM and HFAM conditions, various reactions, regarded as side processes,[34–36] are observed together with the substitution of hydrogen by tritium (an analogous phenomenon has been noted also for other versions of the activation of gaseous tritium[3,32,33]). The relative contributions of the reaction involving the substitution of hydrogen by tritium and the side reactions depend greatly not only on the method of activation of T_2 (for example, the degree of addition to a double bond when the label is introduced by the Wilzbach method can be ten times greater than in the case where HFAM is employed[37]), but also on smaller changes in conditions within the framework of the same method. Thus the yield of addition products in TAM is influenced by the T_2 pressure, the temperature of the incandescent filament, the duration of exposure,[38,39] and even the character of the solvent used in the deposition of the specimen.[24] Structure factors are even more important: under identical conditions in the application of the HFAM, the ratio of the contributions of the reactions involving addition to the double bond and substitution of H by T is 2.6 for oleic acid, approximately 12 for unsaturated aminoacids, and only 0.02 for morphine.[37] This ratio can vary markedly even within the limits of a single series of compounds,[16,35] but, for simple alkenes and cycloalkenes, the saturation of the double bond as a rule proceeds more readily than the substitution of H by T.[16,35,36,39] Under TAM conditions, the substitution of H by T takes place with greater difficulty than the substitution of halogen atoms by T for both halogenoalkanes[40] and halogenobenzenes,[41] the ease of substitution of the halogen increasing in the sequence Cl << Br < I.

In a number of instances "side" reactions such as the saturation of double bonds and dehalogenation can be used for preparative purposes. Indeed, 3-ethoxycarbonyl-Δ^2-dehydroquinuclidine (I) has been converted by the TAM into the corresponding labelled saturated compound (II) and the unsaturated compound (III) in yields of 72 and 5.5% respectively:[42]

Other examples are the synthesis of labelled dihydrotestosterones from testosterone by the HFAM[43] and also the use of a high-frequency discharge (combined with heterogeneous catalysis) for the preparation of tritiated nucleoside monophosphates from the corresponding halides.[44]

The introduction of the tritium label into various classes of organic compounds is examined below.

1. Aliphatic Hydrocarbons

The study of the interaction of atomic tritium with aliphatic hydrocarbons was begun more than 20 years ago, but attention has been concentrated on the theoretical study of the reactions involved and not on the preparative synthesis of labelled compounds. In the early studies it was already shown that for alkanes (pentane and hexane) the degree of dissociation of the carbon–carbon bonds under the influence of tritium atoms, generated under both TAM[45] and HFAM[12] conditions, is much smaller than under the conditions of the Wilzbach method or in reactions with hot tritium atoms.[46] The main process is the substitution of hydrogen by tritium and in the TAM (temperature of W filaments 1750 °C)[45] hexane-*t* and pentane-*t* are obtained in yields greater than 80%. The mechanism of the substitution reaction evidently involves the abstraction of a hydrogen atom from the alkane ($RH + T^{\cdot} \rightarrow R^{\cdot} + HT$) and recombination ($R^{\cdot} + T^{\cdot} \rightarrow RT$). An alternative version is also possible—disproportionation of the alkyl radicals into an alkane and an alkene with subsequent addition of a T atom to the alkene, but the contribution of this mechanism at low temperatures is apparently small, which has also been confirmed by the low yields (5–10%) of high-molecular-weight products.[45] However, when the temperature of the specimen is increased to 90 K, the contribution of the disproportionation reaction increases sharply.[47] The first stage, namely the abstraction of a hydrogen atom, proceeds more readily at a tertiary carbon atom than at secondary and primary carbon atoms.[48]

In the case of cycloalkanes the addition of tritium, leading to the rupture of the carbon ring and the formation of a labelled alkyl radical, competes with the hydrogen abstraction reaction. The degree of this reaction is determined primarily

by the ring strain: under identical TAM conditions, the yield of cyclohexane-*t* from cyclohexane was ~80%,[45] while cyclopropane[49] was converted into cyclopropane-*t* only in 37% yield and the remaining labelled products consisted of acyclic hydrocarbons formed from the $TCH_2CH_2\dot{C}H_2$ radical. The reaction of cyclohexane with T_2 under HFAM conditions also leads to the formation of cyclohexane-*t* as the main labelled product.[12] The energy of the tritium atom plays a very significant role:[49] at a temperature of the tungsten filament of 1180 °C, only ethane-*t* and propane-*t* are formed from cyclopropane in proportions of 73 : 27, their contents among other products being reduced at 1520 °C to 37 and 50% respectively (the content of cyclopropane-*t* is ~14%) and cyclopropane-*t* becomes the main product (37%) only at 1750 °C, but the content of propane-*t* also rises to 23%.

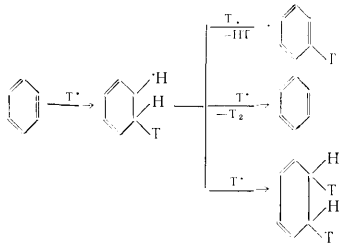
In the interaction of cyclohexane with tritium atoms under TAM conditions at 1800–2250 K, the main labelled products, apart from cyclohexane-*t*, are also cyclohexene-*t* and bicyclohexyl-*t*.[50] Thus the cyclohexyl radicals obtained as a result of the abstraction of hydrogen from cyclohexane (activation energy $E_a \cong 7$ kcal mol^{-1}) enter into all possible reactions—recombination, disproportionation, and dimerisation.

As already noted, the addition of tritium atoms to the double bond in alkenes and cycloalkenes proceeds more readily than the substitution of H by T. For example, E_a for addition to cyclohexene is lower by a factor of 2–4 than for the substitution reaction[36] and the main product (~70%) of the reaction of cyclohexene with T_2 under TAM conditions is cyclohexane-*t*.[36,45,51] Analogously, hex-1-ene is converted in ~70% yield into hexane-*t*.[45] It has been suggested[15] that the saturation of the double bond takes place in two stages—tritium adds in succession initially to the alkene and then to the radical formed.

Considerable differences in the ease of saturation of double bonds have been noted for different alkenes:[15,16,35] propene reacts particularly rapidly, but-1-ene, isobutene, and methylbut-1-enes react more slowly, while the reactions of buta-1,3-diene, pent-1-ene, and finally hex-1-ene are slower still. These differences evidently reflect the differences between the values of E_a at low temperatures.[15] The substitution of hydrogen, whose contribution is ~25% for cyclohexane and hex-1-ene,[45] and the migration of the double bond,[24,34,35] compete with the alkene saturation reaction. It has been suggested[16,24,34,50] that tritium initially adds on to form a labelled alkyl radical, which is then converted into a labelled alkene as a result of the loss of H on interaction either with a T atom or (which is less likely) with another alkyl radical. This mechanism also explains the isomerisation of alkenes under the influence of tritium atoms observed for but-1-ene[34,35] and cyclohexylcyclohexane:[24]

$$RCH{=}CHCH_2R' \xrightarrow{T} RCHT{-}\dot{C}HCH_2R' \xrightarrow{T} RCHTCH{=}CHR' .$$

The direction of isomerisation is determined by thermodynamic factors: but-2-ene does not isomerise to but-1-ene under these conditions.



The data for alkynes are restricted to those for acetylene,[12] which is labelled by tritium under HFAM conditions without the saturation of the triple bond. When the TAM (tungsten filament, 2000 °C) is used, labelled saturation products—ethane and ethylene (25–30 and 18% respectively)—predominate and the yield of HC≡CT falls to 18%.

The reactions of atomic tritium with functional derivatives of aliphatic hydrocarbons have been very little studied. Apart from the halogenopentanes already mentioned as well as aliphatic acids, carbohydrates, and aminoacids (dealt with in separate sections—see below), there are only a few examples. Triethyloxonium tetrafluoroborate $Et_3O^+BF_4^-$ readily exchanges its hydrogen atoms for tritium under TAM conditions (2200 °C, T_2 pressure ~0.01 mmHg).[19,52] The labelled preparation had a high value of a (~5 Ci mmol^{-1}), contained no labile tritium, and did not require special purification, because all the theoretically possible cleavage or hydrolysis products are volatile substances and are removed under the experimental conditions.

Tritium-labelled sodium dodecyl sulphate ($n\text{-}C_{12}H_{25}OSO_3Na$) with $a = 0.014$ Ci g^{-1} has also been obtained by the TAM, a film of a frozen aqueous solution being bombarded.[53] A label has been introduced into dicyclohexylurea ($a = 0.178$ Ci mmol^{-1}) with the aid of the HFAM (pulse discharge, 800 kHz, T_2 corresponding to 25 c) but only ~20% of the tritium introduced was contained in the cyclohexane rings.[54]

2. Aromatic Compounds

The powerful activating influence of the discharge on the incorporation of tritium into aromatic compounds placed in T_2 was already noted comparatively long ago[55–57] and appreciable decomposition of the test substances was not observed. Aromatic compounds also do not decompose under TAM conditions (temperature of tungsten filament 1460 °C, pressure 0.001–0.005 mmHg)[58] but in many instances the saturation of the aromatic ring takes place vigorously. For example, labelled benzene, cyclohexene, and cyclohexane have been obtained from benzene (temperature of tungsten filament 1750 °C, pressure ~0.01 mmHg, their radioactivities being distributed in proportions of 21 : 35 : 39.[45] Evidently labelled cyclohexadienyl radicals (IV) are formed initially:

(7) (8) (9)

(IV)

Their subsequent interaction with tritium atoms can lead to the formation of labelled benzene, unlabelled benzene, or labelled cyclohexadiene, which is converted into labelled cyclohexenes and cyclohexane on combining with more tritium. The formation of cyclohexadienyl radicals on addition of excited H(T) atoms to aromatic compounds has been confirmed by EPR.[48,59,60] The relative contribution of reaction (7) is small and the radiochemical yield of benzene-*t* under these conditions does not exceed 5%.[58] In the reactions involving alkylbenzenes the substitution of H in the side chain competes with the saturation of the aromatic ring. Although this reaction, in the first stage of which H is abstracted with formation of the corresponding benzyl radicals, proceeds much more slowly than the addition to the ring,[61] it is the main process leading to the formation of labelled alkylbenzenes. With increase of the number of alkyl groups, the ability of this reaction to compete increases (i.e. in the sequence benzene < toluene < *o*-xylene < mesitylene).[58]

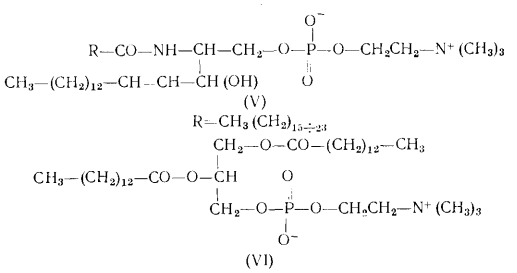
Thus in labelled alkylbenzenes tritium is localised mainly in the side chain (55–67% T for toluene-*t* when the HFAM is used).[62] An analogous phenomenon has been observed[63,64] for labelled aromatic aminoacids (see below). It is of interest that, in other versions of isotope exchange involving alkylbenzenes (the Wilzbach method, reaction with hot atoms,

exchange initiated by ultraviolet light or γ-radiation, and acid catalysis in solution), tritium is localised mainly in the aromatic ring.[62,65]

In addition substituents hinder (under the influence of both electronic and steric factors) the addition of tritium to the ring.[48,58] The H(T) atom never enters the position in the ring where a substituent is present and attacks only the *ortho*- or *para*-positions.[48] On the other hand, the addition to the *meta*-position is difficult, which evidently explains the greater tendency towards the addition of H(T) to 1,3-disubstituted benzenes compared with the 1,2- and 1,4-disubstituted derivatives.[48] Probably, for the same reason the aromatic ring is not involved when the tritium label is introduced into the alkaloid morphine by the HFAM.[37]

Thus when the HFAM and TAM are used, the introduction of the tritium label into aromatic compounds proceeds with greater difficulty than in the case of aliphatic hydrocarbons and it is as a rule impossible to attain high values of a. This is confirmed by the data in Table 1, which includes, together with aromatic hydrocarbons, also aromatic heterocycles—acridine and xanthine. It is significant that, under the conditions presented in Table 1, values of a greater by a factor of 50–100000 (for the HFAM) and 10–50 (for the TAM) had been obtained for certain labelled compounds of other classes under the conditions presented in Table 1.[10,19] Although the TAM is more suitable for the preparative synthesis of labelled aromatic compounds, rigorous comparative studies have not been carried out.

Table 1. Labelled aromatic compounds.



Compound	a, m Ci mmol^{-1}	Refs.
Acridine	0.045	[10]
p-Aminobenzoic acid (Na salt)*	35	[66]
Ethyl *p*-aminobenzoate*	135	[19, 66]
p-Aminosalicylic acid	0.045	[57]
Anthracene	0.515	[10]
Benzoic acid	3.8	[10]
Xanthene	0.423	[10]
9-Methylanthracene	0.04	[10]
Naphthalene	0.01	[10]

*The substance was deposited on a paper support; method of preparation—TAM; in the remaining cases the HFAM was used.

In conclusion we shall point out the likely usefulness of the synthesis of tritium-containing aromatic compounds from halogeno-derivatives. The tritium atoms generated under the TAM conditions substitute the halogen atom in halogenobenzenes; the yields of the substitution products for iodobenzene and bromobenzene are respectively 2.8 and 1.5 times greater than for chlorobenzene,[41] which agrees with the C–Hal bond dissociation energies in the above series.

3. Lipids and Aliphatic Acids

The question of the introduction of the tritium label into lipids is a matter of considerable urgency but the attempts at the direct introduction of tritium by the TAM and HFAM have so far not met with notable success. This can apparently be explained by the extensive cleavage of lipids under the conditions of their interaction with excited tritium atoms (for example, the complete decomposition of egg lecithin and dimyristoylphosphocholine has been observed[67]) and also by the presence in certain lipid molecules of residues of unsaturated aliphatic acids. Nevertheless, labelled sphingomyelin (V) (a = 0.2 c mmol^{-1}) and 1,2-dimyristoyl-*sn*-glycero-3-phosphocholine (VI) (a = 0.02 c mmol^{-1}) have been obtained[67] by the TAM. In the case of sphingomyelin the presence of an admixture of labelled dihydrosphingomyelin, which does not preclude further use of the preparation, was not specially tested for. On the other hand, despite the low value of a, the experiment with lecithin (VI) may lead to new prospects for preparative synthesis: although compound (VI) decomposed fully under the influence of tritium atoms after being deposited on the surface of a glass vessel,[67] after the deposition on a paper support the yield of the labelled preparation proved to be almost quantitative:[19]

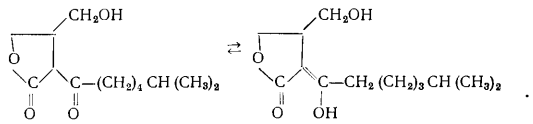
(V)

(VI)

Another method of synthesis of labelled lipids consists in the employment of labelled aliphatic acids, which makes it possible, in particular, to obtain phospho-lipids containing simultaneously the radioactive label and photoreactive groups,[67,68] The results of the use of the TAM and the HFAM for the introduction of tritium into aliphatic acids are presented in Table 2.

Table 2. Labelled aliphatic acids.

Compound	Method	a, m Ci mmol^{-1}	Refs.
11-Aminoundecanoic acid	TAM	300	[67, 68]
Isocaproic acid (Na salt)	HFAM	19.4	[10]
Methyl 12-hydroxystearate	TAM	15	[67]
Oleic acid	HFAM	0.832	[10]
Stearic acid	ED	0.026	[69]



Note. In the TAM the temperature of the tungsten filament was 2000 °C and the walls of the vessel were cooled with liquid nitrogen; the parameters of the HFAM were 2450 MHz and 20 W; ED—excitation with an electric discharge (pressure 100 mmHg).

Appreciable decomposition of carboxylic acids under the conditions of their interaction with tritium atoms has been noted[67,70] and is apparently associated with the abstraction of hydrogen from the carboxy-group: the acyloxy-radicals RCOO$^{\cdot}$ formed are known to be readily cleaved into CO_2 and R$^{\cdot}$. The replacement of the free acids by their salts or esters sharply reduces the degree of decomposition: the yield of the labelled methyl ester of 12-hydroxystearic acid is 75% under conditions where the acid itself is fully

decomposed.[67] As can be seen from Table 2 for 11-aminoundecanoic acid, which is an inner salt, the binding of the carboxy-group also makes it possible to achieve higher values of a.

The mechanism of the incorporation of tritium into the hydrocarbon chain of saturated aliphatic acids is the same as for alkanes. The formation of radicals as a result of the abstraction of H from the carbon atoms in malonic and methylmalonic acid under the HFAM conditions has been confirmed by EPR.[71] As for alkenes, for unsaturated aliphatic acids the addition reaction predominates over the substitution reaction. When the HFAM is applied to oleic acid, labelled stearic and oleic acids are formed in proportions of 2.6 : 1, but the ratio is much greater when the Wilzbach method is used (24.4 : 1).[37]

The so-called A-factor (VII)—the substance which regulates the biosynthesis of the antibiotic streptomycin—should also be included among aliphatic acid derivatives. The labelled A-factor has been obtained[19] in ~30% yield with $a = 0.26$ c mmol^{-1} (TAM, paper support) and saturation products which might have been formed from the enolic forms of the A-factor were not detected:

(VII)

4. Low-Molecular-Weight Bioregulators

The tritium label has been introduced into low-molecular-weight bioregulators (steroids, alkaloids, antibiotics, etc.) only with the aid of the HFAM. The labelled A-factor, the synthesis of which was described above, can be regarded as the only exception#.

For steroids (corticosterone and progesterone), the classical version of the HFAM (2450 MHz, 0.7 mmHg, T_2 corresponding to 80 mCi, 5 min) yielded low results: although the chemical yield was 60–65%, the radiochemical yield did not exceed 1% and $a = 0.0025$–0.003 Ci mmol^{-1}.[75] When the HFAM was used in the case of aflatoxin,[76] similar values of a were achieved, but these increased markedly with increase of the surface area (with the use of a glass paper support), with decrease of the size of the test sample, and with increase of the T_2 pressure. Thus labelled 6-azido-6-dehydrodexamethasone and 21-diazo-21-deoxycorticosterone (0.15 mg, deposition on glass paper, pressure 9 atm) have been obtained by means of the HFAM with $a \cong 1$ Ci mmol^{-1}.[43] It is extremely important that the highly reactive $-N_2$ and $-N_3$ groups are not involved under HFAM conditions. On the other hand, under the same conditions in the case of testosterone the isotope exchange is accompanied by the addition of T_2 to the $\Delta^{4,5}$-bond with formation of labelled 5α- and 5β-dihydrotestosterones.[43]

On the other hand, the double bond in the alkaloid morphine is hardly saturated under HFAM conditions and morphine-t is formed with $a = 0.0027$ Ci mmol^{-1} (for a sample of 1 mg).[37,77] Better results were achieved for the alkaloid 1-cocaine ($a \cong 0.03$ Ci mmol^{-1}), while the local anaesthetics which are its analogues (carbocaine, xylocaine, citanest, tetracaine, and procaine) are labelled less successfully.[78,79]

5. Carbohydrates

The few attempts at the preparative synthesis of labelled carbohydrates by exposure to atomic tritium cannot be recognised as entirely successful, since the values of a for the labelled compounds obtained proved to be low; however, the results achieved are no worse than those obtained when the Wilzbach method is used. Glucose, sucrose, glucose-1-phosphate ($a = 0.006$–0.008 Ci g^{-1}) as well as starch grains[80] (both amylose and aminopectins proved to be labelled) have been labelled with the aid of the TAM;[17] the HFAM has been used to introduce tritium into methyl-β-D-glucoside [a 99 : 1 mixture of He and T_2 and a electrodeless ring discharge (40 mHz) were used], with a radiochemical yield of ~2% and $a = 0.006$ c mmol^{-1},[9] and into dextran (tritium corresponding to 0.5–2 Ci, 1–4 mmHg, 2450 MHz, $a = 0.2$ Ci mmol^{-1}).[76] Under identical conditions, peptides and proteins are labelled to a much greater extent than carbohydrates.[9,76]

Table 3. Labelled nucleic bases, nucleotides, and nucleic acids.

Compound	m, mg	Consumption of tritium, c	Conditions	a, Ci mmol^{-1}	Refs.
Adenine	110	0.08	2450 MHz, 150 W, 0.7 mmHg, 5 min	0.021	[75]
Thymine	80	0.08	ditto	0.0048	[75]
ATP	100	25	800 kHz (pulse conditions), 200 mmHg	0.03	[81]
Guanosine monophosphate	—	—	2000 K, 0.01 mmHg, 2–5 min	10–20	[18]
Deoxycytidine tri-phosphate	—	—	99 : 1 He–T_2 mixture, 80 W, 40 MHz, 0.01 mmHg, 1 h	0.5	[82]
p-Nitrophenyl ester of AMP	—	—	ditto	0.001	[82]
ATP-3′-OCH$_3$	—	—	"	1	[82]
λ phage DNA	—	—	"	0.08	[82]
Total tRNA	—	—	"	0.01	[82]
tRNA from *E. coli*	1	30	2200 K, 0.01 mmHg, 0.5 min	0.3	[19]

Remarks. Labelled guanosine monophosphate and tRNA from *E. coli* were prepared by the TAM, while in the remaining cases the HFAM was used; the chemical yields of adenine and thymine were 85 and 80% respectively, while in the remaining cases the yield was 50% (not indicated for guanosine monophosphate); the radiochemical yields were 21% for adenine, 0.02% for tRNA for *E. coli*, and 3.6% for thymine; in the remaining cases the radiochemical yield was not indicated.

6. Nucleic Bases, Nucleotides, and Nucleic Acids

The direct introduction of tritium into nucleic acids and nucleotides is extremely important in view of the role which these compounds play in biological processes and the large number of studies in which they are employed. It has been shown[75] that the HFAM is much more convenient for this purpose than the Wilzbach method and subsequently the introduction of tritium into certain nucleic bases, nucleoside monophosphates, and nucleic acids with the aid of both the

#There are also reports[72–74] of the use of the TAM for the preparation of the tritium-labelled alkaloid aconitine and tetrodotoxin (the venom from the Fugu fish) with $a \cong 0.5$ c mmol^{-1}, but no experimental data are presented in these communications.

HFAM and the TAM was investigated; the results are presented in Table 3. The extent to which compounds of this class remain undamaged under HFAM and TAM conditions is high but polymeric molecules can be modified without cleavage. In particular, there is a possibility of the addition of tritium to the unsaturated bonds of the heterocyclic DNA and RNA nuclei because solid thymine and uracil form free radicals by combining with hydrogen atoms in a discharge in gaseous hydrogen.[83]

It is also noteworthy that a high-frequency discharge has been used[44,81] for the activation of T_2 in the synthesis of labelled nucleoside monophosphate and uracil by solid-phase reductive dehalogenation. Under HFAM conditions, the pyrophosphate bonds in adenosine triphosphate are ruptured with formation of adenosine diphosphate and adenosine monophosphate (in yields of 22 and 7% respectively), the values of a of which exceed that of labelled adenosine triphosphate by factors of ~1.5 and ~2 respectively.[81]

7. Aminoacids, Peptides, and Proteins

It was already stated above that the reactions with atomic tritium are of special interest as a method for the introduction of the label into proteins. A high degree of radioactivity can be introduced into the protein molecule also with the aid of ^{125}I or ^{131}I, but, firstly, the iodinated proteins are chemically (and frequently biologically) no longer identical with the native proteins, and secondly, the protein iodination methods used until recently involve oxidative reactions.

The synthesis of tritium-containing proteins is also difficult. The biosynthesis of the required product in any kind of satisfactory yield is possible only in a few instances and requires the employment of very high radioactivities of the HTO water and isolation and purification by extremely laborious and carefully elaborated methods. The scope of the chemical synthesis of proteins labelled with tritium is also limited. The greatest successes have been achieved[3] in the case of peptide hormones and toxins, containing up to several tens of aminoacid residues, into the molecules of which tritium had been introduced by the combination of peptide synthesis (from halogenoaminoacids) and catalytic dehalogenation. On the other hand, the exchange methods, particularly the thermal and high frequency activation of gaseous tritium, whose advantages have already been considered in the Introduction, are the most promising and universal for the synthesis of tritium-containing proteins.

Since the interaction of atomic tritium and proteins can involve various processes which depend on the primary, secondary, and tertiary structure of the protein molecules, the study of the general characteristics of this reaction was begun with model compounds—aminoacids and short peptides.[18,78,84] Table 4 shows that, with the aid of the TAM and the HFAM, it is possible to label both aliphatic and aromatic aminoacids. According to the results for alanine and phenylalanine, the TAM makes it possible to achieve higher values of a, but the comparative advantages of the TAM and HFAM for the preparative synthesis of labelled aminoacids have not been specially studied.

Apart from the reaction involving the direct substitution of H by T (Table 4), the reduction with atomic tritium of unsaturated C=C bonds and certain functional groups has also been used for preparative purposes. Thus, under HFAM conditions (20 W, 2450 MHz, T_2 equivalent to 1 Ci, 5 min), 3,4-dehydro-DL-proline undergoes mainly an addition reaction with formation of labelled DL-proline,[37] while DL-alanine-t (a = 0.0004 Ci mmol^{-1}) was the only labelled product of the interaction of α-hydroxyiminopropionic acid with HT (8000 W, 40 mmHg, 10 min).[89] The synthesis (HFAM, 1.5 keV, working gas—hydrogen with an admixture of 0.0001% of tritium, pressure 5×10^{-4} mmHg, 30 min) of labelled phenylthiohydantoin derivatives of aminoacids $RCH(NH_2).CON(Ph)C{=}S$ [13] in 1–10% yield and with $a \cong 0.001$ Ci g^{-1} should also be mentioned. The intramolecular distribution of tritium between the aminoacid residue and the phenyl group was not determined.

Table 4. Labelled aminoacids.

Aminoacid	Method	τ, min	φ, %	η, %	a, Ci mmol^{-1}	Refs.
Alanine	A	6	83	2.2	0.0016	[75, 78]

Remarks. Methods: A—microwave discharge (150 W, 2450 MHz), T_2 equivalent to 0.08 Ci, pressure 0.7 mmHg, DL-aminoacid sample 100 mg; B—microwave discharge under pulse conditions, T_2 equivalent to 25 Ci, pressure 200 mmHg, DL-aminoacid sample 100–150 mg; C—electrodeless ring discharge (80 W, 40 MHz), 99:1 He–T_2 mixture (pressure in the region of target 10^{-4} mmHg), sample 5 mg; D—TAM, temperature of tungsten spiral 2000 K, pressure 10^{-2} mmHg, sample 0.2–1.0 mg; E—microwave discharge (30 W, 2450 MHz), circulation conditions (190 circulations per minute), T_2 equivalent to 0.5–2.0 Ci, pressure 1–4 mmHg. In the case of proline and valine (the L-aminoacid samples were 0.1–0.4 mg each) the test substance was deposited on a paper membrane.

Notation: τ is the duration of exposure and ϕ and η are respectively the chemical and radiochemical yields.

*Cysteine (a = 0.316 Ci mmol^{-1}, yield 50%) was obtained together with cystine.

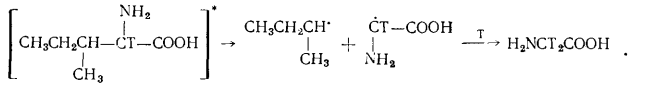
As regards the influence of the experimental conditions, it has been established for the TAM (Table 4, procedure D)[86] that a increases by a factor of approximately 7 with increase of the temperature of the film of the deposited substance from 77 to 300 K (in relation to tyrosine). For the HFAM (procedure A), a change in sample size (from 13 to 100 mg) is only slightly reflected in the value of a but leads to an approximately fourfold increase of the radiochemical yield,[78] while in the case of labelled L-proline (TAM, procedure D) an increase of the sample size from 0.1 to 1 and 10 mg entails a decrease of a by factors of ~2 and ~10 respectively.[87] In

procedure A, the variation of the power of the discharge (within the limits 50–200 W) and of its duration (in the range 3–12 min) has little influence on a and on the radiochemical yield, but both these parameters decrease by a factor of almost 2 with decrease of the time of exposure to 1 min.[78] A twofold increase of the pressure makes it possible to increase a by a factor of 2 but a subsequent increase of the pressure is less effective and for 0.96 c/T_2 the value of a is only slightly greater than for 0.08 c, while the radiochemical yield falls by a factor of ~10. The amount of labile tritium in the labelled aminoacids depends greatly on the reaction conditions. Thus alanine-t, obtained by methods C [9] and D,[86] contained respectively 60 and 90–95% of labile tritium.

The mechanism of the reaction of aminoacids with atomic tritium has been studied almost exclusively under TAM conditions. According to general ideas (see above), in the first stage attack on the molecule of the aminoacid $RCH_2CH(NH_2).COOH$ by the tritium atom results in the abstraction of hydrogen and the formation of HT and the radical $RCH_2\dot{C}.(NH_2)COOH$ (VIII) or $RCHCH(NH_2)COOH$ (IX), which are converted into labelled aminoacids in the second stage on recombination with the tritium atom. The first stage is rate-limiting and the relative contributions of the reactions involving the formation of radicals (VIII) and (IX) can be inferred from the intramolecular distribution of tritium between the α- and β-positions in the labelled aminoacids. Data for such intramolecular distribution in the case of the TAM are presented in Table 5. In all cases the formation of radicals of type (IX) is energetically more favourable, which agrees well with calculated data,[63,64,90] which indicate a greater stability of compound (IX) (greater degree of delocalisation of the unpaired electron) and also a greater mobility of the hydrogen atoms in the β-position (in all cases except alanine; the limiting electron density was used as the criterion). These results also agree with the known behaviour in the formation of free radicals: the abstraction of H from the CH_3 group is more difficult than from the substituted CH_2 group (cf. data for alanine). The influence of substituents in the introduction of tritium into aminoacids by the TAM (see Table 4) is on the whole the same as in the reaction of aminoacids with hydrogen atoms in aqueous solution.[91]

Table 5. Intramolecular distribution of tritium (%) in the labelled aminoacids $R\overset{\beta}{C}H_2\overset{\alpha}{C}H(NH_2)COOH$ obtained with the aid of the TAM.

Aminoacid	R	α-Position	β-Position		Aromatic ring	Refs.
			per C–H bond	total		
Alanine	H	43	19	57	—	[63, 73]
Serine	OH	18	41	82	—	[63, 73]
Cysteine	SH	11	45	89	—	[63, 73]
Aspartic Acid	COOH	30	35	70	—	[63, 73]
Phenylalanine	Ph	5	19	38	57	[90]
Tyrosine	p-HOC_6H_4	8	42	84	8	[64, 88]



The preferential localisation of tritium in the β-position has been observed[92,93] also for labelled L-isoleucine, L-alloisoleucine, and L-valine obtained with the aid of the HFAM. In the case of valine tritium was distributed among the α-, β-, and γ-positions in proportions of 7 : 33 : 60 (i.e. 10% for each γ-C–H bond).

As regards the intramolecular distribution of tritium in labelled aromatic aminoacids—phenylalanine and tryosine (Table 5), the much greater radioactivity of the aromatic ring in phenylalanine can be readily accounted for, because, as already mentioned above, the ring substituent (in the given instance OH in tryosine) greatly hinders the addition of tritium (the rate-limiting stage).

More detailed ideas about the mechanism of the interaction of atomic tritium with aminoacids are based on the fact that the kinetics of the reactions of tritium atoms (formed by the TAM) with phenylalanine and tyrosine at a temperature <200 K deviate from the Arrhenius equation,[88,94] while at a temperature ≤60 K, the rate of reaction is altogether independent of temperature, although even at 30 K these reactions proceed at an appreciable rate.[72,95] The low-temperature kinetic limit indicates a tunnel mechanism (see above). It has been suggested[72,95] that the tunnel effect predominates at temperatures ≤200 K. This is confirmed by the dependence of the intramolecular distribution of tritium in labelled aromatic aminoacids on temperature.[88,95] For tyrosine at 300–400 K and for phenylalanine in the range 77–300 K, a change in the distribution of tritium between the aromatic ring and the side chain is also observed when the duration of exposure is altered,[88,94] which is associated with the losses of tritium from the ring as a result of disproportionation.

The side processes in the interaction of atomic tritium with aminoacids involve the cleavage of the C–C bonds with formation of labelled molecules having a lower molecular weight, the substitution of functional groups by tritium (decarboxylation, deamination, deoxygenation, and desulphurisation), stereoisomerisation, and also the addition of tritium to the aromatic ring and the dissociation of sulphide bridges. The extent of these processes depends both on the reaction conditions and on the structure of the aminoacids.

The cleavage of the carbon skeleton has been observed in many instances. Thus, under the TAM conditions, labelled propane and ethane[86] are formed from alanine, while labelled benzene, toluene, as well as glycine and alanine[94,96] are formed from phenylalanine, the last two acids being obtained also from tyrosine under the same conditions.[94] In many instances the cleavage is apparently caused not by tritium but by the emission from the incandescent tungsten spiral.[94] However, the shortening of the aminoacid chain leading to the formation of lower homologues is a true side reaction and its character is general. Under HFAM conditions, the formation of labelled glycine from L-valine[93] and L-alloisoleucine[92] has been observed; labelled glycine, containing ~20% of the total radioactivity has been obtained from L-isoleucine; it was formed as a result of the cleavage of the excited L-[2-T]isoleucine molecule:[92]

The substitution of functional groups by tritium atoms is also a general process for all aminoacids. As a result of the substitution of the carboxy-groups under TAM conditions, labelled phenylethylamine and tyramine, containing up to 10% of the total radioactivity, are obtained from phenylalanine and tyrosine respectively.[94,96] Deamination under the same conditions leads to the formation of labelled aliphatic acids: propionic acid from alanine,[85] phenylpropionic acid from phenylalanine and tyrosine (in the latter case the phenolic hydroxyl is also replaced by tritium),[94,96,97] and γ-aminobutyric acid from α,γ-diaminobutyric acid,[73] for which deamination is difficult in an acid medium. This agrees with the mechanism[95,97] according to which the tritium atom initially adds to the amino-group and then NH_2T is split off. The

substitution of the hydroxy-group in tryosine by tritium (TAM) leads to the formation of labelled phenylalanine[94] and in the case of cystine (HFAM), the sulphide bridge is readily cleaved with formation of labelled cysteine whose yield and radioactivity (Table 4) exceed the corresponding values for the labelled cystine obtained simultaneously.[81]

The addition of thermal hydrogen atoms to the aromatic rings of L-phenylalanine, L-tyrosine, and DL-tryptophan at 77 K has been detected by EPR.[60] When phenylalanine is tritiated by the Wilzbach method, labelled β-cyclohexylalanine is the main side product,[98] but under TAM conditions the benzene ring of phenylalanine or tyrosine is not saturated.[94]

The question of the racemisation of optically active aminoacids in the course of the introduction of tritium is particularly important, because it determines the suitability of the method for the preparation of tritium-containing proteins with retention of their biological activity. In general, in the reactions of tritium with solid L- or D-aminoacids, the degree of formation of the labelled optical isomer is low. In the Wilzbach method it varies from 1 to ~20%[98,99] and in the HFAM it is even smaller (for example, it amounts to 1.5% for L-valine compared with 4.0% in the Wilzbach method),[93] while the inversion of the configuration at the α-C-atom in L-isoleucine and L-alloisoleucine takes place to the extent of 1.0 and 0.3% respectively.[92] This can be explained by the fact that the α-positions in aminoacid molecules are attacked by tritium atoms only to an insignificant extent—1% for L-alloisoleucine and <8% for L-isoleucine. The predominant attack on the β-position is, however, associated also with the greater degree of epimerisation at the asymmetric β-C-atom. Thus, under HFAM conditions, labelled L- and D-isoleucines and L- and D-alloisoleucines are formed from L-isoleucine in proportions of 72 : 1 : 23 : 4 (in terms of radioactivity), while the same stereoisomers are formed from L-iso-leucine in proportions of 29 : 0.3 : 67 6 : 3.[92]

The racemisation of optically active aminoacids under TAM conditions has been investigated only in relation to L-alanine,[100] which formed a mixture of labelled L- and D-alanines (~70 : 30) at a target temperature of 77 K, while after the introduction of the label by the HFAM (under the conditions of charge transfer involving atomic ions accelerated to an energy of 0.6 keV) the aminoacid did not racemise although it contained ~25% of the added tritium in the α-position. From this, the authors[100] assume that tritium atoms with an energy >1.5 eV interact with aminoacids as a result of direct synchronous substitution of H by T and not via a radical mechanism.

It is noteworthy that the products of the side reactions are dominant overall. For example, the yield (as a percentage of the total radioactivity) of labelled phenylalanine (labelled by the TAM) is ~25% for short exposures (10–30 s), while the main side reactions involve cleavage to glycine (yield 8%) and alanine (yield 10–15%), decarboxylation to phenylethylamine (yield 10–20%), and deamination to phenylpropionic acid (yield 10–20%). For longer exposures (1–20 min), the yields of phenylalanine and tyrosine decreased to ~15 and ~25% respectively.[94]

Since the single free carboxyl and the single free amino-group (which determine the occurrence of both side reactions and the amount of labile tritium) in peptides correspond to not one but several or even several tens of aminoacids residues, one can assume that peptides are more favourable (compared with aminoacids) objects for reaction with atomic tritium. Indeed, the peptide linkage in alanylalanine is not ruptured under TAM conditions,[101] while the fraction of labile tritium in labelled peptides is smaller by a factor of 3–5 than in the labelled aminoacids obtained under identical conditions[9] and the molar radioactivity of peptides is 100–1000 times greater than that of aminoacids.[92] Thus, under identical HFAM conditions, the labelled valine and the peptides containing it, namely Ile–Ile–Val and Phe–Ala–Ala–Val, have been obtained with radioactivities of 1.1, 0.2, and 2 c $mmol^{-1}$ respectively. The data for labelled peptides obtained by treatment with atomic tritium are compiled in Table 6.

Table 6.

Peptide	N	Method	a, Ci $mmol^{-1}$	φ, %	η, %	Refs.
Leu-Tyr-Leu	3	A	0.1	—	—	[10]
Ile-Ile-T-Val	3	A	0.2	—	—	[10]
Val-Ala-Ala-Phe	4	A	2.0	—	—	[10]
T-4 for a mixture obtained on hydrolysis of tobacco mosaic virus	7	B	0.2	—	—	[101]
Asp^1-Val^4-Angiotensin-II	8	C	0.3	40	—	[102]
Bradykinin	9	D	0.1	—	10	[9]
Angiotensin-I	10	E	0.4	32	2	[49, 66]
Gonadotropin releasing factor	10	F	2–3	—	—	[87]
Leuteinizing hormone-releasing factor (luliberin)	10	A	10.6	40	—	[103]
α-Amanitin		A	0.02	—	—	[76]
Somatostatin	14	A	0.75	—	—	[76]
T-8 from the products of hydrolysis of tobacco mosaic virus	20	B	2.8	—	—	[101]
Adrenocorticotropic hormone (ACTH)	39	A	10*	—	—	[76]
Antibiotic A-128	10	B	1–10*	—	—	[18]

Remarks. Method: A—HFAM (20 W, 2450 MHz, T_2 equivalent to ~1 Ci under circulation conditions, pressure 4 mmHg, 5 min), sample ≤10 mg; B—TAM (pressure ~0.01 mmHg, temperature of tungsten filament 2000 K, 2–5 min). The substance was deposited on the walls of a glass vessel cooled with liquid nitrogen; C—electric arc discharge, T_2 equivalent to ~6 Ci, pressure 10 mmHg, 30 min, sample 15 mg; D—HFAM (80 W, 40 MHz), 99 : 1 He–T_2 mixture, pressure 0.01 mmHg, sample 15 mg, E—TAM (T_2 equivalent to 0.03 Ci, pressure 0.01 mmHg, temperature of tungsten filament 2000 K, 0.5 min). The test substance was deposited on paper; F—HFAM (30 W, 2450 MHz, T_2 equivalent to 2 Ci under circulation conditions, pressure 4 mmHg, 15 min). The test substance (0.1–0.5 mg) was deposited on filter paper.

Notation: N is the number of aminoacid residues and φ and η are respectively the chemical and radiochemical yields.

*The biological activity was fully retained.

The aminoacid residues in peptides are labelled to different extents, which should be determined to a first approximation by the chemical structure of these residues. According to the results of model experiments with mixtures of 17 aminoacids, the probability of the introduction of tritium into non-labile positions in different aminoacids under TAM conditions (see Table 7)[20] decreases in the sequence aspartic acid ≥ serine > phenylalanine > tyrosine > cysteine > alanine, which is in general consistent with data for the reactions of atomic hydrogen with aminoacids in solution.[91] However, according to other data,[63,73] the sequence based on the decreasing reactivity of aminoacids under TAM conditions is different: alanine > cysteine > serine > aspartic acid. All these data apparently require revision.

The non-uniform incorporation of tritium into the aminoacid residues of peptides cannot apparently be explained solely with the aid of coefficients similar to those presented in Table 7. There is no doubt that the attack on the aminoacid

residue in the peptide is influenced both by the chemical nature of the neighbouring residues and by the steric structure of the peptide, which is indicated, in particular, by the different tritium contents in the like aminoacid residues in the T-4 and T-8 peptides from the hydrolytic reaction mixture obtained from the tobacco mosaic virus[20,101,104] (Table 6), while in the 20-membered T-8 peptide the deviation from the equi-probable distribution of tritium is significantly greater than in the shorter seven-membered T-4 peptide. Furthermore, the use of a mixture of aminoacids as a model is illegitimate, because the roles of the free amino- and carboxy-groups in the reactions of atomic tritium with both aminoacids and peptides are not comparable.

Table 7. The probability of the introduction of the label into various aminoacids (TAM conditions) per molecule (K) and per C–H bond (K') relative to alanine.

Aminoacid	K	K'	Amonoacid	K	K'
Alanine	1.00	0.33	Lysine	1.60	0.80
Arginine	1.19	0.60	Methionine	1.35	0.67
Aspartic acid	2.75	1.37	Isoleucine	1.48	1.48
Valine	1.72	1.72	Leucine	1.20	0.60
Histidine	1.76	0.88	Proline	1.39	0.70
Glycine	1.81	—	Serine	1.78	0.90
Gutamic acid	1.83	0.91	Tyrosine	1.08	0.54
Cysteine	1.04	0.52	Threonine	2.51	1.51
			Phenylalanine	1.20	0.60

Naturally in proteins the influence of steric factors should be manifested to an even greater extent and it has been suggested[72,105,106] that the very non-uniformity of the intermolecular distribution of tritium in the labelled proteins obtained on treatment with atomic tritium be used for the determination of the tertiary structure. In the case of the labelled sperm whale myoglobin, for example, the radioactivities of the valine-1 and valine-10 residues differed by a factor of 20,[101] and the residues with polar groups together with the N-terminal aminoacid proved most susceptible to attack by tritium atoms; on the other hand, the hydrophobic residues were labelled to a significantly smaller extent.[106] This is consistent with the generally accepted ideas concerning the preferential localisation of the polar aminoacid residues in the surface layer of the protein globule. The suitability, in principle, of the proposed method has been confirmed by X-ray diffraction data for different aminoacid residues in myoglobin although significant deviations have been observed for several residues.

Another application of labelled proteins obtained by treatment with atomic tritium is the determination of their primary structure.[76,101,105] Contrary to the previous case, here it is necessary that all the aminoacid residues should be labelled, i.e. that the label should be "total". It has therefore been suggested[101] that the proteins be denatured, before introducing tritium, by disrupting the order in their structure. Subsequent stepwise Edman degradation of the labelled protein leads to labelled aminoacid derivatives which can be determined in amounts of 0.1–10 nanomoles (depending on the value of a for the initial labelled protein).

Despite the interesting prospects for the investigation of the structure and functions of proteins with the aid of "totally" labelled compounds, hitherto the label has been introduced by treatment with atomic tritium into less than 20 proteins (Table 8); in a number of instances fairly high values of a have been achieved. For comparison, we may point out that labelled proteins with an almost total retention of their enzymic activity but with a only 0.001–0.015 Ci mmol^{-1} can be obtained by a modification of the Wilzbach method proposed recently (pressure ~0.1–35 mmHg, duration of exposure 1–60 h).[113]

Table 8. Labelled proteins.

Protein	Method	a, mCi mg^{-1}	a, m mmol^{-1}	Refs.
Bovine serum albumin	A	0.24	—	[72, 73, 107]
Ditto	B	0.005	—	[8]

α-Chymotrypsin	A	—	24 300	[72, 73]
Cyclo-AMP-dependent histone kinase	A	—	5 000	[112]

Remarks. Method: A—TAM (temperature of tungsten filament 2000 K, pressure 0.01 mmHg, 10–90 s), sample 2–5 mg; B—HFAM (T_2 equivalent to 0.05 Ci, 110 W, 90 s), sample ~20 mg; C—electric discharge (pressure 0.03–0.06 mmHg, 100 μA, 500 W, sample 0.5 g); D—HFAM (T_2 equivalent to 0.5–2 Ci, pressure 2–6 mmHg, 2450 MHz, 78 K, 5–20 min), sample 3–20 mg; E—HFAM (99:1 He–T_2 mixture, 40 MHz, 80 W, pressure 0.001 mmHg), sample ~5 mg; F—HFAM (T_2 equivalent to 10 Ci, pressure ~10 mmHg, 100 μA, 60 kW, 5 min (sample 50 mg).

Apparently further development of research involving labelled proteins, obtained by treatment with atomic tritium, is held back primarily by fears concerning side reactions which might take place during the introduction of the label and damage the structure and functions of the protein molecules. Such side reactions were already considered above for aminoacids and peptides; they are naturally possible also in the interaction of tritium atoms with proteins. Thus, when powdered aromatic aminoacid polymers as well as insulin, carboxypeptidase A, or papain were treated with hydrogen atoms generated under HFAM conditions, the radicals formed as a result of the addition of hydrogen atoms to the aromatic rings,[60,114] which can lead to the saturation of the latter, were identified (from the EPR spectra). The possible rupture of the sulphide bridges is a much greater risk for proteins than for peptides. The cleavage of proteins on application of the TAM has been observed in relation to bovine serum albumin.[107] However, in a number of other cases,[20,101,105,106] the bridges in polypeptides are not ruptured under TAM conditions.

The extent of all the side reactions indicated cannot be predicted *a priori* and can vary greatly for different proteins. On the other hand, the influence of the conditions used in the introduction of tritium on the retention of the native structure of the protein molecules has so far been investigated quite inadequately. All this shows how important it is to separate carefully the labelled native proteins from the products of side reactions. A general consideration of methods for the purification of proteins is outside the scope of the present review but affinity chromatography and, in particular, its variety, namely immunosorption, which has been used successfully in the purification of labelled ribonuclease[110] and serum albumin,[107] appear to be the most promising. The main advantage of these methods is their high specificity; furthermore, they make it possible to determine immediately the degree of retention of biological activity. We may note that, when the labelled protein does not lose its enzyme activity, the modification of some of the aminoacid residues in the course of the introduction of tritium does not prevent its employment in biological experiments, but such preparations are unsuitable for the study of the primary structure.

The difficulty of eliminating the products of side reactions makes another possibility of introducing the tritium label into proteins, namely with the aid of labelled modifying agents, extremely attractive. Many of these agents can be undoubtedly obtained successfully by treatment with atomic tritium. A good example is the labelled triethyloxonium tetrafluoroborate, mentioned above, whose radioactivity, when it is prepared with the aid of the TAM, can reach 5–6 Ci $mmol^{-1}$.[52,66] The use of this preparation for the esterification of terminal carboxyls makes it possible to obtain labelled modified proteins with a high radioactivity.

---o0o---

Thus one may conclude that the thermal activation method is at present the most promising for the preparation of tritium-labelled compounds. Its universality, simplicity of application, low-consumption of tritium, and also the high levels of specific activities make it the most convenient for use in scientific organisations where radioisotope labels are employed in research. It is important to note in this connection that, using a simple apparatus, the investigator can himself introduce the label into the required preparation, including preparations of very complex structure, and obtain as a result a labelled product which is commercially unavailable. The method can be evidently easily converted into one of industrial importance and it may then find extensive applications in the isotope industry manufacturing tritium-labelled organic compounds.

From our point of view it is important to note yet another feature of the thermal activation method whereby it can be converted into a direct instrument for the study of the structures of micro-objects and macro-objects. Here we are dealing with the preferential localisation of the label in thin (3 – 10 Å) surface layers of the target due to the short free path of the reactive atoms. As a consequence, in analysing the distribution of tritium between the molecules constituting the given object or its intramolecular distribution, one can obtain a fairly clear and exact picture of the relative spatial dispostion of the fragments of the object. When applied to biological objects, this implies the possibility of investigating the topography of proteins in membranes and involved complexes (for example, nucleosomes), the steric organisation of biological macromolecules, etc. This application of the thermal activation method has already been shown to be promising and will undoubtedly develop.

The Reactions of Carbene Complexes of Transition Metals with Unsaturated Hydrocarbons

A.I.Syatkovskii and B.D.Babitskii

The influence of the structure of individual carbene complexes of transition metals on the rates and stereoselectivities of their reactions with unsaturated hydrocarbons are examined.
The bibliography includes 114 references.

I. INTRODUCTION

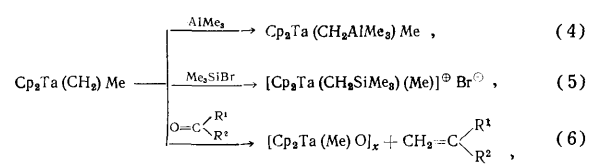
The carbene complexes of transition metals play a decisive role in complex catalytic processes involving the transformation of unsaturated hydrocarbons, such as the metathesis of cyclic and acyclic olefins,[1-6] the cometathesis of olefins with cyclopropanes,[7,8] and the polymerisation of alkynes,[9-11] and also in the formation of cyclopropanes from olefins on decomposition of aliphatic diazo-compound by transition metal salts.[12-15] The catalysts of these processes are as a rule multicomponent systems in which it is extremely difficult to determine the specific parameters of the active centres formed (the degree of oxidation of the metal, its ligand environment, the characteristics of the carbene ligand, etc.). The lack of such information significantly hinders the study of the reaction mechanism and hence prevents a purposeful search for more effective and stereoselective catalytic systems. On the other hand, the considerable progress achieved in the synthesis of a whole series of individual carbene complexes of transition metals, capable of reacting with unsaturated hydrocarbons or cyclopropanes, makes it possible to regard them as adequate models of the active centres in the catalytic processes enumerated above.

Depending on the nucleophilicity or the electrophilicity of the carbene ligand, the reactions of the carbene complexes with olefins can proceed via the following pathways; the conversion of the olefin into a cyclopropane derivative (1), the exchange of alkylidene fragments between the olefin molecule and the carbene complexes (2), and the addition of the carbene ligand to the olefin with formation of a set of new olefins (3):

Scheme 1

The aim of the present review is to discuss the influence of the structures of different carbene complexes on the rates and stereoselectivities of their reactions with olefins. We believe that it is useful to carry out such a survey because the existing reviews on the chemistry of carbene complexes of transition metals are devoted either to electrophilic[16-22] or nucleophilic[23] complexes which naturally precludes the analysis of reactions (1)-(3) from a single standpoint. Furthermore, in the communications enumerated above attention was concentrated on relatively stable carbene complexes for which reactions with unsaturated hydrocarbons are in general uncharacteristic.

This review deals with the reactions of only individual carbene complexes of transition metals and is not concerned with the problems associated with the possible mechanisms of the generation and role of such complexes in catalytic processes.



II. THE METAL–CARBON BOND IN ELECTROPHILIC AND NUCLEOPHILIC CARBENE COMPLEXES OF TRANSITION METALS

X-Ray diffraction and spectroscopic data have shown that in mononuclear complexes of the type $L_nM{=}C(X)Y$ (I) the carbene carbon is sp^2-hybridised, while the M, C, X, and Y atoms are usually located in a single plane.[16-23] The conventional subdivision of carbene complexes in terms of their chemical reactions into electrophilic and nucleophilic involves the consideration of a specific molecule in terms of the predominant contribution of the three possible resonance structures (II)-(IV):

(II) (III) (IV)

For example, the carbene ligand in the tantalum and niobium complexes enters into typical nucleophilic reactions and such complexes have come to be described in terms of the resonance structures (III) and (IV):[23-26]

Here

In the chemical reactions represented by Eqns.(4)–(6) the nucleophilic carbene complexes behave as analogues of ylides, such as, for example, the phosphonium ylides $R_3\overset{+}{P}-\overset{-}{C}H_2$ (where R = alkyl or aryl). Indeed reactions (4) to (6) can be compared with the analogous reactions of phosphonium ylides (the formation of adducts with electron-deficient boron and aluminium compounds, alkylation of ylides with formation of phosphonium salts, and the Wittig reaction respectively).[27]

In contrast to the tantalum complexes examined above, the pentacarbonylcarbene complexes of chromium, molybdenum, tungsten and also certain complexes of iron and rhenium react in conformity with the resonance structures (II) and (III).[28–31]

In electrophilic carbene complexes the attack by nucleophiles is on the carbene carbon atom and reactions (8)–(11) are to some extent similar to the reactions known for individual singlet carbenes†: the formation of ylides in the reactions with phosphines and amines, insertion in the metal–carbon bond, and the carbene–olefin isomerisation:[12,32,33]

$$(CO)_5W[C(OMe)Ph] \xrightarrow{LiPh} Li^{\oplus}\{(CO)_5W^{\ominus}-[C(Ph)_2OMe]\}, \quad (8)$$

$$(CO)_5W(CHPh) \xrightarrow{PPh_3} (CO)_5W[C(H)(Ph)(\overset{\oplus}{P}Ph_3)], \quad (9)$$

$$[Cp(PPh_3)(NO)Re(CH_3)]^{\oplus} \xrightarrow{C_5H_5N} [Cp(PPh_3)(NO)Re(CH_2\cdot C_5H_5N)]^{\oplus}, \quad (10)$$

$$(CO)_5W[C(Me)Ph] \xrightarrow{\Delta} (CO)_5W[CH_2{=}CHPh]. \quad (11)$$

The phenomenological approach to the reactions of carbene complexes examined above is in many instances inapplicable despite its attractive simplicity. For example, it is obscure within the framework of this approach why the carbene ligand linked to an 18-electron centre in the complexes $(CO)_5W(CHPh)$, $(CO)_5Cr[C(OMe)Me]$, or $[Cp(CO)_2Fe(CH_2)]^+$ undergoes electrophilic reactions, while in the electron-deficient complexes of tantalum $Cl_2CpTa(CHCMe_3)$ and $Cp(PMe_3)_2(C_2H_4)Ta.(CHCMe_3)$ containing 14 and 16 electrons respectively in the valence shell of the transition metal the carbene species enters into nucleophilic reactions.[34] The treatment of nucleophilic carbene complexes as analogues of phosphonium ylides is particularly unsatisfactory, because these compounds react similarly only with fairly polar reagents (see Section IV). Furthermore, the representation of the carbene complexes by formulae (II)–(IV) makes it impossible to infer the strength with which the carbene is bound to the transition metal, which is one of the most important factors in the determination of the reaction pathway. For a correct interpretation of the reactivity of carbene complexes, it is necessary to analyse the nature of the bond between the transition metal and the carbene species.

The results of quantum-chemical calculations on carbene complexes by non-empirical[35,36] and semi-empirical[34,37,38] methods have shown that the carbene ligand is bound in the complex mainly as a result of the transfer of electrons from the σ orbital of the carbene carbon to the metal (σ-binding) and the reverse transfer of electron density from the highest occupied molecular orbital (HOMO) of the metal with the corresponding symmetry to the unoccupied $2p_z$ orbital of the carbene (π-binding).

In conformity with the perturbation theory, one can predict that the efficiency of the π-binding is determined by two factors. It is directly proportional to the square of the overlap integral between the HOMO of the metal and $2p_z$ orbital of the carbene and is inversely proportional to the difference between the energies of these orbitals.[34] Calculations for model methylene complexes of chromium, iron, and tantalum have shown that both factors promote the most effective π-binding in the case of tantalum, for which the highest population of the $2p_z$ orbital of the carbene ligand has been obtained.[34]

On the other hand, a semiempirical calculation for the $(CO)_5Cr[C(Me)OMe]$ molecule[37] and the experimental study of the EPR spectra of the radical-anions obtained on chemical reduction of this and similar complexes[39] show that in these compounds the lowest unoccupied molecular orbital (LUMO) of the complexes is almost entirely the $2p_z$ orbital of the carbene fragment, i.e. the π-binding in these complexes is minimal.

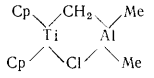
Thus the increase of the effectiveness of the π-binding increases the population of the $2p_z$ orbital of the carbene ligand and hence increases its nucleophilicity. Furthermore, an increase of the effectiveness of the π-binding is equivalent to an increase of the amount of double bond character of the linkage between the metal and the carbene carbon and should therefore be reflected in parameters such as the metal–carbon bond strength and the energy barrier to the rotation of the carbene around this bond in the complex. Experimental data permitting a comparison of the strengths of the metal–carbon bonds in electrophilic and nucleophilic carbene complexes are unfortunately lacking but nevertheless attention should be drawn to the fact that nucleophilic methylene, benzylidene, and neopentylidene complexes of tantalum are more stable in reactions involving the transfer of the carbene ligand than the corresponding electrophilic complexes of tungsten or iron. The possibility of the rotation of the carbene species around the metal–carbon bond in the complex has been studied experimentally[40–46] and with the aid of quantum-chemical calculations.[36,38,47,48] Apparently an increase of the nucleophilicity of the carbene ligand does indeed lead to an increase of the activation energy for rotation although even a semiquantitative estimate of the relative contributions of the electronic and steric interactions to the rotation barrier involves enormous difficulties.

The electron distribution in the carbene ligand and hence its reactivity depend also on the substituents attached to the carbene carbon. For electrophilic complexes, the influence of the nature of α-substituents at the carbene carbon atom on its reactivity can be illustrated by comparing different pentacarbonyl carbene Fischer complexes:

$$(CO)_5M{=}C\begin{matrix}ZR\\ \diagdown\\ R'\end{matrix} \quad (V)$$

where Z = O, N, or S, M = Cr, Mo, or W, and R, R' = alkyl or aryl.

In complexes (V) the presence of substituents capable of behaving as π-donors in the α-position relative to the carbene carbon leads to the transfer of electron density from the ZR group to the $2p_z$ orbital of the carbene, which is responsible for the appearance of partial double bond character in the linkage between the C_{carb} and Z atoms.[16–22] {An analogous effect has been observed also for the compound $[Cp(CO)_2Fe(CHPh)]^+$ and the existence of conjugation between the benzene ring and the carbene carbon in this complex has been demonstrated.[49]} The carbene ligand in the Fischer complexes remains an electrophilic centre, although the capacity of such complexes for reactions with nucleophiles is lower than that of the complexes $(CO)_5W(CHPh)$ and $(CO)_5W(CPh_2)$ which have a similar structure.[19,21,30,50,51]



†The term singlet carbene is used to designate carbene species with zero spin regardless of whether in terms of free energy this is the ground state (CF_2; CCl_2) or the first excited state (CH_2; CHCOOMe).

The transfer of electron density to the carbene carbon in the complex $\{Cp(CO)(PPh_3)Fe[C(Me)OEt]\}^+$ is so great that the complex can react with nucleophiles as a carboxonium salt:[52]

$$\left[Cp(CO)(PPh_3)Fe{-}C(Me)(\overset{\oplus}{O}Et)\right] + I^{\ominus} \rightarrow EtI + Cp(CO)(PPh_3)Fe{-}C(Me)(O) \quad .$$

There are very few data concerning the influence of the substituents at the carbene carbon atom on the reactions of nucleophilic carbene complexes. It has been established[53,54] that, for a fixed ligand environment, the methylene, neopentylidene, and benzylidene complexes of tantalum and niobium differ only in the rate of addition of the carbene ligand to olefins, while the replacement of the ligands in the coordination sphere of the metal is reflected both in the rate of the reaction and in its regioselectivity (Section IV).

In discussing the influence of the substituents at the carbene carbon atom on the reactivity of the carbene complexes, it is necessary to note the existence of a group of nucleophilic complexes in which a kind of stabilisation of the carbene ligand is achieved as a result of the formation of adducts with organoaluminium compounds.[55-58] Among compounds of this kind, the methylene complex of titanium having the structure

(VI)

was studied in greatest detail.[55-57] The carbene ligand in these dinuclear complexes is of the bridge type and manifests nucleophilic properties in its reactions.[55,56] Complexes of type (VI) will be considered in Section IV.

The data described indicate that the nature of the transition metal and its ligand environment determine mainly the nucleophilic or electrophilic character of the chemical reactions of the carbene ligand in the complex, while the substituents in the α-position relative to the carbon atom influence only the relative reactivity without altering as a rule the overall reaction pathway.

In conclusion of this Section we shall return to the question of the legitimacy of representing the carbene complexes of transition metals by the resonance formulae (II)–(IV). The low barrier to rotation about the metal–carbon bond and the considerable polarisation of the latter as a result of the effective transfer of electron density to the metal atom (σ-binding) make it possible to describe fairly correctly the electrophilic carbene complexes by the resonance structure (II). In the nucleophilic carbene complexes the metal–carbon bond is formed as a result of two processes: the transfer of electron density to the metal (σ-binding) and the reverse transfer of electron density to the $2p_z$ orbital of the carbene ligand (π-binding). One can therefore assume that the distribution of electron density in the carbene ligand resembles that in a triplet carbene with a partly filled $2p_z$ orbital rather than distribution in a carbanion (as in phosphonium ylides[59,60]). Such biphilicity is manifested, in particular, in the ability of the carbene ligand in nucleophilic carbene complexes to interact effectively with the π-electron system in olefins (Section IV). Thus the description of nucleophilic complexes by formula (IV) is not entirely correct.

III. THE REACTIONS OF ELECTROPHILIC CARBENE COMPLEXES

Conversion into cyclopropane derivatives is the most typical reaction of the electrophilic carbene complexes with olefins. Like the reactions of free singlet carbenes with olefins, the process proceeds *cis*-stereospecifically.[18-21,29,61,62] Scheme 2 presents the products of the reactions of the benzylidene complexes of iron[62] and tungsten[29,61] with *cis*- and *trans*-but-2-enes and α-olefins;

Scheme 2

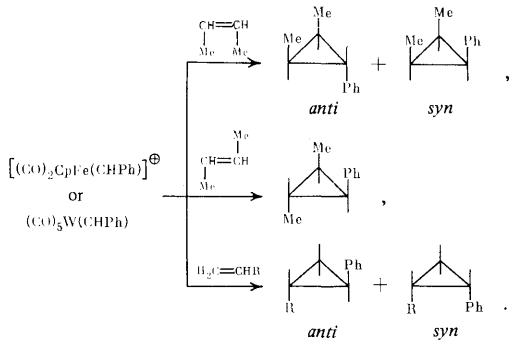


Table 1. The ratio of the *syn*- and *anti*-isomers of cyclopropanes produced in the reactions of $(CO)_5W(CHPh)$ [61] and $[Cp(CO)_2Fe(CHPh)]^+$ [62] with various olefins.

Olefins	$(CO)_5W(CHPh)$	$[Cp(CO)_2Fe(CHPh)]^{\oplus}$
Propene	1.8	7.8
But-1-ene	0.9	6.5
3-Methylbut-1-ene	0.36	4.6
Styrene	9.7	⩾100
cis-But-2-ene	41	>100
Cyclopentene	2.6	⩾200
2-Methylbut-2-ene	94	>50

During the process, there is no preliminary "ejection" of the carbene from the complex and, at least in the stage determining the stereoselectivity of the addition, the carbene remains bound to the transition metal.[18,21,63] The reactivity of the complexes, determined by the electrophilicity of the carbene ligand, varies within wide limits for different compounds. The most reactive complexes are those in which the carbene ligand contains no heteroatoms in the α-position relative to the carbene carbon: $(CO)_5W(CHPh)$, $[Cp(CO)(PPh_3)Fe(CHMe)]^+$, $[Cp(CO)_2Fe(CHPh)]^+$, $[Cp(CO)_2Fe(CH_2)]^+$, etc. Even at −70 °C these complexes enable the corresponding cyclopropanes to be obtained from olefins in high yields.

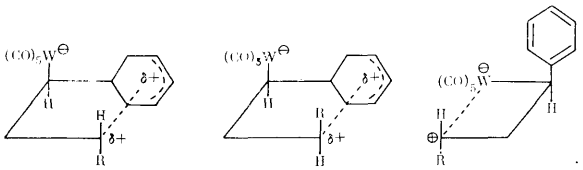
The study of the reactions of the complex $[Cp(CO)_2Fe(CH_2)]^+$ with olefins showed that olefins containing an electron-rich double bond of the type of that in ethyl vinyl ether are more reactive than but-1-ene or cyclohexene.[41] The relative reactivity series for olefins in the reaction with the complex $(CO)_5W(CHPh)$ has been obtained[61] and a satisfactory correlation has been observed with the analogous series for the reaction involving the formation of cyclopropane by free carbenes in the singlet state:[64,65]

$$\underset{\sim 0}{CH_2{=}CH_2} \ll \underset{1.0}{CH_2{=}CHCMe_3} < \underset{10.9}{CH_2{=}CHMe} \sim \underset{7.6}{MeCH{=}CHMe} \ll \underset{850}{MeCH{=}CMe_2} \ll \underset{3500}{CH_2{=}CMe_2} \quad . \qquad (12)$$

The observed reactivity series for olefins shows that the rate of addition of the carbene ligand is determined in the first place by the charge on the most substituted carbon atom

in the olefin. This suggests that, in the transition state arising during the conversion of olefins into cyclopropanes by complexes of the type $(CO)_5W(CHPh)$, charge separation should take place, the excess positive charge being stabilised by the alkyl substituents at the most substituted carbon atom.[61] All these results not only emphasise the electrophilic character of the carbene ligand in the cyclopropane formation reaction but also reveal the similarity of the mechanisms of the reactions of electrophilic carbene complexes and free singlet carbenes with olefins.

When there are no coordination vacancies in the electrophilic complex at the metal atom, the LUMO of the complex is localised at the carbene ligand. The interaction of this complex with an olefin apparently proceeds analogously to the interaction of singlet carbenes with olefins—as electrophilic attack by the unoccupied $2p_z$ orbital of the carbene on the π-electron system of the olefin with formation of cyclopropanes.[66,67]

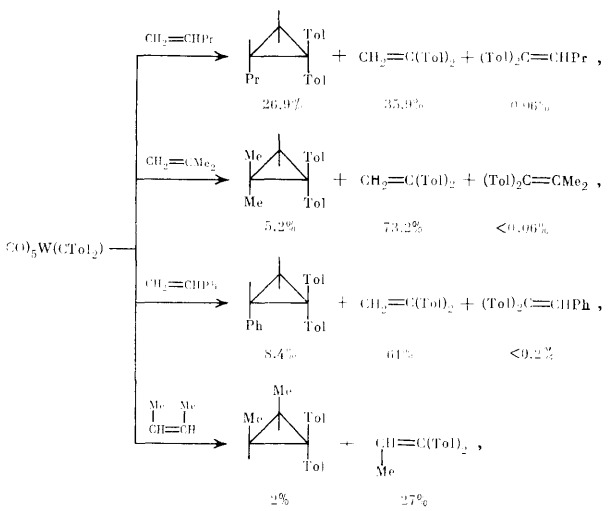


More detailed information about the mechanism of the interaction of the electrophilic complexes with olefins is provided by the study of the influence of the nature of the reactants on the ratio of the *syn*- and *anti*-isomers in cyclopropanes—the reaction products (Scheme 2). Certain results have been taken from the literature[61,62] and are presented in Table 1, which shows that the iron complex gives rise in all cases to higher ratios of the *syn*- and *anti*-isomers of cyclopropanes, but the character of the variation of the stereoselectivity as a function of the structure of the olefin is identical for the two complexes studied. Furthermore, it is possible to identify the following features:

(a) among the products of the interaction of olefins with the above complexes the thermodynamically unfavourable *syn*-isomer is formed predominantly in most cases;

(b) an increase of the steric volume of the alkyl substituents at the double bond in α-olefins decreases the fraction of the *syn*-isomer.

In order to explain the results, a mechanism has been proposed[61] involving the possibility of the stabilisation of the positive charge in the intermediates (VII) and (VIII) by the π-electron system of the benzene ring; the intermediate (VII), leading to the formation of the *syn*-isomer, is energetically more favourable than the intermediate (VIII), since there is no steric repulsion between the R and $W(CO)_5$ groups in it.

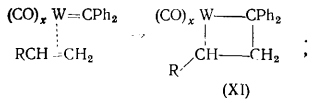


An increase of the steric volume of the substituent R in the olefin decreases the role of the stabilisation by the π-electrons of the benzene ring and the process can proceed via intermediates of type (IX) whose formation is controlled by the difference between the free energies of the reaction products.

(VII) (VIII) (IX)

Experimental confirmation of this hypothesis has been obtained.[62] It has been shown that, on passing from $[Cp(CO)_2Fe(CHPh)]^+$ to the complex $\{Cp(CO)_2Fe[C(H).(p\text{-}CH_3C_6H_4)]\}^+$, which has an electron-donating substituent in the ring, the ratio of the *syn*- and *anti*-isomers in the products of addition to propene increases from 7.8 to 10.0. It is noteworthy that the concept of the stabilisation of the positive charge in the transition state in the cyclopropane formation reaction by the benzene ring had been put forward earlier by Closs and Moss to account for the tendency towards the preferential formation of the *syn*-isomers in the reactions of phenylcarbenes, generated in different ways, with but-1-ene, *cis*-but-2-ene, and 2-methylbut-2-ene.[68-70] Other factors promoting the formation of the *syn*-isomer can probably also exist. It has been established that the reactions of $[Cp(CO)_2Fe(CHMe)]^+$ with styrenes and cyclo-octene result in the formation of cyclopropanes in which the ratios of the *syn*- and *anti*-isomers are 4.7 and >4.5 respectively.[46] On the basis of the analogy with the reactions of free singlet carbenes, one can assume, for example, that the *syn*-disposition of the substituents in the transition state (or the intermediates) favours a more effective charge transfer from the HOMO of the olefin to the LUMO of the carbene.[66,71,72]

If the electrophilicity of the carbene ligand in the complex is reduced as a result of the substituents in the α-position relative to the carbene carbon [this is characteristic, for example, of the Fischer complexes (V)], then its reactivity in relation to olefins diminishes. The dissociation of the metal–carbon bond in such complexes and the transfer of the carbene ligand to the olefin take place at temperatures above 50 °C.[18-21,30,51] However, at the temperatures indicated it is necessary to reckon with the dissociation of the initial compound to form CO and a coordination-unsaturated carbene complex,[19,21,61,73] which leads to a new pathway in the reactions with olefins. Thus ditolylcarbenepentacarbonyltungsten (X) reacts with olefins at ~70 °C to form cyclopropanes and the products of the exchange of the alkylidene fragments.[51,74]

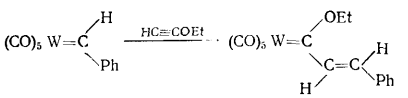


where Tol = *p*-Me–C_6H_4.

The following series of relative reactivities of olefins in relation to complex (X) has been established:[74]

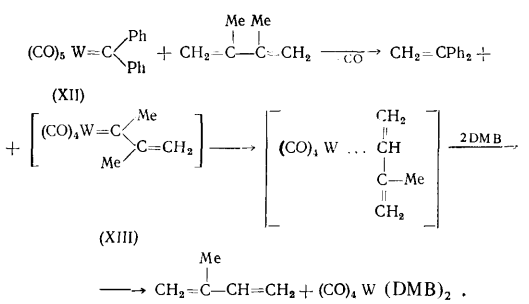
$$\underset{49.5}{CH_2{=}CHPr} > \underset{10.4}{CH_2{=}CMe_2} > \underset{1.0}{MeCH{=}CHMe} > \underset{\sim 0}{MeCH{=}CMe_2}\ .$$

To a first approximation, this series agrees with the relative thermodynamic stabilities of transition metal complexes of olefins[75] but is the reverse of series (12) of the relative reactivities of olefins in the reactions with $(CO)_5W(CHPh)$.



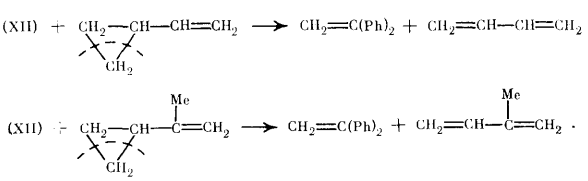
The experimental data obtained agree best with the following scheme: owing to the dissociation of the initial complex during the reaction, a coordination vacancy appears at the metal atom and the reaction with olefins can proceed via a metallacyclobutane intermediate of type (XI):

(XI)



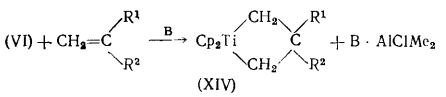
its decomposition in fact leads to the formation of the products of the exchange of alkylidene fragments. Later studies showed that the ratio of the products of the transalkylidenation reaction and the cyclopropanes in the reactions of compound (X) with olefins is independent of the carbon monoxide pressure in the system[73] and cyclopropanes are apparently formed in this instance also via the intermediate (XI). The possibility of the preliminary abstraction of one of the CO groups in the carbene complex apparently arises also in the reactions of the Fischer complexes (V) with olefins containing electron-accepting groups.[21]

Electrophilic carbene complexes can react with acetylenes,[61] dienes,[76,77] and cyclopropanes[78] and the above compounds behave similarly to olefins. For example, the complex $(CO)_5W(CHPh)$ enters into the transalkylidenation reaction with ethoxyacetylene, which behaves as a cyclo-olefin with a ring of "zero" size:[61]



The complexes $(CO)_5W(CPh_2)$ and $(CO)_5W[C(Me)Ph]$ react analogously with ethoxyacetylene.

Diphenylcarbenepentacarbonyltungsten (XII) reacts with 2,3-dimethylbuta-1,3-diene (DMB) in accordance with the following scheme:[76,77]



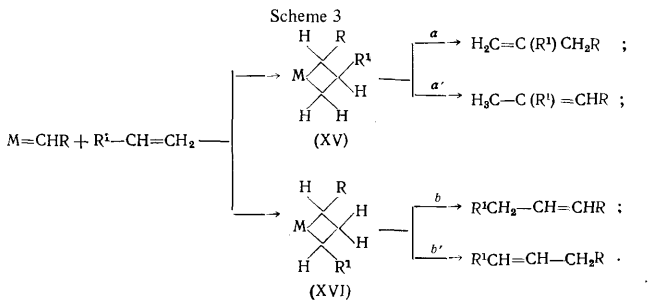
(XIII)

In the first stage the alkylidene fragments are exchanged between complex (XII) and DMB, which results in the formation of 1,1-diphenylethylene and the carbene complex (XIII). The second stage of the reaction consists of the carbene–olefin isomerisation in the intermediate carbene complex (XIII) with formation of an isoprene molecule [cf. Eqn.(11)]. At ~90 °C the same complex (XII) is capable of demethylenating three-membered carbon rings,[78] which can be regarded as a kind of metathesis reaction of cyclopropanes:[7,8,79]

IV. THE REACTIONS OF NUCLEOPHILIC CARBENE COMPLEXES

The difference in the nature of the carbene species in nucleophilic complexes with transition metals and in complexes with phosphines is manifested most clearly in the reactions with olefins having a non-polarised or a weakly polarised double bond. Phosphonium ylides do not react with such olefins, whereas two reaction pathways have been observed for nucleophilic carbene complexes: the exchange of the alkylidene fragments (2) and the addition of the carbene ligand to the olefin with formation of new olefins (3). It has been suggested that both these reactions proceed via a four-centre transition state with formation of intermediates of the metallacyclobutane type. Sometimes it is possible to isolate and characterise such a metallacyclobutane (XIV):[80,81]

(13)

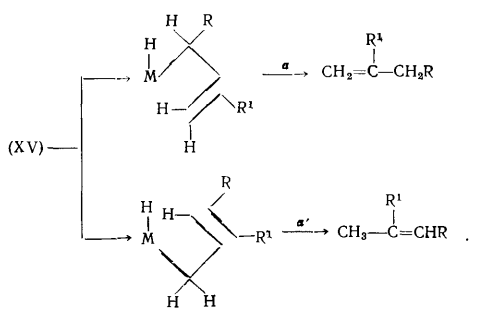


(XIV)

R^1 = t-Bu, R^2 = H; R^1 = iso-Pr, R^2 = H; R^1 = Ph, R^2 = H; $R^1 = R^2$ = H; $R^1 = R^2$ = Me; B = Lewis base.

As a rule, the metallacyclobutane formed decomposes rapidly and its structure can be inferred only on the basis of the reaction products.

Electron-deficient nucleophilic complexes of tantalum and niobium react with α-olefins to form a set of new olefins.[23,53,54,82–84] A reaction of this type has been studied in greatest detail for the tetrahedral complex $CpCl_2Ta(CHCMe_3)$ [83,84] and also for several octahedral complexes of tantalum and niobium having the general formulae $L_2Cl_3M(CHCMe_3)$ and $L_2Cl_3M(CHPh)$, where M = Ta or Nb and L = PPh_3, PPh_2Me, or $PPhMe_2$.[53,54] Four different olefins can be formed in the general case as a result of the reaction:



Scheme 3

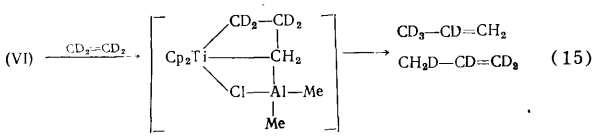
(XV) (XVI)

The ratios of the olefins depend on the structure of the carbene complex and the olefin (Table 2).

The reaction products *a*, *a'*, *b*, and *b'* are formed as a result of β-elimination in the metallacyclobutanes (XV) and (XVI) with subsequent addition of a proton to the α- or α'-position in the metalla-ring.[54,82–84] For example, products *a* and *a'* are formed as follows in the decomposition of the metallacyclobutane intermediate (XV):

(14)

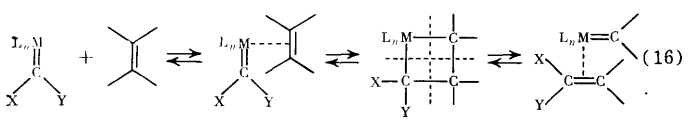
The ratio of the contributions of the pathways $(a + a')/(b + b')$ depends only slightly on the initial carbene complex and the olefin, which indicates the absence of an explicit preference for the formation of the intermediate (XV) or (XVI). Thus



the hypothesis, put forward initially by McLain and co-workers,[82-84] that the polarisation of the metal–carbon bond in the carbene complexes of tantalum and niobium has a decisive influence on the regioselectivity of their reactions with α-olefins has not been confirmed.

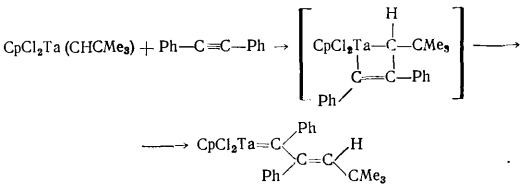
Table 2. Composition of the products of the reactions (as percentages) of the neopentylidene and benzylidene complexes of tantalum with ethylene, propene, and styrene.[54]

Olefin	*a*	*a'*	*b*	*b'*
	$(PMe_3)_2Cl_3Ta(CHPh)$			
Ethylene	—	—	73	27
Propene	49	21	4	26
Styrene	5	49	46	
	$(PMe_3)_2Cl_3Ta(CHCMe_3)$			
Ethylene	—	—	7	93
Propene	8	42	7	43
Styrene	6	35	30	29



Note. Pathways *a* and *b'* and also pathways *a'* and *b* are equivalent for ethylene.

The reaction involving the transfer of the carbene ligand to ethylene with formation of new olefins has also been observed for complex (VI)[55,56] and the distribution of the deuterium label in the reaction products supports the following reaction mechanism:



(15)

If the pathway, discussed above, leading to the decomposition of the metallacyclobutane intermediate via β-elimination is ineffective (the simplest case obtains when there are no protons at the β-carbon atom), then the metallacyclobutane formed can again decompose reversibly into a metal–carbene-olefine complex. The decomposition of the metallacyclobutane can proceed in principle in two ways, which leads to the possibility of the exchange of alkylidene fragments between the transition metal and the olefin:

(16)

For example, it has been established that complex (VI), which effects the irreversible transfer of the methylene ligand to ethylene [reaction (15)] on interaction with isobutene or methylene cyclohexane, exchanges the methylene group with these olefins. If a mixture of isobutene and labelled [^{13}C]methylenecyclohexane is used, then in the presence of complex (VI) the label is distributed between both olefins.[56,57] Another example involves the carbene complex $CpCl_2Ta(CHCMe_3)$, which reacts with ethylene or styrene exclusively in accordance with Eqn.(3). On interaction with diphenylacetylene, the complex gives rise to a kind of transalkylidenation reaction, which proceeds via a metallacyclobutane intermediate:[23,84]:

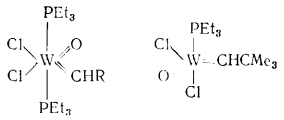
The absence of protons at the β-carbon atom in the metallacyclobutane intermediate is the simplest but not the only factor promoting the transalkylidenation reaction. It is known that, by altering the ligand environment of the metal atom in the complex, it is possible to influence the effectiveness of the β-elimination reaction.[85] It has been shown[54,86] that the relative reactivity in the β-elimination of hydrogen in alkyl compounds of tantalum and niobium is reduced when ligands such as tetrahydrofuran, pyridine, or alkoxy-groups are present in the coordination sphere of the metal, the effect being particularly pronounced in the last instance.

The introduction of the ligands enumerated above into the coordination sphere of the carbene complexes of niobium and tantalum reduces the relative rate of decomposition of the metallacyclobutane intermediate via β-elimination, which increases the yield of the products of the transalkylidenation reaction:[53,54]

$$\underset{\text{(XVII)}}{(PMe_3)_2Cl_3Nb(CHCMe_3)} + CH_2{=}CH_2 \rightarrow \underset{7\%}{CH_2{=}CHCH_2CMe_3} + \underset{93\%}{Me{-}CH{=}CH{-}CMe_3} \quad (17)$$

$$\underset{\text{(XVIII)}}{(THF)_2Cl_3Nb(CHCMe_3)} + CH_2{=}CHEt \rightarrow \underset{73\%}{CH_2{=}CHCMe_3} + \begin{cases} Pr{-}CH{=}CH{-}CMe_3 \\ Et{-}CH{=}CH{-}CH_2CMe_3 \end{cases}\ \underset{17\%}{} \quad (18)$$

$$\underset{\text{(XIX)}}{(PMe_3)(OCMe_3)_2ClNb(CHCMe_3)} + CH_2{=}CHEt \rightarrow \underset{86\%}{CH_2{=}CHCMe_3} + \underset{6\%}{Me_3CCH{=}CHEt} \quad (19)$$



It follows from Eqns.(17)–(19)# that the reaction of complex (XVII)with ethylene proceeds as the transfer of the carbene ligand to the olefin with formation of a set of new olefins, while complex (XIX) undergoes highly selectively the transalkylidenation reaction with t-butoxy-groups: complex (XVIII) is an example of a compound capable of reacting with olefins via both pathways simultaneously. An analogous effect has also been observed for tantalum complexes.[53,54]

The study of the composition of the products of the reactions of neopentylidene complexes of niobium and tantalum with but-1-ene and *cis*-pent-2-ene showed that the relative contribution of the transalkylidenation reaction is greater in the second case.[54] The results obtained suggest that the β-elimination reaction is more probable for α,α'-substituted metallacyclobutanes than for the α,β,α'-substituted derivatives.

Some of the complexes discussed above are capable not only of transferring the initial carbene ligand but also of propagating the kinetic chain in the metathesis reaction. For example, in the metathesis of *cis*-pent-2-ene in the presence of the complex $(PMe_3)Cl(OCMe_3)_2.Nb(CHCMe_3)$, 29 equivalents of but-2-ene and 34 equivalents of hex-3-ene are formed in 24 h per equivalent of the complex. At the same time effective *cis–trans* isomerisation of the initial *cis*-pent-2-ene takes place until the attainment of the composition corresponding to thermodynamic equilibrium.[54]

#Only the main products of the reactions of the initial neopentylidene complexes with olefins are presented in Eqns.(17)–(19).[54]

The formation of the products of the β-elimination of metallacyclobutanes in the course of the reaction with olefins has been observed to some extent for all the carbene complexes of niobium or tantalum (with the exception of the complexes containing the t-butoxy-ligands[53,54]) and for this reason the nucleophilic oxoalkylidene complexes of tungsten (XX) and (XXI), which react with olefins exclusively via the metathesis pathway, are of very great interest:[53,87,88]

(XX) (XXI)

R=H(a); Me(b); Et(c); Ph(d); or CMe_3(e).

According to the data of Wengrovius et al.,[87] complexes (XX) interact with olefins fairly slowly, but their reactivity in the transalkylidenation reaction can be significantly increased by introducing Lewis acid such as $AlCl_3$, $AlEtCl_2$, $SnCl_2$, etc. as additives to the reaction medium. Complex (XXI) is reactive also in the absence of additives and the initial rate of the transalkylidenation of olefins in the presence of complex (XXI) is equal to the initial rate of the same reaction in the presence of the catalytic system (XXe) + $AlCl_3$.[87] This enabled the authors to postulate that complex (XXI) behaves as an active centre, which effects transalkylidenation also in the (XXe) + $AlCl_3$ binary systems§.

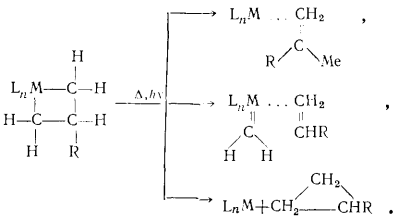
In the reactions of complex (XX) and (XXI) with olefins, it is possible to characterise not only the olefins produced as a result of the transfer of alkylidene fragments but also the carbene complexes formed in the course of the transalkylidenation. For example, the interaction of the neopentylidene complex (XXe) with *cis*-pent-2-ene leads to the formation of approximately equivalent amounts of 2,2′-dimethylhex-3-ene and 4,4′-dimethylpent-2-ene and the corresponding carbene complexes (XXb) and (XXc). On the other hand, in the reaction of complex (XXe) with but-1-ene the only product of the transalkylidenation reaction of the initial complex is 3,3′-dimethylbut-1-ene, while the other possible product, namely 2,2′-dimethylhex-3-ene, was not detected.[87]

The cyclopropane formation reaction, which is most characteristic of electrophilic carbene complexes, has not been observed for nucleophilic carbene complexes of tantalum, niobium, or tungsten. Only one example of the cyclopropane formation reaction is known for the nucleophilic complexes, namely the titanium complex (VI) reacts with isobutene to form 1,1′-dimethylcyclopropane in ~2% yield.[55] It has been established that the fraction of cyclopropanes formed in this reaction increases in the following sequence: ethylene < propene < isobutene; it also increases with the polarity of the solvent employed. A similar reactivity series has been observed for the reactions of electrophilic complexes with olefins [reactions (12)]. It is therefore possible to postulate that the cyclopropane formation reaction involving the titanium complex (VI) proceeds without the formation of a metallocyclobutane intermediate. The fact that the individual compounds $Cp_2\overline{Ti-CH_2-CHR-CH_2}$ (R = t-Bu or iso-Br) do not yield even traces of cyclopropane on decomposition can serve as confirmation of this hypothesis.[80] It is noteworthy that the absence of cyclopropanes from the products of the reactions of nucleophilic carbene complexes with olefins does not imply that this pathway in the decomposition of metallacyclobutanes is in principle impossible (see SectionV).

V, THE PATHWAYS IN THE REACTIONS OF CARBENE COMPLEXES OF TRANSITION METALS WITH OLEFINS

Comparison of the reactions of free carbenes and the carbene complexes of transition metals with olefins shows that complex formation not only alters the reactivity of the carbene species but also leads to the appearance of two new reaction pathways: transalkylidenation (2) and the addition of the carbene to the olefin with formation of new olefins (3). The appearance of these specific reactions, which are not characteristic of free carbenes, has been attributed to the ability of the transition metal atom in the carbene complex to coordinate an olefin molecule with subsequent formation of a metallacyclobutane intermediate [reaction (15)].

The results of Hoffmann's semiempirical calculations show that the energy barrier to the formation of metallacyclobutanes¶ from the carbene complex and an olefin is reduced with increase of the positive charge on the metal.[89] This conclusion agrees well with the experimental finding that metallacyclobutane intermediates are formed preferentially precisely in the interaction of nucleophilic carbene complexes with olefins (see Section IV).



The energy profile of reaction (16) of certain methylene complexes of chromium, molybdenum, tungsten, and titanium with ethylene has been calculated non-empirically.[35,90,91] The free energy of formation of the metallacyclobutane ΔG for the compound $Cl_2Ti(CH_2)$ is -34.5 kcal mol^{-1},[90] which agrees well with the formation of stable metallacyclobutanes (XIV) in the reaction of the titanium complex (VI) with olefins [reaction (13)].[80,81] For the complexes $Cl_4M(CH_2)$, where M = Cr, Mo, or W, $\Delta G > 0$ and diminishes from 25 to 10 kcal mol^{-1} on passing from chromium to tungsten. The results of the calculations show that the free energy of formation of the metallacyclobutane intermediate can depend significantly not only on the nature of the metal but also on its ligand environment. For example, when two chlorine atoms are replaced by the oxo-ligand in the methylene complexes of Group VI metals, the formation of the metallacyclobutane is favoured by energy factors ($\Delta G \cong -20$ kcal mol^{-1}).[35]

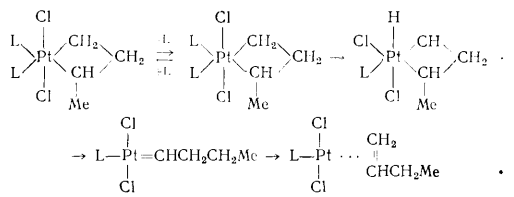
The metallacyclobutane intermediate formed can decompose in different ways, which ultimately determines the direction of the entire reaction of the carbene complexes with olefins. The fact that the individual metallacyclobutane complexes of transition metals yield in the general case on photolytic decomposition the same compounds whose formation is to be expected in the reactions of the corresponding carbene complexes with olefins (Schemes 1 and 4) may serve as confirmation of this concept:

§ A possible mechanism of the activating influence of Lewis acids in such systems has been examined by J.Kress, M.Wesolek, J.P.Le Ny, and J.A.Osborn, Chem.Comm., 1981, 1039.

¶ According to Hoffmann's data,[89] the energy minimum corresponds to a four-centre structure with a distorted metallacyclobutane geometry, which is evidently a consequence of the approximation introduced by Rappé and Goddard.[90]

Scheme 4

(20)



(21)

(22)

In this Section we shall attempt to analyse the factors promoting a particular pathway in the decomposition of metallacyclobutanes presented in Scheme 4.

In the metallacyclobutane intermediates arising in the reactions of nucleophilic carbene complexes of tantalum, niobium, or titanium with olefins, the formation of the products of the decomposition to the metal–olefin complex [reaction (20)] is regarded as a two-stage process involving β-elimination in the metallaring [reaction (14)]. The β-elimination reaction is characteristic to some extent of any mono- or di-alkyl compounds of transition metals[85,92,93] and experimental data confirm the possibility of its occurrence in metallacyclobutanes.[56,94–97]

The mechanism of reaction (20) has been studied in detail for individual metallacyclobutane complexes of platinum(IV).[97–101] It was found that, apart from the decomposition via β-elimination discussed above, this reaction can proceed via α-elimination in the metallacyclobutane with subsequent carbene–olefin isomerisation:[98,100,101]

where L = pyridine, 2-methylpyridine, or 2,6-dimethylpyridine.

Furthermore, the study of the distribution of the deuterium label in the decomposition products

$$(Py)_2Cl_2\overline{Pt[-trans\text{-}CH(Me)-CH(Me)-CD_2]}$$

and

$$(Py)_2Cl_2\overline{Pt-[-CH(Me)CMe_2CD_2]}$$

showed that the decomposition via α-elimination is the dominant process in such cases.[100] At the present time it is difficult to estimate the degree of general validity of the conclusion reached by Ling and Puddephatt,[100] but evidently the possibility of α-elimination must be taken into account in considering the rearrangements of metallacyclobutane intermediates.

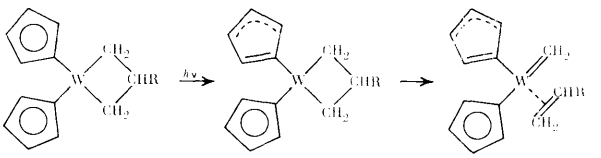
The decomposition of the metallacyclobutane to the metal–carbene–olefin complex (21) leads to the formal reduction of the metal atom†, which imposes a limitation on the scope of the process: the metathesis decomposition of 18-electron compounds requires a preliminary change in the electron environment of the metal in the complex.

†The authors used Hoffmann's approach in which the alkylidene ligand is regarded as a neutral species.[34,89]

In the study of the mode of decomposition of 18-electron metallacyclobutane complexes of platinum having the general formula

$$L_2X_2\overline{Pt-CH_2-CH_2-CH_2}$$

(where X = Cl, or Br; L = TMED, bipy, or phen), it was established that the formation of ethylene is due to the possibility of the dissociation of the initial compound at the metal–halogen bond in a sufficiently polar solvent.[102] When the initial platinacyclobutane is a 16-electron complex of the type



$$L_2\overline{Pt-CH_2-CH_2-CH_2}$$

[where L = PPh_3, $P(Alk)_3$, or bipy], its decomposition in this instance into ethylene and a methylene complex of platinum can be readily achieved in solvents of low polarity.[103]

It has been established that, regardless of the method of decomposition (thermolysis of photolysis), the main products of the reactions of 18-electron metallacyclobutane complexes of tungsten

$$Cp_2\overline{W-CH(R)CH(R)-CH_2}$$

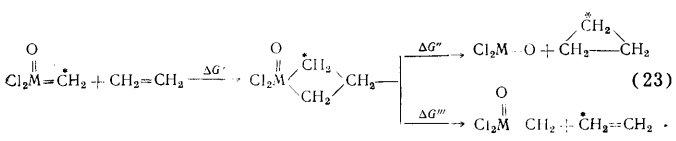
are olefins obtained on decomposition to the metal–olefin complex (20). On the other hand, the decomposition to the metal–carbene–olefin complex takes place only on photolysis of the initial complexes, which is associated with the following chain of transformations via a 16-electron intermediate:[104,105]

(18$\bar{6}$) (16$\bar{6}$) (18$\bar{6}$)

The concerted decomposition of metallacyclobutanes with formation of cyclopropanes [Eqn.(22)] is a typical reductive elimination reaction.[106,107] Analysis of the change in the populations of the frontier orbitals in the decomposition of metallacyclobutanes, carried out by Hoffmann and co-workers, demonstrated the existence of an energy barrier, in terms of symmetry, for reactions (21) and (22): for the d^0–d^4 configurations of the metal in metallacyclobutane, decomposition to the metal–carbene–olefin complex takes place preferentially, while for the d^6 configuration the preferred reaction is reductive elimination with formation of cyclopropanes.[89] This conclusion is in good agreement with experimental data. In the decomposition of the metallacycles

$$Cp_2\overline{W-CH(R^1)CH(R^2)CH_2}$$

(R^1, R^2 = H or Me)[104,105] and



$$Cp_2\overline{Ti-CH_2-CHR-CH_2}$$

(R = iso-Pr or t-Bu),[80] there are virtually no cyclopropanes among the reaction products, while the metallacyclobutane complexes of quadrivalent platinum give rise fairly readily to a compound with a three-membered carbon ring on thermolysis and photolysis. It has been demonstrated[107] in relation to the deuterium-labelled complexes

$$Py_2Cl_2\overline{Pt-CH(R')CH(R^2)\cdot CH(R^2)}$$

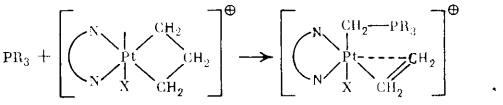
(R = H, D, or Alk) that cyclopropanes are formed as a result of the concerted dissociation of the metal–carbon bonds, although the observed influence of solvent polarity on the rate and selectivity of reaction (22) indicate the possibility of a slight charge separation in the transition state.

The mode of decomposition of the metallacyclobutane intermediate depends not only on the characteristics of the electronic structure of the initial complexes examined above but can be determined to a large extent also by the stability of the final reaction products. The thermodynamic assessment of the preference for a particular decomposition pathway involves the determination of the free energies of all the components and it is wrong to the attempt the prediction of the equilibrium ratio of olefins and cyclopropanes on the basis of the free energies of these compounds,[108] as has been justifiably stated by Grubbs.[109] Indeed a non-empirical calculation of the potential surfaces for the cyclopropane formation and transalkylidenation reactions showed that the relative contributions of the two pathways are determined primarily by the transition metal and its ligand environment[35,91] (Table 3).

(23)

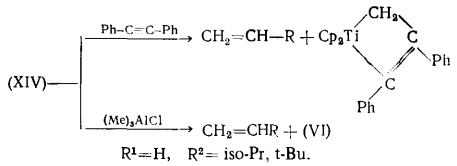
Table 3. Calculated free energies of formation and decomposition of the metallacyclobutane intermediates in the transalkylidenation and cyclopropane formation reactions[35] (kcal mol^{-1}).

M	$-\Delta G'$	$\Delta G''$	$\Delta G'''$
Cr	20	−2	20
Mo	24	42	24
W	18	43	18



It follows from the data in Table 3 that, on passing from the chromium complex to the molybdenum and tungsten complexes, the metathesis pathway leading to the decomposition of the metallacyclobutane becomes energetically preferable to the decomposition with formation of cyclopropanes, which is associated with the increasing stability of the metal–carbon bond in the carbene complexes of molybdenum and tungsten.

The results of the calculations agree well with the experimental observation of the high strength of the binding of the carbene in the oxoalkylidene complexes of tungsten (XX) and (XXI),[110,111] which undergo the transalkylidenation reaction with olefins with a high degree of selectivity (Section (IV). The occurrence of the transalkylidenation reaction also when Mn^+CH_2 reacts with ethylene propene, and isobutene in the gas phase[113] has been explained by the presence of strong metal–carbon bonds ($E_b \approx 94$ kcal mol^{-1} [112,113]).



Thus, if there is competition between the two pathways (transalkylidenation and cyclopropane formation) for the carbene complex in the reaction with an olefin, then an increase of the strength of the metal–carbon bond leads to an increasing role of the former. An unusual experimental confirmation of the concept described is provided by data for the decomposition of metallacyclobutanes in the presence of compounds which stabilise the carbene complex in one way or another. For example, the yield of ethylene, the product of the metathesis decomposition of

$$L_2X_2\overline{Pt-CH_2-CH_2CH_2}$$

(L = TMED, Py, or bipy; X = Cl, Br, or I), increases sharply in the presence of trialkylphosphines,[102] which is apparently associated with the formation, in the course of the reaction, of ylide-like structures containing a stabilised methylene ligand (the possibility of such stabilisation has been demonstrated[114]):

It has been established[80] that, in the presence of tolane and dimethylaluminium chloride, the complex (XIV) undergoes highly selective metathesis decomposition:

Evidently in this case too the mode of decomposition is determined by the possibility of the formation of stable complexes containing a stabilised carbene ligand.

Examination of the reactions of individual carbene complexes of transition metals with unsaturated hydrocarbons shows that the change in the reaction pathway is caused in the first place by the electron distribution in the carbene ligand in the complex. Strongly electrophilic complexes such as $(CO)_5W(CHPh)$ or $[Cp(CO)_2Fe(CHR)]^+$ (R = H, Me, Ph) react with olefins exclusively with formation of cyclopropanes. The absence of coordination vacancies at the transition metal atom and the presence of the highly electrophilic $2p_z$ orbital in the carbene carbon in the complex gives rise to the similarity of the chemical reactivity of such complexes to those of free singlet carbenes.

Fischer complexes are electrophilic complexes in which the electrophilicity of the carbene ligand has been reduced as a result of the presence of electron-donating substituents in the α-position. The reactivity of such complexes depends significantly on the possibility of the formation of coordination vacancies at the transition metal. If the reaction conditions are such that coordination vacancies are not formed, then the Fischer complexes react with olefins like the complexes $(CO)_5W(CHPh)$ and $[Cp(CO)_2Fe(CHR)]^+$ examined above, although the relative reactivity of the Fischer complexes is much lower.

The possibility of the formation of coordination vacancies at the metal atom leads to the occurrence of a specific transalkylidenation reaction which is uncharacteristic of free carbenes and which reflects the capacity of the carbene complex to react with olefins via a metallacyclobutane intermediate. However, studies of the reaction of $(CO)_5W(CPh_2)$ with olefins have shown that in this case too the transalkylidenation is accompanied by the formation of a fairly large amount of cyclopropanes. Presumably the competition between the two decomposition pathways of the metallacyclobutane intermediate is caused by the impossibility of the formation in the electrophilic carbene complex of a strong metal–carbon bond, which is one of the main factors promoting the metathesis decomposition of the metallacyclobutane.

Nucleophilic carbene complexes react with olefins via the formation of metallacyclobutane intermediates. In the case of typical nucleophilic complexes such as $Cp_2Ta(CH_2)Me$ or $(PMe_3)_2Cl_3Ta(CHR)$ (R = Ph or CMe_3) the main pathway in the decomposition of metallacyclobutane intermediate is

β-elimination of a proton; as a result of reactions of such complexes with olefins, the carbene ligand is transferred to the olefin with formation of a set of new olefins.

When electron-donating ligands are introduced into the coordination spehre of the metal in nucleophilic complexes of tantalum and niobium, a decrease of the polarisation of the metal–carbon bond is to be expected. The relative role of β-elimination in the metallacyclobutane then diminishes and transalkylidenation becomes the main pathway in the reactions with such olefins. The oxoalkylidene complexes of tungsten (XX) and (XXI), which undergo a highly selective transalkylidenation reaction with olefins, also belong to nucleophilic complexes with a comparatively weak polarisation of the metal–carbon bond.

Thus, whereas the cyclopropane formation reaction and the reaction involving the transfer of the carbene ligand with formation of new olefins are characteristic of complexes with an appreciable polarisation of the metal–carbon bond, the transalkylidenation reaction is observed for complexes in which the metal–carbon bond is weakly polar.

Calculations of the Thermodynamic Properties of Polymers

L.I.Pavlinov, G.N.Marchenko, and Yu.A.Lebedev

The methods for the calculation of the thermodynamic parameters of various classes of polymers are examined. Together with a description of the classical phenomenological approaches, much attention has been devoted to the description of computational methods involving the modelling of the properties of polymers on the basis of the corresponding parameters of their low-molecular-weight analogues.
The bibliography includes 90 references.

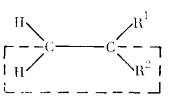
I. Introduction 683
II. Phenomenological methods 683
III. Modelling methods 686

I. INTRODUCTION

The greatest amount of experimental thermodynamic data which have now accumulated in the chemistry of macromolecular compounds refer to a narrow range of linear vinyl polymers and a very small amount is concerned with polymers of other classes. At the same time a significant proportion of these data require a critical assessment and revision. This applies to a large extent to polymers with a complex structure of the repeating units (carbo-, and hetero-chain polyconjugated systems, cyclochain polymers, systems with a benzenoid structure of their macromolecules, etc.), for which it is frequently very difficult and sometimes impossible to estimate experimentally and accurately the contributions to the properties by various phase states of the chains and to take into account the presence of chemical defects and branches in the macromolecules as well as the influence of all possible impurities associated with the use of catalysts, initiators, etc. in the polymerisation process.



This is why modern theoretical methods for the calculation of thermodynamic properties have come to play an extremely important role in the determination of new thermodynamic characteristics of polymers and in the revision of values already available. The attempts at the employment for the solution of this problem of rigorous quantum-chemical methods, which are based on fundamental physical concepts, have encountered mathematical difficulties which cannot be overcome. This factor led to the creation of phenomenological methods, which in many instances make it possible to carry out the required calculations successfully and comparatively simply.

II. PHENOMENOLOGICAL METHODS

A large number of simple and complex phenomenological computational schemes have now been developed on the basis of many years of systematic studies of the thermodynamic properties of various groups of low-molecular-weight compounds.[1-16] Many of these schemes are used successfully in calculations of the thermodynamic parameters of saturated hydrocarbons, olefins, and the simplest organoelemental compounds. The parameters calculated are the heats of combustion and formation, heats of evaporation and fusion, heat capacities, entropies, etc. However, in relation to polymeric substances, the computational methods for the determination of the above characteristics have not yet been adequately developed. The virtual impossibility of the exact determination of the energies of non-valence and resonance interactions between the atoms in macromolecules and also of taking into account different phase states of the polymers may be indicated as the main cause holding back the application of modern computational schemes in such cases. Several more or less successful attempts at the extension to polymers of certain schemes which had been used earlier to calculate the properties of low-molecular-weight compounds are described below.

On the basis of the assumptions made in the calculation of the properties of polymers, the phenomenological methods can be divided by convention into two main groups. In schemes of the first group,[1-6] it is assumed that each given bond in any molecule or macromolecule has a constant characteristic energy. The overall energy of the molecule is found by the summation of the characteristic bond energies, applying corrections to the sum of the energies for the steric effects corresponding to the interaction of atoms not linked by valence bonds.

Calculations by means of these schemes of properties such as the enthalpies of atomisation and formation, which make it possible to obtain fairly accurate results (±0.1–0.2 kcal) for paraffinic and olefinic hydrocarbons, can be applied in principle to a polymer having the corresponding structure. The carefully developed Allen–Skinner scheme[2-4] has been used[11,16] for this purpose; this represents the structure of the polymer of the ethylene type $-CH_2-C(R^1R^2)-$ by a two-membered unstrained ring

in which the "characteristic" energies of the C–H and C–C bonds (including one C–C bond represented by a dashed line) were adopted in accordance with the data for methane and ethane taking into account corrections for the steric interaction of atoms not linked by valence forces. For example, the enthalpy of atomisation ΔH_a^0 (298) of a hydrocarbon polymer is given by the following expression in terms of this scheme:

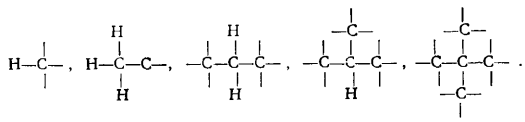
$$\Delta H_a^\circ(298) = N_{CC}E_{CC} + N_{CH}E_{CH} + x\alpha_{CCC} - t\beta_{CCC} - s.1, \qquad (1)$$

where N_{CH} and N_{CC} are the numbers of C–H and C–C bonds in the elementary unit of the polymer, E_{CH} and E_{CC} are the C–H and C–C bond energies, α_{CCC} is the interaction energy for a pair of neighbouring atoms linked by valence bonds with the given carbon atom, x the number of such pairs, βCCC the trigonal energy of the interaction between three carbon atoms each of which is the nearest neighbour of the

other two, t the number of trigonal interactions, A the energy of the *gauche*-butane interaction, and s the number of such interactions.

Table 1 presents the results of the calculations in accordance with this scheme of the enthalpies of formation of a group of vinyl polymers and several new carbochain polymers corresponding to the hypothetical gaseous state of the polymer unit. In order to be able to compare the calculated ΔH^0_{form}(298, gas) and experimental heats of formation of the polymers in the condensed phase [ΔH^0_{form}(298, solid)] and also the calculated and experimental heats of polymerisation of the monomers corresponding to these quantities, the authors[11,16] made the not wholly correct assumption that the heat of evaporation (sublimation) of the elementary polymer units is equal to the heat of evaporation of the monomer. By the condensed state, the authors[11,16] understood any state of the solid polymer, ranging from wholly amorphous to partly crystalline.

On comparing the enthalpies of formation of polymers calculated in accordance with this scheme with the experimental quantities, the following conclusions may be drawn.



(a) For polyethylene and polymers which are monosubstituted derivatives of polyethylene, the agreement between the calculated enthalpies of formation of the polymers and the quantities found experimentally is entirely satisfactory.

(b) The scheme is altogether inapplicable to the calculation of the enthalpies of formation of 1,1-disubstituted derivatives of polyethylene [polyisobutylene, poly(vinylidene fluoride), poly-α-methylstyrene] and also for polymers characterised by considerable non-valence or resonance interactions (polymers with polar and bulky substituents, polymers with heteroatoms in the main chain, and polymers with conjugated bonds). The schemes of Tatevskii,[10] Laidler,[7] Cox,[8] and Benson[9] can be assigned to the second group of phenomenological schemes, which can be used in the calculation of the thermodynamic properties of polymers. A thermodynamic property ϕ is represented in these schemes by a linear function of the numbers of structural elements or bonds n_i in the repeating units of the polymer:

$$\varphi = \sum_i n_i f_i \ , \qquad (2)$$

where f_i is a characteristic constant referred to the structural element of the polymer unit or to a bond of type i.

These methods do not employ corrections taking into account the non-valence and resonance interactions of the atoms and are therefore simpler and more convenient than the methods in the first group, although they are less accurate. The number of characteristic parameters of the structural elements or bonds in these schemes is much larger, which permits calculations of properties taking into account the first-order sphere around the atoms in the structural element (Tatevskii's scheme[10]) or taking into account the hybrid state of the bonds between the carbon atoms (Laidler's and Cox's schemes[7,8]). For example, on the basis of the classification of the first method (Tatevskii's scheme), it is possible to obtain five types of structural elements and five types of coordination of the atoms (one for H atoms and four for C atoms) for alkanes taking into account the first sphere:

Both schemes indicated can be applied in principle to both carbochain polymers and polymers of other classes. The characteristic parameters of the bonds or groups of bonds are set up on the basis of a statistical treatment of a set of experimental data for different compounds in accordance with Eqn.(2).

Table 1 presents the results of calculations by Cox's method of the enthalpies of formation of a group of heterochain polymers and the corresponding enthalpies of polymerisation. In those cases where experimental data are available for the polymers considered, their comparison with the calculated values reveals considerable discrepancies (polyoxyethylene, polyformaldehyde, polytetrahydrofuran) probably as a consequence of the neglect in the calculations of the contribution of the non-valence interactions of the atoms.

Table 1. Comparison of the thermochemical characteristics of polymers calculated in accordance with the Allen–Skinner and Cox Schemes by Somayajla et al.[11] with the experimental values.

*Calculation in accordance with Cox's scheme.
**Estimated theoretically.[16]

The best results were achieved in the calculation of the enthalpies and entropies of polymerisation of monomers with bonds of the type >C=C< and >C=C–C=C<.[12] Depending on the availability of initial experimental data, calculations have been carried out using Eqns.(3) or (4):

$$\left.\begin{aligned} \Delta H^0_{pol}\ (298) = \Delta H^0_c\ (298, \text{M}) - \Delta H^0_c\ (298, \text{P}) = \sum_i n_i^{\text{M}} f_{H,i}^{\text{M}} - \sum_i n_i^{\text{P}} f_{H,i}^{\text{P}}; \\ \Delta S^0_{pol}\ (298) = S^0(298, \text{P}) - S^0(298, \text{M}) = \sum_i n_i^{\text{P}} f_{S,i}^{\text{P}} - \sum_i n_i^{\text{M}} f_{S,i}^{\text{M}}\ ; \end{aligned}\right\} \qquad (3)$$

$$\Delta H^0_{pol}\ (298) = \sum n_{(i\to j)} f_{H(i\to j)},\quad \Delta S^0_{pol}\,(298) = \sum n_{(i\to j)} f_{S(i\to j)} \qquad (4)$$

In Eqn.(3) the quantities $\Delta H_c^0(298, M)$, $S^0(298, M)$, $\Delta H_c^0(298, P)$, and $S^0(298, P)$ are the enthalpies of combustion and the entropies of the monomer and the polymer unit respectively, $f_{H,i}^M$, $f_{S,i}^M$, $f_{H,i}^P$, and $f_{S,i}^P$ are constants for a structural element of type i in the monomer and polymer, and finally n_i^M and n_i^P are the numbers of structural elements of type i in the monomer and polymer. In Eqns.(4) the summation is carried out only over the corresponding pairs of interconvertible structural elements of type i in the monomer and of type j in the polymer and not over all types of structural elements, $f_{(i \to j)}$ being the corresponding constants.

The constants in Eqns.(3) and (4) were calculated from the experimental data for the following physical states (298.16 K, 101.325 kPa): for the gaseous (G) and liquid (L) states in the case of the enthalpy of combustion and only for the gaseous state in the case of the entropy.

Table 2 shows that comparison with the literature data of the enthalpies and entropies of polymerisation, calculated by Eqns.(3) and (4), of compounds such as alkenes, halogeno- and phenyl-alkenes, and styrene, acrylic acid, and methacrylic acid derivatives demonstrates an entirely satisfactory agreement between calculation and experiment. The discrepancies between the calculated and literature data are on average 6.3 kJ mol^{-1} for the enthalpies and 12.5 J mol^{-1} K^{-1} for the entropies.

The above comparison showed that the given scheme can be used to calculate the enthalpies and entropies of polymerisation via the $\rangle C{=}C\langle$ and $\rangle C{=}\overset{|}{C}{-}\underset{|}{C}{=}C\langle$ bonds in the corresponding monomers, for which the change in phase state during the reaction is of three types: monomer (G) → polymer (G), monomer (G) → polymer (S†), and monomer (L) → polymer (S). On the basis of Hess's law, the enthalpies and entropies of polymerisation of the monomers found can be easily converted into the enthalpies of formation and the entropies of the corresponding polymers (subject to the condition that the enthalpies of formation and entropies of the corresponding monomers are known). Unfortunately the method considered does not allow the determination of the given property of the polymer in the crystalline and amorphous-crystalline phases. At the same time the calculations of the thermochemical characteristics of the polymer in the condensed (amorphous) state and in the hypothetical gas phase calculated in this way can hardly ensure a reliable determination of a parameter as important as the energy of cohesion, because the constants employed in the calculation are averaged with respect to different classes of organic compounds and inaccurately reflect the energetic characteristics of specific types of compounds. Furthermore, the classification of different structural elements in the molecules on which the method is based makes it possible to take into account the interaction of atoms only in the immediate environment while long range interactions between atoms, due to the large dimensions of the macromolecules (the molecular weight factor), are completely disregarded.

Together with the difficulties enumerated above, one should also note that the given scheme in the version proposed by Grikina et al.[12] is subject to certain limitations. For example, it cannot be used to calculate the properties of heterochain, cyclochain, and heterocyclic polymers. Naturally, it is necessary to realise clearly that none of the available energy schemes is as yet able to predict correctly and take into account the individual characteristics of separate bonds in the macromolecule for many polymeric systems characterised by structural features such as the steric strain in the chain and bond conjugation.

Thus analysis of many empirical schemes for the calculation of thermodynamic properties of polymers employed nowadays shows in general that their scope is limited. When the structure of the elementary polymer units becomes more complex (for example, when cyclic, heterocyclic, and benzenoid structural elements appear in the polymer chain) the practical application of all the schemes considered becomes more difficult. At the same time, in connection with the vigorous progress in the theoretical and practical branches of polymer chemistry, the need to obtain new thermodynamic data and to test the values already available has arisen in the first place precisely for these complex polymer systems.

Table 2. Comparison with experimental data[16] of the enthalpies and entropies of the polymerisation of monomers via the $\rangle C{=}C\langle$ and $\rangle C{=}\overset{|}{C}{-}\underset{|}{C}{=}C\langle$ bonds calculated[12] by Tatevskii's method.

In order to overcome the difficulties indicated, attempts have been made in the last decade to develop procedures for calculations on the thermodynamics of polymers based on the principle of similarity.[15,18,19] According to this principle, the study of the properties of complex polymers is replaced by the study of the properties of a series of model compounds which reproduce the structure of integral repeating polymer units. Here there is no need to employ a large number of increments other than those necessary to take into account the influence of the two end groups of the model compound on the properties of the repeating units. The practical application of this modelling principle

† S = solid (Ed.of Translation).

provides for the employment of experimental data characterising the given low-molecular-weight model or system of models. On the other hand, the experimental procedures for the determination of thermodynamic data for model substances (combustion, calorimetry, reaction calorimetry, measurements of heat capacity, etc.) are themselves usually less laborious and at the same time more accurate than in the direct investigation of the properties of the polymers themselves.

Different versions of the above modelling method, including the mathematical form of modelling,[40] in which the properties of complex polymers are obtained from those of less complex polymers (the interpolation method) are examined below.

III. MODELLING METHODS

1. The Method of Linear Correlations of the Parameters of Model–Polymer Systems

The methods of similarity theory,[13,14] widely and successfully employed in the chemistry of individual low-molecular-weight compounds, have not as yet been developed adequately in polymer chemistry. A study in which the applicability of the rules of similarity theory to polymers has been demonstrated can be regarded as one of the first steps in this direction.[15]

A modelling method, the essential feature of which consisted in the selection and investigation of the thermodynamic parameters of individual compounds modelling the structure of sections of the macromolecular chains whose length was not less than that of the single repeating elementary unit, has been employed in the determination of the thermodynamic parameters of polymers.[15] Thermodynamic data corresponding to specific sequences of models and polymers investigated previously served as the basis for the calculation of the uninvestigated analogous properties of other polymers. This type of calculation can be performed using a statistical approach[15] in which the correlation coefficient r is used to investigate the interrelation of the properties indicated.

On the basis of general mathematical considerations,[14,20] there should be a linear relation between two functions $f(x, y_1, z_1, \ldots)$ and $f(x, y_0, z_0, \ldots)$, where $y_1, z_1, \ldots$ and $y_0, z_0, \ldots$ are any two sets of fixed values of the arguments y and z, while x is a variable. Here $f(x, y_1, z_1, \ldots)$ cannot be linear with respect to the argument x itself.

The application of this approach to the thermodynamic parameters of any one polymer [$\Delta H_c^0(298)$, $\Delta H_{form}^0(298)$, $S^0(298)$, $\Delta G_{form}^0(298)$, etc.] leads to the expression

$$\varphi_P(x_1, x_2, x_3, \ldots, x_i, \ldots) = \varphi_P^0(x_1^0, x_2^0, x_3^0, \ldots, x_i^0, \ldots) + \sum_i x_i' + \alpha \sum_i \sum_j x_i' x_j' + \alpha^2 \sum_i \sum_j \sum_k x_i' x_j' x_k' + \cdots \quad (5)$$

where x_i', x_j', ... are structural parameters which depend respectively on the arguments x_i, x_j, ...; x_1^0 and x_2^0 are any standard values of the arguments, α is a constant, and $i \neq j \neq k$.

If all the quantities of type x_i' are constant except for x_j', which we shall assume arbitrarily to depend on the nature of the substituent or a group of substituents in the repeating polymer unit, then we obtain the expression

$$\varphi_{P,j} = \varphi_{P,0} + b_P x_j' \quad (6)$$

where $\phi_{P,j}$ and b_P are constants related to parameters of type x_i' corresponding to structural elements whose effect on $\phi_{P,j}$ in a similar series of polymers remains unchanged. The subscript "P" denotes the first combination of constant factors corresponding to the polymer.

On passing to model compounds, it is possible to consider the change in the same quantity x_j' for certain fixed values of the remaining quantities x_i':

$$\varphi_{M,j} = \varphi_{M,0} + b_M x_j' . \quad (7)$$

The subscript "M" denotes the second combination of constant factors corresponding to the model.

From Eqns.(6) and (7), we obtain the expression

$$\varphi_{P,j} = \Delta\varphi_0 + \beta\varphi_{M,j} \quad (8)$$

where $\Delta\phi_0 = \phi_{P,0} - \phi_{M,0}(b_P/b_M)$ and $\beta = b_P/b_M$; it follows from Eqn.(8) that the quantities $\phi_{P,j}$ and $\phi_{M,j}$ depend linearly on one anther, i.e. there is a correlation between them.

It is noteworthy that this conclusion applies to homogeneous interactions in which the chain in the structure of the substituents in the polymer and in the model leads to an additive change in the properties of the system.

Remarks. The correlation of the properties for the physical states designated by (Φ_j) – (Φ_j) combines the variations of the properties in the pairs, in identical states, into a single linear variation; notation: N is the number of pairs, $\Delta\phi$ and β are parameters of Eqn.(8), r is the coefficient of the linear correlation of the properties, and α is the probable error of the correlation.
Note. G = gas, L = liquid, Cr = crystalline (Ed.of Translation).

According to the procedure proposed by Korshak and co-workers,[15] the choice of the polymers and the corresponding models in setting up a correlation series of properties ($\phi_{P,j}$ and $\phi_{M,j}$) must be made assuming an identical hypothetical process (conventional transition) for all the pairs,

relating, in conformity with Eqn.(8), the properties of the polymer unit $(-[-P-]_n-)$, the model $(R^1P_mR^2)$, and the compound R^1R^2:

$$R^1P_mR^2 \rightarrow \frac{m}{n}(-[-P-]_n-)+R^1R^2\ ; \quad m = 1, 2, \ldots, 4;\ n \rightarrow \infty\ . \tag{9}$$

According to this scheme, the polymer macromolecule can be obtained from the molecules of the model compound as a result of the abstraction of the elementary substituents and the formation of the molecules R^1R^2 from them. Compounds whose molecules undergo minimal chemical changes in reaction (9) can be usefully selected as models; in this sense R^1R^2 can be H_2, H_2O, HCl, etc. For example, the properties of vinyl polymers have been calculated[15,18] (Table 3) in conformity with conventional transitions of the type $HP_mH \rightarrow m-[-P-]- + H_2$ ($m = 1, 2$), which permitted the use of correlation pairs of two types:

	Pair (I)	Pair (II)
Polymer (P)	$-CH_2-CHR-$	$-C(R^1R^2)-C(R^3R^4)-$
Model compound (M)	$H-[-CH_2-CHR-]_m-H$ ($m = 1, 2$)	$H-[-C(R^1R^2)-C(R^3R^4)-]_m-H$ ($m = 1$)

In order that calculations based on Eqn.(8) should yield the properties $\phi_{P,j}$ uncomplicated by the influence of the polymer end groups and hence referring to formation of the elementary polymer unit, it is necessary that the degree of polymerisation of the polymers involved in the correlation series should be fairly high. In those cases where it is difficult to select a model compound for the polymeric substance (for example, for a copolymer) corresponding to Scheme 9, it is possible to use a conventional transition with two model compounds R^1PR^2 and R^1SR^2, whose thermodynamic characteristics are known, i.e. a transition of the type

$$R^1PR^2 + R^1SR^2 \rightarrow \frac{1}{n}(-[-PS-]_n-) + 2R^1R^2, \tag{10}$$

where P and S correspond to the monomeric units of the copolymer.

2. Estimation of the Reliability of the Linear Correlation of the Parameters of the Model–Polymer Systems

We shall now consider the question of the reliability of the linear correlation method in relation to the correlation series of parameters for model–polymer systems in which the polymers belong to the vinyl series (Table 3). The constants of the correlation Eqn.(8), needed for the calculation of the thermodynamic parameters of the polymers, were found for three phase states of the latter: ideal gaseous, condensed (amorphous), and ideal crystalline. The coordinates of the reference points for their determination were the tabulated thermodynamic properties of model compounds[17] and certain reliable characteristics of the polymer systems obtained both experimentally (for the amorphous and amorphous-crystalline states of the systems—data from Ref.16#) and by calculation (for the ideal gaseous and crystalline states—data by Korshak and co-workers[15] and Marchenko[18] obtained by extrapolating the properties of oligomers to infinite molecular weight).

Statistical analysis of the correlation between the thermodynamic parameters of the vinyl polymers and models (Table 3) carried out using the Student t-statistic[15,18] showed that it is quite possible to describe this correlation by a linear regression equation with a probable error of the order of 0.1–1.0%. Furthermore, this analysis showed that the probable error can be reduced to $\alpha \leq 0.1\%$ (fiducial probability $P \geq 0.999$) in those cases where the most accurate thermodynamic parameters of the polymers and models are used as the coordinates of the reference points of the regression equation.

It should also be noted that, when there is a correspondence between the phase states of the vinyl polymers and model compounds, the correlation between their enthalpies of formation and entropies can be described on the basis of the constant difference principle, in conformity with which one puts $\beta = 1$ in Eqn.(8) with a probable error of 0.1–1.0%. The application of this method to calculations of the thermodynamic parameters of a series of polymers of practical importance has also been examined by Korshak and co-workers.[19]

The discrepancies between the results of the calculation in accordance with this scheme of the enthalpies of formation, entropies, and heat capacities of polymers and the experimental data, which exceed the probable error of the correlation by 1–5%, can arise, in particular, because the experimental data refer to polymer specimens which have been inadequately investigated from the standpoint of their physical state. More notable discrepancies can be a consequence of inaccuracies in the study of the chemical structures of the polymer specimens.

3. Methods for the Extrapolation of the Properties of Polymer-Analogue Model Compounds to Infinite Molecular Weight

We shall consider yet another version of the modelling method whereby it is possible to calculate effectively the standard thermodynamic parameters of polymers and which will be referred to as the method of extrapolation of the properties of polymer-homologues to infinite molecular weight.[18,19] Hitherto undeservedly little attention has been devoted to studies concerning the calculation of the thermodynamic parameters of polymeric substances. During the last 30 years, only about ten investigations have been reported[21–32] in which mainly the physical characteristics of amorphous polymers were estimated on the basis of the properties of n-paraffins and certain other simplest homologous series (in particular, the densities, surface tensions, cohesion energies, dielectric constants, etc. have been determined) and only a few communications[28–30] have been devoted to the estimation of the thermodynamic parameters of liquid and gaseous paraffinic hydrocarbons with infinitely long chains both unbranched and branched [branches of the type of $-CH(CH_3)-$ and $-C(CH_3)_2-$ at each third, fourth, and fifth carbon atom in the chain]. For example, the heat of formation (per $-CH_2-$ group) of an infinite polymethylene chain in the gaseous state has been found by this method[28] as −20.61 kJ mol^{-1}. The entropy increment per $-CH_2-$ group has been calculated for the same polymer by an analogous procedure[29] as 38.95 J mol^{-1} K^{-1}.

The method of calculation of the thermodynamic properties of polymers considered here is based on the concept of polymeric substances as the limiting members of the corresponding polymer-analogue series of substances; the possibility of estimating these properties by extrapolating the specific characteristics of the members of the polymer-analogue series to infinite molecular weight follows directly from this concept. The application of the method indicated requires the knowledge of the characteristic features of the changes in the thermodynamic properties in the polymer-analogue series of substances, starting with the lowest members of the series, normally employed as models of polymers, and ending with the highest limiting members of the series, whose mixture constitutes in effect real polydisperse polymers. If one begins with the hypothesis that

There is no reference 16 in the Russian text (Ed.of Translation).

the contributions to the parameters of the repeating structural units and the end groups are additive for the highest members of the series, while only small deviations from additivity are characteristic of the lowest members, then a thermodynamic property of the molecule Φ_n, corresponding to the nth member of the series with a molecular weight M_n, can be represented in the following form:

$$\Phi_n = \sum_{i=1}^{n+2} m_i\varphi_i + \delta_n = m_1\varphi_1 + m_2\varphi_2 + nm_0\varphi_0 + \delta_n , \quad (11)$$

where ϕ_0 denotes the specific contribution to the property Φ_n of the repeating structural element of a chain with a mass m_0, ϕ_1 and ϕ_2 are the specific contributions to the property Φ_n by the two end groups with masses m_1 and m_2 respectively, and δ_n is a small correction which becomes a maximum for $n = 0$ (this value characterises the end groups of molecules of the given series) and becomes zero for the highest members of this series, i.e. $\lim_{n\to\infty} \delta_n = 0$.

The nature of the correction δ_n is such that it defines the change in the intensity of the non-valence intramolecular and intermolecular interactions of the atoms and the deformations of the valence angles in the sequence of molecules constituting the given polymer-analogue series. It is quite understandable that it must be taken into account in determining the exact dependence of the thermodynamic properties of the members of the series on the molecular weight. In a study of the variation of the enthalpies of formation of the lowest members of the homologous series of hydrocarbons in the gaseous state, Prosen et al.[32] established that δ_n can be neglected not at $n = \infty$ but much earlier when the number of repeating CH_2 groups in the hydrocarbon corresponds to $n \geq 4$. Thus, starting with $n_0 = 4$, the quantity δ_n becomes zero regardless of the nature of the end groups of the hydrocarbons. For other, longer repeating structural units, for example such as $-C_6H_4-$, $-C_6H_4O-$, $-C_6H_4NHCO-$, etc., we have $n_0 < 4$.

Thus if members corresponding to $n < n_0$ are removed from the homologous series of compounds, then the properties of the remaining members can be described with the aid of only the linear part of Eqn.(11).

In order to characterise the properties of members of a polymer-analogue series, it is useful to introduce two constants which are independent of the molecular weight of the members of the given series:

$$k_\varphi = (m_1\varphi_1 + m_2\varphi_2)/m_0\varphi_0; \quad k_m = (m_1 + m_2)/m_0 . \quad (12)$$

On the basis of Eqns.(11) and (12), it is possible to calculate the required specific contributions to the property Φ_n of the repeating structural element of the polymer in the following manner:

$$\varphi_0 = (\Phi_n - \delta_n)/(k_\varphi + n)m_0 . \quad (13)$$

It is noteworthy that the magnitude of this contribution should not in principle depend on the form of the end groups of the molecules of the polymer-analogue series, which are in the gaseous state or in a condensed phase. On the other hand, the specific value of the given property ϕ_n determined directly from the experimental results contains in all cases a contribution by the end groups of the molecule of the nth member of the series, which depends on n, since the expression

$$\varphi_n = \Phi_n/M_n = \Phi_n/(k_m + n)m_0 , \quad (14)$$

corresponds to it. It follows from a comparison of Eqns.(13) and (14) that

$$\varphi_n = \varphi_0[1 + (k_\varphi - k_m)/(k_m + n)] + \delta_n/M_n \quad (15)$$

where δ_n/M_n corresponds to the specific deviation of the property from additivity.

If one confines oneself in the treatment of a polymer-analogue series only to its terms ($n \geq n_0$) for which one can neglect the ratio δ_n/M_n, then Eqn.(15) assumes a form convenient for the calculation of ϕ_0:

$$\varphi_n = \varphi_0[1 + (k_\varphi - k_m)/(k_m + n)] . \quad (16)$$

As can be seen from Eqns.(15) and (16), by extrapolating ϕ_n to $1/(k_m + n) = 0$, it is easy to obtain the increment of the thermodynamic parameter of the polymer ϕ_0. Furthermore, on the basis of Eqn.(16), it is convenient to estimate the limiting molecular weight of the chains, at and above which the difference between ϕ_n and ϕ_0 should be neglected. Since Eqn.(16) is a fractional-linear function of n, for which $\phi_n/\phi_0 = 1$ is one of the asymptotic forms, the specific property ϕ_n obtained directly from the experimental results can be assumed equal to ϕ_0 only for fairly large values of $n \to \infty$.

When determining the constant parameters k_ϕ and ϕ_0, one can employ, together with Eqns.(15) and (16), simple relations which use the known values of the properties of only two members of the series, for example Φ_n for the nth member and Φ_r for the rth member ($n > r$):

$$k_\varphi = (n\Phi_r - r\Phi_n)/(\Phi_n - \Phi_r); \quad \varphi_0 = (\Phi_n - \Phi_r)/(n - r)m_0 . \quad (17)$$

As stated above, the choice of the given members of the series is limited to the group of substances for which r is greater than a limiting values n_0, starting from which the change of the properties in the series involves a regular increment in $\phi_0(\delta_{n_0} = 0)$.

Since the choice of members of the polymer-analogue series with $n \geq n_0$ for different chain lengths has a negligble influence on the parameters k_ϕ and ϕ_0 found from Eqn.(16), it is logical to suppose that their values do not change also in the case of a polydisperse mixture made up of molecules of the same series. In this case it is clear that the ratio of the properties $\bar{\phi}_n$ and ϕ_0 in the nth fraction of the polydisperse polymer, characterised by the number-average quantities $\bar{\Phi}_n$ and degree of polymerisation $\bar{n}$, can be obtained with the aid of an expression analogous to Eqn.(16):

$$\bar{\varphi}_n/\varphi_0 = 1 + (k_\varphi - k_m)/(k_m + \bar{n}) , \quad (18)$$

where $\bar{\Phi}_n = \phi_0$ only when $\bar{n} \to \infty$. When $\bar{n} = 10^3$ and $k_\phi - k_m = 1$, the approximation $\bar{\phi}_n = \phi_0$ leads to an error of 0.1% in the determination of ϕ_0 and of 10% in the molar quantity for $m_0 = 100$.

It is noteworthy that the character of the variation of the thermodynamic properties of polymeric substances as a function of $\bar{n}$, expressed by Eqn.(18), is general. In particular, it can be shown that the polymerisation equilibrium constants corresponding to the stages involving the interaction of the monomer with the initiator (K_1) and its dimerisation (K_2), trimerisation (K_3), etc. obey analogous relations. The variation of the equilibrium constants in the sequence K_1, K_2, ..., K_n characterises primarily the variation of the thermodynamic properties of compounds in a polymer-analogue series corresponding to this sequence. In the polymerisation of a monomer M in the presence of an initiator XY

$$XY + M \overset{K_1}{\rightleftarrows} XMY,\ XMY + M \overset{K_2}{\rightleftarrows} XM_2Y, \ldots,\ XM_{n-1}Y + M \overset{K_n}{\rightleftarrows} XM_nY$$

which is frequently encountered in practice, the Tobolsky approximation[33] $K_1 \neq K_2$, $K_2 = K_3 = \ldots = K_n = \ldots = K$ holds with adequate accuracy. From it, it is easy to obtain an equation relating the equilibrium constant K to the number-average degree of polymerisation of the polymer chains:

$$K = \frac{1}{[M]}\left[1 - 1/(\bar{n} - 1)\right] , \quad (19)$$

where [M] is the equilibrium concentration of the monomer. Subject to the condition that $\bar{n} \to \infty$, we have $K_\infty = 1/[M]$ and consequently

$$K = K_\infty [1 - 1/(\bar{n} - 1)] . \quad (20)$$

It can be seen that the character of relations (18) and (20) is the same although, compared with Eqn.(20), the initial significance of the constants k_ϕ and k_m, inherent in Eqn.(18), is clearly different. In this case Eqn.(20) shows that, when the Tobolsky approximation is valid, the true value of the equilibrium constant of the n-merisation stage is smaller than the limiting equilibrium constant K_∞ (corresponding to the formation of infinitely long chains) by an amount inversely proportional to the number-average degree of polymerisation of the product.

Another example, confirming the general character of the variation of the thermodynamic properties in a polymer-analogue series, expressed by Eqn.(18), is the analogous dependence of the enthalpy of polymerisation of the monomer on the number-average degree of polymerisation. For example, in the case of α-methylstyrene, this relation has the following form: [34]

$$\Delta H^0_{pol}(298)\ (\text{kJ mol}^{-1}) = 34.74\ (1 + 2.205/\bar{n}). \quad (21)$$

It is possible to quote a much greater number of similar examples. However, here it is more important to note that in all such cases, where the limiting parameter ϕ_0 is found by extrapolating function (18) to the limit $1/(k_m + \bar{n}) = 0$, it is necessary to make preliminary experimental determinations of the number-average values of the property $\bar{\phi}_n$ and degree of polymerisation $\bar{n}$ for several fractions of the polymer. These are extremely laborious and at the same time need to be fairly accurate.

Thus, in order to obtain fundamental thermodynamic characteristics of the polymers such as ϕ_0, which are independent of the average molecular weight and the molecular weight distribution of the polymer macromolecules, one can employ, on the one hand, the version of the modelling method examined above and the corresponding Eqns.(15) and (16) and, on the other hand, one can carry out a direct experimental study of the properties of different fractions of the polymer itself and then calculate ϕ_0 from Eqn.(18). Although the second procedure is now more commonly used in practice, the results obtained by this method as a rule require confirmation and refinement, since for most of them it is impossible to find corrections for the different phase states of the polymer and to allow for the presence of chemical cross-links and chain branches as well as contaminations associated with the employment of initiators, catalysts, emulsifying agents, etc. in the polymerisation process. On the other hand, extrapolation of the properties of the individual models of compounds to $n \to \infty$ in accordance with Eqn.(16), which is used in the first procedure, does not require a complex allowance for corrections associated with the specific features of the synthesis of the polymer and, what is particularly important, this method makes it possible to determine with satisfactory accuracy the properties of polymer chains in three ideal states of aggregation: in the solid (crystalline), liquid, and ideal gas states (Table 4). With the aid of extrapolation, it is then possible to proceed from ideal characteristics to the thermodynamic properties of a real amorphous-crystalline polymer, in the case where the degree of crystallinity of the polymer is known. For example, the enthalpy of formation of a 100% crystalline polymer can be extrapolated to the real degree of crystallinity w on the assumption that the difference between the enthalpies of formation of the polymer for degrees of crystallinity of 0% and w% is proportional to the degree of crystallinity:

$$\Delta H^0_{form}(298;\ w) = \Delta H^0_{form}(298;0\%) - w\ [\Delta H^0_{form}(298;0\%) - \Delta H^0_{form}(298;100\%)].$$

Finally, it is quite possible to infer the energy of formation of the real crystal lattice of the polymer from the difference between the enthalpies of formation of the polymer in the ideal gaseous and crystalline states. [30]

Table 4. Dependence of the specific thermodynamic properties of compounds in homologous series on the molecular weight. [18]

Compound	n	State	φ_0	$(k_\varphi - k_m)\varphi_0$	r
			$\varphi = \Delta H^0_{form}$ (298), kJ g^{-1}

$CN(CH_2)_{2n}H$	1—6	G	1.640	−0.643	−0.9995
$CN(CH_2)_{2n+1}H$	1—5	G	1.620	−0.565	−0.9993

Remarks. ϕ_0 and $(k_\phi - k_m)\phi_0$ are parameters of correlation (16), r is the coefficient of the linear correlation, and α is the error of the correlation, equal in all cases to 0.1%.
Note. G = gas, L = liquid, Cr = crystalline (Ed.of Translation).

A useful consequence of Eqn.(16) is the possibility of employing the relation between two different properties ψ_n and ϕ_n of compounds of the same polymer-analogue series (for compounds of two different series characterised by the same values of k_m and n) in the form

$$\psi_n = A + B\varphi_n , \quad (22)$$

where $A = \psi_0(k_\phi - k_\psi)/(k_m - k_\phi)$ and $B = \psi_0(k_\psi - k_m)/\phi_0(k_\phi - k_m)$. The constants used to determine A and B have the same significance as in Eqn.(16).

Thus relations similar to Eqn.(22) can also be used to extend the range of data both on the compounds of polymer-analogue series and the polymers themselves.

4. The Reliability of the Extrapolation Method
