In order to estimate the reliability of the calculations by the method involving the extrapolation of the thermodynamic parameters of polymers in the ideal gaseous and condensed states, Eqn.(16) has been applied [18] to thoroughly investigated homologous series of compounds of the type $R^1(CH_2)_nR^2$

(R^1, R^2 = H, H, or CN, H).[17] For this purpose, the thermodynamic parameters of compounds of the corresponding series [$\Delta H^0_{form}(298)$, $S^0(298)$, and $C^0_p(298)$] were treated as functions of $1/(k_m + n)$ alternately for three ideal physical states—gaseous, liquid, and crystalline. Table 4 shows that the above relations can be fitted by linear functions of $1/(k_m + n)$ of the type of Eqn.(16) with a high degree of reliability. This is indicated, in particular, by the closeness of the coefficients of linear correlation obtained to unity. Furthermore, statistical analysis of the relations using the Student t-statistic showed that a linear correlation of type (16) holds with a fiducial probability $P \geq 0.999$ for the given homologous series (the error of the correlation $\alpha \leq 0.1\%$).

Extrapolation of the specific values of the thermodynamic functions of n-paraffins to $1/(k_m + n) = 0$ yields the enthalpies of formation and entropies of polyethylene corresponding to three phase states of its macromolecules: ideal gaseous, liquid, and crystalline. Table 4 shows that the results of this extrapolation in the series of even and odd n-paraffins differ somewhat. The difference, for example for the increment of the enthalpy of formation per $-CH_2-$ group in the crystalline state is 0.6%, which exceeds severalfold the experimental error of the given characteristic for n-paraffins (~0.1%). The appearance of this effect may be attributed to different symmetries of the even and odd molecules. The studies by Muller and Lonsdale,[35] Schaerer et al.[36], and Piper[37] showed that the alternation of the melting points between the even and odd n-paraffins (the melting point is higher for the even members) is due to the alternation of two different types of their crystal structure: the orthorhombic modification of the short odd members of the series alternates with the triclinic modification of the even members having $n_C \leq 28$. On the basis of the results of these studies, one can assume that the extrapolation of the thermodynamic properties of crystalline n-paraffins with an even number of carbon atoms ($4 \leq 2n_C \leq 28$, Table 4) to the region of infinite molecular weights yields the properties of the triclinic crystalline modification of polyethylene. An analogous operation for n-paraffins with an odd number of carbon atoms makes it possible to estimate the thermodynamic characteristics of the orthorhombic crystalline modification of polyethylene, which is the commonest type of the unit cell for this polymer.[38]

The results obtained by Marchenko[18] agree with other data.[16,28,29] In particular, the increments in the enthalpy of formation and entropy per $-CH_2-$ group for the gaseous state of the chains of this polymer, listed in Table 4 [$\Delta H^0_{form}(298, \text{gas}) = -1.469 \times 14.027 = -20.602$ kJ mol^{-1} and $S^0(298, \text{gas}) = 2.782 \times 14.027 = 39.02$ J mol^{-1} K^{-1}] are consistent with the enthalpy of -20.61 kJ mol^{-1} and the entropy of 38.93 J mol^{-1} K^{-1} from other studies.[28,29] Furthermore, linear interpolation of the increments of the enthalpy of formation of the fully crystalline state [$\Delta H^0_{form}(298, \text{cryst.}) = -2.093 \times 14.027 = -29.36$ kJ mol^{-1}] and the fully amorphous state [$\Delta H^0_{form}(298, \text{amorph.}) = -1.815 \times 14.027 = -25.46$ kJ mol^{-1}] yields the enthalpy of formation (-28.19 kJ mol^{-1}) for the real amorphous-crystalline state of polyethylene with a degree of crystallinity of ~70%,[39] which agrees well with the experimental value (-28.03 kJ mol^{-1}).[16]

5. The Difference Interpolation Method

The possibility of applying the relations of difference interpolation to calculations of the physicochemical properties of polymers has been pointed out in a number of studies.[18,19,40] According to the difference interpolation method, a thermodynamic property ϕ, which depends on different sets of structural elements m_1, m_2, ..., m_n, can be represented in the form

$$\varphi(m_1, m_2, \ldots, m_n) = \varphi(0, 0, \ldots, 0) + \sum_k C^{\lambda_{m_1}}_{m_1} C^{\lambda_{m_2}}_{m_2} \ldots C^{\lambda_{m_n}}_{m_n} \Delta^{k-\lambda_1+\lambda_2+\ldots+\lambda_n}_{\lambda_{m_1}\lambda_{m_2}\ldots\lambda_{m_n}} \varphi(0, 0, \ldots, 0) \quad (23)$$

where $\phi(0, 0, \ldots, 0)$ is the value of the function ϕ for standard values of the discrete variables m^0_1, m^0_2, ..., m^0_n, $\Delta^k_{\lambda_{m_1}\lambda_{m_2}\ldots\lambda_{m_n}} \phi(0, 0, \ldots, 0)$ are finite differences, and $C^{\lambda_{m_1}}_{m_1}$, $C^{\lambda_{m_2}}_{m_2}$, ..., $C^{\lambda_{m_n}}_{m_n}$ are the numbers of the corresponding combinations.

Eqn.(23) is extremely cumbersome, but its application to calculations on polymers is facilitated by the fact that many macromolcules are linear sequences of isotypical atomic groups. As shown above, the properties of such polymers, starting from a fairly large average mass, cease to depend on the chain length, i.e. for certain average chain lengths the contribution of the end groups to the properties of the polymer is no longer appreciable. The thermodynamic properties of the polymer are in this case a function of the number and type of atoms or groups of atoms constituting the elementary structural chain units.

As an example, Pavlinov et al.[40] examined the vinyl series of polymers. An individual polymer chain of this series was represented in the form $-[-CH_{2-m_1}X_{m_1} - CH_{2-m_2}X_{m_2}-]-$, where X is a univalent substituent (X = H, Cl, CH_3, C_6H_5, etc.) and m_1 and m_2 are the numbers of substituents in the elementary unit (m_1, m_2 = 0, 1, 2; $m_1 \leq m_2$). In this case the properties of the polymer, referred to the elementary unit, are a function of only the two variables m_1 and m_2. Then, approximating to within second order differences, we have

$$\varphi(m_1, m_2) = \varphi(0, 0) + (m_1 + m_2)\,\Delta^1_{1,0}\varphi(0, 0) + \frac{1}{2}[m_1(m_1 - 1) + m_2(m_2 - 1)]\,\Delta^2_{2,0}\varphi(0, 0) + m_1 m_2 \Delta^2_{1,1}\varphi(0, 0). \quad (24)$$

Here the point (0, 0) corresponds to unsubstituted polyethylene and finite differences of the type

$$\begin{aligned} \Delta^1_{1,0}\varphi(0, 0) &= \Delta^1_{0,1}\varphi(0, 0) = \varphi(1, 0) - \varphi(0, 0), \\ \Delta^2_{1,1}\varphi(0, 0) &= \varphi(1, 1) - 2\varphi(1, 0) + \varphi(0, 0), \\ \Delta^2_{2,0}\varphi(0, 0) &= \Delta^2_{0,2}\varphi(0, 0) = \varphi(2, 0) - 2\varphi(1, 0) + \varphi(0, 0) \end{aligned} \quad (25)$$

correspond to different degrees of X-substitution of the polymer unit. It is more convenient to use Eqn.(24) in the form

$$\varphi(m_1, m_2) = \varphi_0 + (m_1 + m_2)\varphi_1 + (m_1 + m_2)^2\varphi_2 + m_1 m_2 \varphi_3, \quad (26)$$

where ϕ_0, ϕ_1, ϕ_2, and ϕ_3 are linear combinations of $\phi(0, 0)$, $\Delta^1_{1,0}\phi(0, 0)$, $\Delta^2_{1,0}\phi(0, 0)$, and $\Delta^2_{1,1}\phi(0, 0)$ of the type $\phi_0 = \phi(0, 0)$, $\phi_1 = \Delta^1_{1,0}\phi(0, 0) - \frac{1}{2}\Delta^2_{2,0}\phi(0, 0)$, $\phi_2 = \frac{1}{2}\Delta^2_{2,0}\cdot\phi(0, 0)$ and $\phi_3 = \Delta^2_{1,1}\phi(0, 0) - \Delta^2_{2,0}\phi(0, 0)$ characterising only the form of the substituent X.

If the order of the substitution in the formation of disubstituted polyethylene is immaterial, i.e. if $\Delta^2_{1,1}\phi(0, 0) = \Delta^2_{2,0}\phi(0, 0)$, then $\phi(m_1, m_2)$ can be represented in the form of a parabolic function of the total substitution number $l = m_1 + m_2$:

$$\varphi(m_1, m_2) = \varphi_0 + \varphi_1 l + \varphi_2 l^2 \quad (27)$$

In terms of their structure, Eqns.(24), (26), and (27) reflect the pair-additive approach of Bernstein.[1] With certain simplifications, it is easy to obtain on the basis of Eqns. (24), (26), and (27) a series of semiempirical schemes for

the calculation of the physicochemical properties of substances.[13,14,41–43]

Table 5. The results[40] representing in the form of the function $\phi(m_1, m_2) = \phi_0 + \phi_1 l + \phi_2 l^2$ the thermodynamic and kinetic experimental data[16,43,46,52] characterising X-substituted derivatives of polyethylene, their thermal decomposition processes, and the polmerisation of X-derivatives of ethylene.

*The results have been obtained[40] by solving a system of three linear equations.
Note. G = gas, L = liquid, and S = solid (Ed.of Translation).

As a consequence of the insufficiency of literature data (see the relevant reviews[16,31,39,43–46]), thermodynamic characteristics of F-, Cl-, and CH_3-substituted polyethylene derivatives such as the enthalpy of formation, the entropy, and the heat capacity have been estimated[40] within the framework of the approximation defined by Eqn.(27). The constants ϕ_0, ϕ_1, and ϕ_2 required for the calculation (Table 5) were obtained in two ways. The first way consisted in solving a system of three linear algebraic equations using the known values of the thermodynamic parameter for all three X-substituted polyethylene derivatives (with l = 0, 1, 2, or l = 0, 2, 3). In this case the non-averaged constants ϕ_0, ϕ_1, and ϕ_2 were used to calculate the properties of the polymers; the calculations of $\phi(m_1, m_2)$ then fully reproduced the reference data despite the possibility of the inaccuracy of the former (see Table 6). In those cases where the number of equations exceeded the number of unknown constants (one property was investigated by different workers), the system was solved by the method of least squares, which yielded more accurate (average) coefficients ϕ_0, ϕ_1, and ϕ_2. Extrapolation of function (27) ("forward" and "backwards") made it possible to obtain the hitherto uninvestigated properties for two other degrees of substitution of the polymer (l = 3, 4 or l = 1, 4; Table 6).

Comparison of the difference terms ϕ_0, ϕ_1, and ϕ_2 (Table 5), found from the enthalpies of formation of F-, Cl-, and CH_3-substituted polyethylenes, corresponding repsectively to the condensed phase and the state of isolated chains shows that the transition of the polymer from the first physical state to the second alters most the quadratic term in the approximation equation (27). Relations of type (27) for the enthalpies of formation of F-substituted polyethylenes (in the gaseous state) and the entropies of Cl-substituted polyethylenes (in the solid state) and also for the enthalpies and entropies of

Table 6. Comparison with experimental data of the thermodynamic and kinetic quantities calculated[40] in terms of the quadratic approximation and characterising X-substituted polyethylenes, their thermal decomposition processes, and the polymerisation of X-substituted derivatives of ethylene.

*1,1-Disubstituted ethylene.
**Results obtained by Pavlinov et al.[40] using the method of linear correlations.
Note. G = gas, L = liquid, and S = solid [numbers in square brackets denote references (Ed.of Translation)].

polymerisation of F- and CH_3-derivatives of ethylene, corresponding to transitions of the type (liq.) → (solid) and (gas) → (solid), differ little from the linear relation, in contrast to the others examined in Table 5. Eqn.(27) can be linear only subject to the condition that $\Delta^2_{1,1}\phi(0, 0) = \Delta^2_{2,0}\phi(0, 0) = 0$. In this case there is a simple additive relation between the property and the degree of substitution:

$$\varphi(m_1, m_2) = \varphi_0 + \varphi_1 l. \qquad (28)$$

An analogous form of approximation has been used, for example, in Szabo's method of increments for C–C bonds.[41]

In this case, on comparing the properties of a series of derivatives of polyethylene with two types of substitution, namely $-[-CH_{2-}m_1\text{-}n_1X_{m_1}Y_{n_1}\text{-}CH_{2-}m_2\text{-}n_2X_{m_2}Y_{n_2}-]-$ (A) and $-[-CH_{2-}m_1X_{m_1}\text{-}CH_{2-}m_2X_{m_2}-]-$ (B), for which the variable factor is only the type of substituent X while the substitution numbers m_1, m_2, n_1, and n_2 and the type of substituent Y are fixed, it is possible to put forward, on the basis of Eqn.(27), a simple relation between the properties of the corresponding members of these series:

$$\varphi_A(X) = \Delta\varphi^0_{A,B} + \varphi_B(X), \qquad (29)$$

because

$$\Delta\varphi^0_{A,B} = \varphi_A(0) - \varphi_B(0) + (\varphi^A_{1,A} - \varphi_{1,B})\,l + (\varphi_{2,A} - \varphi_{2,B})\,l^2 + m_1m_2(\varphi_{3,A} - \varphi_{2,B}) = \text{const}.$$

Eqn.(29) reproduces the rule of constant differences for the properties of isotypical substances formulated by Karapet'yants.[13] Its applicability to vinyl polymers has been confirmed[40] with the aid of pair-correlation analysis.[20] Examination of the relations between the thermodynamic parameters [$\Delta H^0_{form}(298)$ and $S^0(298)$] of two groups of vinyl polymers of the type $-[-CH_2-C(CH_3)X-]-$ and $-[-CH_2-CHX-]-$ with different substituents X (H, CH_3, COOH, $COOCH_3$, and C_6H_5) showed[40] that they are linear with a fiducial probability $P \geq 0.999$ and a probable correlation error $\alpha \leq 0.1\%$. Their linear correlation coefficients are in the range 0.98–0.99. Relations of this kind also make it possible in many instances to estimate thermodynamic parameters where experimental data either do not exist or are difficult to determine.

The application of the interpolation method when the dependence of the thermodynamic and kinetic parameters of polymerisation reactions of the ethylene derivatives $CH_{2-}m_1X_{m_1} = CH_{2-}m_2X_{m_2}$ on the number or type of substituents X is considered merits particular attention. In relation to polymerisation reactions, Eqns.(26) and (27) can be written in an analogous form for both thermodynamic and kinetic reaction parameters, since the number and type of substituents per mole of the monomer which has reacted or been activated do not change in this process.

The parabolic function (27) describes fairly adequately the dependence of the enthalpies and entropies of polymerisation of F-, Cl-, and CH_3-substituted ethylenes on the number l (Table 6). On the basis of the relations $\Delta H^0_{pol} = f(l)$ and $\Delta S^0_{pol} = \phi(l)$ obtained in this way (Table 6), it has been shown[40] that the polymerisation of ethylene derivatives containing three (and, even more so, four) substituents of the type of Cl and CH_3 is thermodynamically unfavourable even at room temperature (298 K), since $\Delta G^0_{pol} = \Delta H^0_{pol} - 298\Delta S^0_{pol} > 0$. At higher temperatures the thermodynamic prohibition of the polymerisation of these systems becomes even more stringent. Judging from the available experimental data (see the relvant reviews[16,46]) and the data in Table 6, the polymerisation of F-substituted ethylenes is thermodynamically allowed for all degrees of substitution of ethylene, because different values of l (1, 2, 3, 4) give high negative values of ΔG^0_{pol}.

The attempt to use the method of finite differences for a quantitative description of the kinetic parameters of a process as complex as the thermal decomposition of compounds of the vinyl series, involving the rupture of the principal bonds, is also of interest.[44,52] The activation energies $E^{\neq}_a$ and half-decomposition temperatures T_{hd} of a series of F- and CH_3-substituted polyethylenes[52] are described by the parabolic function (27) (Table 6) to within several per cent, which corresponds to the experimental error in the determination of these quantities. The parallel variation of $E^{\neq}_a$ and T_{hd} as a function of l in the case of the same substituent can be seen from Tables 5 and 6. The character of the variation of the thermal stability of the polymers with increase of l observed under these conditions in the main confirms the conclusions reached in a study[40] of the thermodynamics of the polymerisation of F- and CH_3-substituted ethylenes.

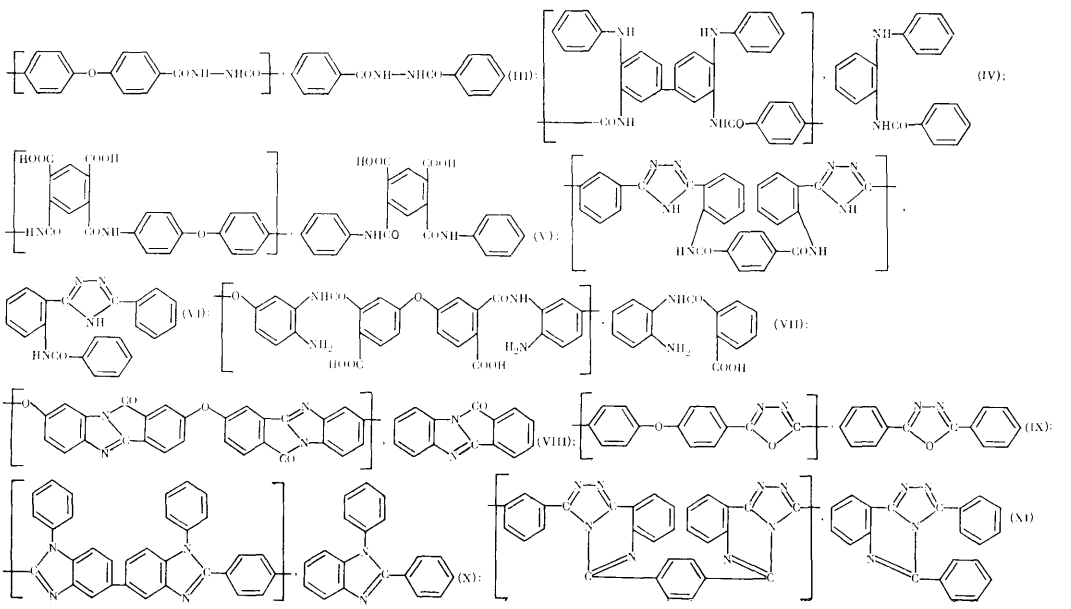
Thus the difference interpolation method yields a fully correct idea about the character of the changes in the properties of the simplest polymer systems as a function of the number and type of side substituents in the chain.

6. Thermodynamic Properties of Polyheteroarylenes

The modelling methods described above can be successfully employed to calculate the thermodynamic parameters not only of polymers with a simple chemical structure but also of complex systems such as polyheteroarylenes.[19] The attempts at an exact determination of the heats of formation of these polycondensation polymers directly with the aid of combustion calorimetry as a rule encounter serious difficulties.[82–88] On the other hand, the application of reaction calorimetry also does not always achieve this aim[18,19] as a consequence of the complexity of the synthesis of the above systems (sometimes involving a multistage process). By virtue of the competition between the main polycondensation reaction of the starting materials with various secondary reaction pathways, many of the rigid-chain polyheteroarylenes have a "heterounit" structure of the macromolecules, i.e. contain an appreciable amount of chemically defective structural fragments.[19,89,90] For example, in the two-stage synthesis of polyheteroarylenes, where polyfunctional amines and dianhydrides (dichlorides) of aromatic di- or tetra-carboxylic acids are used as the starting materials, the final polycondensation products are usually infusible and insoluble substances containing complex combinations of the fragments of the initial, intermediate, and final polymeric structures.[89,90] For this reason, the experimental thermodynamic characteristics of polyheteroarylenes usually require more fundamental checks with the aid of phenomenological computational methods than the analogous characteristics of other less complex polymers.

The thermodynamic properties of polyheteroarylenes have now been calculated so far in only one study[19] with the aid of the method based on the linear correlation of properties in model–polymer systems (Table 7). In the determination of the enthalpies of formation of polyheteroarylenes in the above investigation, the simplest version of the correlation method, namely the rule of constant differences between the properties of isotypical polymers (P_i) and model substances (M_i), was employed. In conformity with this rule, it was assumed that $\beta = 1$ and $\Delta(\Delta H^0_{form}) = \text{const}$. (corresponds to a constant increment in the end groups R^1 and R^2 of the models M_i) in the expression

$$\Delta H^0_{form}(298, P_i) = \Delta(\Delta H^0_{form}) + \beta \cdot \Delta H^0_{form}(298, M_i) \qquad (30)$$



It has already been stated that this approach yields a probable correlation error less than 1% for vinyl polymers. In an approach of this kind the calculation of the enthalpy of formation of an individual polyheteroarylene can be achieved knowing only the difference between the heats of formation $\Delta(\Delta H^0_{form})$ for a reference polymer–model pair and the heat of formation of the model corresponding to the polyheteroarylene. The authors[19] chose as the reference pairs various derivatives of poly-*p*-phenylene and the corresponding aromatic compounds, while the models chosen for polyheteroarylenes were compounds already investigated thermochemically[82–88] and the data for poly-*p*-phenylene were obtained[19] by extrapolating the properties in the polymer-analogue series of compounds with $n = 1, 2, 3$.

The results of such calculations are presented in Table 7, where the following designations for the polymer–model (P_i, M_i) correlation pairs were used:

Table 7. The enthalpies of formation of polyheteroarylenes (kJ mol^{-1}).

(IX)	L	—	—	—	—
	Am-Cr	—	—	6.7 [82]	R + D
	Cr	75.7 [82]	−34.7	—	—
(X)	L	324.7 [84]	621.7	—	—
	Am-Cr	—	—	641.0 [83]; 709.2 [84]	R + D
	Cr	296.6 [84]	575.3	—	—
(XI)	L	433.5 [84]	769.0	—	—
	Am-Cr	—	—	795.4 [86]	R + D
	Cr	399.2 [84]	719.6	—	—

Notation. CC is combustion calorimetry, CC + D is the combustion method combined with the study of the dehydration pressure, R is reaction calorimetry, R + D is the method of reaction calorimetry combined with the study of the dehydration pressure.
Note. L = liquid, Am-Cr = amorphous-crystalline, Cr = crystalline. The numbers in square brackets denote references (Ed.of Translation).

The authors[19] suggest that, by comparing the heats of combustion and formation of polyheteroarylenes calculated in this way by the modelling method and found experimentally, it is possible not only to eliminate certain erroneous experimental data but also to estimate the degree of defectiveness of the chemical structures of the polymer studied. However, one should note that both these problems have a solution only when fairly reliable thermochemical data are available for the individual compounds modelling the repeating fragments in the structures of the polyheteroarylenes, because the accuracy of the calculated characteristics of polymers is determined primarily by the accuracy of the experimental data for the models themselves.

Table 7 compares the experimental[82–88] and calculated[19] enthalpies of formation of nine polyheteroarylenes. The results of the calculations refer to two limiting phase states of the polymers—liquid (three polymers) and crystalline (nine polymers) and the experimental values refer in all cases to an undefined amorphous-crystalline state which in the case of polymers of this kind usually corresponds to an amorphous structure of the specimen and is designated by the authors[82–88] as the solid or condensed phase. For three of the nine polyheteroarylenes indicated in Table 7 (Entries No.2, 8, and 9), the discrepancies between the experimental[83,85,86] and calculated[19] heats of formation for the corresponding liquid-amorphous states lie within a narrow range (13–26 kJ mol^{-1}), which differs little from the range of experimental errors in the heats of formation of these polymers.

However, two additional experimental results,[84] presented in Table 7 for poly[*N*-terephthaloylbis(*N'*-*o*-phenylenediamine)] (No.2) and poly[2,2'-(*p*-phenylene)-1,1'-diphenyl-5,5'-dibenzimidazole] (No.8) can hardly be regarded as correct, as can be seen from their comparison with other experimental data[83] and calculated results. In all the remaining cases the data obtained by the modelling method refer solely to the crystalline polymer and the experimental quantities refer to an undefined amorphous-crystalline state. For this reason, certain difficulties arise in their comparison. Naturally, the difficulties can be partly obviated by estimating with the aid of Bondi's empirical rule ($\Delta H^0_{fu}/T_{fu} = 12.55 + 0.46V_m$, where V_m is the molecular volume) the heats of fusion of the models and then carrying out a rough estimate by Eqn.(30) of the corresponding heats of fusion of the polymers. According to this estimate, the changes in the heats of fusion of the group of nine polyheteroarylenes considered are in the range 40–80 kJ mol^{-1}. Since the observed discrepancies between the experimental and calculated heats of formation of four of the nine polymers (Nos.1, 3, 4, and 7, Table 7) fall within the above range, the discrepancies can probably be accounted for by the influence of the difference between the phase states of the polymers compared and in the case of polyhydrazide (No.1) and poly(*p*,*p'*-diphenyl oxide)pyromellitic acid amide (No.3) relatively small discrepancies in the given characteristics may actually indicate a certain amount of order in the real polymer structures.

Since in the case of the poly-*o*-aminoamidoacid (No.5) and pyrrone (No.6) discrepancies between the experimental and calculated enthalpies of formation exceed severalfold (by a factor of 3–4) the upper limit of the above range of heats of fusion, the authors[19] actually attributed them to the influence of the chemical defectiveness, which had not been taken into account, on the properties of real polymer structures. They actually used this factor to estimate the degree of defectiveness of the chemical structure of the poly-*o*-aminoamidoacid. Korshak and co-workers[19] made an approximate estimate of the content of defective structural elements in the real specimen of the poly-*o*-aminoamidoacid from its heat of combustion[87,88] and the heats of combustion (formation) calculated by the modelling method for pure poly-*o*-aminoamidoacid and poly-*o*-aminoimide (the main types of chemical defects in the initial polymer). It was found that the content of the main homopolymer units in the specimen was only 70 wt.% and that of the "extraneous" poly-*o*-aminoimide units was 30 wt.%.

Comparison of the different experimental procedures for the determination of the enthalpies of formation of polyheteroarylenes with the aid of the data in Table 7 shows that the most reliable method for the determination of this characteristic of polymers, synthesised by a single-state polycondensation process, involves calorimetric study of the synthetic reactions of the given systems. Combustion calorimetry yields in this instance less reliable results. For those polyheteroarylenes which are the products of the thermal cyclodehydration of the initial polycondensation polymers (two-stage synthesis), the best results are obtained via a two-stage method for thermodynamic studies involving the application of combustion calorimetry in the first stage. For this reason, in order to estimate the heat of formation of the initial polyfunctional polymer, in a number of studies[82,83,86] the authors were forced to investigate calorimetrically the synthesis of the polymer and also the thermodynamic characteristics of the corresponding reactants. The temperature dependence of the cyclodehydration pressure of the initial polymer was determined in the second stage, which made it possible to find the enthalpy of the cyclodehydration process. The enthalpy of formation of the final product was then determined with the aid of Hess's cycle taking into account the enthalpies of the intermediate processes.

Thus the data considered above show that, together with the traditional classical phenomenological methods for the calculation of the thermodynamic properties of polymers, it is nowadays possible to employ successfully methods involving their modelling on the basis of data obtained for low-molecular-weight analogues. Different versions of these methods (the method of linear correlations of properties, the method of the difference interpolation of the properties of substituted polymers, and certain versions of the method of extrapolation of properties in polymer-analogue series of compounds) are sufficiently exact and universal.

On the basis of the methods indicated, it is possible to predict successfully the thermodynamic parameters not only of polymers with a simple chemical structure but also of relatively complex polyconjugated structures, namely aromatic polymers and polyheteroarylenes, to which is has so far been impossible to apply any other known approaches. The modelling methods can also be used to calculate the bond strengths in polymer macromolecules and to predict their thermal stability.

Spinodal Decomposition in Polymeric Systems

Yu.S.Lipatov and V.V.Shilov

The characteristics of the phase separation in multicomponent systems in the region of unstable states are considered using the formal treatment of Cahn and Hilliard. The general theories of spinodal decomposition developed recently are briefly discussed. The characteristic features of systems based on high-molecular-weight components are analysed from the standpoint of phase separation using the Debye-van Aartsen relations. The theory of spinodal decomposition developed by de Gennes and Pincus for mixtures based on two homopolymers is examined in detail. The principal results obtained in experimental studies of phase separation of the liquid-liquid type in polymer-solvent and polymer-polymer systems are presented. The possibilities in the application of the concept of spinodal decomposition to a wider range of complex multicomponent systems as well as the results obtained recently by the authors of the review in the study of phase separation in systems of this kind are discussed. The attempts at the analysis of the spinodal decomposition phenomena within the framework of the non-linear thermodynamics of irreversible processes developed by Prigogine are considered.
The bibliography includes 89 references.

I. INTRODUCTION

It is known that, depending on the character of the interaction of the components, binary systems can consist of one or two phases. If a system of this kind consists of only one phase, microregions with a non-homogeneous decomposition of the components, namely composition fluctuations, exist in it. After time intervals of the order of magnitude of the duration of diffusional jumps, such fluctuations are spontaneously generated or dissipated. A characteristic feature on the basis of which a particular system can be classified as a one-phase system, is the presence of an equilibrium distribution of fluctuations.[1] Such a distribution is fully controlled by external conditions and the composition of the system and is independent of time. At the same time, there exist two-phase systems with a high degree of dispersion which are outwardly similar to the one-phase systems. The principal difference between the former systems and one-phase systems is the absence of an equilibrium distribution of microregions of inhomogeneity.

An important difference between one- and two-phase systems also consists in the fact that in the latter systems the microregions of inhomogeneity consist of microvolumes with the properties of pure phases. In principle, the size of such microregions can increase with time until the complete separation of the system into layers. The transition from a one-phase system to a two-phase system is attributed to an enhancement of the intensity of the composition fluctuations and the development of their basis of microregions of new phases. This takes place when the system is in a metastable region (between the binodal and the spinodal) or in an unstable region (within the spinodal) of the phase diagram.

The classical approach to the problem of the stability of phases has been developed by Gibbs.[2] According to Gibbs, the most characteristic points on the free energy—concentration relation $G(c)$ are points of inflexion at which the sign of the second derivative changes. When the condition $\partial^2 G/\partial c^2 > 0$ holds, the diffusion fluxes of the components are directed towards a diminution of the composition fluctuations, while under the condition $\partial^2 G/\partial c^2 < 0$ the directions of the diffusion fluxes are reversed. In this case the intensity of the composition fluctuations in the system increases—as a one-phase system it becomes unstable and should decompose spontaneously into regions with equilibrium compositions. The region of unstable states is bounded on the phase diagram by a curve called the spinodal. On the "outer" side, the region of metastable states bounded by the binodal adjoins the spinodal. In this region, as in the case of a one-phase binary system, the diffusion fluxes of the components are directed towards the diminution of the composition fluctuations. Nevertheless, the segregation of a new phase begins precisely in this part of the diagram. Under these conditions, the occurrence of the energetically unfavourable effect involving the formation of an interface makes the system unstable only in relation to fluctuations whose dimensions are greater than the critical value and the fluctuations themselves have a composition similar to that of the new phase. Such fluctuations are called critical nuclei.

The appearance of such critical nuclei in an A + B mixture, for example nuclei based on component A, leads to the formation around the nucleus of a zone depleted in component A. The diffusion fluxes tend to make good the resulting deficiency and at the same time feed the nucleus which has been formed. This is responsible for the continuous growth of the microvolumes of the new phase. In this

case phase separation proceeds via a mechanism involving nucleation and growth. A characteristic feature of the "classical" theories of nucleation is that the critical nucleus is regarded as a microscopic drop of a pure new phase. The treatment of the kinetic aspects of the appearance, growth, and coalescence of the microregions of the segregated phase within the bulk of the homogeneous solution in the region of metastable states is based on this hypothesis.[3]

A general approach to phase separation in inhomogeneous systems has been developed in the studies of van der Waals, Hart, Cahn and Hilliard.[4-11] The theory of spinodal decomposition in solution developed by Cahn and Hilliard has proved particularly fruitful[7-11] and has been confirmed experimentally by numerous data on phase separation in metallic alloys and inorganic glasses.[12,13] In particular, Cahn and Hilliard have established that the critical nuclei formed on nucleation in the metastable state can differ significantly in their composition from the particles of the new phase.[8] In the immediate vicinity of the binodal, critical nuclei are formed whose composition, radii, and interfaces are indeed close to the characteristics of the classical nuclei of the new phase. However, as the spinodal is approached, the deviations of the concentration in the nuclei from that in the initial solution become smaller to an increasing extent, the radii of the nuclei become increasingly larger, and the work of their formation approaches zero.

II. THEORETICAL IDEAS CONCERNING PHASE SEPARATION IN BINARY SYSTEMS VIA THE SPINODAL MECHANISM

According to the ideas developed by Cahn and Hilliard,[6-8] the free energy of a binary system with small composition fluctuations can be formulated as follows in terms of a linear approximation:

$$F = \int_v [f(c) + k(\nabla c^2)]\,dv \,, \qquad (1)$$

where $f(c)$ is the density of the free energy of the homogeneous system in which the concentration of component A is c and $k(\nabla c)^2$ is the "gradient energy", which represents the first term in the expansion of the free energy, describing its increase as a result of the appearance of the concentration (composition) gradient. Taking into account the expansion of $f(c)$ in terms of the average concentration c_0, the difference between the free energies of the inhomogeneous system and the initial homogeneous solution is

$$\Delta F = \int_v \left[\frac{1}{2}\left(\frac{\partial^2 f}{\partial c^2}\right)_{c_0}(c-c_0)^2 + k(\nabla c)^2\right] dv \,. \qquad (2)$$

Bearing in mind that the quantity $k(\nabla c)^2$ is always positive, the condition for the instability of the system in relation to small composition fluctuations can be written as follows.

$$\partial^2 f/\partial c^2 < 0 \,. \qquad (3)$$

For composition fluctuations corresponding to a periodic variation of the density along the coordinate x, we have

$$c - c_0 = A\cos(qx) \,, \qquad (4)$$

where A is a constant factor and q the wave vector. The sum of such fluctuations for different periods, representing the sum of the Fourier components in the expansion of the concentration, can be regarded as the local difference between the concentrations. The contribution of the component with the wavelength $2\pi/q$ in the relation for the free energy change as a result of composition fluctuations is

$$\frac{1}{4}VA^2\left[\left(\frac{\partial^2 f}{\partial c^2}\right) + 2kq^2\right] \,, \qquad (5)$$

where V is the volume of the system.

When condition (3) holds, the contribution of an expression of type (5) to ΔF becomes negative if the wavelength of the Fourier component reaches the critical value λ_c defined by the expression

$$q_c = \left(-\frac{\partial^2 f}{\partial c^2}\cdot\frac{1}{2k}\right) \,. \qquad (6)$$

In the initial stages of spinodal decomposition, where the linear approximation of the Cahn–Hilliard theory [Eqn.(1)] is valid, the difference between the local chemical potentials of the components can be represented in the form[9]

$$\mu_A - \mu_B = \left(\frac{\partial F}{\delta C_A}\right) - \left(\frac{\partial f}{\partial c_A}\right) - 2k\nabla^2 c_A \,. \qquad (7)$$

In this case the diffusion fluxes of the components are expressed by the relation

$$J_A = -J_B = M\nabla(\mu_A - \mu_B) \,, \qquad (8)$$

where M is a phenomenological coefficient characterising the diffusional mobility of the components. Using the relations presented, the diffusion equation can be reduced to the form

$$\partial c/\partial t = M(\partial^2 f/\partial c^2)\nabla^2 c - 2Mk\nabla^4 c \,. \qquad (9)$$

The coefficient of $\nabla^2 c$ is the diffusion coefficient.

Thus, in contrast to Fick's Second Law, Eqn.(9) contains a term proportional to $\nabla^4 c$. On the spinodal, the diffusion coefficient changes sign, which leads to an enhancement of the composition fluctuations characteristic of spinodal decomposition. Under these conditions, phase separation is initiated by the selective growth of sinusoidal composition fluctuations and takes place on the basis of microregions with small deviations from the composition of the equilibrium solution. The solution of the diffusion equation yields the time variation of the local concentration difference $c - c_0$:

$$c - c_0 = \exp[R(q)t]\cdot\cos(qx) \,, \qquad (10)$$

where $R(q)$ in the exponent represents the so-called amplification factor:

$$R(q) = -Mq^2(1+2q^2). \qquad (11)$$

It is seen from Eqn.(5) that, when $q > q_c$, we have the factor $R(q) < 0$ and consequently the concentration difference diminishes with time. This corresponds to the decay of the composition fluctuations. On the other hand, when $q < q_c$, the quantity $R(q)$ becomes positive and the concentration difference increases with time. The amplification factor has a maximum when

$$q_m = \frac{1}{2}\left[-\left(\frac{\partial^2 f}{\partial c^2}\right)/k\right]^{1/2} \,. \qquad (12)$$

For the maximum value of $R(q)$, a sharp maximum is obtained in the quantity $c - c_0$ specified by Eqn.(10). In the general solution of the diffusion equation one can therefore neglect all the components of the Fourier expansion of the difference $c - c_0$ except that which corresponds to q_m.

Thus in the initial stages of the spinodal decomposition, an exponential increase of the intensity of the composition fluctuations, whose wavelength is defined by Eqn.(12), is observed. The following equation holds between the optimum and critical wavelengths of spinodal decomposition:[9]

$$\lambda_m = \sqrt{2}\lambda_c \,. \qquad (13)$$

For later stages of the spinodal decomposition, i.e. with increase of $c - c_0$, Eqn.(1) becomes a rough approximation, since a continuous increase of $c - c_0$ with time follows from it. In fact the concentration difference cannot exceed a limiting value corresponding to the segregation of microregions of the pure components.

It has been shown[14] that the diffusion equation for later stages of spinodal decomposition becomes

$$\partial c/\partial t = D_1\nabla^2 c - D_2\nabla^4 c + D_1'(\nabla c)^2 + D_n \quad (14)$$

where

$$D_1 = \frac{M}{N_v}\left[\frac{\partial^2 f}{\partial c^2}\right];\ D_2 = 2Mk/N_v;\ D_1' = \partial D_1/\partial c$$

(N_v is the number of atoms per unit volume) and D_n is a higher-order non-linear expression.

In those cases where the volume of the system depends on its composition, the sequence of infinitesimal composition fluctuations in the solid should lead to the appearance of elastic deformations.[11] It has been shown that this results in the appearance of an additional contribution to the free energy of the system described by the expression[10,11]

$$\eta^2 E(c - c_0)^2/(1 - \nu) \quad (15)$$

where E is Young's modulus, ν the Poisson coefficient, and η the linear expansion corresponding to a unit change in the composition. When account is taken of this relation, the contribution of the Fourier component with a wavelength $2\pi/q_m$ to ΔF can be represented by the expression

$$\frac{1}{2}VA^2\left[\left(\frac{\partial^2 f}{\partial c^2}\right) + \frac{2\eta^2 E}{1 - \nu} + 2kq^2\right] \quad (16)$$

Consequently, for a system with elastic deformations resulting from the local change in composition, the limit of stability is defined by the condition

$$\partial^2 f/\partial c^2 + Y = 0 \quad (17)$$

where $Y = 2\eta^2 E/(1 - \nu)$.

Thus elastic stresses stabilise the system. Eqn.(17) yields the position of the so-called coherent spinodal, in contrast to the "chemical" spinodal determined solely by the chemical nature of the components and expressed by the conditions $\partial^2 f/\partial c^2 = 0$.

Cahn's theory nowadays continues to be the main one employed in the study of the kinetics of phase separation via the spinodal mechanism in ageing metallic alloys,[12] in inorganic glasses,[13] etc. The corresponding experiments are based on the application of methods of the low-angle scattering of X-rays.

The application of the Cahn–Hilliard theory to the interpretation of experimental data for the scattering of radiation makes it possible to obtain characteristics such as the optimum and critical wavelengths of the spinodal decomposition, the second derivative of the free energy with respect to composition, the quantities $\eta^2 E/(1 - \nu)$ (if elastic stresses arise in the system), and k in Eqn.(1). The calculations carried out for this purpose are based on the analysis of the time variation of the intensity of X-ray scattering in the region of the diffraction maximum. It has been shown[15] that this variation is defined by the relation

$$I(q, t) = I(q, 0)\exp[2R(q)t] \quad (18)$$

where

$$R(q) = -(D/f'')(f'' + 2\eta^2 E/(1 - \nu) + 2kq^2)q^2 \quad (19)$$

(D is the mutual diffusion coefficient for the components). It follows from the theory that the following main features of spinodal decomposition can be isolated: (1) the linear dependence of the logarithm of the intensity of the scattered radiation on time; (2) the linear dependence of $R(q)/q^2$ on q^2; (3) the presence of an interference maximum in the relation between the intensity of the scattered radiation and the angle. The manifestation of these effects makes it possible to reach a qualitative conclusion concerning the presence or absence of spinodal decomposition and analysis of the corresponding relations permits the determination of the most important characteristics.

It follows from Eqn.(18) that the slope of the linear relation $\ln[I(q, t)] = \phi(t)$ yields $R(q)$. It it is positive, the composition fluctuations in the system are enhanced, i.e. separation via the spinodal mechanism takes place. The quantity $(-2kD/f'')$ can be determined from the slope of the plot of $R(q)/q^2$ against q^2 and $\{-D[1 + 2\eta^2 E/(1 - \nu)f'']\}$ can be estimated from the intercept which the straight line makes on the ordinate axis. Thus all the quantities characterising the phase separation can be obtained for the initial stages of spinodal decomposition.

In the determination of the most characteristic features of spinodal decomposition, studies on the mathematical modelling of phase separation in the region of unstable states on the phase diagram have played a major role. Despite the comparatively small number of such investigations, their results have proved extremely instructive, because they make it possible to follow the appearance, enrichment, and in certain individual instances also the coalescence of the microregions of the heterogeneous structure as a function of time.[16,17] In particular, it has been shown[17] that, for a definite composition of the system, there is a temperature corresponding to the maximum rate of formation of interrelated microregions of the phase separation. In this case the formation of modulated structures in spinodal decomposition corresponds to a comparatively brief period of the development of interacting nuclei. In the course of later stages of the decomposition, hydrodynamically initiated coalescence begins to play an important role. The possibility of modelling the process of phase separation in both the metastable and unstable regions of the phase diagram and also the possibility of obtaining information about the coalescence of the microregions at later stages of the decomposition[17] must be regarded as a significant characteristic of the results obtained in the numerical soluton of a diffusion equation of type (14).

A series of theoretical studies whose aim was a more general description of the phenomenon of spinodal decomposition than had been achieved on the basis of the Cahn–Hilliard theory have appeared recently. The necessity for a more general approach to the analysis of phenomena arising in spinodal decomposition is associated primarily with the fact that the fundamental equation in the given theory [an equation of type (1)] is inapplicable in the general case because, for reasons involving symmetry considerations, it does not take into account contributions proportional to ∇c. A theory[18] based on a set of phenomenological coefficients determined from the conditions for correlation with experimental data has been proposed as one of the alternative formulations of the theory for the description of phase separation in the region of unstable states on the phase diagram.

Another approach developed recently is based on the extension of the perturbation theory for the liquid state to the case of inhomogeneous liquids.[19] The numerical solution of the corresponding diffusion equation, this time for the one-dimensional case, reveals appreciable deviations from the Cahn–Hilliard theory outside the linear regime.

One of the most rigorous versions of the modern theory of phase separation, including the description of nucleation and spinodal decomposition processes, has been developed

by Metiu et al.[20] and Varea and Rodledo.[21] It is based on the consideration of these processes as relaxation phenomena obeying the Markov equation. For a thermodynamic system with such a relaxation process (for example for a liquid in a specified state), the rate of change of the local density $\rho(r, t)$ is defined by the following evolution equation:

$$\frac{\partial \rho(r, t)}{\partial t} = -K\left[1 - \exp\left(\lambda^2\nabla^2/r\right)\frac{\partial\Omega}{\delta\rho(r)}\Big|_{\rho(r,t)}\right], \qquad (20)$$

where K is a constant related to temperature and to the characteristic time of the transitions, Ω the grand thermodynamic potential, and λ the distance traversed by the molecule of the liquid during the characteristic time.

Eqn.(20) describes the rate of the most probable evolution of density fluctuations. In terms of the approximation assuming a small variation in $\rho(r, t)$ compared with λ, the equation first obtained by Cahn[10] is valid:

$$\frac{\partial\rho}{\partial t} = K'\nabla^2\frac{\delta\Omega}{\delta\rho(r)}\Big|_{\rho(r,t)}. \qquad (20')$$

Analysis of Eqns.(20) and (20') shows that $\Omega[\rho(r)]$ can be identified with Lyapunov's function. Here the study of the number and properties of the corresponding stationary solutions is of special interest. The direction of the most probable evolution of this system is defined by the condition

$$\frac{d}{dt}\Omega[\rho(r, t)] \leqslant 0 .$$

In particular, if we have two stationary states $\rho_1(r)$ and $\rho_2(r)$, then on the path from the first to the second, the following condition is valid for the $\Delta\rho(r)$ fluctuation:

$$\Omega[\rho_1(r) + \Delta\rho(r)] > \Omega[\rho_2(r)] .$$

The stationary states are then defined by the condition:

$$\frac{\delta\Omega}{\delta\rho(r)} = \frac{\delta\Omega}{\delta\rho(r)} - \mu = 0 . \qquad (21)$$

Homogeneous states correspond to the trivial solution $\rho(r) = \rho$ of Eqn.(21). At the point where the trivial solution becomes unstable, a branching or bifurcation takes place.

Eqn.(21) yields the condition for the instability of each homogeneous solution in the spinodal region, i.e. an infinite family of inhomogeneous stationary states branches out from each point within the spinodal. The instabilities of the homogeneous solutions are determined either in terms of a mechanical analogy (a large response to an external influence) or in terms of a thermodynamic analogy {the absence of an unambiguously defined minimum in $\Omega[\rho(r)]$}. It has been established that periodic stationary states branch with a specific initial wavelength λ_c. A series of spontaneous fluctuations can cause a transition of the system from the homogeneous state which has become unstable, via the periodic states indicated, to a metastable state. Subsequently there is a possibility of a transition via nucleation from the metastable state to an equilibrium homogeneous state. Regarded as the Lyapunov function (20), the property $\Omega[\rho(r)]$ defines the direction in the sequence of stationary states traversed along the most probable path after the transition to the spinodal region of the phase diagram.

Thus the phenomenon of spinodal decomposition is associated with a large number of pathways whereby the system relaxes to equilibrium. In all cases, after quenching the system develops a periodic inhomogeneity, whose wave vector corresponds to the initial state; after a time, this inhomogeneity increases in amplitude and in wavelength until nucleation begins following the attainment of the metastable state. It has been shown[21] that in this state the fluctuations in different regions of space are independent. Such fluctuations lead to the development of a nucleation process which cannot be described within the framework of the local Cahn–Hilliard approximation.

III. APPLICATION OF THE THEORY OF SPINODAL DECOMPOSITION TO SYSTEMS BASED ON HIGH-MOLECULAR-WEIGHT COMPONENTS

The majority of investigations of phase separation in systems based on high-molecular-weight components are themselves based on the familiar study by Debye[22] devoted to critical opalescence. The relations obtained by Debye for a few systems are in essence analogous to the results of the studies of Cahn and Hilliard examined above. Debye used the following expression for the free energy of a binary system:

$$F = k_BT\int_v d\upsilon\left[\left\{\frac{\varphi_A^0}{\omega_A}\ln\varphi_A^0 + \frac{(1-\varphi_A^0)}{\omega_B}\ln(1-\varphi_A^0) + \right.\right.$$
$$\left.\left. + \frac{\Omega}{2k_BT}\varphi_A^0(1-\varphi_A^0)\right\} + \left(\frac{1}{\omega_A\varphi_A^0} + \frac{1}{\omega_B\varphi_B^0} - \frac{\Omega}{k_BT}\right)\frac{\eta^2}{2} + \frac{H}{2k_BT}(\nabla\eta)^2\right], \qquad (22)$$

where ϕ_A^0 is the volume fraction of component A, ω_A the volume occupied by the molecule of A, ϕ_A the local value of ϕ, $\eta = \phi_A - \phi_A^0$, and

$$\Omega = W_{AA}|\omega_A^2 + W_{BB}|\omega_B^2 - 2W_{AB}|\omega_A\omega_B ,$$
$$H = \frac{1}{6}\left[\frac{W_{AA}}{\omega_A^2}l_{AA}^2 + \frac{W_{BB}}{\omega_B^2}l_{BB}^2 - 2\frac{W_{AB}}{\omega_A\omega_B}l_{AB}^2\right] .$$

The quantities Ω and H are the interaction parameters. Here we have

$$W_{AA} = \int\varepsilon_{AA}d\upsilon,\ W_{AA}l_{AA}^2 = \int r^2\varepsilon_{AA}d\upsilon,$$
$$l_{AA}^2 = \int r^2\varepsilon_{AA}d\upsilon\Big/\int\varepsilon_{AA}d\upsilon$$

where $-\varepsilon_{AA}$ is the energy of the A–A interaction between the molecules and l_{AA} the characteristic distance of the interaction between these molecules.

On the basis of the relations presented above, the contribution to the free energy of the system associated with the inhomogeneous distribution of the components can be represented in the form

$$\Delta F = \int d\upsilon\left[\frac{1}{2}\left\{\frac{\partial^2F_m/V}{\partial^2\varphi_A^2}\right\}_{\varphi_A^0}\eta^2 + \frac{1}{2}H(\nabla\eta)^2\right], \qquad (23)$$

where F_m is the free energy of mixing for a homogeneous solution. It is seen that Eqns.(2) and (23) for the free energy of mixing are almost identical.

Van Aartsen applied the Debye relations to systems based on high-molecular-weight components.[23] He began with the assumption that the Flory–Huggins expression is valid for ΔF_m in the case of a homogeneous solution:[24]

$$\frac{\Delta F_m}{V} = RT\left[\frac{\varphi_A}{\bar{V}_A}\ln\varphi_A + \frac{1-\varphi_A}{\bar{V}_B}\ln(1-\varphi_A) + \frac{\chi}{\bar{V}_A}\varphi_A(1-\varphi_A)\right], \qquad (24)$$

where $\bar{V}_A$ and $\bar{V}_B$ are the molar volumes of the solvent and the polymer respectively.

In this case one can write for the second derivative of the free energy with respect to composition

$$\left\{\frac{\partial^2(\Delta F_m/V)}{\partial\varphi_A^2}\right\}_{\varphi_A^0} = \left[\frac{1}{\bar{V}\varphi_A^0} + \frac{1}{\bar{V}_B(1-\varphi_A^0)} - \frac{2\chi}{\bar{V}_A}\right] \qquad (25)$$

If the relation

$$\chi = A + (B\bar{V}_A/RT) \qquad (26)$$

is valid for the Flory–Huggins parameter χ, Eqn.(25) can be transformed into

$$\left\{\frac{\partial^2(\Delta F_m/V)}{\partial \varphi_A^2}\right\}_{\varphi_A^0} = \frac{2RT}{\bar{V}_A}(\chi_{T_s} - \chi_T) = 2B\left(\frac{T - T_s}{T_s}\right), \qquad (27)$$

where χ_{T_S} is the interaction parameter corresponding to the temperature of the spinodal. It follows from the relations presented that the expression

$$\lambda_m = 2\pi l\,[3(1 - T/T_s)]^{-1/2} \qquad (28)$$

can be written for the optimum wavelength of spinodal decomposition.

Thus the most "critical" parameter for the determination of the dimensional characteristics of the microregions of phase separation in the given instance is the characteristic distance for the interaction of the molecules. Debye assumed that

$$l = 0.5\text{–}2 \text{ nm} \qquad (29)$$

for low-molecular-weight components and

$$l = R/\sqrt{6} \qquad (30)$$

for polymer–solvent systems. Here R^2 is the mean square of the distance between the ends of the polymer chain. For polymer–polymer systems, McMaster[25] suggested that l be determined from the relation

$$l = R/\sqrt{3} \quad . \qquad (31)$$

The most complete treatment of the phenomenon of spinodal decomposition in systems based on two high-molecular-weight components has been carried out in the theoretical studies of de Gennes[26] and Pincus.[27] An extension of the corresponding Flory–Huggins expression for an inhomogeneous system[28] was used in the above studies to formulate the free energy of the system:

$$\frac{F}{k_BT} = \frac{\varphi_A}{N_A}\ln\varphi_A + \frac{(1-\varphi_A)}{N_B}\ln(1-\varphi_A) + \frac{a^2}{36\varphi_A(1-\varphi_A)}(\nabla\varphi_A)^2, \qquad (32)$$

where a is the size of the monomeric unit and N_A and N_B are the degrees of polymerisation of components A and B respectively.

In the de Gennes theory account is taken of the fact that the main mechanism of the movement of molecular chains in polmer–polymer systems involves their reputation or "creep" in a tube formed by the labile nodes of the entanglement network.[29–31]

The time variation of the local composition of the system ϕ_A is related to the flux J_A of component A by the continuity equation

$$\partial\varphi_A/\partial t + \operatorname{div} J_A = 0 \quad . \qquad (33)$$

The Fourier component of the flux for the wave vector J_A is determined on the basis of the corresponding Fourier component of the chemical potential gradient of the given component $\nabla\mu(q)$ by means of the relation

$$J_A(q) = -[\Lambda(q)/k_BT](\nabla\mu(q)), \qquad (34)$$

where $\Lambda(q)$ is the Onsager coefficient. Having found $\nabla\mu$ and leaving in the expression for this quantity only terms linear in $\delta\phi(r)$, we have

$$\frac{\nabla\mu}{k_BT} = \nabla(\delta\varphi_A)\left(\frac{1}{N\varphi_A(1-\varphi_A)} - 2\chi\right) - \frac{a^2}{36\varphi_A(1-\varphi_A)}\nabla^3(\delta\varphi_A) \quad . \qquad (35)$$

Eqns.(33)–(35) have been used to obtain the so-called central relaxation formula:

$$\frac{1}{\tau_q} \equiv \frac{1}{\delta\varphi_q}\frac{\partial(\delta\varphi_q)}{\partial t} = q^2\Lambda(q)\left(\frac{1}{N\varphi_A(1-\varphi_A)} - 2\chi + \frac{a^2q^2}{36\varphi_A(1-\varphi_A)}\right). \qquad (36)$$

The relaxation spectrum, found on the basis of Eqn.(36), defines the initial unstable mode in the binary system and the rate of growth of this mode. Assuming a unique relaxation time for the mode of the wave vector q in a melt of two polymers, the Onsager coefficient obtained by de Gennes assumes the following form:

$$\Lambda(q) \simeq \varphi_A(1-\varphi_A)N_eD_1(qa)^2, \qquad (37)$$

where N_e is the number of monomeric units between the sites where the chains are hooked to one another and D_1 is the coefficient of microscopic diffusion. It follows from Eqn.(37) that the Onsager coefficient is proportional to the square of the wave vector, i.e. increases sharply with decrease of wavelength.

Subject to the condition $\chi \gg \chi_{T_1}$, i.e. after the instantaneous transfer of the system to a region lying within the spinodal on the phase diagram, we have from the central relaxation formula

$$-1/\tau_q = \chi\Lambda(q)q^2(2 - q^2l^2) \qquad (38)$$

where $l = 1/3a\chi^{-1/2}$ is the thickness of the interfacial transitional layer determined on the basis of the Helfand theory for polymer–polymer mixtures.[32,33]

Eqn.(38) shows that, when $ql < \sqrt{2}$, the composition fluctuations are enhanced, i.e. the system passes to the regime of spinodal decomposition. The greatest enhancement is characteristic of the optimum wavelength corresponding to the following wave vector:

$$q_m = 2\sqrt{3}a^{-1}\chi^{1/2} \quad . \qquad (39)$$

It is seen from Eqn.(39) that the optimum wavelength of spinodal decomposition is slightly smaller than the mean square radius of the molecular coil. In principle, this conclusion is inconsistent with the theoretical predictions based on the Debye–van Aartsen theory.

When account is taken of Eqn.(39), the rate of relaxation to the equilibrium two-phase state for the optimum wavelength is defined by the relation

$$-1/\tau_q = D_1N_e\chi a^2l^{-4} \equiv (N_e/\tau_1)\chi^3, \qquad (40)$$

where τ_1 is the time of the microscopic diffusion of a chain segment.

On the basis of the de Gennes central relaxation formula, Pincus[27] amended de Gennes' conclusion concerning the magnitude of the optimum wavelengths of spinodal decomposition. In particular, Pincus took into account the fact that, for the wave vector of non-interacting chains in the melt, there is not one but at least two independent relaxation modes.[34] As a result, we have for the Onsager coefficient when $qR_0 \gg 1$

$$\Lambda(q) = 2T\mu_1(ql)^{-2}[1 - \exp(-q^2R_0^2/6)]\varphi_A(1-\varphi_A), \qquad (41)$$

where μ_1 is the mobility of the monomeric unit.

Thus the Onsager coefficient proves to be proportional to the reciprocal of the square of the wave vector. On combining Eqns.(36) and (41), we obtain the following expression for the rate of relaxation of the system to the state of equilibrium:

$$\frac{1}{\tau_q} = \frac{1}{2}(T\mu_1/L^2)[1 - \exp(-q^2R_0^2/6)][N^{-1} + 2\chi\varphi_A(1-\varphi_A) + (qa)^2/36], \qquad (42)$$

where L is the contour length of the macromolecule. When $\tau_q < 0$, an exponential growth of the intensity of composition fluctuations is observed. The sharp transition from $\chi < 0$

to $\chi > \chi_{T_S}$ corresponds to the fact that the initial unstable mode q_m is specified by the extremum in Eqn.(42), i.e.

$$q_m^{-1} \simeq (R_0/6)\,[\ln(6\chi/\chi_{T_S})]^{-1},\quad \chi > \chi_{T_S} \qquad (43)$$

when the system passes rapidly from the one-phase state for into the region bounded by the spinodal. In the unstable region of the phase diagram near the spinodal, we have

$$q_m^{-1} \simeq (R_0/6\sqrt{3})\,(\chi/\chi_{T_S} - 1)^{-1/2},\quad (\chi - \chi_{T_S})/\chi_{T_S} \ll 1\ . \qquad (44)$$

For the optimum rate of growth of fluctuations in the former case, we obtain

$$1/\tau_{q_m} \simeq T_{rep}^{-1}(\chi/\chi_{T_S}),\quad \chi \gg \chi_{T_S}\ . \qquad (45)$$

In the second case we have correspondingly

$$\frac{1}{\tau_{q_m}} \simeq T_{rep}^{-1}\,(\chi/\chi_{T_S} - 1),\quad (\chi - \chi_{T_S})/\chi_{T_S} \ll 1\ , \qquad (46)$$

where T_{rep} is the time required for the molecular chain to emerge from the entanglements tube.

We shall note the most important features of Pincus' study, which constitutes a further development of the ideas of de Gennes.

1. The unstable mode has a wavelength comparable to the radius of the molecular coil and hence varies in proportion to $N^{1/2}$.

2. The rate of increase of the intensity of the composition fluctuations corresponding to the given mode is proportional to the reputation diffusion constant in the melt, varies as N^{-2}, and its concentration dependence is represented by a curve having the same form as the spinodal.

Thus Pincus' analysis of the phenomenon of spinodal composition in mixtures of homopolymers shows that microphase separation on the scale of distances of the order of magnitude of N_e is possible only for very intense cooling of the one-phase mixture of polymers. This case has been considered by de Gennes[35] in relation to cross-linked polymer blends. Quenching of this extent is equivalent to the fulfilment of the condition $\chi/\chi_{T_S} \gg N/N_e$. This is unlikely in blends of homopolymers under real experimental conditions. It is seen from the foregoing that, in the entire set of multicomponent polymer systems, only polymer–solvent and homopolymer–homopolymer systems have so far been analysed as regards spinodal decomposition in the region of unstable states on the phase diagram; more complex systems have been scarcely considered.

IV. EXPERIMENTAL STUDIES OF SPINODAL DECOMPOSITION IN SYSTEMS BASED ON HIGH-MOLECULAR-WEIGHT COMPONENTS

In the first study of the phase separation of polymer systems in the region of an unstable state, the poly-2,6-dimethyl-1,4-phenyl ether (PDMPE)–caprolactam system was investigated.[36] By measuring the scattered light intensity, it was established that cooling drives the solution to the region of unstable states on the phase diagram and phase separation then occurs via the spinodal decomposition mechanism. Microscopic observations on the phase separation processes have been made in the same system[37] and it was found that the size of the microdrops of the phase enriched in the polymer increases with time.

Phase separation in the PDMPE–toluene system has also been studied,[38] the increase in turbidity being recorded visually, while in another investigation[39] the same system was studied by electron microscopy. In those cases where homogeneous PDMPE–toluene mixtures were cooled to a temperature below T_S, two characteristic phenomena were observed. At a quenching temperature differing only slightly from the spinodal temperature, there is sufficient time for the formation of many nuclei in the system during the passage through the metastable region of the phase diagram. Cooling to a temperature somewhere above T_S gives rise to a pattern typical for phase separation via the nucleation and growth mechanism. On the other hand, if the system is cooled to a temperature somewhat lower than T_S, the electron microscopic patterns reveal the formation of two interlinked structures (structural networks) together with the nuclei.

Thus the rate at which the system passes through the metastable region on the phase diagram determines to a large extent the structure of the liquid mixture. On the other hand, if the homogeneous solutions are cooled to temperatures appreciably lower than T_S, the system passes rapidly through the metastable region and the electron micrographs show mainly interlinked structures characteristic of phase separation via the spinodal mechanism.

Phase separation in the polystyrene–decalin system has been investigated[40] and the dimensions of the regions corresponding to phase separation via the spinodal mechanism have been determined from light scattering data using the fundamental relations of Cahn's theory. The phenomenon of spinodal decomposition also proved to be typical for certain polymeric gels. Thus a diffraction maximum has been observed on the light scattering intensity curves for hydrogels and agarose, which is associated with the formation of regularly arranged phase separation regions.[41] A detailed investigation of phase separation in the sol–gel transition in the given system, occurring when it is cooled, was subsequently carried out.[42]

In conformity with Cahn's theory, in the majority of the studies considered the fulfilment of all the main criteria for the occurrence of spinodal decomposition mentioned above was assessed. It was shown that the occurrence of spinodal decomposition depends in many respects on the rate of transition of the system to an unstable state and, for solutions, also on the concentration, since in highly dilute systems the formation of modulated structures is altogether difficult.[9] In many instances the criteria of spinodal decomposition in solutions at a concentration above the critical value are fulfilled only in the initial stages of phase separation. In later stages nucleation apparently occurs.

A detailed study has been made[43] of phase separation in solutions of gel-forming atactic and isotactic polystyrenes, poly(phenylene oxide) and their mixtures in various solvents.[43] It was observed that the formation of a gel is not associated with crystallisation but is due to the transition of the system to the region of an unstable state on the phase diagram and the formation (as a result of fine dispersion) of microregions enriched in the polymer, the glass points of which are sufficient for the fixation of the ends of various polymer chains in a single vitrified region. The small size of the microregions (approximately 1000 Å) and the high rate of their formation are considered as evidence for the spinodal mechanism of phase separation of the liquid–liquid type. Fusion of the gel is attributed to the fact that, when the microregions are devitrified, the sections of the polymer chains bound by them are liberated. McMaster[25,44] investigated the system comprising the styrene–acrylonitrile copolymer and poly(methyl methacrylate). This system is characterised by a phase diagram with a lower consolute temperature. The interaction parameter can be represented as the sum of the enthalpy and entropy contributions, i.e.

$$\chi = \chi_h + \chi_s \qquad (47)$$

(χ_h and χ_s are the enthalpy and entropy components of the interaction parameter) and Eqn.(27) can be written as follows:

$$\frac{\partial^2 f}{\partial c^2} = \frac{2R\chi_h}{V_1}\left(\frac{T-T_s}{T_s}\right) . \quad (48)$$

The expression for k can be formulated thus:

$$k = \left(\frac{RT\chi}{V_1}\right) l^2/6 . \quad (49)$$

In this case the optimum wavelength of the spinodal decomposition is given by the relation

$$\lambda_m = 2\pi l \left(\frac{3\chi_h}{\chi T} \cdot \frac{T_s - T}{T_s}\right)^{-1/2} . \quad (50)$$

Thus, by neglecting the entropy contribution to the interaction parameter, it is possible to obtain Eqn.(28).[23] The development of phase separation microregions in time has been observed experimentally by transmission electron microscopy.[43] It is significant that, with increase of the heat treatment time, there was a gradual increase of the content of one of the components in the developing microregions. The diffuse interfacial layers then gradually became sharper and it was actually possible to observe the early stages of the coalescence of the microregions. The size of the microregions in the given stages of phase separation is approximately 50–100 nm. The interlinking of various microregions is characteristic of the early stages of the decomposition. For a composition remote from the critical composition, a very slow coalescence process, controlled by the Ostwald ripening mechanism, takes place after the attainment of equilibrium phase compositions.[45] Accordingly, the increase of the volume of the microregions of the disperse phase as a function of time is expressed by the relation

$$d^3 = d_0^3 + 64\tau (x_c V_m) Dt/9RT , \quad (51)$$

where d_0 is the diameter of the microregions after they have attained the composition of the equilibrium phases, x_c the mole fraction of the component entering into the composition of the disperse phase, V_m the molar volume of the given component, τ the disperse phase–matrix interfacial tension, and D the diffusion coefficient for the matrix phase. Using Eqn.(51), McMaster estimated the diffusion coefficient, which proved to be 9×10^{-16} m^2 s^{-1} for 538 K.

The data obtained for the phase separation of mixtures having the critical composition show that a relation of type (1) is applicable only to the description of the earliest stages of decomposition. In particular, as a result of heat treatment at 453 K, it is possible to observe in the course of only 4.4 min the simultaneous increase of the difference between the compositions of the microregions and the size of the latter. Thus, the use of the non-linear version of the Cahn–Hilliard relation of type (14) is now necessary for the description of the kinetics of phase separation.

McMaster[44] estimated the diffusion coefficient in mixtures having the critical composition by means of the relation

$$R(\lambda_m) = \left(-\Omega \frac{\partial^2 f}{\partial c^2}\right) \frac{2\pi^3}{\lambda_m^2} , \quad (52)$$

which follows from the Cahn–Hilliard theory. Accordingly it was found that the diffusion coefficients at 453 and 483 K are 2.6×10^{-18} and 3.3×10^{-17} m^2 s^{-1} respectively.

Thus McMaster was able to explain on the basis of the Cahn–Hilliard theory the most characteristic features of the early stages of the spinodal decomposition of a polymer–polymer system. He predicted correctly the scale level of the separation, which proved to be greater than in systems based on low-molecular-weight components.

In particular, the experimental determination of the diffusion coefficients in the early stages of the decomposition of a system having the critical composition and in the Ostwald ripening of the disperse phase in a system whose composition is remote from the critical composition must be recognised as specially important. A virtually new feature of the interpretation of the phase separation phenomena in polymer systems involves the explanation of the increased rate of growth of the phase separation microregions owing to coalescence due to the viscous flow of the components in "channels" formed by the interlinked structures. The appropriate analysis based on the use of a modified form of the relations for the stability of anisodiametric inclusions[46] yields a satisfactory agreement with experiment.

Nishi et al.[47] investigated the phase separation in the polystyrene (PS)–poly(methyl vinyl ether) (PMVE) system by NMR, light transmission, and optical microscopic methods. This system is also characterised by the presence of a lower consolute temperature. On the basis of morphological observations, the authors noted two types of phase separation in the systems investigated. Phase separation either proceeds at a high rate, giving rise to a characteristic network of interlinked microregions of approximately identical size, or, during slow phase separation, the microregions are spherical in shape from the very beginning. In the former case the microphase structure becomes finer as the temperature increases and in the last stage of the phase separation the microregions grow rapidly, remaining interlinked, and then either break up into small spheres or merge into macrospheres. In the latter case the dimensions of the microregions are small compared with the periods of interlinked structures.

Data obtained by pulse NMR confirmed the continuous variation of the composition of the microregions with time, which agrees with the hypothesis of the spinodal mechanism of the phase separation. Another piece of evidence for the spinodal mechanism is provided by the estimate of the quantity $R(q_m)$ in the Cahn–Hilliard equations, according to which the kinetics of the variation of the composition of the phase separation microregions can be described by the relation

$$c - c_0 = A(q_m) \exp[R(q_m)t] \cos q_m x \quad (53)$$

when

$$R(q_m) = \frac{1}{2} q_m^2 D \quad (54)$$

In the present case the quantity c represents the concentration of PMVE in the phase enriched in polystyrene. On this basis, it follows from Eqn.(53) that the total decrease of Q (of the content of PMVE) in the given phase during phase separation is described by the expression

$$Q = \left[\int_{\pi/2q_m}^{3\pi/2q_m} (c - c_0)\, dx\right]^3 = \left[\frac{2}{q_m} A(q_m)\right]^3 \exp(3R(q_m)t) . \quad (55)$$

We have the following time variation of $\ln Q$:

$$\ln Q = 3 \ln\left[\frac{2}{q_m} A(q_m)\right] + 3R(q_m)\, t \quad (56)$$

whose slope is $3R(q_m)$. The quantity $\ln Q$ is estimated from NMR data. The positive value of $R(q)$ shows that the concentration fluctuations become more intense with time, i.e. in the system containing 50% PMVE at 403 K spinodal decomposition takes place. If q_m is estimated from morphological data, we have for the diffusion coefficient

$$D = -2R(q_m)/q_m^2 = -2.8 \cdot 10^{-17} \text{ m}^2 \text{ s}^{-1} \quad (57)$$

when

$$R(q_m) = 3.82 \cdot 10^{-4}\ \text{c}^{-1};\ q_m = 5.24 \cdot 10^{6}\ \text{m}^{-1}. \quad (58)$$

A negative value of D indicates active transport in the system which is in the region of unstable states on the phase diagram.

The quantity χ, found on the basis of the Debye–van Aartsen theory, is −0.42 at 373 K, $k = 37 \times 10^{-13}$ J m^{-2} (in 1 m^3 of PMVE), and $f'' = -4.1 \times 10^6$ (in 1 m^3 of PMVE). The temperature of the spinodal for the given composition is 391 K and $l \cong 58$ nm.

Thus, on the basis of rigorous quantitative data, the spinodal mechanism of the phase separation in the PS–PMVE system has been demonstrated[47] and the principal characteristics of the phase separation process have been determined. As in the study of the phase separation in the system comprising the styrene–acrylonitrile copolymer and poly(methyl methacrylate) examined above, the periodicity of the modulated structure is much greater than in systems based on low-molecular-weight components. In particular the value of $\langle R^2 \rangle^{1/2}$ found by Nishi et al.[47] is very close to the radius of an unperturbed Gaussian coil. This is in full agreement with the de Gennes–Pincus theory.

The influence of particular factors, which determine the characteristic features of spinodal decomposition, has been examined in a number of studies. In particular, a study[48] has been devoted to phase separation in thin films of the PS–PMVE system. The authors showed that the conditions for spinodal decomposition then depend on the chemical nature of the support and on the thickness of the film. The influence of vitrification and of the presence of a low-molecular-weight component on the phase separation processes in the poly(phenylene oxide)–(*p*-chlorostyrene–*o*-chlorostyrene) copolymer system has been investigated.[49] A very sophisticated low angle technique for the investigation of the X-ray emission spectrum, involving the application of a position-sensitive detector, was used.

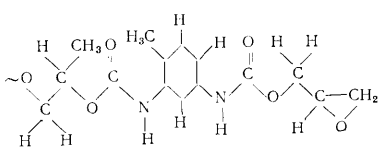
V. CHARACTERISTIC FEATURES OF PHASE SEPARATION IN BLOCK SYSTEMS

The results of a large number of theoretical[50–54] and experimental[55–60] studies show that phase separation is observed under certain conditions in high-molecular-weight compounds whose molecular chains consist of an alternation of blocks of different nature. As a result, microregions with equilibrium composition, whose size and shape depend on the "architecture" of the molecular chains and on the volume fraction of each block, are segregated. Since block polymers can be usefully treated as multicomponent polymer systems as regards phase separation, the same conditions for phase separation (based on the existence of binodals and spinodals) are valid for them as for the systems based on chains of different types not linked chemically. At the same time the results of theoretical and experimental studies have shown that the appearance of differences from traditional multicomponent systems is to be expected for polymeric materials of this kind. It must be assumed that such differences are capable of influencing significantly the phase separation processes and the final structure of multiphase systems.

Evidently, in those cases where the block copolymer relaxes fairly slowly from the spatially homogeneous state, the formation of a microphase structure can take place via the spinodal decomposition mechanism. This problem was considered for the first time with adequate rigour in two investigations[59,60], where it was shown that, whereas the condition for instability in homopolymer blends is considered only as regards instability with respect to separation into infinite homogeneous phases (with a wavenumber $q = 0$), for block copolymers it is considered as regards instability with respect to separation into microphases with a characteristic period of spatial inhomogeneity defined by the wavenumber $q = q_0 \neq 0$.

In the region of stability of a spatially homogeneous state, any small inhomogeneity decays exponeitially with a characteristic relaxation time. As the spinodal is approached, the relaxation times increase and on the spinodal become infinite. In the region of unstable states the amplitude of the inhomogeneities to which correspond negative eigenvalues of the matrix G_q^{-1} (the inverse matrix of the pair correlation functions in q-space) increases exponentially, resulting in the breakdown of the spatially inhomogeneous state. The periodic inhomogeneities with wavenumbers in the specific range $q_1 < q < q_2$ then grow, while the fluctuations with $q < q_1$ and $q > q_2$ again dissipate. After a time, the above range of wavenumbers becomes narrower until the formation of a heterogeneous structure with a characteristic period d_0 and the amplitude of the inhomogeneity increases exponentially. For "highly blended" heteropolymers, the period of the heterogeneous structure is of the order of magnitude of the correlation radius in the system of ruptured units. An increase of the average length of the chemically homogeneous sections results in an increase of the equilibrium values of the periodicity.

In connection with the characteristic features of the equilibrium microwave structure of block polymers, an interesting analogy, observed, on the one hand, in the behaviour of the block copolymers and, on the other hand, in that of multicomponent systems which decompose in the region of unstable states of the phase diagram, merits mention.[61] The point is that the transition from a one-phase solution of the blocks to the state of microphase separation is observed for block copolymers of the styrene–butadiene and styrene–butadiene–styrene systems as the temperature is reduced. A higher degree of microphase separation corresponded to a lower temperature. This was manifested by a gradual increase of the intensity of the low-angle X-ray scattering maxima with decrease of temperature. As shown previously, such phenomena characterise the spinodal decomposition of binary systems.[15] The analogy in the changes in the low-angle scattering curves proved extremely close; together with the characteristic increase of the intensity of the maxima, a decrease of the intensity in the "tail" section of the scattering curve and the presence of a common point of intersection of all the curves (cross-over) have been observed. Taking this factor into account, by analogy with Eqn.(18), Roe et al.[61] proposed the following expression for the intensity of the low-angle scattering in block systems in a state of equilibrium at different temperatures:



$$I(q, \chi) = I(q, 0) \exp(\alpha(q)\chi)\ . \quad (59)$$

Here the multiplier $\alpha(q)$ corresponds to the amplification factor used to describe the spinodal decomposition process and it is assumed that the thermodynamic interaction parameter varies with temperature in accordance with Eqn.(26). The multiplier $\alpha(q)$ has a maximum at $q = q_m$ and is zero at $q = q_c$. The ratio q_c/q_m is close to 1.5 (in the case of spinodal decomposition $q_c/q_m = \sqrt{2}$).

The temperature variation of the logarithm of the intensity of the low-angle scattering for two- and three-block copolymers of the type investigated is linear. This makes the analogy with the changes in the intensity of the low-angle scattering in spinodal decomposition quite unambiguous.

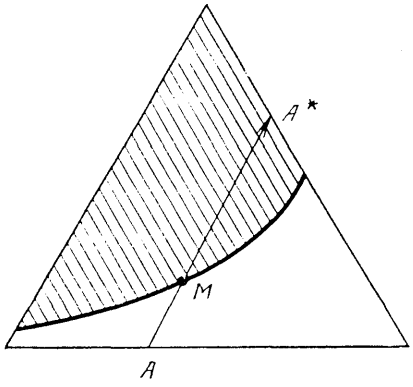
It seems natural to examine the question whether this analogy in the behaviour of block copolymers in equilibrium at different temperatures and blends in significantly non-equilibrium states in the course of spinodal decomposition is fortuitous. It is known that the increase of the period of the inhomogeneous distribution of the components in spinodal decomposition is limited by the finite rate of their diffusion. The latter is determined by the multiplier Dq^2 in Eqn.(11). The possibility of a decrease in the wavelength of the spinodal decomposition is limited by the increase of the free energy of the system [the term $2kq^2$ in Eqn.(11)]. An expression analogous to Eqn.(11), which determines the stability of the periodic microphase structure of systems of the same kind, is also valid for block copolymers at different temperatures. Taking into account the above analogy with the phenomenon of spinodal decomposition, in the case of block copolymers a multiplier similar to Dq^2 should reflect the fact that the microregions based on blocks of any kind are limited in size from below by the size of the corresponding molecular coils. Since the shape of the latter can be represented by the diffusion equation, it is quite possible that the geometrical effect indicated is associated with a multiplier proportional to q^2. On the other hand, the multiplier $f'' - 2kq^2$, which determines the increase of the size of the phase separation microregions, usually occurs in the thermodynamics of inhomogeneous liquid mixtures[8] and is therefore applicable to the description of block copolymers.

It is noteworthy that the phenomena examined above, associated with the microphase separation in block copolymers, have been observed[61] in relation to two- and three-block copolymers with a comparatively high molecular weight. It is all the more interesting that we observed a similar temperature variation of the intensity of the low-angle X-ray scattering for oligomers consisting of a single flexible small block (a butadiene–isoprene copolymer with a molecular weight of 4500) and two quite small terminal rigid blocks,[89]

each of which has a molecular weight of approximately 300. At 433 K this oligomer is characterised by such a weak level of low-angle scattering that it can be regarded as "transparent" in the X-ray emission spectrum. With decrease of temperature, the intensity of the low-angle scattering increases and a distinct maximum (Bragg period 8.3 nm) gradually appears on the intensity curve. In the temperature range up to 293 K its positions remains unaltered.

Thus, when the temperature is varied from 433 to 293 K, a microphase structure is formed in the given oligomer. It follows from the results obtained that the degree of enrichment of the phase separation microregions in a particular component increases under these conditions. This shows that a phase diagram with an upper consolute temperature is characteristic of a block copolymer treated as a binary system. Analysis of the dependence of the logarithm of the scattering intensity on the reciprocal of temperature shows that it is linear. Thus, on the basis of the characteristic features of the low-angle scattering curve and the validity of the Eqn.(59), one may conclude that the temperature variation of the changes in the microphase structure of the given oligomer is analogous, as in the study of Roe et al.,[61] to the structural changes observed in spinodal decomposition.

VI. PHASE TRANSFORMATIONS IN MULTICOMPONENT POLYMER SYSTEMS OCCURRING AS A RESULT OF CHEMICAL REACTIONS



The systems examined above by no means exhaust all the versions of polymer systems potentially capable of undergoing phase separation in the region of unstable states on the phase diagram. It is known that phase separation can occur for reasons other than a change in temperature, pressure, or composition. There is an extremely wide range of systems (particular for high-molecular-weight compounds) for which phase separation is induced by chemical processes: degradation, polymerisation, depolymerisation, etc. In this case the systems can be of the simplest type (the monomer–polymer type) or can be very complex (for example, interpenetrating polymer networks based on several network polymers). The cases where the partial polymerisation of the monomer leads to the phase separation of the system into microregions enriched in the polymer and monomer are particularly widely known. The same is possible also in the partial depolymerisation of a macromolecular polymer.

The phase separation processes occurring on formation of carbon fibres as a result of the high-temperature treatment of polyacrylonitrile or cellulose hydrate fibres (carbonisation or graphitisation) are extremely characteristic and of practical importance.[62] This is known to entail the formation of a microporous structure characteristic of hydrocarbons with a pore size of the order of several nanometers.[63–66] The volume fraction of such micropores can reach 10%. Thus, as a result of carbonisation (heat treatment at approximately 1300 K) or graphitisation (heat treatment at approximately 2300–2800 K), a comparatively homogeneous polymeric material is converted into a heterogeneous carbon–micropores system. This can be explained by the fact that, in the course of the high-temperature treatment, the polymer is converted by chemical reactions into a carbonaceous material and gaseous product dissolved in the latter. At a specific stage of the transformations, phase separation takes place with segregation of liquid and gaseous phases, the latter forming the micropores. The very small sizes of the micropores and their comparatively narrow distribution can be regarded as a consequence of the fact that phase separation takes place via the spinodal decomposition mechanism and not via nucleation and growth.

The phase separation processes in the formation of a network polymer in an oligomer–solvent system have been investigated in relation to the polymerisation of oligoacrylate esters. The initial system consisted of a solution of αω-dimethacrylatebis(diethylene glycol phthalate) in tetrahydrofuran or in its mixtures with toluene or hexane. The polymerisation was carried out via an anionic mechanism. It was shown that the polymerisation of the oligomer leads to a sharp increase of the intensity of the low-angle X-ray diffraction. The cause of such appearance of "turbidity" is microphase separation of the system at the level of approximately 1–100 nm. The characteristics of the microphase structure, estimated from structural data, proved to depend on the type of the low-molecular-weight solvent. This is manifested by the fact that the curves for the distribution of the microheterogeneous regions with respect to size are characterised by different widths.

Since the microheterogeneity thus produced is a result of phase separation in the oligomer–solvent–network polymer system, we shall consider a hypothetical phase diagram for such a system (see Figure). The shaded part of the diagram represents a two-phase region and the unshaded part a one-phase region. The sequence of states occurring in the

system during the polymerisation of the oligomer is indicated by the $A-A^*$ straight line. In the initial state the solution of the oligomer in the solvent constitutes a one-phase system. As the oligomer is consumed, the system intersects the binodal at point M and enters the region of two-phase states. It then tends to separate into phases enriched in the polymer and the solvent. Bearing in mind the traditionally small extent of the region of metastable states in systems based on high-molecular-weight components, one may expect that the nucleation processes play an insignificant role and, after a short time has elapsed following the transition through the binodal, the system enters the region of unstable states on the phase diagram where its separation takes place via the spinodal decomposition mechanism. This is confirmed by the small sizes of the phase separation microregions and their comparatively narrow distribution.

Phase diagram for a polymerising polymer–oligomer–solvent network system. Initial state (A): oligomer–solvent; final state (A^*): network polymer–solvent. During the polymerisation process, the system passes through a sequence of states corresponding to the AA^* straight line. The region of two-phase states is shaded.

Together with phase separation processes, a three-dimensional network of chemical bonds is formed in the system. The cross-linking establishes a definite inhomogeneity in the distribution of the components and hence hinders the further occurrence of the phase separation processes required for the attainment of the state of equilibrium. This leads to the formation, in a system undergoing polymerisation, of a non-equilibrium microphase structure which is a result of incomplete phase separation. For systems containing different solvents, the phase diagrams are characterised by different positions of the phase equilibrium curves. Accordingly the system begins to separate at different times, i.e. for different compositions. Consequently cross-linking leads to different instants of phase separation and different levels of heterogeneity.

The gel produced as a result of polymerisation is a system with alternation of microregions enriched in the network polymer or the solvent. The absence of interference maxima from the low-angle scattering curves shows that polymerisation results in the fixation not of the initial stages of the spinodal decomposition, characterised by a regular alternation of microregions, but of later stages in which this periodicity has already disappeared. The latter may be a consequence of the polydispersity of the microregions formed during later stages of decomposition owing to coalescence.

We believe that such treatment of the appearance of heterogeneity in network polymers formed in the presence of a solvent is more constructive and more general compared with the ideas concerning the appearance of heterogeneity owing to microsyneresis used for purposes of this kind.[67] In this connection it is noteworthy that the thermodynamics of chemical reactions is in essence the non-linear thermodynamics of irreversible processes. The appearance of heterogeneity in reacting systems is therefore the rule rather than the exception. In those cases where diffusion fluxes of the components in systems of this kind are directed along the concentration gradient, diffusion smooths out the local inhomogeneity induced by the occurrence of the reaction. However, if the system is in the region within the spinodal as a result of polymerisation, the diffusion fluxes change direction and do not lead to the smoothing out of the local inhomogeneities. Thus the heterogeneity observed in cross-linked gels can be explained as a result of the formation of dissipative structures (see below), which become fixed as a result of cross-linking.

The kinetics of phase separation in the formation of network block copolymers have been studied in relation to a system whose initial components are oligoisoprene dihydrazide with a molecular weight of 3100 and the diglycidyl ether of di(4-hydroxyphenyl)propane (DGEHP).[68] The system was hardened at a temperature above the point corresponding to the appearance of turbidity (at 383 K). Throughout the hardening process, the scattering of X-rays in the reaction mixture was recorded continuously. The system was initially completely "transparent", but, after a definite polymerisation time had elapsed, a gradual appearance of turbidity was observed. The angular dependence of the X-ray scattering intensity then showed an interference maximum whose magnitude increased with time.

Thus the blend of the initial oligomers is a one-phase system and the formation of a system of chemical bonds between them leads to microphase separation at the level of several nanometers. The time dependence of the logarithm of the scattering intensity in the initial stages of the polymerisation obtained from diffraction data is linear. This shows that in the initial stages of phase separation the rules governing spinodal decomposition are fulfilled in the case considered. This effect, which has not been observed hitherto in systems of the block copolymer type, permits the conclusion that the kinetics of the phase separation of block systems do not differ fundamentally (at least in the early stages) from those of the phase separation of the usual binary systems in the region of unstable states on the phase diagram and involving the spinodal decomposition mechanism.

Studies of the above network polymer over a wide range of temperature have shown that, in the range from 293 to 533 K, the state of microphase separation is maintained. However, the characteristic features of the diffraction patterns discussed in the previous section, which are characteristic of linear block polymers and oligomers, are not then observed. This fact probably indicates significant deviations of the microphase structure of the network polymer from the state of equilibrium at different temperatures. It is to be supposed that this deviation is determined to a large extent by the presence of a three-dimensional network of chemical bonds, which limits the mobility of blocks of different nature and leads to the appearance of non-equilibrium structures. As a result of this, the state of the system can no longer be described from the standpoint of equilibrium thermodynamics.

Microphase separation is a typical process, which occurs also in the formation of interpenetrating polymer networks (IPN).[69,70] In particular, this has been convincingly demonstrated for IPN based on polyurethane and the styrene–divinylbenzene copolymer. It follows from the low-angle scattering data obtained for the above system that the formation of the IPN leads to a significant alteration of the profile of the low-angle scattering curves. Consequently, the formation of microregions enriched in the matrix and penetrated by networks is characteristic of such IPN. Between the regions indicated, there are transitional zones with a smooth profile of the variation of concentration. This picture of the microphase structure indicates the formation of the IPN of "diffuse" microphase regions characteristic of the early stages of the spinodal decomposition. The absence of the interference maxima characteristic of the spinodal decomposition of the system from the low-angle scattering curves for the IPN considered shows that partial coalescence of the segregated microregions has taken place in the system, as a result of which the periodicity in their disposition has been significantly impaired.

Thus network polyblock polymers and IPN are characterised by the presence of stable "diffuse" phase separation microregions, i.e. the degree of segregation of the components in such microregions can be extremely remote from equilibrium values. This quantity is defined by the expression[71,72]

$$\alpha = \overline{\Delta\rho^2} \Big/ \overline{\Delta\rho_c^2} = \overline{\Delta\rho^2} \Big/ [\varphi(1-\varphi)(\rho_1-\rho_2)^2] \quad , \qquad (60)$$

where $\overline{\Delta\rho^2}$ is the average square of the electron density fluctuation calculated from the absolute low-angle scattering intensity, $\Delta\rho_c^2$ the theoretical estimate of the average square of the electron density fluctuation obtained on the assumption of microphase separation at the level of the pure components, ϕ the volume fraction of one of the components, and ρ_1 and ρ_2 are the electron densities of components A and B respectively. A detailed analysis of data on the relation between phase separation and the degree of segregation in various multicomponent systems undergoing phase separation has been carried out in a monograph.[72] We shall consider the question of the relation between two-phase systems and systems with a comparatively high but nevertheless remote from unity degree of segregation of the components.

Numerous experimental data[72] show that the degree of segregation of the system components in microphase separation depends on many factors: the presence or absence of transverse chemical bonds in the system, the cross-linking density, composition, etc. Evidently in the phase separation beginning after the system has passed from the one-phase state to the region of unstable states, the stable entanglement nodes prevent the separation of fragments of different chemical nature, as a consequence of which the system is held in a state of "enforced" blending. This should lead to an additional contribution to the free energy of the system.

Thus the situation is to some extent similar to the phenomenon of the stabilisation of metallic alloys within the region bounded by the limited chemical spinodal. However, for polymer systems, it is at present impossible to obtain an exact estimate of the contribution of the elastic energy arising under these conditions. Even for much simpler systems of the type of low-molecular-weight glasses, it has been shown[16] that the spinodal decomposition is complicated as a result of the possibility of the relaxation of stresses leading to a time variation of the elastic energy. In order to take it into account, the elastic energy at time t can be converted into the elastic energy at time $t + \Delta t$ in accordance with the equation

$$E_{rel}(t+\Delta t) = E_{unrel}(t)\exp(-2\Delta t/S), \qquad (61)$$

where $S = \nu_\nu \Theta M^0/\lambda^2 G_S$, ν_ν is the shear viscosity, G_S the modulus of shear, M^0 the mobility of the molecules, and Θ the thermal energy per molecule.

It is quite evident that the contribution of the elastic energy in complex multicomponent systems is minimal at the beginning of the phase separation process and should increase with increase of the difference between the compositions of the microregions. As a result, when the thermodynamic driving force of the phase separation is balanced by the contribution due to elastic stresses caused by the entanglements of fragments of the network structure, the system is stabilised in a state of partial separation of the components.

The limit of the stability of the stressed state of a polymer system is in this case characterised by the position of the curves located below the chemical spinodal. This curve reflects the real condition governing the transition to the two-phase state. We have called it the lower real spinodal. We note yet again the significant difference between the concept of the coherent spinodal introduced by Cahn and the concept of the real spinodal which we have resorted to in order to describe the limit of stability in the transition to the two-phase state of polymer systems.[73] The coherent spinodal is known[9,10] to be a curve outside which no processes involving the decomposition of the one-phase solution are possible. The real spinodal is a curve separating the state of partial phase separation from the two-phase state. It follows from Eqn.(17) that, for systems with an upper consolute temperature (UCT), the real spinodal passes below the corresponding chemical spinodal. It must be assumed that for certain systems, such as polyblock network polymers or interpenetrating polymer networks, the region of unstable states within the lower real spinodal lies far below the chemical spinodal and may be altogether inaccessible.

The results of temperature studies of the epoxydiene networks examined above have shown that systems of this kind can be not only in a state of enforced blending but also in a state of enforced microphase separation of the components. If the presence of a UCT is characteristic of systems of this kind, then completion of the transition to the state of a one-phase solution corresponds to a curve lying above the chemical spinodal. This curve can be called the upper real spinodal. Its position is determined by the elastic stresses, which are necessary, in the absence of free migration of blocks of different chemical nature, for the transition of the system with microphase separation to the one-phase state by heating.

Thus, depending on the previous history, multicomponent polymer systems with a three-dimensional network of chemical bonds can possess a more or less extensive region in the vicinity of the chemical spinodal in which states with partial phase separation of the components are realised. Evidently, in the transition from the one-phase state to the two-phase state, one-phase systems with an equilibrium distribution of composition fluctuations exist above the chemical spinodal. Below the real spinodal, there are two-phase systems with a definite degree of dispersion.

In the system between the chemical and real spinodals, there are also microregions with an inhomogeneous distribution of the components. However, they can no longer be regarded as equilibrium composition fluctuations, because thermodynamic forces, tending to cause phase separation, displace the system from the state of equilibrium towards an approach to the two-phase state. Despite the failure of the phase separation process to reach completion, the region of states between the chemical and real spinodals is relatively stable. However, in terms of the concept of "one-phase–two-phase system", within the framework of which we operate

in considering binary systems, there are no analogues of such intermediate states.

Systems of this kind can be usefully segregated from the set of one- and two-phase systems. The expression "concentration fluctuation" really has no bearing on the microregions (states) in the system located in the region of the phase diagram between the chemical and real spinodals, because it is applicable only to one-phase systems. Nor can they be called microphase regions, because the latter are characteristic only of two-phase systems. Bearing in mind that the microregions of inhomogeneity in systems intermediate between one- and two-phase systems are in principle capable of passing into microphase regions, they can be regarded as virtual microphase regions and can be referred to accordingly as phasons.[73] The system located in the region of states between the chemical and real spinodals is a system of the phason type.

We shall consider how such a system differs from the "classical systems" undergoing spinodal decomposition in the Cahn–Hilliard theory. According to the conditions in the phase separation mechanism, the term Y in Eqn.(17), which defines the limit of instability (i.e. the onset of spinodal decomposition), can be a function of time, temperature, the degree of segregation attained at the given instant, etc. After the system has reached the region of the chemical spinodal and, following the loss of stability, processes increasing the contribution of Y develop in it in the course of time, after which, following the attainment of a particular instant (as a consequence of relaxation processes or chemical reactions), they diminish this contribution. Therefore, having begun to decompose, the system can be additionally stabilised at some stage or the stabilisation effect vanishes completely. If this condition did not obtain, then, on transition through the chemical spinodal, the system would have undergone no changes whatever. This factor actually determines the appearance of phason systems, the main characteristic of which is the degree of separation into phases. Specific dimensions of the order of magnitude of tens of nanometers are characteristic of the corresponding microregions of heterogeneity.

VII. EXAMINATION OF SPINODAL DECOMPOSITION WITHIN THE FRAMEWORK OF THE FORMALISM OF THE NON-LINEAR THERMODYNAMICS OF IRREVERSIBLE PROCESSES

The conditions for thermodynamic equilibrium in isolated systems is an entropy maximum, while for systems at a fixed temperature it is a minimum in the Helmholtz free energy. When these requirements are taken into account, the corresponding systems can be described by equations whose solution corresponds to the so-called thermodynamic branch. If the action on the system is varied in such a way that the latter moves further and further away from equilibrium, non-equilibrium thermodynamics makes it possible to formulate an adequate condition for the stability of the thermodynamic branch.[74,75] On the other hand, if this condition is not fulfilled, then the thermodynamic branch can become unstable and the appearance of a new structure characterised by coherent behaviour will become possible in the system.

Thus a new type of organisation, linking the coherent space–time behaviour of the system to dynamic processes within it, can arise outside the region of stability of the thermodynamic branch. In the studies of Prigogine and co-workers,[74,75] it has been shown that the so-called dissipative structures appearing under these conditions differ significantly from the "equilibrium structure" studied by classical thermodynamics. An analogy has been noted,[76,78] between the alternation of low- and high-energy regions, characteristic of the dissipative structures, and the appearance of modulated structures as a result of spinodal decomposition. Having expressed the thermodynamic forces and fluxes in terms of concentration gradients, Prigogine showed that the following relation is valid for the increment in the generation of entropy near the stationary state of the system:

$$\Delta P = \int_V \left[\frac{1}{2} \delta^2 P + \sum_{kl}' R_{kl} \nabla c_k \nabla c_l + \ldots \right] , \qquad (62)$$

where

$$R_{kl} = D_{kl} \left(\frac{1}{T} \frac{\partial \mu_l}{\partial c_k} \right) .$$

For a binary system, the last term of Eqn.(62) is analogous to the term $k(\nabla c)^2$ in Eqn.(2) and $\frac{1}{2}(\partial^2 f/\partial c^2)(c - c_0)^2$ corresponds to $\frac{1}{2}\delta^2 P$ in the expansion of the increment of the generation of entropy. Thus the spinodal can be regarded as representing the condition for the equality of the excess generation of entropy to zero. Comparison of the above relations makes it possible to express the wavelengths of the modulated structure in spinodal decomposition in the following form

$$\lambda_m = \left[-8\pi (c - c_0)^2 \sum_{kl}' R_{kl} + \ldots \Big/ \sum_k \delta J_k \delta X_k \right] , \qquad (63)$$

where J_k and X_k are the generalised flux and force. Consequently the formation, as a result of phase separation, of diffuse microregions intermediate between the initial one-phase and the resulting two-phase systems can be regarded as a result of the breakdown of the stability of the phase separation process within the spinodal. The thermodynamic forces then tend to a minimum and the kinetic fluxes can increase in one part of the system and decrease in another, leading to the formation of dissipative structures.

---o0o---

As already mentioned, the theory of spinodal decomposition was developed approximately 20 years ago by Cahn, Hilliard, Hillert and their successors to describe the processes occurring in metallic alloys. In the thermodynamics of polymers this period has been characterised by an intense development of a general theory of polymer solutions. During the last 20 years, much attention has been devoted to the application of the Flory–Huggins theory of solutions to the description of polymer blends and their thermodynamic compatibility has come to be regarded as one of the most important factors determining the operational properties of polymeric materials. Studies on spinodal decomposition in polymer system began to develop only in the last 10 years. We believe that this has been due to the increasing practical application of polymer blends, as shown, in particular, by the publication of a number of large monographs on these questions.[79–82]

The data which we have considered show that the spinodal mechanism of phase separation in polymer blends is the decisive factor in structure formation in such blends and hence in establishing the entire set of the physicomechanical properties of these materials. In the first place one should note polymeric composite materials and the clear tendency to employ in the latter second generation binders. Such binders may be either alloys and blends of thermoplastic polymers or systems of the type of interpenetrating, half-interpenetrating, and segregated networks,[83] which should

be regarded as hybrid binders.[88] A characteristic feature of second generation binders is that in essence they are themselves composite materials whose properties are determined to a large extent by their phase state and, as can be seen from the foregoing, by the character and the degree of completion of the phase separation in hybrid binders during their formation. An important task in the thermodynamics of polymer–polymer blends is therefore the accumulation of experimental data and the determination of the fundamental characteristics of the phase separation via the spinodal mechanism as a function of the parameters of the thermodynamic interactions of the components, the conditions in their polymerisation or polycondensation, the cooling regimes, and similar factors.

Only the main theoretical postulates have now been formulated and the applicability of the theory to the description of the experimental data has been demonstrated in relation to what are so far limited instances. The question of the relation between the phase separation conditions and the conditions for the interaction of binary polymer systems with fillers is important for the creation of composite materials based on second generation binders. Only a limited number of experimental data are so far available on this question.[84–87] At the same time one may claim that the introduction of a filler into the system can exert at least two different effects on the spinodal decomposition. If one of the components of the binary system interacts preferentially with the surface, the filler should promote an increase of the rate of phase separation. If the energies of the interaction of the components with the surface are approximately the same, then, as a consequence of the adsorption effects and the overall decrease of molecular mobility near the interface, phase separation processes may be inhibited. It can be shown that, under certain conditions, there is also a possibility of a change in the positions of the phase equilibrium curves (binodal and spinodal) under the influence of the surface of the solid.

The data presented in this review show that the structures arising as a result of spinodal decomposition in polymer–polymer systems then remain in a metastable state, i.e. as a rule the spinodal decomposition does not reach the stage where the system is fully separated into two coexisting phases. Otherwise studies on these lines would have been only of purely theoretical interest. However, it follows from this that evidently the most adequate description of the structures produced can be achieved using the principles of irreversible thermodynamics and the concept of dissipative structures. We believe that studies on polymer–polymer systems within the framework of the formalism of irreversible thermodynamics should have priority in the future over studies based on the apparatus of the classical thermodynamics of phase equilibria.

The Preparation of Monomers for the Synthesis of Fluorocarbon Polymers by the Oxidation of Fluoro-olefins

L.F.Sokolov, P.I.Valov, and S.V.Sokolov

The oxidation reactions of fluoro-olefins are examined: the conditions under which they take place, the characteristic features of the mechanism, and the composition and structure of the products formed. Attention is concentrated on the oxidation reactions of industrial perfluoro-olefins, namely tetrafluoro-ethylene and hexafluoropropene, and also on the methods of synthesis of the most important products of the oxidation of fluoro-olefins - fluorocarbonepoxides and oligomeric perfluoro-polyesters.
The characteristics of the physicochemical properties and the main applications of oxygen-containing products of the oxidation of fluoro-olefins are discussed.
The bibliography includes 154 references.

CONTENTS

I. Introduction 711

III. Electrochemical and heterogeneous-catalytic oxidation of fluoro-olefins 713
IV. The oxidation of fluoro-olefins via a radical mechanism 714
V. Characteristic features of the physicochemical properties and main applications of the fluoro-olefin oxidation products 719

I. INTRODUCTION

Fluorocarbon polymeric materials (plastics, elastomers, and lubricants) play an important role in the application of atomic energy, in machine construction, in chemical industry, and in other branches of the economy by virtue of their high chemical and thermal stability. The chemistry and technology of "second generation" fluoro-polymers, namely oxygen-containing polymers, is nowadays developing vigorously. The introduction of ethers and reactive functional groups into the main chain and into the side groups of fluorocarbon polymers makes it possible to extend significantly the temperature range of their use, while retaining a high chemical stability. A way of synthesising the monomers for oxygen-containing fluorocarbon polymers was discovered in the course of the study of the oxidation reactions of fluoro-olefins.

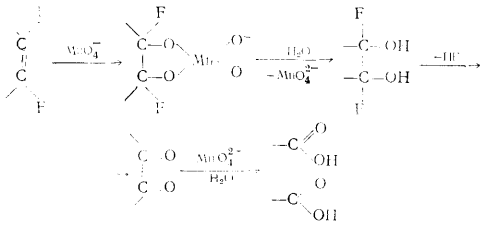
In contrast to saturated fluorocarbon compounds, which have a high chemical and thermal stability,[1,2] fluoro-olefins are readily oxidised at the double bond via both ionic and radical mechanisms and in this respect show similarity to hydrocarbon olefins. There is also a similarity in the chemical nature of the products of the oxidation of hydrocarbon and fluorine-containing olefins, but the mechanism of the oxidation of fluoro-olefins and the properties of the products have important characteristic features.

Among the products of the oxidation of fluoro-olefins, epoxides and oily products with a perfluoropolyether structure are of greatest practical interest.

Perfluoroepoxides were first obtained approximately 20 years ago by the oxidation of fluoro-olefins by a number of investigators simultaneously[3-9] and this approach to the synthesis of fluorocarbon epoxides still remains virtually the only one available.

The practical importance of fluorocarbon epoxides is indicated by the fact that the manufacture of the most important of these, namely epoxyhexafluoropropane (EHFP), was initiated in the USA in the middle 1960's.[10-12] The perfluoropolyether oils formed in the high-temperature photochemical oxidation of hexafluoropropene, are manufactured on an industrial scale under the trade name "Fomblin" in Italy and under the trade name "PEF" in the USSR.[13] A number of oxygen-containing fluorocarbon materials of practical importance have been obtained on the basis of the oxidation products of fluoro-olefins: solvents, surfactants, thermally and chemically stable fluororubbers with improved frost resistance,[14,15] perfluoropolyether oils and greases with exceptionally effective viscous-temperature characteristics,[13] fluorinated plastics with improved thermal stability,[16] perfluorinated ion-exchange membranes,[17-19] polymers with selective permeability to gases,[20] etc.

The great practical value of the above materials stimulated vigorous investigation of the oxidation reactions of fluoro-olefins. A number of reviews on the synthesis, properties, and applications of fluorocarbon epoxides[21-23] and oxygen-containing fluorocarbon polymers,[10,13,24] involving questions concerning the oxidation of fluoro-olefins, have been published in recent years, but there is no systematic review of the literature data on the oxidation of fluoro-olefins.



This review discusses what we believe to be some of the most significant questions of the mechanism of the oxidation of fluoro-olefins and the characteristics of the properties of their oxidation products. Attention has been concentrated on the oxidation reactions of two important industrial perfluorinated olefins, namely tetrafluoroethylene (TFE) and hexafluoropropene, with formation of the most important oxidation products—fluorocarbon epoxides.

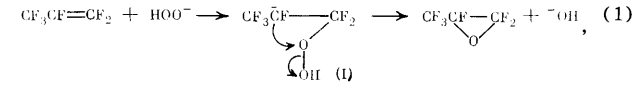
II. IONIC OXIDATION REACTIONS OF FLUORO-OLEFINS

The oxidation of fluoro-olefins via the ionic mechanism proceeds under mild conditions (atmospheric pressure, room or reduced temperature) in the liquid phase in polar solvents; the oxidants are compounds containing active oxygen: hydrogen peroxide, metal hypohalites, potassium permanganate, etc.

The most important feature of the oxidation of fluoro-olefins via the ionic mechanism is preference for the nucleophilic mechanism due to the increased sensitivity of fluoro-olefins to nucleophilic attack.[25] The epoxidation of fluoro-olefins is accompanied by the simultaneous reaction

leading to the cleavage of the carbon skeleton at the olefin double bond. The first studies were devoted to oxidation processes with dissociation of the double bond and their results have been examined in a review.[25] The most important of these methods involves oxidation with potassium permanganate in neutral or basic aqueous and acetone media. A characteristic feature of such reactions is total hydrolysis of the C–F bonds involving the carbon atoms at the double bond undergoing the dissociation; this entails the formation of carbonyl-containing products: carboxylic acids, CO_2, and ketones:[25]

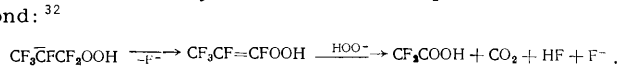
The hydrolysis of C–F bonds takes place as a consequence of the instability of the intermediate perfluorinated alcohols.[1] The partial conversion of the bound organic fluorine into an inorganic form is a serious technological disadvantage of ionic oxidation processes.



Fluoro-olefins are oxidised by hydrogen peroxide and metal hypohalites in an alkaline medium with preferential formation of epoxides accompanied by side reactions involving oxidation with dissociation of the double bond and also the total hydrolysis of the C–F bonds where the carbon atoms are also part of the double bond undergoing dissociation and the formation of carbonyl-containing products.

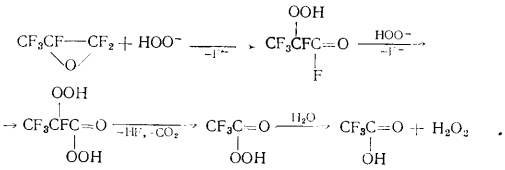
The process in which fluoro-olefins are oxidised by an alkaline solution of hydrogen peroxide, developed as early as 1967,[26] still remains one of the main procedures for the synthesis of fluorocarbon epoxides. The oxidation proceeds only in an alkaline medium and the nature of the alkaline agent has no significant influence on the process. KOH, NaOH, NH_4OH, etc. are usually employed. The reaction medium is water; below 273 K, a mixture of water with organic solvents such as methanol and ethanol is used to prevent freezing.[3,26–29] Fluoro-olefins are sparingly soluble in water and alcohol and the reaction therefore proceeds at the interface between the fluorocarbon and aqueous alcoholic phases. The pressure in the system has almost no effect on the oxidation reaction; the process is usually carried out at atmospheric pressure and temperatures between 223 and 323 K;[26] with increase of temperature, the yield of the epoxide diminishes owing to oxidation with rupture of the double bond and with decrease of temperature the rate of epoxidation is appreciably reduced.

An important feature of the method is its universality; it is suitable for the epoxidation of aliphatic fluorocarbon α-olefins,[3,26] internal and cyclic perfluoroalkenes,[30] incompletely fluorinated alkenes,[26] perfluorinated dienes,[31] etc. and the increase of the number of carbon atoms in the fluoro-olefins from 3 to 20 does not influence the rate of epoxidation.[26] However, epoxytetrafluoroethane (ETFE) cannot be obtained by this method.[3,10–12,30]



The oxidation with an alkaline solution of hydrogen peroxide is the first method of synthesis of a fluorocarbon epoxide applied on an industrial scale: the Dupont Corporation (USA) has manufactured EHFP since the middle 1960's by oxidising HFP with a 30% aqueous hydrogen peroxide in the presence of methanol and KOH at 243 K and pH of the medium above 8.[10] The yield of EHFP is then about 45%.[11,12] The EHFP obtained in this way contains only HFP and CO_2 as impurities.

The following epoxidation mechanism, incorporating a stage in which the hydroperoxide anion adds to the fluoro-olefin by a nucleophilic mechanism with subsequent elimination of a hydroxide anion, has been proposed:[10]



(1)

The intermediate anion (I) can also eliminate a fluoride ion, which leads ultimately to oxidation with rupture of the double bond:[32]

Under oxidation conditions, EHFP reacts relatively easily with the hydroperoxide anion to form acid products:[32]

The acid products formed neutralise the alkali which catalyses the oxidation. Because of this, the reaction is carried out with continuous supply of alkali to the solution in a far from catalytic amount.[33] When the addition of alkali is stopped, the process is rapidly arrested and the selectivity with respect to the oxide is reduced (Fig.1). The low selectivity (50–70%) even at a low conversion of the olefin (Fig.1) is striking. The selectivity in the epoxidation of other fluoro-olefins by hydrogen peroxide is within the same limits.[2,16]

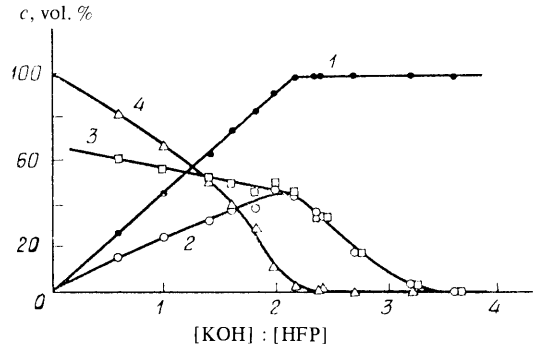


Figure 1. The influence of the molar ratio [KOH]:[HFP] on the composition of the products of the oxidation of HFP (c) with an alkaline aqueous-alcoholic solution of hydrogen peroxide at 273 K: 1) coversion of HFP; 2) yield of EHFP relative to the initial HFP; 3) yield of EHFP relative to the HFP which has reacted; 4) content of HFP in the oxidation products.[32]

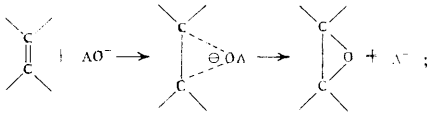
A yield of the epoxide of the order of 50% is obtained also in another familiar process: the nucleophilic oxidation of fluoro-olefins by alkali and alkaline earth metal hypohalites in an aqueous alkaline medium in the presence of an aprotic

polar solvent (acetone, diglyme) at room temperature and atmospheric pressure.[34,35]



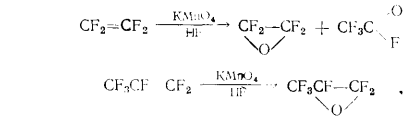
The low selectivity of the epoxidation in nucleophilic oxidation reactions of fluoro-olefins is due to the fairly high probability of the elimination of the fluoride ion from the intermediate anion (I) and the partial consumption of the epoxide in the reaction with the nucleophilic epoxidising agent.

For comparison, one may note that hydrocarbon olefins undergo epoxidation as a rule via an electrophilic mechanism and the oxidants are hydroperoxides and peracids and there is a quantitative (95–99%) yield of the epoxide and the C–H bonds are not involved.

Valuable information about the direction of attack on the double bond by the epoxidising agent and about the structure of the transition state is provided by data on the stereochemistry of the epoxidation reaction. The preferential formation of the epoxide and the stereospecificity of the epoxidation of hydrocarbon olefins by hydroperoxides and peracids are due to the specific direction of electrophilic attack on the bonding orbital of the double bond and the formation of an intermediate π-complex in the reaction[37] (see also Mathieu and Panico,[38] p.319).

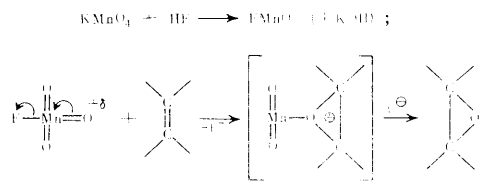
The nucleophilic mechanism of the epoxidation of hydrocarbon olefins operates only in the oxidation of αβ-unsaturated carboxylic acids by alkaline hydrogen peroxide[39] and the reaction is non-stereospecific.[40,41] The latter is due to the specific direction of the nucelophilic attack on the antibonding π* orbital of the hydrocarbon olefin[38] (p.295) and the formation in the reaction of an intermediate carbanion of type (I) in which there is ready rotation about the C–C bond.[40,41]

In this connection, a report of the stereospecificity of the nucleophilic epoxidation of fluoro-olefins by hypohalites in an alkaline medium is of special interest:[34,36] since the double bond in fluoro-olefins is depleted in electron density[1] (pp.25, 30), this indicates nculeophilic attack on the bonding π orbital of the fluoro-olefin and the formation of an intermediate cyclic π-complex in the reaction:



$AO^- = ClO^-$ BrO^- etc.

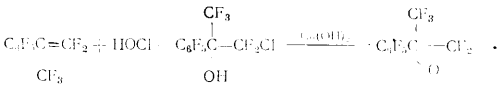
Thus, the fact that in the chemistry of fluoro-olefins electrophilic epoxidation via hydroperoxides and peracids has been replaced by reactions involving nucleophilic epoxidation by alkaline hydrogen peroxide and hypohalites via the opposite mechanism is a consequence of the radical alteration of the nature of the interaction of the double bond with the epoxidising agent on passing from olefins to fluoro-olefins. The mechanism of the attack on the double bond of the fluoro-olefin by the nucleophilic epoxidising agent is analogous to the mechanism of the attack on the double bond of a hydrocarbon olefin by the electrophilic epoxidising agent.



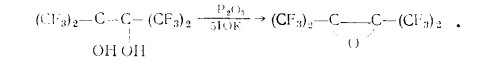
The reversal of the reaction mechanism in relation to the analogous reactions in organic chemistry is characteristic of fluorocarbons. For example, alkylation in the chemistry of hydrocarbon compounds is catalysed by acids,[38] while in the organofluorine chemistry it is catalysed by bases;[42] the catalytic role played by the proton, which is a strong acid in an aqueous medium, in organic chemistry is frequently assumed in organofluorine chemistry by the fluoride ion, which is a strong base in an aprotic medium.[1]

One example of the reversal of the mechanism is the opoxidation of fluoro-olefins by peracids discovered by Knunyants and co-workers:[43,44] methyl perfluoromethacrylate and also its derivatives are readily epoxidised by *p*-nitroperbenzoic acid in absolute ether at room temperature, but in this case the Prilezhaev reaction proceeds via a nucleophilic mechanism as a consequence of the exceptionally high electrophilicity of the perfluoromethacrylic acid ester.

The sensitivity of fluoro-olefins to electrophilic attack is low, so that their oxidation via an electrophilic mechanism is hindered. The only instance of the epoxidation of fluoro-olefins via an electrophilic mechanism is oxidation by potassium permanganate in anhydrous hydrogen fluoride at 203 K:[45]



The reaction proceeds via a stage involving electrophilic attack by manganic acid fluoride on the double bond:[45]



The ionic oxidation reactions of fluoro-olefins examined are characterised by a high rate and take place under mild conditions in reactive polar solvents (water, alcohols, HF, etc.) using as oxidants compounds with active oxygen (H_2O_2, $KMnO_4$, metal hypohalites, and peracids). The complete absence of polymeric products with perfluoropolyether and perfluoropolyperoxide structures, characteristic of radical oxidation reactions of fluoro-olefins, is striking. Overall, the ionic oxidation reactions of fluoro-olefins are characterised by a much lower selectivity of the epoxidation compared with the electrophilic epoxidation of hydrocarbon olefins.

The method of synthesis of fluorocarbon epoxides involving the dehydrogenation of halogenoalcohols in the presence of aqueous solutions of alkalies on brief (5–10 min) heating to 348–373 K has been developed:[119,120]

The epoxide is also formed on dehydration of perfluoropinacol:[21]

However, only the syntheses of fluorocarbon epoxides via fluoro-olefin oxidation reactions are of practical importance.

III. ELECTROCHEMICAL AND HETEROGENEOUS-CATALYTIC OXIDATION OF FLUORO-OLEFINS

In terms of their conditions, the chemical nature of the oxidants employed, and the character of the products formed, the reactions indicated occupy an intermediate position between ionic and radical oxidation reactions of fluoro-olefins. Metallic silver is known to have unique catalytic activity in relation to the epoxidation of ethylene by oxygen.[46–48]

Tetrafluoroethylene is also oxidised by oxygen in the presence of a silver catalyst with formation of epoxytetrafluoroethane (ETFE), carbonyl difluoride (CDF), and small amounts of perfluorocyclopropane and oligomers with a poly(difluoromethylene oxide) structure. Below 400 K, TFE is not oxidised in the presence of silver, but at a higher temperature virtually the only oxidation products are ETFE and CDF, i.e. the reaction proceeds via two pathways like the oxidation of ethylene:[47]

$$CF_2{=}CF_2 + \frac{1}{2}O_2 \rightarrow CF_2{-}CF_2{-}158\ \text{kJ}; \quad (2)$$

$$CF_2{=}CF_2 + O_2 \rightarrow 2COF_2 - 614\ \text{kJ}. \quad (3)$$

In the range 403–433 K, there is a virtually linear increase of the rates of formation of ETFE and CDF with increase of temperature (Fig. 2) accompanied by a constant selectivity of the epoxidation in the range 55–67 vol.%,[49] which agrees with the selectivity of the epoxidation of ethylene in the presence of silver.[45–47] The optimum temperature of the epoxidation of TFE in the presence of silver is 410–430 K,[49] i.e. appreciably below the optimum temperature of the epoxidation of ethylene, which is in the range 500–570 K;[45–47] with increase of temperature, CDF becomes the only product.

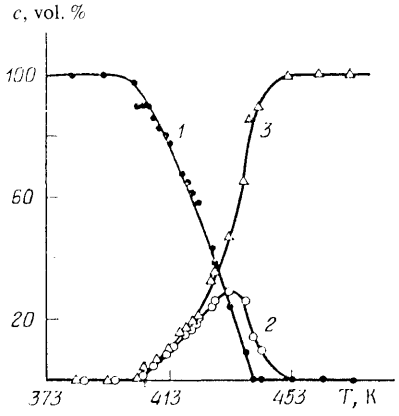


Figure 2. Temperature variation of the composition of the products of the heterogeneous-catalytic oxidation of TFE by atmospheric oxygen in the presence of a granulated silver catalyst in a flow reactor at atmospheric pressure, for the molar ratio O_2 : TFE = 1.2, and at a space velocity of the supply of TFE of 1.1 min^{-1}: 1) TFE; 2) ETFE; 3) CDF.[49]

The above data indicate a higher catalytic activity of silver in the epoxidation of TFE compared with the epoxidation of ethylene. This conclusion agrees well with the mechanism of the epoxidation in the presence of silver: TFE is much more active than ethylene in reactions with nucleophiles,[25] which facilitates its reaction with oxygen chemisorbed on the surface of silver in the form of the peroxide anion, which is the epoxidising agent.[45,46,50]

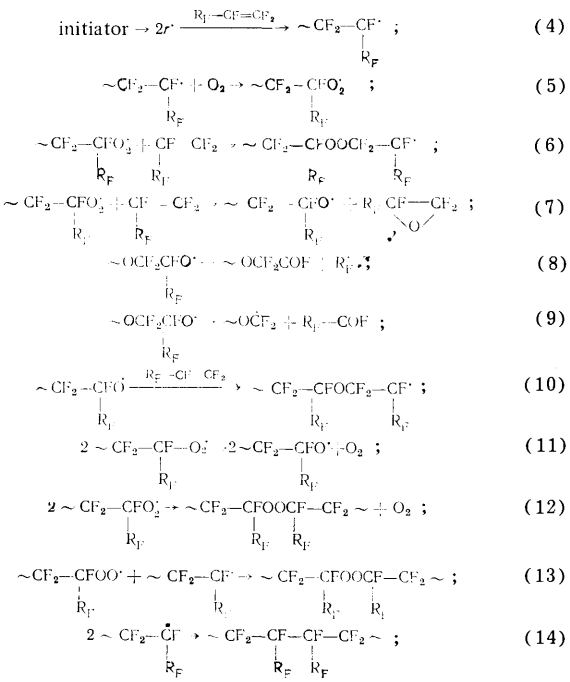
The activation energies for the epoxidation of TFE [reaction (2)] and the formation of CDF [reaction (3)] in the presence of the silver catalyst in the temperature range 408–433 K are respectively 100 ± 18 and 128 ± 35 kJ mol^{-1}, i.e. they exceed somewhat the activation energies for the analogous stages in the oxidation of ethylene:[49] and 80 and 90 kJ mol^{-1}.

The carbonyl difluoride formed in the oxidation of TFE is a highly active fluorinating agent,[1] so that the silver catalyst is poisoned as a result of the formation of surface silver fluorides.[48] The silver catalyst fully deactivated in relation to the reaction (2) behaves in reaction (3) analogously to inert quartz packing:[51] it does not initiate oxidation below 500 K; at 503 K a branched chain oxidation reaction with formation of CDF alone begins.

The heterogeneous-catalytic epoxidation of fluoro-olefins in the presence of silica gel,[52–54] which has no analogue in the chemistry of hydrocarbon compounds, is of interest. Before use as the catalyst, the silica gel is first activated at 448–673 K in a stream of air and the fluoro-olefin for 0.5 to 25 h. The oxidation is carried out in a flow reactor at atmospheric pressure, the space velocities at which the fluoro-olefin and the oxygen are supplied are 0.22 and 0.11 min^{-1}, and the optimum epoxidation temperatures are 463–498 K for HFP and 273–323 K for TFE. A yield of EHFP in excess of 80% relative to the HFP which has reacted is then attained for a conversion of 10–40%.[52–53] In the epoxidation of TFE the yield of the epoxide is more than 70% relative to the olefine which has reacted for a conversion of the latter of 40–90%.[54]

There are no data concerning the mechanism of the epoxidation of fluoro-olefins in the presence of silica gel, the process is poorly reproducible, and silica gel decomposes vigorously during activation and oxidation owing to its reaction with CDF with formation of gaseous CO_2 and SiF_4. In the activation of silica gel there is a possibility of partial conversion of surface SiOH groups into the hypofluorite groups SiOF, which can initiate radical oxidation.[54]

The electrochemical epoxidation of HFP in 80% acetic acid, acetonitrile, and an alkaline solution of sodium perchlorate using a perfluorinated ion-exchange membrane of the "nafion" type for the separation of the cathodic and anodic compartments occupies an intermediate position as regards conditions and mechanism.[55–56] At 293 K, atmospheric pressure, and a current density of 10–50 mA cm^{-2} the process is characterised by a selectivity of the epoxidation of 45–65% for a conversion of HFP of 30–50%; the current yield is 20–35% and the side products are CO_2, HF, and C_2F_5COOH.

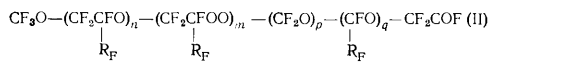


IV. OXIDATION OF FLUORO-OLEFINS VIA A RADICAL MECHANISM

Terminal fluoro-olefins are readily oxidised by molecular oxygen in both gas and liquid phases. There is at present no doubt about the fact that the oxidation of fluoro-olefins proceeds via a free-radical chain mechanism involving a large number of elementary chain propagation and termination stages and also a stage in which the free radicals decompose and which leads to the formation of non-radical products. The composition of the products and the mechanism of the oxidation of fluoro-olefins therefore vary within wide limits depending on the process conditions. For chain oxidation reactions, the selectivity is a function of the chain length, the degree of conversion, and process conditions (solvent, temperature, surface of reaction vessel) and depends on the constants for the elementary stages of the process and also on the concentrations of the substances involved in the chemical reaction.[58]

The mechanism of the oxidation of perfluoro-olefins differs little from the mechanism of the oxidation of unsaturated hydrocarbon analogues. In fluoro-olefins the C–F bond,

whose energy is 448–485 kJ mol^{-1},[1,59] is stronger than the C–H or C–C bond and the oxidation therefore proceeds directly at the double bond and not at the C–F bond. The process is more selective and proceeds with a much smaller number of side products than in the oxidation of olefins, where reaction takes place via a stage in which the hydrogen atom is abstracted preferentially from the α-position relative to the double bond of the olefin.[60,61] The oxidation of fluoro-olefins results in a formation of carbonyl-containing products with a smaller number of carbon atoms than in the initial olefin (acyl fluorides, ketones) and oligomeric products with a perfluoropolyether and perfluoropolyperoxide structures. The C-F bond is also not involved in the formation of these products.



The composition of the products indicates the applicability in the oxidation of fluoro-olefins of the Mayo–Sianesi scheme, which treats oxidation as the simultaneous radical copolymerisation of the olefin and oxygen and the decomposition of the growing radicals:[62,63]

where R_F = F, perfluoroalkyl, or perfluoroalkoxy-group and $\dot{r}$ is the initiator radical.

Only terminal fluoro-olefins are oxidised via a radical mechanism.[10–13] Internal and cyclic fluoro-olefins are almost inert to radical oxidation, which agrees with their low reactivity in radical polymerisation.

The initiated oxidation of terminal fluoro-olefins proceeds already at a temperature below 273 K with the predominance of stages (5) and (6), characterised by a lower activation energy compared with the stages leading to the formation of the epoxide and acid fluorides [stages (7)–(9)]. The main products of the low-temperature oxidation are oils with the perfluoropolyether and perfluoropolyoxide structures having the general formula[13]

Perfluoroalkyl radicals combine with oxygen much faster than the fluoro-olefin molecule and for this reason blocks consisting of several fluoro-olefin fragments are absent from the polymer.[63] The low-temperature oxidation of fluoro-olefins is initiated by ozone,[64,65] oxygen difluoride,[66] etc. The low-temperature oxidative polymerisation of fluoro-olefins under the influence of ultraviolet radiation, which, apart from initiation, induces the conversion of the peroxy-groups into ether groups in the polymer formed, is technologically the most effective.

The oxidative photopolymerisation of fluoro-olefins is carried out in the temperature range from 173 to 353 K and the optimum oxidation temperature for TFE and HFP is 263 K.[67,68] Pressure is used only to keep the fluoro-olefin in the liquid state.[67]

The oxidation proceeds via a free-radical chain mechanism with degenerate chain branching. Chain branching takes place as a result of the photolysis of the perfluoroacyl fluoride and peroxides which have accumulated during the reaction as a result of photolysis. The quantum-chemical yield of the oxidative photopolymerisation of fluoro-olefins is in the range from 10 to 85.[63,69] The radiation-chemical yield in the oxidative polymerisation of HFP at 300 K under the influence of ^{60}Co γ-rays exceeds 160.[70] The effective activation energy for the oxidative photopolymerisation of perfluorinated alkyl vinyl ethers 2.1–4.2 kJ mol^{-1}.[69] In initiation by ultraviolet light, radiation with wavelengths in the range 2600–3200 Å is the most effective;[63] radiation with wavelengths below 2600 Å induces the preferential formation of peroxy-groups, while longer-wavelength radiation promotes the formation of the perfluoropolyether structure.[71]

Fluoro-olefins and oxygen hardly absorb the ultraviolet light from mercury quartz lamps; in practice sensitisers are not used in liquid-phase photochemical oxidation. The reaction begins after a short induction period during which a small amount of products having the perfluorodialkyl peroxide and perfluoroacyl fluoride structures accumulate in the system and subsequently initiation takes place as a result of the photolysis of these compounds.[63] The applicability of scheme (4)–(14) to the description of the kinetics of the oxidative photopolymerisation of fluoro-olefins has been demonstrated by Sianesi and has been discussed in two communications.[9,13]

Only the oxidative photopolymerisation of TFE [72–76] and HFP [63,67,77–79] is of practical value and the main bulk of publications have been devoted to the development of the process in relation to these two monomers. The oxidative photopolymerisation of HFP is carried out in the bulk of the olefin, the yield of the transparent viscous product having structure (II) exceeds 90%, the average degree of polymerisation is 30–40 units, the hexafluoropropylene oxide units are joined mainly "head to tail",[63] and the side products are gaseous COF_2, CF_3COF, and EHFP.[67]

The oxidative photopolymerisation of TFE is carried out in an inert solvent, the yield of the viscous polymeric product having structure (II) and a molecular weight of 10^4–10^5 is 40–50%,[63] the distribution of the difluoromethylene oxide and tetrafluoroethylene units in the chain is random, the peroxy-groups are mainly linked to the CF_2–CF_2 units, and CDF and ETFE are formed as gaseous products.[63]

Oxidative photopolymerisation of HFP is a simple and cheap method of synthesising perfluoropolyether oils.[13,80] The ratio of the peroxide and ether units in the polymer is defined by the equation[63]

$$\frac{m}{n} = \frac{k_{13}\,[\mathrm{HFP}]}{2\,(1 + k_{11}/k_{12})\,k_{12}^{1/2} I^{1/2}},$$

where k_{11}, k_{12}, and k_{13} are the rate constants for the elementary stages and I is the density of the radiation.

With increase of the temperature of the initiated oxidation of fluoro-olefins, stages (7)–(9) involving the decomposition of the growing radicals, which have higher activation energies than stages (5) and (6), become dominant. As a consequence of this, the yield of the polymeric products with structure (II) falls, the molecular weight decreases, fragments of the difluoromethylene oxide structure predominate in the polymer, and the yield of the epoxide and the carbonyl-containing products, formed as a result of oxidation with rupture of their double bond, increases.[63] In the range 370–420 K the main fluoro-olefin oxidation product is the epoxide, while at temperatures above 470 K the products resulting from the dissociation of the double bond are virtually the only ones.

By studying the kinetics of the low-temperature oxidation of HFP in the gas phase and using the principle of the quasi-stationary concentrations of free radicals, it has been shown on the basis of the scheme presented above[13] that the rate of reaction is described by the equation

$$\frac{d[O_2]}{dt} = \frac{1}{2}\left(1 + \frac{k_{11}}{k_{12}}\right) I \text{ and } \frac{d[HFP]}{dt} = \frac{1}{2}\frac{k_{11}}{k_{12}} I ,$$

while the rate of the photochemical low-temperature oxidation of HFP in the liquid phase is given by the equations

$$-\frac{d[O_2]}{dt} = \left(1 + \frac{k_{11}}{k_{12}}\right) I + k_{13}(I/k_{12})^{1/2}[HFP] ,$$

$$-\frac{d[HFP]}{dt} = 2\left(\frac{k_{11}}{k_{12}}\right) I + k_{13}(I/k_{12})^{1/2}[HFP] ,$$

The equations for the rates of formation of the epoxide (w_e) and carbonyl-containing oxidation products formed with dissociation of the double bond (w_c) from the fluoro-olefin (M) are as follows:

$$w_e = k_7[M]\left(\frac{w_i}{S}\right)^{1/2} , \quad (15)$$

$$w_c = (k_9 + k_8)\frac{k_7[M](w_i/S)^{1/2} + k_{11}(w_i/S)}{k_5 + k_9 + k_{10}[M]} , \quad (16)$$

where w_i is the rate of initiation and

$$S = k_{12} + 2k_{13}\frac{k_6 + k_7[M]}{k_5[O_2]} + k_{14}\frac{(k_6 + k_7)^2[M]^2}{k_5^2[O_2]^2} . \quad (17)$$

Compared with the rate of formation of carbonyl-containing products [Eqn.(16)] the rate of epoxidation [Eqn.(15)] depends to a greater extent on the concentration of the olefin and to a lesser extent on the rate of initiation. The selectivity of the epoxidation in the radical oxidation reactions of fluoro-olefins therefore increases with increasing olefin concentration and with decrease of the rates of initiation.

At low oxygen concentrations, chain termination takes place mainly via reaction (14), the rates of reactions (12) and (13) can be neglected, and the expression for the rate of epoxidation becomes

$$w_e = \frac{k_7 k_5[O_2]}{k_{14}^{1/2}(k_5 + k_7)} \cdot w_i^{1/2} , \quad (18)$$

i.e. the rate of epoxidation is proportional to the concentration of oxygen and is independent of the concentration of the olefin.

At high oxygen concentrations, where the main chain termination reaction is reaction (12) and the rates of reactions (13) and (14) can be neglected, the expression for the rate of epoxidation becomes

$$w_e = k_7[M]\left(\frac{w_i}{k_{12}}\right)^{1/2} , \quad (19)$$

i.e. the rate of epoxidation is independent of the oxygen concentration and is proportional to the olefin concentration. Under these conditions, the effective activation energy for epoxidation E_{eff} is defined by the expression

$$E_{eff} = \frac{1}{2}E_i + E_7 - \frac{1}{2}E_{12} , \quad (20)$$

where E_i is the activation energy for the initiation stage and E_{12} the activation energy for the recombination of the peroxy-radicals, which is zero.[81] The initiated oxidation of fluoro-olefins by oxygen at an elevated temperature is carried out in a flow regime in the gas phase at atmospheric pressure; sometimes the volume of the reactor is filled with an inert solvent.

The photoinitiated oxidation is of practical interest as the most effective method of synthesis of ETFE. Among processes of this type, the gas-phase oxidation of TFE has been most thoroughly investigated. Here too radiation at a wavelength below 3200 Å is the most effective.[82] Sensitisers are used in this reaction: mercury vapour,[83] bromine, chlorine, nitrogen oxides, hydrogen bromide,[82] etc. Bromine is the most active in this series of sensitisers.

A biradical chain mechanism is feasible for the gas-phase photochemical oxidation of fluoro-olefins sensitised by mercury vapour:[83,84,86]

$$Hg \xrightarrow{h\nu} Hg^* \xrightarrow{C_2F_4} C_2F_4^* \xrightarrow{O_2} \dot{C}F_2\dot{O}_2 + \ddot{C}F_2$$

$$\dot{C}F_2\dot{O}_2 + C_2F_4 \rightarrow C_2F_4O + COF_2 ,$$

$$\dot{C}F_2\dot{O}_2 + \ddot{C}F_2 \rightarrow 2COF_2 .$$

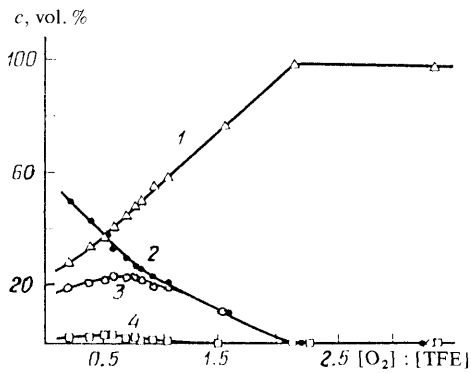


Figure 3. The influence of the molar ratio $[O_2]:[TFE]$ on the composition of the products of the gas-phase photochemical oxidation of tetrafluoroethylene by atmospheric oxygen at 365 K, at atmospheric pressure, and for a residence time in the reaction zone of 1.5 min and the molar ratio $Br_2:TFE = 2 \times 10^{-4}$: 1) CDF; 2) TFE; 3) ETFE; 4) perfluorocyclopropane.[87]

The gas-phase oxidation of TFE by oxygen in a flow reactor at atmospheric pressure, a temperature of 370–400 K, for the molar ratio $O_2:TFE = 0.8$, for a residence time of the reactants in the reaction zone of 1.5 min, and for a power of a moderate pressure mercury quartz lamp of 1395 W is characterised by yields of ETFE of 21–23% relative to the TFE which has reacted for a conversion of the latter of 65–70% (Fig.3).[82,87] CDF is a side product in the process

and the yield of oligomeric products does not exceed 5%.[82] The oligomeric products formed at an elevated temperature have the poly(difluoromethylene oxide) structures (III) and (IV) [88,89] with a low content of peroxy-groups:

$$CF_3O-(CF_2O)_n-CF_2COF \quad (III) \qquad CF_3O-(CF_2O)_n-COF \quad (IV)$$

The structure of the oligomers is determined by the lower rate of decomposition of the corresponding alkoxy-radicals ($\sim CF_2OCF_2O^{\cdot} \rightarrow \sim CF_2O^{\cdot} + COF_2$) compared with the rates of reactions (8) and (9), because the dissociation energy of the C–O bond in perfluoropolyethers (418 kJ mol^{-1}) [10] exceeds significantly the energy of the C–C bond, which is 338–376 kJ mol^{-1}.[10]

The oxidation reactions of fluoro-olefins are much more exothermic than the oxidation reactions of olefins. The exothermic effect in the oxidation of TFE to CDF is 614 kJ mol^{-1}, while in the analogous reaction involving the oxidation of ethylene to formaldehyde 286 kJ mol^{-1} is evolved.[90] The energetic stabilisation of the reaction products is therefore important in the fluoro-olefin oxidation reactions designed to obtain incomplete oxidation products, particularly expoxides. Thus, in the oxidation of TFE or HFP by atomic oxygen in the gas phase, the excited epoxide molecules formed initially do not have enough time for stabilisation and decompose with formation of CDF and difluorocarbene.[84–86]

The increase of the efficiency of the energetic stabilisation of the products resulting from the oxidation being carried out in the liquid phase leads to an increase of the yield of the epoxide. The photochemical oxidation of TFE by oxygen at 390 K in a flow regime with the reactor volume filled by an inert perfluorinated solvent makes it possible to raise the yield of TFE to 60–70% relative to the TFE which has reacted.[11,12,82] This process is one of the most effective methods of synthesis of TFE and is used as a preparative method for this purpose.[11,12] However, judging from the existing publications, there is as yet no industrial manufacture of ETFE by this procedure.

The radical oxidation of fluoro-olefins via scheme (4)–(14) is effectively initiated, apart from ultraviolet radiation, by ionising radiation, ozone, and oxygen difluoride.

The radiation-chemical oxidation of fluoro-olefins in the gas phase at an elevated temperature leads to the formation of an epoxide, carbonyl-containing products of oxidation with rupture of the double bond, and a small amount of polymers having the difluoromethylene oxide structures (III) and (IV).[82,91] An increase of the hardness of the ionising radiation reduces the yield of the epoxide and the degree of conversion of the olefin:[91] a fall of temperature entails a decrease of the degree of conversion and of the relative yield of gaseous products,[91] but the ratio of the yields of CDF and the epoxide remains constant under these conditions; an increase of the pressure entails some increase of the rate of the gas-phase radiation-chemical epoxidation of TFE,[92] the yield of the epoxide diminishing with increase of the oxygen : olefin ratio.[92] The radiation-chemical yield of the gas-phase oxidation of TFE and chlorotrifluoroethylene by molecular oxygen at room temperature and atmospheric pressure and under exposure to X-rays (50 kV) is in the range 900–3300.[74]

The gas-phase oxidation of fluoro-olefins by ozonised oxygen at room or an elevated temperature makes it possible to obtain epoxides in satisfactory yields. The oxidation of TFE by ozonised oxygen in a flow reactor at 288 K with the molar ratios $TFE:O_3 = 31.7$ and $TFE:O_2 = 1$ makes it possible to obtain ETFE in 46% yield relative to the TFE which has reacted for a conversion of the latter of 41.3%.[93] The yield of the polymeric products having structure (II) and a molecular weight of 1.5×10^3 is 19%.[93] The main structural unit of the polymer is CF_2O; the number of terminal CF_3O groups in the polymer is twice as large as the number of acid fluoride groups;[63] when the molar ratio $TFE:O_2$ is raised from 0.5 to 1.8, the number of peroxy-groups in the polymer falls from 5 to 3 per 100 CF_2O units; the content of C–C bonds in the polymer is then almost constant and is 5–6 bonds per 100 CF_2O units.[63]

It is possible to epoxidise TFE with pure ozone at 273 K, whereupon the yield of the epoxide is 50% for the molar ratio $O_3:TFE = 0.01$,[94] but, with increase of this ratio, the yield of the epoxide falls sharply and for the molar ratio $O_3:TFE = 1$ virtually the only product is CDF.[94]

Tetrafluoroethylene reacts readily with OF_2 in the dark to form an equimolar mixture of CF_4 and CDF; ETFE was not then detected.[95] Under the influence of ultraviolet radiation, the main reaction product is the epoxide.[21,95] For example, irradiation of a mixture of HFP and OF_2 with quartz ultraviolet light in the gas phase at room temperature in the course of 12 h leads to a yield of EHFP of 42% for a conversion of HFP of 57%.[95]

Catalytic epoxidation of fluoro-olefins by oxygen difluoride in the presence of silver difluoride is also known.[21,96] The reaction is carried out in a stainless steel flow reactor in the gas phase or in the presence of an inert solvent for the molar ratio OF_2 : olefin = 1 : 1 (at 333 K); the yield of the epoxide in the oxidation of HFP is 23 vol.%.[96]

In the presence of molecular oxygen OF_2 is an effective initiator of the oxidation of fluoro-olefins and the main oxidation product is the epoxide.[97]

The oxidation of fluoro-olefins initiated by oxygen difluoride proceeds at a temperature as low as 238–253 K; with increase of temperature, the rate of reaction increases and becomes technologically acceptable, starting from room temperature. The optimum epoxidation temperature depends on the chemical nature of the olefins and is in the range between room temperature and 393 K. The process is characterised by a series of kinetic features inconsistent with the Mayo–Sianesi scheme defined by Eqns.(4)–(14). Under the otpimum conditions, the yield of the epoxide exceeds 90%,[97] while according to the Mayo–Sianesi scheme the selectivity of the epoxidation should not exceed 67 vol.%.[62] The main side products are CDF, perfluoroacetyl fluoride, and small amounts of a polymeric product.[97] With increase of the amount of OF_2 introduced into the reaction mixture, the rate of oxidation and the yield of the epoxide relative to the olefin which has reacted also rise, which likewise conflicts with the Mayo–Sianesi scheme [see Eqns.(15) and (16)]. For example, in the oxidation of 6-monohydroundecafluorohex-1-ene in bulk at 393 K in the course of 4 h, an increase of the amount of OF_2 supplied to the reactor from 1.6 to 1000 ml per 1000 ml of oxygen leads to an increase of the degree of conversion of the olefin from 87.8 to 100% and to an increase of the yield of the epoxide from 59.4 to 92% relative to the olefin which has reacted.[97] The above features of the process show that, in the presence of oxygen, oxygen difluoride behaves not only as an initiator but also as a highly effective epoxidising agent.

The epoxidation with the $OF_2 + O_2$ mixture is more selective and proceeds steadily in the liquid phase, in the bulk of the olefin, or in an inert solvent.[97]

The formation of only products of oxidation with rupture of the double bond [polymeric products having structures (III) and (IV)] in the absence of epoxides is characteristic of the thermal or initiated oxidation of fluoro-olefins by oxygen in the gas phase at temperatures above 473 K.[72,98–100] The reaction of TFE with the oxygen in a shock wave results in the formation of CO_2, CF_4, C_2F_6, etc. together with CDF, but ETFE is absent.[101]

When the thermal oxidation of fluoro-olefins with oxygen is carried out in the liquid phase, the epoxide is formed as the main product; in addition, carbonyl-containing products of oxidation with rupture of the double bond and oligomeric products having structures (III) and (IV) are formed.[102-105] The oxidation is carried out at 320–520 K, the optimum temperatures for the epoxidation of different fluoro-olefins not being the same:[102] they are 348 K for chlorotrifluoroethylene, 360–380 K for TFE, and 400–420 K for HFP.

It is best to keep the molar ratio O_2:olefin below unity, since in the presence of an excess of oxygen the yield of the epoxide is reduced.[102] The solvents employed are perhalogenated compounds, for example, $CF_2ClCFCl_2$, CCl_4, etc. In order to maintain the fluoro-olefin in the liquid phase, the oxidation is carried out at an elevated pressure.

The thermal liquid-phase oxidation of fluoro-olefins is a degenerate-branched chain process, which is indicated by the S-shape of the kinetic curves (Fig.4), the complete supporession of the oxidation following the addition of inhibitors, even weak ones such as quinone or nitroxy-radicals, and the elimination of the induction period on treatment with initiators even at 50 °C (in the absence of an initiator, the oxidation becomes appreciable only at temperatures above 100 °C after a prolonged induction period).[106]

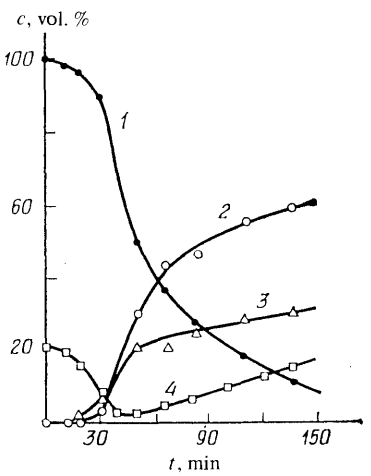

Figure 4. Kinetic curves for the thermal liquid-phase oxidation of HFP by compressed air (rate of supply 9 litre h^{-1}) in Khladon-113 at an initial HFP concentration of 0.13 M, 423 K, and a pressure of 5 MPa: 1) HFP; 2) EHFP; 3) trifluoroacetyl fluoride; 4) O_2 content in effluent gases from the reactor.[109]

The branching agents are the oligomeric peroxy-compounds with structures (III) and (IV) formed.[106,107] The chemical and nature of the solvent, the material of the reactor, and the state of the walls exert a marked inlfuence on the yield of the epoxide and other oxidation products.

The metallic surface of the reaction vessel has a catalytic effect on reactions leading to the formation of acid fluorides and oligomeric products, the selectivity with respect to the epoxide being reduced.[106] In stainless steel reactors in Freon-113, the yiled of EHFP does not exceed 40–50% relative to the HFP which has reacted, while in PTFE reactors the yield of the epoxide reaches 70–80%.[106,107] The effect of the reactor walls is reduced when the solvents employed are highly viscous liquids, consisting of mixtures of aliphatic fluorocarbons and perfluorinated ethers,[106] owing to the decrease of the rate of diffusion of the species decomposing on the wall.

In contrast to the low-temperature photoinitiated oxidation of TFE and HFP, where the rate of reaction and the selectivity are independent of the ratio of the oxygen and olefin concentrations and depend solely on the radiation intensity,[13] the ratio of the rates of accumulation of the corresponding epoxides and acyl fluorides in the thermal oxidation increases linearly with increase of the fluoro-olefin concentration[109] and diminishes with increase of the initial O_2 concentration.[110] A decrease of the selectivity with respect to the epoxide as a function of the O_2 concentration has also been observed in the oxidation of a number of olefins:[62,111]

$$\frac{w_{ox}}{w_{ol}} = \frac{1}{A + B[O_2]}, \qquad (21)$$

where w_{ox} is the rate of formation of the olefin oxide, w_{ol} the rate of consumption of the initial olefin and A and B are constants which incorporate the ratios of the rate constants for the elementary stages. In most cases this type of relation is observed only over a certain part of the O_2 concentration range.

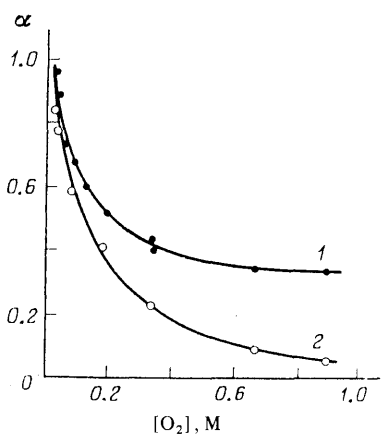

Figure 5. Dependence of the selectivity of the epoxidation α of perfluoro-octene (curve *1*) and HFP (curve *2*) on the initial O_2 concentration.[110]

At initial O_2 concentrations appreciably less than the initial fluoro-olefin concentration, the selectivity with respect to the epoxide is close to 100% and falls sharply with increase of the O_2 concentration, tending to a definite limit, which depends on the nature and length of the hydrocarbon chain of the fluoro-olefin (Fig.5). It follows from Table 1 that the oxidation of TFE in an excess of oxygen yields only COF_2 and a polymer, while in the oxidation of HFP and perfluoro-octene the yields of the corresponding epoxides reaches 20 and 36% with respect to the consumed olefin.

These data show that the mechanism of the oxidation of olefins put forward in a number of studies[4,14,62] cannot account either for the limit in the selectivity with respect to

the oxide on further increase of the O_2 concentration or for the high yields of the epoxides. It permits a theoretically feasible yield not greater than 66%, whereas in the oxidation of certain olefins and fluoro-olefins containing more than two carbon atoms their selectivity with respect to the epoxide reaches 70–100% for a conversion in an excess of 50%.[102,107,110,113] In order to explain such a high selectivity in the epoxidation of fluoro-olefins, the decrease of the process selectivity with increase of the O_2 concentration, and also the accumulation of equimolar amounts of CDF and acyl fluorides in which the number of carbon atoms is one less than in the initial olefin, the oxidation mechanism was supplemented[109] by the stage involving decomposition of the perfluoroperoxyalkyl radicals into two epoxide molecules:

$$RO_2-CF_2-\underset{\underset{R_F}{|}}{CF}OOCF_2\dot{C}F \rightarrow 2R_F\underset{\diagdown O \diagup}{CF}-CF_2 + R\dot{O}_2 \ , \qquad (22)$$

and also a stage involving the isomerisation and decomposition of the perfluoroalkylperoxy-radicals with rupture of the carbon skeleton:[106]

$$RO_2CF_2-\underset{\underset{R_F}{|}}{CF}-O\dot{O} \longrightarrow RO_2-CF_2-\underset{\underset{O-O}{\diagdown\diagup}}{CF}-R_F \longrightarrow R\dot{O}_2 + R_FCOF + COF_2 \qquad (23)$$

Table 1. Dependence of the yield of the epoxide on the length of the carbon chain of the fluoro-olefin for the ratio O_2 : fluoro-olefin = 3.

Fluoro-olefin	T, K	α, %	Refs.
C_3F_4	265	0	[112]
C_3F_6	393	20	[114]
C_8F_{16}	370	36	[110]

Notation: T is the oxidation temperature and α the yield of the fluoro-olefin oxide.

This pathway, leading to the formation of acyl fluorides, is dominant for long oxidation chains. If the chains are short, then the reaction of perfluoroalkoxy-radicals, formed in a quadratic interaction of the perfluoroalkylperoxy-radicals [reactions (8) and (9)], makes a significant contribution to the overall rate of formation of acyl fluorides:

$$RO_2-CF_2-\underset{\underset{R_F}{|}}{CF}\dot{O} \xrightarrow{O_2} \begin{cases} \longrightarrow RO_2-CF_2-COF + R_F\dot{O}_2 \ , \\ \longrightarrow RO_2-CF_2O\dot{O} + R_FCOF \ , \end{cases}$$

$$R_F = CF_3, \ldots C_nF_{2n+1} \ .$$

This regime is attained at high rates of initiation comparable to the rate of oxidation (chain length ≤ 10 units). In the liquid-phase oxidation of HFE a linear dependence of the ratio of the rate of accumulation of the sum of perfluoroacetyl fluoride and CDF to the rate of formation of EHFP on the square root of the rate of initiation is observed.[114] It is known that an excess of oxygen in free radical oxidation reactions results in the predominance of the system of $R\dot{O}_2$ radicals[60] which cannot produce the epoxide if one adopts the mechanism of the epoxidation of fluoro-olefins and the formation of perfluoroacyl fluorides [reactions (22) and (23)] presented above. However, in the oxidation of perfluoro-octene even at high oxygen concentrations (Fig.5) the formation of epoxyperfluoro-octane is observed (up to 40 mole % relative to the perfluoro-octene which has reacted).

In order to account for the observed limit in the selectivity of the expoxidation of fluoro-olefins as the O_2 concentration increases, it has been suggested that, as in the oxidation of the usual olefins,[113] a molecular epoxidation mechanism as well as the radical mechanism can operate in the oxidation of fluoro-olefins.[110] One of the possible pathways in the non-radical epoxidation mechanism is apparently the interaction of the cyclic peroxide formed via a radical mechanism:[113,115]

$$RO_2-CF_2-\underset{\underset{R_F}{|}}{CF}O\dot{O} \rightarrow R\dot{O}_2 + R_F-\underset{\underset{O-O}{\diagdown\diagup}}{C}-CF_2 \ , \qquad (24)$$

On the one hand, this peroxide can react with a second fluoro-olefin molecule to produce two epoxide molecules and, on the other, it can decompose into perfluoroacetyl fluoride and COF_2:

$$R_F-\underset{\underset{O-O}{\diagdown\diagup}}{\overset{F}{\overset{|}{C}}}-CF_2- \longrightarrow R_F-COF + COF_2 \ , \qquad (25)$$

$$\xrightarrow{R_FCF=CF_2} 2R_F-\underset{\diagdown O \diagup}{CF}-CF_2 \ . \qquad (26)$$

The introduction of a molecular mechanism of the epoxidation of fluoro-olefins made it possible to explain virtually all the observed kinetic features: the high selectivity of the epoxidation, the appearance of a limit in the selectivity with respect to the epoxide as the initial O_2 concentration increases, the formation of equimolar amounts of CDF and perfluoroacyl fluoride containing a smaller number of carbon atoms than in the initial olefin, and also the influence of the reaction vessel wall, which catalyses the decomposition of the above peroxides and the peroxy-radicals with dissociation of the C–C bond.

High-temperature oxidation by molecular oxygen in order to obtain epoxides is possible only for terminal fluoro-olefins, while internal and slight fluoro-olefins do not give rise to epoxides.[102] The oxidation of TFE and chlorotrifluoroethylene by this method is difficult to achieve for technical reasons owing to the risk of explosion. Thermal liquid-phase epoxidation of HFP is a highly effective method of synthesis of EHFP;[10] the process has been carried out by the Dupont Corporation[10,103,104] in a stainless steel autoclave in a continuous regime at 430 K, at a pressure of 2.8 MPa, and for the molar ratio O_2 : HFP = 0.6. The solvent employed was Khladon-113. After 20 min, up to 70% conversion of HFP is attained and the yield of the epoxide is more than 70%.[102,104]

Apart from the fluoro-olefin oxidation reactions, fluorocarbon epoxides can be obtained by other methods, for example by the addition of difluorocarbene to ketones or acyl fluorides:[116–118]

$$CF_3COCF_3 + \ddot{C}F_2 \rightarrow (CF_3)_2\underset{\diagdown O \diagup}{C}-CF_2 \ ,$$

$$CF_3COF + \ddot{C}F_2 \rightarrow CF_3-\underset{\diagdown O \diagup}{CF}-CF_2 \ .$$

Analysis of the patent and scientific literature shows that the fluoro-olefin oxidation processes can be readily achived, have many kinetic features distinguishing them from olefin oxidation processes, and make it possible to obtain fluorocarbon epoxides and perfluoropolyethers in high yields from readily available starting materials.

V. CHARACTERISTIC FEATURES OF THE PHYSICOCHEMICAL PROPERTIES AND MAIN APPLICATIONS OF THE FLUORO-OLEFIN OXIDATION PRODUCTS

In contrast to hydrocarbon epoxides, which have significantly higher boiling points than the corresponding olefins, the boiling points of fluorocarbon epoxides are close to those

of the corresponding fluoro-olefins (Table 2), which greatly hinders their separation. ETFE, whose boiling point differs considerably from that of TFE, is an exception; their mixture can therefore be comparatively readily separated by distillation. Under industrial conditions, extractive distillation of a mixture of EHFP and HFP in the presence of substituted benzenes, carbon tetrachloride, chloroform, etc. is recommended.[126,127]

Table 2. Certain physical constants of the epoxides and the corresponding olefins.

Compound	T, K*	Absorption band, cm^{-1}	Refs.

$CF_2=CF(CF_2)_4—CF—CF_2$ (O)	379	—	[31]

*T = boiling point.

The fluorocarbon epoxide ring has an absorption band in the range 1460–1610 cm^{-1},[3,21,22] while the ring of the carbon epoxides absorbs in the range 1240–1260 cm^{-1}.[123]

Fluorocarbon epoxides hardly dissolve in water, diglyme, etc., but they are readily soluble in fluorocarbon solvents, Freons, etc.[10] In contrast to this, epoxyethane is miscible with water in all proportions and is readily soluble in many of the usual hydrocarbon solvents.[46]

Fluorocarbon epoxides are thermally less stable than their hydrocarbon analogues. For example, the thermal decomposition of epoxyethane begins at 620 K and is characterised by an activation energy of 209–238 kJ mol^{-1}.[46] Epoxytetrafluoroethane is stable only at a reduced temperature and it is recommended that it be stored at 195 K.[12] Even at room temperature, ETFE readily isomerises to trifluoroacetyl fluoride on the walls of the vessel.[12] Above 323 K, ETFE undergoes thermal decomposition:[30,118,128]

$$CF_2(O)CF_2 \rightarrow COF_2 + \ddot{C}F_2 ,$$

The reaction is of first order with respect to ETFE and the rate constant is given by[128]

$$k = 10^{13.7}\exp(-132000/RT)\,s^{-1}\ \text{(Ref.128)}$$

With increase of pressure, the rate of decomposition of ETFE also rises and in the liquid phase there is a possibility of the explosive decomposition of ETFE, the products being CF_4, COF_2, and carbon.[10,30]

The thermal stability of fluorocarbon epoxides depends significantly on their structure. For example, epoxyperfluorocyclopentane is stable up to 573 K.[30] EHFP decomposes above 420 K:[21,30,118]

$$CF_3CF(O)CF_2—CF_3COF + \ddot{C}F_2 ,$$

$$\ddot{C}F_2—\ddot{C}F_2 \rightarrow CF_2=CF_2 + CF_2(CF_2)CF_2 \rightarrow —(CF_2)_n— .$$

The thermal stability of fluoro-olefins is significantly greater than that of the corresponding epoxides. For example, HFP undergoes thermal decomposition above 820 K.[129]

As a consequence of the relatively high electron density at the oxygen atom of the hydrocarbon epoxide ring, its opening proceeds via a stage in which the proton attacks the oxygen atom with the intermediate formation of an oxonium cation.[123] The high electronegativity of fluorine lowers the susceptibility of the oxygen atom in the fluorocarbon epoxide ring to electrophilic attack and the opening of the latter takes place as a rule owing to nucleophilic attack on the β-carbon atom with the intermediate formation of an alkoxide anion:[3,9]

$$R_F—CF(O)CF_2 + A^- \rightarrow R_F—\underset{A}{CF}—CF_2O^- \rightarrow R_FCFCOF + F^- ;$$

A = anion.

The anionic polymerisation of fluorocarbon epoxides is of practical importance and its elementary chain propagation stage involves the opening of the epoxide ring by an alkoxide anion with formation of an addition product:[10]

$$CF_3CF(O)CF_2 \xrightarrow{F^-} CF_3CF_2CF_2O^- \xrightarrow{n\,C_3F_6O} F—(CFCF_2O)_n—CF_2CF_2O^-$$

$$\downarrow\uparrow \qquad\qquad \downarrow\uparrow$$

$$C_2F_5COF + F^- \qquad F—(CFCF_2O)_n—CF_2COF + F^- .$$

The anionic polymerisation of fluorocarbon epoxides proceeds in an aprotic polar solvent in the presence of sources of fluoride ions.[10] A relatively low degree of polymerisation of the order of 70–100 is then attained,[10,130] which is due to the high probability of the stage involving chain transfer as a result of the elimination of a fluoride ion from the perfluoroalkoxy-anion.[10] There are at present no methods for the synthesis of high-molecular-weight solid polymers from perfluorinated epoxides,[10,13] which resembles the initial situation in the polymerisation of hydrocarbon epoxides.[131] After stabilisation, low-molecular-weight EHFP oligomers are used as working (functional) liquids and cooling agents.[10–12] EHFP and ETFE dimers and trimers are used to obtain highly effective surfactants[132,133] and fluorinated polyacrylates,[134] the latter being used to impart oil- and water-repellant properties to fabrics and paper and for the protection of steel, glass, etc. against corrosion.

The anionic polymerisation of EHFP has been achieved in the USA[10–12] on an industrial scale, the aim being to synthesise thermally and chemically stable perfluoropolyether

oils having the structure

$$F-(CF(CF_3)-OF_2O)_n-CF_2CF_3 \quad (n = 72)$$

and fluorocarbon solvents with the structure

$$F-(CF(CF_3)-CF_2O)_m-CFHCF_3 \quad (m = 1-9)$$

The oxidation of fluoro-olefins results in the formation of carbonyl-containing compounds; the property of these compounds of greatest practical importance is their ability to combine with EHFP via an ionic mechanism to form (after pyrolysis) perfluorinated alkyl vinyl ethers, for example:[135]

$$COF_2 + CF_3CF(O)CF_2 \xrightarrow[\text{diglyme}]{CsF} CF_3OCF(CF_3)COF \xrightarrow[ZnO]{570-600\,K} CF_3OCF=CF_2 .$$

Perfluorinated alkyl vinyl ethers readily copolymerise via a radical mechanism with a number of fluoro-olefins, for example, with TFE, to form a modified polytetrafluoroethylene of the type of PFA Teflon, capable of being worked by casting under pressure and by extrusion,[136] or fluororubbers.[14, 15,137-139]

Methods for the synthesis of perfluorinated alkyl vinyl ethers with functional groups in the ω-position have been developed on the basis of perfluorobisacyl fluorides and EHFP, for example:[140]

$$FOC-(CF_2)_n-COF + CF_3CF(O)CF_2 \xrightarrow[\text{diglyme}]{CsF} FOC-(CF_2)_n-CF_2OCF(CF_3)COF \rightarrow$$

$$\xrightarrow[470K]{Na_2CO_3} FOC-(CF_2)_{n+1}-OCF=CF_2 \xrightarrow[3)\,P_2O_5]{1)\,CH_3OH\ 2)\,NH_3} NC-(CF_2)_{n+1}-OCF=CF_2 .$$

Perfluorinated alkyl vinyl ethers with functional groups are used to synthesise vulcanisable perfluorinated rubbers.[138,140]

A method has been developed for the synthesis of perfluorinated alkyl vinyl ethers with a sulphonyl fluoride group (V) on the basis of TFE, SO_3, and EHFP:[141]

$$CF_2=CF_2 + SO_3 \xrightarrow{313K} FSO_2CF_2COF \xrightarrow[CsF,\ \text{diglyme}]{CF_2(O)CF_2} \rightarrow$$

$$\rightarrow FSO_2CF_2CF_2OCF(CF_3)CF_2OCF(CF_3)COF \xrightarrow[Na_2CO_3]{500K} FSO_2CF_2CF_2OCF(CF_3)CF_2OCF=CF_2 .$$

(V)

Perfluorinated copolymers used for the preparation of thermally and chemically stable ion-exchange membranes of the type of "Nafion" for fuel cells[19] and electrolysers in the chlorine industry[142] are obtained by the copolymerisation of compound (V) with TFE.

Perfluoropolyoxa-alkylene dicyanides are obtained from perfluorobisacyl fluorides and fluoro-olefin oxides:[5,6]

$$FOC-R_F-COF + CF_2(O)CFX \xrightarrow[\text{diglyme}]{CsF} \rightarrow$$

$$\rightarrow FC(=O)CFX-(OCF_2CFX)_m-OCF_2R_FCF_2O-(CFXCF_2O)_n-CFXC(=O)F \rightarrow$$

$$\xrightarrow[3)\,P_2O_5]{1)\,CH_3OH\ 2)\,NH_3} NCCFX-(OCF_2CFX)_m-OCF_2R_FCF_2O-(CFXCF_2O)_n-CFXCN$$

where R_F is a perfluoroalkylene containing between 0 and 20 carbon atoms and X is usually F or CF_3.

Perfluoropolyoxa-alkylene dicyanides are used to synthesise perfluorinated triazine rubbers with improved frost resistance.[13]

Apart from the syntheses based on reactions with fluoride oxides, fluorocarbon carbonyl-containing compounds have many other applications of practical importance: CDF is used for the fluorination of the carbonyl group to CF_2 (Sheppard and Sharts [1]); surfactants and fire resistant and oil- and water-repellant substances for the impregnation of fabrics have been obtained from hexafluoroacetone;[143] CDF, hexafluoroacetone, and perfluoroaldehydes are used as monomers in radical copolymerisation,[13] etc.

Polymeric products of the oxidation of fluoro-olefins containing peroxy-groups are used for the initiation of radical polymerisation.[67,70,77]

The reduction of peroxy-groups in the above polymers (for example with hydrogen, metal hydrides, etc.[144]) leads to the formation of bifunctional linear perfluoropolyethers used as monomers in polycondensation processes and also as surfactants with high chemical and thermal stability,[70,72,91,98, 145,146] as emulsifying agents in the polymerisation of TFE,[144] and as water-repellant agents for the impregnation of fabrics.[98,145,146] Modified products of the decomposition of perfluoroperoxide polymers are also used in the last two cases.[146]

In order to stabilise them (to remove peroxy- and terminal acid fluoride groups), the polymeric products of the oxidation of fluoro-olefins are treated with fluorine at 370–620 K [147] and sulphur tetrafluoride,[98] are heated at 520 K,[70] are irradiated with ultraviolet light,[70] and are heated with alkali up to 420–620 K.[70,147]

The stabilised products with the perfluoropolyether structure obtained are employed as thermally and chemically stable oils and bases for greases, as dielectrics and heat exchangers,[70,72,98,145] and as plasticisers and solvents for fluorine-containing polymers.[91,145]

The main application of the products of the oxidation of fluoro-olefins is the introduction of oxygen-containing groups into fluorocarbon polymers. In this connection it must be emphasised that, in terms of the character of their influence on the properties of fluorocarbon polymers, the oxygen-containing groups can be divided into two categories. The first includes ether groups, whose influence is due to their chemical inertness and low potential barrier to rotation about the single C–O bond.[13-15] The introduction of ether groups into fluorocarbon polymers sharply reduces the rigidity of the polymer chains, which alters many physical properties associated with the flexibility of the macromolecules and in the first place decreases significantly the glass point, the thermal stability of the fluoropolymers remaining virtually unchanged under these conditions and lying in the range 520–570 K.[13-15] The electron-accepting properties of fluorocarbon alkyl groups and the *p,p*-conjugation of the unshared electron pairs of the heteroatom and the nearest fluorine atoms are responsible for the high chemical inertness of the perfluorinated ethers.[1,2,13] By virtue of this, fluorocarbon polymers with ether groups retain a high chemical stability. Thus perfluoropoly(propylene oxide) is stable in solvents such as liquid oxygen, N_2O_4, boiling concentrated nitric acid, and 90% hydrogen peroxide, in fluorinating agents such as gaseous fluorine (up to 470 K) and boiling ClF_3 and CoF_3 (up to 470 K), in strong acids such as concentrated H_2SO_4 (up to 590 K), P_2O_5 (up to 650 K), and BF_3 (up to 670 K), and in strong bases such as fused NaOH (up to 570 K), $(CH_3)_3N$ (up to 670 K), and $NaOCH_3$ (up to 650 K), in contact with metals, etc.[10,148] A consequence of the chemical inertness of perfluoropolyethers is their biological inertness and non-flammability.[11,12]

However, a certain degree of basicity of the ether groups in perfluoropolyethers remains and is manifested in reactions with Lewis acids, for example with $AlCl_3$ (even at 370 to 420 K) [2,149] and by a considerable decrease of the thermal stability of perfluoropolyethers in the presence of metals such as aluminium, titanium, and their alloys; the thermal stability

of oils of the type of "Fomblin" decreases under these conditions from 670 to 520 K,[149] while contact between fluorocarbon polymers and metal surfaces has almost no influence on their thermal stability.

Another manifestation of the residual basicity of the ether groups in perfluoropolyethers is an increase of the intermolecular interaction forces compared with fluorocarbon polymers, as a result of which perfluoropolyethers are readily soluble in fluorinated solvents while they remain insoluble in hydrocarbon solvents,[148,149] and expansion of the temperature range of their existence in the liquid phase[2] and a sharp improvement of their viscosity-temperature characteristics.[13]

When the carbon atoms in the α-position in ethers are incompletely fluorinated, a sharp impairment of the properties of the polymers is observed: the CF_2OCH_2 group is chemically less stable than the non-fluorinated ether bond, being particularly readily hydrolysed.[13]

The degree of modification of the properties of fluorocarbon polymers depends on the number of ether groups introduced into the main chain or into the side groups. The structure of the perfluoropolyether having a statistical distribution of the CF_2CF_2O and CF_2O units with the difluoromethylene oxide units predominating is optimal as regards the glass point and the viscous-temperature properties. Perfluoropolyether oils with the above structure are highly viscous and very stable at low temperatures:[13,63,150] their glass points are of the order of 120 K, their thermal stabilities are 600–630 K, and the temperature coefficients of their viscosity are low.

In terms of thermal stability, the optimum structure of perfluoropolyethers is that of perfluoropoly(ethylene oxide) $(CF_2CF_2O)_n$, whose thermal stability (770–820 K) [151] is unique for polymers with a flexible chain. The presence of difluoromethylene oxide groups in the perfluoropolyether chain lowers the thermal stability of the polymer, particularly on contact with metals.[13]

Reactive groups whose chemical reactivity is significantly higher than that of the analogous groups in hydrocarbon polymers belong to the second category of oxygen-containing groups introduced into fluorocarbon polymers by means of fluoro-olefin oxidation products. For example, the carboxy-groups are more acid and the carbonyl groups are more electrophilic,[1,152] as a result of which fluorinated polymers with functional groups in the main chain, for example, fluorine-containing polyesters, polyamides, polyurethanes, etc., have a low chemical stability, particularly in an alkaline medium.[13]

The introduction of reactive functional groups into fluorocarbon polymers as terminal or side groups imparts to the polymers a capacity for chemical vulcanisation, ion-exchange and catalytic activity, etc. These groups are introduced as a result of copolymerisation with fluoro-monomers containing a functional group in the ω-position.[5,140] The functional groups employed are COOH, COOR, $CONH_2$, CN, $CF-CF_2$ (with O), SO_2F, etc.[17,139–141,153]

After vulcanisation, the reactive functional groups usually no longer affect the chemical properties of the copolymer and their influence on the physical properties of the vulcanised material is manifested only owing to the increase of the strength of the cross-links.[139] However, the introduction of a large number of reactive functional groups induces a sharp change of both chemical and physical properties of fluoro-polymers. For example, a copolymer has been obtained from TFE and the sulpho-olefin (V), which exhibits not only an ion-exchange activity but also differs significantly from polytetrafluoroethylene in its physical properties: it swells in water to the extent of 25 wt.%[19] and dissolves in polar organic solvents such as ethanol, butanol, $C_6H_5N(CF_3)_2$, etc.[154]

Examination of the main applications of the products of the oxidation of fluoro-olefins shows that this reaction leads to key monomers for the synthesis of fluorine-containing polymers.

The Quantum Chemistry of Unusual Oxidation States of the Lanthanides and Actinides

V.I.Spitsyn and G.V.Ionova

The electronic structure and properties of the actinides in unusual oxidation states have been examined within the framework of quantum-chemical ideas. Hartree-Fock atomic calculations for the actinide series, and molecular orbital calculations for the octahedral oxyanions of uranium, neptunium, plutonium, and americium in high and highest oxidation states, and for the octahedral chloro-complexes of the actinides(III) and (IV) from protactinium to einsteinium, have been carried out. These calculations have been used to examine the possible existence of various new oxidation states of the actinides.
A cation-cation interaction mechanism has been proposed. The characteristic features of the *trans*-effect in the chemistry of the actinides have been examined. New possibilities for using the Mössbauer isomer shifts at the actinide nuclei to interpret chemical properties have been demonstrated. The influence of relativistic effects on the chemical properties of the actinides has been analysed. In particular, it has been shown that the high value of the spin-orbit splitting is responsible for the gradual stabilisation and stability of the bivalent state at the end of the actinide series, the significant difference in the stability of the lanthanides(IV) and actinides(IV), and the possibility in principle of obtaining lanthanyl groups at the end of the lanthanide series.
The bibliography contains 138 references.

III.	Higher oxidation states of the lanthanides and actinides	728
IV.	Influence of relativistic effects on the properties of the compounds of the heavy elements	739

I. INTRODUCTION

In recent years there has been a marked increase in interest in compounds of the *f*-elements, because of their varied practical applications. Practical requirements are making it necessary to carry out more detailed studies of "classical" compounds of the bivalent and tervalent lanthanides and actinides, and to prepare new compounds in new oxidation states. Lanthanides and actinides are interesting objects of research studies, since the question of the discovery of new oxidation states can now be raised for only a few elements of Mendeleev's periodic system.

Quantum chemistry plays an important role in the study of extremal oxidation states. The evaluation of the present state of valence theory depends on the field of chemistry. Several thousand molecular orbital calculations have been carried out for organic systems, slightly fewer for inorganic systems, and only about thirty for actinide

molecules. This is due to a number of factors, primarily the fact that the experimental data which are usually employed in theoretical calculations are not available for the actinides; many are highly radioactive and difficult to obtain. To this must be added the significant mathematical difficulties: the carbon atom has six electrons, whereas the curium atom has ninety six, and the quantum-chemical study of a system of sixteen carbon atoms involves less difficulty than the study of any curium molecule.

The use of computers has led to considerable progress in lanthanide and actinide valence theories. Overall, however, the progress resulting from the use of computers has been less than seemed likely in the nineteen-sixties, when calculations by the Roothaan method began to be carried out for the first time in the Soviet Union. The existence of computers and their availability make the ideological content of quantum-chemical calculations and their relation to experiment of primary importance, since computers only process ideas. The mathematical apparatus of quantum mechanics is most effective in those cases where the chemical model of the phenomenon is clarified in collaboration with experimentalists, and afterwards an apparatus is selected using a computer, calculator, or slide rule, adequate for the problem being posed and effective for its solution. When applied to the study of extremal oxidation states of the lanthanides and actinides, this approach means not only the use of up-to-date quantum-mechanical atomic and molecular orbital calculations but also the search for various correlations on the basis of the experimental results obtained.

The Soviet experimental school has accumulated a large amount of experience in the study of extremal oxidation states of the lanthanides and actinides: Cm(VI),[1] Md(I),[2] Pu(II),[3] Pu(VII),[4] Am(VII),[5] Np(VII),[6] and Tm(IV) [7] have been discovered. This makes it possible to raise the question of the quantum-chemical prediction of the existence of both higher and lower oxidation states of the lanthanides and actinides: univalent lanthanides and actinides, plutonium(VIII) and americium(VIII), oxidation states of 5+, 6+, and 7+ for curium, 5+ and 6+ for californium and berkelium, and 4+ for holmium, erbium, and thulium. The prediction of a given oxidation state is an important aspect of the problem. The study of the electronic structure and properties of the lanthanides and actinides in unusual oxidation states is a no less important and apparently more complex question, including a number of problems: the determination of redox potentials, ionic radii, the geometry of molecular systems, and the study of reaction mechanisms, energy structure, etc.

The present review is devoted to the theoretical study of new oxidation states of the lanthanides and actinides and the investigation of the regular features of their structure in relation to Mendeleev's periodic law.

II. STABILITY OF THE LOWER OXIDATION STATES OF THE *f*-ELEMENTS

1. Characteristics of the Univalent State

A number of experimental studies have been devoted to the attempt to obtain lanthanides or actinides in univalent or singly-charged states. Fong[8] studied the reduction of lathanides to the singly-charged state in crystalline lattices. In particular, the broad absorption band in the thermoluminescence spectra of γ-irradiated Sm^{2+}/KCl specimens has been assigned to the electronic transition $4f^6 6s^1 \cdot\cdot 4f^5 6s^2$, corresponding to the reduction of Sm^{2+} to the univalent state. Similar experiments were carried out[9] for Sm^{2+}/KCl and Eu^{2+}/KCl specimens; no evidence in support of the formation of Eu^+ was obtained. Subsequently, experiments were carried out[10] including the additional high-temperature treatment of Sm^{2+}/KCl and Eu^{2+}/KCl specimens in potassium vapour. This gave fundamentally new (at T = 4.2 K) absorption bands in the thermoluminescence spectra of these specimens, which were assigned to the univalent states Sm^+ and Eu^+. Fong's data on the preparation of univalent europium were confirmed in 1978.[11]

A series of unique studies in the synthesis of univalent lanthanides has been carried out.[12–15] The compounds LnX, where Ln = La, Ce, Pr, Nd, Gd, Tb, Dy, Ho, Er, and Lu; and X = Cl, Br, were synthesised. The compounds obtained have a layer structure, and are isostructural with ZrCl or ZrBr.[15] Zirconium chloride has the sodium chloride structure with alternating layers of Zr and Cl atoms parallel to the (001) face. The coordination polyhedron of the Ln atom is an antiprism of Ln_3–Cl_3 atoms.[15] A characteristic feature of the structure is the presence of a bond between the metal atoms, so that these compounds have the properties of two-dimensional metals.

Among actinide atoms, an attempt has been made to obtain mendelevium(I); the conclusion that mendelevium(I) exists was based on its ability to cocrystallise with potassium hexachloroplatinate.[2]

In all the experiments, the crystal lattice acts as an additional factor stabilising the univalent state (KCl or K_2PtCl_6); in the compounds prepared in the works cited,[12–15] the corresponding factor is the formation of Ln_6 metal clusters. The methods of high-temperature chemistry have detected the existence of many neutral molecules with the formula LnF.[16] These are unstable molecules, analogous to the univalent alkaline earth metal halides; they have similar dissociation energies, for example: E_d(CaF) = 125.5 kcal mole^{-1}, E_d(SmF) = 127 kcal mole^{-1}, E_d(SrF) = 129.5 kcal mole^{-1}, and E_d(NdF) = 130 kcal mole^{-1}. Stable compounds of the univalent lanthanides and actinides have not been obtained in solution or the gas phase.

Experiments on the study of solid specimens raise a number of important theoretical problems regarding the electronic structure of these elements in the univalent state, namely: 1) the nature of the electron configuration of the *f*-elements; 2) the stability of the lower oxidation states in the actinide series; 3) the analogy between the actinides in lower oxidation states and other elements of the periodic system.

The valence possibilities of an atom are determined by the number of unpaired electrons, unshared electron pairs, unfilled atomic orbitals (AO), and the energy of excitation from one electronic state to another. For most elements of the lanthanide and actinide series, the electron configuration of the ground state is $f^n s^2$, so that the univalent state is realised when one *s*-electron is involved in chemical bond formation, and the other remains localised, as in the univalent alkaline earth metal halides. In contrast to the elements of group II, however, in the singly-charged lanthanides and actinides there may be rearrangement of the electron configuration, stabilising this state: $M^+(f^n s) \rightarrow M^+(f^{n+1})$ or $M^+(f^n s) \rightarrow M^+(f^{n-1} s^2)$, where M = Ln, An. For the group II elements there is no "inner" atomic orbital which might have been involved in a stabilisation process.

It is of interest to compare the excitation energies E_1 of the transition $f^n s \rightarrow f^{n+1}$ for singly-charged lanthanides and actinides (Table 1). Using the Hartree–Fock Hamiltonian as the zeroth approximation and applying perturbation theory to the calculation of the correction to the kinetic energy operator and to take account of spin–orbit coupling, and also the Darwin correction, the present

authors calculated the excitation energies for the singly-charged lanthanides and actinides.[18,19] The data in Table 1 lead to the following conclusions.[23]

Table 1. Promotion energies of the transition $f^n s \rightarrow f^{n+1}$ for singly-charged actinide and lanthanide ions (kcal mole^{-1}).[18-22]

Note. Numbers in square brackets denote references (Ed. of Translation).

1. The energies of excitation into the univalent state for the singly-charged actinide ions are lower than those of the corresponding lanthanide ions.
2. The energies of excitation into the univalent states are lower for the second half of the actinides than for the first half, with the exception of Pu^+, which also has a low excitation energy $f^6s \rightarrow f^7$.
3. For the second half of the actinides, with increase in the atomic number, the excitation energy decreases, and the lowest excitation energy is shown by Md, at which the f^{14} shell is filled.
4. Of the lanthanides, Sm^+ ($f^6s \rightarrow f^7$ transition) and Pm^+ have the lowest excitation energies.

In addition to the electron configuration $f^n s$, an atom may be univalent in the electron configurations $f^n d$ and $f^n p$. The energy E of excitation into these states, however, is much greater than that into the state $f^n s$, and $E(f^n p) > E(f^n d) > E(f^n s)$. For all singly-charged actinides, the values of $E(f^n p)$ are greater than $E(f^n s)$ by ~3 eV. For U^+, Np^+, and Pu^+, the energy of the $f^n d$ electron configuration is higher than that of $f^n s$ by 1.0–1.5 eV; for the other elements of the actinide series, this difference gradually increases, reaching 3 eV for Md. These data indicate that for the univalent actinides, bond formation involves chiefly the 7*s* orbital; the 6*d* orbitals may play a small part in bond formation in the middle of the series (for U, Np, and Pu), but the 7*p* orbitals remain excited for all the univalent actinides; the 5*f* orbitals, like the other valence configurations ($f^n ds^2$, $f^n s^2$, $f^n sd$, etc.), remain core orbitals, deeper than the *s* orbital. Thus in the electron configuration $f^n s$ for the singly-charged actinide ions An^+, it is more difficult to remove an electron from an *f* orbital than from the *s* orbital; the difference in the ionisation energies $I_f - I_s$ is 2.1 eV for Pu, 3.3 eV for Am, 0.6 eV for Cm, 1.4 eV for Bk, 2.4 eV for Cf, 2.5 eV for Es, 2.1 eV for Fm, and 3 eV for Md.[20-22]

A second way in which the univalent state is stabilised is associated with the transfer of an *f* electron to the *s* level, that is $f^n s \rightarrow f^{n-1} s^2$. With a low excitation energy, a filled s^2 electron shell is formed. The data in Table 2 show that the values of the excitation energies $E_2(f^n s \rightarrow f^{n-1} s^2)$ are low, except for samarium and europium. It may be assumed that in the previously synthesised[12-15] monohalides LnCl, Ln = La, Ce, Pr, Nd, Gd, Tb, Ho, Er, the second route to the stabilisation of the univalent state is followed. They therefore have a distorted CdI_2 or $Mg(OH)_2$ structure, in which the central atoms also have an unshared pair of s^2 electrons. At the same time, samarium and europium differ from the other lanthanides: univalent europium should be the analogue of the alkaline earth elements, but Sm^+ can be stabilised by the first mechanism.

Table 2. Excitation energies for Ln^+ and An^+.[21]

An	$10^{-3} E_2$, cm^{-1}	Ln	$10^{-3} E_2$, cm^{-1}	An	$10^{-3} E_2$, cm^{-1}	Ln	$10^{-3} E_2$, cm^{-1}
Ac	—28.20	La	—6.75	Cm	—2.09	Gd	3.44
Th	—17.50	Ce	5.52	Bk	5.00	Tb	5.50
Pa	—8.00	Pr	16.00	Cf	12.00	Dy	12.336
U	—4.66	Nd	17.50	Es	12.00	Ho	10.00
Np	2.00	Pm	17.00	Fm	9.00	Er	7.00
Pu	8.19	Sm	24.00	Md	17.00	Tm	12.50
Am	18.50	Eu	33.00				

The univalent state in solution is characterised by the oxidation potential of the reaction

$$An^+_{aq}(f^{n+1}) \rightarrow An^{2+}_{aq}(f^n) + e$$

or

$$An^+_{aq}(f^{n-1}s^2) \rightarrow An^{2+}_{aq}(f^{n-1}s^1) + e$$

The factors determining the stability of the univalent state can be considered. The energy balance of the reaction is determined by the difference between the ionisation energy of the actinide ion in the univalent configuration and the energy of excitation from the univalent to the bivalent state $\varepsilon_1 = I - E_1$, and also by the difference in the free energies of hydration for these oxidation states, δF_n.

Table 3. Ionisation energies of singly-charged lanthanide and actinide ions in the electron configuration $f^{n-1}s^2$.[24,25]

Configuration	Term	Ln	$10^{-3} I'$, cm^{-1}	An	$10^{-3} I'$, cm^{-1}
f^0s^2	^1S	La	17.5	Ac	18.0
f^1s^2	^1F	Ce	33.8	Th	27.9
f^2s^2	^3H	Pr	47.9	Pa	47.2
f^3s^2	^4I	Nd	45.7	U	59.0
f^4s^2	^5I	Pm	44.6	Np	66.5
f^5s^2	^6H	Sm	55.5	Pu	101.4
f^6s^2	^7F	Eu	68.9	Am	88.0
f^7s^2	^8S	Gd	7.9	Cm	59.3
f^8s^2	^7F	Tb	24.4	Bk	91.7
f^9s^2	^6H	Dy	34.7	Cf	108.0
$f^{10}s^2$	^5I	Ho	32.5	Es	118.7
$f^{11}s^2$	^4I	Er	27.4	Fm	136.7

Factors increasing the stability of the univalent state are a high value of the ionisation energy of the singly-charged ion and a low excitation energy. From data on the ionisation energies of $An^+(f^n s)$, calculated in the relativistic Hartree–Fock approximation,[19] and from the excitation energies E_1 (Table 1), it follows that in the second half of the actinide

series, the most stable univalent state, corresponding to the minimum value of E_1, is shown by mendelevium. For univalent states stabilised by the second mechanism with the production of the electron configuration $f^{n-1}s^2$, the stability of the univalent state to oxidation is also determined by the quantity $\varepsilon_2 = I' - E_2$, where the corresponding values relate to the electron configuration $f^{n-1}s^2$. Table 3 gives the values of the ionisation energies for the electron configuration $f^{n-1}s^2$.[24,25] Comparison of the values of E_2 and I' shows that: 1) in the lanthanide series, the stability of the univalent state in solution with respect to oxidation is low; 2) in the actinide series, the stability of the univalent state in solution is higher than for the corresponding lanthanides.

2. Ionic Radii

The determination of the ionic radii of the actinides in lower oxidation states is important for establishing the similarity in the properties of the actinide elements and the elements of other groups of Mendeleev's periodic system. The solution of this problem is difficult, because of high radioactivity and the difficulty of obtaining the heavy actinides. At present, californium is apparently the last element for which ionic radii can be calculated from structural data. There are extremely few published data on the ionic radii of the actinides in lower oxidation states. Of the bivalent actinide compounds, americium di-iodide has been prepared; the measured interatomic distance in this compound, $R_{Am-I} = 3.28-3.40$ Å, indicates that the ionic radius of americium is 1.12–1.24 Å.[26]

Comparison of the lattice parameters of AmI_2 and EuI_2 [27] indicated that $R_{Am^{2+}} = 1.1$ Å, $R_{Eu^{2+}} = 1.09$ Å, and comparison of the lattice parameters of $EuBr_2$, $CfBr_2$, and $SrBr_2$ showed that $R_{Cf^{2+}} = 1.08$ Å. The similarity in the crystallisation coefficients of Sr^{2+} and Fm^{2+} with $SmCl_2$ indicates that the ionic radii of these elements differ by not more than 5%. Finally, comparison of the behaviour of Sr, Ca, and No in extraction and ion-exchange systems[28] indicated that the ionic radius of nobelium(II) lies in the range of the ionic radii of strontium and calcium.

Quantum-chemical methods make it possible to calculate the distance from the nucleus to that part of the ion where there is the maximum electron density R_{max}. Slater[30] has shown that the value of R_{max} for singly-charged ions is related to the crystal ionic radius by the simple relationship $R_{cr} = c_n R_{max}$, where c_n is a coefficient which depends on the principal quantum number n of the outer valence shell of the ion. For the f-elements of a given series, existing in the same charge state and therefore having the same valence f-orbital, the value of c_n apparently remains constant for the elements of the entire series. The Slater functions are crude approximations for the f-elements; better agreement can be obtained using the Hartree–Fock radii of the maximum electron density, calculated in the relativistic approximation.[24,25]

The Hartree–Fock values of R_{max} for the lanthanides and the crystal ionic radii of these elements in the tervalent state have been used[29] to calculate the coefficients c_n, which were found to be constant for all elements of the 4f series ($c_n = 1.257$). Similarly, the coefficients remain constant for the tervalent actinides from plutonium to einsteinium ($c = 1.21$). Pauling's relationship for isoelectronic ions[31] has been used to calculate the ionic radii for univalent and bivalent actinides;[30] the following values were obtained for the ionic radii of the doubly-charged actinide ions (Å):

Am^{2+}	Cm^{2+}	Bk^{2+}	Cf^{2+}	Es^{2+}	Fm^{2+}	Md^{2+}	No^{2+}
1.17	1.16	1.14	1.06	1.05	1.05	1.04	1.02

The ionic radii of the doubly-charged actinides calculated in this way agree with available experimental data. Thus the value of $R_{No^{2+}}$ lies in the range between the ionic radii of strontium and calcium.[32] The ionic radius of Fm^{2+} is close to the ionic radii of Sr^{2+} and Sm^{2+}; the ionic radius of Cf^{2+} agrees with the experimental data, which show that CfI_2 and CdI_2 are isostructural, and is close to the suggested[27] value of 1.08 Å.

The value obtained for the ionic radius of Am^{2+} shows good agreement with the experimental internuclear distance R_{Am-I} in AmI_2. Published data[27] on the ionic radius of americium, $R_{Am^{2+}} = 1.1$ Å, do not agree with the Hartree–Fock calculations, since the proportional relationship between $R_{max}(Am^{2+})$ and $R_{cr}(Am^{2+})$ breaks down. The value 1.21 Å was obtained[30] for $R_{cr}(Md^{+})$; the ionic radius of Md^{+} calculated in this way is close to that of Ag^{+} (1.13–1.26 Å).

III. HIGHER OXIDATION STATES OF THE LANTHANIDES AND ACTINIDES

1. Relationship Between the Oxidation Potentials and the Electronic Structure of the Central Atom

The marked increase in interest in compounds of the f-elements in unusual oxidation states can be attributed to two factors. Firstly, the discovery of nuclear decay and the subsequent development of nuclear energy have led to the detailed study of the chemistry of the lanthanides, the principal fission products found in the nuclear reactor, and of the chemistry of the transuranium elements, which are also formed at the same time. Secondly, there has been an increase in the role of the lanthanides and actinides in industry and a consequent increase in the need to study their properties and predict nontrivial oxidation states.[34]

It has been suggested[33] that einsteinium(IV) should exist in compounds with the fluorite structure. French workers, using thermochromatography, were the first to prove the existence of einsteinium(IV) fluorides,[35] and also curium(V) and (VI).[138] The behaviour of EsF_4 in the gas phase is analogous to that of CmF_4, BkF_4, and CfF_4.

It has been suggested that einsteinium(IV), fermium(IV) and mendelevium(IV) can exist as the double salts $Li_3.AnF_7$,[36] and berkelium(V), californium(V), and einsteinium(V) as the oxygen compounds Li_7AnO_6.[34] It has also been suggested that einsteinium(VI) and fermium(VI) can be obtained as the hexafluorides.[37] These suggestions, which undoubtedly contain elements of new ideas, have not been confirmed by calculations, estimations, or other evidence.

French workers,[38] on the basis of a calculation of the thermodynamic characteristics of the 5f elements, estimated the stability of berkelium(V) and californium(V), and showed that Cf(V) should be stable, and Bk(V) unstable, in aqueous solutions. The stability of a given oxidation state is determined by the oxidation potential of the reaction $An^{z+}(m) \rightarrow An^{z'+}(m+1) + e$, which in turn is determined by all the changes taking place when the central ion with effective charge z and oxidation number m is converted into a state with oxidation state $m+1$ and charge z'. The free

energy change F in the oxidation, $F = \pm\varepsilon + I + \Delta F_h$, includes the ionisation energy I, the energy $\pm\varepsilon$ used in the rearrangement of the electron configuration of the ion An^{z+} in the change from the state with oxidation number m to the state with oxidation number $m + 1$, and ΔF_h is the change in the free energy of hydration.

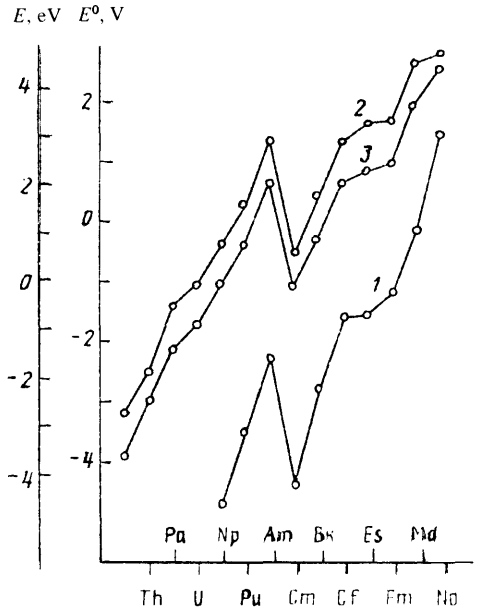

Figure 1. Dependence of the oxidation potentials E^0(II–III) (*1*) and the excitation energies $E = \varepsilon(f^n) - \varepsilon(f^{n-1}d)$ (*2*) and $E = \varepsilon(f^n s^2) - \varepsilon(f^{n-1}ds^2)$ (*3*) on the atomic number of the element.[107]

Within the framework of the covalent model, the electron configurations of the bivalent state $f^n s^2$ and the tervalent state $f^{n-1}ds^2$ in the approximation of the ionic model are f^n and $f^{n-1}d$ respectively. In both approximations, the value of ε changes in the same sense as the potentials E^0(II–III).[57] Fig. 1 gives the dependence on the atomic number of the elements of the oxidation potentials E^0(II–III) and the excitation energy, calculated for the two electron configurations from published data.[20–22] The main regular features of the dependence of other oxidation potentials on the atomic number of the element are also determined by the energy used up in the rearrangement of the electron levels of the actinide atoms or ions.[57,59] Change in the heats of hydration leads to renormalisation of the oxidation potentials, without changing their course. The linear relationship between the oxidation potentials and the energy of excitation of an f-electron into the d-level (Figs. 2 and 3) makes it possible, from the correlation rules alone, to judge whether a transition into the next oxidation state takes place. In this connection, an important role is acquired by calculations of the energy of the f- and d-levels in actinide and lanthanide atoms and ions.

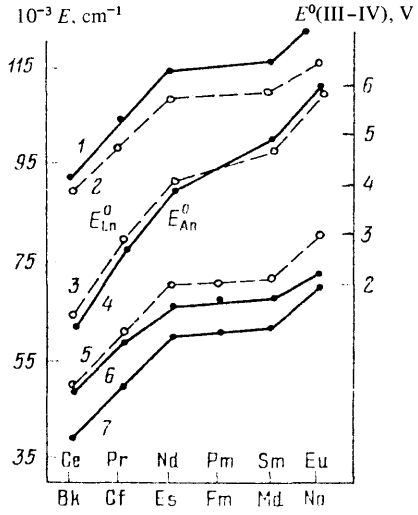

Figure 2. Change in the same sense in the oxidation potentials E^0(III–IV): *3*) Ln, *4*) An, and excitation energies for triply-charged lanthanide and actinide ions:[107] *1*) $An(f^n \to f^{n-1}p)$, *2*) $Ln(f^n \to f^{n-1}s)$, *5*) $Ln(f^n \to f^{n-1}d)$, *6*) $An(f^n \to f^{n-1}s)$, *7*) $An(f^n \to f^{n-1}d)$.

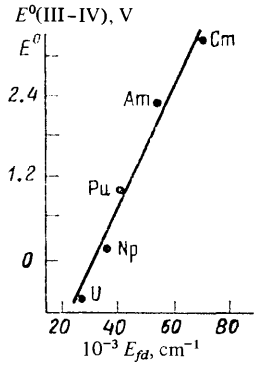

Figure 3. Linear relationship between the oxidation potentials E^0(III–IV) and the excitation energy.[107]

2. The Approximation Based on Calculations for Free Atoms and Ions

Atomic calculations give the first representations of the energy levels of atoms, and characterise the radial wavefunctions. These calculations can be used to reach important chemical conclusions about the possible oxidation states of atoms, the regular features of the change in stability, the specific features of the behaviour of the

actinide ions in solids, etc. Although calculations for molecules are used to reach definite chemical conclusions, calculations for atoms and ions are rarely used to interpret chemical data. These calculations may be useful, however, for an understanding of qualitative chemical regularities.

Atomic calculations for the actinides have an extensive history. Herman and Skillman[39] found solutions of the Hartree–Fock–Slater equation for all atoms up to element 103. Almost simultaneously,[40] the Hartree equation was solved with an exchange correction to the total energy. The first relativistic calculations for atoms, including uranium, were carried out[41] without allowance for exchange. Subsequently,[42] relativistic calculations were carried out with allowance for exchange by Slater's method, and account was taken of the effect of the finite dimensions of the nuclei.[43] Unfortunately, these calculations do not always correlate with the chemical properties. In Ref. 43, for berkelium and fermium, the electron configurations f^8ds^2 and $f^{11}ds^2$, corresponding to a more stable tervalent state, were obtained, whereas in fact they are more stable in the bivalent state. The difference in the energies of the 5*f*-orbitals of californium and einsteinium should not be so large as found in Ref. 43, since the oxidation potentials E^0(II–III) for these elements are similar.[44]

The use of the Slater exchange potential for large radii is an approximation, since the potential tends to zero according to an exponential law, and not as r^{-1}. The use of different coefficients[45–47] in the exchange potential improves the results, although the crude asymptotic form of the approximation is preserved. A number of authors have studied the question of why the local approximation is crude for large radii.[48–50] In Ref. 51, a first-order correction was introduced into the local approximation, using as the functions of the zeroth approximation the functions obtained in Ref. 52. The results[51] also show some lack of agreement with experiment. For the plutonium atom, the calculated energy of the 5*f* orbital is higher than that of the 7*s* orbital, whereas the opposite relationship should be observed. The energy parameters obtained[51] for americium indicate a very low ionisation energy (2.885 eV), and also show that it should be stable in the univalent or tervalent states, but not in the bivalent state; the energy parameters of berkelium correspond to stable tervalent and quinquevalent states. None of this agrees with experiment. Moreover, for Cf, the difference between the energy of the 5*f* and 7*s* orbitals is so small that its electron configuration should lead to a stable sexavalent state, which again does not agree with experiment. Beginning from einsteinium, however, adequate qualitative agreement between the calculated and experimental parameters is observed.

Hartree–Fock calculations of the electronic structure of atoms have been carried out by Mann.[53] Although these were non-relativistic calculations, exchange terms were taken into account without approximation; it was found that the 7*s* orbital (6*d* orbital in Refs. 43 and 51) is responsible for the ionisation energy. Although the values of the energy of the 6*d* orbitals obtained by Mann[53] are slightly low, the energies of the 5*f* orbitals give qualitatively the regular chemical features relating to the stability of the bivalent and tervalent states of the actinides. The absolute values of the energies of the 5*f* orbitals obtained in Ref. 53 differ by a factor of 2–2.5 from those obtained in Refs. 43, 51, and 54. In Ref. 53, these energies are systematically too low, possibly due to the neglect of relativistic effects.

In a series of calculations by Desclaux, the Dirac–Fock equation was solved without approximations for the exchange terms; the nuclei were regarded as spheres with uniform charge distribution,[54] in accordance with the published procedure.[55,56] A noteworthy feature is the small difference in the orbital energies of the 6*d* and 7*s* levels, which explains many experimental facts. In the thorium atom, the 6*d* orbital is deeper than the 7*s* orbital, that is thorium is an analogue of the transition elements; for protactinium, uranium, neptunium, and curium, on the other hand, the 7*s* orbital is lower than the 6*d* orbital, and this explains the stabilisation of the electron configuration f^ns of their singly-charged ions.[54]

In the first half of the series, the energies of the valence 5*f* orbitals differ little from the energies of the 6*d* and 7*s* orbitals, indicating that the elements of the first half of the series tend to form higher oxidation states. In the second half of the series, this difference gradually increases, again in agreement with the experimentally observed stabilisation of the bivalent state in the second half of the actinide series. The absolute values of the energies of the 5*f* orbitals explain their participation in chemical bond formation and the sequence in the arrangement of the molecular orbitals in actinide molecules and complexes.

Thus many atomic calculations give correctly the regular features of the electronic structure of the lower oxidation states of the actinides An(II) and An(III), and this gives grounds for using these calculations for the higher oxidation states also. The present authors carried out a series of calculations for the atoms of the 5*f* elements in excited configurations with the participation of the 6*d* orbitals and positively charged ions by the Hartree–Fock method with allowance for relativistic corrections.[61] According to these calculations, carried out for actinide ions in the electron configuration f^n,[19] the energy of removal of the last *f*-electron (Ry) increases sharply on going from Ac to Pu:

Ac	Th	U	Np	Pu
1.53068	2.70432	5.43696	6.97975	8.63445

The correlation of these ionisation energies with the known oxidation potentials corresponding to the change to higher oxidation states leads to a high potential for plutonium: E^0(VII–VIII) ≅ 4 V.

When applied to the change to a higher oxidation state, it may be assumed that the relative depth of the potential well for the $5f^1$ electron configuration is determined by the energy of splitting of the ^2F term as a result of spin–orbit coupling. Using the calculated[19] spin–orbit coupling constants for the actinides in the f^1 electron configuration from the actinium atom to the americium atom (cm^{-1})

Ac	Th	Pa	U	Np	Pu	Am
707	960	1211	1472	1747	2038	2337

for correlation with the known potentials also gave a high oxidation potential for plutonium: E^0(VII–VIII) ≅ 4 V; the oxidation potential obtained for the americium couple was even higher: E^0(VIII–IX) ≅ 5.8 V.

An important factor in the comparative estimation of the stability of f^n electron configurations with $n > 1$ is the interelectronic interaction, determined by the Racah parameters E^0, E^1, E^2, E^3. The ionisation energy[62] of an *f*-element in the electron configuration f^n can be expressed in terms of the Racah parameters and *W*, the Coulomb energy in the field of the positively charged core, imitating the cloud of the inert gas radon (Table 4).

The change in the energy of the electrostatic interaction with change in the number of electrons determines the binding energy of the valence electrons with the core. For example, exchange interaction increases the ionisation energy in the electron configuration f^{10} by $+12E^3$, makes no contribution to the electron configuration f^{11}, and decreases the ionisation energy in the electron configuration f^{12} by

$-12E^3$. The parameter W also changes with change in the number of electrons, but these changes are not so great for the lanthanides as for the actinides; thus for the 4*f*-elements, the parameter E^3 can influence the relative stability of a given oxidation state along the series. The stabilities of the 4+ oxidation states of the lanthanides show interesting regular features. From the experimental values of the oxidation potentials E^0(III–IV), it follows[58,75] that the stability of the 4+ oxidation state decreases on going from cerium to neodymium in the first half of the series and from terbium to dysprosium in the second. In other words, the stability of the 4+ oxidation state decreases towards the end of the series.

Table 4. Ionisation energy of actinides with the electron configuration f^n.[62]

n	$I=E(f^{n-1})-E(f^n)$	n	$I=E(f^{n-1})-E(f^n)$
1	W	8	$W-7E^0-9E^1$
2	$W-E^0+9E^3$	9	$W-8E^0-9E^1+9E^3$
3	$W-2E^0+12E^3$	10	$W-9E^0-9E^1+12E^3$
4	$W-3E^0$	11	$W-10E^0-9E^1$
5	$W-4E^0-12E^3$	12	$W-11E^0-9E^1-12E^3$
6	$W-5E^0-9E^3$	13	$W-12E^0-9E^1-9E^3$
7	$W-6E^0$	14	$W-13E^0-9E^1$

When the change in the parameter E^3 for the electron configurations f^{10}, f^{11}, and f^{12}, corresponding to triply-charged holmium, erbium, and thulium, is taken into account, the opposite trend in the stabilities of the 4+ oxidation state can be expected for these elements: Ho < Er < Tm. This is confirmed by the fact that for holmium, erbium, and thulium, there is a decrease in the energies of excitation from the f^n (n = 10, 11, 12) to the $f^{n-1}d$, $f^{n-1}p$, and $f^{n-1}s$ states.[19] For the actinides, there is a gradual increase in the corresponding energies from californium to nobelium (Fig. 4). These facts indicate that the stability of the 4+ oxidation state increases towards the end of the lanthanide series from holmium to thulium, and decreases towards the end of the actinide series from einsteinium to nobelium, that is in the actinide series on going from Es to No, the most stable 4+ oxidation state is shown by einsteinium, whereas in the lanthanide series it is shown by thulium. The preparation of compounds of thulium(IV)[7] and einsteinium(IV),[35] Cs_3TmF_7 and EsF_4, confirmed these theoretical predictions.

The sharp increase in the ionisation energy for the half-filled f^7 electron configuration compared with the f^8 configuration is due to the appearance of the term $-9E^1$ for n = 8. When applied to Cm, this means that it gives up an electron with greater difficulty in the tervalent state than in the quadrivalent state, but in the quinquevalent state the binding of the remaining five electrons to the core is decreased as a result of electrostatic repulsion, so that Cm(V) should be more readily converted into Cm(VI), compared with the conversion of Cm(IV) into Cm(V). Finally, Cm(VI) and Cm(III) are analogues in the sense that the interelectronic interaction parameter E^3 does not make a contribution to the binding energy of the remaining electrons to the core. Thus the potential E^0(VI–VII) for Cm should be high, like E^0(III–IV). Even this qualitative approach determines the chemical properties. For a quantitative estimate of the oxidation potentials, the correlation with the energies of the *fd*-transitions can be used.[64–68]

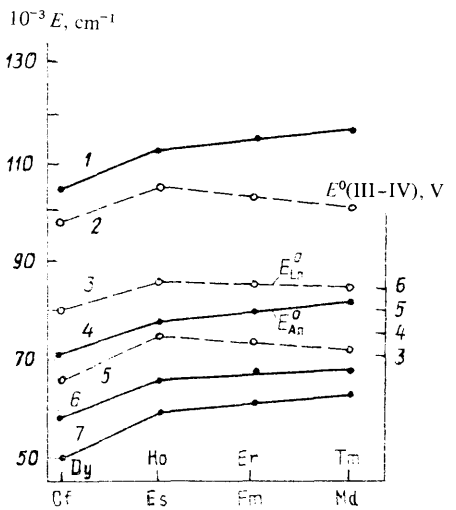

Figure 4. Change in the opposite sense in the oxidation potentials E^0(III–IV): *3*) Ln, *4*) An, and the excitation energies for triply-charged actinides and the corresponding lanthanides:[107] *1*) An($f^n \rightarrow f^{n-1}p$), *2*) Ln($f^n \rightarrow f^{n-1}s$), *5*) Ln($f^n \rightarrow f^{n-1}d$), *6*) An($f^n \rightarrow f^{n-1}s$), *7*) An($f^n \rightarrow f^{n-1}d$).

Published data on the transition energies have been obtained from the atomic spectra and the spectra of multiply ionised ions,[20,21,69,70] from thermochemical data for metals,[20,21] the electronic spectra of compounds,[71,72] the spectra of actinide ions in matrices, from Hartree–Fock calculations for free atoms and ions with allowance for relativistic corrections,[39–43,45–47,51–56] and finally by linearisation of the parameters of Coulombic and spin–orbit interactions.[22] The absolute magnitudes of these quantities do not always coincide, due chiefly to the marked broadening of the bands in the spectra as a result of spin–orbit coupling. Thus for uranium with a charge of 5+ in the electron configuration f^1, the terms of the ground state ^2F and the first excited state ^2D are split by spin–orbit coupling $^2F \rightarrow {}^2F_{5/2} + {}^2F_{7/2}$, $^2D \rightarrow {}^2D_{3/2} + {}^2D_{5/2}$ by 7609 cm^{-1} and 9511 cm^{-1}.[69] In accordance with the increase in the atomic number, the splitting energy of the ^2F term for Np^{6+} and Pu^{7+} increases. There is an analogous increase in the splitting energy of the ^2D term.[69] Thus for the transuranium elements it is possible to speak only of a qualitative charge dependence of the energy of the *fd* transition. On the basis of available experimental data on the energies of *fd* transitions, the present authors calculated the difference in the energies of the f^n and $f^{n-1}d$ states for the multiply ionised ions from actinium to curium; the data obtained are given in Table 5.[19,63,68] The correlation of the values of E_{fd} obtained with the known oxidation potentials indicates that curium(VI) is stable in solution: E^0(V–VI) = 5.1 V, whereas E^0(IV–V) = 1.7 V and E^0(VI–VII) = 2.7 V. The preparation of curium(VI)[1] confirmed these theoretical predictions. This approach indicated that californium(V)

is stable,[73] as confirmed experimentally,[74] and also that einsteinium(VI) is stable, E^0(V–VI) = 1.5 V. According to these estimates, berkelium(V) and californium(VI) should be unstable in solution.

Table 5. Excitation energies from the f^n electron configuration to $f^{n-1}d$ (10^{-3} E_{fd}, cm^{-1}).[63]

3. Molecular-Orbital Analysis of Octahedral Complexes

Since the discovery of septavalent neptunium, plutonium, and americium,[4–6] a large amount of experimental material has accumulated,[76] and the problems still to be solved have become clear. These problems are related primarily to the study of the electronic structure of compounds of neptunium(VII), plutonium(VII), and americium(VII), and cover a wide range of questions: the electron density distribution, the structure of the energy levels, the regular features of the change in the ionisation energies and electron affinity, the determination of the oxidation potentials, and the interpretation of the electronic spectra. The discovery of the highest oxidation state of neptunium raised the question of the possible existence of plutonium(VIII), which can be resolved only by a systematic study of the high oxidation states of uranium, neptunium, plutonium, and americium.

To resolve these problems, Pershina[77,78,95] carried out a a series of molecular orbital calculations for octahedral oxyanions UO_6^{7-}, UO_6^{6-}; NpO_6^{7-}, NpO_6^{6-}, NpO_6^{5-}; PuO_6^{6-}, PuO_6^{5-}, PuO_6^{4-}; AmO_6^{6-}, AmO_6^{5-} [77–80] by the semi-empirical molecular orbital method[81] using numerical Hartree–Fock functions.[53] The choice of objects of study is not accidental: most compounds of the actinides in the highest oxidation states in solution, and also those obtained by solid-phase synthesis, are oxygen compounds.

It follows from molecular orbital calculations that the effective charges on the central atoms do not exceed 2+ (Table 6). For isoelectronic anions they decrease with increase in the atomic number of the central atom. Table 6 shows that the populations of the 5*f* orbitals differ considerably from those given by crystal field theory. The population of the 6*d* orbitals corresponds to approximately two electrons. This is an interesting fact, since the ground state of the neutral atoms does not contain more than one 6*d* electron. With increase in the oxidation state of the actinide, the population of the 6*d* orbital increases; at the same time the population of the 5*f* orbital decreases, that is the oxidation is accompanied by the excitation of an electron into the 6*d* level. The population of the 7*s* orbital is low, and changes little from one compound to another.

A typical energy level diagram for octahedral oxyanions is shown in Fig. 5 for the UO_6^{7-} ion. The low-lying energy levels correspond to the interaction of the 2*s* and 2*p*σ orbitals of the oxygen atoms and the 7*s*, 6*d*, and 5*f* orbitals of the actinide atom. These are predominantly ligand orbitals. The next group of levels corresponds to pure σ or mixed (σ–π) molecular orbitals. In all the anions studied, the system of bonding levels is completed by quasi-degenerate molecular orbitals (MO), corresponding to oxygen atomic orbitals (AO), which are separated from the antibonding MO by an energy gap of width Δ*E*. For the diamagnetic ions UO_6^{6-}, NpO_6^{5-}, and PuO_6^{4-}, the values of Δ*E* are low, indicating the possible existence of polarisation temperature-independent paramagnetism.

Table 6. Populations of the *s*-, *d*-, and *f*-orbitals (*e*).[77,78]

Orbital	U(V)	U(VI)	Np(VI)	Np(VII)	Pu(VI)	Pu(VII)	Pu(VIII)	Am(VI)	Am (VII)
s	0.29	0.28	0.28	0.26	0.27	0.25	0.23	0.26	0.25
d	2.10	2.30	2.21	2.34	2.10	2.25	2.40	2.08	2.21
f	1.75	1.47	2.80	2.70	4.04	3.92	3.84	5.19	5.11

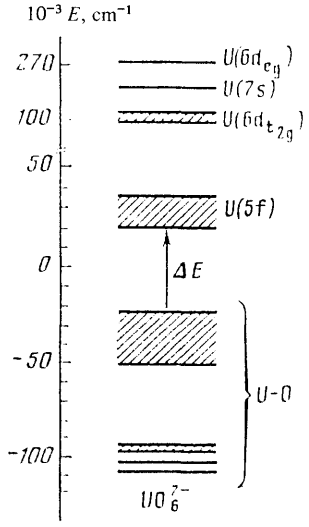

Figure 5. Typical energy level diagram for octahedral oxyanions of the actinides: the uranium(V) oxyanion.[107]

In the isoelectric ions, the magnitude of the crystal field splitting increases from U(VI) to Np(VII) and Pu(VIII) (Fig. 6). The magnitude of the splitting increases with increase in the oxidation state of the central ion; for example, for PuO_6^{6-}, PuO_6^{5-}, and PuO_6^{4-}, the magnitude of the splitting is 18030, 23260, and 28080 cm^{-1} respectively.[77–80]

In the highest oxidation states, the ionisation potential is determined by the molecular orbital t_{1u}. The energy of this MO decreases on going from U(VI) to Np(VII) and Pu(VIII) in accordance with the decrease in the effective negative charge on the ligands. As a result of the stabilisation of the 5*f* orbitals of the actinide atoms with increase in the atomic number in the isoelectronic anions,

the energy of the non-bonding $2\Gamma_7^-$ level decreases in the order U(VI) > Np(VII) > Pu(VIII), so that the electron affinity for PuO_6^{5-} is ~5.8 eV. This is apparently one of the main reasons for the instability of plutonium(VIII) in the oxyanion form. In anions with the $(2\Gamma^-)^1$ configuration, this level is also stabilised with increase in the atomic number of the actinide; thus U(V) is readily converted into U(VI), whereas plutonium(VII) is not oxidised.

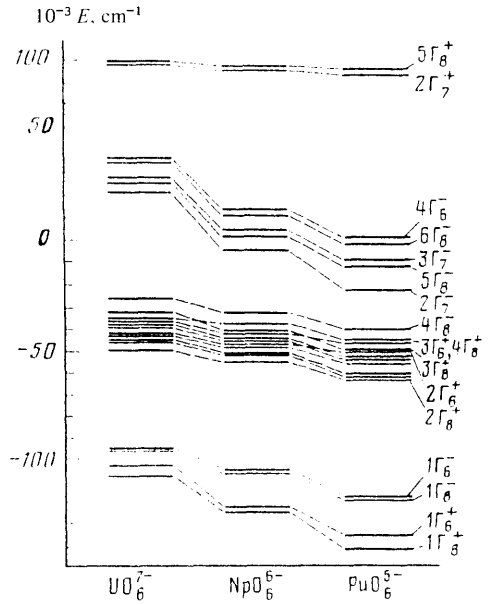

Figure 6. Change in the energy levels in isoelectronic oxyanions with increase in the atomic number of the actinide.[107]

Usually, three groups of bands are interpreted in the electronic spectra of actinide compounds: *ff*, *fd*, and charge-transfer transitions. This interpretation has been carried out in detail for uranium, neptunium, and plutonium hexahalides,[82-88] for actinyl ions,[89] and for a number of complexes.[90-93] The *ff* transitions in various octahedral oxyanions have been assigned.[94] A complete analysis of the electronic spectra on the basis of molecular orbital calculations for the entire series of octahedral oxyanions from U to Am has not been carried out. In the diamagnetic anions of U(VI), Np(VII), and Pu(VIII), the lowest transitions take place from the molecular orbitals $3\Gamma_6^+$ and $4\Gamma_8^+$ into antibonding MO with symmetry Γ_7^- and Γ_8^-. This leads to the existence of seven charge-transfer transitions allowed by the dipole selection rules (Table 7). Seven fine-structure bands appear in the absorption spectrum. This absorption band is displaced towards longer wavelengths in the series U(VI) → Np(VII) → Pu(VIII).

Additional absorption bands may also appear in the spectrum, since many of the MO are practically non-bonding. Two such additional bands are formed by transitions from the orbitals $2\Gamma_6^+$, $3\Gamma_8^+$ and $1\Gamma_6^+$, $2\Gamma_8^+$ (Table 7).

Table 7. Energies of the charge-transfer bands (10^{-3} *E*, cm^{-1}).[78]

Transition	UO_6^{6-}	NpO_6^{5-}	PuO_6^{4-}
$3\Gamma_8^+ \rightarrow 5\Gamma_8^-$	45.6	32.3	26.6
$3\Gamma_6^+ \rightarrow 6\Gamma_8^-$	57.7	45.2	39.8
$4\Gamma_8^+ \rightarrow 2\Gamma_7^-$	40.2	25.1	15.6
$4\Gamma_8^+ \rightarrow 5\Gamma_8^-$	45.6	32.3	26.6
$4\Gamma_8^+ \rightarrow 3\Gamma_7^-$	51.2	35.6	31.4
$4\Gamma_8^+ \rightarrow 6\Gamma_8^-$	57.7	45.2	39.8

$2\Gamma_6^+ \rightarrow 5\Gamma_8^-$	51.9	38.2	32.0
$2\Gamma_6^+ \rightarrow 6\Gamma_8^-$	64.0	51.1	45.2
$3\Gamma_8^+ \rightarrow 2\Gamma_7^-$	42.1	30.3	23.5
$3\Gamma_8^+ \rightarrow 5\Gamma_8^-$	47.6	37.6	34.5
$3\Gamma_8^+ \rightarrow 3\Gamma_7^-$	53.1	40.8	39.3
$3\Gamma_8^+ \rightarrow 6\Gamma_8^-$	59.4	50.5	47.7
$3\Gamma_8^+ \rightarrow 4\Gamma_6^-$	60.2	51.4	51.6
$2\Gamma_8^+ \rightarrow 2\Gamma_7^-$	56.2	41.9	33.0
$2\Gamma_8^+ \rightarrow 5\Gamma_8^-$	61.6	49.2	43.9
$2\Gamma_8^+ \rightarrow 3\Gamma_7^-$	67.2	52.5	48.8
$2\Gamma_8^+ \rightarrow 6\Gamma_8^-$	73.7	62.1	57.2
$2\Gamma_8^+ \rightarrow 4\Gamma_6^-$	74.2	63.1	61.0

Extensive experimental material has been published[76] on the electronic absorption spectra of actinides(VII) (Pu, Am) in alkaline solutions. The regular features in the spectra, corresponding to charge-transfer bands, are the same as for the highest oxidation states. Fine structure of the main band is observed, apparently as a consequence of spin–orbit coupling of the energy levels in the complex, particularly the levels with a large contribution from the 5*f* orbitals of the atoms. For systems with the $5f^1$ electron configuration of the actinide (UO_6^{7-}, NpO_6^{6-}, PuO_6^{5-}), transitions of the *ff* type appear, with calculated energies lying in the ranges 4170–14340, 5944–17020, and 9070 to 22040 cm^{-1} respectively.[77,78] The energies of the *fd* transitions in these complexes and the experimental values of the oxidation potentials E^0(V–VI) for uranium and E^0(VI–VII) for neptunium[76] make it possible to estimate the oxidation potential for plutonium: E^0(VII–VIII) = 3.7 V. This confirms the conclusion, based on atomic calculations, that plutonium(VIII) is unstable in solution.[78]

A similar analysis of the electronic structure and properties has been carried out for the octahedral chloro-anions of actinides(III) and (IV) $AnCl_6^{z-}$.[95,96] In the An(IV) complexes, the populations of the 6*d* orbitals decrease with increase in the atomic number of the element, smoothly on going from Pa to Np and then more sharply on going to Pu, and the populations of the 5*f* orbitals increase in the same direction. The energies of the charge-transfer transitions pass through an extremal value for curium (Table 8). The calculations of the energies of the *ff* transitions give good agreement with experiment (Table 9);

this makes it possible to use the calculated values of the energy for those complexes for which there are no experimental data. The energies of the *fd* transitions and their correlation with known oxidation potentials have been used to determine the oxidation potential E^0(IV–V) for californium, which indicated that californium(V) is stable.[80]

Table 8. Energies of the charge-transfer bands (10^{-3} E, cm^{-1}) for octahedral chloro-complexes $AnCl_6^{2-}$.

4. Cationic Forms of the Highest Oxidation States of Uranium, Neptunium, and Plutonium

Since plutonium(VIII) is unstable as PuO_6^{4-},[107] the question of its possible existence as molecules or cations arises. The PuO_4 molecule with tetrahedral or square coordination of the ligands should have an even greater electron affinity than the oxyanion. The cationic form of high oxidation states of neptunium and plutonium, in particular NpO_2^{2+} and PuO_2^{3+}, have been regarded as realistic by a number of authors,[97] so that the existence of PuO_2^{4+} might also be assumed.

The change in the stability of the isoelectronic ions in the series PaO_2^+, UO_2^{2+}, NpO_2^{3+}, PuO_2^{4+} can be considered.[98] In the maximum overlap model, linear spatial coordination of the nuclei corresponds to either *fd* or *fs* hybridisation, and angular coordination corresponds to *ds* hybridisation. This means that if in the actinide ion An^{z+} in the electron configuration of the ground state there is a closely-lying *d* or *s* level, the dioxo-cation AnO_2^{z+} obtained will be stable in the linear coordination. The energies ε of the transfer of an *f*-electron from the ground state to the excited electron configuration of lowest energy can be compared for the isoelectronic ions Pa^+, U^{2+}, Np^{3+}, and Pu^{4+} (Table 10). For Pa^+, excitation into the electron configuration f^3d or f^3s requires a greater expenditure of energy than excitation into the configuration f^2ds, corresponding to an angular molecule.[20–22] The preference for angular coordination distinguishes the protactinium ion from other actinyl ions. For the U^{2+} ion, the electron configuration of the ground state is $f^3d(^5L_6)$. It coincides with the electron configuration of the U^{2+} ion in the uranyl group.[99,100] Thus the doubly-charged uranium ion is able to adopt linear coordination without the expenditure of energy on *fd* hybridisation and without the participation of inner 6*p* orbitals (Table 10).

Table 10. Excitation energies (10^{-3} E, cm^{-1}) for An^{z+} in AnO_2^{z+}.[98,107]

Electron configuration	PaO_2^+	UO_2^{2+}	NpO_2^{3+}	PuO_2^{4+}
f^3d	18.04	0.00	31.60	47.00
f^2ds	1.20	—	—	—
		UO_2^+	NpO_2^{2+}	PuO_2^{3+}
f^1d		12.50	4.10	44.00
f^2ds		0.289	41.00	—
			NpO_2^+	PuO_2^{2+}
f^2d			12.80	9.80
f^1ds			0.49	57.00

It is of interest to compare the geometry of the UO_2^{2+} ion with that of the MoO_2^{2+} or WO_2^{2+} ions. Thus for the doubly-charged molybdenum ion [ground state $d^4(^5D)$], the first excited state $d^3s(^5F)$ corresponds to angular coordination and $\varepsilon \cong 30000$ cm^{-1}, whereas the excited d^3p state corresponding to linear coordination, is higher, $\varepsilon \cong 75000$ cm^{-1}.[101] Thus the dioxo-cations of the transition elements and the corresponding actinides evidently have different geometries.

The electron configuration of the ground state of the triply-charged neptunium ion and the quadruply-charged plutonium ion is $f^4(^5I)$. The energy of excitation of an *f*-electron into the *d*-level is $(38 \pm 7) \times 10^3$ cm^{-1} for Np^{3+} and 47×10^3 cm^{-1} for Pu^{4+}.[20–22] This leads to the qualitative conclusion that for the isoelectronic linear actinyl ions UO_2^{2+}, NpO_2^{3+}, and PuO_2^{4+}, the stability decreases on going from uranium to plutonium. The high excitation energy and the high electron affinity, greater than for the PuO_6^{4-} oxyanion and the PuO_4 molecule, make the cationic form of plutonium PuO_2^{4+} unstable. The published range of values for the energy of excitation of Np^{3+} into the f^3d-state is fairly wide, however: 31×10^3 $cm^{-1} \leqslant \varepsilon \leqslant 45 \times 10^3$ cm^{-1}.[20,21] Attempts to measure this quantity have a long history. In 1960, Carnall and Cohen[102] found from the absorption spectra of Np^{3+} in 1 M $HClO_4$ that the value of ε ($f^4 \rightarrow f^3d$) lies in the range 31×10^3–43×10^3 cm^{-1}. In 1965, Marcus and Shiloh[103] detected in the absorption spectra of neptunium(III) in concentrated solutions two intense bands at 26040 cm^{-1} and 32050 cm^{-1}, which they assigned to the $f^4 \rightarrow f^3d$ electron transition. The absorption and emission spectra of single crystals of $LaCl_3$ containing $NpCl_3$ were obtained in 1967.[104] A large group of bands, assigned to *ff* transitions, was detected in the range 5000–25000 cm^{-1}, and it was concluded that the energy of the $f^4 \rightarrow f^3d$ transitions lies above 25000 cm^{-1}. Recently, Carnall and co-workers[105] recorded the low-temperature absorption spectrum of $NpCl_3$ and $NpBr_3$ in the range 3300–43000 cm^{-1}. The spectra of both compounds showed broad intense bands in the range 26000–32 000 cm^{-1}, assigned to *fd* transitions. Nugent and co-workers,[22] on the basis of a systematic treatment of low-lying electron configurations, calculated the energy of excitation into different electronic states of the actinides and their ions. According to their calculations,

the excitation energy of the $f^4 \rightarrow f^3d$ transition for Np^{3+} is 31600 cm^{-1}. Finally, Carnall, Fried, and Wagner,[106] on the basis of the recorded spectra of the triply-charged ions of the elements from U to Cf in matrices, concluded that the lowest energy of excitation into the f^3d state for Np^{3+} is 26000 cm^{-1}. For comparison, it may be noted that the excitation energy of the transition $f^7 \rightarrow f^6d$ for Am is 23.9×10^3 cm^{-1} [22] or $(24 \pm 3) \times 10^3$ cm^{-1}.[20,21] Since AmO_2^+ exists, although it is less stable than other doubly-charged actinyl ions, it might be thought that NpO_2^{3+} might exist. There are two factors, however, determining stability: the ratio of the energies of the AO of the central atom and the ligands and their degree of overlap. The present authors[107] calculated the radial wavefunctions and energies of the valence AO for An^{z+} ($z = 0-5$) using a relativistic version of the Hartree–Fock method, and obtained the following results.

1. For the doubly-charged ions of the elements of the first half of the actinide series, the energy of a 5*f* orbital lies in the range 15–20 eV, that is it is close to the energy of the 2*s* and 2*p* orbitals of the oxygen atom.
2. The energy of a 5*f* orbital of the triply-charged actinide ions is much lower than that of the 2*s* and 2*p* orbitals of the oxygen atom.
3. The overlap integrals of the valence AO of the triply-charged actinide ions with the AO of oxygen are small, since the 5*f* orbitals are greated contracted, and the 5*f* electrons tend to remain localised.

All this prevents the formation of a stable NpO_2^{3+} cation, not to mention PuO_2^{4+}, since with further increase in the charge, the 5*f* electrons are localised to an even greater extent.

The isoelectronic series UO_2^+, NpO_2^{2+}, and PuO_2^{3+} can be considered. It has been established experimentally[21] that for the singly-charged uranium ion the ground state is $f^3s^2(^4I_{9/2})$; its first excited state $f^3ds(^6L_{11/2})$ lies only 289 cm^{-1} above the ground state, that is it almost coincides with the ground state, but the next excited state $f^4s(^6I_{7/2})$ lies 4664 cm^{-1} above the ground state.[20-22]. The linear coordination of the nuclei in UO_2^+ can apparently be non-rigid under certain conditions; the main condition is a low effective charge on the uranium atom, not exceeding +1.5. It may be assumed that in compounds with a uranyl group containing uranium(VI) and donor ligands, which decrease the effective charge on the uranium atom, possible deviation from the linear structure is not excluded. The energies of the transition for the doubly-charged neptunium ion into excited states correspond to a stable state and linear coordination of the nuclei in NpO_2^{2+}. The plutonyl ion PuO_2^{3+} is unstable for the same reason as NpO_2^{3+}.

A noteworthy feature is that the cationic forms examined here are three-atom systems which do not have ligands (or solvent molecules) in the equatorial plane. Donor ligands, which increase the electron density on the central atom and decrease the effective charge, would lead to stabilisation of the triply-charged cationic forms.

In a number of experimental papers[108] it has been suggested that in acidic media, septavalent Np exists as the singly-charged cation NpO_3^+. It was of interest to use quantum-chemical ideas to examine different geometric forms of this cation and to estimate the possibility of its existence as an independent oxo-group.[109] The method used was the X_α scattered wave method in the model of touching spheres. The criterion for the central metal atom being chemically combined with the oxyger atoms surrounding it is the existence of a minimum on the potential energy curve. This is equivalent to the statement that in a certain range of interatomic distances there is a strictly determined set of filled molecular levels, determined by the symmetry point group of the molecule. Since the dependence of the total energy of a molecule on the interatomic distance cannot be determined reliably in the X_α method, the possibility of existence and the stability of the NpO_3^+ cation being considered was estimated from the viewpoint of the existence of the correct standard electronic structure.[109] Three geometric configurations of NpO_3^+ were examined:[109] a *T*-shaped structure with symmetry C_{2v}, a pyramidal structure with symmetry C_{3v}, and a planar triangular structure with symmetry D_{3h}. The calculation showed that NpO_3^+ cannot exist as an independent stable oxo-group of septavalent Np, in contrast to the analogous oxo-cations of the septavalent *d* transition metals, for which both the planar triangular configuration and the pyramidal configuration exist.

5. The Use of the Principle of Orbital Symmetry to Explain the Mechanism of Cation–Cation Interactions

After Woodward and Hoffmann had demonstrated the effectiveness of the application of the principle of orbital symmetry to explain reaction mechanisms in organic chemistry, this principle became a fundamental theoretical concept.[110] The present authors attempted to apply the principle of preservation of orbital symmetry to cation–cation reactions in the chemistry of the actinides.

It has been established that actinides(V) AnO_2^+, where An = U, Np, Pu, and Am, tend to react with various "active" cations, in particular UO_2^{2+}, Fe^{3+}, In^{3+}, and Th^{4+}.[110-115] A number of regular features have been established experimentally, and can be explained on the basis of quantum-chemical considerations: only actinyl ions containing actinides(V) tend to undergo cation–cation interaction (CCI); the PuO_2^{2+} ion, isoelectronic with NpO_2^+, does not react with UO_2^{2+} ions even in 3 M uranyl perchlorate solution; the degree of CCI of UO_2^{2+} with AnO_2^+ decreases with increase in the atomic number in the series: $UO_2^+ > NpO_2^+ > PuO_2^+ > AmO_2^+$; CCI between AnO_2^+ and active cations is accompanied by a change in the electronic absorption spectrum of AnO_2^+ and by the appearance of new bands; the interaction of NpO_2^{2+} with AnO_2^+ is weaker than for UO_2^{2+}; and the degree of CCI increases with decrease in the energy corresponding to the maximum of the charge-transfer band in the absorption spectrum of the aquo-complex of the active cation.[116] In the present review, a mechanism of CCI is proposed, and a quantum-chemical explanation is given for the experimental regular features.

In the symmetry point group $D_{\infty h}$, the 5*f* atomic orbitals of an actinide atom are split into σ_u, π_u, δ_u, and Φ_u orbitals, and the 6*d* orbitals are split into σ_g and π_g orbitals. Thus for UO_2^{2+}, which has 12 valence electrons, the electron configuration of the energy levels has the form $\sigma_g^2\pi_u^4\pi_g^4\sigma_u^2\Phi_u\delta_u\pi_u^*\sigma_u^*$. This configuration is preserved in all other actinyl ions AnO_2^{z+}, but with different filling numbers for the non-bonding Φ_u and δ_u levels. In solution, actinyl ions have tetragonally distorted octahedral geometry $AnO_2L_4^{z+}$ (where L represents a ligand) with symmetry point group D_{4h}. Fig. 7 shows the form of the molecular orbitals and the correlation of the symmetry of the orbitals for both point groups. On going from the free ion AnO_2^{z+} to $AnO_2L_4^{z+}$, splitting of the Φ_u level takes place, and new orbitals are added, corresponding to the interaction of the actinide with the ligands L in the equatorial plane.

The reaction between UO_2^+ and UO_2^{2+} can be considered. This interaction takes place by the overlap of the occupied molecular orbitals of UO_2^+ with unoccupied orbitals of UO_2^{2+},

and conversely. To interact, these orbitals must have the same symmetry.[110] Molecular orbital calculations for octahedral complexes containing actinides(V) and actinides(VI), AnO_6^{7-} and AnO_6^{6-}, where An = U, Np, Pu, and Am, showed showed[117] that the last occupied molecular orbital has t_{1u} symmetry. For the point group D_{4h} this corresponds to the interaction of e_{2u} and a_{2u} orbitals, and for the symmetry group $D_{\infty h}$ it corresponds to the interaction of occupied σ_u orbitals and unoccupied or partly occupied δ_u orbitals. According to calculation,[100] the energy of the occupied σ_u orbital in UO_2^{2+} is −17.75 eV, whereas the energies of the unoccupied Φ_u and δ_u orbitals in UO_2^{2+} are lower and amount to −22.88 eV and −22.72 eV respectively. This important feature determines all the specific characteristics of the interaction of the ion-containing actinides(V) and actinides-(VI), since the occupied σ_u orbital in UO_2^+ will donate electron density to the unoccupied δ_u orbital in UO_2^{2+}. The analogous interaction between the UO_2^{2+} (σ_u^2) and UO_2^+ (δ_u) orbitals is energetically unfavourable, since the donor orbital in UO_2^{2+} is much lower than the acceptor orbital in UO_2^+.

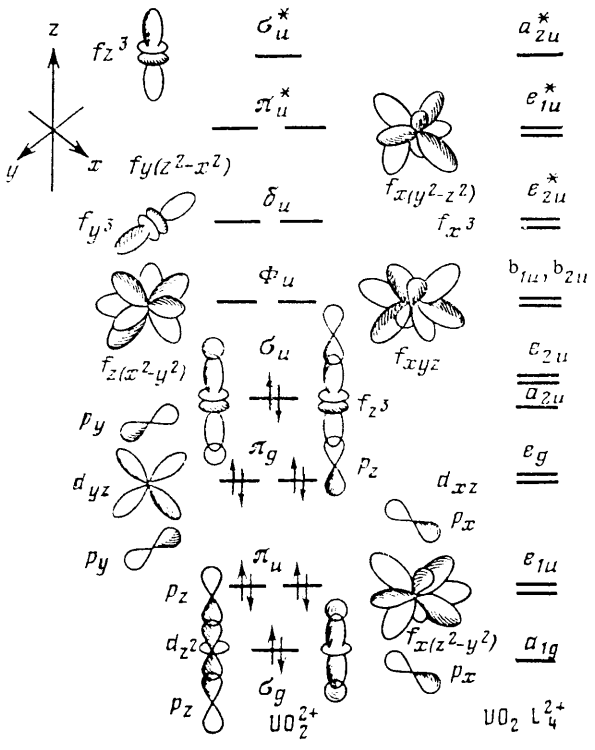

Figure 7. Qualitative energy level diagram for the uranyl ion. The change in the levels on formation of bonds with ligands L in the equatorial plane is shown on the right.[107]

This interaction scheme assumes that the ligand L in the equatorial plane is replaced, and that a U(VI)–O–U(V)–O bond is formed. The mechanism of the removal of L from $UO_2L_4^{2+}$ can be represented in terms of orbital symmetry theory.[110] Fig. 8*a* shows the symmetry of the intermediate state, which is obtained by the interaction of the antibonding orbital e_{2u}^* in $UO_2L_4^{2+}$ and the bonding orbital a_{2u} in $UO_2L_4^+$. The intermediate state symmetry requirements make necessary the rupture of the U(VI)–L bond and the formation of the U(VI)–O–U(V) bond, in which the oxygen atom of the actinyl ion containing the actinide(V) is the bridging atom. After the removal of the ligand L, the bridging oxygen atom will undergo a bonding interaction with both uranium atoms through both $f\sigma$ and $f\pi$ bonds (Fig. 8*b*).

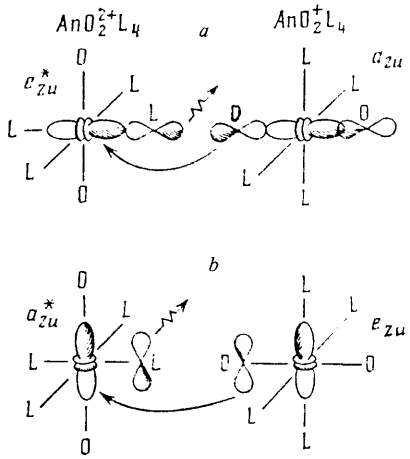

Figure 8. Interaction of the donor–acceptor type between unoccupied molecular orbitals of a uranyl complex containing uranium(VI) and the occupied orbitals of an actinyl complex containing an actinide(V):[107] *a*) σ-bond interaction, *b*) π-bond interaction.

Thus in the complexes AnO_2^+–UO_2^{2+}, the quantitative characteristic of CCI is the magnitude of the energy gap between the donor a_{2u} (or σ_u) and acceptor e_{2u}^* (or δ_u) orbitals, that is

$$E_{\sigma_u}(AnO_2^+) - E_{\delta_u}(UO_2^{2+}) = \Delta, \quad E_{a_{2u}} - E_{e_{2u}^*} = \Delta'$$

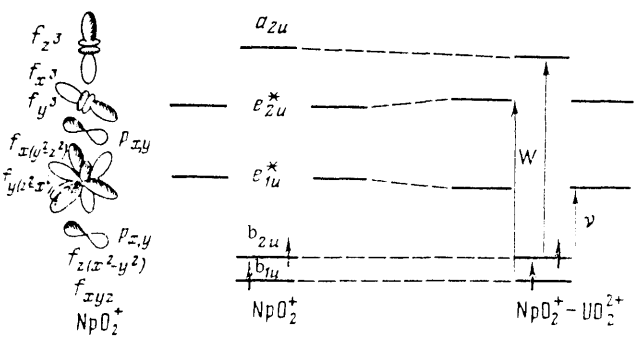
The greater Δ or Δ′, the more energetically favourable the cation–cation interaction of the donor–acceptor type. When Δ is negative, that is when the acceptor levels lie above the donor levels, CCI does not take place. On going from UO_2^+ to NpO_2^+, PuO_2^+, and AmO_2^+, the occupied σ_u^2 orbital is lowered, approaching the δ_u orbital of UO_2^{2+}, that is the magnitude of Δ decreases and the strength of the CCI decreases in the same direction.

This approach immediately explains why the PuO_2^{2+} ion, which is isoelectronic with NpO_2^+, does not react with the uranyl ion containing uranium(VI). Interaction between two UO_2^{2+} ions obviously does not take place, because $\Delta < 0$. The electron configuration of PuO^{2+} has the form $\sigma_g^2\pi_u^4\pi_g^4\sigma_u^2 \cdot \Phi_u^1\delta_u^1$. The donor level σ_u^2 in PuO_2^{2+} lies even lower than in UO_2^{2+}, and $\Delta < 0$, while $|\Delta_{PuO_2^{2+}-UO_2^{2+}}| > |\Delta_{UO_2^{2+}-UO_2^{2+}}|$, that is the UO_2^{2+}–PuO_2^{2+} interaction is even less favourable than UO_2^{2+}–UO_2^{2+}. The fact that PuO_2^{2+} and NpO_2^+ are isoelectronic does not lead to reaction, since the two *f* electrons

above the occupied "core" cloud, situated in the Φ_u and δ_u orbitals, do not interact with UO_2^{2+}, and from symmetry considerations remain non-bonding. In PuO_2^{2+}, the acceptor levels δ_u and Φ_u each contain one unpaired electron, and although these levels, as in UO_2^{2+}, are lower than the donor levels σ_u^2 in AnO_2^+, their ability to attract electron density from the O atom is lower, because of electron–electron repulsion. Thus the actinyl ions NpO_2^{2+} and PuO_2^{2+} containing actinides(VI) interact with AnO_2^+ less strongly than UO_2^{2+}. The mechanism of formation of the dimeric cation–cation complex $(NpO_2^+)^2$ ($\Delta = 0$) is fundamentally different, and involves mainly covalent interaction. Complex formation between AnO_2^{2+} and AnO_2^+ involves the modification of all the molecular orbitals in AnO_2^+. If the bond An(VI)–O with the bridging atom is sufficiently strong, the change involves both the core bonding levels and the antibonding levels of the *f* type. The change in the latter can be considered for the case of the dinuclear system UO_2^{2+}–NpO_2^+. Complex formation leads to practically no change in the positions of the b_{1u} and b_{2u} levels. Thus the ligands L take part in the formation of σ-bonds, so that the b_{2u} orbital will be non-bonding, and the b_{1u} orbital remains non-bonding from symmetry considerations. The positions of the subsequent e^*_{2u}, e^*_{1u}, and a^*_{2u} levels is influenced primarily by the non-equivalence of the Np(V)–O bonds in NpO_2^+. The internuclear distance to the bridging oxygen atom increases, the lengths of the equatorial bonds also increase, and the bond Np(V)–O with the terminal oxygen atom becomes shorter. These changes are due to the specific manifestation of the *trans*-effect in the actinides,[59,118,119] which is the opposite of the *trans*-effect in the transition elements. As a result, the energy of the e^*_{2u} level corresponding to $f\sigma$ interaction of Np(V) with the ligands of the equatorial plane, increases. The energy of the level $\sigma_u = f_z^3 + \phi_1 + \phi_2$ decreases, since one ϕ_2 orbital will correspond to interaction with a terminal oxygen atom, and the other will correspond to interaction with a bridging oxygen atom. The influence of these effects on the position of a level of the $f\pi$ type is less than that for the $f\sigma$ type, so that the splitting of the e^*_{1u} molecular orbital is slight, although its energy should decrease as a result of the decrease in the strength of the bond with the bridging oxygen atom. These changes influence the transitions of the *ff* type (Fig. 9). When the published interpretation[89] of the electronic absorption spectrum of NpO_2^+ is taken into account, it must be concluded that the main transitions take place from the non-bonding Φ_u and δ_u levels into the antibonding π^*_u and σ^*_u orbitals. The lowering of the e^*_{1u} level leads to a displacement of the most intense band with energy $\nu = 10\,200$ cm^{-1} towards the red range of the spectrum, and the splitting of the e^*_{1u} and e^*_{2u} levels leads to the appearance of a new band in the energy range 12000–13 000 cm^{-1}. This qualitative picture becomes much more complicated when allowance is made for the effect of spin–orbit coupling.

In the electronic spectrum of the combined UO_2^{2+} complex, the modification involves mainly charge-transfer bands. The absorption spectrum of the combined NpO_2^+ complex shows additional absorption bands, not related to *ff* transitions, since splitting of various levels takes place in the system of core orbitals, leading to a lowering of the symmetry of the complex from D_{4h} to C_{4v}.

According to this mechanism of CCI, the extent of this interaction should correlate with a number of parameters. It has already been noted that in the interaction UO_2^{2+}–AnO_2^+, where An = U, Np, Pu, and Am, the magnitude of the energy gap determines the degree of interaction. For the values of Δ, the position of the unoccupied $\sigma_u(UO_2^{2+})$ level can be used as the starting point for the measurement, so that the energy of the σ_u level in AnO_2^+ will be the principal determining parameter. The lower the energy of this level, the smaller the negative charge on the oxygen atoms, and the lower the degree of cation–cation interaction. At the same time, the lower the energy of this level, the smaller (for $\Delta > 0$) the magnitude of Δ, and the degree of CCI decreases. In the actinyl ions containing actinides(V), the effective negative charge on the oxygen atoms decreases on going from UO_2^+ to AmO_2^+. According to a published calculation[9] the electron density distribution in UO_2^+ is as follows: O(−0.915)–U(+2.83)–O(−0.915). According to calculations carried out by the present authors[120] for the octahedral oxyanions of the highest oxidation states AnO_6^{7-} or AnO_6^{6-}, where An = U–Am, with increase in the atomic number of An, the magnitude of the negative charge decreases by approximately 0.02–0.05 *e* on each oxygen atom.[120] It may be assumed[117] that in the americyl ion containing americium(V), the electron density distribution has the form: O(−0.8)–Am(+2.6)–O(−0.8).



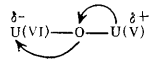


Figure 9. Splitting of the energy levels of the *f*-type in the cation–cation interaction in NpO_2^+.[107]

Thus the chemical ideas based on the electron density distribution[115] and the theoretical molecular orbital ideas about CCI coincide. The presence of an effective negative charge on the oxygen atoms in AnO_2^+ is an insufficient condition for CCI, however. In the actinyl ions AnO_2^{2+} containing actinides(VI), the oxygen atoms again have a fairly high negative charge, O(−0.27)–U(+2.54)–O(−0.27) [100] [or O(−0.3)–U(+2.6)–O(−0.3) [99]], which might have led to the transfer of electron density to the U(VI) atom and the formation of the dinuclear system ...U(VI)–O–U(VI)... The presence of an excess of negative charge on an oxygen atom of one of the actinyl ions also does not lead to interaction; thus on the basis of effective charges alone, CCI might have been expected between O(−0.3)–U(+2.6)–O(−0.3) and O(−0.1)–Am(+2.2)–O(0.1) when the uranyl ion is a ligand relative to the americyl ion. Since this interaction has not been detected experimentally, it must be assumed that the charge should be not only negative or in excess in one cation compared with the other, but that it must ensure an energetically favourable arrangement of the donor and acceptor levels σ_u and δ_u.

The degree of cation–cation interaction should correlate with other parameters in addition to the effective charges. The degree of cation–cation interaction increases with

decrease in the energy corresponding to the charge-transfer band in the aquo-complexes of the active cations.[116] Thus in the series $E_{UO_2^{2+}} < E_{Fe^{3+}} < E_{In^{3+}} < E_{Th^{4+}}$, where E is the energy of the charge-transfer band, the degree of CCI increases in the opposite direction. Thus the quantity E in the aquo-complexes is defined as $E = E_L - E^*$, where E_L is the energy of the ligand level L in ML_6^{2-} or $AnO_2L_4^{2+}$, and E^* is the energy of the orbitals of the central atom. In UO_2^{2+}, the energy E^* corresponds to the position of the acceptor level. If E_L is assumed to be approximately constant in all the complexes, the energy of the charge-transfer band will depend on the position of the level E^*, which also determines the degree of CCI: the lower this level, the lower the energy of the charge-transfer band and the greater the degree of CCI. The nature of the solvent should have a definite influence on the CCI, since the position of the levels of the central atom in the active cations depends on the interaction with solvent molecules.

Since the position of the donor level σ_u in AnO_2^+ determines to some extent the energy of the charge-transfer band in AnO_2^+ and the potential E^0(V–VI), a qualitative correlation should be observed between the degree of CCI and these quantities. The correlation can be only qualitative, since these quantities also depend on the position of the f-levels, which in AnO_2^+ have no significant influence on the CCI. A correlation between the degree of CCI and the oxidation potentials E^0(V–VI) [116] in the AnO_2^+–AnO_2^{2+} system is apparently justified, since the transfer of electron density δ in the complex (A)

corresponds to the partial reduction of the actinide(VI) atom.

In conclusion it may be noted that the position of the ions containing actinides(V) does not appear exceptional from the viewpoint of CCI. Cation–cation interaction takes place if the energy of an unoccupied acceptor orbital in one system is lower than the energy of a donor orbital in the other system, and the acceptor orbital is predominantly an orbital of the central atom. This situation may arise not only between cations, although if the acceptor system is a cation, it is known that the first unoccupied level is fairly low.

One of the criteria for the existence of CCI in complexes with identical central atoms M is apparently the ability of M to form mixed-valence compounds. Essentially, PtF_3 or $CsAuCl_3$, which in the crystalline state are made up of M(II)–M(IV) and M(I)–M(III) ions, to some extent model CCI in a crystal. About 40 elements in Mendeleev's periodic system form mixed-valence compounds,[121] in many of which an ordered arrangement of the cations with different oxidation states is produced below the critical temperature or pressure.[122] The established[123–127] criterion for the existence of a charge-ordered state $I - 2mV < 0$, where I is the energy of the one-centre electron repulsion, V the energy of the electron repulsion between centres, and m the number of nearest neighbours, also determines the stability of the cation–cation complex: in a complex of type (A), the electron–hole attraction $-2V\delta$ should be greater than the electron repulsion $I\delta$.

It can apparently be assumed that other types of cation–cation interaction will be found among the transition elements, among the actinides, and between them. If triply-charged AnO_2^{3+} cations existed, they would interact with AnO_2^{2+} according to the same regular features as AnO_2^{2+} with AnO_2^+. Three model systems with the same geometry can be considered: UO_2^{2+}, UO_2^+, and UO_2. The UO_2^{2+}–UO_2 interaction is most favourable, since for this interaction, $\Delta = 12.8$ eV;[100] the presence of two f electrons has no influence on the interaction, since in UO_2 they remain non-bonding. In the UO_2^+–UO_2 interaction, the acceptor level in UO_2^+ is partly occupied; thus the cation–cation interaction UO_2^+–UO_2 would be weaker than UO_2^{2+}–UO_2.

In the molecules of the same type UF_6, NpF_6, and PuF_6, the acceptor level in UF_6 is higher than the ligand levels in NpF_6 and PuF_6.[128] Comparison of the positions of the levels in UF_6 and UF_6^- shows, however, that the unoccupied acceptor level in UF_6 is lower than the donor level of the same symmetry in UF_6^-.[85]

6. The *trans*-Effect in the Chemistry of the Actinides

The specific features of the *trans*-effect in the chemistry of the actinides has recently attracted the attention of a number of workers.[59,118,129] Thus *trans*- and *cis*-configurations have been detected in $Cs_2UO_2Cl_4$ and $Cs_2WO_2Cl_4$ respectively. This difference was first explained[59] using the maximum overlap model. Other workers[118,129] raised the question of the fundamental difference in the *trans*-effects in $MoCl_5^-$, where M = Mo, or W, and in $UOCl_5$ (Fig. 10). The *trans*-effect observed in the uranium compounds is the direct opposite of the *trans*-effect in the analogous transition metal complexes: in the first compounds, the metal–halogen *trans*-bond is longer than the equatorial bonds, whereas in the second case the uranium–halogen *trans*-bond is shorter than the equatorial bonds.

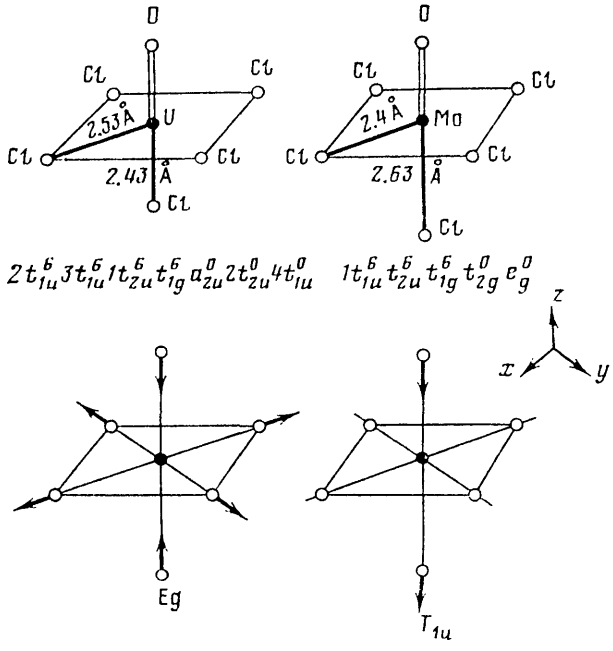

Figure 10. Comparison of the *trans*-effects in compounds of the same type formed by actinide and transition elements.[59]

Systematic MO calculations carried out by the present authors[117,119,131,132] make it possible to explain this fundamental difference using the electronic–vibrational

model of heteroligand inorganic complexes.[129] The energy of the substituted and deformed complex is represented in the form of a series with respect to powers of the normal coordinates q_ν characterising the deformation. If the energy of the non-substituted complex in the equilibrium configuration is taken as the zeroth term of the expansion, the expansion will contain a term which is linear with respect to q_ν and which leads to a change in the geometry of the non-substituted complex. In the MO method, the energy component linear with respect to q_ν has the form:[129]

$$E = 4 \sum_{\nu,o,u} \frac{\langle \psi_o H \psi_u \rangle \left\langle \psi_o \frac{\partial H}{\partial q_\nu} \psi_u \right\rangle}{\Delta_{ou}} q_\nu \quad \text{or} \quad E = kq_\nu$$

Here, ψ_o and ψ_u are the wavefunctions of the occupied and unoccupied MO respectively, Δ the magnitude of the energy gap between these MO, and H the one-electron substitution operator.

The main qualitative difference between actinide complexes and transition metal complexes of the same type is the difference in the sequence of the MO (see Fig. 10). As a result, the active mode leading to distortion will be a mode of E_g symmetry in the actinide complexes, and a mode of T_{1u} symmetry in the complexes of d transition elements. Using calculations for oxygen compounds, in particular UO_6^{6-}, it can be shown that the coefficient k in the expression for E is greater than zero in those cases where the $1t_{2u}$ and $2t_{2u}$ molecular orbitals mix as a result of the influence of the vibrational mode E_g. This means that when four substituents are introduced into UO_6^{6-} along the x and y axes, that is $UO_2L_4^{n-}$, the decrease in the total energy corresponds to $q_\nu < 0$, or in Cartesian coordinates: $q_\nu = 1/\sqrt{12}\ (2z_1 - 2z_4 - x_2 + x_5 - y_3 + y_6)$. A negative value for q_ν corresponds to an increase in the length of the equatorial bonds and a decrease in the length of the axial bonds.

This conclusion is confirmed by X-ray diffraction data for compounds containing the uranyl group. In UO_6^{6-}, the U–O distance is 2.08 Å, and in $UO_2L_4^{n-}$ this distance is 1.7–1.8 Å, whereas the U–L distances are much greater than 2.08 Å, for molecules with different ligands: NO_3^-, H_2O, $(Et_2ONCO)^-$, $MeCOO^-$, CO_3^{2-}.[133] Using the same approach in an examination of mono-substituted $UOCl_5^-$, the present authors took UCl_6 as a basis and obtained an increase in the length of the equatorial internuclear distances U–Cl compared with the U–Cl *trans*-bond.[59] In the d^0 complexes of molybdenum and tungsten, the last occupied t_{1u} and t_{2u} orbitals are mixed with the unoccupied t_{2g} orbital by a vibrational mode of symmetry T_{1u}, leading to the opposite change in the distances. In systems with the electron configuration f^n, the *trans*-effect should decrease with increase in the number of f-electrons. For those complexes for which the f-levels are occupied, the *trans*-effect should be the same as in compounds of the d-elements. In complexes with partly occupied f-levels, both vibrational modes may be active, so that the resulting effect may be extinguished.

IV. INFLUENCE OF RELATIVISTIC EFFECTS ON THE PROPERTIES OF THE COMPOUNDS OF THE HEAVY ELEMENTS

It is only in recent years that objective conditions have been created for studying the influence of the relativistic effect on the properties of the compounds of the heavy elements. A stimulus for this study was provided by the development of calculation methods and computing techniques, and also the practical interest in compounds of the heavy elements. It has been suggested[134,135] that the main anomalies in the second half of Mendeleev's table are due to the relativistic effect. These anomalies are the unique properties of gold compared with copper and silver, and of mercury compared with cadmium and zinc, the lanthanide contraction, the inert pair effect, the unique properties of the 6+ oxidation state of uranium, neptunium, and plutonium, the influence of spin–orbit coupling on magnetic properties, for example in Os(VI) compounds, the tendency towards stabilisation of the oxidation states from III to I in the indium subgroup and from IV to II in the carbon subgroup on going to the heavy elements, etc.

When it becomes necessary to take account of a given effect, attempts to explain many regular chemical features on the basis of this effect appear quite natural. This was the case, for example, with the excited nd orbitals of the atoms of phosphorus, sulphur, chlorine, and xenon. It was later found that the part played by nd orbitals for the atoms of these elements had been greatly overestimated.

Another outstanding example relates to the problem of the localisation and delocalisation of electrons. The extensive application of MO methods in calculations for molecules and the zone scheme for the solid state has practically displaced calculation schemes in which account is taken of localised states. A step back has now been taken, and the Heitler–London scheme is again beginning to be used.

The part played by relativistic effects is undoubtedly important, but it apparently should not be overestimated. In the discussion of the influence of relativistic effects on the properties of the heavy elements, it seems appropriate to distinguish three cases, where the relativistic effect: 1) completely determines the property or feature; 2) increases its strength; and 3) acts in a direction opposite to the orbital effect. In the properties of the heavy elements, the relativistic effect appears through the relativistic contraction of the $s_{1/2}$ and $p_{1/2}$ clouds, spin–orbit splitting, and destabilisation of d- and f-electrons.[134] The first effect is due to the fact that the mass of an electron depends on its velocity, the second is due to the splitting of the energy levels corresponding to the quantum numbers j, and the third is due to the high values of the angular momenta of the d- and f-electrons, the weaker attraction to the nuclei, and the more diffuse character. These effects lead to the high stability of the uranyl ion and the sexavalent forms of uranium, neptunium, and plutonium.[135]

Generally speaking, the high stability of the uranyl ion is also explained within the framework of the simple MO method, since this system contains 12 valence electrons, which occupy all the bonding MO, and the antibonding orbitals remain unoccupied. In the series of U(VI) compounds there are stable and less stable systems: on going along the series UO_4^{2-}, UO_6^{6-}, UO_2^{2+}, the stability increases, although the relativistic contraction of the 7s orbital and the opening of the 5f orbitals are everywhere the same. The properties of the compounds of U, Np, and Pu in the 6+ oxidation state can also be explained within the framework of relativistic approximations, that is they do not belong to those "specific" properties which cannot be understood even qualitatively without allowance for relativistic effects.

The influence of the relativistic spin–orbit effect on the stability of lanthanides and actinides in the 2+, 3+, and 4+ oxidation states and the tendency to form mixed-valence compounds and new oxidation states has been examined.[95,96,136,137] It was shown above that the oxidation potentials correlate with the excitation energy $E(f^n \rightarrow f^{n-1}d)$: a

high excitation energy "hinders" the oxidation, and the ion remains in the original configuration f^n, and a low excitation energy facilitates oxidation and the change to the state with the electron configuration $f^{n-1}d$. Thus a high spin–orbit splitting energy, E_{so}, in the f^n electron configuration, which brings the f^n and f^{n-1} electronic states "closer together", increases the tendency for the oxidation state to increase.

Table 11 gives the values of E_{so} and E_{fd} for the f^n electron configuration of the doubly-charged actinides. For uranium and neptunium, $E_{so} > E_{fd}$, so that the excited f^{n-1} states overlap with the terms of the f^n states. This leads to unstable bivalent forms for uranium and neptunium. For plutonium, the bivalent state is more stable, since for it, $E_{so} < E_{fd}$. For americium, $E_{so} \ll E_{fd}$, and the stability of the bivalent form reaches a maximum value in the first half of the actinide series. For curium, as for uranium and neptunium, $E_{so} > E_{fd}$, so that the bivalent state is unstable. For berkelium, $E_{so} \cong E_{fd}$, which corresponds to an increase in the stability of the bivalent form. For californium, $E_{so} < E_{fd}$, and for einsteinium, fermium, mendelevium, and nobelium, as a result of the decrease in E_{so} and the increase in E_{fd}, this inequality is preserved and increases. This leads to an increase in the stability of the bivalent state in the second half of the actinide series.

The stabilities of Ln(II) and Ln(III) can be compared analogously (Table 12). The successive decrease in E_{so} in the first half of the series and the increase in E_{fd} indicate gradual stabilisation of the bivalent state. This approach makes it possible not only to understand the regular features of the change in the oxidation potentials but also to answer the question of why they have different absolute values for corresponding lanthanides and actinides. Thus in the first halves of the series (U–Am and Nd–Eu), the relationship $E^0(\text{II–III})_{Ln} < E^0(\text{II–III})_{An}$ is preserved. For neodymium and promethium, $E_{so} < E_{fd}$, whereas for uranium and neptunium, $E_{so} > E_{fd}$. The difference $E_{fd} - E_{so}$ is much smaller for plutonium than for samarium, and E_{fd}(Am) < E_{fd}(Gd).

In the second half of the actinide series, gradual stabilisation of the bivalent states takes place, whereas in the second half of the lanthanide series this regular feature is not observed, the break in the trend taking place at holmium. Comparison of holmium and einsteinium shows a vast difference: for holmium, $E_{so} \cong E_{fd}$, whereas for einsteinium, $E_{fd} - E_{so} \cong 10000$ cm^{-1}. Similarly, for fermium, $E_{fd} - E_{so} \cong 25000$ cm^{-1}, whereas for erbium this quantity is ~5000 cm^{-1}. This difference is responsible for the difference in the oxidation potentials E^0(II–III) for the lanthanides and actinides. In addition to the difference in the oxidation potentials, this leads to the situation where states with mixed oxidation numbers are not observed in the second half of the actinide series, whereas at the end of the lanthanide series, thulium shows mixed oxidation states Tm(II)–Tm(III) in many compounds.

For the triply-charged ions of the lanthanide series, E_{fd} is much greater than E_{so}, so that the energy of spin–orbit splitting should not have a significant influence on the oxidation potentials (Table 13). The situation is completely different in the actinides: for protactinium, E_{so} is close to E_{fd}; for uranium, $E_{fd} > E_{so}$, but they are similar; for Np and Pu, E_{fd} increases slowly, and at the same time E_{so} also changes little. This corresponds to gradual destabilisation of the 4+ oxidation state. On going to curium, E_{so} decreases, and E_{fd} increases sharply, leading to a further decrease in the potential E^0(III–IV). As a result of the decrease in E_{fd} and the increase in E_{so}, the 4+ oxidation state is more stable for berkelium than for curium and americium. E_{fd} for californium is intermediate between the values for Am and Cm, but E_{so} is much larger than for

these elements. The absolute magnitude of the potential E^0(III–IV) for californium should apparently be less than 3.2 V.

The magnitude of the spin–orbit splitting of the ground state term of the f^n electron configuration can be related to the stability and geometry of the actinyl groups. It was shown above that if an actinide ion An^{z+} has closely-situated d- or s-levels, the resulting dioxo-cation will be stable for linear coordination of the nuclei. A high value of E_{so} for An^{2+} corresponds to stability of the linear AnO_2^{2+} system. On going from U^{2+} to Am^{2+}, both effects, orbital and relativistic, act in the same direction: E_{so} decreases, and E_{fd} increases, that is the stability of the actinyl groups decreases. For doubly-charged uranium, the most favourable situation is created for the formation of the dioxo-cation: $E_{fd} = 0$, and E_{so} is greater than for Np, Pu, Am, and Cm. UO_2^{2+} does not contain antibonding electrons. All this together determines the stability of the uranyl group. Beginning from NpO_2^{2+}, the number of antibonding electrons increases, so that CmO_2^{2+} should have the electron configuration $\sigma_g^2\pi_u^4\pi_g^4\sigma_u^2\Phi_u^4\delta_u\pi_u\sigma_u$, when the antibonding Φ_u level is completely occupied. In CmO_2^{2+}, however, the antibonding effect due to the four electrons in the Φ_u level is to some extent quenched by the marked spin–orbit effect and the small expenditure of energy in fd hybridisation, so that the CmO_2^{2+} cation is stable.

A comparative analysis of E_{so} and E_{fd} helps to explain why lanthanyl groups are not obtained. For doubly-charged neodymium, promethium, and samarium, the values of E_{so} are small, and $E_{fd} > E_{so}$, whereas for their analogues uranium, neptunium, and plutonium, on the contrary, $E_{fd} < E_{so}$. The values of E_{so} and E_{fd} are similar only at the end of the lanthanide series (Gd, Tb, Ho, Er). Although in the lanthanyl groups of these elements after gadolinium the next antibonding level δ_u is occupied, decreasing the strength of the bond, the decrease in strength should be less than that for their actinide analogues, since the crystal field splitting for the 4f levels is less than that for the 5f levels. In any case, the formation of lanthanyl groups in the second half of the lanthanide series cannot be regarded as impossible.

Thus on the basis of a scheme taking account of the relativistic splitting of the f^n electron configuration and the excitation energy E_{fd}, it is possible to explain a number of important regular features of the electronic structure of the lanthanides and actinides: the gradual stabilisation of the bivalent state in the first half of the lanthanide series and in the second half of the actinide series; the absence of gradual stabilisation of the bivalent state in the second half of the lanthanide series; the marked difference in the oxidation potentials E^0(II–III) in the first halves of the lanthanide and actinide series; the formation of states with mixed valence at the end of the lanthanide series, and the absence of these states at the end of the actinide series; the fundamental difference in the stability of the 4+ oxidation state for the actinides and lanthanides; and possible stabilisation of lanthanyl groups at the end of the series.

In all cases examined, the two effects act in the same direction. The relativistic effect is greater for the lower oxidation states E^0(II–III), since the values of E_{so} and E_{fd} are comparable. The two effects separately give qualitatively the change in the oxidation potentials, but the orbital effect also gives the quantitative relationship. It can apparently be stated that the relativistic effect does not determine the regular features, although it makes a significant contribution to the quantitative characteristics. The influence of the relativistic effect on the states of atoms in higher oxidation states is weakened, since the orbital effect suppresses the relativistic effect, particularly for the tervalent lanthanides. For the actinides, however, the relativistic effect may be significant in the estimation of the oxidation potentials E^0(III–IV), as clearly confirmed for californium.

---o0o---

Thus quantum chemistry is finding the most varied applications in the study of the electronic structure and properties of the actinides, from the prediction of the possibility of existence of unusual oxidation states to the explanation of reaction mechanisms. In spite of considerable progress, however, many unsolved problems remain, particularly in the study of unique oxidation states in the second half of the actinide series, where experimental studies are made difficult by the high radioactivity and the difficulty of obtaining the elements.

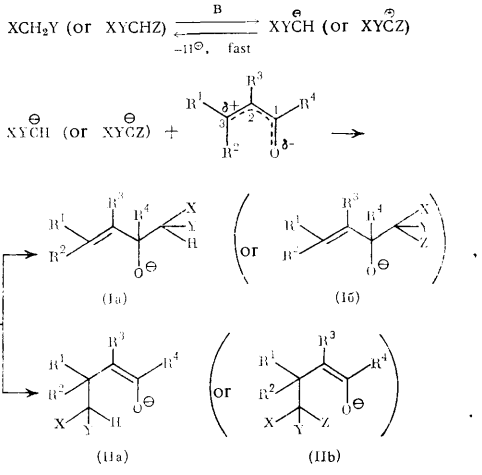
Nucleophilic Addition of CH Acids to αβ-unsaturated Aldehydes and Ketones

L.A.Yanovskaya, G.V.Kryshtal', and V.V.Kul'ganek



Data on the nucleophilic addition of CH acids of the type XCH_2Y and XYCHZ to αβ-unsaturated aldehydes and ketones are surveyed primarily from the standpoint of the influence of various factors on the mode of reaction (addition to the C=O or C=C bond).
The bibliography includes 116 references.

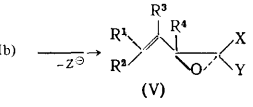
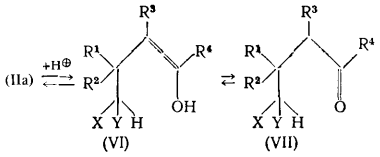
IV. Conditions and mode of the reaction 751

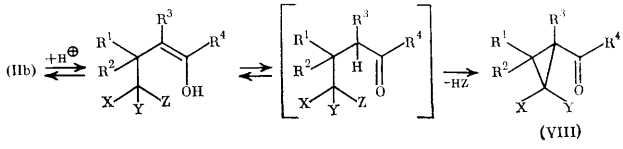
I. INTRODUCTION



The addition of CH acids of the type XCH_2Y and XYCHZ (X, Y, and Z are atoms or groups stabilising carbanions) to αβ-unsaturated aldehydes (enals) and ketones (enones) in the presence of bases is of great synthetic importance, since it makes it possible to lengthen the carbon chain in a single stage and to introduce various substituents into the molecule. This reaction is also of interest from the theoretical point of view because, as a consequence of the delocalisation of the electron density in the C=C–C=O system, enals and enones behave as ambident electrophiles and the addition of carbanions of the type $\overset{\ominus}{C}HXY$ and $\overset{\ominus}{C}XYZ$ to these compounds can proceed via two pathways: addition to the carbon atom of the carbonyl group C(1) or to the carbon atom involved in the double bond C(3). This results in the formation of oxy-anions of types (Ia) and (Ib) or (IIa) and (IIb):

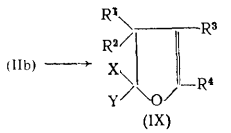


Protonation of the oxy-anions (Ia) leads to the formation of allyl alcohols (III), which are converted into conjugated dienes of type (IV) (products of the Knoevenagel reaction) on elimination of water from the 1,2-position:



The oxy-anions (Ib) (Z = Hal) are stabilised as a result of the elimination of $Z^{\ominus}$ and cyclisation to the epoxides (V) (the Darzens reaction):

The protonation of the oxy-anion (IIa) leads to the saturated aldehyde or ketone (VII) via the enol (VI) (the Michael reaction):



On the other hand, the protonation of the oxy-anion (IIb) and subsequent elimination of HZ from the 1,3-positions yield the cycloproane (VIII):

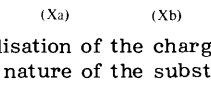
Thus the stabilisation of oxy-anions of type (I) results in the formation of the products of the 1,2-addition of CH acids to enals or enones (to the C=O group), while stabilisation of oxy-anions of type (II) results in the formation of products of 1,4-addition (to the C=C bond). The nature of the final reaction product depends on the nature of the CH acids, the substrate, the base used to generate the carbanions, and on the reaction conditions. All the reactions described above have been achieved and widely used to synthesise a wide variety of allyl alcohols,[1-3] conjugated dienes,[4,5] epoxides,[6] aldehydes and ketones,[7-11] and cyclopropanes,[12-17] all with functional group substituents.

The possible mechanisms of the stabilisation of the oxy-anions (IIb) examined permit the conclusion that there is yet another type of stabilisation of this oxy-anion, namely its conversion into 2,3-dihydrofuran (IX) via the elimination

of the anion $Z^{\ominus}$ with 1,5-cyclisation [compound (IX) can be formed also from the intermediate enol via the elimination of HZ]:

(IIb) (IX)

Indeed the first example of such a reaction, involving the formation of 3-formyl-2,3-dihydrofurans by the interaction of bromomalonic ester with arylidenemalonaldehydes, has been observed recently.[18]



However, it is noteworthy that the addition of CH acids to enals and enones is by no means regioselective in all cases and a mixture of 1,2- and 1,4-addition products is frequently formed in various proportions. In order to ensure the regio-selectivity of the reaction and hence the possibility of the synthesis of the required products (III)–(V) and (VII)–(IX), it is necessary to investigate the influence of various factors and in the first place the structure of the CH acids, the enone, or the enal, the nature of the base used to generate the carbanions, and the conditions (temperature, solvent, and additives) on the mode of reaction and the possible further transformations of the compounds obtained.

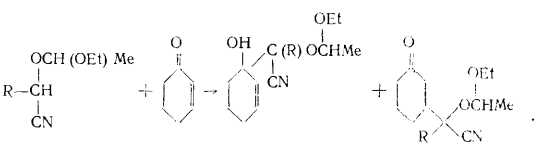
In the present review we have considered and attempted to survey the data obtained in the last 10–15 years on the addition of CH acids of the type XCH_2Y and XYCHZ to enals and enones from the standpoint of the influence of the above factors on the mode of addition.

II. THE INFLUENCE OF THE STRUCTURE OF CH ACIDS ON THE MODE OF THE REACTION

The reactivity of CH acids is determined by the ease of deprotonation and the rate of reaction of the carbanions formed. The overall rate of addition of CH acids to enals and enones is limited by the stage involving the formation of oxy-anions. The overall rate increases with the increase in the number of electron-accepting or electronegative groups in the CH acid molecule. For CH acids of the type XCH_2Y, the activating effect of electron-accepting groups increases in the sequence RCO < HCO < ROCO < CN < RSO_3 < RSO_2 < NO_2.[7]

For carbanions generated from XCH_2Y, it is possible to adopt two extreme structures—(Xa) where the charge is localised at the carbon atom and (Xb) where the charge is fully delocalised.[19]

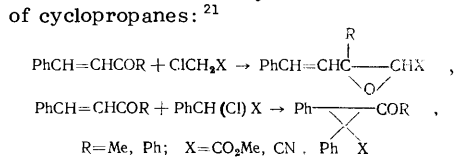
(Xa) (Xb)



The degree of delocalisation of the charge in the carbanion is determined by the nature of the substituents in the molecule of the initial CH acid and its geometry. Within the framework of the theory of perturbations of molecular orbitals (PMO), an increase of the degree of charge delocalisation leads to an increase of the energy of the highest occupied molecular orbital (HOMO) and to an increase of the stability of the carbanion; the nucleophilicity of the carbanion and the rate of addition to the carbonyl group decrease simultaneously. Other conditions being equal, the addition of CH acids to the C=O group should be favoured by an increase of the localisation of the charge at the nucleophilic centre, by the decrease of the level of the HOMO, and by the increase of the acidity of the CH acid, i.e. the addition to the C=O bond is controlled by the charge. On the other hand, an increase of the degree of delocalisation of the charge at the nucleophilic centre, the raising of the level of the HOMO, and a decrease of the acidity of the CH acid should favour the addition to the C=C bond, i.e. it should take place under orbital control.

By the term "charge control", we understand the electrostatic interaction between the reactants. Its extent can be estimated as the product of the charges on the carbon atoms participating directly in the formation of the new bond. By the term "orbital control", we understand the energy of the interaction between the molecular orbitals of the reactants. This energy has a quantum-mechanical origin, which can be estimated from the equation

$$E_{orb} = \beta^2 C_N^2 C_E^{*2} S_{NE}^2 / (E_E^* - E_N) ,$$

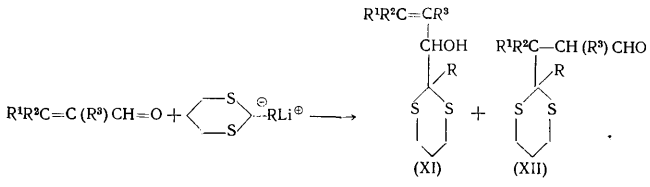


where C_N and C_E are the coefficients of the π orbitals of the carbon atoms which are directly involved in the formation of the new bond, i.e. of the π orbitals of the highest occupied molecular orbital (HOMO) of the nucleophile and the lowest unoccupied molecular orbital (LUMO) of the electrophile respectively, S_{NE} is the overlap integral between these orbitals, E_N and E_E are their energies, and β is a coefficient with the dimensions of energy.

The mode of reaction can be influenced by steric factors. Usually an increase of the bulk of the substituents R in CH acids of the type XYCHR leads to an increase of the contribution of the 1,4-addition. For example, the carbanion generated from 1-cyano-1-(1-ethoxyethoxy)ethane by treatment with lithium diethylamide in tetrahydrofuran (THF) at −78 °C forms predominantly the products of addition to the C=O bond on interaction with cyclohex-2-enone, while the carbanion generated from 1-cyano-1-(1-ethoxyethoxy)hexane gives rise to a mixture of the 1,2- and 1,4-addition products in proportions of 2.7:1.0 under the same conditions:[20]

The role of the charge or orbital control can be traced by studying the reaction of a chalcone and benzylideneacetone with the carbanion generated by treating derivatives of chloroacetic or α-chlorophenylacetic acids with a base [NaH or t-BuONa in hexamethylphosphoramide (HMP), $(Me_3Si)_2NNa$ or $(Me_3Si)_2NLi$ in THF].[21]

Regardless of the method of generation of carbanions, under kinetically controlled conditions at room temperature the reaction involves only the C=O bond in the case of $ClCH_2X$ with formation of epoxides or in the case of PhCH(Cl)X it involves exclusively the C=C bond with formation of cyclopropanes:[21]



This difference between the modes of reaction is fully explicable when account is taken of the fact that the carbanions generated from $ClCH_2X$ belong to type (Xa), while those generated from PhCH(Cl)X belong to type (Xb); consequently charge control is most probable for the former reaction and orbital control for the latter reaction. In conformity with this, the rate of reaction of the carbanions

$\ominus$
$ClCHX$, where X = CO_2Me, or CN, with behzaldehyde is higher than that with benzylideneacetone,[22,23] which is associated with the higher formal positive charge on the C(1) atom in the C=O group of benzaldehyde.[24,25] Similarly the carbanions $PhC(Cl)X$, where X = CO_2Me or CN, react with the chalcone faster than with benzylideneacetone, which can be explained by the lower energy of the LUMO in the chalcone (the HOMO levels of the nucleophiles are identical in both reactions).[26,27]

In agreement with the above, the carbanions generated from 2-chloroacetates or 2-chloropropionates react with 4-t-butylcyclohex-2-enone only via the C=O group regardless of the counterion ($Na^{\oplus}$, $Li^{\oplus}$, $K^{\oplus}$, $MgX^{\oplus}$).[28] However, the carbanions generated by treating methyl 2-chloropropionate with bases add to the C=C bond in methyl vinyl ketone, although the yield of the adduct is low (~10%).[28] This can apparently be explained by the specific features of the structure of methyl vinyl ketone [the absence of steric hindrance at the C(3) atom in the vinyl group—see Section III below].

We may note that, when carbanions of the type $PhC(Cl)COOR$ or $PhC(Cl)COCH_3$ are used in the reaction with methyl vinyl ketone, the yields of the corresponding cyclopropanes increase in the former case to 58% and in the latter case to 70–75%,[29,30] which is probably associated with the increase of the orbital control with increase of the degree of delocalisation of the charge in carbanions. This can probably explain the addition of carbanions of the type $ArC(SR)Alk$, $AlkC(SeR)CN$, and other anions of the type R_3C to cyclohex-2-enone and other enones exclusively at the C=C bond under the conditions of kinetic control at −78 °C.[31,32] Carbanions with a highly delocalised charge, generated from di- or tri-nitromethane and also from dinitroethane by treatment with solid potassium carbonate, pyridine, and other bases in solution in ether, dioxan, or aqueous methanol, add to methyl styryl ketone, phenyl vinyl ketone, methyl vinyl ketone, and acrolein, also giving rise to Michael addition products in yields >90%.[33–36]

Interesting results have been obtained in the study of the reactions of enals with carbanions generated from 2-R-1,3-dithianes by treatment with lithium di-isopropylamide in a THF–HMP mixture. This resulted in a mixture of 1,2- and 1,4-adducts whose ratio depended only on the structure of the enal but not on the nature of the substituents R in the nucleophile:[37]

It follows from the data presented in Table 1 that the carbanions generated from 2-phenyl-1,3-dithiane, where there is a great possibility of charge delocalisation, react preferentially via the C=C bond, while the carbanions generated from 1,3-dithiane, where there is no such possibility, tend to add to the C=O bond. It is noteworthy that the accumulation of the substituents in the 3-position of the enal increases the content of the 1,2-adducts in the mixture (see also Section III); the reaction of 3,3-dimethylacrolein with 1,3-dithane also leads to the formation of only the 1,2-adduct, which can be explained by the steric hindrance in the attack on the 3-position by the carbanion.[37]

Interesting results have been obtained in the study of the reactions of mesityl oxide with the carbanions generated by treating the trimethylsilyl ethers of the cyanohydrins of *p*-substituted benzaldehydes with lithium di-isopropylamide in 1,2-dimethoxyethane (DME). Depending on the nature of the substituent in the *para*-position in the benzaldehyde molecule, a mixture of 1,2- and 1,4-adducts was formed in different proportions and the effect of the substituent was linearly correlated with the Hammett σ_n constants for the addition to both the C=O and C=C bonds:[38]

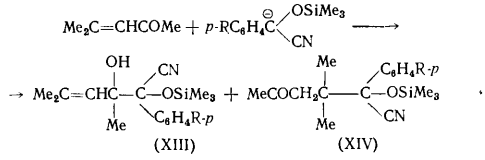


Table 1. The ratio of products (XI) and (XII) formed in the reaction of enals with 2-R-1,3-dithianes.[37]

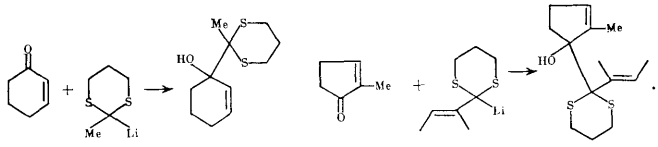
Enal	R	*W*, %*	Content in mixture, %	
			(XI)	(XII)
MeCH=CHCHO	H	70	55	45
MeCH=CHCHO	Ph	80	5	95
CH_2=C(Me)CHO	H	70	45	55
CH_2=C(Me)CHO	Ph	80	5	95
Me_2C=CHCHO	H	55	100	0
Me_2C=CHCHO	Ph	50	65	35
PhCH=CHCHO	H	75	75	25
PhCH=CHCHO	Ph	85	35	65

*Overall yield of products (XI) and (XII).

Table 2. The influence of the nature of the *para*-substituents in p-$RC_6H_4C(OSiMe_3)CN$ on the ratio of products (XIII) and (XIV).[38]

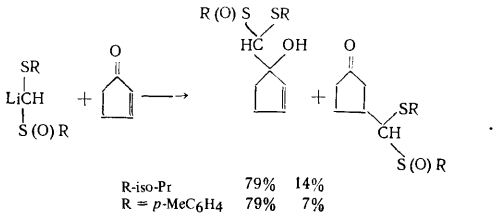


R	*W*, %*	Content in mixture, %		R	*W*, %*	Content in mixture, %	
		(XIII)	(XIV)			(XIII)	(XIV)
Me_2N	96	100	0	Cl	100	62	38
MeO	95	95	5	CF_3	100	28	72
H	92	78	22	CN	95	0	100

*Overall yield of products (XIII) and (XIV).

Table 2 presents data for the influence of the nature of the *para*-substituent in the benzaldehyde ring on the ratio of products (XIII) and (XIV) in the mixture. It is seen that the contribution of the addition to the C=O bond diminishes on passing from clearly electron-donating substituents (Me_2N, MeO) to electronegative or electron-accepting substituents (CF_3, CN). This feature can be fully accounted for by the fact that, owing to the +*M* effect, electron-donating substituents promote a greater localisation of the charge at the nucleophilic centre, while electronegative or electron-accepting substituents actually favour the delocalisation of the charge as a result of the −*I* and correspondingly −*M* effects.

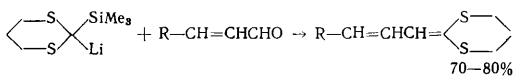
However, one should note that the energy of the HOMO in p-Me_2N-$C_6H_4\overset{\ominus}{C}(OSiMe_3)CN$ is greater than the energy of the HOMO in p-$NCC_6H_4\overset{\ominus}{C}(OSiMe_3)CN$; this should promote orbital control, which is not in fact observed: in the reaction with the trimethylsilyl ether of benzaldehyde cyanohydrin, the product of addition to the C=O bond is formed exclusively. Hence one may conclude that, other conditions being equal, the mode of reaction is influenced to a greater extent by the charge delocalisation than by the height of the energy level of the HOMO (see also Section III). The ratio of compounds (XIII) and (XIV) is determined by the simultaneous influence of the charge and orbital control. The magnitude of the calculated oxidation-reduction potentials of p-$RC_6H_4CH(OSiMe_3)CN$ and enones[38] shows that the mechanism with orbital control is more probable for addition to the C=C bond rather than the mechanism with electron transfer which had been proposed on the basis of a number of data for the addition of lithium dialkyl cuprates to the double bond.[39]



A strong influence of the structure of the nucleophile on the mode of reaction has been observed also for other examples. Thus cyclic thioacetals of the type of 1,3-dithianes, containing alkyl groups in the 2-position (for example, 2-methyl-1,3-dithiane [1]) or alkenyl groups [for example, 2-(but-2-en-2-yl)-1,3-dithiane,[40] add to cyclohex-2-enone in THF at -78 °C only at the C=O bond when the carbanions are generated by treatment with n-BuLi. The reaction with 2-methylcyclopent-2-enone proceeds in the same way:

The carbanions generated under the same conditions from aliphatic thioacetals of the type $R-CH(SR^1)[S(O)R^1]$ react via the C=C bond in enones:[41]

$$R\overset{\ominus}{C}(SR^1)(S(O)R^1) + CH_2{=}CHCOR^2 \rightarrow R^2COCH_2CH_2\underset{\displaystyle S(O)R^1}{\overset{\displaystyle SR^1}{\underset{|}{\overset{|}{C}}}}-R$$



It has been shown for the addition of $CH_2(SR)[S(O)R]$ to cyclic enones using lithium di-isopropylamide in THF at -78 °C to generate the carbanion that the ratio of the 1,2- and 1,4-adducts is also influenced by the nature of the substituent R in the thioacetal component of the CH acid:[41]

R-iso-Pr	79%	14%
R = p-MeC_6H_4	79%	7%

Steric hindrance is apparently manifested in this case.

The carbanions generated from CH acids containing the trimethylsilyl group at the nucleophilic centre, for example, from Me_3SiCH_2X, where X = $P(S)Ph_2$, PPh_2, SPh, or $P(O)(OEt)_2$, or from 2-trimethylsilyl-1,3-dithiane by treatment with n-butyl-lithium always add to the C=O bond in enals and enones:[42]

The addition of CH acids to enals via a Michael reaction has been little investigated until recently. The view that nucleophiles add to enals preferentially at the C=O bond is still encountered in the literature.[4,5,8] This view is based on the fact that enals readily undergo the Knoevenagel reaction with CH acids in the presence of pyridine, piperidine, and sodium acetate.[4,5] Furthermore, enals form cyanohydrins on treatment with hydrocyanic acid.[43] The cause of the confusion is that the application of strong bases, such as alkali metal hydroxides, alkoxides, hydrides, or amides, organometallic compounds, ground alkali metals, etc. to the generation of carbanions in the Michael reaction is complicated in the case of enals by the self-condensation and polymerisation of the enals, further reactions of the addition products, the "anomalous" Michael reaction, etc.[44-46] On the other hand, the use of milder bases leads to the Knoevenagel reaction (see above).

Systematic study of the order of the addition of CH acids to enals became possible only after the introduction of the method of phase transfer catalysis into practical organic synthesis.[47-50] In this method the carbanions are generated from CH acids with a 50% solution of NaOH (or other alkalis) in a liquid–liquid system or with solid alkali (NaOH, KOH, K_2CO_3, Na_2CO_3, etc.) in a liquid–solid phase system in the presence of catalysts (onium salts, crown-ethers, etc.). The most successful variant in the reactions with enals proved to involve the application of a liquid–solid phase system [Na_2CO_3–benzene–triethylbenzylammonium chloride (TEBAC)] for the generation of carbanions from malonic, acetoacetic, and cyanoacetic esters.[51-53] Under these conditions, the mode of reaction depends greatly on the nature of the CH acid. Thus the carbanions $\overset{\ominus}{C}H(CO_2Et)X$, where X = CO_2Et or COMe, add exclusively to the C=C bond in enals without substituents in the 3-position (acrolein and methacrolein) and also to 3-monosubstituted enals (for example, crotonaldehyde, cinnamaldehyde, etc.):

$$XCH_2COOEt + R{-}CH{=}CH{-}CHO \rightarrow R{-}\underset{\displaystyle XCHCO_2Et}{\overset{\displaystyle CHCH_2CHO}{\underset{|}{\overset{|}{CH}}}}$$

X=CO_2Et, COMe; 44–75%

Table 3. Certain characteristics of malonic and cyanoacetic acids*.

Carbanion	$q_N^{\bullet\bullet}$, e	C_N	E_N, eV
$[HC(COOH)_2]^{\ominus}$	−0.435	−0.630	−4.424
$[NCCHCOOH]^{\ominus}$	−0.479	−0.660	−3.254

*Calculations performed in accordance with a CNDO/2 programme.[55]

**Here q_N is the π-electronic charge on the carbanionic centre.

The carbanions generated from cyanoacetic ester add to the C=C bond only in enals unsubstituted in the 3-position. 3-Substituted enals react with cyanoacetic ester at the C=O bond, which can be explained if account is taken of the most important characteristics[54] of malonic and cyanoacetic acids and their esters, which determine the charge and orbital control of the nucleophilic addition (Table 3).

In considering the data in Table 3, one should note that, compared with the malonic acid carbanion, the cyanoacetic acid carbanion has a significantly greater coefficient of its HOMO and a higher level of the HOMO, which should favour orbital control. However, the charge on the cyanoacetic carbanion is higher than that on the malonic acid carbanion which is responsible for the predominance of charge control, other conditions being equal. The latter probably obtains also in the reaction of 3-substituted enals with cyanoacetic esters. There is no doubt that steric hindrance due to the substituents in the 3-position in the enals also plays a major role.

It is of interest that the carbanions generated from cyanoacetic ester on treatment with potassium fluoride in acetonitrile in the presence of dibenzo-18-crown-6 ether add only to the C=C double bonds of the chalcone, forming adducts via the Michael reaction in a yield of ~90%.[56] This result is apparently associated with the fact that acetonitrile solvates the $K^{\oplus}$ ion fairly effectively and impairs its complex formation reaction with the CO group, which as a rule alters the regioselectivity of the reaction and leads to preferential attack on the 3-position of the enal.[57]

The reaction between the chalcone and ethyl 2-nitroacetate in a homogeneous medium (in toluene in the presence of 1-dimethylamino-2-hydroxy-1-methyl-2-phenylethane as the catalyst at room temperature) or in a two-phase system [in acetonitrile with KI in the presence of (2-hydroxy-1-methyl-2-phenylethyl)(dimethyl)ethylammonium bromide or (benzyl)(2-hydroxy-1-methyl-2-phenylethyl)dimethylammonium chloride as the catalyst] proceeds analogously:[58]

$$PhCH{=}CHCOPh + XCH_2CO_2Et \rightarrow \underset{\displaystyle XCHCO_2Et}{\overset{\displaystyle PhCHCH_2COPh}{|}} .$$

When X = CN, the yield is 90%, while for $X = NO_2$ the yield amounts to 10% (in a homogeneous medium) and 40% (in the two-phase system).

The presence of three stabilising substituents at the carbanionic centre frequently causes the reaction to take place only at the C=C bond of the enal or enone. Thus methyl 2,2-di(phenylthio)acetate reacts with acrolein, crotonaldehyde, etc. in DME in the presence of catalytic amounts of Triton B to form only adducts resulting from the reaction involving the C=C bond:[59]

$$R{-}CH{=}CHCHO + (PhS)_2CHCOOMe \rightarrow \underset{\displaystyle (PhS)_2CCOOMe}{\overset{\displaystyle R{-}CHCH_2CHO}{|}} .$$
24—85%

Under the standard conditions of phase transfer catalysis (CH_2Cl_2–50% NaOH solution–TEBAC with addition of NaOH solution to the mixture of components)[16,60,61] or in an alcoholic solution in the presence of sodium alkoxide,[12] enals react with bromomalonic ester to form formylcyclopropanes:

$$R{-}CH{=}CH{-}CHO + BrCH(CO_2Et)_2 \longrightarrow \underset{\displaystyle EtO_2C \quad CO_2Et}{\overset{\displaystyle R \qquad\qquad CHO}{\diagup\!\diagdown}} ;$$

R=H, Me, Ph, $(MeO)_2CH$ (yield 43–48%); R=MeCH=CH, Cl_2C=CH, PhCH=CH (yield 15–29%).

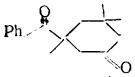
1,1,2,2-Tetra(ethoxycarbonyl)ethane is always formed in the reaction as a side product. Thus in this case the reaction involves the C=C bond. It is noteworthy that, when the alkoxide method is used, the reaction products are formed only in the case of acrolein and crotonaldehyde. The alteration of the order of mixing, i.e. the addition of the reactant mixture to a mixture of the 50% NaOH solution, the solvent, the TEBAC, results in the formation of formylcyclopropane only from acrolein, while the remaining enals polymerise under these conditions.[13] However, enones more resistant to alkalis give rise to acylcyclopropanes in high yields, for example:

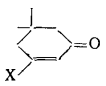
$$MeCOCH{=}CH_2 + BrCH(CO_2Et)_2 \rightarrow \underset{\displaystyle EtO_2C \quad CO_2Et}{\overset{\displaystyle MeCO \qquad\qquad}{\diagup\!\diagdown}} .$$

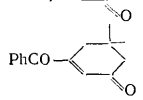
The occurrence of the reaction at the C=C bond in the case of carbanions stabilised by three electron-accepting and electronegative substituents can undoubtedly be accounted for by the increase of the degree of delocalisation of the charge.

In a series of studies devoted to the elucidation of the order of addition of the carbanions generated by treatment of CH acids having between one and three stabilising substituents with lithium di-isopropylamide in THF or DME, the features associated with the influence of the structure of the carbanions on the mode of reaction were elucidated. It was found that highly basic ("hot") nucleophiles of the type of carbanions derived from 2-methyl-1,3-dithianes[62] or 2-(2-ethoxyethoxy)propionitrile[63] and also the salts $H_2\overset{\ominus}{C}COO^{\ominus}.2Li^{\oplus}$[64] and $N\overset{\ominus}{C}CH_2.Li^{\oplus}$[65] add irreversibly to enones even at low temperatures, giving rise to a mixture of products of reactions involving the C=O and C=C bonds. Nucleophiles such as 1,3-dithianyl-2-phenyl-lithium,[66] $NC\overset{\ominus}{C}HPh.Li^{\oplus}$,[65] or $Ph\overset{\ominus}{C}.(CO_2R)X.Li^{\oplus}$ (where R, X = H, SePh; Me, SeMe; Me, OMe; Me, Me)[69] initially add to the C=O bond; however, when the temperature is raised, the 1,2-adducts formed rearrange spontaneously to 1,4-adducts, whose thermodynamic stability is higher. Nucleophiles of the type $NC\overset{\ominus}{C}(CH{=}CHMe)OCHMeOEt,Li^{\oplus}$,[65] $Ph\overset{\ominus}{C}(R)[S(O)R^1].Li^{+}$,[68,69] and $(EtS)_2\overset{\ominus}{C}CO_2Me.Li^{\oplus}$[70] add irreversibly to the C=C bond, but, depending on the structure of the enone, there is also a possibility of the irreversible addition to the C=O bond.

In contrast to the nucleophile $Ph\overset{\ominus}{C}(CN)(OSiMe_3).Li^{\oplus}$,[38] the nucleophile $NC\overset{\ominus}{C}HP(O)(OEt)_2.Li^{\oplus}$[71,72] reacts with enones of the type $R_2C{=}CHCOMe$ at the C=O group. Nucleophiles such as 1,3-dithianyl-2-phenyl-lithium[66] or $Me_2\overset{\ominus}{C}(CO_2Me).Li^{\oplus}$[67] react analogously even in solvents of low polarity at −78 °C.







III. THE INFLUENCE OF THE STRUCTURE OF ENALS AND ENONES ON THE MODE OF THE REACTION

The direction of the nucleophilic addition of CH acids of the type XCH_2Y and XCHYZ depends on the structure of the enals. In the case of enones such a dependence is not usually observed. Table 4 presents the results of the reactions of aliphatic and cyclic enones with the carbanions generated from the trimethylsilyl ether of benzaldehyde cyanohydrin by treatment with lithium di-isopropylamide in ether. 1,4-Adducts are formed exclusively under these conditions[73] and hydrolyse smoothly and in high yields to 1,4-diketones on treatment with 2 *N* HCl, Et_3NHF, or $(PhCH_2)Me_3NF$. The method described is convenient for the synthesis of these compounds.

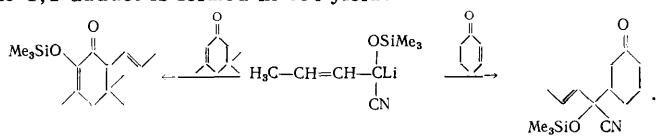


Table 4 shows that all the ketones used in the above study,[73] with the exception of 4-chloropent-3-en-2-one, form adducts in high yields. A decrease of the yield is observed when the cyclic ketones contain a substituent in the 3-position relative to the keto-group and the decrease is in

order of increase of the bulk of the substituent (Cl > EtO > Br). Apparently, the steric hindrance generated in relation to attack by the nucleophile on the 3-position plays the main role in this case. It may be that this also accounts for the absence of reaction in the case of 4-chloropent-3-en-2-one, where, apart from the methyl group, a bulky chlorine atom is present in the 3-position (in addition, account must be taken of the unfavourable influence of the +*M* effect of the chlorine atom).

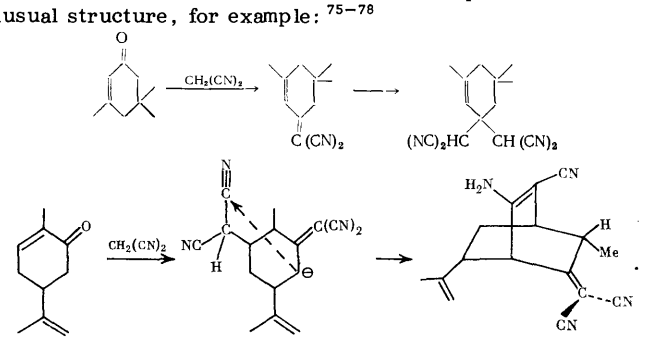

Table 4. Products of the addition of the trimethylsilyl ether of benzaldehyde cyanohydrin to various ketones.[73]

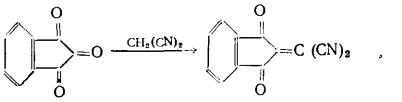
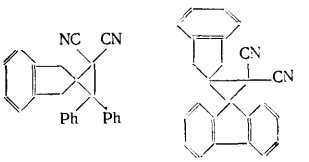
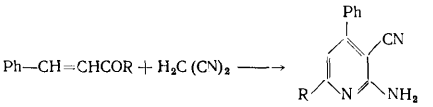
Ketone	Product of addition or subsequent hydrolysis	Yield, %
$Me_2C{=}CHCOMe$	$Me_2C(PhC(OSiMe_3)CN)-CH_2COMe$	84
$PhCH{=}CHCOMe$	$PhCH(PhC(OSiMe_3)CN)-CH_2COMe$	87
		96
$MeCCl{=}CHCOMe$	not formed	0
		45
		40 (X = Cl) 20 (X = EtO) 10 (X = Br)



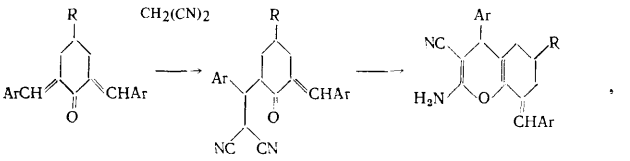
The major role of steric effects is also indicated by the interaction between the carbanion generated from the trimethylsilyl ether of crotonaldehyde cyanohydrin and cyclohex-2-enone or 3,5,5-trimethylcyclohex-2-enone in THF. In the former case the reaction proceeds via the C=C bond (the yield of the adduct is ~72%), while in the latter case the 1,2-adduct is formed in 53% yield:[74]



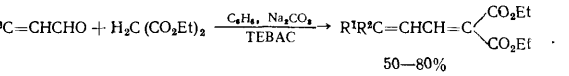
In this connection one should note that the interaction of malonodinitrile with enones in which the C=O group is sterically hindered takes place in DMF in the presence of potassium fluoride via a Michael reaction, while in the absence of steric hindrance the Knoevenagel reaction takes place initially. In a number of instances the formation of an active conjugated system under these conditions promotes the further addition of malonodinitrile to the conjugated system via the Michael reaction and the formation of products of unusual structure, for example:[75–78]



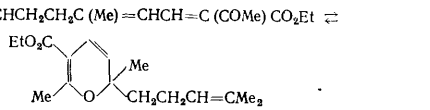
It is of interest that the uncatalysed reaction of malonodinitrile with indan-1,2,3-trione in benzene proceeds via a Knoevenagel reaction with formation of 2-dicyanomethyleneindan-1,3-dione:[79]



The Michael addition of malonodinitrile to enones makes it possible to introduce two cyano-groups into the molecule and to obtain new interesting compounds by further reactions. Thus 2-dicyanomethyleneindan-1,3-dione reacts with diphenyldiazomethane or 9-diazofluorene[79] to form spirocyclopropanes:



The reaction of equimolar amounts of malonodinitrile with enones in the presence of an excess of ammonium acetate leads to the formation of 4,6-disubstituted 2-amino-3-cyanopyridines in 60–70% yield:[80–81]



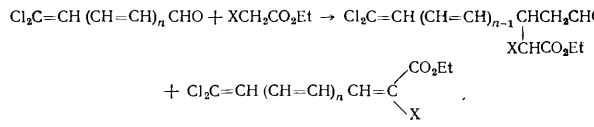
The reaction of chalcones with malonodinitrile results in the formation of 2-amino-4,6-diarylnicotinonitriles, whose hydrolysis leads to substituted nicotinamides.[82] The interaction of diarylidenecyclohexanones with malonodinitrile in the presence of sodium ethoxide or hydroxide can be used to synthesise chromones in 60–90% yield:[82]

A striking example of the influence of the structure of the substrate on the mode of the addition reaction involving enals is the interaction of malonic ester with 3,3-disubstituted enals in which the 3-position is undoubtedly sterically hindered; in this case the reaction is of the Knoevenagel type. Thus the corresponding dienes are formed from 3,3-dimethylacrolein, 3,3-dichloroacrolein, or citral:[51–53]

Citral reacts via a Knoevenagel reaction also with acetoacetic ester to give a mixture of open-chain and cyclic reaction products, which is one of the examples of valence isomerisation:[51–53,83–85]

Very interesting results have been obtained in the reaction between malonic or acetoacetic ester and ω,ω-dichloropolyenals in the C_6H_6–Na_2CO_3–TEBAC system.[53] The simultaneous formation of products of addition to both the C=C and

C=O bonds is observed in this case. Table 5 presents the ratios of the products of the reactions of ω,ω-dichloropolyenals with malonic, acetoacetic, and, for comparison, cyanoacetic esters:



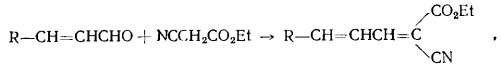


Table 5. The contents (%) of products of the addition of XCH_2CO_2Et (where X = CO_2Et, COMe, or CN) to the C=C and C=O bonds in ω,ω-dichloropolyenals. [53]

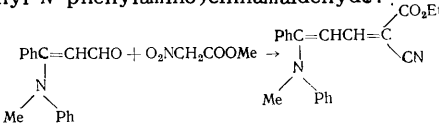
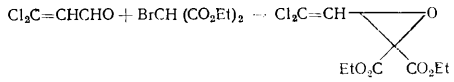
CH acid	n=0		n=1		n=2	
	C=C	C=O	C=C	C=O	C=C	C=O
$H_2C(CO_2Et)_2$	0	100	75	25	*	*
$H_2C(COMe)CO_2Et$	0	100	45	55	18	82
$H_2C(CN)CO_2Et$	0	100	0	100	0	100



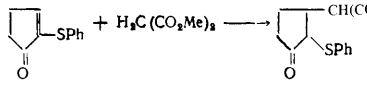
*Does not react.

Evidently, the mode of reaction is determined by the length of the chain of conjugated double bonds. The occurrence of the reaction exclusively at the C=O bond of 3,3-dichloroacrolein (n = 0) can be explained primarily by the steric hindrance in the attack by the carbanion on the 3-position. An increase in chain length naturally leads to the elimination of the steric effect of the terminal substituents and the formation of adducts via the reaction at the C=C bond becomes possible, which is in fact observed in reality in the interaction of 5,5-dichloropenta-2,4-dienal (n = 1) with malonic and acetoacetic esters, the product of the Michael reaction predominating in the former case. 7,7-Dichlorohepta-2,4,6-trienal (n = 2) does not react with malonic ester and the reaction with acetoacetic ester gives rise to a mixture in which the product of the Knoevenagel reaction predominates.

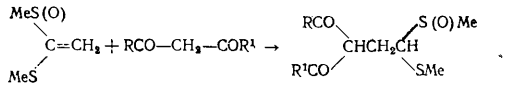
In the same system (C_6H_6–Na_2CO_3–TEBAC), sorbaldehyde, 5-phenylpenta-2,4-dienal, and 7-phenylhepta-2,4,6-trienal do not react with malonic or acetoacetic ester. Enals with markedly electron-donating substituents in the 3-position, for example, 3-dimethylaminoacrolein, also do not react with acetoacetic ester. [86] However, the interaction of enals of the type of 3-dimethylaminoacrolein, [86] 5-phenylpenta-2,4-dienal, and ω,ω-dichloropolyenals [53] with cyanoacetic ester, which most probably takes place under charge control, leads to the formation of the products of the Knoevenagel reaction:



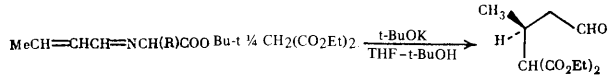
Methyl 2-nitroacetate reacts analogously at the C=O bond of 2-(*N*-methyl-*N*-phenylamino)cinnamaldehyde: [87]



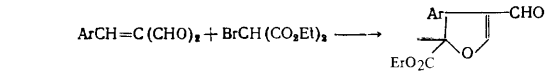
On treatment with nitromethane or cyanoacetic ester in the presence of piperidine, 2-nitro-3-phenylaminoacrolein also gives rise to 1,2-adducts. [88,89]



In contrast to acrolein and 3-monosubstituted enals, 3,3-disubstituted enals do not react with bromomalonic ester in the CH_2Cl_2–50% NaOH solution–TEBAC system, while in the DMF–K_2CO_3–TEBAC system the reaction is of the Darzens type. For example, 3,3-dichloroacrolein gives rise to 3-(β,β-dichlorovinyl)-2,2-di(ethoxycarbonyl)epoxyethane under these conditions: [18]



Addition to the C=C bond is apparently favoured by the presence of the thioester residue at the double bond in the α-position relative to the CO group. Thus 2-phenylthiocyclopent-2-enone very readily combines with dimethyl malonate in the presence of sodium methoxide in methanol: [90]



Certain keten derivatives can be introduced into the Michael reaction. Thus the interaction of keten thioacetals with the carbanions generated by treating malonic or acetoacetic ester or acetylacetone with sodium hydride in THF at −78 °C results in the formation of adducts via the reaction at the C=C bond in yields of 91–98%: [91]

In order to synthesise optically active aldehydes, the reaction involving the addition of malonic ester to aldimines, obtained from crotonaldehyde and optically active aminoacids, was employed. [92] The subsequent hydrolysis yielded (*S*)(+)-aldehydes in optical yields from 48 to 54%:

Finally we may mention yet another instance where the structure of the enal has a decisive influence on the structure of the final product. This involves the formation of formyldihydrofurans by the reaction of arylidenemalonaldehydes with bromomalonic ester in the DMF–K_2CO_3–TEBAC system: [18]

The formation of formyldihydrofurans can be explained by the possibility of the stabilisation of the anion of type (IIb) (formed in the reaction) by the elimination of $Br^{\ominus}$ with cyclisation or via the elimination of HBr from the 1,5-position of the enol formed by the protonation of (IIb) (as a consequence of the influence of the CHO group, which increases its stability, this enol can cyclise to dihydrofuran before it isomerises to a saturated aldehyde, which can be converted into a cyclopropane on subsequent elimination of HBr from the 1,3-positions).

Table 6 presents the results of the calculation of the electronic structures of the enals. Evidently, in all the enals investigated, the greatest positive charge is localised at the C(1) atom of the C=O group. Consequently, reactions whose mode is determined by the electrostatic interaction (charge control) should proceed preferentially at this atom. The highest coefficient C_E^* of the LUMO of enals is that of the π electron orbital of the C(3) atom involved in the

C=C bond. The reactions whose mode is determined by orbital control should therefore take place at the C(3) atom.[93]

Table 6. Certain characteristics of enals.[93]

Enal	$e^{\bullet}_{\sigma+\pi}$, e		$c^{\bullet}_{E}$	
	C (1)	C (3)	C (1)	C (3)
H_2C=CHCH=O	0.225	0.003	0.511	—0.576
MeCH=CHCH=O	0.225	0.060	0.461	—0.579
Me_2C=CHCH=O	0.224	0.101	0.423	—0.579
H_2C=C(Me)CH=O	0.217	—0.028	0.503	—0.567
MeCH=C(Me)CH=O	0.217	0.029	0.449	—0.572
ClCH=CHCH=O	0.232	0.124	0.485	—0.523
Cl_2C=CHCH=O	0.234	0.221	0.453	—0.613
Cl_2C=CHCH=CHCH=O	0.160	0.090	0.336	—0.475

*Here $e_{\sigma+\pi}$ are the $\sigma + \pi$ electronic charges on the atoms.

The relative contributions of the Coulombic (charge) and orbital interactions can be estimated by employing the ratio of the terms I_1/I_2, where I_1 characterises the Coulombic interaction and I_2 the orbital interaction. The data obtained for acrolein and its methyl derivatives are presented in Table 7. Evidently, in all cases the introduction of methyl groups hardly alters either ΔE or the index ratio I_1/I_2, so that the mode of reaction cannot be predicted on the basis of the relations obtained, although it does vary as a function of the nature of the reactants, which can be deduced from the experimental data discussed above.[93]

Table 7. Energy data for the reactions of certain enals with the C-anions of malonic and cyanoacetic acids.[93]

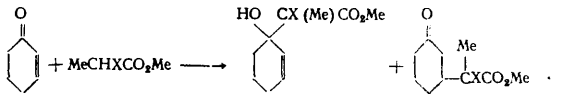
Enal	ΔE, eV		$I_1(C(1))/I_2(C(3))$
	⊖CH(COOH)$_2$	⊖CH(CN)COOH	
H_2C=CHCHO	—6.30	—5.43	3.70
MeCH=CHCHO	—6.24	—5.37	3.55
Me_2C=CHCHO	—6.16	—5.29	3.65
H_2C=C(Me)CHO	—6.26	—5.39	3.62
MeCH=C(Me)CHO	—6.13	—5.26	3.52

Notation: $\Delta E = E_N^{HOMO} - E_E^{LUMO}$, $I_1 = q_N q_E$ (π, σ) is the index of Coulombic interaction, and $I_2 = C_N^2 C_E^2/(E_E - E_N)$ is the index of orbital interaction.

The mode of the addition reaction can be significantly influenced by the steric hindrance associated with the different bulks of the H atom and the methyl group (or the chlorine atom), because the addition of carbanions to enals leads to a considerable deformation of the structure of one of the carbon atoms of the enal, which changes from planar to pyramidal as the carbanion approaches. Table 8 presents the "pyramidalisation" energies of the C(1) and C(3) centres for acrolein and its methyl and chloro-derivatives, calculated as differences between the energies of the pyramidal and planar enals. It is evident from these data that in the case of acrolein the conversion of the terminal carbon atom C(3) involved in the C=C bond into a pyramidal form is most favourable. The substitution of one of the hydrogen atoms at C(3) by a methyl group leads to a qualitative alteration of the result. The conversion of the C(1) atom of the carbonyl group into the pyramidal form is energetically more favourable; the substitution of the second hydrogen atom at C(3) by a methyl group increases the difference to 9 kcal mol^{-1}. The substitution of hydrogen atoms by chlorine atoms leads to a qualitatively similar result as the introduction of a methyl group. Thus the substitution of the hydrogen atoms at C(3) by methyl groups or chlorine favours the alteration of the mode of the addition reaction by virtue of steric factors.

Table 8. The relative* energies of the "pyramidalisation" (E) of the C(1) atom for R^1R^2C=CHCH=O (according to the data of Kryshtal' et al.[93]).

R^1	R^2	E, kcal mol^{-1}
H	H	4
H	Me	—3
Me	Me	—9
H	Cl	—1
Cl	Cl	—4



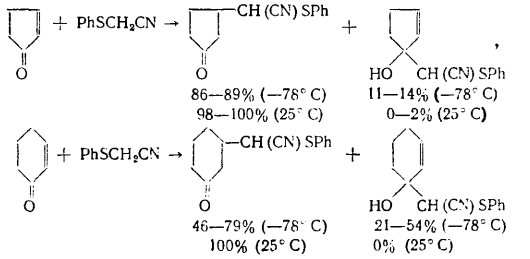
*The energy of the structure with the pyramidalised C(3) atom has been adopted as zero.

IV. CONDITIONS AND MODE OF THE REACTION

Studies in recent years have shown that the mode of addition of CH acids, including those of the XCH_2Y and XCHYZ types, to enals and enones depends very strongly on the reaction conditions—primarily on temperature, the nature of the solvent, and additives.

Temperature

The dependence of the mode of addition of CH acids to enones on temperature has been clearly demonstrated for the addition to cyclohexenones of the carbanions generated from $MeCHXCO_2Me$, where X = OPh, OMe, SPh, SMe, or Me, under the influence of lithium di-isopropylamide.[94] It was established that, under the conditions of kinetic control at −78 °C, the addition is exclusively to the C=O group (except in the case where X = SPh); on raising the temperature, it is possible to alter the mode of addition of the nucleophile (Table 9):



The addition of methyl 2-phenylthiopropionate takes place only in the 1,4-positions both at −78 °C and 25 °C. The introduction pf tje SMe substituent (the $-I$ and $+M$ effects)

probably increases the energy of the HOMO of the nucleophile and leads to a change from charge to orbital control. The absence of this effect when the SPh group is introduced is apparently associated with the fact that this group increases the level of the HOMO to a lesser extent, because the *n* electron pair of the S atom interacts not only with the nucleophilic centre but also with the benzene ring.

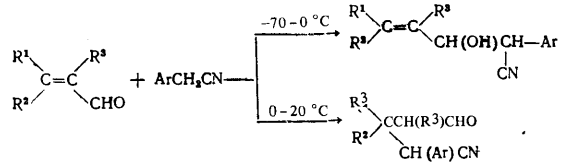


Table 9. The influence of temperature on the mode of addition of methyl 2-X-propionate to cyclohex-2-enone. [94]

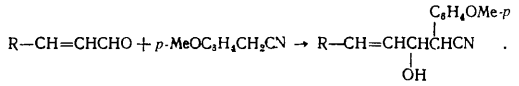
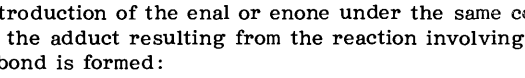
X	Yield of 1,2-adduct, %		Yield of 1,4-adduct, %	
	−78° C	+25° C	−78° C	+25° C
OPh	88	—	8	84
OMe	75	5	12	62
SPh	—	—	75	86
SMe	63	—	7	85
Me	88	7	5	83

Analogous results have been obtained in the study of the addition of phenylthioacetonitrile to cyclopent-2-enone and cyclohex-2-enone in THF and in ether using lithium di-isopropylamide to generate the carbanions. [95] The 1,2-adducts are formed in appreciable amounts at −78 °C, while at room temperature the products are exclusively or mainly the 1,4-adducts:



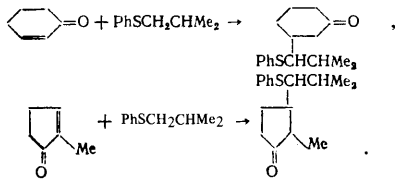
The addition of the carbanions generated from arylacetonitriles by treatment with lithium di-isopropylamide to enals in THF yields at temperatures from −70° to 0 °C the products of the reaction involving the C=O group or at temperatures from 0° to 20 °C the products of the reaction involving the C=C bond: [96]



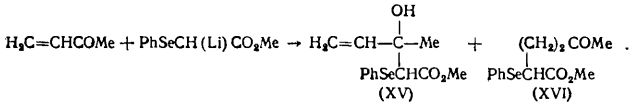
The 1,2-adducts are thus the main reaction products under the conditions of kinetic control, while the 1,4-adducts are the products under the conditions of thermodynamic control. However, the 1,4-adducts can be formed also under the conditions of kinetic control (see below).

Solvents

The very great influence of solvents on the mode of addition of nucleophiles to enones and enals has been frequently noted but has found an explanation only in recent years. [57] The most striking example is the shift of the equilibrium in the reaction of enones towards 1,4-addition in the presence of HMP. [2] Thus the interaction between *p*-methoxyphenylacetonitrile (the carbanion is generated under the influence of n-BuLi at −78 °C) and cyclohex-2-enone or enals of the type R−CH=CHCHO in THF always takes place with the dominant formation of allyl alcohols:



However, when HMP is added to the reaction mixture before the introduction of the enal or enone under the same conditions, the adduct resulting from the reaction involving the C=C bond is formed:



The reaction between cyclohex-2-enone or 5-isopropenyl-2-methylcyclohex-2-enone and the carbanions generated from $Me_2CHCH(SePh)(SPh)$, [2] 2-R-1,3-dithianes, 1,1-di(phenylthio)alkanes, or 1,1-di(methylselenyl)alkanes by treatment with n-BuLi takes place analogously. [97] The 1,4-adducts are formed preferentially under kinetic conditions at −78 °C (the content of the 1,2-adducts does not exceed 1–7%). This is one of the examples illustrating the possibility of the formation of the 1,4-adducts when the reaction takes place under kinetic control. The effect of HMP in this instance consists in the fact that the above solvent solvates vary effectively the lithium ions, which are known [57] to increase the regioselectivity of the process in favour of 1,2-addition under both charge and orbital control as a result of complex formation via the C=O group and the consequent decrease of the energy level of the LUMO of the enone or enal and the increase of the coefficient for the C(2) atom. Solvation interferes with complex formation to a greater extent the greater the solvating capacity of the solvent.

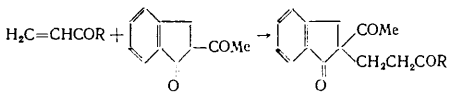
The addition of HMP is widely used for synthetic purposes. For example, the employment of a mixture of THF and HMP at −78 °C in the reactions of the carbanions generated by the action of n-BuLi on isobutyl phenyl sulphide with cyclohex-2-enone and 2-methylcyclopent-2-enone makes it possible to obtain satisfactory yields of the 1,4-adducts: [98]

The addition of HMP has a considerable influence also on the reaction of methyl vinyl ketone with a selenyl-substituted carbanion. [99] Thus, when the reaction is carried out at −78 °C in THF, a mixture containing 81% of compound (XV) and 19% of compound (XVI) is formed; the addition of a small amount of HMP lowers the content of compound (XV) in the mixture to 15% and increases that of compound (XVI) to 85%:

Sometimes, in order to achieve the regioselectivity of the 1,4-addition, it is necessary not only to add HMP but also to increase the reaction temperature. For example,

lithium selenoacetates add to cyclohex-2-enone in THF at −78 °C with formation of a mixture of the 1,2- and 1,4-adducts in proportions of 95:5; the addition of HMP alters the ratio to 20:80 and only an increase of temperature to −45 °C makes it possible to achieve the ratio 5:95.[99]

As a rule, highly polar protic solvents, such as water or alcohols, promote the 1,4-addition. This is also favoured by dipolar aprotic solvents (DMF, DMSO, HMP, etc.) and the change from protic to aprotic dipolar solvents usually increases the rate of reaction, because the basicity of the carbanions in such a medium increases as a consequence of the absence of specific solvation. Incidentally, in certain cases the addition is also facilitated by specific solvation. For example, in solvents such as acetonitrile, carbon tetrachloride, or toluene, the chalcone does not react with nitromethane in the presence of quinine, *N*-methylephedrine, or L(−)-*N*-phenylethylamine as catalysts. However, in methanol the 1,4-adducts are formed in yields of 60–80% under the conditions of weak optical induction (optical yield 1–3%):[100]



$$PhCH{=}CHCOPh + \overset{\ominus}{C}H_2NO_2 \rightarrow PhCHCH_2COPh \quad (CH_2NO_2)$$

The explanation is that in aprotic solvents chiral amines cannot ensure the generation of a carbanion from nitromethane, while in methanol this process is facilitated owing to the stabilisation of the carbanion formed as a consequence of the formation of hydrogen bonds with the solvent molecule. The use of *N*-benzylquininium fluoride or *N*-dodecylephedrinium fluoride as catalysts in toluene makes it possible to obtain the reaction products in yields of the order of 90% and with an optical yield up to 10–23%, which can most probably be attributed to the involvement of the fluoride anion in the process.[101]

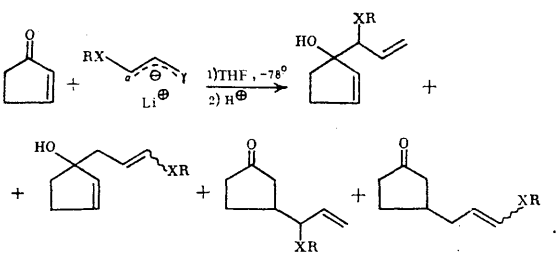
Table 10. The influence of solvents on the mode of addition of 1,3-dithiane to enals.[37]

Enal	Content of adducts, %			
	in THF	in THF + HMP	in THF	in THF + HMP
	Addition to C=C		Addition to C=C	
MeCH=CHCHO	35	95	65	5
PhCH=CHCHO	15	65	85	35
H_2C=C(Me)CHO	35	95	65	5
Me_2C=CHCHO	0	35	100	65

There is no doubt that the structure of the enone and the carbanion plays a major role. Thus methyl vinyl ketone readily reacts with the carbanion generated from 1-nitro-1-*p*-tolylsulphonyloxymethane, 2-acetyl-2,3-dihydro-1-indanone, or 2-acetyl-2-[2-acetyl(or formyl)ethyl]-2,3-dihydro-1-indanone in the presence of quinine to form 1,4-adducts in high yields (87–93%) and with a high optical activity (optical yield up to 56%)[101] both in toluene and in carbon tetrachloride. Acrolein and crotonaldehyde react analogously:

Addition in the 1,4-positions also takes place in reactions with the carbanions generated from methyl 2-methylacetoacetate, ethyl 2-phenylcyanoacetate, and 2-ethoxycarbonylcyclopentanone; however, the carbanion obtained from 2-acetylcyclopentanone does not react with enones and enals under these conditions.[101]

The influence of solvation is strikingly manifested in the reaction between the trimethylsilyl ether of benzaldehyde cyanohydrin and mesityl oxide.[38] A mixture of products of addition to both the C=C and C=O bonds is formed rapidly and irreversibly in THF or DME and also in a mixture of these solvents under the conditions of kinetic control. On the other hand, when the reaction is carried out in ether, also under kinetic control, only the addition to the C=C bond is observed:



$$Me_2C{=}CHCOMe + Ph\overset{\ominus}{C}(CN)OSiMe_3\ Li^{\oplus} \rightarrow$$
$$\rightarrow Me_2C{=}CH{-}\underset{\displaystyle OH}{\underset{|}{C}}(CN)(OSiMe_3)Ph + Me_2CCH_2COMe \quad (PhC(CN)OSiMe_3)$$

When 1,3-dithiane reacts with enals, a shift towards an increase of the yield of the 1,4-adducts is observed on passing from THF to its mixture with HMP (Table 10).

Thus the above data show that polar solvents frequently promote the addition to the C=C bond.

The influence of solvation of the proportions of the 1,2- and 1,4-adducts has been studied in detail for the following nucleophiles: $(MeCH{=}CH)\overset{\ominus}{C}(CN)OCHMeOEtLi^{\oplus}$, $Ph\overset{\ominus}{C}(SR)S.(O)R^1Li^{\oplus}$, $(EtS)_2\overset{\ominus}{C}CO_2MeLi^{\oplus}$, and $H\overset{\ominus}{C}(CN)P(O)(OEt)_2Li^{\oplus}$. It has been established that, when the counterion is a lithium ion, then in THF or DME at −55 °C the above carbanions exist in the form of solvate-separated ion pairs. On the other hand, in ether, which solvates lithium ions only slightly, the same carbanions exist in the form of close (contact) ion pairs.[102–106] In the first case, the carbanion interacts only weakly with the counterion (lithium), so that a complex is formed between the lithium and the oxygen of the carbonyl group. The complex formation increases the electrophilicity of the carbonyl group by increasing the charge on the C(2) atom and by decreasing the energy level of the π^*(C=O) LUMO, which favours attack by the nucleophile on the C(1) atom.[57] In the second case the nucleophile interacts strongly with the counterion (lithium) and the latter, which interacts only weakly with the oxygen of the carbonyl group, forms an associated species. Ion pair association reduces the nucleophilicity of the carbanion as a result of the decrease of the charge on the nucleophile and the decrease of the energy level of its HOMO, which promotes the attack by nucleophiles on the C(3) atom.[57] The reversal of the direction of reaction when THF (or DME) is replaced by ether in the interaction of mesityl oxide with the carbanion generated from the trimethylsilyl ether of benzaldehyde cyanohydrin by treatment with n-BuLi can be explained by the fact that the solvate-separated ion pairs $Ph\overset{\ominus}{C}(CN)(OSiMe_3)\,||Li^{\oplus}$ are then converted into the close ion pairs $[Ph\overset{\ominus}{C}(CN)(OSiMe_3)][Li^{\oplus}]$,[73,106] which is accompanied by a decrease of the negative charge on the carbanionic centre and is responsible for the preferential attack on the C(3) atom despite some decrease of the energy of the HOMO of the nucleophile.

An interesting example of the change of direction of the reaction as the solvent composition is altered is provided by the reaction of cyclopent-2-enone with the carbanion generated by treating $RXCH_2CH{=}CH_2$ with n-BuLi at −78 °C.[107] In THF the reaction proceeds in accordance with the mechanism

This results in the formation of mainly a mixture of the α- and γ-1,2-adducts. The addition of only one mole of HMP results in a sharp change in regioselectivity and mainly the α-1,4-adduct is obtained (Table 11). We may note that a decrease of the amount of added HMP leads to the appearance of α- and γ-1,2-adducts in the mixture. A complete inversion of the direction of reaction in this instance can probably be accounted for by the fact that the effective solvation of lithium ions increases the energy of the HOMO of the nucleophile and leads to orbital control, which promotes 1,4-addition.[107-110] The change in the regioselectivity of the addition of CH acids to enals and enones by the addition of HMP is nowadays already used fairly widely in organic synthesis, for example, in the synthesis of α,α,β-trisubstituted ketones and natural products (confertin, aromatin, etc.).[111]

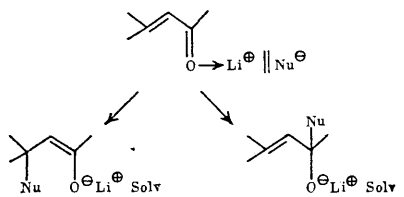


Table 11. The influence of the nature of solvents on the composition of the products of the reaction of cyclopent-2-enone with $RXCH_2CH = CH_2$ (according to the data of Binus and Haynes[107]).

R	X	Solvent	Composition of reaction products, %				Overall yield, %
			α-1,2	γ-1,2	α-1,4	γ-1,4	
Ph	S	THF	60	18(1.0:1.1)	12	8(1.0:4.2)	85
Ph	S	THF + HMP**	0	0	95	5	89
Ph_3C	S	THF	30	70	—	—	30
Ph_3C	S	THF + HMP**	0	0	90	10	30
Me	S	THF	64	36(1.0:0.6)	0	0	87
Me	S	THF + HMP**	0	0	95	5	89
t-Bu	S	THF	42	58(1.00:0.25)	0	0	85
t-Bu	S	THF + HMP**	0	0	95	5	85
Ph	Se	THF	58	20	12	10(1.0:1.9)	79
Ph	Se	THF + HMP**	0	0	95	5	81

*The ratio of the *Z*- and *E*-isomers is given in brackets.
**One mole of HMP was added.

Additives and the Mode of Reaction

It has been established in recent years that the introduction of certain additives into the reaction mixture makes it possible, by the change of solvent, to alter the regioselectivity of the addition of CH acids to enals and enones. Table 12 illustrates, for example, the influence of additives on the ratio of 1,2- and 1,4-adducts in the reaction of mesityl oxide with the trimethylsilyl ether of benzaldehyde cyanohydrin in the presence of n-BuLi.[73] Evidently, the addition of 12- crown-4 ether, which fully displaces the reaction towards 1,2-addition in DME and even in ether leads to the formation of 76% of the products of addition to the C=O bond, evidently exerts the greatest influence. This is undoubtedly associated with the formation of stable complexes between 12-crown-4 ether and lithium ions[112,113] (see the previous Section). The addition of *N,N,N',N'*-tetramethylethylenediamine (TMEDA) and lithium bromide and perchlorate hardly alters the mode of reaction but the introduction of magnesium bromide increases the content of the 1,4-adducts in the mixture. It may be that a complex is formed in this case between the solvated nucleophile ion pair and the enone via the carbonyl group and is capable of ensuring both reaction pathways, involving the 1,2- and 1,4-positions:

The slight tendency towards an increase of the content of the 1,4-adducts (from 22 to 26–28%) following the addition of lithium salts is also probably associated with the analogous complex formation reaction.

Table 12.

Solvent	Additive	Compn. of reaction products, %		Overall yield, %
		via C=O bond	via C=C bond	
DME	—	78	22	98
DME	TMEDA*	80	20	98
DME	12-crown-4 ether*	100	0	88
Ether	12-crown-4 ether*	76	24	90
DME	LiBr**	72	28	91
DME	$LiClO_4$**	74	26	91
THF	$MgBr_2$***	42	58	97

*One mole in relation to the substrate was added.
**Saturated solutions in a 2:1 DME–hexane mixture.
***0.5 of a mole in relation to the substrate was added.

It is noteworthy that the reaction of the t-butylthioallyl anion with cyclopent-2-enone in THF in the presence of three moles of TMEDA leads to an 80% yield of only a mixture of the α-1,2-isomer (41%) and the γ-1,2-isomer (59%), while the addition of copper(I) iodide entails the formation of the 1,4-adduct alone in a 75% yield.[107] The complete shift towards 1,4-addition in the reaction of ethyl propionate with 2-phenylthiocyclopent-2-enone in THF at −78 °C was induced by the addition of a complex of copper iodide with trimethyl phosphite.[111] This resulted in the formation of 2-phenylthio-3-(1-ethoxycarbonylethyl)cyclopentanone in a 64% yield as a mixture of four diastereoisomers in proportions of 18:2:9:71. In the absence of the additive, only the 1,2-adduct was formed, namely 1-hydroxy-1-(1-ethoxycarbonylethyl)-2-phenylthiocyclopent-2-ene.[111]

Finally, mention should be made of the effect of yet another factor on the mode of reaction, namely the pressure. It has been shown that the addition of ethyl- and n-butylmalonic esters to the C=C bond of the chalcone does not take place at atmospheric pressure. However, an increase of the pressure to 10–15 kbar makes it possible to obtain the products of the Michael addition in yields of 70–95%.[114-116]

---oOo---

By virtue of the advances achieved in the study of the nucleophilic addition of CH acids of the type of XCH_2Y and XYCHZ to enones and enals, it has now become possible to achieve the regioselective addition in the 1,2- and 1,4-positions by selecting the appropriate nucleophiles, enones and enals, bases for the generation of the carbanions, solvents, and additives. 1,2-Addition is favoured by selecting nucleophiles with the charge most highly localised on the nucleophilic centre (CH acids with low pK_a), the use of enones and enals with sterically hindered C(3) atoms or with electron-donating substituents in the 3-position, the use of bases whose cations form complexes with the oxygen of the carbonyl group most readily, and the application of solvents promoting the formation of solvate-separated ion pairs comprising the carbanion and the counterion (the base cation) as well as additives forming complexes with the cations.

1,4-Addition is promoted by selecting nucleophiles with the most delocalised charge (CH acids with high pK_a), the employment of enones and enals without substituents giving rise to steric hindrance at the C(3) atom, and the application of bases whose cations are poor complex forming agents in relation to the oxygen atom of the carbonyl group and solvents promoting the formation of close ion pairs between the carbanion and the counterions.

Advances in the Chemistry of α, α, α′, α′-Tetrasubstituted Piperidines

L.N.Yakhontov

The stages in the development of the chemistry of piperidines with a sterically hindered nitrogen atom and the practical importance of compounds of this class are examined. The methods of synthesis of 2,2,6,6-tetra-alkylpiperidines published in the literature, and their chemical properties and reactions are surveyed: processes occurring without the growth of a carbon skeleton, condensations with the formation of new C-C bonds, and reactions involving a change in the heterocyclic skeleton of the molecules. The characteristics of the stereochemistry and in particular of the conformations of 2,2,6,6-tetrasubstituted piperidines are analysed.
The bibliography includes 174 references.

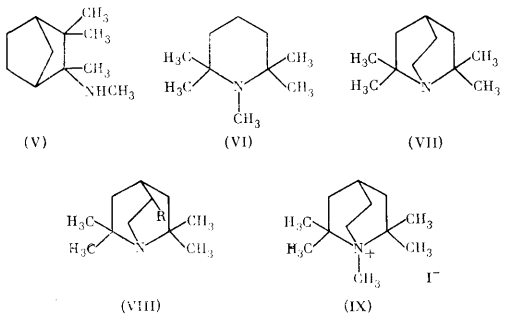
I. INTRODUCTION

The introduction of various kinds of substituents into the α- and α′-positions relative to the nitrogen atom in N-heterocyclic systems leads to a significant alteration of the chemical properties of the compounds. Effects of this kind were examined in our previous study[1] for N-heteroaromatic substances in relation to 2,6-disubstituted pyridines.

In contrast to heteroaromatic derivatives, where various electromeric effects (both effects transmittable via the bonds and "shield effects"), play an important role, steric effects associated with the shielding of the heterocyclic nitrogen atom are of primary importance for heteroparaffins of the type of α,α,α′,α′(2,2,6,6)-tetrasubstituted piperidine. Unfortunately the number of theoretical studies on this problem is inadequate and the reviews devoted to the synthesis and chemical reactions of 2,2,6,6-tetrasubstituted piperidines are altogether lacking. The thorough review articles and monographs on iminoxy-radicals of the type of 2,2,6,6-tetramethylpiperidin-1-yloxy-radical are the only exception.[2-17]

II. STAGES IN THE DEVELOPMENT OF THE CHEMISTRY OF α,α,α′,α′-TETRASUBSTITUTED PIPERIDINES

Studies on 2,2,6,6-tetrasubstituted piperidines having a hindered heterocyclic nitrogen atom were begun more than a hundred years ago when triacetoneamine was isolated from the products of the interaction of acetone with ammonia and its structure was established as 2,2,6,6-tetramethyl-4-piperidinone (I).[18,19] For a long time, the study of compounds of this series reduced to the synthesis of derivatives of compound (I) involving the carbonyl group and the nitrogen of the piperidine ring. Data on the local anaesthetic activity of α-eucaine (II), a derivative of 1,2,2,6,6-pentamethylpiperidine which is a cheaper, less toxic, and more heat resistant analogue of cocaine (III), were published in the only communication on the biological properties of substances of this type.[20] However, in view of the intense local irritant action of compound (II), it was soon eliminated from medical practice by β-eucaine (IV), which is free from this disadvantage:



(I) (II) (III) (IV)

A new stage in the study of 2,2,6,6-tetrasubstituted piperidines was begun in the 1950's in connection with the search for ganglion-blocking agents. By that time it had been established that, in contrast to the ganglion-blocking quaternary ammonium compounds widely used in medical practice but poorly assimilated from the gastrointestinal tract and secondary amines with a hindered nitrogen atom of the type of camphonium (V), which exert a secondary central activity (depression of the central nervous system, tremor), 2,2,6,6-tetramethylpiperidines unsubstituted in the 1-position and 1-alkyl-2,2,6,6-tetramethylpiperidines, which exhibit an intense ganglion-blocking activity, are rapidly assimilated following peroral administration and are free from side effects on the central nervous system.[21] Among compounds of this group, the most active proved to be 1,2,2,6,6-pentamethylpiperidine (VI) which has been introduced into medical practice under the names pempidine, pyrilene, genoriol, perolysen, etc. and is still used as an effective ganglion-blocking agent.[22-24]

The study of numerous analogues of compound (VI) [25-35] showed that steric hindrance of the nitrogen atom is a more important factor for the ganglion-blocking activity of compounds of this type than a change in the structure of the heterocycle. An increase in the bulk of the substituent at the nitrogen atom lowers the activity. The introduction of a

double bond into the ring does not affect the activity but reduces the duration of action and increases the toxicity:[27-29]

(V) (VI) (VII)

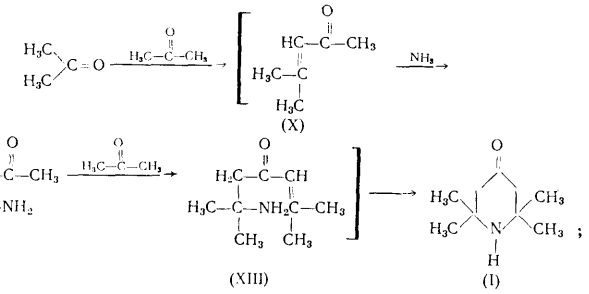
(VIII) (IX)

Ganglion-blocking and sedative properties have also been shown by triacetoneamine (I),[36-38] which has been given the name tempidone in Bulgaria. Further studies designed to search for ganglion-blocking agents more active than pyrilene led to the development of new methods of synthesis of 2,2,6,6-tetramethylpyridines[28,39-41] and then to the synthesis of the quinuclidine analogue of compound (VI)—the medicinal drug temekhin (VII).[42] The latter exhibits an activity which is three times more selective than that of pyrilene (VI) in relation to muscarinic cholinoceptor autonomic ganglia, the cortical substance of suprarenal glands, and carotid body without influencing the nicotinic cholinoceptor system of skeletal muscles. Temekhin is characterised by a broad spectrum of its therapeutic activity, is manufactured by the chemical-pharmaceutical industry of the USSR, and is used in medicine as a ganglion-blocking and hypotensive agent.[43] The additional introduction of the 8-methyl-group into the temeckin molecule to give compound (VIII, R = CH_3) increased somewhat the toxicity of the preparation with retention of its activity. The increase in the length of the 8-alkyl chain or conversion into 8-substituted functional derivatives (VII) leads to a further increase of toxicity with the simultaneous reduction of the ganglion-blocking effect.[44-46] The activity of the preparation changes in another direction on quaternisation as the bridgehead nitrogen atom. 2,2,6,6-Tetramethylquinuclidine methiodide (IX), which has been called imequine,[47] is also manufactured by the chemical-pharmaceutical industry of the USSR and is used in medical practice for the creation of artificial hypotonia in surgical operations, in the treatment of the oedemas of the lungs and the brain and the chronic hypotonia associated with kidney failure, and for the prevention and arrest of hypertonic crises. In all cases imequine behaves as a drug which is stronger, more easily controlled, less toxic, and more convenient for practical use than a preparation having a different chemical structure (arfonad) used for such purposes outside the USSR.[43]

The organisation of the manufacture of initially pyrilene and then temekhin and imequine, whose synthesis is based on the use of triacetoneamine(I), created a realistic industrial raw material base for the preparation of various derivatives of 2,2,6,6-tetramethylpiperidine.

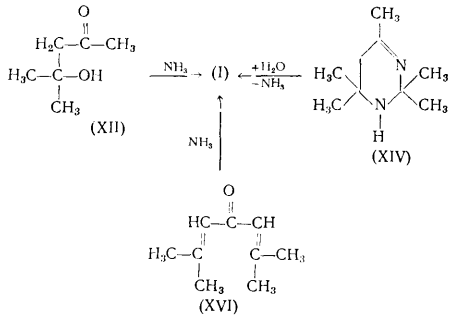
A new stimulus to the development of the chemistry of 2,2,6,6-tetrasubstituted piperidines was provided by studies and practical employment of iminoxy-radicals.[2-17] 2,2,6,6-Tetramethyl-4-oxopiperidine 1-oxide (X), which is an iminoxy-radical based on triacetoneamine whose stability is due to steric factors, was first obtained in a pure form in 1962.[48] This was followed by numerous studies of various methods of synthesis of 2,2,6,6-tetramethylpiperidin-1-yloxy-radicals and their reactions involving the participation of both the free-radical function and others in which the unpaired electron does not participate. Iminoxy-radicals of the 2,2,6,6-tetramethylpiperidine series are widely used in the solution of many theoretical and applied problems in experimental biophysics, the chemistry of high-molecular-weight compounds, analytical and forensic chemistry, biochemistry, and molecular biology (as spin labels and probes, paramagnetic inhibitors, and stabilisers), in instrument making (lasers and masers, current sources, magnetometers, and dosimeters), etc. The availability of fairly careful reviews and monographs on the chemistry and applications of paramagnetic 2,2,6,6-tetrasubstituted piperidin-1-yloxy-radicals[2-17] makes it possible to restrict the present review to the consideration of mainly only diamagnetic 2,2,6,6-tetrasubstituted piperidines, which are used in many instances as the starting materials for the synthesis of stable iminoxy-radicals.

At the present stage of development of the chemistry of 2,2,6,6-tetrasubstituted piperidines, a fairly vigorous development of all the trends established in this field as a result of historical factors has continued. The study of the theoretical and preparative problems of the chemistry of 2,2,6,6-tetrasubstituted piperidines has been concentrated in recent years on the elucidation of the characteristics of the conformation of sterically hindered piperidines, the determination of the contribution of axial and equatorial α-methyl groups to the stereochemistry of other substituents,[49-51] the ionisation potentials of the photochemical reactions of the test substances,[52-54] etc.



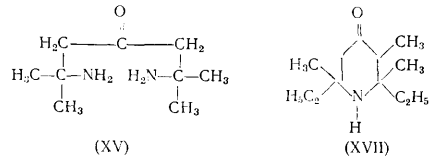
Together with the extensive studies on nitroxy-radicals, 2,2,6,6-tetramethylpiperidine-1-thiyl radicals,[55] 2,2,6,6-tetramethylpiperidine-1-nitrenes,[56] and 2,2,6,6-tetramethylpiperidin-1-yl radicals[57] have been obtained and have aroused interest.

Vigorous search for new biologically active 2,2,6,6-tetrasubstituted piperidines[53,54,58-66] is being continued and studies on the employment of compounds of this class for the formation of polymeric materials are developing.[67-72]



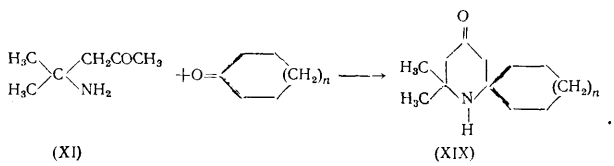
III. METHODS OF SYNTHESIS OF α,α,α′,α′-TETRASUBSTITUTED PIPERIDINE SYSTEMS

In considering the methods for the closure of 2,2,6,6-tetrasubstituted piperidine rings developed hitherto, one should note that attention has been concentrated on the synthesis of 2,2,6,6-tetramethyl-4-piperidinone (triacetoneamine). The vast majority of 2,2,6,6-tetrasubstituted piperidines known at present have been synthesised from triacetoneamine. According to the method[18] for the synthesis of compound (I) developed as early as 1874, ammonia was passed into acetone with heating.[19,73] Subsequently the process was carried out at room temperature and calcium chloride was added to the reaction mass to improve the absorption of ammonia and to bind the water formed during the reaction.[74-76] Different versions of this process have been developed: with the ammonia passed in several portions into a mixture of acetone and calcium chloride taking into account the amount of ammonia[40,77] and with subsequent maintenance of the reaction mass at 20 °C for 4 days[28,40,78] or with boiling it in the course of 6 h.[79] A special apparatus has been proposed for the reaction providing for the periodic separation of the calcium chloride solution[80,81] and it has been demonstrated that many protic and Lewis acids exert a catalytic influence on this process.[82-84] The application in this reaction of liquefied ammonia of the ammine complex of calcium chloride prepared beforehand has been described.[85] However, in all cases the reaction does not proceed unambiguously[78] and the yield of triacetoneamine relative to the acetone employed is about 30%.



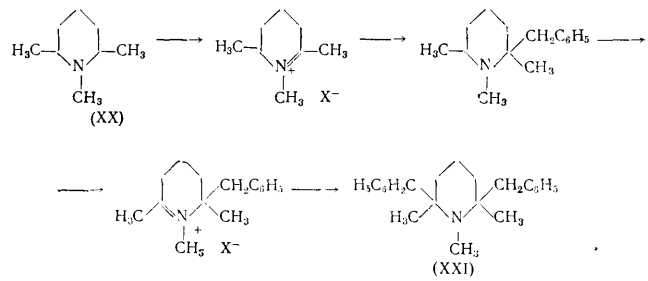
The interaction of acetone with ammonia apparently proceeds via the formation of mesityl oxide (X) and diacetoneamine (XI),[86] compound (XI) being the main reaction product at room temperature.[87] Diacetone alcohol (XII),[77] diacetonamine,[74,77,88] mesityl oxide,[77] acetonin (2,2,4,4,6-pentamethyl-2,3,4,5-tetrahydropyrimidine) (XIV),[77,78,87,89] triacetonediamine (XV),[90] etc. have been detected as side products in the synthesis of triacetoneamine.

(X) (XI) (XIII) (I)



(XII) (XIV) (XVI)

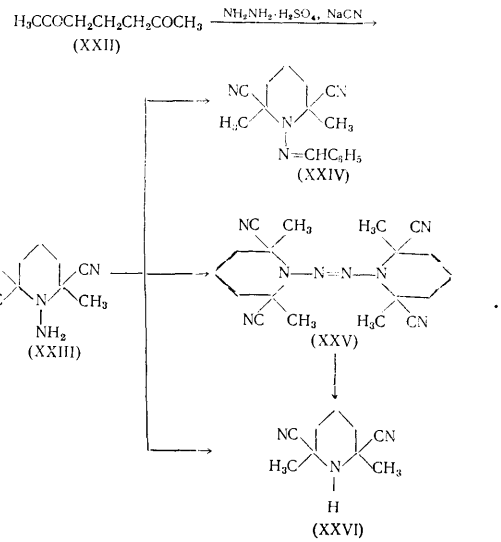
(XV) (XVII)



Triacetoneamine can also be obtained from phorone (XVI) and ammonia,[73,91,92] from acetonin (XIV) and water in the presence of calcium chloride,[78] and from diacetone alcohol (XII) by catalytic condensation with ammonia.[78] Despite the fact that the yields of triacetoneamine in the above reactions are somewhat higher (from 48 to 68%), the lower availability of the starting materials precludes preference being given to these procedures in the synthesis of compound (I) compared with the classical method involving the condensation of acetone with ammonia.

An analogous condensation of ethyl methyl ketone with ammonia has been used to synthesise 2,6-diethyl-2,3,6-trimethyl-4-piperidinone (XVII).[93] When diacetoneamine was allowed to react with cyclopentanone (XVIII, $n = 0$) and cyclohexanone (XVIII, $n = 1$), compounds (XIX, $n = 0$ and 1) were synthesised in yields of 20 and 54% respectively:[78]

(XI) (XIX)



A novel method for the conversion of 1,2,6-trimethylpiperidine (XX) into 2,6-dibenzyl-1,2,6-trimethylpiperidine (XXI) consists in a twofold repetition of the reactions involving the oxidation of the piperidine derivative by mercury acetate to the corresponding Δ'-dehydro-derivatives in yields of the order of 66–67% and subsequent addition of benzylmagnesium bromide to the double bond in yields of 95–96% in accordance with the scheme[94]

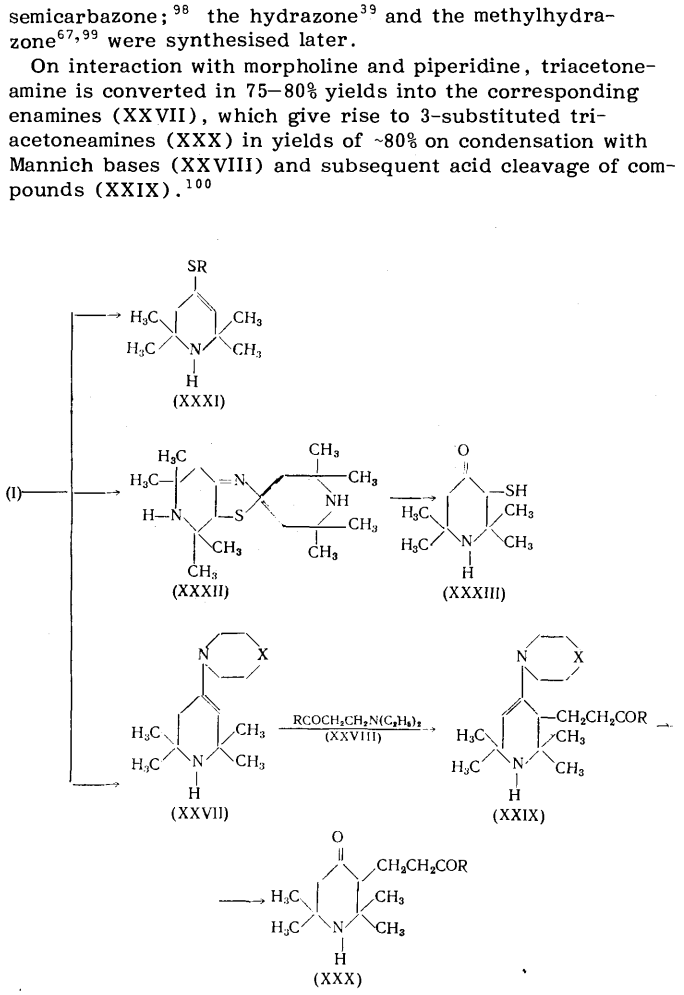
(XX) (XXI)

Unfortunately analogous reactions using alkylmagnesium halides failed to yield satisfactory results.[94]

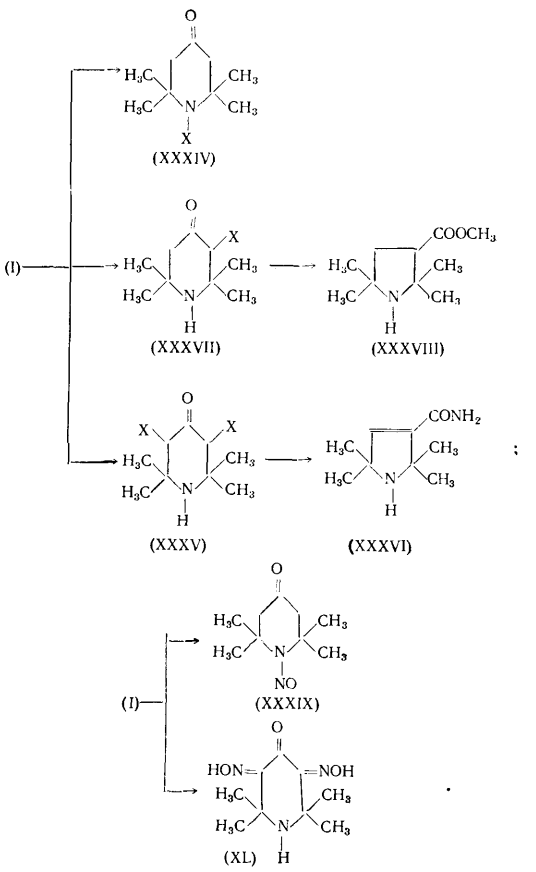
The reaction of heptane-2,6-dione (XXII) with hydrazine sulphate and sodium cyanide, which results in the formation of 1-amino-2,6-dicyano-2,6-dimethylpiperidine (XXIII), has been described. The latter reacts with benzaldehyde to form the benzylidene derivative (XXIV) and, on oxidation with potassium permanganate, it is converted into the tetrazine (XXV). The cleavage of the tetrazene with hydrobromic acid and treatment of the *N*-amino-compound (XXIII) with sodium nitrite in an acid medium led to 2,6-dicyano-2,6-dimethylpiperidine (XXVI):[95]

(XXII) (XXIV) (XXIII) (XXV) (XXVI)

IV. CHEMICAL REACTIONS OF α,α,α',α'-TETRASUBSTITUTED PIPERIDINES



The comprehensive study of the reactivity of triacetoneamine has been important for the development of the chemistry of 2,2,6,6-tetrasubstituted piperidines.

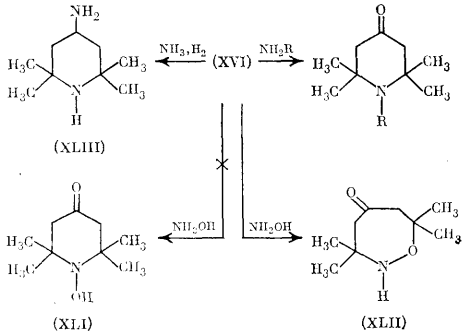


1. Reactions without the Growth of the Carbon Skeleton

Typical derivatives involving the carbonyl group of compound (I) were obtained already in the early stages of the investigation: the oxime,[96] the phenylhydrazone,[97] the

semicarbazone;[98] the hydrazone[39] and the methylhydrazone[67,99] were synthesised later.

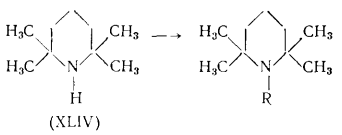
On interaction with morpholine and piperidine, triacetoneamine is converted in 75–80% yields into the corresponding enamines (XXVII), which give rise to 3-substituted triacetoneamines (XXX) in yields of ~80% on condensation with Mannich bases (XXVIII) and subsequent acid cleavage of compounds (XXIX).[100]



Compound (I) reacts with ethanethiol and thiophenol in an alcoholic hydrochloric acid solution and is converted into *S*-substituted 4-mercapto-2,2,6,6-tetramethyltetrahydropyridines (XXXI),[101] while the interaction with sulphur and ammonia gives rise to 5,5,7,7-tetramethyl-1,2,5,6,7,7a-hexahydrothiazolo[5,4-*c*]pyridine-2,4-spiro-4-(2′,2′,6′,6′-tetramethylpiperidine) (XXXII), which readily hydrolyses to 3-mercapto-2,2,6,6-tetramethyl-4-piperidinone (XXXIII).[80]

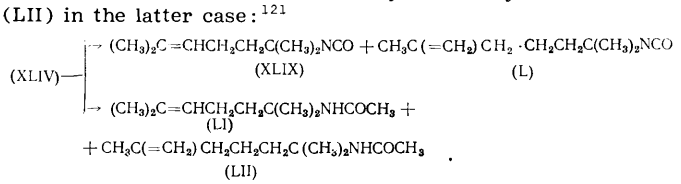
Compound (I) reacts with halogens in polar media to form the *N*-halogeno-derivative (XXXIV)[101–103] or, under more severe conditions, 3,5-dihalogeno-derivatives (XXXV), where X = Cl or Br.[91,102] On treatment with ammonia, the latter undergo ring contraction with formation of 2,2,5,5-tetramethyl-2,5-dihydropyrrole-3-carboxamide (XXXVI).[91] In non-polar media, the halogenation of compound (I) makes it possible to obtain the 3-monohalogeno-derivatives (XXXVII, X = Cl or Br), which react with sodium methoxide to give the methyl ester of 2,2,5,5-tetramethylpyrrolidine-3-carboxylic acid (XXXVIII) as a result of ring contraction.[104] In acetonitrile or aqueous methanol, compound (I) reacts with $FClO_3$ to form the *N*-fluoro-derivative (XXXIV, X = F) and the reaction is of first order with respect to each reactant.[105] Depending on the reaction conditions, the nitrosation of compound (I) can proceed with formation of the *N*-nitroso-derivative (XXXIX)[106] or the derivatives (XL) substituted in the 3,5-positions.

The *N*-halogenation[107] and *N*-nitrosation processes[56,57,108] have been used also in the case of other 2,2,6,6-tetrasubstituted piperidines. 1-Chloro-2,2,6,6-tetramethylpiperidine has found an application as a chlorinating agent.[107]



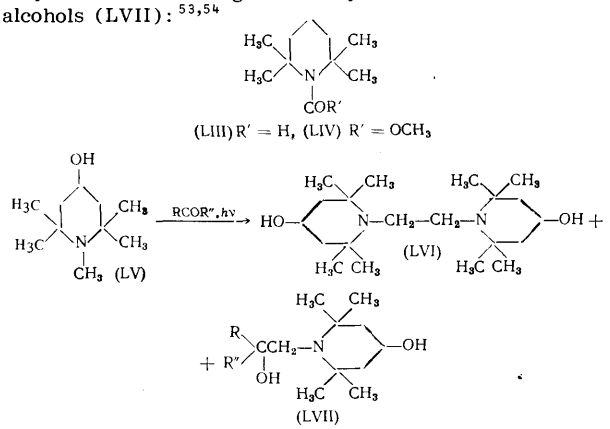
1,2,2,6,6-Pentamethyl-4-piperidinone has been obtained by methylating triacetoneamine with methyl iodide. However, a more convenient and more general method for the introduction of the *N*-methyl group into 2,2,6,6-tetramethylpiperidine derivatives proved to involve their treatment with a mixture of formaldehyde and formic acid.[39,40,109,110] In order to obtain compounds with more bulky substituents at the nitrogen atom, derivatives of 2,2,6,6-tetramethylpiperidine are treated with the corresponding halogen-containing compounds or epoxyethane derivatives.[27,41,64,111–116]

Another version of the synthesis of *N*-alkyl- and *N*-arylalkyl-2,2,6,6-tetramethylpiperidines involves the interaction of the corresponding primary amines with phorone.[73] It is noteworthy that the analogous reaction of phorone with hydroxylamine does not lead to 1-hydroxytriacetoneamine (XLI), as described previously,[90] but to hexahydro-3,3,7,7-tetramethyl-1,2-oxazepin-5-one (XLII).[117] 4-Amino-2,2,6,6-tetramethylpiperidine (XLIII) has been obtained by the reductive ammination of phorone with ammonia and hydrogen at 110–150 °C and 100–180 atm in the presence of various catalysts:[118]



(XLI) (XLII)

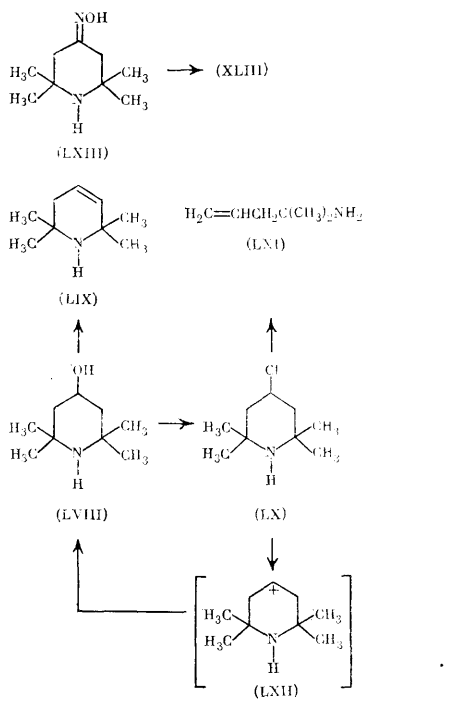
On reaction with butyl-lithium and subsequent treatment with alkyl halides, 2,2,6,6-tetramethyl-1-propynylpiperidine (XLV), synthesised by alkylating 2,2,6,6-tetramethylpiperidine (XLIV), was converted into the αβ-ynamino-derivative (XLVI) which gives rise to the corresponding amides (XLVII) on hydration:[119]



(XLV) R = C≡CCH$_3$,
(XLVI) R = C≡CCH$_2$R',
(XLVII) R = COCH$_2$R',
(XLVIII) R = COC$_6$H$_5$.

The *N*-benzoyl derivative (XLVIII) has been obtained by the reaction of compound (XLIV) with benzoyl chloride in benzene in 55% yield.[120,121] However, the reaction with phosgene and acetyl chloride resulted in the opening of the piperidine ring with formation of 1,1,5-trimethylhex-4-enyl isocyanate (XLIX) and 1,1,5-trimethylhex-5-enyl isocyanate (L) in the former case and *N*-(1,1,5-trimethylhex-4-enyl)-acetamine (LI) and *N*-(1,1,5-trimethylhex-5-enyl)acetamide (LII) in the latter case:[121]

1-Methoxycarbonyl-2,2,6,6-tetramethylpiperidine (LIV) has been obtained by the electrochemical oxidation of 1-formyl-2,2,6,6-tetramethylpiperidine (LIII) in methanol at a platinum anode,[122] while in the photochemical oxidation of 1,2,2,6,6,-pentamethyl-4-piperidinol (LV) by ketones the process involves the *N*-methyl group with formation of the dimeric product (LVI) and 2,2,6,6-tetramethyl-4-piperidinols alkylated at the nitrogen atom by the residues of the tertiary alcohols (LVII):[53,54]

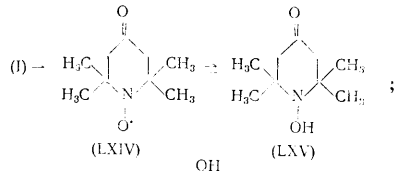


(LIII) R' = H, (LIV) R' = OCH$_3$

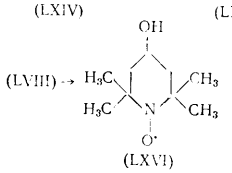
(LV) (LVI) (LVII)

The oxo-group is usually eliminated from the 4-position of triacetoneamine and other 2,2,6,6-tetramethyl-4-piperidinones by the Wolff–Kishner reduction with hydrazine hydrate and potassium hydroxide in triethylene glycol,[76,120] ethylene glycol,[40] or glycerol[28] in 50–70% yields. In the reactions with sodium tetrahydroborate,[93] lithium tetrahdyroaluminate,[109] sodium in alcohol, sodium amalgam,[93] and hydrogen in the presence of a nickel catalyst[109] or in the electrochemical reduction,[123] the products are, as was to be expected, the corresponding 2,2,6,6-tetramethyl-4-piperidinols. Under these conditions, the alcohol (LVIII), with the equatorial disposition of the hydroxy-group and the chair configuration of the heterocycle, was obtained from triacetoneamine.[124] On treatment with thionyl chloride, the above alcohol is readily converted into the dehydropiperidine derivative (LIX), but, on reaction with hydrochloric acid, compound (LVIII) gives rise to 4-chloro-2,2,6,6-tetramethylpiperidine (LX).[125] On alkaline hydrolysis, the chloride (LX) undergoes synchronous fragmentation with formation of 2-amino-2-methylpent-4-ene (LXI) and is simultaneously converted at a lower rate into 2,2,6,6-tetramethyl-4-piperidinol via the carbonium ion (LXII)[126] (see the Scheme below).

Scheme

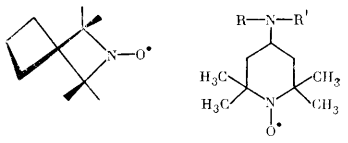


(LXIII) (LIX) (LXI) (LVIII) (LX) (LXII)



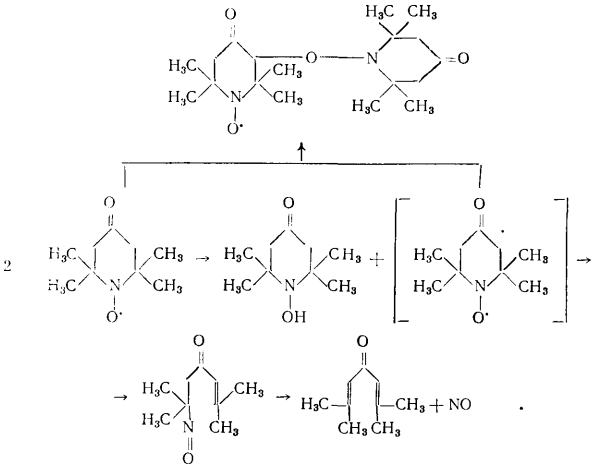
In order to investigate the spasmolytic and antiviral activities, the esters of the alcohol (LVIII) were obtained[127,128] and were used to synthesise the guanidine derivatives.[39] The reduction of the oxime of triacetoneamine (LXIII), both catalytic and with lithium tetrahydroaluminate, yielded 4-amino-2,2,6,6-tetramethylpiperidine.[39]

Cautious oxidation of triacetoneamine with hydrogen peroxide in the presence of catalysts (tungsten, molybdenum, or vanadium salts) leads to the stable iminoxy-radical (LXIV),[48] which forms an oxime, a semicarbazone, and a 2,4-dinitrophenylhydrazone,[48] undergoes the Wolff–Kishner reduction[129] and the Beckmann rearrangement,[130,131] enters into a modified Wittig reaction,[132] and gives rise to a spirohydantoin derivative[133] without involving the centre where the unpaired electron is localised. At the same time the catalytic



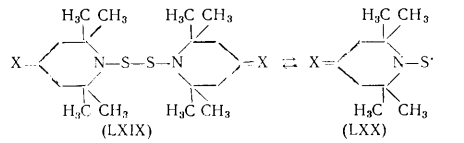
reduction of compound (LXIV) in the presence of palladium leads to a diamagnetic substance—1-hydroxytriacetoneamine (LXV).[48] Fermi's salt (potassium nitrosodisulphonate) is used to convert the *N*-hydroxy-compounds (LXV) into the iminoxy-radical (LXIV):[134]

(LXIV) (LXV)

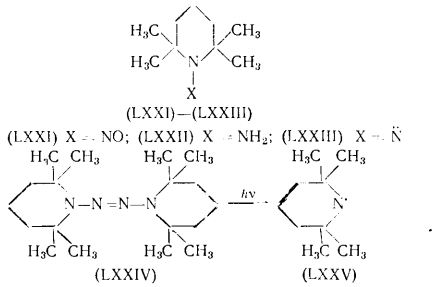


(LXVI)

(LXVII) (LXVIII)



The corresponding 4-hydroxy-2,2,6,6-tetramethylpiperidin-1-yloxy-radical (LXVI) has been obtained by oxidising compound (LVIII) with hydrogen peroxide.[135] The use of peracids for the same purpose involves simultaneously the 4-hydroxy-group, converting it into the oxo-group.[136] The 2,2,6,6-tetramethyl-4-oxo-piperidin-1-yloxy-radical (LXIV) has the symmetrical twist-conformation (LXVII) in the solid state,[137] while in the gas phase[138] and in solution[139] the nitrogen atom is at the apex of the pyramid. The relative instability of compound (LXIV) is associated with the activation of the hydrogen atoms in the 3- and 5-positions adjoining the carbonyl group, which leads to a slow disproportionation of the radical in accordance with the scheme[140]



The iminoxy-radical (LXIV) can be used for the effective binding of the benzoyl and benzyl radicals. Acylation of the iminoxy-radical (LXVI) at the hydroxy-groups proceeds without involving the radical centre.[8,135,141–145] Substituted 4-amino-2,2,6,6-tetramethylpiperidin-1-yloxy-radicals (LXVIII) have been obtained by the reductive amination of compound (LXIV) by primary and secondary amines in the presence of sodium cyanohydroborate at pH 5–9.[146–150]

The study of the mechanism of the oxidation of compound (XVIII) by cumenyl hydroperoxide showed that the rate-determining stage is the formation of the N-radical-cation, which reacts with the excess hydroperoxide and is converted into an intermediate quaternary *N*-hydroxyammonium salt, which dissociates to the iminoxy-radical.[151] Many other methods of synthesis of various stable nitroxy-radicals by the oxidation of 2,2,6,6-tetrasubstituted piperidines and via a wide variety of reactions of 4-hydroxy-2,2,6,6-tetramethylpiperidin-1-yloxy-, 2,2,6,6-tetramethyl-4-oxopiperidin-1-yloxy, and 4-aminopiperidin-1-yloxy-radicals without involving the *N*-oxy-group have been published in the literature. These methods have been described in detail in reviews.[2–7] Problems concerning the relation between the electronic structure of the iminoxy-radicals and their acute toxicity have been considered.[152]

Further investigations showed that compounds (I) and (XLIV) react with sulphur dichloride in dimethylformamide and are converted into the disulphides (LXIX), which dissociate on heating to 2,2,6,6-tetramethylpiperidine-1-thiyl radicals (LXX), which readily dimerise on cooling.[55] In less polar solvents (hexane, ether) the process leads towards the formation of polysulphides containing from three to five sulphur atoms.[55]

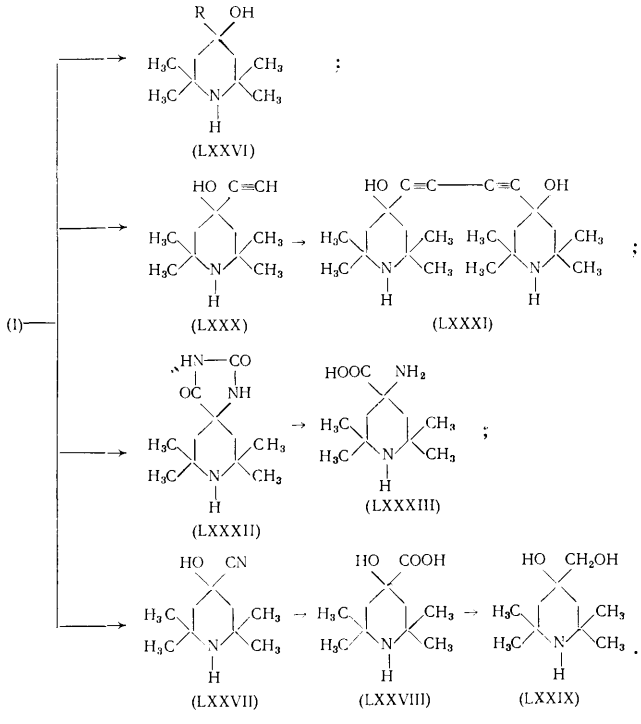
(LXIX) (LXX)

(LXXI)—(LXXIII)

(LXXI) X = NO; (LXXII) X = NH_2; (LXXIII) X = N

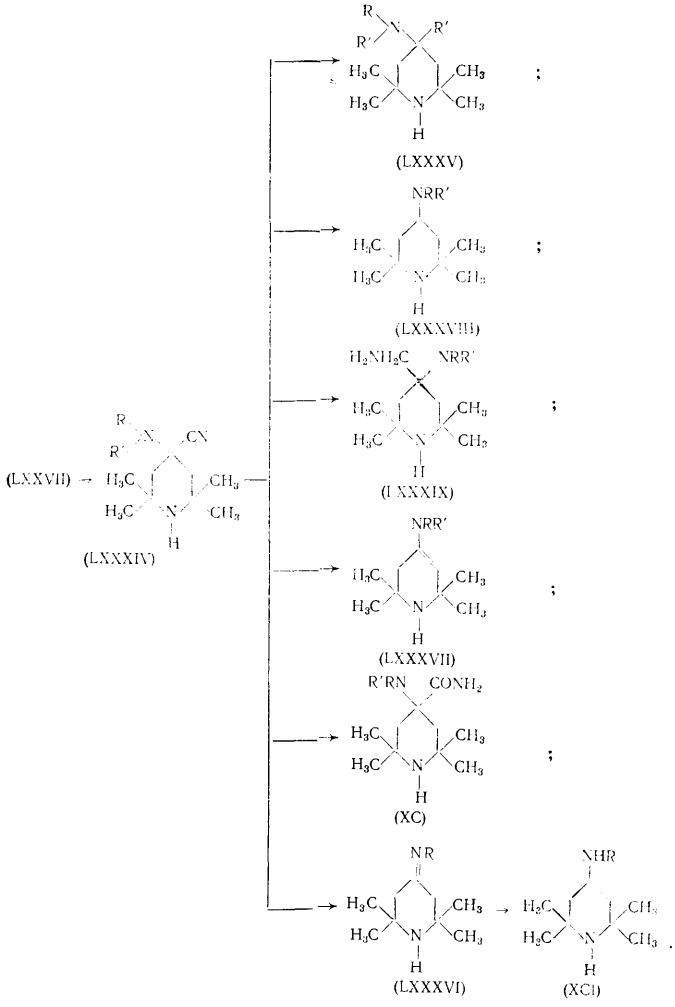
(LXXIV) (LXXV)

The reduction of 2,2,6,6-tetramethyl-1-nitrosopiperidine (LXXI) with lithium tetrahydroaluminate yielded 1-amino-2,2,6,6-tetramethylpiperidine (LXXII),[153] whose treatment with t-butyl hypochlorite in ether at −78 °C in the presence of triethylamine led to the formation of *N*-(2,2,6,6-tetramethylpiperidine)nitrene (LXXIII).[56] Other nitrenes of this type have been described in the literature.[154–156] The ultraviolet spectrum of compound (LXXIII), recorded at −78 °C, is characterised by an appreciable absorption due to the $n\pi^*$ transition, while the intense absorption at 1595 cm^{-1} in the infrared spectrum indicates a considerable amount of double bond character in the N–N group in the ground state. At 0 °C the nitrene (LXXIII) readily decomposes and the rate of decomposition in solutions is inversely proportional to the solvent polarity. There is a simultaneous bimolecular reaction leading to the formation of 1,1-tetrazene (LXXIV).[56] The photolysis of compound (LXXIV) generates the 2,2,6,6-tetramethylpiperidinyl radical (LXXV), which is much less stable than iminoxy-radicals. It readily splits off hydrogen from solvents and is readily oxidised by oxygen to the nitroxide {the labelled [^{17}O] nitroxide has been synthesised using $^{17}O_2$}.[57] The 2,2,6,6-tetramethyl-4-oxopiperidinyl radical, whose stability is low, has been obtained by the photolysis of *N*-bromotriacetoneamine (XXXIV, X = Br).[157]



2. Reactions Involving the Formation of New C–C Bonds at the Piperidine Ring

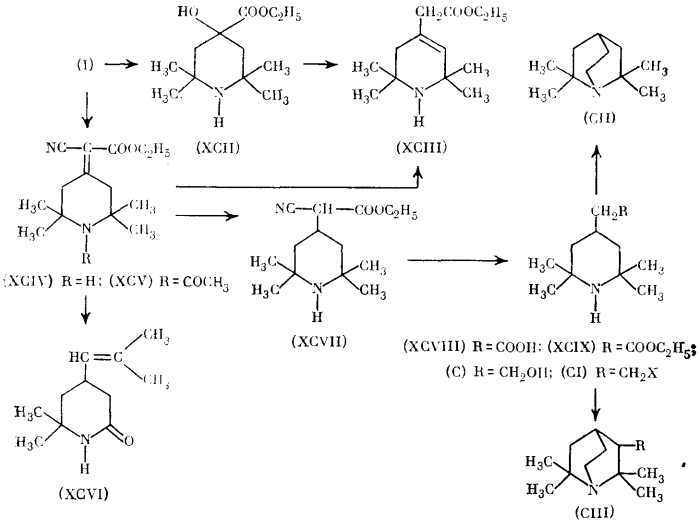
Together with the reactions described above, which take place mainly without the growth of the carbon skeleton at the piperidine ring, processes involving the formation of new C–C bonds due to various condensations involving the heterocyclic skeleton of the molecule occupy an important place in the chemistry of 2,2,6,6-tetrasubstituted piperidines.



Using the appropriate Grignard reagents, 4-ethyl-(4-phenyl)-4-hydroxy-2,2,6,6-tetramethylpiperidines (LXXVI, R = C_2H_5 or C_6H_5) have been synthesised from triacetoneamine,[158] while the reaction with acetone cyanohydrin yielded 4-cyano-4-hydroxy-2,2,6,6-tetramethylpiperidine (LXXVII),[109] which was hydrolysed to 4-hydroxy-2,2,6,6-tetramethylpiperidine-4-carboxylic acid (LXXVIII)[109] and reduced to the diol (LXXIX).

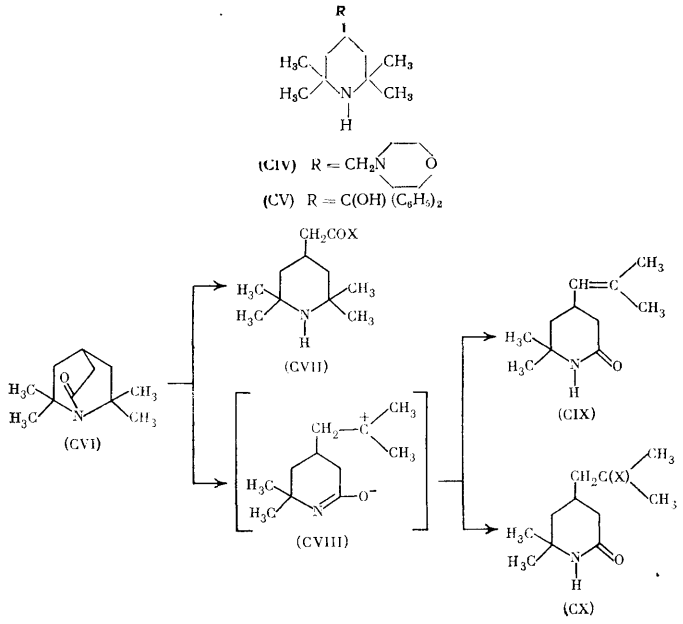
Compound (I) has been converted by acetylene synthesis into 4-ethynyl-4-hydroxy-2,2,6,6-tetramethylpiperidine (LXXX), whose oxidation by oxygen in the presence of copper ammine gives rise to 1,4-bis(4-hydroxy-2,2,6,6-tetramethylpiperidin-4-yl)butadiene (LXXXI).[39] The triple bonds were reduced catalytically in the formation of compound (LXXXI).[39]

Compound (I) has been converted by reaction with sodium cyanide and ammonium carbonate into the piperidinohydantoin derivative (LXXXII),[115] which was then hydrolysed to the aminoacid (LXXXIII):



The reaction of the cyanohydrin (LXXVII) with ammonia or various aliphatic and aliphatic-aromatic amines in methanol readily gives rise to 4-amino-4-cyano-2,2,6,6-tetramethylpiperidines (LXXXIV) even at 0–20 °C.[110,111] Aromatic amines do not enter into this reaction.[110] The interaction of the aminonitriles (LXXXIV) with Grignard reagents leads to 4-alkyl-4-amino-2,2,6,6-tetramethylpiperidines (LXXXV),[111] while heating of compounds (LXXXIV) above 50 °C causes the splitting of hydrogen cyanide and the formation of the imino-derivatives (LXXXVI) or (in the case of tertiary amines) the enamines (LXXXVII).[110] On treatment with lithium tetrahydroaluminate, the aminonitriles (LXXXIV) readily lose their cyano-group and are converted into the *N'*-substituted 4-amino-2,2,6,6-tetramethylpiperidines (LXXXVIII) and only in the case where R = H and R' = H or $CH_2C_6H_5$ in compound (LXXXIV) are the triamines (LXXXIX) produced.[110] The hydrolysis of the nitrile group to the amide group in the aminonitriles (LXXXIV) is achieved with 90% sulphuric acid at 100 °C. Triacetoneamine is then formed together with the aminoamides (XC).[112] The imino-derivatives (LXXXVI) have been reduced catalytically to the corresponding amines (XCI).[159]

The condensation of triacetoneamine with ethyl bromoacetate under the conditions of the Reformatskii reaction results in the formation of 4-ethoxycarbonylmethyl-4-hydroxy-2,2,6,6-tetramethylpiperidine (XCII),[160] which can be dehydrated to the unsaturated ester (XCIII) by reaction with thionyl chloride or phosphoryl chloride. The corresponding methyl ester and the free acid have also been obtained from the product of the reaction of compound (I) with cyanoacetic ester.[160] The Knoevenagel condensation of compound (I) with cyanoacetic ester takes place readily in the presence of ammonium acetate in boiling benzene in the course of 1 h. More prolonged boiling in benzene or the use of higher-boiling solvents (toluene, xylene) lead to

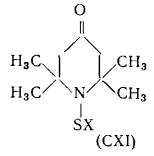


the *N*-acetylation of compound (XCIV) and the rearrangement of the resulting compound (XCV) to the unsaturated piperidinone (XCVI).[160] The hydrolysis of the nitriloester (XCIV) and subsequent partial decarboxylation are accompanied by the migration of the double bond to an endocyclic position and the ester (XCIII) is obtained after subsequent esterification.[161] Catalytic reduction of the exocyclic double bond in compound (XCIV) with the aid of palladium proceeds much more readily than the reduction of the endocyclic double bond in compound (XCIII). In order to synthesise the saturated acid (XCVIII), compound (XCIV) is therefore hydrogenated in a neutral medium in the presence of a palladium catalyst (in the presence of nickel or in hydrogenation using palladium and platinum in an acid medium, the nitrile group is involved) and the resulting compound (XCVII) is hydrolysed and partly decarboxylated. The high yield in the intermediate stages make it possible to carry out the process without isolating compounds (XCIV), (XCVII), and (XCVIII) and to obtain compound (XCIV) after esterification in an overall yield of 50% relative to triacetoneamine.[161]

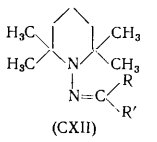
The reduction of the ester (XCIX) with lithium tetrahydroaluminate, the subsequent substitution of the hydroxy-group by halogen, and cyclisation lead to 2,2,6,6-tetramethylquinuclidine (CII):[42,161]

Treatment of compound (XCVII) with alkyl halides in the presence of alkali metal alkoxides makes it possible to obtain derivatives *C*-alkylated in the side chain which have been converted into 3-alkyl-2,2,6,6-tetramethylquinuclidines (CIII) in accordance with schemes analogous to that described above.[44]

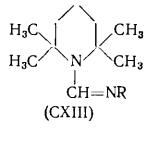
The conversion of the acid (XCVIII) into morpholide and the reduction of the latter with lithium tetrahydroaluminate led to the formation of 2,2,6,6-tetramethyl-4-(*N*-morpholinomethyl)piperidine (CIV)[46] and the reaction of the ester (XCIX) with phenyl-lithium afforded (2,2,6,6-tetramethylpiperidin-4-yl)diphenylmethanol (CV).[46]



The conversion of the acid (XCVIII) into the chloride and treatment of the latter with triethylamine made it possible to synthesise 6,6,7,7-tetramethyl-2-quinuclidinone (CVI)[162,163]—a compound which is formally a bicyclic amide. However, its rigidly fixed structure with its unbound electron pair of the bridgehead nitrogen atom directed in space along the symmetry axis of the molecule rules out the possibility of the overlap of the above pair of *p* electrons with the π electrons of the C=O bond. As a result, compound (CVI) lacks the mesomeric effects characteristic of amides, the nitrogen atom exerts a purely inductive influence on the neighbouring carbonyl group, and compound (CVI) lacks amide properties but is a highly reactive acylating agent.[164,165] Its bridgehead nitrogen atom retains its highly nucleophilic properties in quaternisation and protonation reactions (pK_a = 6.37 ± 0.05 in water) and its carbonyl group has ketone and not amide properties [in the infrared spectra ν(CO) = 1755 cm^{-1} for the base, 1811 cm^{-1} for the hydrochloride, and 1820 cm^{-1} for the methiodide; it is reduced by lithium tetrahydroaluminate to CHOH and not to the CH_2 group, etc.]. Compound (CVI) reacts with various protic nucleophiles (water, alcohols, amines, etc.), the reaction involving the dissociation of the CO–N bond and the formation of 2,2,6,6-tetramethylpiperidine-4-acetic acid or its derivatives (esters, amides, etc.) (CVII). The reaction with nucleophiles in aprotic media (phenyllithium in ether, phosphorus pentachloride in benzene, excess of acetone cyanohydrin, lithium tetrahydroaluminate) entails the dissociation of the N–$C(CH_3)_2$ bond and the carbonium ion (CVIII) formed initially is stabilised either via deprotonation with formation of 4-(2-methyl-1-propenyl)-2-piperidinone (CIX) or via the addition of nucleophilic residues and the formation of substances of type (CX).



V. CHARACTERISTIC FEATURES OF THE CONFORMATIONS OF SHIELDED PIPERIDINE DERIVATIVES



Data concerning the conformation of the 2,2,6,6-tetramethylpiperidin-1-yloxy-radical, a stable iminoxy-radical, have already been presented above. In recent years increasing attention has been devoted to the investigation of the characteristic features of the conformations of diamagnetic

sterically hindered 2,2,6,6-tetra-substituted piperidines. The preferential chair conformation of triacetoneamine and 1,2,2,6,6-pentamethyl-4-piperidinone has been established by ^{1}H NMR and the dipole moment and electro-optical Kerr effect methods, in the latter case with an equatorial orientation of the N–CH_3 group.[166–168] For the corresponding 2,2,6,6-tetramethyl-4-phenyl-4-piperidinol and 1,2,2,6,6,-pentamethyl-4-phenyl-4-piperidinol, there is an equilibrium between the chair and boat conformations with a 10% content of the latter, stabilised by an intramolecular hydrogen bond.[167,169] In the series of 1-*S*-substituted triacetoneamines (CXI, X = CCl_3, C_6H_5, t-C_4H_9, or CH_3), the activation energy for rotation about the N–S bond is significantly lower than in the corresponding 2,2,6,6-unsubstituted 4-piperidinones.[170]

The application of ^{1}H and ^{13}C NMR and X-ray diffraction showed that the conformational changes in compounds of the type of derivatives of 2,2,6,6-tetramethyl-1-piperidinyliminomethylene (CXII) [49,171–174] and 2,2,6,6-tetramethyl-1-piperidinylmethyleneimine (CXIII) [173] are hindered and that their preferred conformation is one where the planes of the N=C bond and of the piperidine ring are at right angles. On passing to 2,6-dimethylpiperidine derivatives, the planes of the N=C bond and the piperidine ring are coplanar for axial methyl groups and at right angles for equatorial methyl groups. *N*-Nitroso-2,2,6,6-tetramethylpiperidine has a coplanar arrangement of the planes of the piperidine ring and the N=O group.[49–51]

(CXI)

(CXII)

(CXIII)

Photoelectron spectroscopic studies have shown that the introduction of four methyl groups in the 2,2,6,6-positions in the piperidine ring lowers the ionisation potential of the free electron pair of the nitrogen by 0.66 eV,[52] and the contribution of each axial methyl group is ~0.26 eV and that of the equatorial methyl group is ~0.1 eV.

Thus the introduction of 2,2,6,6-substituents into the piperidine ring lowers the conformational mobility of the latter, facilitates its opening accompanied by various rearrangements, increases the stability of nitroxy-, nitrothiyl, and other free radicals, increases significantly the ganglion-blocking activity of the compounds, and almost completely abolishes their analgesic activity.

The above effects are associated mainly with the steric influence of the four $\alpha,\alpha,\alpha',\alpha'$-substituents and create a basis for the practical application of substances of this class.

Phosphorus-containing Polysulphides (Methods of Synthesis and Chemical Properties)

B.A.Khaskin

The methods of synthesis and chemical properties of compounds containing the $>\!P(=X)-(S)_n-$ (X = O or S, n = 2-4) fragment are examined. The unusual chemical behaviour of phosphorus-containing polysulphides in the reactions with nucleophiles and electrophiles is discussed.
The bibliography includes 170 references.

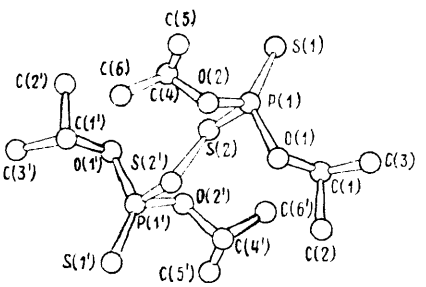
I. INTRODUCTION

Despite the fact that phosphorus-containing polysulphides have been know for a long time, their chemical properties have begun to be studied in detail only in recent years. Nevertheless the presence of phosphorus-containing fragments introduces a definite specificity into the chemical behaviour of these compounds, which differ appreciably in their reactivity from aliphatic and aromatic polysulphides.[1] It must also be emphasised that phosphorus-containing polysulphides are the starting materials for the synthesis of a wide variety of organophosphorus compounds, including those which are difficult to obtain by other means.

This review is devoted to phosphorus-containing polysulphides—the "symmetrical" polysulphides (I), in the molecules of which the polysulphide bridge links two phosphorus-containing groups, and the "asymmetric" polysulphides (II), where there is only one such group. This review is a first attempt at a survey of the methods of synthesis and chemical properties of these compounds.



$$\underset{(I)}{R_2\overset{X}{\overset{\|}{P}}-S_n-\overset{X}{\overset{\|}{P}}R_2} \qquad \underset{(II)}{R_2\overset{X}{\overset{\|}{P}}-S_n-R'}$$

Here X = O or S, n = 2–4, and R and R′ are various organic and inorganic substituents linked to the phosphorus and sulphur atoms either directly or via the atoms of other elements.

Considerable advances have been made recently in the study of the reactivity of phosphorus-containing polysulphides and also in their employment for the synthesis of new structures among organophosphorus compounds.

II. THE STRUCTURE OF PHOSPHORUS-CONTAINING POLYSULPHIDES

The structure of symmetrical phosphorus-containing polysulphides is examined below in relation to bis(di-isopropoxythiophosphoryl) disulphide investigated by X-ray diffraction (see Figure).[2] The bond lengths and valence angles are indicated in Table 1. The data obtained do not preclude the possibility of the presence of a centre of symmetry located between the two sulphur atoms S(2) and S(2′). The S(2)–S(2′) distance (2.09 Å) is greater than in tetraethylthiuramide sulphide (1.999 Å).[3] The atoms surrounding the phosphorus atom have a distorted tetrahedral configuration; a plane can be drawn through the C(4)–O(2)–P(1)–O(1)–C(1) atoms to within 0.04 Å.

The structure of bis(di-isopropoxythiophosphoryl) disulphide according to Tkachev et al.[2]

Table 1. The bond lengths and valence angles in bis(di-isopropoxythiophosphoryl) disulphide.[2]

Bond length, Å		Valence angles, deg	
S(1)—P(1)	1.89	S(2′)—S(2)—P(1)	99.1
S(2)—P(1)	2.07	S(1)—P(1)—S(2)	102.8
S(2)—S(2′)	2.09	S(1)—P(1)—O(1)	122.0
P(1)—O(1)	1.57	S(1)—P(1)—O(2)	117.0
P(1)—O(2)	1.53	S(2)—P(1)—O(1)	108.0
O(1)—C(1)	1.44	S(2)—P(1)—O(2)	111.0
O(2)—C(4)	1.47	O(1)—P(1)—O(2)	95.0
C(1)—C(2)	1.52	P(1)—O(1)—C(1)	121.0
C(1)—C(3)	1.49	P(1)—O(2)—C(4)	119.0

		O(2)—C(4)—C(6)	104.0
		C(3)—C(1)—C(2)	112.0
		C(5)—C(4)—C(6)	112.0

In the case of phosphorus-containing tri- and tetrasulphides, the structure of the polysulphide chain is of interest. Combined infrared and Raman spectroscopic data show

that the R–S–$(S)_n$–S–R polysulphide chain in phosphorus-containing polysulphides is unbranched.[4] Table 2 presents the absorption maxima in the infrared and Raman spectra of bis(diethoxythiophosphoryl) polysulphides in the range 400–700 cm^{-1} when the stretching vibration bands of the S–S, P–S, and P=S bonds are located. Evidently the bands which are intense in the Raman spectra have a low intensity in the infrared spectra and conversely. The unbranched nature of the structure of phosphorus-containing polysulphides is indicated by the fact that this feature holds best for centro-symmetric structures.[5] It must be emphasised that the bands cannot be assigned to different conformers, since the relative intensities remain constant as the temperature is altered.

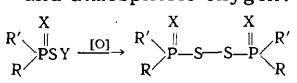

Table 2. The band maxima (ν, cm^{-1}) in the infrared and Raman spectra of bis(diethoxythiophosphoryl) polysulphides (bands of low intensity are indicated in brackets).[4]

III. METHODS OF SYNTHESIS

1. Symmetrical Phosphorus-containing Disulphides

The commonest method of synthesis of phosphorus-containing disulphides involves the oxidation of phosphorothioic and phosphorodithioic acids or their salts. The oxidants employed are the halogens (chlorine, bromine, and iodine),[6–19,21] hydrogen peroxide,[6,20,22] sodium nitrite (in the presence of sulphuric acid),[22–24] nitrous acid,[25] dimethylsulphoxide,[26] sulphuryl or thionyl chloride,[27–30] potassium hexacyanoferrate(III),[31] and atmospheric oxygen:[32]

where X = O or S, Y = H or a metal, and R and R′ are substituted or unsubstituted alkyl, aryl, alkoxy-, aryloxy-, or amino-group or a fluorine atom.

Best results are achieved when one employs acid salts, since the reactions of certain dialkylphosphorodithioic acids with iodine in an acid medium are reversible.[33] In an alkaline medium the oxidation by iodine proceeds as far as the phosphates and sulphates and it is therefore not possible to obtain disulphides under these conditions.[34,35]

It must be emphasised that, together with the disulphides, trisulphides are formed in yields up to 12% in the oxidation of phosphorodithioic acids by certain oxidants (Br_2, KI + I_2, H_2O_2) in an acid medium.[9,21] Concentrated sulphuric acid converts phosphorodithioic acids into a mixture containing up to 49% of the disulphide, 27% of the trisulphide, and 11% of phosphorothioic acid.[22] The ease of the oxidation of *O,O*-dialkyl phosphorodithioates depends on the nature of the alkyl residue (Table 3).

Phosphorus-containing disulphides with a C–P bond can be obtained from secondary phosphines via stages involving the formation of phosphinothious and phosphinodithioic acids with subsequent oxidation:[38]

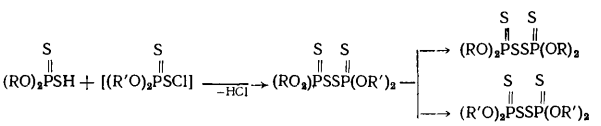

Table 3. The oxidation-reduction potentials *E* for the reaction $(RO)_2P(S)S^- - e \rightarrow (RO)_2P(S)SS(S)P(OR)_2$.[36,37]

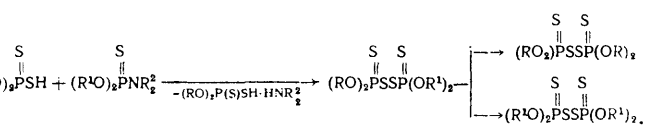
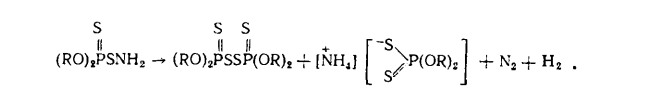


R	*E*, V	R	*E*, V
CH_3	0.315	C_6H_{13}	0.015
C_2H_5	0.255	iso-C_3H_7	0.196
C_3H_7	0.187	iso-C_4H_9	0.158
C_4H_9	0.122	iso-C_5H_{11}	0.086
C_5H_{11}	0.050		

Disulphides are formed from phosphorodithioic acids when the latter interact with dialkoxythiophosphorylsulphenyl chlorides:[39–42]

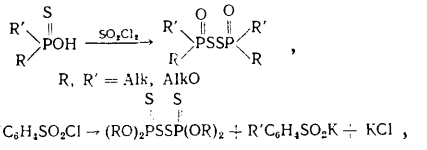
Symmetrical phosphorus-containing disulphides (R = R′) have been obtained successfully by this method. In the case of various alkyl groups (R and R′), the isolation of the disulphide in a pure form present considerable difficulties owing to the ease of their disproportionation to the corresponding symmetrical disulphides.[40]



The reactions of phosphorodithioic acids with dialkoxythiophosphorylsulphenamides proceed analogously:[40]

The interaction of *N*-substituted thiophosphorylsulphenamides with phosphorus acid halides in an alkaline medium results in the formation of phosphorus-containing disulphides:[43]

The decomposition of thiophosphorylsulphenamides, which apparently proceeds via a free-radical mechanism, also leads to the formation of disulphides:[44]

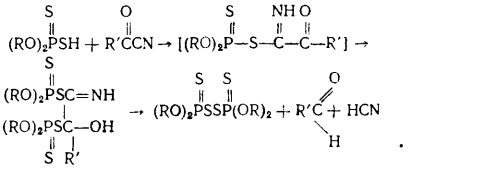


According to Mel'nikov and co-workers,[45,46] the formation of phosphorus-containing disulphides in the reactions of phosphorodithioic acids with diazonium salts in an acid medium also involves a free-radical mechanism:

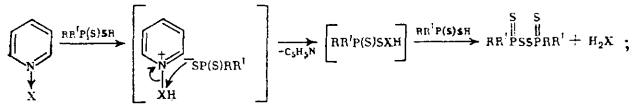
Several specific methods whereby one can obtain bis(dialkoxyphosphoryl) disulphides have been discussed in the literature. These include the reactions of dialkyl phosphites with sulphur monochloride,[47] i.e.

the condensation of acid phosphinothioates, phosphonothioates, phosphorothioates, and phosphorodithioates in the presence of sulphuryl chloride[29,30] or sulphonyl chlorides,[91] i.e.

the reactions of *O,O*-dialkylphosphorodithioic acids with *O,O*-dialkyl *S*-methyl phosphorodithioates,[48] i.e.



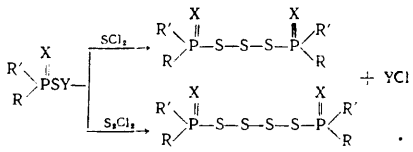
and the interaction of pyrophosphorothioates with dialkoxyphosphorylsulphen chlorides,[49]



Bis(dialkoxyphosphoryl) disulphides with higher alkyl substituents (propyl and butyl) can be obtained from bis(dimethoxyphosphoryl) disulphide by its interaction with aqueous solutions of the salts of the corresponding phosphorus acids:[20]

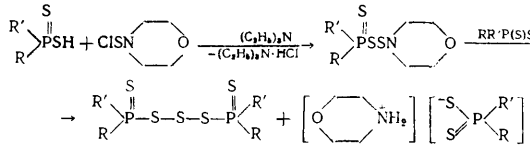
Phosphorus-containing disulphides are obtained as side products in certain reactions. For example, the interaction of phosphorodithioic acids with nitriles of pyruvic and benzoylformic acids results in the formation of a bisphosphorylated iminocarbinol, one of the decomposition pathways of which leads to a phosphorus-containing disulphide:[50]

Disulphides are also formed in the reaction of phosphorodithioates with sulphimines, *N*-iminopyridinium betaines, and pyridine *N*-oxide:[51–53]



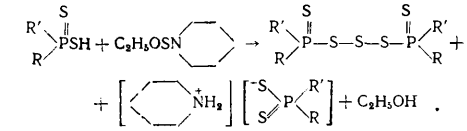
R, R' = C$_6$H$_5$, AlkO; X = O, NC$_6$H$_4$NO$_2$-4, NCOC$_6$H$_5$.

2. Symmetrical Phosphorus-containing Tri- and Tetrasulphides



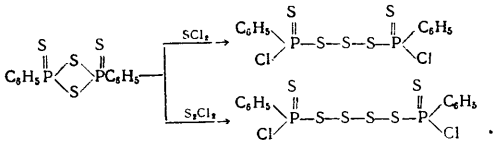
A phosphorus-containing trisulphide was isolated for the first time in the recrystallisation of diethyl phosphinodithioate from carbon disulphide and was described as bis(diethylphosphinyl) trisulphide.[54] A mixture of symmetrical tri- and tetra-sulphides is formed in the interaction of alcohols with phosphorus pentasulphides. Depending on the conditions (temperature, duration of heating), the content of trisulphides in the mixture can then range from 37 to 63% and that of the tetrasulphides from 19 to 28%.[37,55]

The commonest method of synthesis of phosphorus-containing tri- and tetra-sulphides involves the interaction of phosphorodithioic acids or their salts with sulphur di- or mono-chloride:[6,7,56–60]



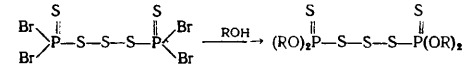
where Y = H or metal, X = O or S, and R,R' is an alkyl-, alkoxy-, or substituted alkoxy-group[6,7,56,58] or R = alkyl and R' = S.[59,60]

Symmetrical phosphorus-containing trisulphides have been obtained from *O,O*-dialkylphosphorodithioic or alkoxyalkylphosphonodithioic acids and morpholinylsulphenyl chloride.[41–61] The reaction apparently proceeds via the intermediate formation of thiophosphoryl morpholino disulphide:



The reaction with ethoxypiperidino sulphide proceeds analogously:[42]

When dialkoxythiophosphoryl *N*-mono(di)alkylamino disulphides were allowed to interact with phosphorothioic acids, bis(dialkoxythiophosphoryl) tetrasulphides were isolated.[62]



Halogen-substituted phosphorus-containing polysulphides are extremely interesting. Fluorine-substituted polysulphides are obtained by oxidising the corresponding fluorine-containing phosphorodithioic acids.[59,60] Bis(phenylchlorothiophosphonyl) polysulphides are obtained by treating phenylthionophosphine sulphide with sulphur di- or monochloride:[63]

Bis(dibromothiophosphoryl) trisulphides are formed readily when phosphorus polysulphides P_4S_n, where n = 3, 5, or 7, are treated with bromine:[64,65]

The interaction of bis(dibromothiophosphoryl) trisulphides with alcohols gives rise to bis(dialkoxythiophosphoryl) trisulphides:[65]

Individual reactions leading to the formation of phosphorus-containing tri- and tetra-sulphides as side products are known in the literature. Thus bis(diethylthiophosphinyl) trisulphide can be isolated in a low yield in the reaction of bis(dimethylamino)diethylphosphinylborane with sulphur:[66]

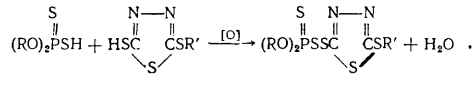
$$[(CH_3)_2N]_2BP(C_2H_5)_2 + S \rightarrow (C_2H_5)_2\overset{S}{\overset{\|}{P}}-S-S-\overset{S}{\overset{\|}{P}}(C_2H_5)_2 + B_2[N(CH_3)_2]_4 \quad .$$

Phosphorus-containing polysulphides are formed together with phosphinodithioic acids and disulphides in the interaction of secondary phosphines with sulphur.[54]

In the oxidation of potassium and nickel salts of *O,O*-diethylphosphorodithioic acids with selenous acid, bis(diethoxythiophosphoryl) tetrasulphide is one of the reaction products.[67]

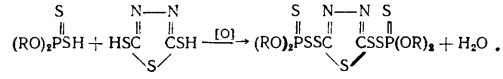
3. Asymmetric Phosphorus-Containing Polysulphides

Phosphorothioic and phosphorodithioic acids or their salts can be used to synthesise asymmetric phosphorus-containing disulphides. On interaction with various organosulphenyl chlorides, they give rise to a wide variety of disulphides:[42,68-81]



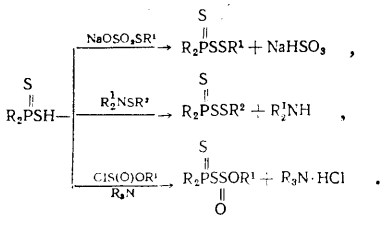
$$(RO)_2\overset{X}{\overset{\|}{P}}SY + ClSR' \rightarrow (RO)_2\overset{X}{\overset{\|}{P}}SSR' + YCl \ ,$$

where X = O or S, Y = H or metal, and R′ = alkyl, substituted alkyl, aryl, substituted aryl, carbamoyl, alkoxycarbonyl, and various ester and heterocyclic groups.



Phosphorodithioic acids react with aminosulphenyl chlorides to form dialkoxythiophosphoryl amino disulphides:[41,61,68-70]

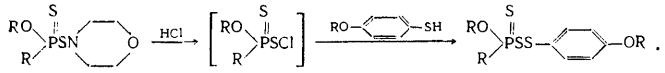
$$(RO)_2\overset{S}{\overset{\|}{P}}SY + ClSNR_2' \rightarrow (RO_2)\overset{S}{\overset{\|}{P}}SSNR_2' + YCl \ .$$



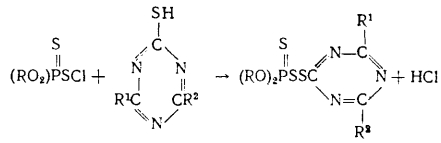
Asymmetric phosphorus-containing disulphides with thiadiazole residues are obtained by the joint oxidation of *O,O*-dialkylphosphorodithioic acids and 2-mercapto-1,3,4-thiadiazoles:[82]

In the presence of a twofold excess of phosphorodithioic acid, compounds with two symmetrical disulphide groups are formed analogously from dimercapto-derivatives:

Asymmetric phosphorus-containing disulphides and sulphonylthio-derivatives can also be obtained by the reaction of phosphorodithioic acids with sodium alkyl thiosulphates,[83] sulphenamides,[61,85] and alkylsulphurous acid chlorides:[84]



Many asymmetric phosphorus-containing disulphides are obtained by the reaction of dialkoxyphosphoryl- and dialkoxythiophosphoryl-sulphenyl chlorides with compounds containing the mercapto-group:[76,86-88,93]

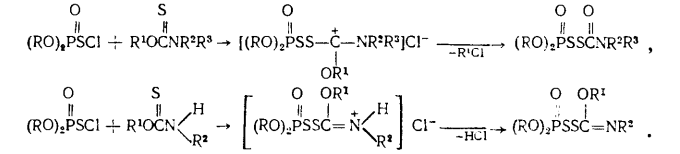


$$(RO)_2\overset{X}{\overset{\|}{P}}SCl + R'SH \rightarrow (RO)_2\overset{X}{\overset{\|}{P}}SSR' + HCl \ .$$

It is noteworthy that, in contrast to phosphorylsulphenyl chlorides, the majority of thiophosphorylsulphenyl chlorides are unstable. However, in many studies these substances were isolated in a pure form using various organophosphorus compounds as intermediates in the synthesis.[39,61,89]

The preparation of asymmetric disulphides from thiophosphorylsulphenamides in the presence of HCl should be assigned to reactions of the same type, since the corresponding thiophosphorylsulphenyl chloride is an intermediate under these conditions:[61]

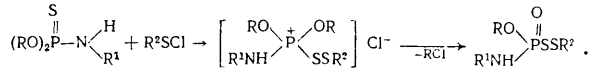
The interaction of dialkoxythiophosphorylsulphene chlorides with mercaptotriazines in the presence of an acceptor which absorbs the hydrogen chloride evolved leads to dialkoxythiophosphoryl triazinyl disulphides:[90]



Dialkoxythiophosphorylsulphene chlorides react with derivatives of carbonic and carbamic acids to give the corresponding phosphorus-containing disulphides:[92]

$$(RO)_2\overset{O}{\overset{\|}{P}}SCl + R^1S\overset{X}{\overset{\|}{C}}R^2 \rightarrow (RO)_2\overset{O}{\overset{\|}{P}}S\overset{X}{\overset{\|}{C}}R^2 + R^1Cl \ ,$$

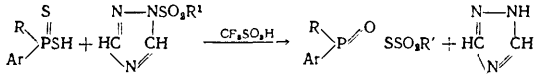
where X = O or S, R = alkyl, R^1 = H, a metal, or alkyl, and R^2 = alkoxy-, aryloxy-, or amino-group.



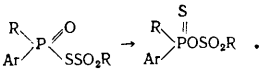
Certain alkoxythiocarbamates also react with dialkoxyphosphorylsulphenyl chlorides. It is remarkable that, depending on the structure of the substituent at the nitrogen atom, final reaction products of different structure are formed:[92]

It has been noted in some reports that, on heating or prolonged storage, compounds containing the thiocarbamoyl residue are converted from the thiolo- into the thiono-form:[92]

$$(RO)_2\overset{O}{\overset{\|}{P}}S\overset{S}{\overset{\|}{C}}NR^1R^2 \rightarrow (RO)_2\overset{S}{\overset{\|}{P}}O\overset{S}{\overset{\|}{C}}NR^1R^2 \ .$$

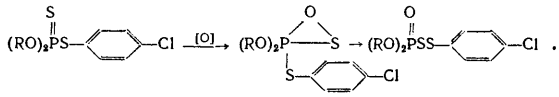


Asymmetric phosphorus-containing disulphides are also the products of the reactions of phosphorothioic acid amides with organosulphenyl chlorides. The formation of a disulphide in this instance is apparently a consequence of the decomposition of the intermediate quasi-phosphonium compound:[94]

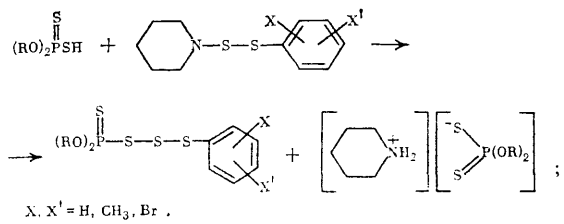


A novel method of synthesis of diethoxyphosphoryl acetyl disulphide from *O,O*-diethyl *S*-methyl phosphorodithioate and thioloacetic acid has been proposed by Michalski and coworkers:[48]

$$(RO)_2\overset{O}{\overset{\|}{P}}SOCH_3 + CH_3CSH \rightarrow (RO)_2\overset{O}{\overset{\|}{P}}SS\overset{O}{\overset{\|}{C}}CH_3 + CH_3OH \ .$$

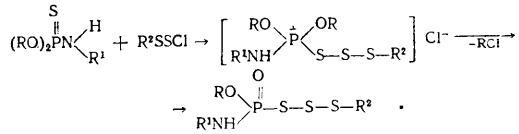


The method of synthesis of sulphonylthio-derivatives by sulphonating sulphotriazoles with alkylarylphosphinodithioic acids in the presence of trifluoromethanesulphonic acid[84] is also of interest:



Analogously to compounds containing the thiocarbamoyl residue,[92] *S*-sulphonylphosphinothioates slowly isomerise to the corresponding P–S derivatives at 20 °C:[84]

Asymmetric phosphorus-containing disulphides are obtained by oxidising the esters of phosphorodithioic acid with 3-chloroperbenzoic acid. Three-membered heterocycles are apparently formed as intermediates in this reaction:[95]

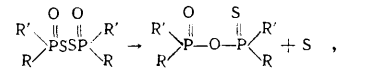


Asymmetric phosphorus-containing trisulphides have been investigated to a much smaller extent. Several examples of the preparation of such compounds have been described in the literature. One of these involves the interaction of *O*,*O*-dialkylphosphorodithioic acids with amino disulphides:[96]

X, X' = H, CH_3, Br .

Trisulphides are also formed in the reactions of phosphorothioic acid amides with organothiosulphene chlorides:[97]

IV. CHEMICAL PROPERTIES



Despite the fact that phosphorus-containing polysulphides are quite readily available, systematic studies of their reactions have been begun comparatively recently and have led to the development of methods of synthesis of a number of classes of organophosphorus compounds whose preparation by other methods presents significant difficulties.[1,97]

The presence of several reaction centres in the molecules of phosphorus-containing polysulphides imparts unusual features to their chemical behaviour. These compounds react with both electrophiles and nucleophiles, the reactions involving and not involving the rupture of the polysulphide chain.

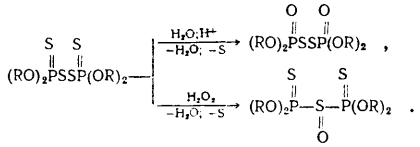
Among the phosphorus-containing polysulphides, the disulphides are the most thoroughly investigated group; tri- and tetra-sulphides have been studied to a much lesser extent.

1. Thermal Stability

The thermal stability of phosphorus-containing polysulphides depends to a large extent on their structure. Thus, whereas bis(diethoxythiophosphoryl) disulphide begins to decompose only at 180 °C,[98] the corresponding dialkyl-, dialkoxy-, and alkylalkoxy-phosphoryl compounds are gradually converted into pyrophosphorothioates, even at room temperature, while on heating the process is rapid:[29]

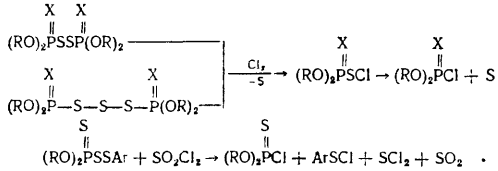
where R and R' = alkyl or alkoxy-group.

Analogous behaviour has also been observed in the series of tri- and tetra-sulphides. Bis(dialkoxythiophosphoryl) trisulphides and bis(dialkoxythiophosphoryl) tetrasulphides are comparatively stable at room temperature, but on heating or prolonged storage they decompose with liberation of sulphur.[4] Bis(dialkoxyphosphoryl) trisulphides and bis(dialkoxyphosphoryl) tetrasulphides are much less stable; they begin to evolve sulphur at room temperature after only several days.[4]



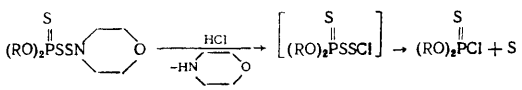
2. Oxidation and Chlorination

Bis(dialkoxythiophosphoryl) disulphides are quantitatively oxidised by iodine in an aqueous alkaline medium:[34,35]



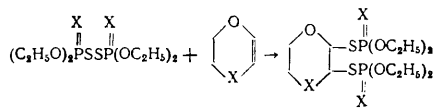
An analogous reaction takes place also when other oxidants are employed.[7]

Depending on the reaction conditions, the oxidation of bis(dialkoxythiophosphoryl) disulphides with hydrogen peroxide can give rise to both bis(dialkoxyphosphoryl) disulphides[99] and bis(dialkoxythiophosphoryl) sulphoxides:[100]



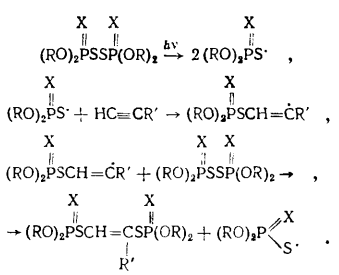
The chlorination of various symmetrical and asymmetric phosphorus-containing disulphides and trisulphides with chlorine or sulphuryl chloride entails the rupture of the polysulphide chain with formation of phosphoryl- or thiophosphoryl- sulphenyl chlorides,[6,9,101–104] but, under the reaction conditions, the latter evolve sulphur, giving rise to phosphorothioic acid chlorides as the final products:

The chlorination or bromination of bis(hexafluorodimethylthiophosphinyl) disulphide leads to the chloride or bromide of hexafluorodimethylphosphinous acid;[105] this disulphide reacts with hydrogen chloride or bromide to form mixtures of hexafluorodimethylphosphinodithioic acid and its halide.[105]



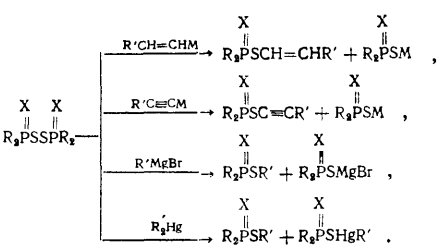
The reaction of dialkoxythiophosphoryl morpholino disulphide with hydrogen chloride proceeds with rupture of the S–N bond. According to Almasi and Plaskucz,[41] the unstable

dialkoxyphosphoryl chloride sulphide is an intermediate in this reaction:



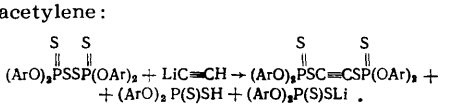
3. Addition to Multiple Bonds

An interesting type of reaction of phosphorus-containing disulphides is addition to multiple bonds.[106,107] Bis(diethoxyphosphoryl) bis(diethoxythiophosphoryl) disulphides react with dioxene and thioxene in the presence of iodine to form the corresponding phosphorothioic acid esters:



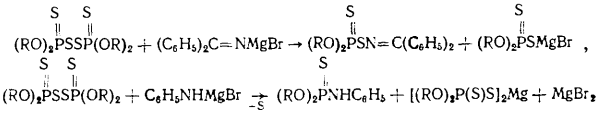
where X = O or S.

The reaction of phosphorus-containing disulphides with acetylenic hydrocarbons takes place under irradiation with ultraviolet light and apparently has a radical mechanism:[108]



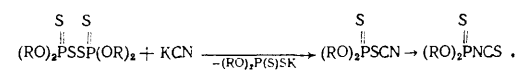
4. Interaction with Organometallic Compounds

Phosphorus-containing disulphides react with organometallic compounds with dissociation of the disulphide bond and the formation of the corresponding phosphorothioic and phosphorodithioic acid esters.[109–113] The literature contains examples of such interaction with alkyl-lithium, alkylpotassium, alkylsodium, metal derivatives of alkenes and alkynes, Grignard reagents,[110–113] and organomercury compounds:[114]

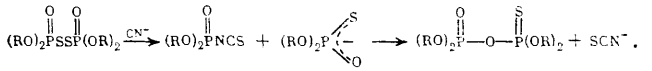


where R = aryl or alkoxy-group, X = O or S, and M is a metal.

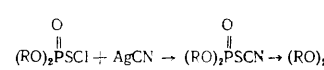
Bis-derivatives are also sometimes formed, for example, from lithioacetylene:



The reactions with *N*-magnesio-derivatives either give a low yield of the corresponding sulphenamides or phosphorothioic acid amides are formed as a result of desulphurisation:[113,115]

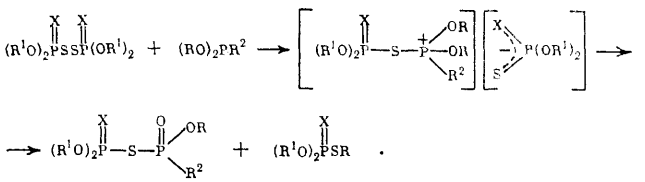


5. Reactions with Hydrocyanic Acid Salts

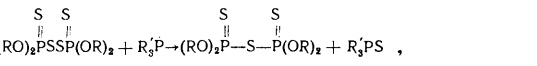


The reactions of hydrocyanic acid salts with bis(thiophosphoryl) disulphides involve the initial formation of the corresponding thiocyanates,[116,117] which subsequently isomerises to the isothiocyanates:

In the case of bis(phosphoryl) disulphides the final products of this reaction are either pyrophosphoromonothioates or, depending on the structure of the groups attached to the phosphorus atom, isothiocyanates:[49,118]



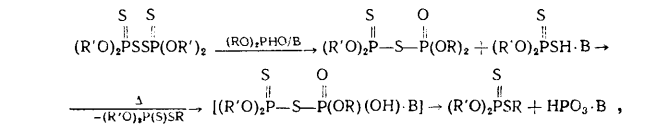
The thiocyanates of *O,O*-dialkylphosphoric acids, obtained by the reaction of phosphorylsulphenyl chlorides with silver cyanide, are stable only in solution at −5 °C. They isomerise at room temperature to the isothiocyanates:[49]



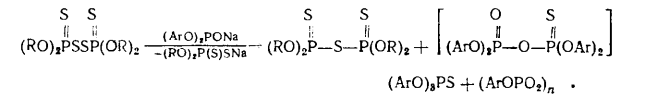
6. Reactions with Tervalent Phosphorus Derivatives

The interactions of bis(phosphoryl) and bis(thiophosphoryl) disulphides with various tervalent phosphoryl derivatives have been studied in detail.[49,119–128] Some of these reactions constitute convenient methods for the synthesis of many organophosphorus derivatives. It is most likely that such reactions proceed via the mechanism of the Arbuzov reaction with formation of an intermediate quasi-phosphonium salt.

The character of the final reaction product depends on the mode of decomposition of this intermediate. Thus bis(dialkoxyphosphoryl) and bis(dialkoxythiophosphoryl) disulphides react with phosphite and phosphonite esters to form pyrophosphates and the esters of phosphorothioic and phosphorodithioic acids,[49,119–123]

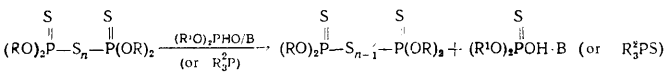


The reactions of phosphorus-containing disulphides with triaryl phosphites, phosphorous acids tris(*N,N*-diethylamide), and triphenylphosphine[123–125] proceed with the desulphurisation of the disulphides and the formation of pyrophosphorotrithioates:



where R = alkyl or phenyl and R′ = phenyl, alkoxy-group, or diethylamino-group.

Bis(dialkoxythiophosphoryl) and bis(diaryloxythiophosphoryl) disulphides react with salts of phosphorous acid in accordance with the mechanism of the Michaelis–Becker reaction:[127,128]



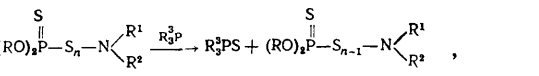
where B is a base.

The formation of pyrophosphorotrithioates and triaryl phosphorothioates has been observed in the reactions of bis(dialkoxythiophosphoryl) disulphides with alkali metal salts of diarylphosphorothioic acids:[124,128]

The formation of the triaryl phosphorothioate has been explained by the disproportionation of the tetra-aryl pyrophosphorothioate.

The interaction of phosphorus-containing tri- and tetrasulphides with an equimolar amount of dialkyl or trialkyl phosphite and also triphenylphosphine entails the desulphurisation of these compounds with formation of di- and tri- sulphides respectively:[142]

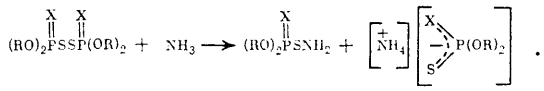
where R and R^1 is an alkyl, R^2 is an alkoxy-group or phenyl, n = 3 or 4, and B is a base.



The reactions of phosphorus-containing tri- and tetrasulphides with tervalent phosphorus derivatives apparently proceed analogously to the reactions of the disulphides, via a stage involving the formation of an unstable quasi-phosphonium compound. However, in contrast to the disulphides, the intermediate formed is more polar and its desulphurisation is observed as a consequence of the rupture of the disulphide bond. In the presence of an excess of the di- or tri-aryl sulphite, the reaction does not stop at the stage described above: the disulphides formed react further with the phosphites to form asymmetric pyrophosphorodithioates as well as esters of phosphorothioic and phosphorodithioic acids:[129]

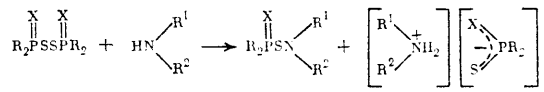
Asymmetric phosphorus-containing disulphides react with triethyl phosphites with rupture of the S–S bond to form the triesters of phosphorothioic and phosphorodithioic acids:[121,126]

In the reaction with trialkyl phosphites or triphenylphosphines, phosphorus-containing amino polysulphides undergo desulphurisation with formation of products containing one sulphur atom less:[62]



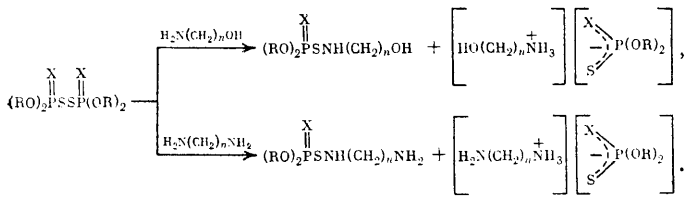
where n = 3 or 4 and R^3 is an alkoxy-group or phenyl.

7. Reactions with Ammonia, Amines, and Hydrazines



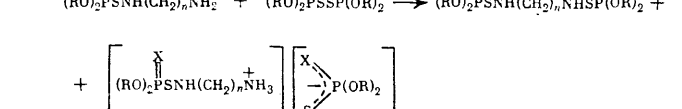
In the reactions of symmetrical phosphorus-containing disulphides with nitrogen-containing bases having a mobile hydrogen atom, the sulphide bond is broken and the corresponding phosphorylsulphenamides and the ammonium salts of phosphorothioic or phosphorodithioic acids are formed. The reaction is general for different amines.[44,130–135] With its aid, thiophosphorylsulphenamides unsubstituted at the nitrogen atom and *N*-monoalkyl-substituted derivatives have become available, whereas it had been impossible to obtain them by the methods known previously.[136]

On reaction with ammonia at approximately 5 °C, bis(dialkoxyphosphoryl) and bis(dialkoxythiophosphoryl) disulphides form high yields of dialkoxyphosphoryl- and dialkoxythiophosphoryl-sulphenamides:[44,137]



The reaction is rapid and the phosphorylsulphenamides obtained are vacuum-distilled. They are insufficiently stable on storage but are stable at low temperatures and can be used as intermediates in the synthesis of various derivatives.[138]

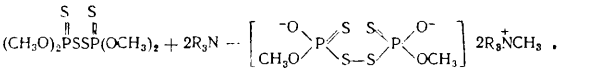
The substitution of a hydrogen atom in the amide group increases the stability of phosphorylsulphenamides. Thus primary and secondary aliphatic amines react with bis(phosphoryl) and bis(thiophosphoryl) disulphides to form more stable sulphenamides:[130,132,139,140]



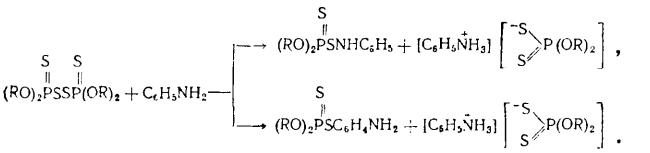
where R is an alkoxy- or aryloxy-group or aryl and X = O or S.

Hydroxyalkylamines and diamines react analogously:[134,141]

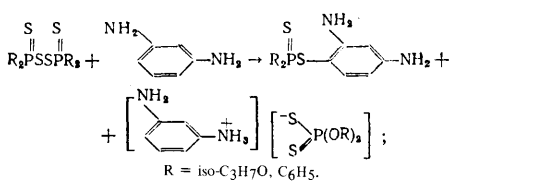
Aliphatic diamines can give rise to bisphosphorylated derivatives:[141]



Alicyclic secondary amines react with disulphides in accordance with an analogous mechanism,[140,142] but the reaction with ethyleneimine involves the simultaneous opening of the three-membered ring together with the formation of thiophosphorylethyleneimide:[134]

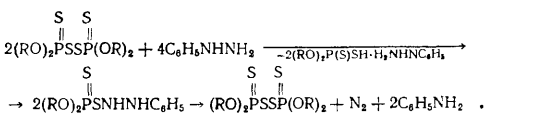


On reaction with tertiary amines, bis(dialkoxythiophosphoryl) disulphides behave as alkylating agents,[143,144] forming the salts of quaternary ammonium bases. This

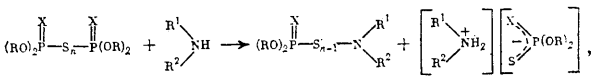


reaction takes place particularly readily with bis(dimethoxythiophosphoryl) disulphide:[143]

Bis(dialkoxythiophosphoryl) disulphides react with aromatic amines in an unusual manner.[145] The reaction with aniline at 90–95 °C takes place with rupture of the sulphide bond via two pathways with formation of *N*-phenylthiophosphorylsulphenamide and the product of the substitution of hydrogen in the aromatic ring by the thiophosphorylmercapto-group:



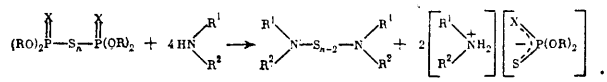
The reaction of phosphorus-containing disulphides with *m*-phenylenediamine proceeds under milder conditions (on heating a mixture of the initial components in benzene) and the main products are *S*-(diaminophenyl)-substituted derivatives of phosphorodithioic acids and substitution takes place in the 4-position of *m*-phenylenediamine:[145]



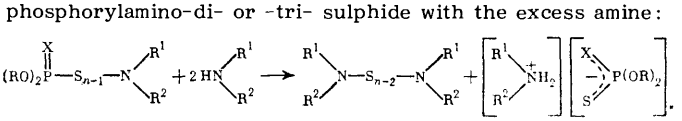
R = iso-C_3H_7O, C_6H_5.

The interaction of phosphorus-containing disulphides with aromatic and aliphatic hydrazines is also interesting. It is not possible to isolate the corresponding thiophosphorylsulphenichydrazide, which apparently decomposes with formation of the initial disulphide, aniline, and nitrogen. In the presence of an excess of phenylhydrazine, the disulphides react almost completely:[131]

In contrast to the reaction with phenylhydrazine, the analogous reaction of disulphides with *N*,*N*-dimethylhydrazine leads to the formation of the dimethylammonium salt of *O*,*O*-dialkylphosphorodithioic acid and not its dimethylhydrazinium salt.[131] This can be explained by the more basic properties of the dimethylamine formed compared with those of the initial dimethylhydrazine.

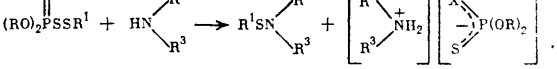


The reactions of phosphorus-containing tri- and tetrasulphides with amines had been virtually uninvestigated previously. Several studies devoted to the interaction of amines with the tri- and tetra-sulphides showed that the main product is the salt of the amine and the corresponding phosphorothioic acid; other phosphorus-containing reaction products could not be isolated.[57,65] It has been established in recent years that, in the interaction of phosphorus-containing tri- and tetra-sulphides with primary and secondary aliphatic or alicyclic amines, the disulphide bond nearest the phosphorus atom is ruptured with formation of the corresponding asymmetric polysulphides containing one sulphur atom less and of the salts of *O*,*O*-dialkylphosphorothioic or *O*,*O*-dialkylphosphorodithioic acids:[147,148]



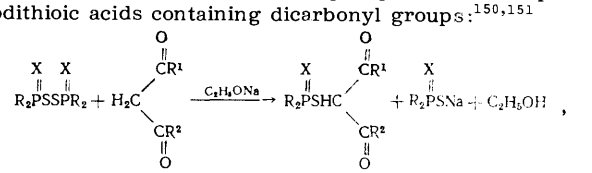
where X = O or S, *n* = 3 or 4, R = alkyl, R^1 = H or alkyl, and R^2 = alkyl (R^1 and R^2 can together form a heterocyclic group).

Dialkoxyphosphoryl *N*-mono(or *N*,*N*-di)alkylamino disulphides are readily vacuum-distilled, while the corresponding dialkoxyphosphoryl and dialkoxythiophosphoryl trisulphides decompose on distillation. The infrared, ^{1}H NMR, and ultraviolet spectra are most informative as regards these compounds. The infrared spectra contain the characteristic absorption band of the N–H group (3320 cm^{-1}), δ_{N-H} = 3.85–4.71 p.p.m. in the ^{1}H NMR spectra, while the ultraviolet spectra exhibit absorption at 226 and 281 nm for the di- and tri-sulphides respectively.[4] The stability of such structures is apparently due to the stabilisation of the molecule by the resonance interaction involving the 3*d* orbitals of the sulphur and phosphorus atoms, which is confirmed by the bathochromic shift of the absorption maximum in the ultraviolet spectra on passing from the disulphide to the trisulphide.[146,149]

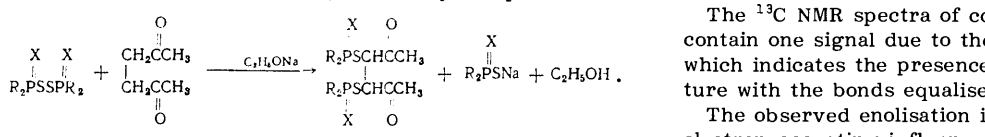


The reactions of tri- and tetra-sulphides with an excess of aliphatic amines result in a quantitative formation of bis(dialkylamino) sulphides or bis(dialkylamino) disulphides together with salts of phosphorothioic or phosphorodithioic acids:

This is explained by the reaction of the intermediate thiophosphorylamino-di- or -tri- sulphide with the excess amine:

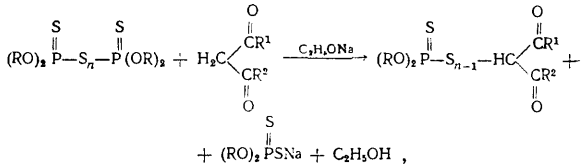


It must be emphasised that, in contrast to the reaction of symmetrical disulphides, the interaction of asymmetric phosphorus-containing disulphides with primary and secondary amines results in the formation of sulphenamides without a phosphorus atom, while the organophosphorus part of the molecule enters into the composition of the corresponding ammonium salt in the form of a phosphorus-containing anion:[94]



8. Reactions of Phosphorus-containing Polysulphides with a CH Acid

One of the characteristic pathways in the reactions of phosphorus-containing polysulphides involves their interaction with dicarbonyl compounds. Thus the reactions of phosphorus-containing disulphides with β- and γ-dicarbonyl compounds, namely with the sodio-derivatives of acetoacetic ester, acetylacetone, acetoacetanilide, malonic acid ester, and acetonylacetone involve the dissociation of the disulphide bond and the formation of esters of phosphorothioic or phosphorodithioic acids containing dicarbonyl groups:[150,151]

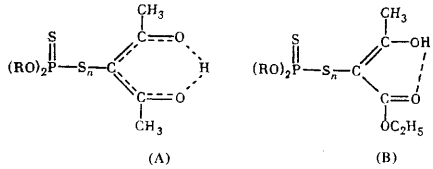


where R = aryl or alkoxy-group, $R^1 = CH_3$ or C_2H_5O, $R^2 = CH_3$, C_2H_5O, or C_2H_5NH, and X = O or S. It must be emphasised that the reaction leads to the formation of the corresponding *C*-derivative.[151]

Depending on the conditions (the ratio of the reactants and process temperature), the sodio-derivatives of γ-dicarbonyl compounds interact with either one disulphide molecule, as in the case of β-dicarbonyl derivatives, or with two such molecules to form disubstituted γ-dicarbonyl compounds:

The more mobile the hydrogen in the molecule of the carbonyl compound, the greater the ease of the reaction with phosphoryl disulphides.

In the interaction of phosphorus-containing tri- and tetrasulphides with the sodio-derivatives of malonic ester, acetoacetic ester, or acetylacetone, the disulphide bond nearest to the phosphorus atom is ruptured and the corresponding asymmetric di- or tri-sulphides are formed together with salts of phosphorodithioic acids:[152]



where R = alkyl, R^1 and R^2 = alkoxy-group or CH_3, and $n = 3$ or 4.

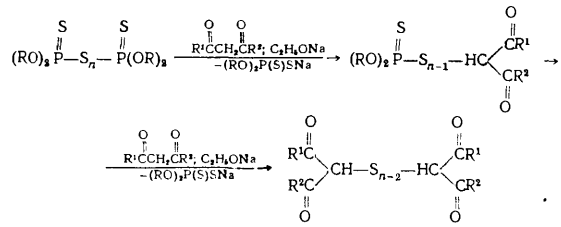
Table 4. Spectroscopic characteristics of diacetylmethyl and alkoxycarbonylacetylmethyl dialkoxythiophosphoryl polysulphides.[152]

n	^{1}H NMR spectrum (δ, p.p.m.)		I.r. spectrum (ν, cm^{-1})		^{13}C NMR spectrum (δ, p.p.m.)		U.v. spectrum	
	OH	CH_3	H . . . O	—C=C—	=C—CH_3	=C—OC_2H_5	λ_{max}, nm	lg ε
				Compounds of type (A)				
2	17.1	2.43	1570	—	195.77	—	231	3.1
3	17.6	2.45	1575	—	195.66	—	240	3.9
				Compounds of type (B)				
2	13.7	2.43	1580	1635	184.81	171.59	232	4.1
3	13.7	2.43	1585	1640	184.81	171.68	240	4.6

Analysis of the infrared, ultraviolet, and ^{1}H and ^{13}C NMR spectra showed that the di- and tri-sulphides formed, (A) and (B), are almost wholly enolised in both non-polar solvents and in a pure form. The chemical shift of the signal due to the hydroxyl proton in the ^{1}H NMR spectra (Table 4) indicates the formation of an intramolecular hydrogen bond between the enolic hydroxyl and the oxygen of the carbonyl group:

(A) (B)

Table 4 shows that the chemical shift of the signal of the enolic proton hardly changes with increase of temperature to 70 °C and following a change in the nature of the solvent, which indicates the stability of the chelate structure formed. The number of sulphur atoms in the chain also does not affect the chemical shift. The content of the enolic form in compounds of this type is 98%; on passing from CCl_4 as the solvent to CH_3CN, the content of the keto-form increases to 4%.[152]



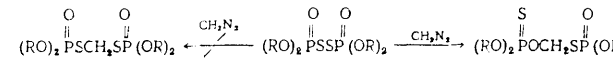
The ^{13}C NMR spectra of compounds of type (A) (Table 4) contain one signal due to the carbon of the carbonyl group, which indicates the presence of a quasi-symmetrical structure with the bonds equalised in pairs.[153]

The observed enolisation is a consequence of the strong electron-accepting influence of the thiophosphoryl disulphide and trisulphide groups, which entails a decrease of the electron density on the methyl carbon atom and hence an increase of the acidity of the CH group.

An increase of the wavelength and of the extinction coefficients in the ultraviolet spectra of compounds of types (A) and (B) (Table 4) on passing from the disulphide to the trisulphide indicates the presence in this compound of an unbranched structure of the polysulphide chain.[154]

The products of the reaction of phosphorus-containing polysulphides with sodiomalonic ester exist in the keto-form, as shown by the absorption band at 1740 cm^{-1} in the infrared spectra, the presence of the signal due to the proton in the CH group (δ = 4.4 p.p.m.), and the absence of the signal of the enolic proton in the ^{1}H NMR spectra.

In the interaction of symmetrical tri- or tetra-sulphides with an excess of a β-dicarbonyl compound, the disulphide bonds closest to the phosphorus atom are ruptured in succession and the corresponding mono- or di-sulphides without phosphorus are formed:[152]

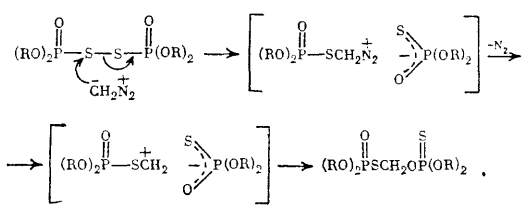


9. The Interaction of Phosphorus-containing Polysulphides with Diazo-compounds

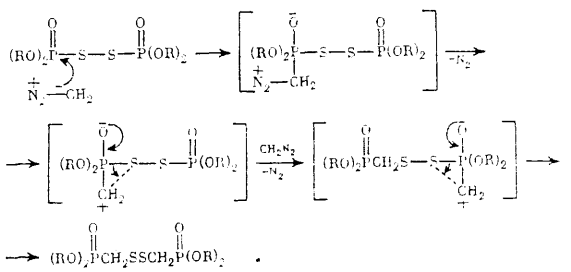
The interaction of phosphorus-containing polysulphides with diazo-compounds has been studied only in recent years.[155-163] It is stated in the literature that aromatic disulphides, in particular diphenyl disulphide, react with the Simmons–Smith reagent (iodomethylzinc iodide ICH_2ZnI) and also with the esters of diazocarboxylic acids in the presence of a catalyst to form the products of the insertion of the corresponding carbene in the disulphide bond. On the other hand, dialkyl sulphides do not react with the Simmons–Smith reagent and the reaction with diazocarboxylic acid esters takes place with only an insignificant yield.[164,165]

These data show that the activity of the disulphides in relation to diazo-compounds is significantly influenced by their structure. The presence of electron-donating substituents reduces and that of electron-accepting substituents increases the reactivity of the disulphides. The latter factor is manifested in the reaction of phosphorus-containing polysulphides with diazo-compounds in reactions of the carbene and non-carbene types.

It is of interest that, in contrast to aromatic disulphides, bis(dialkoxyphosphoryl) disulphides never form products of the insertion of the methylene group in the S–S bond on reaction with an excess of diazomethane in an ethereal solution under various conditions (under irradiation by light from a mercury lamp, in daylight, or in the absence of illumination); this reaction leads to the formation of a low yield of asymmetric products—dialkoxythiophosphoryloxy—dialkoxyphosphorylthiomethanes:[155]



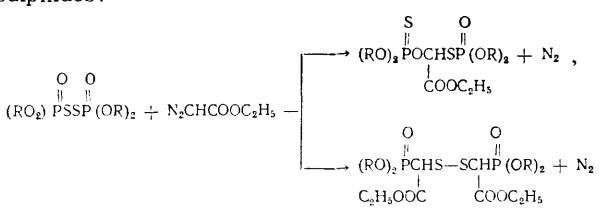
where R = alkyl.



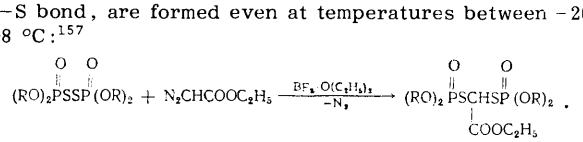
The ^{31}P NMR spectra of these compounds consist of two singlet signals with δ_P = 21–23.7 p.p.m. and 65.2–68.2 p.p.m., which are characteristic of quinquevalent phosphorus in the phosphoryl and thiophosphoryl groups respectively. The ^1H NMR spectra show a doublet of doublets due to the CH_2 group with δ_H = 5.28–5.40 p.p.m. ($^3J_{P(O)H}$ = 19.5 Hz, $^3J_{P(S)H}$ = 13.5 Hz), which also confirms the presence in the molecule of the phosphoryl and thiophosphoryl groups and the asymmetry of the structure formed. The infrared spectra contain an absorption band in the range 1260–1275 cm^{-1} (due to the vibrations of the P=O bond). The absorption band corresponding to the P=S group is shown in the Raman spectra in the range 615–630 cm^{-1}.[155]

Since the given reaction results in the formation of products containing the thiophosphoryl group instead of one of the initial phosphoryl groups, the reaction has been called the phosphoryl–thiophosphoryl rearrangement.[155]

It is believed that, at least in the absence of illumination, bis(dialkoxyphosphoryl) disulphides interact with an undissociated diazomethane molecule. This reaction can be represented by different schemes. One of these involves attack by diazomethane on one of the sulphur atoms with rupture of the disulphide bond and the formation of an intermediate structure with an ambident thiophosphoryl anion and a phosphorus-containing diazonium cation; the last species, which is an unstable intermediate, gives off nitrogen and is converted into the more stable phosphorus-containing carbonium ion, which attacks the rigid end of the triad, namely oxygen, in the $(O\therefore P\therefore S)^-$ ambident system:

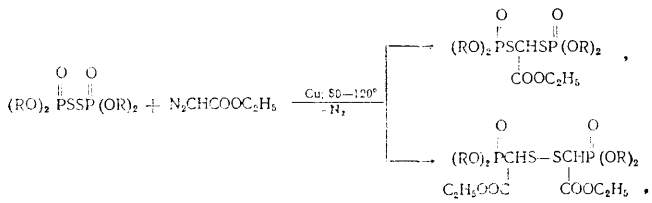


The interaction of bis(dialkoxyphosphoryl) disulphides with diazomethane in the absence of illumination is not restricted to the phosphoryl–thiophosphoryl rearrangement and is accompanied by the formation of the products of insertion of two methylene groups in both P–S bonds of the disulphide with retention of the S–S bond and the symmetry of the structure.[156] The formation of products of the P–S insertion has been represented by a scheme involving successive attack by diazomethane on the phosphorus atom of the disulphide with the intermediate formation of a dipolar diazonium ion, its decomposition to N_2 and a dipolar carbonium ion, and the 1,2-migration of the P(O)SS fragment to the carbonium centre; an analogous sequence of stages after the attack by a second diazomethane molecule leads to the final product:



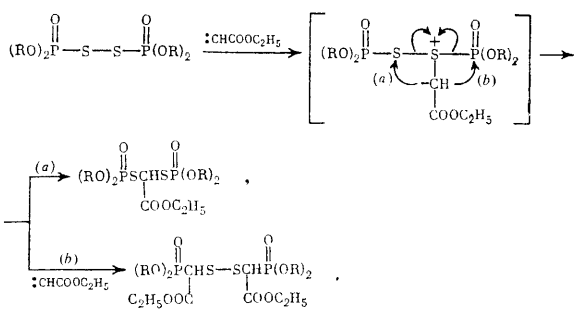
The ^1H NMR spectrum of the products of insertion in the P–S bond of the disulphide (R = iso-C_3H_7) contains a doublet associated with the methylene protons of the CH_2 group having δ_H = 2.21 p.p.m. ($^2J_{PH}$ = 15 Hz). The $^{31}P-\{^1H\}$ NMR spectrum consists of a singlet with δ_P = 24.9 p.p.m.; the infrared spectrum contains an absorption band due to the P=O group in the region of 1260 cm^{-1}.[156]

The interaction of bis(dialkoxyphosphoryl) disulphides with diazoacetic ester involves (as in the reaction with diazomethane) under conditions not promoting the formation of a carbene, involves both the phosphoryl–thiophosphoryl rearrangement with formation of dialkoxythiophosphoryloxy-dialkoxyphosphorylthioacetic esters and the insertion of the ethoxycarbonylmethylene group in both P–S bonds with formations of bis(ethoxycarbonyldialkoxyphosphonomethyl) disulphides:[156]



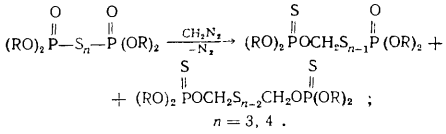
The two competing reactions take place at different rates and, depending on the process conditions, it is therefore possible to obtain each reaction product separately or their mixture in different proportions.

The reaction under the conditions of the catalytic generation of ethoxycarbonylcarbene leads to different results. When bis(dialkoxyphosphoryl) disulphides react with diazoacetic ester in the presence of catalytic amounts of boron trifluoride etherate, bis(dialkoxyphosphorylthio)acetic esters, the products of the insertion of ethoxycarbonylcarbene in the S–S bond, are formed even at temperatures between –20° and +8 °C:[157]

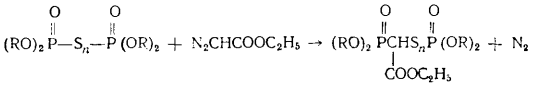


The ^1H NMR spectra of these compounds contain a triplet due to the methylidyne proton of the $CHCOOC_2H_5$ group with δ_H = 4.90–5.04 p.p.m. ($^3J_{PH}$ = 13.5 Hz). A singlet with δ_P = 21.1–21.6 p.p.m. can be observed in the $^{31}P-\{^1H\}$ NMR spectra. The infrared spectra contain absorption bands corresponding to the stretching vibration frequencies of the P=O (1265–1275 cm^{-1}) and C=O (1745 cm^{-1}) bonds.[157]

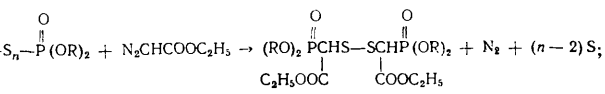
Under the conditions of the catalytic generation of the carbene in the presence of copper powder at 80 °C in benzene or at 80–120 °C in the absence of the solvent, the formation of the product of the insertion of ethoxycarbonylcarbene in the S–S bond of the disulphide is accompanied by the competing reaction involving insertion in both P–S bonds:[157]



The insertion of ethoxycarbonylcarbene in the S–S bond apparently proceeds via a stage involving the formation of an unstable sulphonium ylide with subsequent 1,2-migration of the phosphorylsulphenyl group from the sulphonium sulphur atom to the ylide carbon atom (pathway *a*). The insertion of ethoxycarbonylcarbene in the P–S bond is also regarded as a process involving the intermediate formation of a sulphonium ylide with subsequent migration of the phosphoryl group from the sulphonium sulphur atom to the ylide carbon atom (pathway *b*):[157]

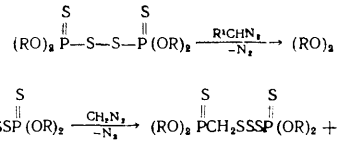


Since insertion in the P–S bond is observed also under conditions which do not promote the formation of carbenes, it is necessary to take into account the possibility of the reaction with an undissociated molecule of the diazo-compound. However, in this case the reaction centre is apparently the phosphorus atom and not the sulphur atom in the disulphide molecule.



Phosphorus-containing tri- and tetra-sulphides form the products of the phosphoryl–thiophosphoryl rearrangement on interaction with diazomethane:[158]

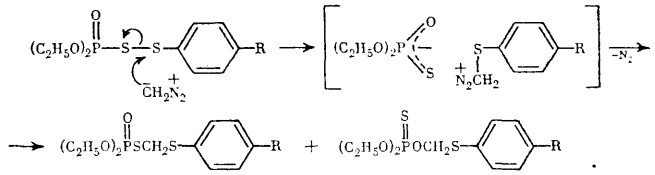
In the reaction with diazoacetic ester there is no rearrangement and the products of the insertion of the ethoxycarbonylmethylene group in one of the P–S bonds of the polysulphide are formed in a high yield:[159]



In the presence of an excess of diazoacetic ester, two ethoxycarbonylmethylene groups are inserted in the P–S bonds of the polysulphides and desulphurisation takes place:[159]

$n = 3, 4$.

Reactions analogous to those described above have also been considered in relation to thiophosphoryl di-, tri-, and tetra-sulphides:[160–162]



where R = alkyl and R′ = H or $COOC_2H_5$.

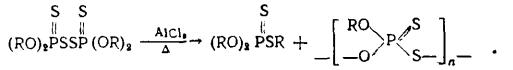
In the case of bis(dialkoxythiophosphoryl tetrasulphides the sequence of the insertions of the methylene group initially in one and then in the other S–S bond of the polysulphide has been observed with the aid of ^1H NMR spectroscopy. This is indicated by one doublet due to the protons of the CH_2 group with $\delta_H = 4.02$ p.p.m. ($^3J_{PH} = 18$ Hz), appearing initially in the spectrum, and then by the second doublet with $\delta_H = 3.75$ p.p.m. ($^3J_{PH} = 18$ Hz).[162]

It has been suggested that the phosphoryl–thiophosphoryl rearrangement takes place in the reaction with an undissociated molecule of the diazo-compound, while the S–S insertion is a reaction of the carbene type. The P–S insertion reaction can apparently be both of the carbene and non-carbene types.

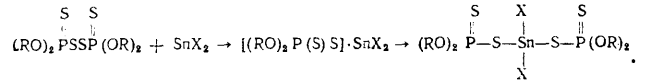
As regards phosphorus-containing disulphides with an asymmetric structure, it has been reported that the methylene group is inserted in the S–S bond of aryl diethoxyphosphoryl disulphide in its interaction with diazomethane.[95] The products of the rearrangement were obtained in an insignificant yield.[166] It is believed that the formation of arylthiodiethoxyphosphorylthiomethane and arylthiodiethoxythiophosphoryloxymethane proceeds via the "diazonium" mechanism; the diazonium cation interacts with the thiophosphoryl anion to a greater extent via the sulphur atom and to a lesser extent via the oxygen atom of the ambident $(O\cdots P\cdots S)^-$ triad:[166]

The reactions of phosphorus-containing polysulphides with diazo-compounds make it possible to obtain organophosphorus compounds which had been difficult to synthesise otherwise or had been altogether unknown and lead to interesting possibilities for the study of the carbene reactions in the chemistry of organophosphorus compounds.

10. The Reactions of Phosphorus-containing Disulphides in the Presence of Lewis Acids



When phosphorus-containing disulphides react with aromatic hydrocarbons and alkyl aryl ethers in the presence of Lewis acids, the corresponding S-aryl esters of phosphorothioic acids are formed:[167,168]



where R = alkoxy-group or phenyl. One must note that, in the case where the unsubstituted alkyl aryl ethers are employed, a mixture of isomers is formed whose separation presents certain difficulties.

When bis(dialkoxythiophosphoryl) disulphides are used, alkylation of the aromatic ring is also observed and in some cases this reaction predominates.[167,168]

In the presence of Lewis acids, bis(dialkoxythiophosphoryl) disulphides are capable of self-alkylation:[167]

The interaction of phosphorus-containing disulphides with tin dihalides is of interest:[169,170]

A complex of tin dihalide is apparently formed initially. The subsequent redistribution of electron density leads to the rupture of the S–S bond and the formation of S–Sn valence bonds.

---o0o---

Thus the unusual chemical behaviour of phosphorus-containing polysulphides renders this group of compounds extremely promising for use in organic synthesis in order to obtain new types of organophosphorus compounds or compounds of this kind which have been hitherto difficult to obtain.

Oligomerisation Reactions of Vinyl Monomers Containing Functional Groups

V.P.Yur'ev, G.A.Gailyunas, and O.T.Kofanova

The results of studies on the oligomerisation reactions of vinyl monomers containing functional-group substituents using metal-complex catalytic systems and thermal and electrochemical methods are surveyed. The chemical reaction mechanisms are examined.
The bibliography includes 127 references.

III. Co-oligomerisation of vinyl monomers with unsaturated hydrocarbons 790

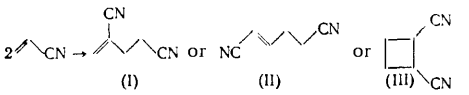
I. INTRODUCTION

The oligomerisation and co-oligomerisation reactions of α-olefins and 1,3-dienes, whereby it is possible to obtain a series of linear and cyclic products of potential interest to various branches of industry, have been thoroughly investigated and extensively described in the literature. The mechanisms and kinetics of these reactions, occurring in the presence of metal-complex catalytic systems, have been established.

The behaviour of olefins containing functional groups in reactions of this kind has not been studied quite so widely. Nevertheless the presence of a polar substituent in the olefin molecule alters the electron density in the double bond and is reflected in the course of the oligomerisation process.

In the present review an attempt has been made to survey the available literature data on the oligomerisation of vinyl monomers with functional groups and also on their co-oligomerisation with olefins, dienes, and trienes.

The vinyl monomers with functional groups consist mainly of α,β-unsaturated nitriles and esters as well as vinyl derivatives of silicon.

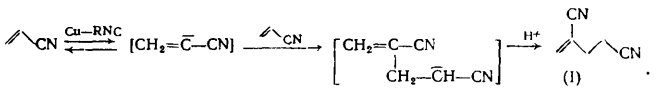


The possibility of the successful oligomerisation and co-oligomerisation of these compounds in the presence of metal-complex catalytic systems to form polyfunctional products containing a definite number of units of the initial monomer in the molecule has been demonstrated. Many of them can be of definite interest for industrial use and some are already manufactured in fairly large quantities.

The data presented in this review may prove useful in the selection of catalysts and reaction conditions ensuring high yields of the required block polymers based on vinyl monomers with functional-group substituents.

II. OLIGOMERISATION OF VINYL MONOMERS

1. Oligomerisation of Acrylonitrile

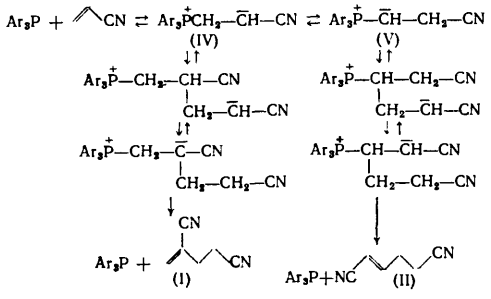


Depending on the selected conditions, the oligomerisation of acrylonitrile leads to the formation of linear dimers [α-methyleneglutaronitrile (I) and 1,4-dicyanobut-1-ene (II)], cyclic dimers [*cis*- and *trans*-1,2-dicyanocyclobutanes (III)], and higher oligomers (tri-, tetra-, and hexa-mers, etc.); the latter are formed as a rule in comparatively small amounts as admixtures to the dimeric products:

Dicyanocyclobutanes (III) are formed on thermal and photochemical cyclodimerisation of acrylonitrile. Thus, when acrylonitrile is heated to 200–300 °C, a mixture of cyclic dimers (III) is obtained in a yield of 2.5% of theoretical.[1] Approximately 4% of 1,2-dicyanocyclobutanes are formed in the photoinitiated dimerisation of acrylonitrile in the presence of sensitisers—benzophenone, 9,10-dibromoanthracene, xanthone, and others.[2] The same yield of cyclic dimers has been obtained as a result of photodimerisation in the presence of copper monochloride, which forms an intermediate coordination complex with acrylonitrile.[3] A 10% degree of conversion of acrylonitrile into 1,2-dicyanocyclobutanes has been achieved by carrying out photochemical dimerisation in the presence of molybdenum or tungsten carbonyls and reaction promoting agents, for example, triphenylphosphine.[4]

The selective formation of the linear dimer (I) has been observed in the dimerisation of acrylonitrile in the presence of binary catalytic systems consisting of copper, iron, or cobalt acetylacetonate and t-butyl- or cyclohexylisonitrile, but cyclohexylisonitrile can be used only in combination with copper and cobalt acetylacetonates, since in the presence of iron compounds it begins to polymerise appreciably lowering the catalytic activity of the system.[5,6] An obligatory condition is the presence of a proton-donating solvent, for example, a mixture of t-butyl alcohol with acetonitrile In the absence of a solvent acrylonitrile polymerises almost completely in the presence of catalytic systems of this kind. It is noteworthy that isonitrile–copper(I) oxide systems are inactive in the oligomerisation reactions of acrylonitrile.

The proposed mechanism of the dimerisation of acrylonitrile in the presence of metal–isonitrile systems involves the formation of intermediate carbanionic complexes whose existence has been confirmed by deuterium exchange reactions:[5]



The dimerisation proceeds fairly slowly (20 h is required to obtain appreciable yields at 110 °C). The yield of the dimer (I) depends on the composition of the catalyst and reaches 50–52%.

α-Methyleneglutaronitrile is obtained in high yields (up to 68–72%) when two-component catalytic systems incorporating organic or inorganic zinc, cobalt, chromium, and aluminium salts, as well as nitrogen-containing Lewis bases (tertiary amines containing aliphatic, alicyclic, and aromatic groups or heterocyclic amines) are used.[7–11] The reaction proceeds at 20–70 °C. A small amount of the trimer (2,4,6-tricyanohex-1-ene) was found in the reaction products.

A mixture of the linear dimers (I) and (II) is formed on dimerisation of acrylonitrile in the presence of phosphorus(III) compounds.[12–31] The ratio of the isomers depends to a large extent on the nature of the organophosphorus compounds and on the solvent, temperature, and other factors. A degree of conversion of acrylonitrile not exceeding 7–9% has been achieved in dimerisation in the presence of tributyl- and triphenyl-phosphines at 45–50 °C.[12] The formation of the dimers was accompanied by the appearance of considerable amounts of the trimer (1,3,5-tricyanohex-1-ene), the hexamer, and other oligomers. The acrylonitrile hexamer 3,6-di(cyanoethyl)-1,3,6,8-tetracyano-*trans*-oct-4-ene was first detected in the oligomerisation of acrylonitrile in the presence of triphenylphosphine at 80 °C in the course of 2–4 weeks.[32]

The study of the dimerisation of acrylonitrile in the presence of triarylphosphines at 160–175 °C led to an increase in the degree of conversion of acrylonitrile to 36% and of the yield of the dimers to 85% (relative to the monomer which has reacted).[19,20] Best results have been obtained using tri(*p*-tolyl)phosphine as the catalyst. The higher nucleophilicity of methyl-substituted triarylphosphines compared with triphenylphosphine not only increases the degree of conversion of acrylonitrile but also reduces the content of the isomer (II) in the mixture of dimers from 39 to 30–32%. In dimerisation in the presence of the still more nucleophilic tri(*p*-anisyl)phosphine, the content of compound (II) falls to 9%.

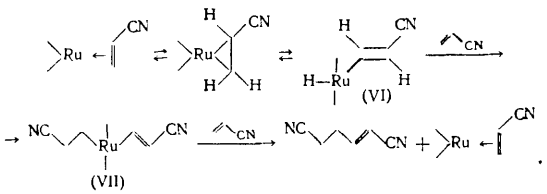
The proposed mechanism of the dimerisation of acrylonitrile in the presence of tertiary phosphines includes the formation of two types of intermediate species—the phosphonium-substituted carbanion (IV) and the phosphorus ylide (V); the reactions of these species lead to the formation of α-methyleneglutaronitrile (I) and 1,4-dicyanobut-1-ene (II) respectively:[12,20]

The choice of the proton-donating solvent for the dimerisation reaction merits special attention. On passing from t-butyl alcohol to triethylsilanol, which exhibits a higher protolytic activity, the yield of the dimers increases by 20–30% other conditions being equal.[20] The absence of a source of protons promotes chain propagation and the formation of higher oligomers. In order to suppress the polymerisation reaction, it is recommended that inhibitors, namely hydroquinone, t-butylcatechol, phenothiazine, and others, be added to the reaction mixture.

A high yield of α-methyleneglutaronitrile (99%) and a satisfactory degree of conversion of acrylonitrile (up to 40%) have been achieved by carrying out continuous dimerisation in a cascade of three reactors in the presence of tri(cyclohexyl)phosphine at 80-140 °C. A mixture of t-butyl alcohol and benzene was employed as the solvent.[17]

The selective conversion of acrylonitrile into 1,4-dicyanobut-1-ene(II) takes place in the presence of catalytic amounts of the phosphonites $XArP(OR)_2$ and the phosphinites $(XAr)(Ar)POR$ or $(XAr)_2POR$, where R = alkyl or cycloalkyl, Ar = phenyl or naphthyl, and X is an electron-donating substituent: an alkyl, alkylamino-, or alkoxy-group.[25–31]

It is recommended that in this instance the dimerisation of acrylonitrile be carried out at low temperatures (below 75 °C) in the presence of a proton-donating alcoholic solvent mixed with an aprotic hydrocarbon cosolvent. An obligatory condition which must be observed to ensure a high rate of dimerisation is the employment of absolutely dry reagents and solvents, since moisture reacts with the catalyst, forming inactive compounds. When the catalyst and the mixed solvent are chosen correctly, the yield of the linear dimer (II) is 85–89% for a degree of conversion of acrylonitrile of 66–75%.[30]



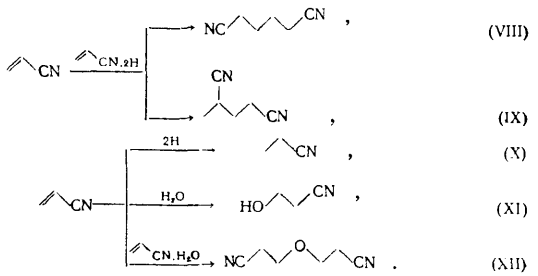
In the presence of bismuth compounds ($BiCl_3$, Bi_2O_3, $BiPh_3$, etc.) a high selectivity is achieved in the formation of 1,4-dicyanobut-1-ene (80%), but the degree of conversion of acrylonitrile is low (1–2.5%).[33] It has proved possible to enhance the catalytic effect of bismuth by adding the compounds of other metals (Sb, Co, Rh, Ir, and Ru), as a result of which the degree of conversion of acrylonitrile increases to 18%.[34–37]

The preferential formation of 1,4-dicyanobut-1-ene(II) has been observed in the dimerisation of acrylonitrile in the presence of catalytic systems containing ruthenium.[38–47] Apart from ruthenium chloride, which has come to be most widely used, the ruthenium salts of inorganic and organic acids or ruthenium complexes can be used as the main component of the catalysts. In order to accelerate the reaction and suppress the formation of side products, some workers recommend the addition of promoting agents—compounds of copper, silver, palladium, cadmium, tin, alkali metals, and alkaline earth metals.

Hydrogen plays an important role in the reaction. In the absence of hydrogen, the dimerisation of acrylonitrile in the presence of ruthenium catalysts hardly occurs. The role of hydrogen is explained by its involvement in the formation of a ruthenium hydride complex, which interacts with acrylonitrile to form the cyanoethyl complex $>Ru-CH_2-CH_2-CN$. The insertion of a second acrylonitrile molecule in the Ru–C bond leads to the dicyanobutylruthenium complex $>Ru-\underset{CN}{CH}-CH_2-CH_2-CH_2-CN$, which decomposes with liberation of 1,4-dicyanobut-1-ene. The main reaction is accompanied by the appearance of fairly large amounts of propionitrile (about 50%) and adiponitrile (up to 4%)—the products of the reaction of the cyanoethyl- and dicyanobutyl-ruthenium complexes with hydrogen.[38]

The study of the dimerisation of acrylonitrile in the presence of ruthenium catalysts in a deuterium atmosphere suggested a reaction mechanism involving the intermediate formation of the catalytically active cyanovinylruthenium hydride complex (VI) as a result of the insertion of the metal in the vinyl carbon–hydrogen bond. The interaction of the complex (VI) with a second acrylonitrile molecule leads

to the dimeric complex (VII), which decomposes with formation of 1,4-dicyanobut-1-ene and the regeneration of the catalyst:[48]



In the absence of hydrogen but in the presence of added electron-donating ligands, which form a coordinate bond with ruthenium (amines, carboxylic acids and their salts), the acrylonitrile dehydrodimerisation products—a mixture of the geometrical isomers of 1,4-dicyanobuta-1,3-diene—are formed preferentially.[49] Equimolar amounts of 1,4-dicyanobuta-1,3-diene and propionitrile have been obtained on dimerisation of acrylonitrile in the presence of catalytic platinum complexes incorporating diethylamine ligands: $(C_2H_4)Pt.(Et_2NH)Cl_2$ and $Et_2NHCH_2CH_2Pt(Et_2NH)Cl_2$.[50]

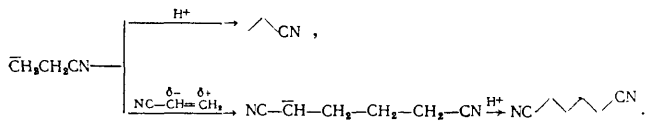
The acrylonitrile hydrodimer, namely adiponitrile (VIII), merits special attention, because it is one of the monomers used in the large-scale manufacture of nylon-6,6. Apart from the dimerisation reaction, already mentioned above, of acrylonitrile in the presence of ruthenium catalysts in an atmosphere of hydrogen, where adiponitrile is formed as an admixture to the main product (1,4-dicyanobut-1-ene),[38,51-53] it can be obtained in a mixture with another hydrodimer, namely 2-methylglutaronitrile (IX), on dimerisation of acrylonitrile in the presence of catalytic systems of three types containing iron and cobalt carbonyls:

$$Fe(CO)_5 \text{ or } Co_2(CO)_8 + \text{alkali} + H_2O;$$
$$Fe(CO)_5 \text{ or } Co_2(CO)_8 + NaBH_4 \text{ or } LiAlH_4;$$
$$Co_2(CO)_8 + H_2.$$

It is recommended that the reaction be carried out at 110 °C at a pressure of 80 atm in benzene or methanol with addition of a polymerisation inhibitor.[54] In all cases appreciable amounts of propionitrile (X) are formed in addition to the hydrodimers. In aqueous media acrylonitrile reacts partly with water to form ethylenecyanohydrin (XI) and biscyanoethyl ether (XII):

A satisfactory yield (90–100%) of adiponitrile has been achieved by dimerising acrylonitrile in the presence of Co(O) complexes, in particular $Co(N_2)(PPh_3)_3$.[55] The possibility of the selective hydrodimerisation of acrylonitrile to adiponitrile using an alkali metal amalgam has been reported:[56-58]

This well known method, used in preparative organic chemistry, has been tested on large-scale experimental apparatus. The course of the reaction is greatly influenced by the stability of the intermediate free radicals, the radicals generated on the surface of the amalgam being more stable than those in solution; the polymerisation of acrylonitrile is therefore not observed in this process. The yield of adiponitrile in the first runs was 60–62% and was later increased to 85–90% relative to the acrylonitrile which has reacted and finally more than 95% of adiponitrile was obtained in a polar solvent—acetonitrile with added water and a quaternary ammonium salt. The main reaction is accompanied by the appearance of small amounts of propionitrile.[58]



The formation of a side product (alkali metal chloride) and the high consumption of the amalgam must be regarded as disadvantages of the amalgam method for the hydrodimerisation of acrylonitrile. Studies are therefore being continued in order to improve the amalgam method and to replace potassium amalgam by the cheaper sodium amalgam, which is formed in large amounts as an intermediate in the manufacture of chlorine from caustic soda by the electrolysis of common salt. The successful completion of these studies will make it possible to combine the manufacture of adiponitrile with the electrolysis of common salt and thus ensure the supply of cheap adiponitrile.

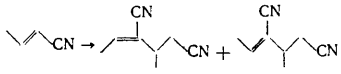
A convenient method for the synthesis of dimeric products from the initial unsaturated compounds is that of direct cathodic hydrodimerisation. This method has been fairly extensively developed and the cathodic hydrodimerisation of acrylonitrile with formation of adiponitrile has been achieved on the industrial scale.[58-60]

In the first stage of the process a radical-anion is formed at the cathode and then rapidly transformed into a carbanion:

At a comparatively high pH of the aqueous solution and high acrylonitrile concentrations the carbanion undergoes nucleophilic addition to a second monomer molecule, forming a dimeric carbanion, which is protonated to give adiponitrile. At a low pH (less than 2) and low acrylonitrile concentrations (less than 10%) the carbanion is protonated with formation of propionitrile:

In anhydrous electrolytes higher acrylonitrile oligomers are formed.

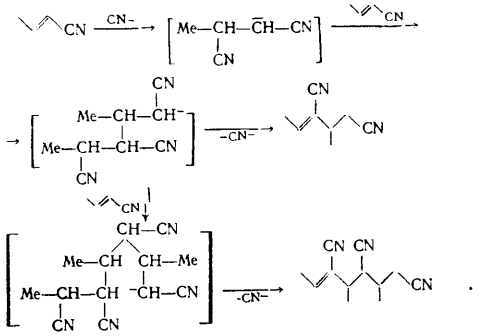
In order to increase the yield of adiponitrile and suppress the formation of side products, it is necessary to maintain the acrylonitrile concentration in the electrolyte above 10%. With the aim of increasing the electrical conductivity and solubility of acrylonitrile, the hydrodimerisation is carried out in a solution of a quaternary ammonium salt (tetraethylammonium toluene-p-sulphonate) or in a mixture of aqueous solutions of potassium phosphate and tetraethylammonium phosphate.



The reaction is carried out at 25–50 °C at lead or graphite cathodes using a current density of 25–100 A dm^{-2} (lead) or 4–15 A dm^{-2} (graphite). The yields with respect to the test substance and the current reach 90–93%.

The electrochemical method of synthesis of adiponitrile competes successfully with the chemical methods, which are employed under more severe conditions. At the present time industrial and large experimental plants for the electrochemical hydrodimerisation of acrylonitrile, operating in the USA, England, Japan, Belgium, and the Federal Republic of Germany, produce more than 170000 tonnes of adiponitrile

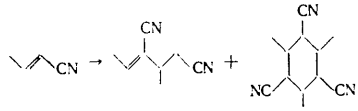
annually and the unit capacity of the plants has been raised to 90000 tonnes per annum.



2. The Oligomerisation of α(β)-Alkyl-substituted αβ-Unsaturated Nitriles

Few studies have been devoted to the oligomerisation of αβ-unsaturated nitriles substituted in the β-position. In the investigation of the dimerisation of αβ-unsaturated carbonyl compounds and nitriles in the presence of binary catalytic systems comprising copper(I) and copper(II) compounds and isonitriles considerable attention has been devoted to the dimerisation of crotononitrile, which results in the formation of a mixture of geometrical isomers of 1,3-dicyano-2-methylpent-3-ene: [5,61]

In contrast to acrylonitrile, the dimerisation of crotononitrile proceeds readily in the presence of copper(I) oxide–t-butyl- or cyclohexyl-isonitrile systems without the need for the presence of proton-donating solvents (acrylonitrile polymerises under these conditions). At 90 °C the yield of crotononitrile dimers in the presence of such systems reaches 90% after only 1 h. [61] Copper acetylacetonate and chloride as well as copper(II) oxide can also be employed for the dimerisation of crotononitrile, but they are less active. It is of interest that the copper compound—isonitrile systems are effective only when the substituent in the β-position is a primary or secondary alkyl group. Compounds with a tertiary alkyl or aryl group in the β-position do not dimerise.

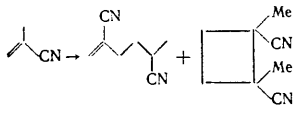


The crotononitrile dimer has been obtained in 52–54% yield together with a mixture of trimers in 33% yield in the oligomerisation of crotononitrile in the presence of tetraalkylammonium cyanides, in particular $(Et_4N)_3[Co(CN)_5]$ and $(Et_4N)_3[Co(CN)_5O_2]$. The more reactive acrylonitrile is fully polymerised in the presence of catalysts of this type. The mechanism of the oligomerisation of crotononitrile has been formulated as follows: [62]

The prolonged (up to 2 h) induction period when tris(tetraethylammonium) pentacyanocobaltates are used could not be accounted for.

Crotononitrile also oligomerises when yet another nucleophilic anionic cobalt(I) complex is employed, namely cobalt N,N′-ethylenebis(salicylideneiminate). [63] The use of this complex in the form of the sodium salt im dimethylformamide leads to the formation of the dimer (1,3-dicyano-2-methylpent-3-ene) in 68% yield and the trimer (1,3,5-tricyano-2,4-dimethylhept-5-ene) in 20% yield. In this case too acrylonitrile gives rise to a solid polymer and a small amount of α-methyleneglutaronitrile is formed only after the addition of t-butyl alcohol (a weak proton donor) (the yield of the acrylonitrile dimer is ~50 times smaller than that of the crotononitrile dimer). According to the author, acrylonitrile promotes the conversion of the active univalent cobalt complex into an inactive bivalent cobalt compound.

In the presence of the potassium–benzylpotassium catalytic system the oligomerisation of crotononitrile results in the formation of the dimer (1,3-dicyano-2-methylpent-3-ene) and a cyclic trimer (1,3,5-tricyano-2,4,6-trimethylcyclohexane): [64]



The reaction is carried out in the presence of an excess of toluene or methylcyclohexane at 110 °C. After 1 h, the degree of conversion of crotononitrile reaches 88.5%. The yield of the mixture of *cis*- and *trans*-1,3-dicyano-2-methylpent-3-enes (in proportions of 67 : 33) is 20–23%, while that of the trimer is 67–75%. When potassium is replaced by sodium, the yield of the oligomerisation products is reduced to 30–35%, other conditions being equal, although the ratio of the dimer and trimer remains unaltered.

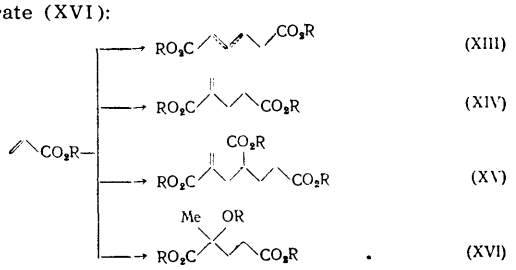
The data presented permit the conclusion that the dimerisation of β-alkyl-substituted αβ-unsaturated nitriles requires the presence of powerful nucleophiles. The latter induce the polymerisation of acrylonitrile, but weaker nucleophilic catalysts can be used to achieve its dimerisation.

Several studies have been devoted to the oligomerisation of methacrylonitrile. A patent, [10] in which the oligomerisation of acrylonitrile is considered in detail, mentions the possibility of the oligomerisation of methacrylonitrile in the presence of catalytic systems comprising the zinc or cobalt salts of trifluoromethanesulphonic acid and triethylamine, but there are no data concerning the composition and yield of the oligomerisation products and also the degree of conversion of the initial monomer.

The possibility of obtaining α-methylene-δ-methylaldipodinitrile (a linear methacrylonitrile dimer) in the presence of a mixed catalyst containing α- or β-naphthylamine and $NiCl_2$ has been investigated. [65] The reaction is carried out at 220–230 °C. Apart from the main product, small amounts of the cyclic dimer (1,2-dicyano-1,2-dimethylcyclobutane) and a trimer, whose structure is not given by the authors, are formed under these conditions.

When methacrylonitrile is heated in the presence of polymerisaton inhibitors, a mixture of α-methylene-δ-methyladipodinitrile with cyclic dimers (*cis*- and *trans*-1,2-dicyano-1,2-dimethylcyclobutanes) is formed: [66]

Large amounts of a trimer and higher oligomers have also been detected in the reaction products. As the reaction temperature is altered, the ratio of oligomers of different structure changes within wide limits. At 340 °C the fraction of the linear dimer is about 50% of the reaction products, while at 200 °C the cyclic isomers predominate in the reaction mixture.



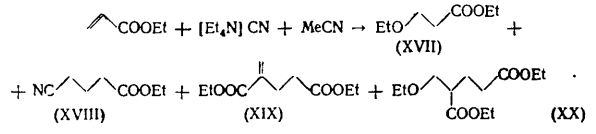
The cyclic methacrylonitrile dimer is formed in a very low yield (2%) as a result of the photodimerisation of methacrylonitrile in the presence of univalent copper. [3] Copper(I) chloride, which is readily soluble in the initial monomer, forms a coordination complex with the latter, ensuring the activation of the double bond and promoting ring closure.

The concentration of CuCl in methacrylonitrile should be not less than 8×10^{-3} M, since otherwise methacrylonitrile begins to polymerise.

Thus the oligomerisation reactions of unsaturated nitriles make it possible to obtain mainly linear dimers whose composition depends on the catalyst employed and the selected reaction conditions. Best results have been obtained using the electrochemical method for the hydrodimerisation of unsaturated monomers with functional groups.

3. The Oligomerisation of Alkyl Esters of Acrylic Acid

The oligomerisation of alkyl acrylates yields mainly three isomers: dialkyl Δ^2- or Δ^3-dihydromuconates (XIII) and dialkyl α-methyleneglutarate (XIV). In certain cases the dimerisation is accompanied by the formation of small amounts of the linear trimer (XV) and dialkyl α-alkoxy-*d*-methylglutarate (XVI):



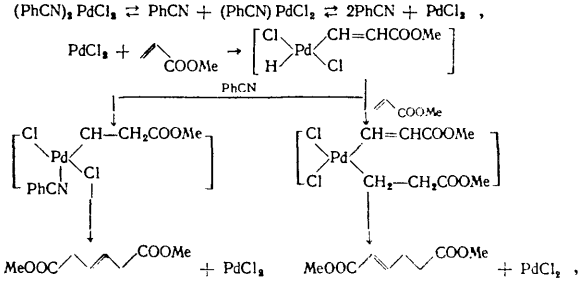
When copper–isonitrile binary systems are used, methyl acrylate is less reactive than acrylonitrile and significant results (yields of the dimer of 11%) are obtained only in the presence of the copper(I) oxide—isonitrile system and a proton-donating solvent. Without the solvent, the monomer polymerises very slowly and, when copper(I) oxide is replaced by copper or cobalt acetylacetonate, the yield of dimethyl α-methyleneglutarate falls to 1–2%.[5]

An analogous picture is observed when binary systems consisting of aluminium or zinc halides and nitrogen-containing Lewis bases are used. In this case too alkyl acrylates proved to be inert. Whereas the yield of the acrylonitrile dimers exceeds 50% in the presence of such catalysts, methyl acrylate gives rise to only 5% of dimethyl α-methyleneglutarate under identical conditions.[8]

There have been a number of reports concerning the possibility of the dimerisation of alkyl acrylates in the presence of organophosphorus compounds.[67–69] In the experiments performed with a solution of ethyl acrylate in t-butyl alcohol in the presence of triphenylphosphine a very low degree of conversion of the initial monomer into a mixture of diethyl α-methyleneglutarate and diethyl Δ^2-dihydromuconate was observed even after two weeks at 40 °C.[12]

Diethyl α-methyleneglutarate has been obtained in 67% yield when ethyl acrylate was dimerised in the presence of tributylphosphine in acetonitrile at 40–45 °C.[67] When tris(ethoxycarbonylethyl)phosphine was used, the yield of the diester fell somewhat, but remained fairly high (47%). The only side product in these reactions is the trimer, formed in small amounts.

A complex mixture of oligomerisaton products is obtained when less active catalysts, namely tetra-alkylammonium cyanides, are used:[62]



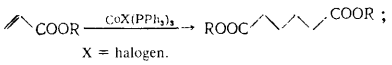
When the reactor is cooled to 5 °C, it is possible to obtain solely compounds (XVII) and (XX). Their formation shows that the ethoxy-group is displaced from the initial product under the reaction conditions with its subsequent addition to the activated double bond. The proton necessary for the formation of compound (XVII) is obtained following the Hoffmann cleavage of the tetraethylammonium cation. The yield of the dimer (XIX) is very low; compound (XVIII) is formed as a result of the addition of acetonitrile to the olefin via the Michael reaction, which the authors believe to be catalysed by the ethoxide anion (tetraethylammonium cyanides do not catalyse this reaction).

The anionic complex cobalt N,N'-ethylenebis-salicylideneiminate promotes the conversion of ethyl acrylate into diethyl α-methyleneglutarate with an insignificant admixture of the trimer.[63] After 10 h, the degree of conversion of the initial monomer reaches 40%. The anionic oligomerisation of methyl and ethyl acrylates has been investigated in the presence of sodium methoxide or ethoxide in anhydrous methanol and ethanol respectively.[70] In both cases the degree of conversion of the monomers is 80–90% after 24 h at the boiling point; in addition to dialkyl α-methyleneglutarate, the corresponding saturated alkoxy-derivative (XVI) was detected in the reaction products. It is noteworthy that in the case of ethyl acrylate the amount of unsaturated dimer obtained is greater than for methyl acrylate.

The preferential formation of dimethyl Δ^2-dihydromuconate is observed when ruthenium or rhodium trichloride trihydrate is used.[71] It is recommended that the reaction be performed in methanol or tetrahydrofuran. A temperature of 140 °C was sufficient for the attainment of a high yield of the dimer in the presence of $RhCl_3 \cdot 3H_2O$ and the formation of higher oligomers was not observed. $RuCl_3$ is less active in this reaction and 48% of the dimer was obtained only at 210 °C. The promoting influence of ethylene, whose addition makes it possible to reduce the reaction temperature to 150 °C and to increase the yield of the dimer to 56%, was unexpected Admittedly a small amount of methyl pent-3-enoate appears in the reaction products under these conditions as a result of the co-oligomerisation of ethylene with methyl acrylate.

Bivalent palladium complexes proved to be fairly active in the dimerisation reactions of alkyl acrylates.[72,73] The readily soluble, non-hygroscopic dichlorobisbenzonitrile complex, which catalyses the dimerisation of methyl acrylate in accordance with the mechanism

is very convenient for this purpose. After 23 h at 113 °C, the degree of conversion of methyl acrylate reaches 67% and the selectivity with respect to linear dimers exceeds 90%. The ratio of the Δ^2- and Δ^3-isomers varies in the range 50 : 50–67 : 33 depending on the reaction conditions.[72]



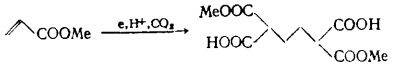
The high process selectivity led investigators to seek ways of increasing the effectiveness of palladium catalysts. The inadequate degree of conversion of alkyl acrylates (67%) is attributed to the comparatively rapid loss of activity by dichlorobis(benzonitrile)palladium.[74]

It was found that the addition of *p*-benzoquinone prevents not only the reductive deactivation of the catalysts but also the radical polymerisation of the monomer; the degree of conversion of the initial monomer increases to 75–92% and the necessary reaction temperature falls to 81 °C. It has been suggested that complexes more reactive than the initial complex may be formed between palladium phenoxide and the benzoquinone reaction products.[74]

Silver tetrafluoroborate exerts an even stronger activating effect on the catalytic $PdCl_2$ complexes.[75] Depending on the catalyst/$AgBF_4$ ratio, the rate of dimerisation of methyl acrylate increases by 1–2 orders of magnitude and the selectivity changes in favour of dimethyl Δ^2-dihydromuconate. $AgBF_4$ has an analogous effect also on the dichlorophosphine-palladium complexes $(PhP)_2PdCl_2$ and $(Bu_3P)_2PdCl_2$, which hardly catalyse the dimerisation of alkyl acrylates in the absence of this additive. The activated complexes are especially selective and it is possible to obtain with their aid a virtually pure Δ^2-isomer (the admixture of dimethyl Δ^3-dihydromuconate does not exceed 1–3%).

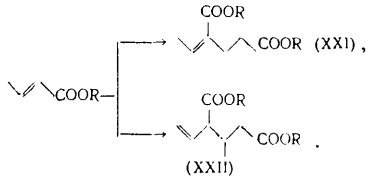
It has been suggested that silver tetrafluoroborate promotes the formation of free coordination-unsaturated centres in the catalytically active complex as a result of the partial dissociation of the neutral ligand, which is confirmed by the impossibility of activating by $AgBF_4$ complexes containing chelating ligands such as 1,2-bis(diphenylphosphino)-ethane and 1,2-bis(N,N-dimethylamino(ethane.

In the presence of triphenylphosphine complexes of cobalt in protic solvents, alkyl acrylates undergo reductive dimerisation with formation of the corresponding dialkyl adipates:



The hydrodimerisation of methyl vinyl ketone to octane-2,7-dione takes place successfully in the presence of cobalt complexes containing bipyridyl ligands:[76]

The electrochemical hydrodimerisation of alkyl acrylates, which takes place exclusively "tail to tail", is characterised by a high selectivity and satisfactory yields.[61,77] The yield of the hydrodimers depends on the composition of the electrolyte and the nature of the alkyl moiety in the ester group (it decreases with increased number of carbon atoms). Thus in an alkaline solution the yield of the methyl acrylate hydrodimer reaches 73%, while only 40% of diethyl adipate is formed from ethyl acrylate; in order to increase the yield of adipate to 75%, it is necessary to raise the electrical conductivity of the solution with the aid of quaternary ammonium salts. It has been altogether impossible to obtain the butyl acrylate hydrodimer by the electrochemical procedure.[77]



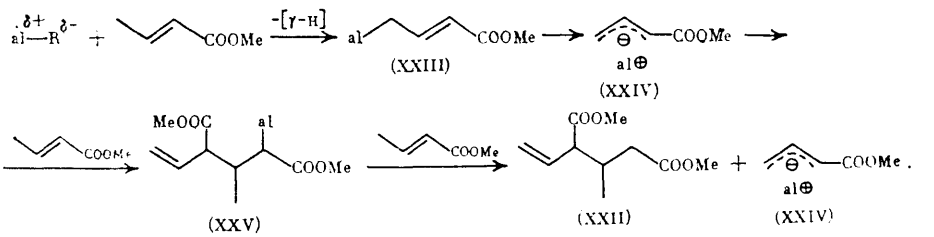
A very interesting product, namely the dimethyl ester of butane-1,1,4,4-tetracarboxylic acid, has been obtained in yields up to 47% by the electrochemical reduction of methyl acrylate in the presence of carbon dioxide:[78]

Great importance must be attributed to reactions of this type, since they lead to yet another possibility for the direct utilisation of carbon dioxide in organic synthesis.

4. Oligomerisation of the Alkyl Esters of Crotonic Acid

Depending on the catalyst, the oligomerisation of alkyl crotonates proceeds with formation of the dialkyl esters of 2-methylpent-3(or 4)-ene-1,3-dicarboxylic acid—compounds (XXI) and (XXII) respectively:

Some of the catalytic systems used for crotononitrile are suitable for these reactions. A mixture of the *cis*- and *trans*-isomers of compound (XXI) is formed from alkyl crotonates in the presence of the copper(I) oxide–cyclohexylisonitrile system in a fairly satisfactory yield (albeit lower than in the case of crotononitrile).[61,79] At 90 °C the yield of the methyl crotonate dimers reaches 70% after 3 h (the ratio of the *cis*- and *trans*-isomers in the mixture is 80 : 20). A characteristic feature is the need to employ a large excess of cyclohexylisonitrile relative to copper(I) oxide. When cyclohexylisonitrile is replaced by t-butylisonitrile, the reaction slows down (the yield of the dimers is only 50% after 12 h). Under these conditions, ethyl crotonate is more inert (the yield of the dimers does not exceed 15% after 14 h even at 100 °C).

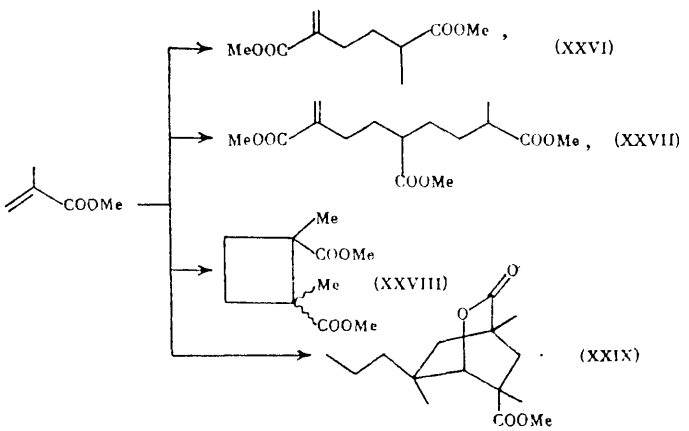


In the presence of tetraethylammonium cyanide in acetonitrile, ethyl crotonate dimerises with formation of 67% of the diethyl ester (XXI).[62]

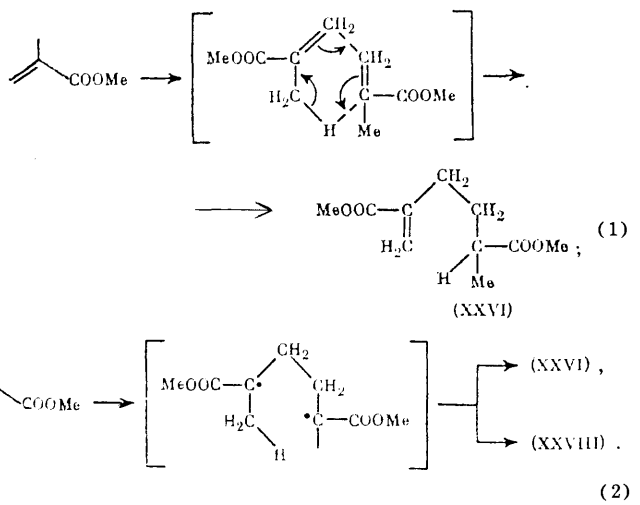
Ethyl crotonate dimerises very rapidly and almost quantitatively at 110 °C in the presence of the potassium–benzylpotassium catalytic system in solution in toluene.[80] In contrast to crotononitrile, ethyl crotonate dimerises very selectively under these conditions—90% of the product consists of the dimer (XXI) and the content of the *cis*-isomer is higher than in the case of crotononitrile (81% instead of 67%).

A very pure dimethyl ester (XXII) has been obtained in a study of the oligomerisation of methyl crotonate in the presence of the trimethyl- or triethylaluminium–sparteine systems.[81,82] A mixture of compounds (XXI) and (XXII) in proportions of 11 : 73–54 : 34 (depending on the solvent employed) with an admixture of 12–16% of the diastereoisomers (XXII) is formed in the presence of the isobutylaluminium–sparteine system.

A mixture of compounds (XXI) and (XXII) in proportions of 97 : 3–69 : 31 has been obtained using the triethylaluminium–triethylamine catalytic complex; the content of the dimer (XXI) increases with reaction time, while the amount of compound (XXII) diminishes simultaneously, which shows that the dimer (XXI) is formed as a result of the isomerisation of compounds (XXII). It is noteworthy that acrylonitrile and methyl methacrylate polymerise fully in the presence of such catalytic systems.



The author showed by experiments with methyl crotonate deuteriated in the α- and γ-positions that the reaction is initiated by the abstraction of the acid γ-proton from methyl crotonate by the catalytic complex and proposed the following reaction mechanism:



Here al represents the Et_2Al–sparteine residue. The abstraction of the γ-proton results in the formation of the intermediate complex (XXIII), which can have the delocalised structure (XXIV). This complex attacks the methyl crotonate molecule with formation of the adduct (XXV), which is converted into the dimer (XXII) with regeneration of the active complex (XXIV).

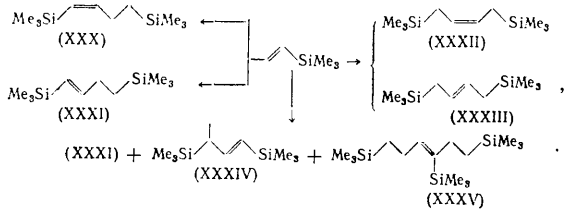
5. Oligomerisation of Alkyl Methacrylates

The esters of methacrylic acid and in the first place methyl methacrylate are known to be widely used in the manufacture of film-forming polymers. The appearance of oligomers of different structure in the course of the polymerisation of methacrylates stimulated investigators to study the conditions and mechanism of the formation of oligomers during the heat treatment of the alkyl esters of methacrylic acid. The probability of the formation of the following methyl methacrylate oligomers has been demonstrated: dimethyl 1-methylene-4-methyladipate (XXVI), trimethyl non-1-ene-2,5,8-tricarboxylate (XXVII), dimethyl *cis*- and *trans*-1,2-dimethylcyclobutane-1,2-dicarboxylates (XXVIII), and a cyclic trimer—methyl 4,6,7-trimethyl-3-oxo-7-propyl-2-oxabicyclo[2.2.2]octane-6-carboxylate (XXIX):

In one of the early studies[66] it was shown that, when methyl methacrylate is heated for 12 h at 225 °C, mainly the linear dimer (XXVI) and the linear trimer (XXVII) are obtained. The same products have been synthesised by the thermal oligomerisation of methyl methacrylate at 100°, 120°, and 130 °C [83] (we may recall that an appreciable proportion of the methacrylonitrile reaction products consist of cyclic dimers under these conditions). Two possible dimerisation mechanisms have been considered: the "ene-enophilic" (1) and the biradical (2) mechanisms:

It has been suggested[83] that in the latter case chain termination and disproportionation of the biradical take place in the course of the reaction with formation of the linear dimer (XXVI) and that only a small proportion of the methacrylate cyclises to the tetrasubstituted cyclobutane (XXVIII).

However, on the basis of the study of the kinetics of this process, it was concluded that the formation of compound (XXVIII) agrees with the biradical initiation mechanism, while the linear dimer and trimer are obtained via the "ene-enophilic" mechanism.[84]

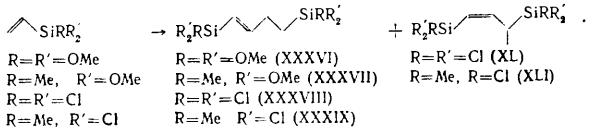


The methyl methacrylate trimer, obtained under the influence of diethylaluminium chloride in the presence of 2,2'-azobisisobutyronitrile as the initiator, has been identified as the bicyclic lactone (XXIX).[85]

6. Oligomerisation of Vinyl Derivatives of Silicon

The oligomerisation of vinyl derivatives of silicon with formation of di-, tetra- and octa-mers was first mentioned in connection with the study of the polymerisation of these monomers.[86,87] The specific synthesis of the linear dimers of trimethylvinyl- and triethylvinyl-silanes was achieved in 1961 by the reaction of the monomers with triisobutylaluminium.[88] For a number of years no studies on these lines were performed and it is only recently that reports have appeared concerning the results of the investigation of the oligomerisation of vinylsilanes in the presence of metal complex systems.[89,90]

Three-component systems consisting of nickel, cobalt, or titanium compounds, as organoaluminium reductant, and triphenylphosphine or triphenylstibine as the electron-donating additive have been investigated. The nickel and cobalt compounds have been used as chelates and the titanium compound was tetrabutoxytitanium. In the

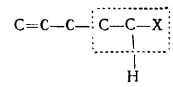


presence of such metal complex catalysts trimethylvinylsilanes give rise mainly to disilylbutenes with different configurations and with different positions of the double bond:

In the presence of the system prepared by treating cobalt 8-hydroxyquinolate with triethylaluminium in the presence of triphenylphosphine, trimethylvinylsilane dimerises with formation of 1,4-bis(trimethylsilyl)-*cis*-but-1-ene (XXX) in 30% yield relative to the monomer which has reacted. The replacement of triphenylphosphine by triphenylstibine leads to the formation of the *trans*-isomer (XXXI) in the same yield. The metal complex system comprising nickel acetylacetonate, triethylaluminium, and triphenylphosphine in the absence of a solvent showed no catalytic activity in relation to vinylsilanes, but the use of dichloroethylene as the solvent led to the formation of a mixture of compounds (XXXII) and (XXXIII) in proportions of 1:1 and in 86% yield. When the organoaluminium reductant is replaced by trichlorosilane, the dimer (XXX) is obtained in 30% yield.

Whereas the nickel and cobalt catalysts make it possible to obtain only unbranched trimethylvinylsilane dimers, the system comprising tetrabutoxytitanium, triethylaluminium and triphenylphosphine promotes the formation of the branched dimer *trans*-1,3-bis(trimethylsilyl)-3-methylprop-1-ene (XXXIV) together with the linear dimer (XXXI). In addition the formation of the linear trimer 1,2,3-tris(trimethylsilyl)hex-3-ene (XXXV) has been noted. The oligomers are formed in the proportions (XXX):(XXXIV):(XXXV) = 2:3:1. It is noteworthy that the titanium system is the only one in the presence of which it has been possible to detect the formation of the trimethylvinylsilane trimer.

The oligomerisation of trimethoxyvinyl- dimethoxymethylvinyl-, trichlorovinyl-, and dichloromethylvinyl-silanes in the presence of the system comprising tetrabutoxytitanium, triethylaluminium and triphenylphosphine has been investigated at 100–120 °C (contact time 6–10 h): [90]

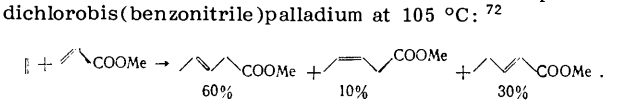


The dimerisation of methoxy-derivatives of vinylsilanes proceeds with a high selectivity. The *trans*-isomers [compounds (XXXVI) and (XXXVII)] are obtained in a yield up to 80% for a degree of conversion of the monomers of 49%. Chloro-substituted vinylsilanes dimerise less vigorously in the presence of the titanium system. Trichlorovinylsilane gives rise to a mixture of the *cis*- and *trans*-isomers (XXXVIII) and (XL) in proportions of 1:1, in 35% yield, and with a degree of conversion of the monomer of 42%. A mixture of dichloromethylvinylsilane dimers (XXXIX) and (XLI) in proportions of 1:2 is obtained in the same yield (35%).

III. CO-OLIGOMERISATION OF VINYL MONOMERS WITH UNSATURATED HYDROCARBONS

1. Co-oligomerisation with Olefins

In the early stages of the investigation vinyl monomers with functional groups were subjected to a high-temperature (200–300 °C) thermal interaction with olefins. [91,92] A study was made of the behaviour of a large number of enophiles (acrylonitrile and methacrylonitrile, methyl esters of acrylic and methacrylic acids, acrylic acid, etc.) with propene, butenes, isobutene, and certain higher olefins. [91] In all cases the reaction results in the formation of adducts of the type



[the C–C atoms printed bold indicate the initial position of the double bond in the olefin, H is the hydrogen atom which has migrated, and C–C–X is the skeleton of the enophile with the activating functional group X (CN, COOR, etc.)]. A higher yield of adducts (up to 49%) is attained when 1,1-disubstituted ethylenes are used, for example, isobutene, while in the case of normal olefins the yield is sharply reduced (down to 18% for propene and 4% for but-2-ene). Furthermore, when normal olefins are employed, the formation of a branched adduct, whose amount increases with the number of carbon atoms in the olefin, is observed: [92]

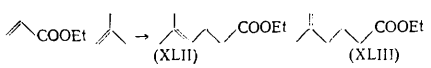
In the codimerisation of methyl acrylate with n-hept-1-ene, the amount of the branched adduct is 25% of the total adducts.

The use of catalysts makes it possible to carry out the codimerisation under milder conditions. In the presence of ruthenium chloride, methyl acrylate reacts with an excess of ethylene at 150 °C to form a mixture of codimers (esters of pent-3-enoic acid, yield 47%) and esters of acids containing seven (12%) and nine (9%) carbon atoms. [71] A methyl acrylate dimer (yield 23%) and butene were also found among the reaction products. The same products have been obtained in the presence of rhodium chloride at 120 °C.

Three isomeric products of the codimerisation of ethylene with methyl acrylate in an overall yield of 47% relative to the methyl acrylate which has reacted are formed in the presence of dichlorobis(benzonitrile)palladium at 105 °C: [72]

An analogous mixture but with a lower yield has been obtained using the complex $[C_2H_4PdCl_2]_2$ as the catalyst. [93]

Lewis acids exert a particularly favourable effect on reactions of this kind, permitting a reduction of the reaction temperature to 25 °C and even lower. [94–99] The catalytic effect of a large number of such compounds has been studied: BF_3, BCl_3, BBr_3, $SbCl_5$, $TiCl_4$, $SnCl_4$, $AlCl_3$, and alkylaluminium chlorides ($EtAlCl_2$, Et_2AlCl, Et_3Al, $Et_3Al_2Cl_3$, Me_2AlCl, etc.). The choice of the catalyst depends on the reactivity of the enophile. Esters, including acrylates and crotonates, require stronger Lewis acids—$AlCl_3$ or $EtAlCl_2$. Aldehydes and ketones are much more reactive—in particular acrolein and crotonaldehyde react successfully with olefins in the presence of weaker Lewis acids—$ZnCl_2$ and Me_2AlCl. The use of alkylaluminium chlorides makes it

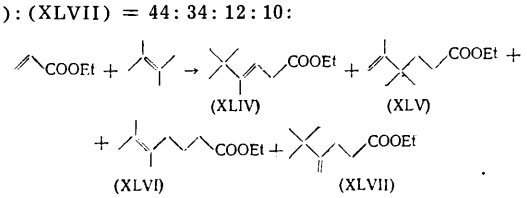


possible to avoid the proton-initiated side reactions (polymerisation of the olefin, isomerisation of the double bond in the olefin and in the co-oligomerisation products).

The results of the co-oligomerisation of vinyl monomers having functional groups with olefins depend not only on the reactivity of the enophile but also on the structure of the olefin. The following reactivity series has been found for olefins in co-oligomerisation reactions catalysed by Lewis acids: 1,1-di- > tri- > tetra- ≫ mono- > 1,2-di-substituted ethylenes.[98] As a consequence of the inadequate reactivity of long-chain olefins, for example oct-1-ene, even the presence of a strong Lewis acid ($AlCl_3$) is ineffective in the interaction of such olefins with acrylates. In such cases the addition of NaCl and KCl to $AlCl_3$ has been found to have a positive effect, permitting the formation of a codimer of methyl acrylate and oct-1-ene-, namely methyl undec-5-enoate, in 40% yield. The admixture of the unbranched ester does not exceed 4%.[96]

A satisfactory treatment of the mechanism of the co-oligomerisation reactions between vinyl monomers having functional groups and olefins in the presence of Lewis acids has not so far been achieved. According to a preliminary assessment, the interaction of the olefin with the enophile proceeds via a stage involving the formation of a complex between the enophile and the Lewis acid via a negatively charged oxygen or nitrogen atom in the enophile molecule. The activated molecule is also attacked by the other reactant in the mixture with formation of an adduct.[99]

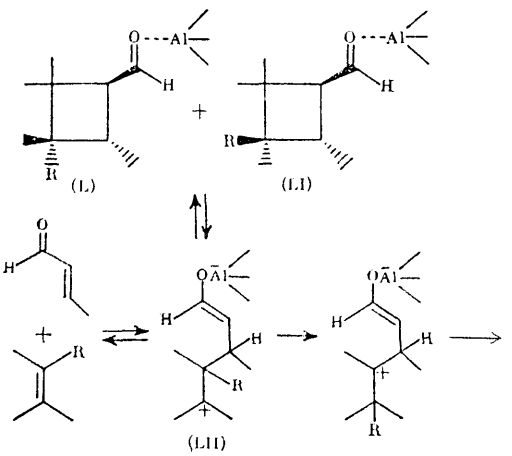
The composition of the co-oligomerisation products formed depends not only on the structure of the initial monomers but also on the reaction conditions. In certain cases the results obtained by different workers investigating the behaviour of the same compounds under identical conditions proved to be contradictory. Thus it has been stated[100] that the co-oligomerisation of methyl acrylate with olefins in the presence of $AlCl_3$ leads to the corresponding substituted cyclobutanes. However, another investigator[95] obtained linear adducts of methyl acrylate with olefins (2-ethylbut-1-ene and methylpent-1-ene) in the presence of the same catalyst.



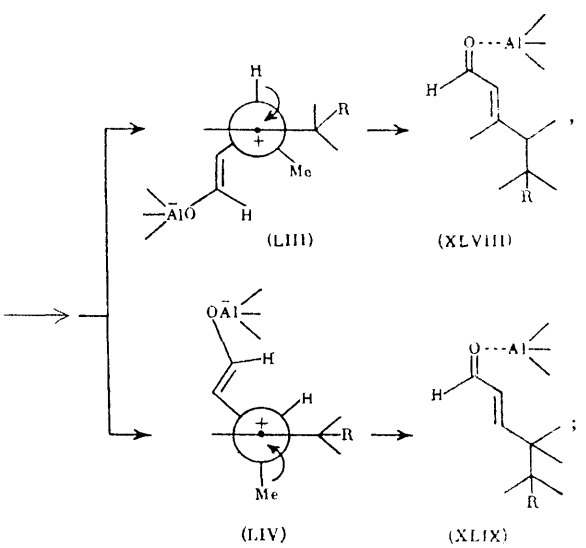
The formation of linear co-oligomers of ethyl acrylate with isobutene in the presence of $AlCl_3$ has been noted.[94] The composition of the products obtained under these conditions depends greatly on the reaction medium. The ethyl esters of 5-methylhex-4-enoic acid (XLII) and 5-methylenehexanoic acid (XLIII) are obtained in proportions of 8:1 in a mixture of dichloroethane and nitromethane:

(XLII) (XLIII)

Only the isomer (XLIII) is obtained in dry benzene.



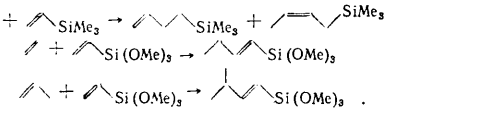
The interaction of ethyl acrylate with 2,3-dimethylbut-2-ene in a dichloroethane–nitromethane mixture led to the formation of four codimers in the proportions (XLIV):(XLV):(XLVI):(XLVII) = 44:34:12:10:



(XLIV) (XLV) (XLVI) (XLVII)

In dry benzene these monomers reacted more selectively to form compound (XLV) (only trace amounts of other isomers were found in the reaction products).

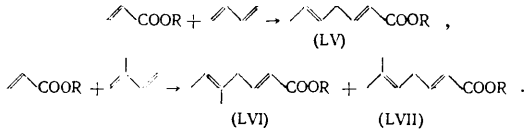
Linear and cyclic products, whose composition depends greatly on the reaction temperature, have been obtained by the reaction of αβ-unsaturated aldehydes and ketones with olefins in the presence of $EtAlCl_2$.[97] For example at 0 °C in benzene the interaction of crotonaldehyde with 2-methylbut-2-ene leads to the formation of 63% of the codimer (XLVIIIa) and 17% of the codimer (XLIXa). A mixture of 81% of cyclobutane (La), 7% of cyclobutane (Lla), 10% of the codimer (XLVIIIa), and 2% of compound (XLIXa) has been obtained at −80 °C in an overall yield of 77%. It has been suggested that the reaction proceeds via a stage involving the formation of the intermediate zwitter-ion (LIIa):



R = H (a), Me (b).

When 2-methylbut-2-ene was replaced by 2,3-dimethylbut-2-ene, the picture changed somewhat. At 25 °C the formation of only the codimer (XLIXb) in 69% yield was noted. The cyclobutane (Lb) and the codimer (XLIXb) were obtained in yields of 60% and 22% respectively in the temperature range from −80° to −40 °C. The absence of compound (XLVIIIb) is explained by the strong steric interaction between the methyl and t-butyl groups in the conformer (LIIIb).

Trimethylvinyl- and trimethoxyvinyl-silanes react with ethylene and propene in the presence of catalytic systems consisting of cobalt or titanium compounds, triphenylphosphine, and triethylaluminium in the molar proportions 1 : 1 : 4 with formation of the corresponding codimers:[101]



At 120 °C and for a contact time of 8–9 h the yield of the trimethylvinylsilane codimers with ethylene reaches 50% for a degree of conversion of the monomers of 65%. The codimer of trimethoxyvinylsilane and ethylene has been obtained in 36% yield for a degree of the conversion of the monomer of 80% in the presence of a catalyst containing tetrabutoxytitanium, triphenylphosphine, and triethylaluminium.

In the interaction of trimethoxysilane with propene the yield of the dimer does not exceed 28% and the degree of conversion of the monomer is 31%.

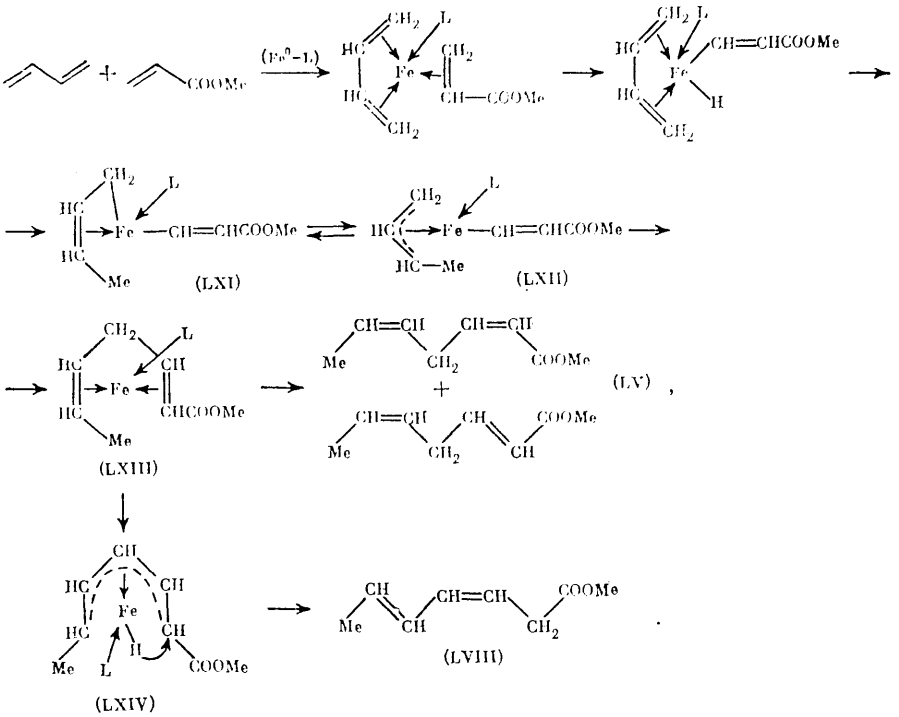
In all the reactions described, 10–25% of the products of the linear dimerisation of vinylsilanes were formed together with the codimers; the dimerisation of α-olefins has not been observed.

2. Co-oligomerisation of the Alkyl Esters of αβ-Unsaturated Carboxylic Acids with Dienes, and Trienes

The co-oligomerisation with dienes has been investigated in fair detail. In the early studies devoted to the co-oligomerisation of alkyl acrylates with buta-1,3-diene and isoprene the corresponding linear dienes were obtained and the structures of the alkyl esters of hepta-4,6-dienoic and 6-methylhepta-4,6-dienoic acids respectively were attributed to them.[102–104] However, it was subsequently shown that the alkyl esters of hepta-2,5-dienoic acid (LV) or 5-methylhepta-2,5-dienoic acid (LVI) and 6-methylhepta-2,5-dienoic acid (LVII) are formed:[105]

When cobalt acetylacetonate and triethylaluminium are used as the catalytic system, the yield of the co-oligomers of butadiene with alkyl acrylates is 20–30% and in the case of isoprene it amounts to 35–45%. The esters of hepta-3,5-dienoic acid (2–3%) and oligomers with a high molecular weight have been detected in the reaction products.

Conditions have been found for the codimerisation of isoprene with methyl acrylate whereby it is possible to obtain a mixture of *cis*- and *trans*-6-methylhepta-2,5-dienoic acids in 70–80% yield relative to the methyl acrylate which has reacted for a degree of conversion of isoprene of 70–80% and of methyl acrylate of 90–95% in the presence of catalytic systems incorporating cobalt(II) acetylacetonate, and organoaluminium reductant, and an electron-donating modifying agent.[106] Apart from triethylaluminium, which is most widely employed, tris(3-methylhepta-4,6-dienyl)aluminium and tris(cyclohexenylethyl)aluminium have been used, as reductants, because they do not ignite on contact with air and water and ensure a higher yield of co-oligomers. Triphenylphosphine, triphenylstibine, and triphenoxystibine proved to be the best modifying agents. The ratio of the *cis*- and *trans*-isomers (~2 : 1) is independent of the catalyst and the reaction conditions. Small amounts (2–5%) of a cyclic adduct, the methyl ester of cyclohex-3-ene-1-carboxylic acid, were found in the reaction products. The content of higher oligomers did not exceed 2–5%.

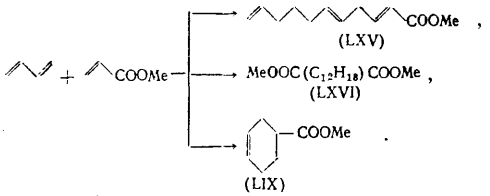


The behaviour of 1,3-dienes and alkyl acrylates in the presence of iron-containing complex catalysts has been studied in very great detail.[107–113] As a result of the co-oligomerisation of buta-1,3-diene with methyl acrylate in the presence of systems comprising iron acetylacetonate and trialkylaluminium, a mixture of the methyl esters of hepta-2,5-dienoic acid and hepta-3,5-dienoic acid (LVIII) is formed with the former predominating (80–87%), compound (LVIII) being produced as a result of the isomerisation of the ester (LV), which could be prevented in certain cases.[107,108] In addition, insignificant amounts of the methyl esters of hepta-4,6-dienoic acid and cyclohex-3-ene-1-carboxylic acid (LIX) have been found. The overall yield of codimers does not exceed 34–35% relative to the initial methyl acrylate. The optimum temperature range is 60–90 °C, since at lower temperatures the degree of conversion of the initial monomers is insignificant, while at higher temperatures cyclodimerisation begins to predominate. The ratio of the initial reactants has little influence on the yield of the required products, while the ratio Al : Fe has a significant effect on the process selectivity. The addition of powerful electron-donating compounds, namely amines, phosphines, and phosphites, which increase the activity of the catalyst, has a considerable effect. As a rule, the presence of these ligands in the reaction medium promotes the formation of the cyclic dimer. The best yields of linear codimers have been obtained using triphenylstibine Ph_3Sb and triphenyl antimonite $(PhO)_3Sb$.[109]

The degree of conversion can be altered and the codimerisation can be directed towards the formation of a particular product also with the aid of solvents. In solution in benzene the degree of conversion of the monomers reaches 95–100%, but most of them are converted into higher oligomers and the yield of codimers varies in the range 10–50% depending on the modifying agent. The selectivity of the codimerisation carried out using ethers as solvent is very high. In this case the yield of the geometrical isomers of the methyl esters of hepta-2,5-dienoic acid reaches 100% relative to the methyl acrylate which has reacted, but the degree of conversion of the monomers falls to 45–55%.[109] The combination of methylene chloride (solvent) with pyridine (electron donor) makes it possible to obtain the virtually pure (93.6%) cyclic codimer (LIX).

The authors explain the high selectivity of the reaction in ethers, particularly in tetrahydrofuran, by the fact that the ether, which is an active two-electron ligand, creates steric hindrance to the approach of the codimer molecules to the metal, while the sterically less hindered monomer molecules are coordinated without special difficulty.

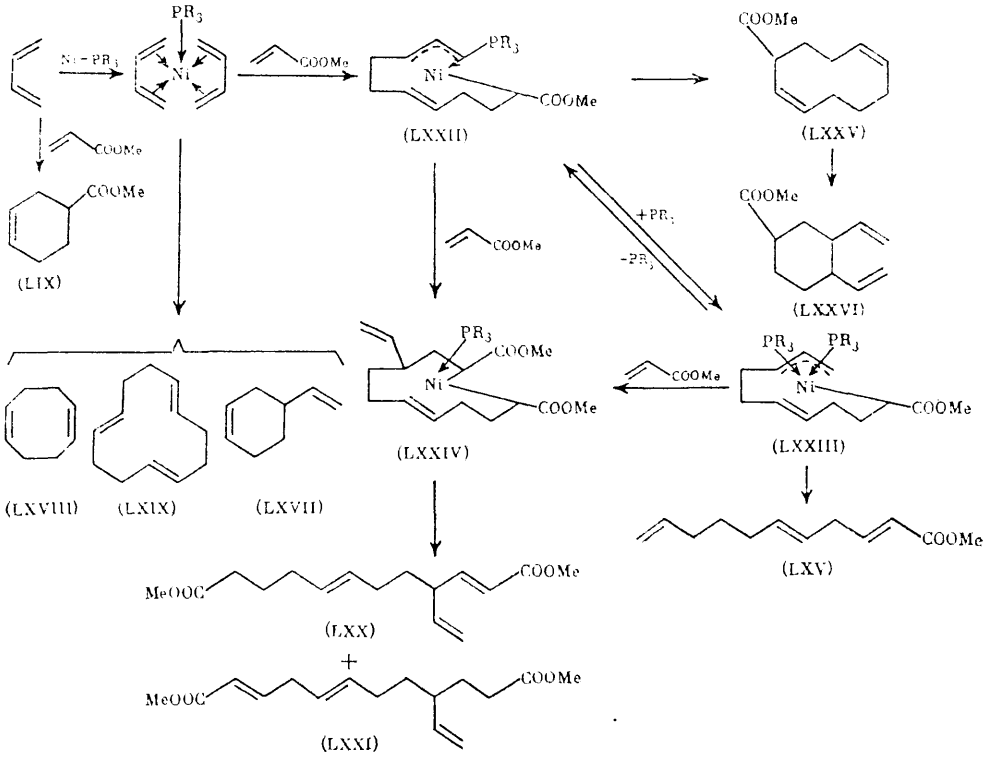
The influence of the addition of copper, cobalt, nickel, manganese, and lanthanide (La, Ce, Eu, Tb, Dy, and Sm) acetylacetonates on the activity and selectivity of the catalytic system $Fe(acac)_3$–$SbPh_3$–$AlEt_3$ has been investigated.[110] With the exception of $Sm(acac)_3$, which increases the yield of the co-oligomerisation products by 12.5%, the derivatives of the other elements not only had a negative effect on the yield of the co-oligomers but also promoted the appearance, together with the esters of hepta-2,5-dienoic acid, of the ester of the conjugated hepta-3,5-dienoic acid and the cyclic adduct (LIX). Depending on the nature of the added metal and its amount, it is possible to obtain the conjugated ester or the cyclic adduct in a virtually pure form (98.5–100%), but in a low yield.



Experiments with deuterated monomers suggested the following mechanism of the codimerisation reaction:[107,111,112]

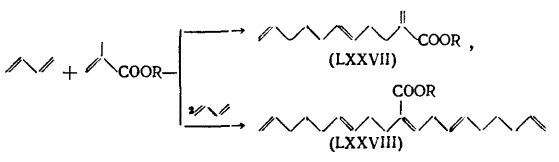
The interaction of butadiene with methyl acrylate includes the stage involving the oxidative addition of methyl acrylate to the iron atom, which leads to the hydride complex (LX), within which a proton is transferred to the activated butadiene molecule; isomerisation results in the formation of the σ,π-allyl complex (LXII). The subsequent dimerisation of the coordinated ligands leads to the formation of a new intermediate complex (LXIII); in the presence of an excess of the monomers the latter decomposes with formation of the stereoisomeric methyl esters of hepta-2,5-dienoic acid and the initial complex. In benzene (instead of tetrahydrofuran) solution the final reaction product is the isomer (LVIII) with conjugated double bonds, whose formation proceeds via the hydride complex (LXIV). The low process selectivity in the formation of codimers in benzene solution can be accounted for by the involvement of the resulting conjugated ester in subsequent reactions, leading to higher oligomers.

The co-oligomerisation of acrylic and methacrylic acids with an excess of 1,3-dienes in the presence of zerovalent nickel complexes leads to other products, formed from two and more molecules of the initial monomers. The catalyst is prepared by reducing nickel acetylacetonate (or other nickel salts) with an organoaluminium reductant in the presence of butadiene and an electron-donating organophosphorus modifying agent (phosphine or phosphite) with the addition of an inert diluent—benzene, toluene or other hydrocarbons.[114,115]



The available data on the composition of the co-oligomerisation products are contradictory. Thus it has been stated[115] that the co-oligomerisation of methyl acrylate with buta-1,3-diene at 120–165 °C leads to the formation of the methyl esters of undeca-2,5,10-trienoic acid (LXV) and cyclohex-3-ene-1-carboxylic acid (LIX), as well as the dimethyl ester of dodecatrienedicarboxylic acid (LXVI) in yields of 40.3, 8.2, and 46.5% respectively:

Other workers[116,117] obtained under the same conditions a mixture containing methyl undeca-2,5,10-trienate (LXV), 4-vinylcyclohexene (LXVII), cyclo-octa-1,5-diene (LXVIII), *trans, trans, trans*-cyclododeca-1,5,9-triene (LXIX), methyl cyclohex-3-ene-1-carboxylate (LIX), methyl 4-vinyldodeca-2,7-dienedioate (LXX) and methyl 4-vinyldodeca-7,10-dienedioate (LXXI). The yield of compound (LXV) varies in the range 15–25%.

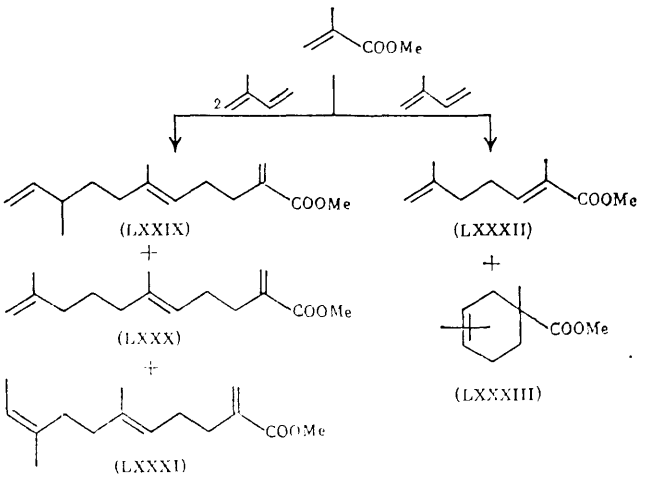


Extensive studies have been made on the influence of the structure of electron-donating modifying agents, organoaluminium reductants, and solvents on the yield and composition of the products of the co-oligomerisation of methyl acrylate with butadiene.[116] The highest yield of the ester of undeca-2,5,10-trienoic acid(LXV) (75%) has been obtained in the presence of a catalyst consisting of nickel acetylacetonate, triphenylphosphine, and tris(3-methyl-hepta-4,6-dienyl)aluminium in proportions of 1 : 2 : 4. Triphenyl phosphite and tris(β-ethoxyethyl) phosphite drive the reaction towards the formation of compounds (LXX) and (LXXI), whose contents in the reaction products reach 87 and 83% respectively for an overall yield of the co-oligomers of 96%.[117] The temperature range 120–160 °C is optimal for the synthesis of compound (LXV); the maximum yields of the esters of vinyldocadienedioic acids are obtained in the range 40–80 °C depending on the structure of the activator. The most suitable solvents are toluene, benzene, and hexafluorobenzene.

The authors proposed the following co-oligomerisation mechanism:[116,117]

In the first stage butadiene and methyl acrylate are coordinated to the zerovalent nickel atom and form a coordination-unsaturated nickel σ,π-complex (LXXII) which can give rise to two 18-electron complexes (LXXIII) and (LXXIV) depending on the temperature. At an elevated temperature the complex (LXXIII), which gives rise to the ester of undeca-2,5,10-trienoic acid (LXV), is more stable. The insertion of methyl acrylate in the π-allyl–Ni bond at a lower temperature leads to the irreversible conversion of the complex (LXXIII) into the σ,σ-complex (LXXIV), which is transformed into the isomeric esters of vinyldodecadienedioic acids (LXX) and (LXXI). The formation of methyl 3,4-divinylcyclohexane-1-carboxylate (LXXVI) can be represented as a process proceeding via a stage involving the formation of the cyclic co-oligomer (LXXV) with its subsequent Cope rearrangement to the ester (LXXVI).

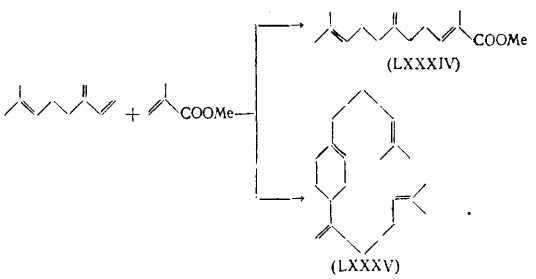
Numerous studies of the influence of various factors on the co-oligomerisation of buta-1,3-diene with methacrylic acid esters in the presence of nickel catalysts showed that three main products are formed: alkyl undeca-1,5,10-triene-2-carboxylate (LXXVII) and two isomeric alkyl esters of nonadeca-1,6,9,13,18-pentaene-10-carboxylic acid (XXVIII):[118]



At 50 °C in the presence of a catalytic system comprising nickel acetylacetonate and triethylaluminium without activator, the yield of compound (LXXVII) reaches 24% and that of compound (LXXVIII) 54%. An increase of temperature promotes the formation of butadiene cyclisation products: cyclo-octa-1,5-diene and cyclododeca-1,5,9-triene.

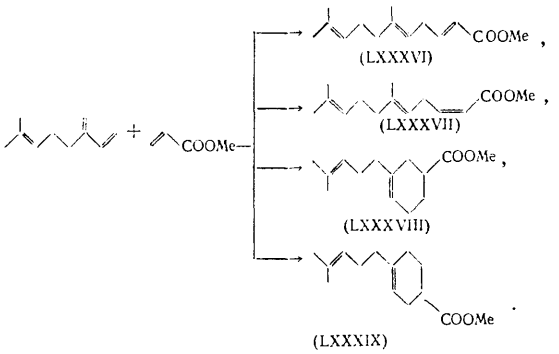
One cannot say that all the data obtained reflect very clearly the influence of the structure of electron-donating ligands on the course of the co-oligomerisation of butadiene with alkyl methacrylates and the authors' conclusions can therefore be adopted only with some reservations. They believe that phosphines inhibit co-oligomerisation. Phosphites, particularly tris(o-biphenylyl) phosphite, promote the formation of cyclo-octa-1,5-diene (yield up to 60%). Phosphorous acid trimorpholide promotes the formation of compound (LXXVIII) in a good yield (69% after 120 h at 20 °C). In the presence of triphenylphosphines the above co-oligomer was isolated in a yield of 62% under analogous conditions. An appreciable yield of compound (LXXVIII) (79–87%) has been obtained in the presence of triphenylstibine. Like triphenylarsine, this ligand is more reactive and selective than triphenylphosphine (in the presence of triphenylarsine it was possible to achieve a 93% yield of methyl nonadeca-1,6,9,13,18-pentaene-10-carboxylate). Very high yields of compound (LXXVIII) (up to 88–92%) have been obtained using pyridine as the ligand. Its methyl, methoxy- and chloro-derivatives are less reactive.

The influence of the nature of nickel compounds on the results of the co-oligomerisation of buta-1,3-diene with methacrylates has been investigated.[118] In the presence of catalytic systems containing chloride ions co-oligomerisation does not occur. Satisfactory results have been obtained when nickel acetylacetonate was replaced by benzene-soluble nickel salts of lauric, palmitic, and certain other organic acids.



The co-oligomerisation of methyl methacrylate with isoprene and myrcene has been investigated in the presence of a homogeneous nickel catalyst (nickel acetylacetonate, reductant—ethoxydiethylaluminium).[119] The reaction with isoprene in the presence of this catalyst gives rise to three

main products: the methyl esters *trans*-6,9- and *trans*-6,10-dimethyl-2-methyleneundeca-5,10-dienoic acids (LXXIX) and (LXXX) and methyl *trans*, *cis*-6,9-dimethyl-2-methyleneundeca-5,9-dienoate (LXXXI) in proportions of 4 : 1 : 2 in an overall yield of 61% relative to the isoprene which has reacted.[119] Methyl *trans*-2,6-dimethylhepta-2,6-dienoate (LXXXII) and a cyclic adduct of isoprene and methyl methacrylate (LXXXIII) in an amount of 3% have also been found in the reaction products.



The co-oligomerisation was carried out at 66–76 °C for 8 h in toluene The degrees of conversion of isoprene and methyl methacrylate were 36 and 18% respectively. There was a considerable proportion (27.6%) of high-boiling products (residue after distillation).

Myrcene reacts with methyl methacrylate in the presence of nickel catalysts much more readily than isoprene. After only 1 h at 100 °C, the degree of its conversion reaches 95%, while that of methyl methacrylate reaches 20%. The main reaction products are methyl *trans*-2,10-dimethyl-6-methyleneundeca-2,9-dienoate (LXXXIV) (11.2%) and camphorene (LXXXV) (35.2%):

The co-oligomer of myrcene and methyl methacrylate with a molecular weight of 372 (27.6%) and high-boiling fractions of unknown composition (~23%) are formed as by-products.[119]

The codimerisation of myrcene with methyl acrylate has been been investigated in the presence of iron and cobalt complexes. It leads to the formation of linear codimers—methyl 6,10-dimethylundeca-2-*cis*(*trans*), 5-*trans*, 9-trienoates (LXXXVI) and (LXXXVII) and cyclic diene synthesis products (LXXXVIII) and (LXXXIX):[120]

Apart from these compounds, up to 8–10% of unidentified higher oligomers are formed in the reaction. The yields and proportions of the linear and cyclic codimers depend on the composition of the catalyst and the reaction conditions.

The maximum yield of the co-oligomerisation products is 75–80% relative to the myrcene which has reacted (the unreacted monomer is fully returned to the reactor); the degree of conversion of myrcene is up to 60–68%. The highest yield of linear codimers has been obtained in the presence of the catalytic system comprising $Fe(acac)_3$, PPh_3, and $AlEt_3$ in tetrahydrofuran. Cyclic esters are formed in this case in an amount of 17% of the total yield of the codimer. The content of cyclic products increases to 36–43% when $SbPh_3$, $P(C_6H_{11})_3$, and $Sb(OPh)_3$ are used as modifying agents. Cobalt compounds direct the reaction towards the formation of cyclic esters. Thus the addition of only 1% of cobalt acetylacetonate to the above catalytic system increases the yield of cyclic codimers to 50%. The complete replacement of iron acetylacetonate by cobalt acetylacetonate makes it possible to obtain the almost pure cyclic ester (LXXXVIII).

The solvents have an appreciable influence on the course of the reaction. On passing from ester solvents to aromatic hydrocarbons, the overall yield of codimers falls, but the fraction of cyclocodimerisation products and higher oligomers increases. A temperature of 50 °C is optimal; when it is reduced to 25 °C, the necessary reaction time increases sharply (from 10 to 100 h) and the yield of the codimers also remains low under these conditions.

The methyl esters of *cis*, *trans*, *trans*- and *trans*, *trans*, *trans*-undeca-2,5,9-trienoic acids in an overall yield up to 80% have been obtained on co-oligomerisation of methyl acrylate with octa-1,3,6-triene in the presence of systems consisting of iron or cobalt acetylacetonate, a phosphine modifying agent, and triethylaluminium.[121]

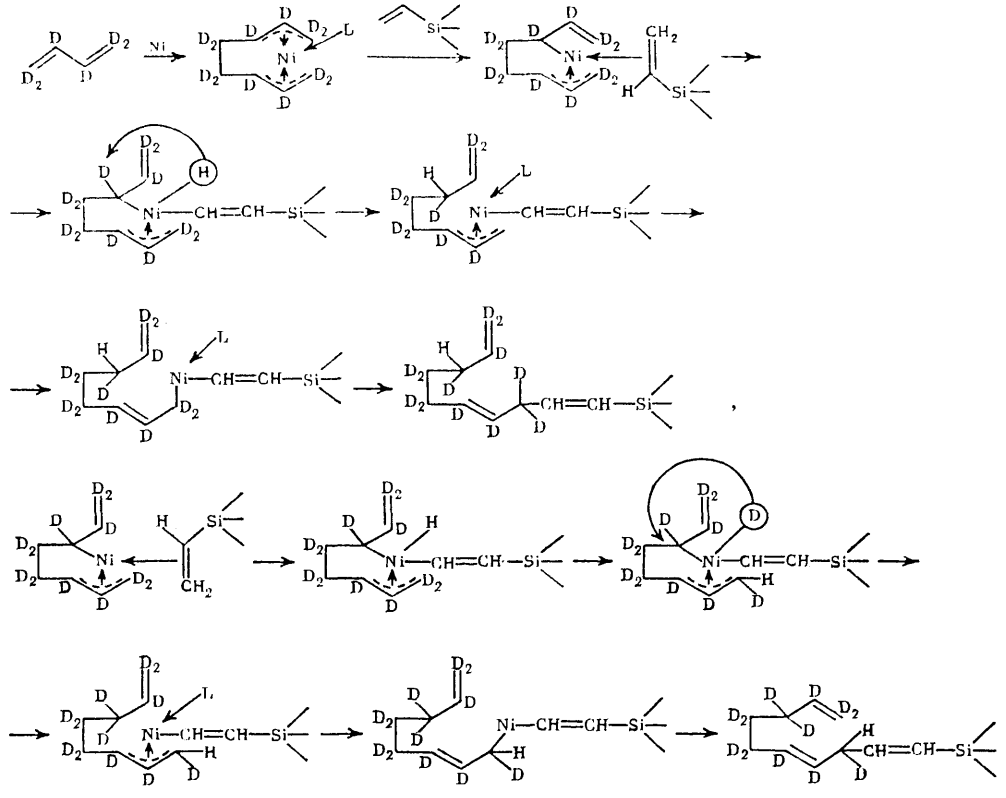
The possibility of the electrochemical cross-hydrodimerisation of 1,3-dienes, in particular butadiene, with ethyl acrylate and crotonate has been described.[122] The reaction proceeds via the recombination of intermediate radical-anions formed on the surface of the cathode at −15° or −20 °C. Dimethylformamide (DMF), anhydrous or containing 10% of water, or a 2:1 mixture of hexamethylphosphoramide and isopropyl alcohol with added tetrabutylammonium iodide, which increases the electrical conductivity of the electrolyte, have been used as solvents.

The composition and yield of the reaction products depend on the composition of the electrolyte. Thus in anhydrous DMF ethyl acrylate reacts with butadiene to form 1% of ethyl *trans*-hept-5-enoate (the product of the codimerisation of one molecule of buta-1,3-diene with one molecule of ethyl acrylate), 2.5% of diethyl *trans*-dec-5-enedioate (the product of the codimerisation of one molecule of buta-1,3-diene with two molecules of ethyl acrylate), and 7.5% of diethyl adipate

(the ethyl acrylate hydrodimerisation product). In aqueous DMF the yield of the ester of *trans*-dec-5-enedioic acid increases to 6.5%, that of diethyl adipate rises to 60%, while the ester of *trans*-hept-5-enoic acid was not detected in the reaction products.

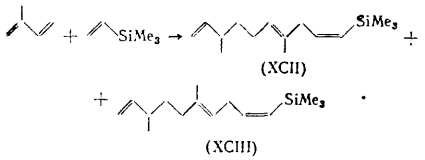
Ethyl crotonate reacts with buta-1,3-diene in anhydrous DMF to form 8.7% of ethyl *trans*-3-methylhept-5-enoate and 5% of diethyl 3,4-dimethyladipate. In a mixture of the amide and the alcohol the yield of the 3,4-dimethyladipic ester increases to 68.7% and 7.9% of diethyl *trans*-3,8-dimethyldec-5-enedioate is formed instead of 3-methylhept-5-enoic acid ester.

3. Co-oligomerisation of Vinyl Derivatives of Silicon with Dienes and Trienes



The linear co-oligomerisation of vinylsilanes with dienes and trienes is a new convenient procedure for the preparation of silicon-containing polyenes, which can serve as starting materials for the synthesis of a whole series of valuable products. These reactions have become the subject of study comparatively recently but extensive experimental data have already accumulated. These confirm that reactions of this kind can be carried out effectively.

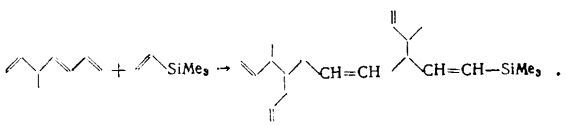
The co-oligomerisation of butadiene with trimethylvinyl- and trimethoxyvinyl-silanes in the presence of the catalytic system consisting of nickel acetylacetonate, triphenylphosphine, and triethylaluminium has been investigated.[123–125] The co-oligomerisation with trimethylvinylsilane (100 °C, 8–10 h) results in a mixture of the silyldecatrienes (XC) and (XCI) in proportions of 1:1, which is obtained in a yield of 72%:



(XC) (XCI)

A change in the ratio of the initial monomers does not affect the composition of the reaction products. The formation of cyclic co-oligomers and homo-oligomers of the initial reactants has not been detected. Under analogous conditions, trimethoxyvinylsilane reacts with butadiene to form only one product—*cis*, *trans*-1-trimethoxysilyldeca-1,4,9-triene. The interaction of trimethylvinylsilane with deuterated butadiene has been studied and this has led to the following reaction mechanism:

Under the conditions described above, isoprene and trimethylvinylsilane react to form a mixture of isomeric silylated trienes (XCII) and (XCIII) in proportions of 3:1 and in a yield of 82%: [125]



(XCII)

(XCIII)

Trimethoxyvinylsilane reacts with isoprene more selectively, giving rise to a 75% yield of pure *cis*, *trans*-1-trimethoxysilyl-5,8-dimethyldeca-1,4,9-triene. The only product of the co-oligomerisation of trimethylvinylsilane with piperylene is *trans*, *trans*-1-trimethylsilyl-3,7-dimethyldeca-1,4,9-triene (yield 70%):

Trimethylvinylsilane is more inert in the reaction with 3-methylhepta-1,4,6-triene. The yield of a mixture of the geometrical isomers of 1-trimethylsilyl-3-(1′-but-3′-enyl)-7-(1′-prop-3′-enyl)-8-methyldeca-1,4,9-trienes was only 30%:

The interaction of butadiene with trimethylvinylsilane in the presence of the catalytic system comprising nickel chloride, triphenylphosphine, and ethylaluminium sesquichloride($AlEt_{1.5}Cl_{1.5}$) is of the type of a telomerisation reaction and is completed by the formation of telomers having the general formula $H(CH_2CH{=}CHCH_2)_nC(=CH_2)SiMe_3$, where $n = 1-5$.

After 5 h at 60 °C, a mixture of hexadienyl- and decatrienyl- silanes is formed in an overall yield of 97% and with a degree of conversion of trimethylvinylsilane of 42%. [126] On increasing the temperature to 100 °C and the reaction time to 8 h, tetradecatetraenyl- and octadecapentaenyl-silanes are formed together with hexadienyl- and decatrienyl-silanes in an overall yield of 73% and with a degree of conversion of trimethylvinylsilane of 85%. Homo-oligomers of butadiene were not detected in the reaction products.

The co-oligomerisation of dichloromethylvinylsilane with butadiene in the presence of a catalyst consisting of tetrabutoxytitanium, triphenylphosphine, and triethylaluminium proceeds with formation of a mixture of *trans*, *trans*-hexa-1,4-dienyl- and *trans*, *trans*, *trans*-deca-1,4(5),8-trienyldichloromethylsilanes in proportions of 2:3. [127] The co-oligomerisation of butadiene with dimethoxymethylvinylsilane has been carried out successfully in the presence of the same titanium catalytic system, but in this case the formation of a mixture of decatrienylsilane isomers was established. [127] The use of nickel chloride, triphenylphosphine, and ethylaluminium sesquichloride made it possible to improve the selectivity of the reaction and to obtain the pure cotrimer—*trans*, *trans*-deca-1,4,9-trienyldimethoxymethylsilane. [127]

---o0o---

Analysis of the data presented shows that catalytic systems permitting the oligomerisation reactions of olefins containing powerful electron-donating or electron-accepting substituents in direct proximity to the double bond have already been investigated. These processes resemble the oligomerisation reactions of olefins without functional groups which have been thoroughly studied. Further successful search for effective catalytic systems should therefore be directed towards the selection of the appropriate ligand environment around variable-valence metals, which will make it possible to achieve the required mode of oligomerisation of vinyl monomers ensuring the introduction into the final product of the necessary number of the functional groups present in the initial monomer. The highly effective electrochemical oligomerisation reactions of substituted olefins also merit the most careful attention.

Structure and Properties of Block Copolymers of Polystyrene and Polybutadiene

A.A.Askadskii, T.A.Andryushchenko, and P.I.Zubov

Recent studies of the structure and properties of block copolymers of polystyrene and polybutadiene are reviewed, with special emphasis on the effect of the structure and of the formation conditions for the samples on the interrelated physico-mechanical properties. Problems associated with the macro- and micro-layering of block copolymer solutions are examined in detail. Work on the analysis of block copolymer structures from measurements of sorption characteristics is reviewed in the light of an assumed relaxation mechanism for the sorption and swelling processes. The prospects of controlling the structure and properties of block copolymers are shown to be good.
The bibliography contains 190 references.

I. INTRODUCTION

The literature on the structure and properties of block copolymers is now extensive. Some recent reviews[1-4] include work on the structure and properties of block copolymers published up to 1976: they deal mainly with thermoelastoplastics, i.e. systems in which fairly large flexible blocks of elastomers are chemically bound to equally large rigid blocks.

Thermoelastoplastics in the form of block copolymers are thought to be promising materials with a wide range of prospective applications in technology.[5] They are simple to prepare and not very different from ordinary plastics in the fabrication of components. The addition of block copolymers (for example, polystyrene/polybutadiene) of the styrene–butadiene–styrene type (SBS) to ordinary plastics polyethylene, polypropylene, polystyrene) improves their elasticity and raises their impact resistance. Yet the workability of the compositions remains almost the same as that of the initial plastics. The potential applications of block copolymers stem from the overall effect of these properties. The most substantial developments have been achieved for block copolymers of polystyrene and polybutadiene, and the present review will deal mainly with these systems.

Block copolymers (especially those based on polystyrene) have attracted sustained development because their practical applications are already considerable.[6-11] The rheological properties of block copolymers are complex, and they differ from those of the dispersed system and of homopolymers. These problems are specially reviewed in Ref. 12. Other review articles[13-16] discuss the morphology of block copolymers, their mechanical properties, and the dependence of their properties on composition and on the measurement conditions.

This review will examine in detail only the most recent results, published in the last few years, though reference to earlier work will be made, where necessary, to make the presentation more logical. No attempt will be made to deal with the historical aspects of the problem.

II. CONFORMATIONAL STATE OF MACROMOLECULES IN SOLUTIONS. EFFECT OF THE COMPOSITION OF THE SOLVENT MIXTURE. MICRO- AND MACRO-LAYERING OF BLOCK COPOLYMER SOLUTIONS

As was stated above, block copolymers consist of large fragments of one polymer chemically bound to fragments of another polymer. In the case of block copolymers of polystyrene and polybutadiene the central block is a fragment of a polybutadiene chain, and the two end blocks are polystyrene (this is the commonest structure, though other variants are possible).

The behaviour of block copolymers in solution was studied even in earlier work. The characteristic form of block copolymers produces specific structures even in dilute solutions, though some workers believe that theories developed for homopolymers[17-19] can be applied to block copolymers. It has been shown fairly convincingly that intramolecular phase separation often takes place in dilute solutions. As a result, micelles are formed, consisting of the block whose thermodynamic affinity for the solvent is lower, with a shell of the block whose thermodynamic affinity for the solvent is higher.[20-22] By varying the composition of the surrounding medium we can control the segregation of the blocks, as has been predicted theoretically.[23-25] The structure of the micelles can be varied by adding a selective precipitant, and this method has been used widely to control the properties of the resulting samples.[26-32] The introduction of a selective precipitant into a block copolymer solution causes coiling of one of the blocks and hence lowers the characteristic viscosity of the solution.[33-36]

Micro-layering in solutions of block copolymers and the mutual compatibility of the two blocks depend on the type of solvent, and on whether the solvent is a common solvent for both blocks or a selective solvent for one of them.[37] In the determination of the phase state of block copolymers in solution the most important consideration is the intermolecular interaction between the blocks and their interaction with the solvent. A change from dilute to concentrated solutions is not always possible: specific conditions

may be necessary. Thus for an equimolar ratio of the components in a copolymer of the ABA type this change is possible only in solvents selective towards the central block;[38] in other solvents phase separation takes place, with precipitation of the polymer.

Depending on the character of the intermolecular interaction between the like and the unlike blocks, the chains of block copolymers may take on different shapes.[39] Thus if the AA and BB interactions are negligible, and the AB interaction results in attraction between the segments, the chains are coiled into a tight ball. On the other hand in the case of mutual attraction between like blocks and mutual repulsion between unlike blocks we observe a collapse of the chains of a three-block copolymer.

Of course, the type of structure formation in block copolymers in solution depends not only on the concentration but also on the type of the solvent. If we use a solvent which is thermodynamically poor for the polybutadiene blocks (for example, ethyl acetate) the ternary block copolymer of polybutadiene and polystyrene in solution forms spherical or worm-like micelles whose core consists of polybutadiene blocks.[40]

As was mentioned above, in selective solvents the block copolymers form micelles consisting of a dense core (contributed by the less soluble component) and a shell, containing the more soluble component and therefore swelled by the solvent. The tendency of block copolymers to form micelles depends on their composition, on the molecular weight of the blocks, and on other factors. For block copolymers of polystyrene with polybutadiene the micelle formation process is conveniently studied in n-alkane solutions. A study[41] by light scattering and sedimentation methods has shown that depending on the molecular weight of the blocks, on the type of solvent, on the concentration of the polymer in solution, and on the temperature, the system can exist as a homogeneous solution and as a micellar structure, with possible transitions between the two states. The molecular weight of the polystyrene has the dominant effect on the type of structure formation in the solutions. If these blocks have a relatively small molecular weight (less than 10000) true solutions are formed in n-alkanes, but if their molecular weight is greater than 20000 only micellar solutions are formed. We note that the number of molecules in the micelle depends on the method of preparing the solution and on the molecular weight of the polystyrene blocks. Micelle formation in solutions of block copolymers of polystyrene and polybutadiene in selective solvents is discussed also in Ref. 42.

In work with solutions of block copolymers (in particular, ternary block copolymers of polystyrene and polybutadiene) it is important to allow for the special behaviour and for the instability of these substances. Thus an anomalous opalescence has been observed in solutions of this block copolymer in isopropyl acetate,[43] which is a selective solvent for polystyrene. The anomaly occurs in a narrow temperature range (37–35 °C): it is due to a change in light scattering caused by the formation of large particles under these conditions. The opalescence temperature decreases as the concentration of the solution is decreased, and micelles of normal size are formed. The formation of anomalously large micelles is an unstable process which can be observed over periods of several hours.

A metastable state was observed[44] in a detailed study of the viscosity of binary block copolymer solutions (polystyrene and polybutadiene) in solvents selective for the individual blocks as well as in mixtures of these solvents. Transitions from one type of micelle to the other were observed after changing the composition of the mixture (by gradually changing from a solvent selective for one of the blocks to a solvent selective for the other); the transition occurs through a region of metastability. This transition is accompanied by characteristic changes in the viscosity of the solution and in the selective sorption coefficient for one of the components of the mixture. All these properties depend on the molecular weight of the blocks of polystyrene and polybutadiene.

The association of block copolymers in selective solvents has been studied[45] with hydrogenated block copolymers of polystyrene and isoprene. At high concentrations of the selective solvent and low temperatures, compact monodispersed micelles were formed. At lower concentrations of the selective solvent and higher temperatures, the associations were larger and polydispersed.

The conformational state of block copolymers in dilute solutions has been analysed in a computer experiment,[46] applying the Monte Carlo method to a simple cubic lattice in which self-intersections were forbidden. The most significant conclusion[46] was that in ternary block copolymers the middle block has a higher swelling coefficient than in a homopolymer of the same structure. Furthermore the ternary block copolymer is larger than the equivalent binary block copolymer. These results were confirmed by experimental measurements of viscosity and light scattering in the same investigation.[46]

Various methods have been used to study micro-layering in solutions of block copolymers. One of these consists in determining the solubility parameters of the blocks of the copolymer and of the solvent.[47] This approach in many cases allows qualitative predictions of the phase state of the block copolymer–solvent system as a function of the chemical structure of the blocks and of the solvent molecules. An alternative approach relies on a theoretical analysis of the thermodynamics of the micelle formation processes and of phase separation in dilute solutions of block copolymers.[48]

The compatibility of the blocks in block copolymers may differ from that of the corresponding homopolymers. This effect is observed[49] in thermodynamic studies, for example in calculations of the free energy of mixing of the components. It is found that the homopolymers are less easily integrated than blocks of the same structure incorporated in a block copolymer.

Many workers have analysed the micro-layering effect theoretically and tested their results experimentally. The theory proposed by Leary and Williams[50] was further developed by Pico and Williams:[51] it relates to systems in which the polymer is predominant and the solvent is present only in small amounts. It is shown that even if the solvent is good for both blocks the system can undergo micro-phase separation at high enough concentrations, as in the case of cooled melts. By assigning a geometrical shape to the domains consisting of blocks of either component the Gibbs free energy could be calculated. A comparison of these results with those for a random mixture of the components allowed the layering temperature of the system and its dependence on the volume fraction of the solvent to be determined. The lowest layering temperature is obtained when the solubility parameter of the solvent is equal to the half-sum of the solubility parameters of the blocks of which the copolymer is composed.

The proposed model was tested experimentally by light transmission and by rheological methods.[52] Plasticised samples of the block copolymer were used in light transmission measurements, and the frequency dependence of the dynamic viscosity of the same samples was measured over a wide temperature range. Dipentane (a good solvent for both types of block) was used as the plasticiser/solvent. At the layering temperature of the micro-blocks all the measured

characteristics show a sudden change, and therefore this temperature can be measured very accurately. The agreement between experiment and theory was good except when the micro-layering temperature was lower than the glass transition temperature of the polystyrene blocks.

Many studies of the rheological properties of block copolymer solutions have been reported.[53-55] If the chosen solvent is a good solvent for both blocks the rheological behaviour of the solution is the same as that of a homopolymer solution. In the presence of selective solvents, in which the solubility of one of the blocks is temperature-dependent, very different properties are observed.[53]

Similar results were reported from a study[54] of the rheological behaviour of concentrated solutions of block copolymers of polystyrene and polybutadiene, having a four-pointed star structure. When a solvent common to both blocks was used the rheological behaviour of the solutions was indistinguishable from that of homopolymer solutions. When the solvent was selective for one of the blocks the rheological results were difficult to reconcile with conventional views.

The work was later extended[55] to other solvents and other methods of studying rheological properties. The rheological behaviour of block copolymers in solutions can be explained by postulating a macroscopic network formed by the polystyrene domains in the solution. This network is unstable and can be broken down by mechanical stresses.[56] Intermolecular interaction, depending on the type of solvent and on its selectivity towards the blocks, can play a major role in these effects.

As was pointed out above, the type of structure of a block copolymer in solution depends on the concentration. The appearance of viscoelastic properties in these systems suggests[57] the formation of a continuous lamellar structure (arising from the polystyrene domains) at high concentrations. Below some limiting concentration the solution develops a network whose points consist of polystyrene domains. The solution becomes truly molecular only at high dilutions.

There are also reports[58] that block copolymers in solutin can exist in a mesomorphic state at high concentrations.

Various papers discuss the compatibility of block copolymers in solution with homopolymers having the same structure as one of the blocks. Thus the compatibility of polystyrene/polybutadiene block copolymers with a butadiene homopolymer in solution was determined viscometrically, and compared with the compatibility of polybutadiene with the random copolymer.[59] The latter was found to be more compatible with polybutadiene, the compatibility decreasing as the molecular weight of the block copolymer increases.

The second virial coefficient for block copolymers of polystyrene and polybutadiene and for mixtures of polystyrene and polybutadiene of the same composition was determined (in different solvents) by an osmometric method.[60] A difference between the second virial coefficients was detected for these systems, but the difference was decreased by raising the temperature and by increasing the proportion of polystyrene in the mixture. Structure formation by the block copolymers in solution was studied using the polarised luminescence method, and it was shown that globular, dumb-bell, and other structures can develop, depending on the type of solvent.[61]

Brief mention should be made of the special features of the fractionation of block copolymers. Fractionation methods applicable to block copolymers, including gel chromatography, precipitation chromatography, and fractional precipitation are discussed in Ref. 62. Compositional non-uniformity in block copolymers has been successfully analysed by gel-permeation chromatography.[63] The study of the molecular weight of block copolymers by gel chromatography is complicated by the special structure of these materials, which causes difficulties in the choice of solvent. A detailed discussion of these problems will be found in Ref. 64. The specific problems of the chromatographic separation of block copolymers on porous adsorbents are discussed in Ref. 65. The separation theory developed in that work[65] can identify the most favourable conditions for accurately separating a block copolymer according to the length of one of the blocks.

A convenient method for detecting compositional non-uniformity in block copolymers is centrifuging in a density gradient, obtained by using two solvents of different density. This technique allows the separation of fractions in which the concentration of polystyrene varies between very narrow limits.[66]

The molecular structure of block copolymers (i.e. the length and molecular-weight distribution of the blocks) can be controlled by introducing various lithium-organic compounds into the reaction mixture.[67] This process, too, is affected by the specific structure of the block copolymers, which differ substantially from those of homopolymers prepared under similar conditions.

To complete the description of the behaviour of block copolymers in solution we should note that the nature of the intermolecular interaction of the repeating units of different blocks, both with each other and with the solvent molecules, has been studied extensively in recent years. These interactions are very important in studies of the phase state of block copolymers in solution. Depending on the nature of the intermolecular interaction, which dictates the choice of a selective solvent or precipitant, dilute solutions can be replaced by concentrated solutions, the conformation of the chains in solution can be varied, and micellar structures in which the cores consist of blocks of either type can be obtained.

Another important aspect of the problem is the rheological behaviour of block copolymer solutions. In recent work on this topic the rheological behaviour of the solution (which depends on concentration) has been used to study the structure of block copolymers in solution. It is generally assumed that macroscopic networks whose nodes consist of domains of one of the blocks are formed in concentrated solutions. Concentration of the solution favours the formation of a lamellar structure, though in some cases the solution can show a mesomorphic structure. The macroscopic network can be broken down either by diluting the solution or by mechanical stresses. This approach can account for the rheological properties without postulating mechanical meshing of the chains in the solutions.

Thus block copolymers offer a convenient model system for studying the behaviour of polymer solutions, since they offer almost limitless possibilities of controlling the structure by varying the chemical arrangement of the blocks, their length and relative position, by varying the concentration of the solution, by using selective precipitants and solvents, etc. When solid samples are prepared from solutions of block copolymers all these aspects of their previous history can affect their structure and mechanical properties, as shown in the following Section.

III. STRUCTURE AND MECHANICAL PROPERTIES OF BLOCK COPOLYMERS IN THE SOLID STATE

The structure of block copolymers (and especially of block copolymers based on polystyrene and polybutadiene) was carefully studied even in the earliest work.[68-70] Structural

changes produced by increasing the content of polybutadiene phase in the polymer have been studied,[71] and various types of structure have been detected. At low concentrations of the polybutadiene fraction spherical domains are formed, dispersed in the polystyrene matrix, but at higher concentrations the polybutadiene forms cylindrical domains in a hexagonal packing arrangement. A further increase in the concentration of polybutadiene produces layer structures (alternating sheets of polybutadiene and polystyrene); the next stage is phase inversion, with cylindrical domains of polystyrene arranged in a polybutadiene matrix, and lastly the polystyrene domains become spherical at very high concentrations of polybutadiene (up to 80%).

The effect of the chemical structure of the blocks on the structure of binary block copolymers has been studied by low-angle X-ray scattering and by electron microscopy.[72] The thickness of the layers and of the layer structure in binary block copolymers increases if polystyrene is replaced by poly-α-methylstyrene or by poly-2-vinylnaphthalene (while keeping the molecular weight constant). The parameters of the layer structure are affected also by the thermodynamic properties of the solvents and by the concentration of the solutions.

The structure of block copolymers of polystyrene and polybutadiene has been studied[73] by varying the concentration of the vinyl component in the polybutadiene block from 10 to 60%. This change in chemical structure was shown to lower the degree of ordering of the system at the supermolecular level.

A theory which allows the size of the spherical domains to be calculated and their free energy to be estimated has been proposed.[74] This theory was tested by an experimental study of block copolymers of polystyrene and polybutadiene.

A thermodynamic analysis of a system composed of a block copolymer with cylindrical domains has been reported.[75] The size of the domains and the distance between them were calculated as a function of the composition of the block copolymer. Subsequently the thickness of the phase layers was also calculated.[76]

Various methods of studying the micro-phase separation of block copolymers in the solid state have been used, including X-ray structural analysis,[77] transmission electron microscopy,[78] and others.[79,80] Thus the nature of the domain structure in block copolymers of polystyrene and polybutadiene has been determined by low-angle X-ray diffraction and by transmission electron microscopy.[78] For polystyrene contents below 25% the films prepared from solutions in benzene (common solvent) and in cyclohexane (solvent specific to polybutadiene) contain spherical domains of polystyrene showing a high degree of segregation. Films prepared from solution in ethyl methyl ketone contain domains of polybutadiene dispersed in a polystyrene matrix.

The formation of block copolymer structures depends on the width of the molecular weight distribution (MWD) of the chains in the blocks. If the distribution is similar in each block (either narrow, or wide) and the concentration of the components is the same, the phase structure will also be approximately the same.[81] On the other hand if the polystyrene blocks have a narrow MWD and the polybutadiene blocks have a wide MWD the structure of the block copolymer becomes similar to that of a sample with a narrow MWD of all the components and a lower polybutadiene content. For the opposite relationship of the MWD of the blocks the structure is again similar to that of a sample with a narrow MWD of all the components, but this time with a lower concentration of polystyrene.[82] Because of its dependence on the MWD distribution of the blocks the structure of the block copolymers affects the properties of the material. A wide MWD favours the formation of a lamellar structure, which lowers the tensile strength and increases elongation. Samples with a narrow MWD display Newtonian flow over a wider range of shear rates than samples with a wide MWD.[82]

Micro-layering is essential to the development of toughening in block copolymers. This type of layering appears only when the molecular weight of the blocks exceeds a critical value. For example, for the block copolymers of polystyrene and polybutadiene the critical molecular weight of the polystyrene fragments was found[83] to be 2500, and that of the polybutadiene fragments 6000. At lower molecular weights no micro-layering was detected, and the toughening effect of the rigid blocks was absent. Conversely, in mixtures of polymers layering occurs at much lower molecular weights: for example, in a mixture of polystyrene and polyisoprene layering is observed at a molecular weight of polystyrene of 500.[84]

Changes in structure of block copolymers of polystyrene and polybutadiene as a result of heat treatment have long been known.[85] Annealing at temperatures above the glass transition point of the rigid block leads to equilibration in only a few minutes, whereas many hours are needed to reach equilibrium at temperatures below the glass transition point of the rigid block, in spite of the high elasticity of the sample as a whole. At higher temperatures the intensity of the low-angle X-ray reflexions decreases, and still further increase in temperature suppresses the reflexions completely, but the low-angle diffraction properties are fully restored by lowering the temperature.[86] Thus heating causes a gradual suppression of the phase structure of the block copolymer and a transition into a homogeneous system. However, the size of the transition regions stays almost constant during heating, i.e. an intermixing of different blocks appears to take place. This process is reversible, and micro-layering is restored by cooling.

Thus at high temperatures a transition from a two-phase to a single-phase structure may take place. In the case of block copolymers of polystyrene and polybutadiene this transition is observed[87] at 140–150 °C. The rheological properties of the samples change at the same time: non-linear mechanical behaviour is replaced by a linear behaviour, with a substantial decrease in elasticity. The existence of a transition from non-linear to linear rheological behaviour at 150 °C, caused by the breakdown of a multi-phase structure and the formation of a single-phase structure, has been confirmed calorimetrically.[88]

The specific structure of the block copolymers and the type of aggregation of the blocks allow us to produce some unusual structures in these polymers by special methods. Thus if samples of block copolymers of polystyrene and polybutadiene are oriented and then annealed at a relatively high temperature (for example, at 155 °C for 18 h) an oriented macroscopic lattice is formed: this is suggested by low-angle X-ray diffraction and electron microscopy measurements,[89] which detected the formation of a macroscopic lattice of polybutadiene cylinders in a polystyrene matrix. This type of micro-phase separation influences the properties of the system.

Different methods of analysis of the structure of oriented block copolymers[90] have indicated the possibility of a mesomorphic structure for block copolymers in this state. The rigid domains can form either cylinders or lamellae, and within the domains the macromolecules can be coiled in a bundle, as shown by measurements of double refraction and i.r. dichroism.

Previous studies of the orientation of the structure elements in block copolymers by low-angle X-ray diffraction,

electron microscopy, and other methods have been supplemented[91] by a study of the depolarisation of scattered light (in the polystyrene/polyisoprene block copolymer system). The method can detect small changes caused by the orientation of structure elements in block copolymers.

We shall now turn to an analysis of the structure and of the mechanical properties of block copolymers. The early work[92-94] was aimed mainly at the behaviour of these materials under uniaxial elongation conditions; hysteresis phenomena were also examined. The optico-mechanical properties of block copolymers[95] have been studied, and a detailed study of relaxation processes in these materials has been reported.[96] In both these investigations[95,96] an attempt was made to interpret the results by the classical theory of high elasticity, the rigid polystyrene domains being treated as filler particles incorporated in a polybutadiene matrix and not effectively involved in the relaxation processes. Some attempts to apply the classical theory of high elasticity to these systems were successful, but the general validity of the theory has not been confirmed.

The mechanical properties of block copolymers are influenced by the type of solvent used to prepare film samples for measurement. The influence of the properties of the solvent (measured by the solubility parameter) on the tensile curves and on the limiting strength and deformation properties is discussed in Ref. 97. A marked effect of the thermodynamic affinity of the solvent for each of the blocks on the shape of the tensile curves was noted in samples of polystyrene/polybutadiene block copolymers of different composition. As was subsequently established, the properties of the solvent from which the films are cast determine the hysteresis of the mechanical properties.[98]

The effect of the type of solvent on the structure and mechanical properties of block copolymers of polystyrene with hydrogenated polyisoprene or hydrogenated polybutadiene has been studied extensively.[99] Increasing the affinity of the solvent for the polystyrene fragments causes a transition from spherical to cylindrical polystyrene domains, though a lamellar structure is also possible for the block copolymers of polystyrene with hydrogenated polybutadiene. Increasing the anisotropy of the rigid domains causes a transition from samples with properties similar to those of unfilled rubber to materials showing induced elasticity.

The fracture mechanism in styrene–diene ternary block copolymers depends on the conditions used in their preparation and orientation. It has been shown[100] that crack propagation under tension at right angles to the axis of the flexible fragments causes brittle fracture, whereas if the cracks are propagated in a direction parallel to the bundles of flexible fragments plastic fracture is observed. The fracture surface is different in the two cases.

The block structure of these copolymers (as opposed to the random distribution of the units in conventional copolymers) affects not only the limiting mechanical and other properties of the material but also its compressibility. For example, for identical compositions the specific volume and compressibility of the random copolymer of styrene and butadiene are greater than those of the block copolymer of polystyrene and polybutadiene.[101]

The presence of rigid domains in block copolymers suggests a model in which flexible chains are held between neighbouring pairs of rigid domains: this model shows neither deformation nor swelling.[102] It can be used to calculate the elastic modulus, the partial molar free energy of swelling, and the dependence of the stress on the strain. When examining the effect of the structure on the mechanical properties of block copolymers it is important to allow for the polydispersivity of the sample and its influence on these properties.

By fractionating samples of block copolymers of polystyrene and polybutadiene it was shown[103] that the elastic modulus calculated from the stress–strain plot is slightly higher for the narrow fractions than for the original samples.

The prospective applications made possible by the control of the properties of ternary block copolymers through changes in the chemical structure of the blocks are demonstrated in Ref. 104. In this work polymers based on styrene, α-methylstyrene, ethylene sulphide, etc. were used as the rigid end blocks, whereas the flexible central blocks were polymers based on isoprene, butadiene, hexamethylenetrisiloxane, etc. In block copolymers of polystyrene and polybutadiene an increase in concentration of polystyrene was found to increase the strength of the material, but not in block copolymers of polystyrene with polyisoprene. In general good strength is achieved by using a high enough molecular weight for the end (polystyrene) blocks: according to these authors[104] it should be greater than 6000.

Hydrogenation of block copolymers based on polystyrene and polybutadiene causes a change in the mechanical properties of the samples: an increase in elastic modulus, etc.[105] Block copolymers show changes in properties also under the influence of radiation, though these changes reflect the special structural features of the materials.[106] Increasing the concentration of polybutadiene fragments in the block copolymer makes the properties more sensitive to the radiation: the strength decreases, the hardness and stiffness increase, the thermal diffusivity increases, and the swelling tendency is affected. All these effects arise from the cross-linking of the polybutadiene blocks, which thus cease to be inert fillers and become active sites in the network.

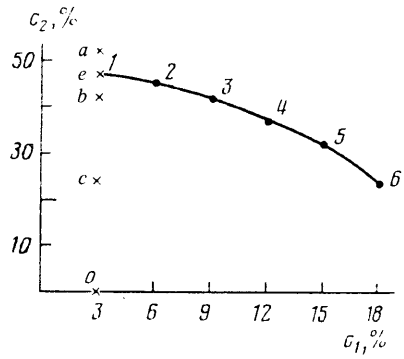

Figure 1. Nephelometric titration curve for solutions of the block copolymer of polystyrene and polybutadiene in benzene against iso-octane: c_1 is the concentration of polymer, c_2 is the concentration of iso-octane, *1–6* are compositions on the nephelometric titration curve, the crosses denote the compositions used to prepare the samples for these experiments.[115]

We should again stress the fact that changes in the structure of block copolymers produced by varying the type of solvent during film preparation can result in changes in properties as substantial as those produced by varying the chemical structure of the copolymer. The shape of the tensile curves is affected not only by the composition of the

block copolymer but also by the thermodynamic properties of the solvent from which the sample is cast.[107,108] Controlling the structure of the block copolymer by varying the composition of the solvent is a convenient method of minimising internal stresses in coatings.[109]

In studies of the adhesion strength of these materials the properties of the surface layers of block copolymers have been monitored by the changes in resonance frequency of a quartz prism on which a layer of polymer had been deposited. According to these experiments[110] an increase in the concentration of polystyrene decreases the number of bonds to the substrate and lowers the adhesive strength.

So far our discussion has been confined to the effect of the structure of the block copolymers on the limiting strength and deformation properties. Let us now examine the relaxation properties of block copolymers under static conditions.

The structure of block copolymers makes these materials specially suitable for studies of the mechanical properties of two-phase systems. The effects of physical ageing on the relaxation properties of block copolymers of polystyrene and polybutadiene have been studied, and the dependence of the time to reach equilibrium on the duration of the annealing treatment has been determined.[111,112] The prediction of the behaviour of polymers under creep conditions from stress relaxation data has been demonstrated[113] for block copolymers of polystyrene and polybutadiene. The strongly non-linear viscoelastic behaviour of these materials is noteworthy.

The most detailed studies of the relaxation properties of block copolymers of polystyrene and polybutadiene are reported in Refs.114 and 115. The samples used in this work contained between 30 and 62% of polystyrene, and they had a wide range of properties. As was stated above, these block copolymers are a convenient medium for the study of the effect of polymer structure on the viscoelastic behaviour of the sample. The structure of these copolymers can be easily changed during the preparation of films from solutions by varying the composition of the solvent, which can be either a mixture of a solvent and a selective precipitant for one of the blocks or a homogeneous solvent with different solubility parameters for the two blocks. The solvent most commonly used in this work is benzene,[114,115] while iso-octane has been used as a selective precipitant for polystyrene blocks. A nephelometric titration curve was used to determine the composition of the solvent medium (Fig.1). The region below the curve corresponds to true solutions, the region above the curve to dispersions. The points in Fig.1 give the composition of the solvent medium used in the preparation of samples of block copolymer film.

The stress relaxation curves for block copolymer films prepared from solvent media of different composition were also determined in the same investigation.[114,115] The measurements were made in the strain region between 5 and 600% at temperatures between −30 and +80 °C. It was found that the addition of a selective precipitant for polystyrene

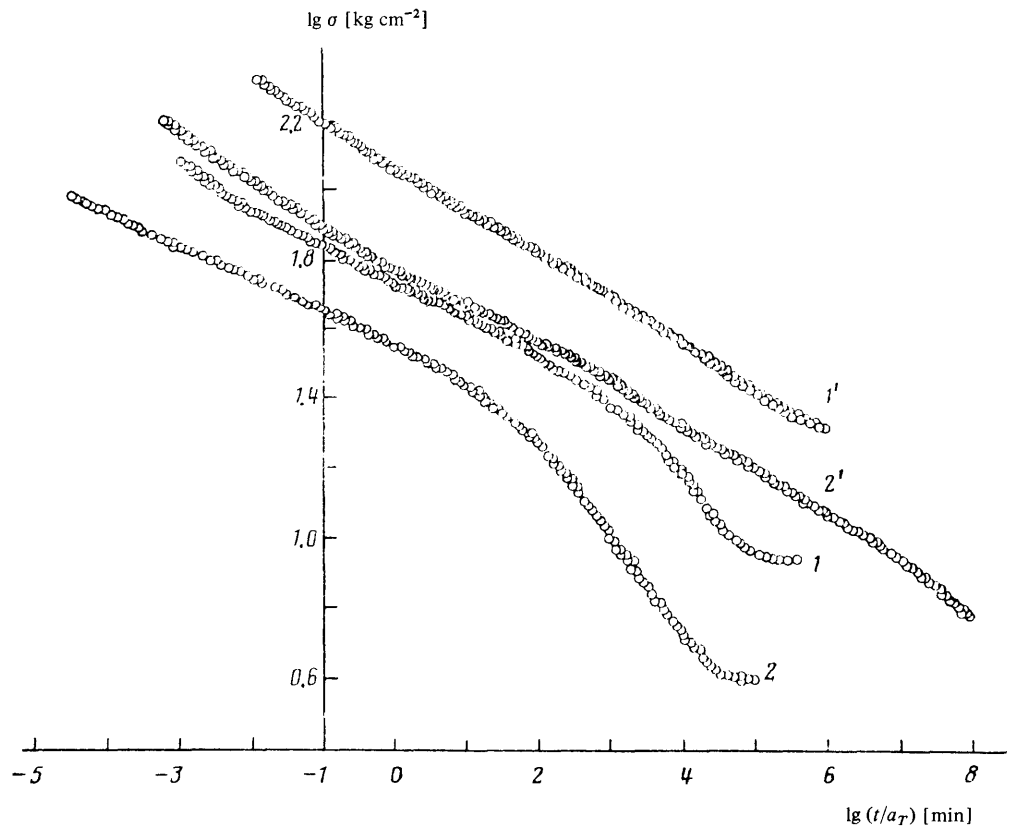

Figure 2. Generalised relaxation curves for deformations by 10% (*1*, *2*) and by 400% (*1'*, *2'*): *1*) and *1'*) are for samples formed from solution, *2*) and *2'*) for samples formed from a dispersion[115] (a_T is the shift factor).

blocks accelerates the stress relaxation, and at the same time the equilibrium elastic modulus is lowered, the effects being observed at all temperatures. Irrespective of the initial concentration of the block copolymer in the mixture of solvent and precipitant, the films formed from a true solution show a much greater equilibrium elastic modulus and relaxation time than films prepared from dispersions.[115] A sharp decrease in equilibrium modulus and in relaxation time can be induced by forming the film from a mixture of solvent and precipitant of composition close to the phase separation curve but on the true solution side.

Fig. 2 shows, as an example, the generalised relaxation curves for films prepared from a solution (point "0" in Fig. 1) and from a dispersion (point "a" in Fig. 1). The generalised curves were obtained by shifting the stress relaxation curves along the lg t axis. The generalised curves for samples prepared from dispersions are invariably found in the region of lower stresses than those for samples prepared from solutions. This may be due to coiling of the polystyrene blocks as a result of the addition of a selective precipitant, with formation of a compact structure which does not contribute so effectively to the relaxation process.

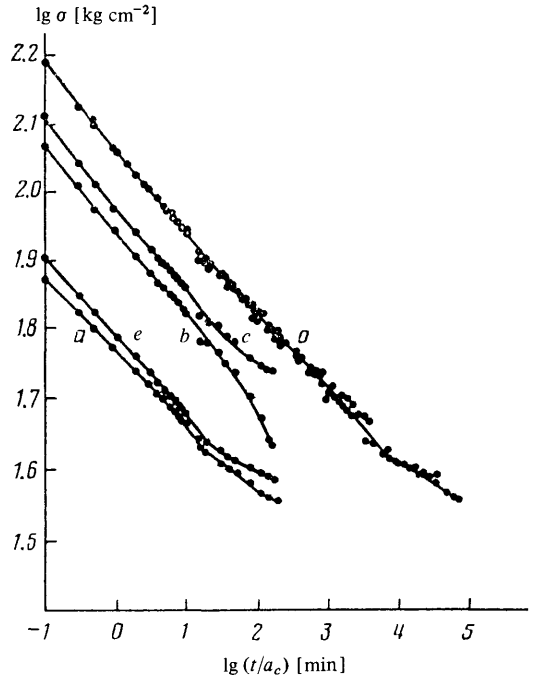

Figure 3. Initial and generalised stress relaxation curves for films prepared at different concentrations of the selective precipitant, ε = 400%, curves numbered as in Fig. 1.[115]

This conclusion is consistent also with the relaxation curves for samples prepared from media with different concentrations of the selective precipitant. These curves can be reduced to a single curve, shown in Fig. 3, by a shift along the lg t axis. In this case the reduced parameter is not the temperature but the concentration of selective precipitant. The plot of the logarithm of the shift factor lg a_c against $(c - c_0)$, where c is the concentration of the selective precipitant and c_0 is the concentration used in the reduction, has the characteristic shape shown in Fig. 4, indicating the presence of a narrow range of concentrations of the precipitant in which the relaxation processes are strongly accelerated. In the case of this particular block copolymer (containing 62% of polystyrene) the critical concentration of precipitant is 45%.

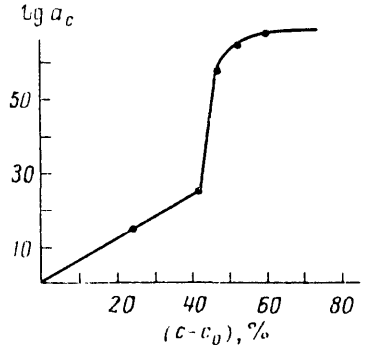

Figure 4. Plot of lg a_c against $(c - c_0)$.[115]

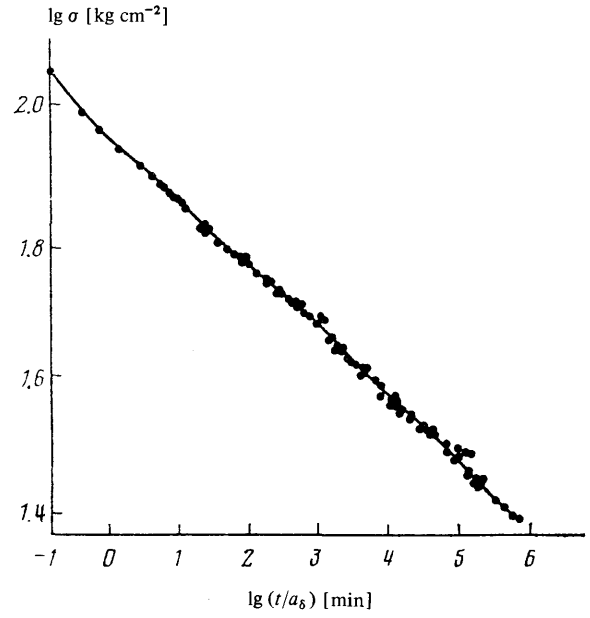

Figure 5. Generalised stress relaxation curve for samples formed from different solvents (ε = 10%).[115]

The relaxation properties of a block copolymer can also be controlled by preparing samples from solvents with different solubility parameters δ. The initial and the generalised relaxation curves for samples prepared from solvents with different values of δ are shown in Fig. 5. Increasing the δ value of the solvent to a value equal to or greater than the characteristic value for the polystyrene blocks causes a

marked increase in the relaxing and the equilibrium stresses. Hence by changing the solvent medium we can substantially affect the relaxation properties of block copolymers, and we can lower, or raise, the strength of the equilibrium stresses, i.e. we can control the degree of completion of the relaxation process.

To generalise this conclusion the relaxation curves (corresponding to different values of δ) were shifted along the $\lg t$ axis to merge into the previously obtained generalised curve (see Fig. 5). The dependence of the shift factor $\lg a_\delta$ on $(\delta_0 - \delta)$ is shown in Fig. 6, where δ_0 is the solubility parameter for dioxan. As the solubility parameter δ increases, the shift factor decreases.

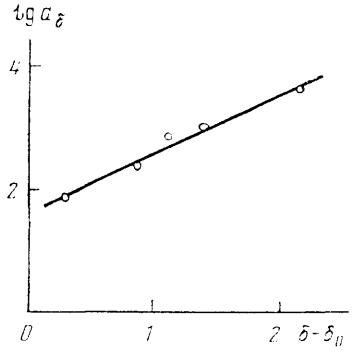

Figure 6. Plot of the shift factor $\lg a_\delta$ against $(\delta - \delta_0)$.[115]

Thus the study[114,115] of the mechanical (relaxation) behaviour of block copolymers has revealed extensive prospects for controlling the relaxation properties of these materials, depending on the previous history of the formation of the film samples from solution. Obviously, studies of the relaxation properties allow us to reach definite conclusions as to the activity of the rigid particles formed by the polystyrene domains which act as a strength-enhancing filler.

The durability and creep properties of polystyrene and polybutadiene block copolymers under conditions of uniaxial tension are discussed in several papers.[116–118] Both reversible and irreversible deformation is observed in the creep process, and the durability is decreased by an expression which is characteristic of rubber. The activation energies of the fracture, creep, and viscous flow processes are identical, suggesting that all three processes take place by the same mechanism (involving the breakdown of the domain structure).

The relaxation properties of block copolymers have been studied also in melts. The relaxation of the stresses in a melt of the block copolymer of polystyrene and polybutadiene after stopping the deformation has been measured.[119] It was found that the stress decays not to zero (as in linear elastomers based on homopolymers) but to some final value which is greater, the shorter the deformation time of the melt. Hence the evidence for a network structure is present also in the melt. The existence of a final stress was detected also in a study[120] of stress relaxation in block copolymers at relatively high temperatures. This behaviour of block copolymers under conditions of stress relaxation in the melt is attributed to the formation of star-shaped structures after the initial breakdown of the domain structure originally present in the melt by the action of the shear deformations.[121]

The relaxation properties of block copolymers under conditions of dynamic mechanical interaction have been studied in depth. We shall not dwell on any particular investigation, but we shall merely point out that in addition to the strengthening effect of the rigid blocks we find two maxima in the temperature dependence of the slope of the mechanical losses[122–125] for many of these copolymers. There is also a change in the temperature dependence of the shift factor, detected by applying the temperature–time superposition principle to the analysis of the experimental results.[126,127] Deviations from the usual dependence, described by the Williams–Landel–Ferry equation, are observed at temperatures above the glass transition temperature of the polystyrene phase of the block copolymer of polystyrene and polybutadiene.

As in the case of the parameters of the static mechanical properties, the type of solvent used in the preparation of the sample has an important effect on the results of dynamic mechanical tests. Thus the dependence of the dynamic mechanical properties of films of a ternary block copolymer of polystyrene, polyethylene, and polybutene on the solubility parameter of the solvent used in casting the film has been studied.[128] Because of the better dispersion of the polystyrene domains and of the possibility of contacts between these domains the use of a good solvent causes a large increase in the accumulation modulus of the system. If a poor solvent is used the polystyrene blocks are isolated and cannot form mutual contacts: as a result, the relaxation of the stresses is rapid, and the accumulation modulus decreases.

The structure of block copolymers and the tendency of their fragments to aggregate lead to an unusual effect of the rate (or frequency) of the mechanical interaction and of the temperature, and also of the magnitude of the mechanical stress, on the dynamic mechanical properties of the samples. Thus at low shear rates the block copolymers of polystyrene and polybutadiene behave as dispersed systems showing marked thixotropy.[129] At high shear rates the viscoelastic behaviour of these systems is determined mainly by the polybutadiene matrix. Similar effects are observed at high shear stresses. The viscoelastic properties of block copolymers of polystyrene and polybutadiene at low temperatures are similar to those of rubber. At high temperatures (above the glass transition temperature of the polystyrene fragments) even low-amplitude deformations produce a small amount of viscous flow in spite of the substantial residual aggregation of the polystyrene blocks mentioned above.

A similar study by a different method is reported in Ref. 130. The samples were block copolymers of polystyrene and polybutadiene in which the molecular weight of the polystyrene blocks was much lower than that of the polybutadiene fragments. Measurements of the dynamic shear modulus and of the dynamic viscosity over a wide range of temperature showed that the temperature–time superposition principle applies in these systems, the temperature dependence of the dynamic viscosity dropping sharply at 142 °C (in the low-frequency region). At high frequencies a different behaviour is observed. From these results the authors concluded[130] that a critical temperature exists for block copolymers at which the domains formed by the rigid blocks begin to collapse and the material becomes more homogeneous.

Detailed studies of the dynamic mechanical properties of ternary block copolymers of the ABA type of different chemical structure have been reported.[131] The end blocks

were polystyrene, and the central block was polybutadiene, polyisoprene, polydimethylsiloxane, etc. Most of the work was carried out at temperatures above the glass transition temperatures of both blocks. The main difference between the mechanical behaviour of the block copolymers and of the homopolymers is a higher value of the dynamic viscosity, due to the aggregation of the polystyrene domains. This aggregation is found even at temperatures above the glass transition temperature of polystyrene. The aggregation is less evident in block copolymers containing polyisoprene as the central block. An analysis of the dynamic mechanical behaviour of these systems has shown that differences between the solubility parameter for the central block and for the end blocks play a major role.

The dynamic mechanical behaviour of block copolymers of polystyrene with polybutadiene, hydrogenated polybutadiene, polyisoprene, hydrogenated polyisoprene, and polydimethylsiloxane has been fully analysed.[132] Both binary and ternary block copolymers were studied. The work was aimed mainly[132] at demonstrating the influence of the molecular weight distribution of the block copolymers on the relaxation transitions. Two relaxation transitions were observed, corresponding to the devitrification of the two phases, and the temperatures of these transitions were shown to depend on the type of molecular weight distribution. The high-temperature transition takes place at a lower temperature than in homo-polystyrene.

The relaxation properties of block copolymers have been studied not only by dynamic mechanical methods but also by various other physical methods: dielectric, i.r. spectroscopic, etc. Careful attention is currently paid in studies of the dielectric properties of polymers to processes associated with the boundaries of structural formations. In this respect block copolymers are specially interesting, because they are micro-heterogeneous systems. A theoretical and experimental study[133] of dielectric relaxation has shown that at low frequencies the experiment is adequately described by the theory, though allowance is needed for both the bulk concentration of components and the type of supermolecular structure in the calculation of the dielectric parameters.

Transitions resulting from molecular mobility in the interphase regions have also been detected by the positron annihilation method.[134]

Transition in block copolymers and in their solutions are reliably observed ultrasonically, using the form of the adsorption and the velocity of the ultrasound.[135] Two transitions, corresponding to the devitrification of the polybutadiene and polystyrene phases, were observed in the initial block copolymers. The same transitions were observed in the swelled samples, but in this case the transitions were shifted towards lower temperatures. In solutions high-frequency attenuation is enhanced, due to the presence of micellar formations. The study of the acoustic properties of block copolymers of polystyrene and polybutadiene has shown[135] that the glass transition temperature (which is related to the polybutadiene phase) depends on the concentration of the polystyrene component and on the method of preparation of the sample. Extruded samples show a characteristic increase in glass transition temperature.

The relaxation properties of block copolymers have also been studied by thermally stimulated current and thermoluminescence methods.[137]

In general, each of the components of a block copolymer can influence the glass transition temperature of the other component, which depends on the length of the block. An analysis of this effect[138] has clarified the dependence of the glass transition temperature of the polystyrene component on the length of the polystyrene block. The second components of the block copolymers were polyisoprene and polydimethylsiloxane blocks, whose compatibilities with polystyrene are different. Nevertheless the decrease in glass transition temperature caused by a decrease in the length of the polystyrene block was about the same in the two cases. This suggests that the change in glass transition temperature is not always determined by the level of compatibility and may also depend on other factors (for example, internal stresses).

The relaxation properties of block copolymers have also been studied (as was mentioned above) by i.r. spectroscopy.[139] The micro-heterogeneous structure of the block copolymers results in a non-monotonic decrease in optical density with increase in temperature.

A detailed analysis of relaxation transitions in block copolymers of polystyrene and polybutadiene has been carried out by a dilatometric method.[140] The character of the transitions was found to depend not only on the molecular weight and composition of the block copolymer but also on the previous thermal history of the sample. Thus in samples containing 44 wt.% of polystyrene the transitions were observed at 0.87 T_g and (0.92–0.95)T_g. Heating the samples to 40 °C causes these transitions to disappear, and annealing at 55 °C induces a new transition at $T = 0.90T_g$. All these effects have been ascribed[140] to ordering of the inter-phase regions during annealing.

It is interesting to compare the dilatometric characteristics of block copolymers with those of mechanical mixtures of homopolymers having the same composition.[141] Whereas several transitions are detected at temperatures below the glass transition temperature of polystyrene, no relaxation processes are observed in mixtures of polystyrene and polybutadiene.

Several papers discuss the rheological behaviour of block copolymers, which is important for optimising the technological processing of these materials. The special rheological behaviour of block copolymers is ascribed[142] to the formation of a stable physical network and to the possibility of transition to the highly elastic state at high shear rates (of course, this refers to a melt of the block copolymer at high temperature). During the technological treatment of block copolymers of the SKS type, the only changes are a slight swelling and a small shrinkage.

The rheological properties of ternary block copolymers of polystyrene and polybutadiene have been compared with those of polybutadiene rubber.[143] The most significant result was that the block copolymer shows a non-linear dependence of the logarithm of the viscosity on the reciprocal temperature, which cannot be described by the conventional relations which apply to homopolymers.

The rheological behaviour of ternary block copolymers has been described by a model[144] in which the interfacial layer between the matrix and the domains embedded in it plays the main role in controlling the rheological properties. The effect of structure on non-Newtonian flow, phase inversion, etc. can be described by introducing three segmental friction coefficients.

The rheological behaviour in the pre-stationary region of the deformation of block copolymers of polystyrene and polybutadiene has been studied.[145] These systems are characterised by an anomalous dependence of the limiting shear strength on the shear rate: under these conditions an important role is played by orientation effects.

Considerable effort is being devoted to the development of micro- and macroheterogeneous systems free from the brittleness found in the homopolymers which form the rigid domains in block copolymers. A recent review[146]

of this topic discusses, in addition to the traditional methods of preparing block copolymers and their mixtures with homopolymers, some original approaches such as polymerisation of the monomer from one of the blocks in a solution of the complete block copolymer. Of course, this method applies to the formation of composite materials, which can also be prepared by other methods.

As was stated above, block copolymers offer very attractive possibilities of controlling the properties of synthetic materials. Even more important prospects of controlling the structure and properties of these materials are created by mixing block copolymers with homopolymers of various structures. Whereas in block copolymers we observe micro-phase separation of the system and phase inversion, in the case of mixtures of a block copolymer with homopolymers having the same structure as the fragments of the block copolymer we find both micro- and macro-layering.[147] The nature of the phase separation depends mainly on the difference in molecular weight between the homopolymer and the corresponding blocks, and also on the composition of the components of the mixture. If the molecular weight of the homopolymer is approximately equal to (or smaller than) the molecular weight of the corresponding block the homopolymer dissolves in the blocks of the copolymer. In the opposite case we observe macro-layering, and the homopolymer forms a separate phase, while the corresponding blocks of the copolymer distribute themselves at the boundary of this phase. In the first case (micro-heterogeneity) the specific impact viscosity stays low. The best result was obtained[147] for a micro-heterogeneous system in which the particles of the copolymer are dispersed in the polystyrene matrix.

As we have already pointed out, mixtures of block copolymers with homopolymers having a constitution analogous to that of the corresponding blocks are being intensively studied at present. The properties of these systems are sensitively dependent on the micro-domain structure of the block copolymers and on their deformation mechanism.[148] One possible mechanism is the formation of micro-cracks under tension in the rigid domains in the block copolymer (for example, in the polystyrene domains), which requires a large expenditure of energy. Another mechanism consists in the formation of a macroscopic neck in the rigid component of the block copolymer: this mechanism has been confirmed in samples with a micellar structure. A successful combination of a block copolymer and a homopolymer should produce a system with impact-resisting and other useful properties. Thus the rheological behaviour of mixtures of polystyrene and ternary block copolymers of polystyrene and polybutadiene under shear conditions is typical of mixtures of incompatible polymers, the addition of a small amount of the block copolymer to the polystyrene causing an increase in the viscosity and the elasticity of the melt.[149]

The structure and the dynamic mechanical properties of mixtures consisting of the normal block copolymer of polystyrene and polybutadiene (SBS type) and of a branched block copolymer have been studied.[150] The mixtures were prepared in a way which kept the concentration of polystyrene constant (75%) but allowed the block length to be varied. The structure of the samples can be controlled during preparation so as to vary not only the mechanical properties and their anisotropy, but also the glass transition temperature of the rubber-like component embedded in the polystyrene matrix. In general the use of mixtures of block copolymers offers very wide prospects of controlling their structure: samples containing structure elements varying from spherical to rod-like have been obtained in this way.

Macro-heterogeneous compositions based on block copolymers of polystyrene and polybutadiene of the SBS type and containing prescribed amounts of polystyrene as a filler can be prepared by the pressure casting method.[151] Optical and microscopic studies have shown that the addition of polystyrene leads to phase layering of the system. Composite materials based on block copolymers are conveniently prepared by using rollers or rubber mixers. Changes in composites based on thermoelastoplastics and polystyrene have been studied by a thermomechanical method and by hydrostatic weighing.[152]

Ternary block copolymers have been mixed with binary block copolymers in order to control their physical and mechanical properties.[153]

Composite materials can also be prepared by adding various fillers to block copolymers (for example, technical carbon). The effective density of nodes in the three-dimensional network of block copolymers of polystyrene and polybutadiene has been shown to increase with the concentration of technical carbon added to the block copolymer.[154] Increasing the dispersion of the filler has the same effect.

Block copolymers have been used to prepare vulcanisates by cross-linking hexachloro-*p*-xylene in the presence of metal oxides.[155]. The presence of these oxides allows the formation of coordination and adsorption bonds, which raise the strength of the vulcanisates. The relaxation properties of these materials have also been studied,[155] and shown to be controllable through changes in the characteristics of the bonds.

We shall conclude this discussion by reviewing the work on structural changes in block copolymers during deformation. Both direct structural methods and thermodynamic approaches have been used in this analysis.

A detailed study of the structural changes accompanying the deformation of block copolymers of polystyrene and polybutadiene is reported in Ref. 156. In the first elongation cycle the dependence of the stress on the deformation has the characteristic shape found in glassy polymers (the concentration of polystyrene was 48%). In a repeated elongation cycle the stress–strain relationship is typical of elastomers. The reason for these changes is that the first elongation causes breakdown of the initial lamellar structure to give small particles, so that the sample is converted into a polybutadiene matrix filled with dispersed particles. After a rest period the sample tends to revert to its initial structure, and heat treatment at 59 °C (which is well below the glass transition temperature of polystyrene) restores the initial structure almost completely. This effect suggests[156] the presence of a substantial inter-phase layer containing both polystyrene and polybutadiene blocks: this structure could cause a decrease in the glass transition temperature of polystyrene. However, in the absence of dynamic mechanical data the suggested mechanism[156] can only be tentative.

Electron microscopy and low-angle X-ray diffraction methods have been used to study the structural changes accompanying the transition from the "hard" to the rubbery state during mechanical elongation of block copolymers of polystyrene and polybutadiene and of their mixtures with polystyrene.[157–159] The results are similar to those discussed above: regular deformation of the lamellae is observed in the initial stages of elongation (up to 5%), then the lamellae undergo shear, fracture, reorientation, and collapse successively, and in the last stages of collapse a structure with polystyrene domains uniformly distributed in the polybutadiene matrix is produced.

A similar result was obtained in a study of the deformability of block copolymers of polystyrene and

polybutadiene containing different amounts of polystyrene.[160] The polybutadiene blocks contained fragments with *cis*- and *trans*- structures. The breakdown of the domain structure of the block copolymer and its dispersion in the polybutadiene matrix were again observed; annealing restored the initial structure and properties.

The break-up of the cylindrical domain structure formed by polystyrene blocks is observed most clearly during elongation of the block copolymers in the direction of the cylinder axis.[161] The same behaviour is observed in rheological studies.[161] In the presence of a small mechanical stress the domain structure of the block copolymer is preserved, but above some critical stress the giant networks formed by the domains begin to collapse. This produces a break in the plot of shear stress against shear rate. When the domain structure is fully broken down the viscosity of the block copolymer is described by the normal flow curves, and the temperature dependence of the viscosity by the Williams–Landel–Ferry equation.

The simultaneous application of small-amplitude dynamic deformations and large static deformations produces a mechanical loss peak at the point where the initial structure of the block copolymer is broken down by the static deformation.[163] Under these conditions the height of the peak increases with time, because the breakdown of the initial structure affects increasingly deep layers. The destruction of the initial structure of the block copolymer is accompanied by the formation of an oriented structure as a result of the development of large highly elastic deformations in the polybutadiene matrix.[164]

The deformation behaviour of block copolymers of polystyrene and polybutadiene (SBS type) has been studied[165] with allowance for the anisotropy of the structure of the material. Samples having a structure of the "single crystal" type were studied, i.e. samples in which the cylinders consisting of polystyrene domains were packed in a parallel arrangement in the polybutadiene matrix. As a result, the deformation behaviour in extension was different in directions parallel to and perpendicular to the cylinder axes. Under extension at right angles to the cylinder axes the cylinders (being hexagonally close packed) undergo affine deformations, like the sample as a whole. This deformation is reversible, but when it exceeds 10% we observe a well defined irreversibility attributed to the formation and development of cracks in the sample. In parallel deformation the fluidity limit is reached at low elongations, and the Mullins–Patrikeev effect is clearly shown. After a period of rest (especially with annealing) the sample becomes more elastic, and the effect can be explained by the dispersion of the cylinders after the first elongation and their re-establishment after the rest period. Thus the system displays thixotropic properties.

Structural changes during the deformation of isotropic and of oriented polymers have been compared.[166] In oriented samples, having an initial structure of the single crystal type, deformation in a direction perpendicular to the cylinder axes initially distorts the crystalline arrangement and then produces bends in the crystal (at the weakest points). The crystals (in the shape of a flat zig-zag) are deformed at the bends during subsequent extension. On the other hand if the deformation is applied in a direction parallel to the cylinder axes it causes the cylinders to break into residues about 1000 Å long. Under these conditions, and for small elongations, the orientation of the initial structure elements (for example, the cylinders) is retained, since the elongation is achieved by the deformation of the highly elastic matrix.[167]

The detailed thermodynamics of the deformation and fracture processes of block copolymers of polystyrene and polybutadiene have been investigated for systems containing 40–50% of the polystyrene phase, and the special features of the thixotropic processes in the solid phase, whose rate is strongly temperature-dependent, have been studied.[168–171] An analysis of the energy balance of the softening processes using a high-precision calorimeter showed that the softening caused by deformation depends on the break-up of the polystyrene phase, especially during the initial stages of the process, and that the process is accompanied by an increase in the internal energy of the sample. During the thixotropic recovery period the stored energy is dissipated, and the recovery process itself (as stated above) is strongly temperature-dependent: it goes to completion in a few seconds at 100 °C, as opposed to 5–10 days at room temperature.

The deformation calorimetry method has been used to show that at high deformations the increase in stress is due to the acceptance of the load by the polystyrene domains, and to the deformation of these domains, and not to the limited extensibility of the polybutadiene chains. On the whole, the morphology of the polystyrene phase is the main controlling factor in the deformation behaviour of block copolymers of polystyrene and polybutadiene.

The changes in lamellar structure caused by the elongation of block copolymers of polystyrene and polybutadiene, and their elimination by annealing, have been studied thermodynamically.[172] The thermodynamic properties of the materials were calculated theoretically by introducing an approximation[173] in which the space between the domains is assumed to be much narrower than the domains themselves. With this assumption the free energy could be calculated as the sum of the following quantities: the energy associated with the surface tension, the energy associated with the topology of the blocks at the interface, and the change in entropy. In this case the entropy decreases, since the samples should have a uniform density over the entire volume. By calculating the free energy of the system and minimising it a theoretical estimate of the periodicity and of the disposition of the domains could be obtained.

The influence of structure on various properties (hardness, strength, thermo-mechanical characteristics) has been studied with star-shaped block copolymers of polystyrene and polybutadiene.[174] The main effort was devoted to a comparison of the initial properties with those of deformed samples. As in other work it was found[174] that in the first experiment the star-shaped block copolymers exhibited the phenomenon of induced elasticity: the effect was more clearly marked than in linear thermoelastoplastics (20% higher than the Shore hardness). At the second deformation the polymer becomes more elastic, but its initial structure and properties can be restored by annealing. These phenomena are attributed[174] to the formation of an interfacial transition layer consisting of polystyrene bridges, which are broken during the first deformation cycle.

The properties of block copolymers have been studied[175] at relatively low temperatures and their structural transitions have been examined in depth.

Thus the main areas of research on the structure and properties of block copolymers in the solid state are the application of the latest physical methods for studying structures (low-angle X-ray diffraction, transmission electron microscopy, thermodynamic analysis, positron annihilation, ultrasonics, etc.), and also wide-ranging rheological studies covering large changes in temperature, stress, and deformation rate. Two series of papers on the latter topic deserve special mention. One series[116–118] deals

with the rheological behaviour of block copolymers under uniaxial elongation conditions. This work highlights the single mechanism common to fracture, creep, and viscous flow processes in block copolymers, involving the collapse of the initial domain structure. The other series of papers describes a study of the mechanical behaviour of these materials by deformation calorimetry, which has demonstrated the fundamental effect of the domains formed by the rigid blocks on the shape of the tensile curve.

To review the thermodynamic approaches to the analysis of block copolymer structures we must stress the problem of determining the parameters of the effective network by using the expressions of the classical theory of high elasticity. In principle the size of the fragment between the points of the network M_C can be determined if the equilibrium elastic modulus E_∞ is known. In the earlier work the quantity M_C had been found to coincide in many cases with the molecular weight of the flexible (for example, polybutadiene) blocks. It is important to establish the correct way of determining the equilibrium elastic modulus in the case of a block copolymer. We know that in lattices with chemically defined nodes the equilibrium stress (elastic modulus) can be determined from the stress relaxation curve, but the relaxation process should not only have gone to completion at the given temperature (for a given deformation) but the stress should also have been allowed to reach its equilibrium value after upward and downward temperature excursions. In block copolymers the nodes of the network are the domains formed by the rigid blocks, and an increase in temperature can cause softening of the nodes and substantial changes in the relaxing stress. Therefore the correct determination of the equilibrium stress in block copolymers remains an open problem, though experimental data convincingly demonstrate[114,115] the important influence of the rigid domains on the rheological properties and show that these domains do not act as an inert filler but take an active part in the formation of the set of relaxation properties of block copolymers, including those observed in studies by the swelling method.

IV. DETERMINATION OF THE STRUCTURE OF BLOCK COPOLYMERS BY THE SWELLING METHOD

The swelling (or sorption) method has been used to determine the structure of block copolymers in two variants. Firstly, the effective length of the flexible (for example, polybutadiene) blocks has been determined, and secondly the method has been used to study the structural changes accompanying the swelling, and the influence of the method of preparation and of the previous thermal history of the sample on its sorption characteristics.

Several procedurally important aspects must be included in the analysis of block copolymer structures by the sorption method.[176] The first is the dependence on the thickness of the sample of the diffusion coefficient D determined from sorption and desorption data. For example, the parameter D increases from 10^{-8} to 30×10^{-8} cm^2 s^{-1} as the thickness of a film of the block copolymer of polystyrene and polybutadiene is increased from 50 to 300 μm.[176] The second special feature is the dependence of D on the type of substrate used to prepare the film. Lastly, annealing of the sample also tends to increase the value of D.

There have been many attempts to determine the length of the elastic block from data on the swelling behaviour. In all this work swelling was allowed to take place in a solvent which is selective towards the elastic blocks. In some cases satisfactory agreement between calculated and experimental lengths of the elastic block (for example, polybutadiene) was obtained,[177,178] but in other cases the discrepancy was serious.[179–181]

The Flory–Huggins interaction parameters have been determined by sorption measurements for styrene–butadiene copolymers of different composition.[182] In these determinations, it is important to remember that the segmental mobility of the polybutadiene blocks in the copolymers is smaller than the chain mobility in the initial polybutadiene.[183] This is not surprising, since the transport process is obstructed by the polystyrene domains, which are impervious to the solvent vapour.

The changes in structure of ternary block copolymers during swelling and desorption, and the re-establishment of the initial structure by annealing, have been studied by the low-angle light scattering method.[184] Rods of the polystyrene blocks oriented at different angles retain their orientation during swelling in iso-octane, but changes are observed after evaporation of the solvent. This behaviour is characteristic of block copolymers of polystyrene and polybutadiene, but not of the analogous copolymers of polystyrene and polyisoprene.

The effect of the solvent used to cast the block copolymer samples on the sorption and desorption of *p*-aminoazobenzene has been studied. The differences in structure of the block copolymer resulting from changes in the type of solvent (for example, phase inversion) are reflected by changes in the diffusion coefficient and in the temperature dependence of the rate of desorption. The large increase in the rate of desorption at higher temperatures is attributed to devitrification of the polystyrene phase[185] because of the changes in the glass transition temperature of polystyrene as a function of the type of solvent used in the preparation of the film.

The properties of block copolymers of polystyrene and polybutadiene in film form depend on the substrate used in the preparation of the sample. This dependence is clearly seen in experiments on the sorption of cyclohexane vapour in film samples deposited on glass, Teflon, or mercury. The rate of approach to sorption equilibrium is determined by the type of substrate used. Films prepared on solid substrates develop internal stresses which are thought[186] to influence the packing density of the macromolecules and hence the diffusion coefficient. However, we should note that the mechanical stress itself can affect the diffusion coefficient through its influence on the relaxation time (see below).

In another paper from the same laboratory[187] the effect of the structure of block copolymers of polystyrene and polybutadiene on the sorption curves and on D is discussed for a sample containing 25% of polystyrene. The sorbate was iso-octane. The structure of the samples was varied by using different substrates (glass, mercury, Teflon) for film preparation, and also by varying the thickness of the films. The diffusion coefficient was found to depend on the size and on the number of the polystyrene domains in the block copolymer. Therefore the sorption experiments are an effective method for the analysis of the structural changes in block copolymers.

A detailed study[188] of the relaxation mechanism of the swelling of polymers, which determined the kinetics of the process, is relevant in this context. It is assumed that the diffusion of low-molecular liquids or vapours in polymers is determined not only by the penetration of the sorbate molecules into the pores of the polymer but also (and to a large extent) by conformational rearrangements of the macromolecules, i.e. by the relaxation phenomena which accompany the diffusion process. Under these conditions we observe degeneracy of the long relaxation times. The

suggestion that the swelling of polymers is related to conformational rearrangements in the macromolecules and to the degeneracy of long relaxation times was first put forward in Ref. 189. It has since been confirmed by calculations and experiments.[188]

The more recent work[188] is based on a mathematical model of the process in which the viscoelastic polymer medium responds to interactions with the sorbate molecules. The associated model of the viscoelastic body consists of two Aleksandrov–Lazurkin elements connected in parallel; this model was used in calculations of stress relaxation and creep processes for these materials.

The same workers[188] had previously introduced the concept of a time-dependent diffusion coefficient, and had obtained a solution of the differential equation for Fick's second law in which the diffusion coefficient is expressed in terms of Einstein's system of equations for the Brownian motion (which includes the velocity of the diffusing species). Having determined this velocity from the proposed model the authors[188] found the time dependence of the diffusion coefficient and used it to calculate the dependence of the mass of the diffusing species on time by the expression

$$\frac{M(t)}{M(\infty)} = A_1(1 - e^{-t/\theta_2^*}) + A_2(1 - e^{-t/\theta_4^*})$$

where θ_2^* and θ_4^* are the characteristic times of the relaxation, A_1 and A_2 are constants related to the parameter of the model, and $M(t)$ and $M(\infty)$ are the time-dependent and the final mass of the diffusing species respectively. Experimental data[188] for the block copolymer of polystyrene and polybutadiene are described reasonably well by this expression if two time lags are used. The calculated values of $M(t)$ are accurately consistent with the experimental kinetic sorption curves (Fig. 7). The formation of maxima and minima on the kinetic sorption curves was also analysed.[188] It was found that these mass oscillations can be ascribed to standing waves formed in the cylindrical cavity of a McBain balance at some pressures of vapour, the waves being diffuse rather than elastic in nature.

Other measurements of the sorption kinetics of the vapours of various liquids by block copolymers of polystyrene and polybutadiene have also been reported.[188] The equations were found to give an accurate description of the kinetics of the process, and the time lags determined from sorption data agreed reasonably well with the relaxation times obtained in independent stress relaxation experiments.

Relaxation experiments carried out in a medium of the sorbate[188] confirmed the assumption that the penetration of sorbate into the polymer causes degeneracy of the long relaxation times. All these results indicate that the relaxation mechanism associated with the swelling of the polymers is the main determining factor in the sorption process.

A statistical analysis of the behaviour of block copolymers during swelling, allowing for the conformation of the chains connecting the domains, has also been described.[190]

Thus the sorption process, which is accompanied by a large change in volume (i.e. by swelling), is closely bound to the relaxation processes involving conformational rearrangements of the macromolecules. These rearrangements are responsible

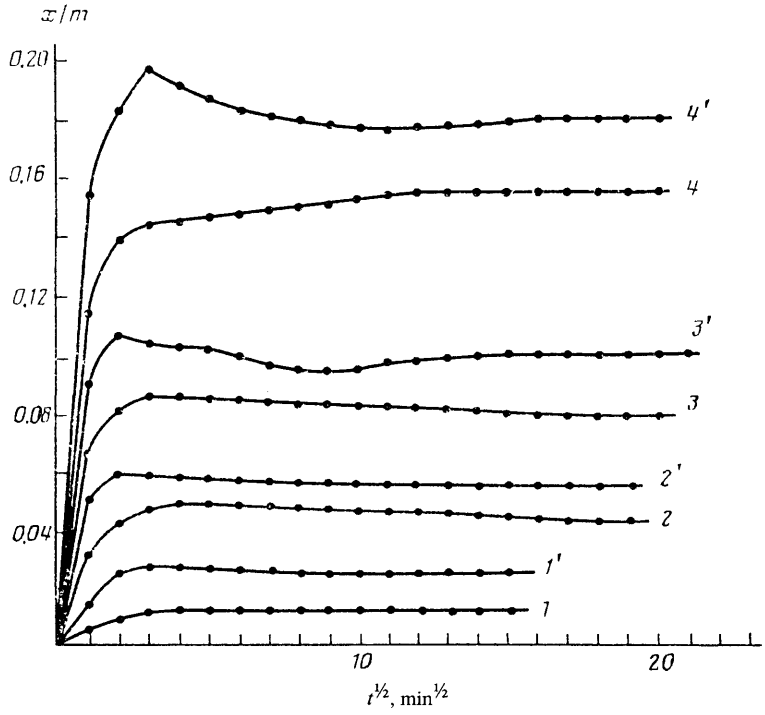

Figure 7. Kinetic curves for the sorption of iso-octane vapour on a block copolymer of polystyrene and polybutadiene containing 30% of polystyrene blocks. The ratio p/p_S is: *1*) and *1'*) 0.2, *2*) and *2'*) 0.4, *3*) and *3'*) 0.6, *4*) and *4'*) 0.8. Numbers without primes and with primes correspond to samples prepared from solution and from dispersion respectively[188] (x/m is the increase in weight of the sample caused by sorption, p/p_S is the relative vapour pressure of the solvent).

for the time-dependence of the diffusion coefficient. Allowing for this time-dependence gives an accurate description of the swelling kinetics and explains many other features of the process.

The Use of Lanthanide Shift Reagents in the Analysis of the Micro-structure of Polymers by NMR Spectroscopy

Yu.E.Shapiro

The principal results obtained by using lanthanide shift reagents (LSR) to analyse the micro-structure of polymer chains by ^{1}H and ^{13}C NMR spectroscopy have been examined. A short theoretical introduction to the LSR method has been given, and the magnetic properties of the lanthanides have been examined from the viewpoint of their possible use as LSR. Particular attention has been paid to the solution of the main problems in the structural analysis of polymer chains: the determination of stereoregularity and the nature of the alternation of the monomer units along a copolymer chain, and the investigation of the distribution of *cis*- and *trans*-units and the conformational mobility of homopolymer chains with and without polar groups. The bibliography contains 57 references.

I. INTRODUCTION. THE MICRO-STRUCTURE OF POLYMERS

The physicochemical properties of a polymer are determined chiefly by the structure of the repeat unit of the chain, but there are practically no ideal regular chains. Real polymers contain the most varied chain structural defects, which can produce significant changes in the properties of the polymer. Information on the distribution of defect units of different types along the chain provides a quantitative reflection of the micro-structure of the polymer.

High-resolution NMR now occupies a dominant position in the study of the micro-structure of polymer chains.[1-4] Because of the marked dependence of the electronic shielding of the nuclei on the chemical environment, the displacement of the signals in the NMR spectra takes place as a consequence of not only the alternation of chemically different monomer units but also the alternation of the relative configurations of successive identical monomer units containing pseudo-asymmetric carbon atoms. This makes it possible to use NMR spectroscopy to solve three types of problem: 1) the composition analysis of the distribution of monomer units along the chain, including the determination of the type of orientational connection "head to head", "head to tail", and "tail to tail"; 2) measurement of the degree of stereoregularity of the chain; and 3) conformational analysis, including the study of phase transformations (of the globule–coil type).

Experimental approaches to the analysis of the micro-structure of the chain are associated with the measurement of the relative concentration of different fragments and the sequence of monomer units from the integral intensities of their signals in the NMR spectrum. The maximum length of this fragment which can be identified by NMR at present does not exceed 8–9 monomer units.[5] Thus the experimental data describe directly the distribution of the units only in short sections of the chain. To analyse the distribution of the units along the entire chain of the macromolecule, it is necessary to assume that the processes controlling the growth of the chain during polymerisation are random in character and are described by Bernoulli or Markov statistics of first and second orders.[4]

The information provided by the NMR spectra of polymers (particularly ^{1}H NMR) is decreased, however, by the fact that the nuclei of aliphatic groups around which there are no electronegative atoms give signals with similar chemical shift values. Moreover, there are a whole range of fundamental physical factors[5] leading to broadening and overlap of the NMR signals from different structural sequences of the polymer chains. Thus the number of polymers which can be readily analysed is small, and to investigate the micro-structure of polymers it is usually necessary to use either shift reagents or NMR spectrometers with a superconducting magnet, or a combination of these methods.

II. LANTHANIDE SHIFT REAGENTS IN NMR SPECTROSCOPY. THEORY OF THE METHOD

The influence of paramagnetism on the characteristics of nuclear resonance was detected by Bloembergen and Dickinson.[6] The characteristic features of NMR in paramagnetic systems have been examined in detail in a large number of theoretical and experimental studies[7-10] and summarised in a number of reviews and monographs.[11-15]

The paramagnetic centres include lanthanide cations having an unpaired electron. The interaction between the unpaired electron and the nucleus whose magnetic resonance is being observed is revealed by an isotropic hyperfine shift of the signal,[7] a change in the nuclear relaxation times T_1 and T_2, and in the nuclear polarisation of the spins as a result of the Overhauser effect.[8] These changes give information on the electronic and geometric structure of the ligands joined to the paramagnetic centres.

1. The Paramagnetic Shift

The isotropic shift of the signals in the NMR spectra of paramagnetic substances is determined by the sum of two types of interaction: contact and pseudocontact.

A Fermi contact shift takes place if the spin density of the unpaired electron is delocalised and is transferred through a system of chemical bonds to the nucleus whose resonance is being observed. A contact shift obeys the Curie law and in the case of a one-spin state with an isotropic g-tensor is described by the equation:[6]

$$\frac{\Delta H}{H_0} = -\frac{Ag^2\beta^2}{g_N\beta_N}\cdot\frac{s(s+1)}{3kT}$$

where A is the hyperfine interaction constant, g_N the nuclear g-factor, β_N the nuclear magneton, H_0 the intensity of the external magnetic field, β the Bohr magneton, g the Landé

factor, k the Boltzmann constant, T the absolute temperature, and s the spin quantum number of the electron.

The contact shift of a signal is observed with the condition that $T_{1e}^{-1} \gg A$, where T_{1e} is the electronic spin–lattice relaxation time. Contact shifts are large for oxygen and nitrogen nuclei coordinated directly to the paramagnetic centre, and also for carbon chemically combined with these atoms. For more distant atoms, including all protons, the contact shifts are small, and the paramagnetic shifts observed in the NMR spectra have pseudocontact character.[11-15]

The pseudocontact shift is determined by the dipole–dipole interaction of the spins of the unpaired electron and the nucleus whose resonance is being observed; its magnitude depends on the electron configuration of the paramagnetic ion, the degree of magnetic anisotropy of the ligand field, and temperature.

The magnitude of the pseudocontact shift of a signal is inversely proportional to the cube of the distance from the paramagnetic centre to the nucleus being observed, and depends on angular factors. For axial symmetry of the complex, the pseudocontact shift is determined[7] by the McConnell–Robertson equation:

$$\frac{\Delta H}{H_0} = -\frac{\beta^2 s(s+1)}{9kT}(g_{\parallel}^2 - g_{\perp}^2)\frac{3\cos^2\theta - 1}{r^3} \qquad (2)$$

where $g_{\parallel}$ and $g_{\perp}$ are the components of the g-tensor of the magnetic anisotropy in directions parallel to and perpendicular to the principal axis of the complex, r the distance to the nucleus, and θ the angle between the radius vector $\boldsymbol{r}$ and the principal axis of the complex.

The dependence of the pseudocontact shift on the geometry of the complex,[7] described by Eqn.(2), makes it possible to assign the signals in the spectrum of a ligand with known structure or to solve the inverse problem, that is from the known assignment to obtain information on the geometry of a molecule.[10-16]

2. Paramagnetic Broadening

In the presence of a paramagnetic centre, broadening of the NMR signals is observed, due to the acceleration of the relaxation of the nuclear spin and the influence of exchange by molecules of the substrate between bound and free states. The main factor determining the width of the NMR signals of the substrate is the electronic spin–lattice relaxation time of the paramagnetic ion T_{1e}. For the complexes of ions with small values of $T_{1e} \ll \hbar/Ag\beta$ (Eu^{3+}, Pr^{3+}, Nd^{3+}), slight broadening is observed. Ions with large $T_{1e} \gg \hbar/Ag\beta$ (Gd^{3+}, d elements such as Mn^{2+}) give extensive broadening.[14]

The spin–lattice T_1 and spin–spin T_2 relaxation times for nuclei with spin 1/2 in the presence of a paramagnetic centre are determined by the Solomon–Bloembergen equations.[8] The first terms of these equations are due to dipole–dipole interaction, and depend on the distance r between the nucleus being observed and the paramagnetic centre. This interaction is determined by the correlation time of the dipole electron–nucleus interaction τ_c. The second terms, which do not depend on r, are characterised by the correlation time of the contact interaction τ_e. The relaxation times are influenced only by variable effects whose correlation times are of the same order of magnitude as the period of the Larmor precession of the nuclear spins.

The correlation times are determined by the expressions

$$\tau_c^{-1} = \tau_R^{-1} + \tau_S^{-1} + \tau_M^{-1} + \tau_D^{-1} \qquad (3)$$

$$\tau_e^{-1} = \tau_S^{-1} + \tau_M^{-1} \qquad (4)$$

where τ_R, τ_S, τ_M, and τ_D are the correlation times corresponding to rotational motion, relaxation of the electron spin, and chemical and diffusion exchange respectively.

3. The Magnetic Properties of the Lanthanides and Their Use as Shift Reagents

Lanthanides have short electronic spin relaxation times $\tau_S \cong 10^{-12}$–10^{-13} s at 300 K. Exceptions are provided by ions with the $4f^7$ electron configuration (Gd^{3+}, Eu^{3+}), which have long times τ_S ($\tau_S \cong 10^{-10}$ s for Gd^{3+}). The unique position of Gd^{3+} among the lanthanides is related to the fact that its ground state is $^8S_{7/2}$, $L = 0$, and the magnitude of the angular momentum is determined entirely by the spin. This state does not interact with an electric field, so that the rate of relaxation of the electron spin decreases.

Thus the lanthanides, except Gd^{3+} and Eu^{3+}, should have little influence on the magnetic resonance line width, if chemical exchange is sufficiently rapid, and they can be used as shift reagents. Gadolinium, like the ions of d elements, is a relaxation (broadening) reagent. The action of Eu^{3+} as a shift reagent is due to the displacement of the ground and excited states.

The theoretical calculation of the magnitude of pseudocontact shifts brought about by the lanthanides has been described.[9]

The correct interpretation of the data obtained using lanthanide shift reagents (LSR) also gives complete pictures of the structure of compounds in solution, which can only be compared with X-ray diffraction data for determining crystal structures. The LSR most widely used as paramagnetic probes are europium and praseodymium salts and their complexes with 2,2,6,6-tetramethylheptan-3,5-dione (dpm), 1,1,1,2,2,3,3-heptafluoro-7,7-dimethyloctan-4,6-dione (fod), and d-camphor. The salts are used in polar solvents. In most known cases, europium salts displace the signals towards strong fields, and praseodymium salts towards weak fields.[16] In non-polar solvents, complexes with the above ligands, lanthanide tris(β-diketonates), are used, for example $Eu(fod)_3$, $Pr(dpm)_3$; europium β-diketonates usually displace NMR signals in the spectra of substrates towards weak fields, and praseodymium towards strong fields.[17]

NMR spectra obtained in the presence of LSR are interpreted by two methods. The first involves the qualitative analysis of the spectrum modified using LSR. In the second case the shift values are used to obtain information on the structure of the substrate.

The qualitative interpretation of the spectra does not require assumptions about the nature of the bond between the LSR and the substrate. When the LSR is added, the assignment of the signals in the NMR spectrum of the substrate is simplified because of the difference in the induced shift of the signals from different nuclei. It follows from Eqn.(2) that a greater shift is undergone by the signals of nuclei situated closer to the coordination centre of the substrate molecule.

To obtain information on the structure of a substrate from Eqn.(2), it is necessary to have a large amount of data on the structure of the complex. Some of these data can be obtained by X-ray diffraction and from luminescence spectra.[15] This does not however eliminate the difficulties associated with the need to separate from the induced total paramagnetic shift of the signal the pseudo-component, which is determined by the geometry of the substrate.[17]

All methods for separating the contributions of contact and pseudocontact shifts are based on the difference in the dependence of their magnitude on the atomic number of the

lanthanide. The behaviour of the signals in the presence of europium and gadolinium is most informative for investigating the question of the existence of contact shifts in a given system.[12,16] If a shift is detected in the presence of gadolinium, this indicates the existence of a contact shift of the signal from the nucleus of the substrate being considered, since the pseudocontact shift induced by gadolinium is zero. By measuring the displacement of the signals from the same nuclei in the presence of different lanthanides, it is possible to obtain a system of linear equations which make it possible to determine quantitatively the contact and pseudocontact contributions to the induced shifts.[12,15] An unsatisfactory feature of all existing methods of separation is the need to make an assumption about the axial symmetry of the complex.[15]

III. THE USE OF LANTHANIDE SHIFT REAGENTS TO ANALYSE THE MICRO-STRUCTURE OF A POLYMER CHAIN

1. The Separation of Signals from Stereosequences

The first applications of LSR to study a number of polymers with functional groups were aimed merely at simplifying the form of the NMR spectra.[18-29] The addition of $Eu(dpm)_3$, $Eu(fod)_3$, and $Pr(fod)_3$ improved the resolution of the signals in the spectra of polymethyl methacrylate (PMMA), polyvinyl methyl ether, polyvinyl ethyl ether, polyvinyl acetate, polypropylene oxide, polysiloxane,[18,19] polyesters,[20,21] polyols,[22-26] polylacetones,[27,28] polypeptides,[29] and other polymers.

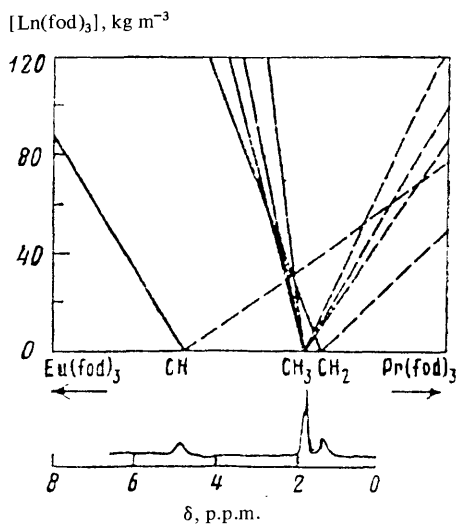

Figure 1. Influence of the concentration of $Eu(fod)_3$ (continuous lines) and $Pr(fod)_3$ (broken lines) on the ^1H NMR spectrum of polyvinyl acetate solution.[18]

Guillet and co-workers[19] were the first to discover that the shifts of the triad signals from the methyl and methoxycarbonyl groups of PMMA in o-dichlorobenzene decrease in the following order when an LSR is added (*i*-, *h*-, and *s*- denotes iso-, hetero-, and syndiotactic triads): $s\text{-}CCH_3 > i\text{-}CCH_3 > h\text{-}CCH_3 > i\text{-}OCH_3 > s\text{-}OCH_3 > h\text{-}OCH_3$. The order of change in the shifts is different in benzene: $i\text{-}CCH_3 > h\text{-}CCH_3 > s\text{-}CCH_3 > i\text{-}OCH_3 > h\text{-}OCH_3 > s\text{-}OCH_3$. This difference reflects the dependence of the conformation of the polymer on the micro-tacticity.[18-20]

Fig.1 shows the ^1H NMR spectrum of polyvinyl acetate in $CDCl_3$ and the influence of the addition of small quantities of $Eu(fod)_3$ and $Pr(fod)_3$ to the solution.[18] Both reagents separate the signal from the methoxycarbonyl proton into iso-, hetero-, and syndiotactic triads. The slopes of the straight lines on the diagram characterise the relative magnitude of the induced shift. $Pr(fod)_3$ produces larger shifts than $Eu(fod)_3$, and slightly greater paramagnetic broadening.

The determination of the micro-tacticity of poly-β-substituted β-propiolactones is a fundamental problem in the study of stereoregulation. A promising route to its solution has appeared with the use of $Eu(dpm)_3$ to separate the signals from meso (*m*) and racemic (*r*) diads in the ^{13}C NMR spectra.[27] The stereospecificity of induced paramagnetic shifts is due to the difference of 1–4° in the values of the angles θ in Eqn.(2) for the neighbouring carbon atoms of ^{13}CO and $^{13}CH_2$ in the *m* and *r* configurations of the polymer chain as a consequence of the restricted rotation relative to the bond joining these atoms.

The influence of $Eu(dpm)_3$ and $Dy(fod)_3$ on the ^{15}N NMR spectra of polypeptides has been studied.[29] The spectra of Z–Glu–Leu–*Leu–OMe (Fig.2) show that the addition of $Dy(fod)_3$ produces a selective shift of the ^{15}NH signals from different aminoacids. This is due to the difference in the chemical and spatial environments of the nitrogen atoms.

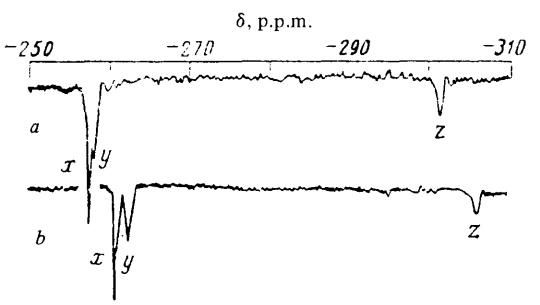

Figure 2. ^{15}N $\{^1H\}$ NMR spectra of a solution of Z–Glu–Leu–*Leu–OMe in CH_2Cl_2 before (*a*) and after (*b*) the addition of $Dy(fod)_3$ in the ratio N/Dy = 60 : 1. The chemical shifts are measured from the signal of $^{15}NO_3$ [29] (*x*—*Leu, *y*—Leu, *z*—Glu).[29]

The paramagnetic shift values depend on the distribution of the europium ions between different coordination centres in polyethylene glycol and polyformaldehyde chains.[22] It should be noted, however, that few authors take account of this distribution, which is capable of influencing the interpretation of the spectra considerably, particularly in the determination of the transformation of the polymer chain.

2. The Conformational Mobility of Homopolymer Chains

All approaches to the examination of the conformation of polymer chains are based on the use of some form of the McConnell–Robertson equation (2) after separation of the

contact and pseudocontact contributions to the induced paramagnetic shift. It is therefore of interest to examine the stereospecific contact interaction in the NMR spectra of polyol–lanthanide complexes (La^{3+}, Pr^{3+}, Nd^{3+}, Eu^{3+}, Tb^{3+}, Yb^{3+}).[26] If the chain has a planar zigzag conformation, the main contribution to the paramagnetic shift is made by contact interaction. In other cases, the isotropic shift of the signal is predominantly pseudocontact. This was used[30] to establish the possible conformations of iso- and syndiotactic PMMA in solution by comparing the observed values of the pseudocontact shift with the values of the geometric factor $(1-3\cos^2\theta)/r^3$ in Eqn.(2), calculated for all planar or spiral conformations of the chain.

Fig.3 gives the dependence of the values of the induced paramagnetic shifts $\Delta\delta$ of the signals from the protons of three groups (α-CH_3, CH_2, and OCH_3) for iso- and syndiotactic PMMA in solutions in $CDCl_3$ and C_6D_6 on the $Eu(dpm)_3$ concentration. The values of $\Delta\delta$ depend on the distance of the protons from the coordination site, and for syndiotactic PMMA also on the nature of the solvent.

In spite of the fact that a flexible polymer chain cannot have a fixed conformation in solution,[4] it has been shown that isotactic PMMA exists in a right-hand spiral (10/1) conformation. The *trans*-zigzag conformation established for syndiotactic PMMA is a unique case of planar or spiral conformation.

The influence of the shift reagents $Eu(dpm)_3$ and $Pr(dpm)_3$ on the ^1H NMR spectra of a solution of atactic poly-4-vinylpyridine (P-4-VP) in $CDCl_3$ has been studied in the temperature range 28–100 °C.[31] The micro-structure of radical P-4-VP, determined from the ^1H and ^{13}C spectra, corresponds effectively to Bernoulli statistics with $P_m = 0.52$. The shifts of the proton signals in the spectra of the polymer, induced by adding $Eu(dpm)_3$, are due to pseudocontact interaction. The values of the geometric factor were calculated for fragments of the macromolecule with regular iso- or syndiotactic-sequences. The conformations of the polymer were determined from the maximum probability of agreement between the experimental and calculated values of the induced shifts. The concentrations of the structures $[2_1]$ = 47 mole % (TTGG), $[Z_S]$ = 28 mole % (*trans*-zigzag), and $[3_1]$ = 25 mole % (isotactic) agree with the proposed model of the micro-tacticity of P-4-VP. The temperature dependence of the shifts of the ^1H signals indicated a change in the ratio of the conformations of P-4-VP towards an increase in the concentration of the syndio-*trans*-form.

$Eu(fod)_3$ was used similarly to determine the concentration of the TGT conformation of the sequence COCCOC in polyethylene glycol.[25] When europium is added to the polymer solution, the NMR signals assigned to the ethylene protons in the polymer segments separate into four groups of signals from the ethylene protons, close to the end of the chain, and a singlet in a weak field from TGT. The concentration of the TGT form increases rapidly with increase in the number-average molecular mass of the polymer.

3. Analysis of the Nature of the Alternation of Monomer Units Along the Polymer Chain

The use of LSR makes it possible to obtain extensive information on the distribution of the monomer units along copolymer chains, not obtainable by other methods of physicochemical analysis.[32] A necessary condition for the applicability of shift reagents to the analysis of the micro-structure of copolymers, as in the case of homopolymers, is the presence of atoms with an unshared pair of electrons (nitrogen or oxygen) in the main or side chains. The copolymers studied with a nitrogen atom in the side chain include copolymers of acrylonitrile with 1,3-dialkenes,[33–37] and with an oxygen atom, the copolymers of methyl methacrylate (MMA)[38–40] and α,β-unsaturated ketones with 1,3-dialkenes,[41–43] of methyl methacrylate with styrene,[44] and of ethylene with vinyl acetate.[45] In spite of the complexity of the interpretation of the spectra, the LSR method has been applied successfully to copolycondensed polymers containing an oxygen atom in the main chain.[46,49]

The application of the LSR method to copolymers containing a hetero-atom in the side chain is based on the fact that the signals of the triads having a large number of coordination centres, for example CN or CO, and hence a large number of polar (P) monomer units undergo a larger induced lanthanide shift than triads containing chiefly non-polar (N) units. The magnitude of the induced paramagnetic shift of the signals from the triads increases in the series NPN < NPP < PPP, NNN ≪ NNP < PNP.[32–34] This was used to assign the signals in the spectra, and the results agreed well with the results obtained by ^{13}C NMR spectroscopy[47] and with existing statistical theories describing the nature of the growth of the polymer chain.[37–42]

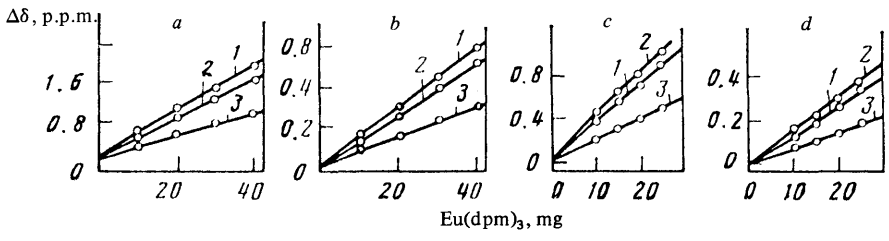

Figure 3. Dependence of the induced paramagnetic shift of the signals of CH_2 (*1*), CH_3 (*2*), and OCH_3 (*3*) on the quantity of $Eu(fod)_3$ for iso- (*a*,*c*) and syndiotactic (*b*,*d*) PMMA at 25 °C (*a*,*b*) and 80 °C (*c*,*d*) in $CDCl_3$.[30]

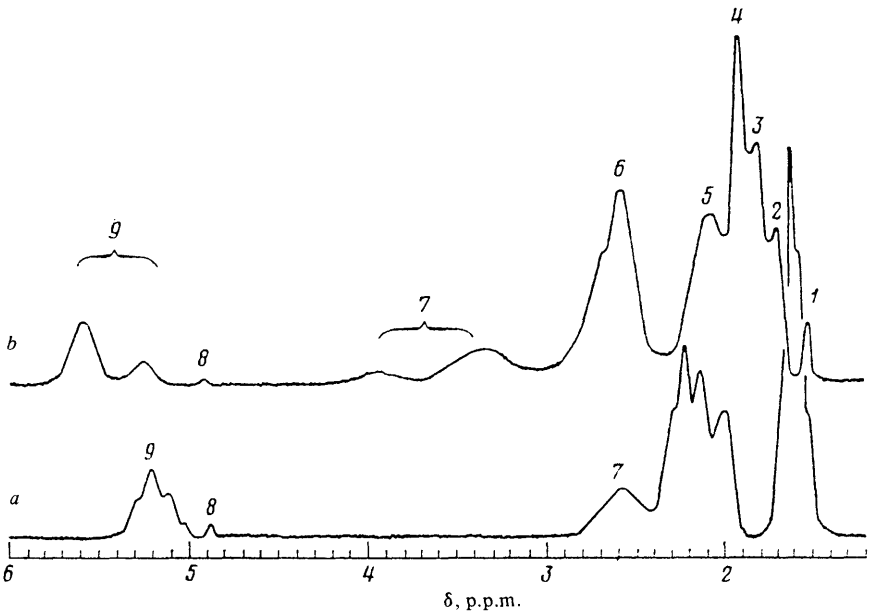

Figure 4. ^{1}H NMR spectra of a solution of the copolymer of isoprene (I) and acrylonitrile (A) (51.2 mole % A) in $CDCl_3$: *a*) without the addition of Eu(fod)$_3$, *b*) after the addition of Eu(fod)$_3$ at a mass ratio Eu(fod)$_3$:copolymer of 1:1. Assignment of the signals: *1*) CH_3-III; *2*) CH_3-AII, CH_2-III; *3*) CH_2-IAI; *4*) CH_3-AIA; *5*) CH_2-AII; *6*) CH_2-AIA + AAI + AAA; *7*) CH–CN; *8*) 1,2-I; *9*) =CH-III + AII + AIA.[35]

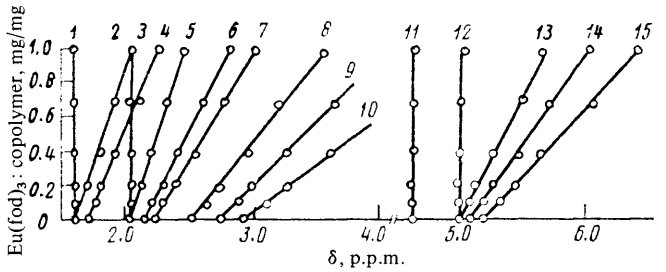

Figure 5. Dependence of the magnitude of the induced paramagnetic shift of the ^{1}H NMR signals of the triad and tetrads in the spectrum of the copolymer of isoprene with acrylonitrile (40 mole % A) on the mass ratio Eu(fod)$_3$: copolymer. CH_3: *1*) III, *2*) IIA; CH_2: *3*) IIA, *4*) IAI, *5*) IAAI, *6*) IAAA, *7*) AAAA; CH, A: *8*) IAI, *9*) IAA, *10*) AAA, *11*) 1,2-I; $=CH_2$, =CH: *12*) III, *13*) AII, *14*) AIA, *15*) AAIA.[36]

Fig.4 gives the ^{1}H NMR spectra of the copolymer of isoprene (I) with acetonitrile (A) before and after the addition of Eu(fod)$_3$. Fig.4*b* shows that after the addition of Eu(fod)$_3$ to the copolymer solution, the signals from different triads containing acetonitrile units are separated and displaced to weaker fields. Fig.5 gives the dependence of the magnitude of the induced paramagnetic shift on the ration Eu(fod)$_3$:copolymer for the signals of the copolymer of isoprene with acetonitrile. The magnitude of the induced shift of the signals increases in the series IAI < IAA < AAA; III ≪ IIA < AIA; CH_3 < CH_2-I ≤ =CH < CH_2-A < CHCN.[36,37] The last series proves that the nitrogen of the nitro-group [cyano group, (Ed. of Translation)] is coordinated to europium.

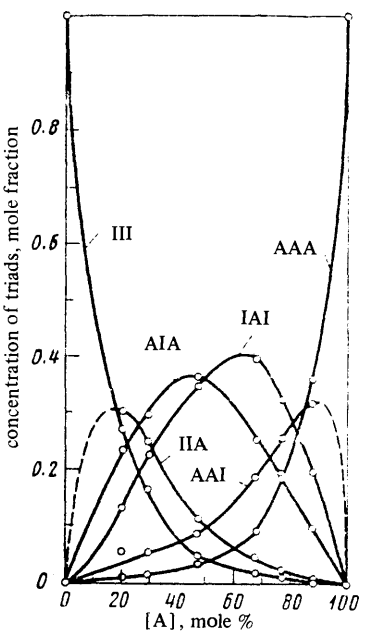

Figure 6. Dependence of the triad composition of copolymers in the mass of isoprene with acrylonitrile on the acrylonitrile concentration.[32]

The values of the integral intensities of the signals from different triads give information on the micro-structure, and make it possible to find the statistics of the distribution of

the monomer units along the chain. Fig.6 gives the dependence of the triad composition of the copolymers of isoprene with acetonitrile, obtained by copolymerisation in the mass, on the acetonitrile concentration [A]. The asymmetry of the arrangement of the maxima on the curves indicates that the nature of the growth of the copolymer chain does not correspond to Bernoulii statistics and that there are mutually opposed tendencies in the formation of the chain by the monomer units: isoprene tends to undergo homopolymerisation, and acetonitrile to undergo heteropolymerisation.[33]

The micro-structure of industrial SKN-18, -26, -40 butadiene–nitrile rubbers with different acetonitrile concentrations was studied analogously.[34] The absence of shift, induced by the addition of $Eu(fod)_3$, of the signal from the 1,2-structures of butadiene and separation into its components made it impossible to reach conclusions about the isolation of the 1,2-structures within the butadiene micro-blocks.

The micro-structure of copolymers of MMA with 1,3-dialkenes has been analysed using a shift reagent.[38–40] $Pr(fod)_3$ was used to determine the micro-structure of copolymers of MMA with isoprene.[38] The growth of the chains of the copolymers obtained in the mass obeys first-order Markov statistics with copolymerisation constants $r_{MMA} = 0.26$ and $r_I = 0.625$.

First-order Markov statistics also describe the copolymer of chlorophene with MMA, since the concentration in it of the pentad with an MMA unit at the centre, determined from the splitting of the methoxyl signal when $Eu(dpm)_3$ is added, agrees with that calculated from the copolymerisation constants.[39]

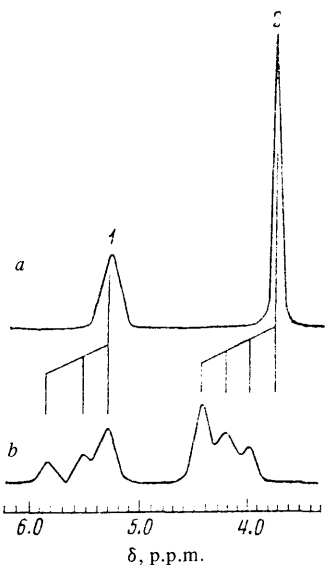

Figure 7. ^1H NMR spectra of a solution of the copolymer of butadiene with MMA in CCl_4: *a*) without the addition of $Eu(fod)_3$, *b*) after the addition of $Eu(fod)_3$; *1*) CH= (MBM, BBM, BBB), *2*) OCH_3 (MMM, MMB, BMB). The signals from the triads were recalculated in the direction of increase in the field.[40]

Fig.7 shows the ranges of the signals from the alkene and methoxyl protons of the copolymer of butadiene (B) with MMA (M).[40] When $Eu(fod)_3$ is added to a solution of the copolymer, these signals are split into the signals from the triad. The magnitude of the induced paramagnetic shift of the signals increases in the series BBB ≪ BBM < MBM; BMB < BMM < MMM; $-CH_2-B <$ =CH– < $-CH_2-M <$ $-OCH_3 <$ CCH_3. The values of the induced shifts indicate that the carboxyl and ester oxygen atoms are coordinated to europium.

The information on the micro-structure of copolymers, obtained by NMR spectroscopy using shift reagents, makes it possible to reach conclusions about the mechanism and topochemistry of the copolymerisation. For example, the dependence of the micro-structure of emulsion copolymers of isoprene with acetonitrile and of butadiene with MMA on the stability of the layer of surface-active agent (SAA) on the surface of the polymer–monomer particle has been established.[32,33,35–37,40] Fig.8 clearly shows the relationship between the criterion of the stability of the layer of SAA (the half-width $\Delta\nu_{1/2}$) of the signal from $(CH_2)_n$ in the ^1H NMR spectrum of mixed micelles of sodium alkylsulphonate (SAS) with potassium dresinate (PDR)[48] and the triad composition of the copolymers obtained in these systems.[35,37] The chain growth of the emulsion copolymers of isoprene with acetonitrile is described by first-order Markov statistics.[35]

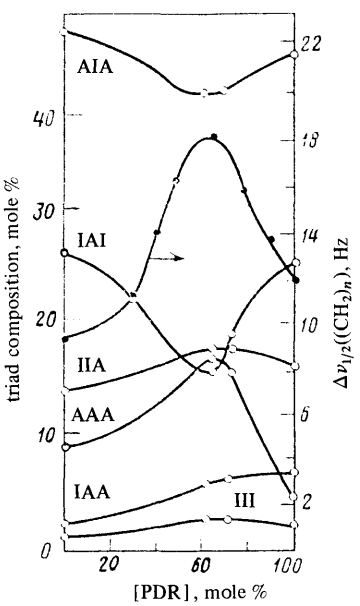

Figure 8. Dependence of the concentration of the triads and $\Delta\nu_{1/2}((CH_2)_n)$ in the ^1H NMR spectra of micelles of SAS and PDR on the PDR concentration.[37]

Analogous results on the influence of the stability of the SAA layer on the micro-structure have been obtained for emulsion copolymers of butadiene with MMA.[40] The SAA used were salts of aliphatic acids, differing in methylene chain length or in the number and position of double bonds, and hence in the stability of the SAA layer on the surface of the polymer–monomer particle. In particular, increase in the length of the methylene chain leads to an increase in the packing density and stability of the SAA layer.[40] Fig.9 shows that the dependence of the concentration of block and alternant triads in the copolymers on the length of the methylene chain is linear. The growth of the chain of the

emulsion copolymers of butadiene with MMA obeys first-order Markov statistics. The results made it possible to distinguish the zones in which homopolymerisation of monomers of different polarity takes place.[35,36,40]

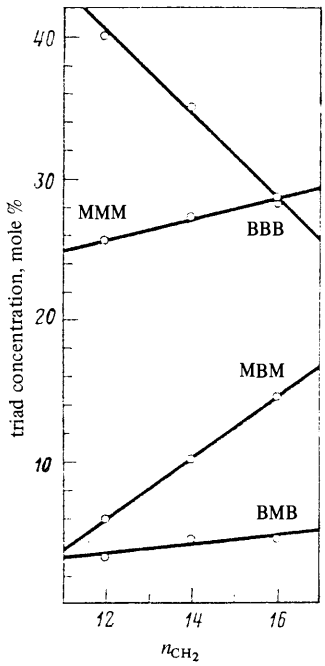

Figure 9. Dependence of the concentration of the triads in the emulsion copolymer of butadiene with MMA on the number of methylene groups in the molecules of the saturated aliphatic acid emulsifiers.[40]

The shift reagent $Eu(fod)_3$ has also been used to analyse the micro-structure of copolymers of α,β-unsaturated ketones (K) with isoprene (I), obtained by radical copolymerisation in the mass and in solution.[41-43] When $Eu(fod)_3$ was added, the signal from the alkene protons was separated into three components, which were assigned to the triads III, IIK, and KIK (listed in the direction of decrease in the field).[41] The experimental values of the concentrations of the triads show good agreement with those calculated from the ^{13}C NMR spectra and from the values of the copolymerisation constants, determined independently (by copolymerisation directly in the NMR spectrometer). The high concentration of the triad KIK confirms the tendency for the copolymers studied to show alternation.[42]

The addition of $Eu(fod)_3$ to a solution of the copolymer of methyl methacrylate with styrene leads to an increase in the resolution in the spectrum of the signals from triad configurations giving a contribution to the signal from the OCH_3 group.[44] The orientation of the LSR molecule in the copolymer chain is determined by the steric influence of the aromatic ring.

The ^1H NMR spectra of copolymers of ethylene with vinyl acetate have been interpreted using $Eu(fod)_3$.[45] The displaced signals from the methine and methyl acetate protons were assigned to the triad sequences of vinyl acetate, and their concentration was compared with that calculated from Bernoulli's model. Comparison of the results showed good agreement.

^1H NMR spectroscopy using $Eu(fod)_3$ and $Pr(fod)_3$ as LSR has been used to analyse the distribution of monomers in the chains of copolyarylates based on dimethyl-bis-phenol, phenolphthalein, and terephthalyl chloride, obtained by high-temperature polycondensation in α-chloronaphthalene.[46] The coefficients of the non-regularity of the copolyarylate chain were determined from the splitting, in the presence of the shift reagent, of the signal at 8.40 p.p.m. from terephthalyl chloride into peaks from the triad. In the copolyarylate synthesised at the isokinetic temperature (200 °C) for the given system, the copolymer units are distributed along the chain according to a random law, whereas in the copolyarylates obtained at other temperatures, copolymer blocks tend to form.

The use of LSR gives a good effect in ^{13}C NMR spectroscopy, as shown by an analysis of the distribution of sequences from the "unreliable", in the sense of the assignment of the signals, spectra of the homo- and copolymers of 1,3,5-trioxane and 1,3,5-trioxepane with 1,3-dioxolane.[49]

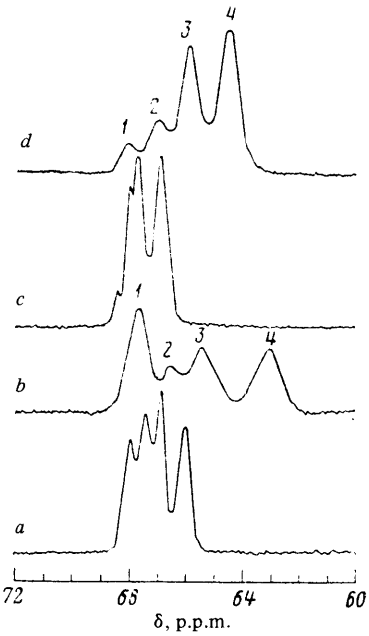

Figure 10. ^{13}C $\{^1H\}$ NMR spectra of the methine carbons of the VA units of a VC–VA copolymer (55 mole % VA) (*a*,*b*) and of the VP units of a VC–VP copolymer (70 mole % VP) (*c*,*d*) before (*a*,*c*) and after (*b*,*d*) the addition of $Pr(fod)_3$ in the ratio $Pr(fod)_3$:copolymer = 0.5. Solvent C_6D_6, temperature 50 °C. Assignment of the signals: *1*) VC–VA(VP)–VC, *2*) VC–VA(VP)–VA(VP), *3*) iso-VA(VP)–VA(VP)–VA(VP), and *4*) stable homotriads.[50]

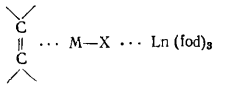
In any case, the use of LSR in ^{13}C NMR spectroscopy improves the resolution of the signals, for example, $Pr(fod)_3$ has been used[50] to separate the methine signals of copolymers of vinyl chloride (VC) with vinyl acetate (VA) and vinyl propionate (VP). The ^{13}C NMR spectra (Fig.10) show that



when $Pr(fod)_3$ is added, the methine signal separates into four peaks, corresponding to different triad configurations.

An approach analogous to that described for copolymers has been used to study the distribution of epoxide groups in epoxy-*cis*-polybutadiene and epoxy-*cis*- and epoxy-*trans*-polypentene polymers with different degrees of epoxidation by ^1H [51] and ^{13}C [52] NMR spectroscopy. When $Eu(fod)_3$ was added to the polymer solution, the signals from the $-CH_2-\underset{O}{C}-C$, $-CH_2-C=C-$, and $-CH=CH-$ groups separate into signals from the triad sequences of the epoxidised (E) and non-epoxidised (N) units. The magnitude of the induced paramagnetic shifts of the signals increases in the series: NNN $\ll$ NNE < ENE; NEN < NEE < EEE; $-CH=CH-$ < $-CH_2-C=C-$ < $-CH_2-\underset{O}{C}-\underset{O}{C}-$ $\leqslant -CH-\underset{O}{CH}-$. The calculation showed that the distribution of the epoxide units in the epoxypolyalkenylenes obeys Bernoulli statistics.

4. The Distribution of *cis*- and *trans*-Units in Polymers Not Containing Polar Groups

The shift reagent method has been widely used to analyse the micro-structure of polymers and copolymers containing units with polar groups. This method, however, can give useful information on the micro-structure of polymer chains containing double bands, but without polar groups. One of the methods of "depositing" the lanthanide on the polymer is by the selective chemical modification of the polymer chain, for example by epoxidation. It should be noted, however, that selective chemical modification involves considerable difficulty.

A recent paper[53] proposed the use, for alkenes, of lanthanide shift reagents combined with Ag, Pd, and Rh salts, which are capable of forming π-complexes with alkenes and complexes with lanthanides of the type:

where M is a metal atom, and X a group capable of coordinating to a lanthanide.

It has been shown possible[54,55] to "deposit $Eu(fod)_3$ on π-complexes of the double bonds of a polymer chain with $AgNO_3$. This method, based on the established[56] difference in the stability constants of the π-complexes of silver with *cis*- and *trans*-alkenes, makes it possible to distinguish *cis*- (C) and *trans*- (T) isomers, and also the diads CC, CT(TC), and TT without deuteriation and spin–spin decoupling for any working frequencies of the ^1H NMR spectrometer.

Fig.11 gives the ^1H NMR spectra of polybutadiene solutions before and after the addition of the $AgNO_3$–$Eu(fod)_3$ system. After the addition of the shift reagent, the signals from the methylene and alkene protons of polybutadiene are split into two (*cis*- and *trans*-) and three (CC, CT(TC), TT) components. The magnitude of the induced paramagnetic shift increases linearly as far as a mass ratio $Eu(fod)_3$: polybutadiene = 3 : 1, after which the relationship reaches a plateau, since possible coordination sites on the polymer molecule are exhausted.

Thus the use of LSR to analyse the micro-structure of macromolecular compounds and to investigate the mechanism of the polymerisation of those polymers in whose NMR spectra the signals from monomer or stereo-sequences are not resolved, is extremely effective. The determination of the

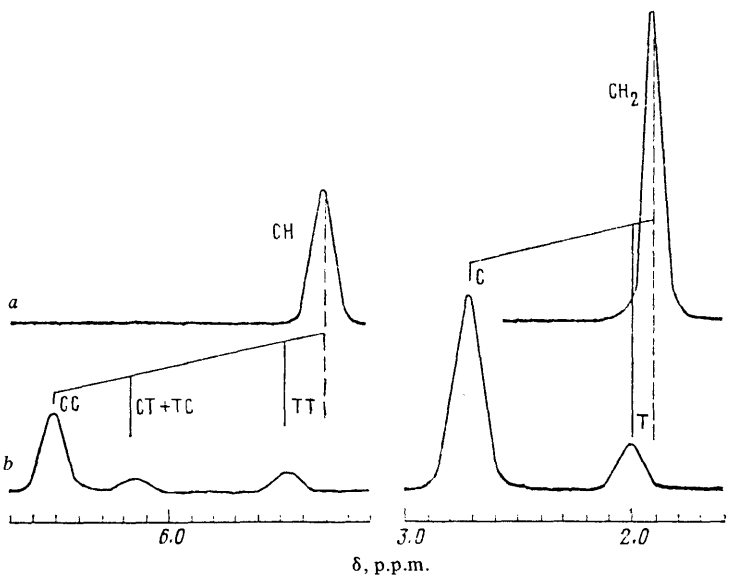


Figure 11. ^1H NMR spectra of a solution of polybutadiene in $CDCl_3$ before (*a*) and after (*b*) the addition of $AgNO_3$–$Eu(fod)_3$.[55]

correspondence of the chain growth to a particular statistic makes it possible to detect the influence of fine effects of intermolecular association[57] on the mechanism of polymerisation.

The High-temperature Microcalorimetry of Inorganic Substances

N.D.Topor and Yu.L.Suponitskii

The essential features of high-temperature microcalorimetry have been described, and the possibilities provided by its use in various fields such as inorganic chemistry, mineralogy, power engineering, etc. have been demonstrated. The procedures of high-temperature microcalorimetry have been classified according to the types of process studied: solution, oxidation, hydrogenation, dissociation, phase transformations, the mixing of melts, etc., and illustrated for substances with different compositions and uses: metals, oxides, salts, synthetic and natural compounds, and minerals. The results of the studies have been compared with data obtained by calorimetry involving solution in aqueous solutions and by combustion calorimetry. The bibliography contains 423 references.

I. INTRODUCTION

Heat-conducting calorimeters,[1] the theory and practice of which were developed by Tian[2] and Calvet,[3-9] have been called microcalorimeters, because of their high sensitivity in the measurement of the heats of various reactions and physical transformations. The name indicates that it is possible to measure very small quantities of heat (microcalories) using specimens with different masses and dimensions. Microcalorimeters are usually classified as instruments for low (90–500 K), medium (273–700 K), and high (273 to 2100 K) temperatures. The present review deals chiefly with microcalorimeters for high temperatures (273–1800 K), and the possibilities provided by their use in chemistry, mineralogy, the production of ceramics, metallurgy, and other fields. The types of microcalorimeter indicated do not differ fundamentally from one another. The main differences are in the construction of the working thermostats (blocks), where the detector cells surrounded by the thermojunctions are placed; in the materials from which they are made; and also in the construction of the apparatus for initiating the reactions. The heat losess from a high-temperature calorimter increase in proportion to T^4; in practice, this means that the loss of heat at 1000 K will be eight times greater,

and that at 1500 K 27 times greater, than that at 500 K. The fact that it is impossible to eliminate these losses makes it difficult to use more accurate adiabatic and other calorimeters at high temperatures (1050–1600 K).[10,11]

The design of high-temperature microcalorimeters (HTMC) makes it possible, instead of eliminating the heat losses from the working cells, to achieve their practically complete compensation during the experiment. Thus in spite of the lower accuracy of the measurements compared with the above-mentioned calorimeters, HTMC have the advantages of simplicity, convenience in use, and reliability of the measurements in long experiments at high temperatures (1000–1800 K). A high-temperature microcalorimeter is a universal heat-measuring instrument, which can be used to determine the enthalpies of various chemical reactions, physical transformations, and phase transformations (fusion, volatilisation, adsorption, mixing of solutions, polymorphic transformations, order–disorder transformations, etc.). Compared with other calorimeters, HTMC make it possible to study heterogeneous reactions and not only to determine the quantity of heat liberated or absorbed but also simultaneously to study the kinetics of the process. These and a number of other advantages have led to the extensive application of high-temperature microcalorimetry in chemistry,[12–16] mineralogy,[17–22] metallurgy,[23–30], the study of the thermodynamics of solid solutions (order–disorder transformations),[31,32] etc. HTMC are now also used to study the thermochemistry of salt and metallic systems used to accumulate solar energy and ground heat.[33–36]

II. ESSENTIAL FEATURES OF THE METHOD AND APPARATUS

High-temperature microcalorimeters (1300 K) appeared in 1955–1966[37–39] after the development of the theory of heat-conducting calorimeters[40–42] and the construction of electronic regulators for maintaining high temperatures in the block with a high accuracy.[43–45] The design of the Setaram Calvet high-temperature microcalorimeter (1000 °C) is shown in Fig. 1. The actual microcalorimeter consists of two calorimeter cells placed symmetrically in cylindrical holes in a massive block made of stainless steel[46] or fused alumina.[47] A battery of Pt–PtRh (13%) thermocouples (396 junctions) is placed between the outer surface of each detector cell and the cylindrical surface of the hole in the block. The batteries of the two cells are connected according to a differential scheme. Some of the thermocouples can be used to generate the Peltier effect in the detector cells.[4,48,49]

A slight change in the temperature of the block produces identical heat fluxes to the two cells, and identical EMF's are produced in the thermo-batteries, and as a result of the differential connection they compensate one another. A change in temperature in one of the cells produces an EMF which is proportional to the intensity of the heat flux from this detector cell to the block (or conversely). This EMF is amplified and recorded graphically using a recorder. The area bounded by the heat-liberation curve and the zero line, which is proportional to the heat of the process being studied, is measured using planimeters, electronic integrators, or computers.[50,51] The form of the curve defines the thermal power of the process at each moment of time, so that its kinetics can be studied.[52–54] The instrument is calibrated to determine its basic constants, that is its sensitivity and time constant.[4,8] The geometric form of the specimen and the degree of filling of the cell influence the nature of the curve, and may introduce errors into the time constant of the instrument.[55,56]

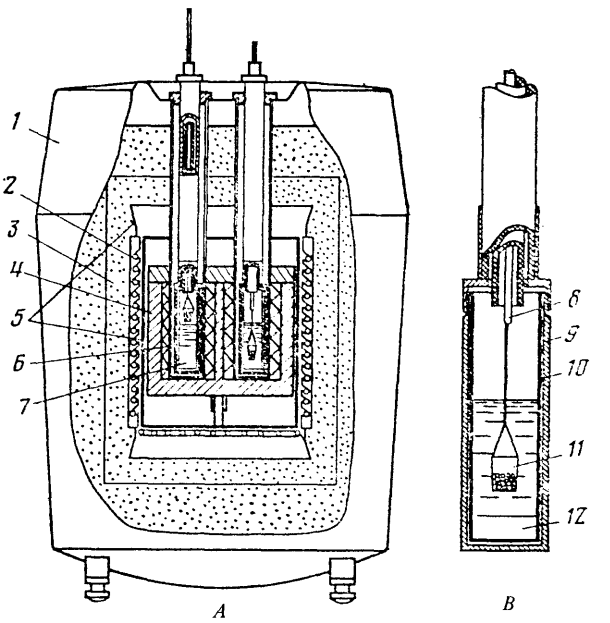

Figure 1. *A*) Calvet microcalorimeter; *1*) calorimeter casing, *2*) heater, *3*) furnace, *4*) massive block, *5*) metal screens, *6*) thermocouples, *7*) calorimetric cell; *B*) calorimetric cell: *8*) ceramic rod, *9*) metal cell casing, *10*) platinum beaker, *11*) platinum crucible, *12*) solvent melt.

The constants of the microcalorimeter are determined experimentally by various methods: by electrical calibration from the Joule effect, by placing an ohmic resistance in the detector cell;[57] by measuring the known heats of fusion or solution of standard chemical compounds;[25,58,59] from the known heats of chemical reactions;[60–64] and by mixing† standard substances for which the temperature changes in enthalpy are known. The calibration using the Joule effect can also be carried out without an ohmic resistance, by using the resistance of the thermocouples surrounding the detector cell (Peltier effect); when calibration from the Peltier effect is used, there is no heat flux along the leads.[49,65] Electrical calibration from the Joule effect has not been widely used in high-temperature microcalorimetry. HTMC are mainly calibrated by mixing, that is the basic constants of the instrument are determined from the change in the heat content of standard specimens of Pt, Au, or Al_2O_3, which after being brought to constant temperature at 298 K are dropped into the working cell of the microcalorimeter, heated to the required temperature.[66,67] The mixing method is used to calibrate calorimeters which are to be used to measure high-temperature enthalpies or to measure the enthalpies of solution of metals and compounds in various solvent melts. In a number of procedures, additional apparatus is introduced into the cells, for example to initiate chemical reaction. The possibility of introducing various pieces of equipment into the working cells (ampoules, manipulators, initiating assemblies, stirrers) represents the main advantage of HTMC over the other types of calorimeter.

† Other terms are encountered in the literature: the dump method, drop calorimetry.

Methods involving the programming and complete automation of the calorimetric experiment have been widely used in recent years.[68-70]

Large high-temperature microcalorimeters. Extensive development of high-temperature microcalorimetry took place after the foundation, in 1957, of the Institut de Microcalorimetrie et de Thermogenese de Marseille,[71] in whose workshops the first high-temperature microcalorimeters (1300 K) were constructed;[46] using their pattern, the firm of Setaram in Lyons began the mass production of instruments with the following technical characteristics: temperature range 300–1300 K, heating rate 0.5–60 K h^{-1}, sensitivity 2.5 mJ mW^{-1} or 4 μV mW^{-1}, time constant 120–130 s (1100 K); dimensions of the working cells: diameter 17 mm, height 80 mm, volume 15 cm^3; parameters of the HTMC: height 100 cm, diameter 60 cm, mass 300 kg. This HTMC (1300 K) belongs to the class of large microcalorimeters, and as a result of its temperature stability under isothermal conditions it can be used to carry out long experiments (weeks or months). Large high-temperature microcalorimeters (1300 K) have been used mainly to study the thermochemistry of metals and metallic alloys.[40,55,72-75] Assemblies making it possible to carry out experiments in air or in an inert medium and in a vacuum, depending on the aims of the study of solid–liquid metallic systems, have been developed.[74-86]

To increase the sensitivity and improve the reproducibility of the results in the measurement of the heat content and the determination of the heat capacity of solids, a special working cell was used,[19] with a partition and a semi-automatic device for dropping the specimen into the cell.[87,88] A simple procedure for determining the heats of fusion and solution involves dropping the solid specimen (298 K) into the liquid situated in the working cell of the calorimeter at the given temperature[27,28,88] (Fig. 2*a*). A disadvantage of this method is that the thermal effect of the process being recorded consists of two effects: an endothermic effect due to the change in the enthalpy of the solid substance, and the thermal effect of the solution of the solid in the liquid. The two effects are superimposed on one another, and their separation in the integration of the areas under the curves is difficult and leads to large errors, which are difficult to take into account.[17] Much better results in the determination of heats of solution are obtained when the solid is suspended in a small dish at a short distance from the liquid, and dropped into the liquid after temperature equilibrium has been reached, for example by opening a clamping mechanism, controlled from outside the apparatus (Fig. 2*b*).[80] Very reliable and accurate results are obtained by the "indirect drop" procedure. The solid specimen, at room temperature, is dropped into a graphite ampoule situated above the melt, and brought to the same temperature as the melt in the calorimeter (Fig. 2*c*). When temperature equilibrium has been reached, the solid specimen is lowered by means of a manipulator into the liquid for the measurement of the enthalpy of solution. The procedure can be carried out in a vacuum and in an inert atmosphere.

In the study of the enthalpies of mixing of molten salts, one of the salts in a sealed quartz ampoule is lowered into the working cell containing a melt of the other salt. When temperature equilibrium has been reached, the ampoule is broken by a manipulator, and the enthalpy of mixing of the melts or the solution of the solid salt in the melt is measured (Fig. 2*d*).[89-92] To determine the enthalpies of solution of small specimens, a special device to start the reaction was constructed for use with Setaram HTMC.[71] To prevent corrosion, the device was made of a ceramic oxide (Al_2O_3) and a heat resistant alloy which did not form a scale up to 1600 K. The successful microcalorimetric study of metals and alloys led to the development, in various laboratores, of specieal HTMC (1500 K and 1880 K) for studying the partial enthalpies of the reaction of oxygen with non-stoichiometric oxides of iron, uranium, zirconium, etc. In these instruments, as a result of the intensive radiative transfer of heat, direct contact between the thermocouples and the wall of the cell or block is not necessary. The calibration is carried out from the known enthalpies of oxidation of thorium by oxygen.[93-98] HTMC (1000 K) with graphite or platinum cells in which it is possible to carry out experiments in a vacuum have been constructed to study the enthalpies of solution of metals in liquid aluminium and tin[99,100] and to measure the enthalpies of mixing of liquid metals with sulphur and selenium.[101]

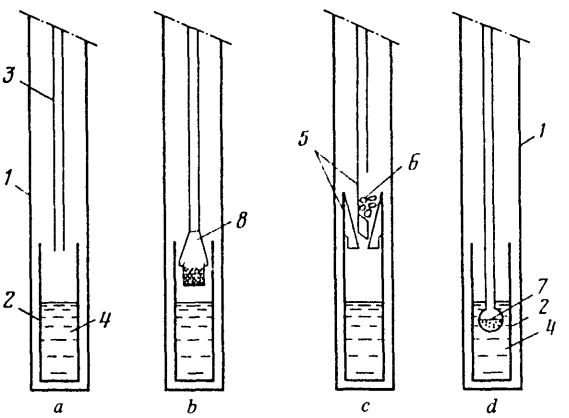

Figure 2. Types of reaction assembly placed in the calorimeter to measure the enthalpies of solution in melts: *1*) cell casing, *2*) platinum reaction vessel, *3*) directing tube, *4*) solvent melt, *5*) graphite specimen holder for heating to the temperature of the solvent and for dropping it, *6*) specimen, *7*) ampoule containing the specimen, *8*) holding clamp for heating the specimen to the temperature of the solvent and for dropping it.

In 1955, Kleppa (USA) constructed a high-temperature heat-conducting microcalorimeter with one working cell, designed for the study of the solution of metals at 800 K,[37] and in the period 1960–1966 he developed HTMC with two working cells,[12,38,102,103] designed for the study of the solution of oxides and silicates in oxide melts, selected for the first time for these purposes in another study.[104] In a subsequent model, the Chromel/Alumel thermojunctions were replaced by Pt–PtRh (13%) thermojunctions, and the HTMC were calibrated by mixing using platinum and gold specimens. Kleppa was the first to use an original device for initiating solution, placed symmetrically in both cells. An HTMC operating up to 1100 K with a quartz device for "starting" the reaction was constructed[105] for determining the enthalpies of solution of solid inorganic compounds in melts with the composition $3Na_2O.4MoO_3$ by Navrotsky's method.

High-temperature microcalorimeters with a small number of thermocouples. Heat-conducting calorimeters with a limiting working temperature of up to 1800 K have recently been developed. The blocks of these calorimeters are made of molybdenum and have smaller dimensions; some workers[106,107]

have used planar PtRh (6%)–PtRh (30%) or WRh (5%)–WRh (10%) thermo-batteries with a smaller number of thermocouples, placed in an aperture in the side of the working cell. This HTMC is designed to operate in air and in a vacuum at 800–1800 K.[108,109] Another type of calorimeter, manufactured by Setaram, differs from the HTMC (1300 K) produced by the same firm in that both calorimeter cells of fused Al_2O_3 are arranged in it vertically and coaxially one above the other (Fig.3). The detector cells, the thermobattery, and the device for circulating argon and for cooling with water are placed in a vertical heater with a large uniform temperature zone; the temperature of the heater can be raised to 2000 K. The procedure for carrying out measurements with this apparatus in the study of metals and metallic systems has been described,[110–113] but its possibilities have not been fully studied. In the next type of heat-conducting microcalorimeter, in contrast to the Tian–Calvet microcalorimeter, the junctions of the thermo-batteries were connected in series.[114,115] This HTMC can operate in the temperature range 298–1500 K or 103–900 K under programmed heating conditions in a vacuum or in a medium of inert gases. A heat-conducting microcalorimeter of spherical shape, in which the liquid components, in a sealed quartz ampoule, are mixed by rotating the calorimeter through 180° has been constructed for determining the heats of mixing of volatile, solid, and liquid salts. The HTMC is calibrated from the Joule effect using a calibration resistance, and the uncertainty of the determination of the enthalpies of mixing is 4%.[116]

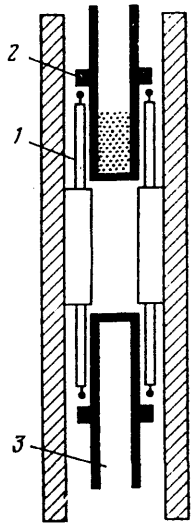

Figure 3. Diagram of the vertical arrangement of the cells in the HTMC (1800 K): *1*) thermocouple, *2*) reaction assembly with the melt, *3*) empty cell.

Heat-conducting calorimeters of the DTA type. Heat-conducting microcalorimeters fitted with a temperature controller for maintaining a stable rate of heating (or cooling) while preserving the advantages of HTMC are acquiring the additional functions of instruments for quantitative thermal analysis. It is difficult, however, to carry out experiments under programmed heating conditions using large HTMC (1300 K) with a large number of thermojunctions, with a large time constant. The heating rate should be low (0.5 to 8 K h^{-1}), or stability of the zero line is not achieved. The long time required to carry out the experiment, and the need to decrease the senstivity of the instrument, make large HTMC unsuitable for experiments under constant heating conditions, although the possibility does exist (for determining large thermal effects, for example on fusion).[39,64,90,95,117,118]

In the USSR, one of the first microcalorimeters for studying the rates of heterogeneous solid–gas reactions and dissociation at 770 K was constructed in the Chemistry Department of Moscow State University.[119] A microcalorimeter designed for the study of heat capacities, phase transformations, the ageing of metals, etc., operating at 400–1100 K, has been described[120]. A differential microcalorimeter, constructed[121] in accordance with the Calvet principle and operating in the range 300–1000 K, is designed mainly for quantitative thermal analysis; it is calibrated electrically, has an accuracy of 3–5%, and the mass of the specimen is 0.6–6 g.

Microcalorimeters designed to operate under conditions of heating and cooling (1–20 K min^{-1}) are called "scanning calorimeters". The Setaram differential scanning microcalorimeter (DSC) combines the accuracy and sensitivity of the traditional HTMC with the speed of carrying out the experiments characteristic of DTA.[122,123] This DSC operates in the range 150–1000 K under isothermal and scanning conditions; the operation of the instrument is controlled by a computer, and the time constant of the detector is 12 s.

III. ENTHALPIES OF SOLUTION OF INORGANIC COMPOUNDS

In many calorimetric procedures, enthalpies of solution provide a basis for determining enthalpies of formation, which are fundamental thermochemical characteristics used in chemistry, mineralogy, metallurgy, power engineering, etc.[124–135] Various refractory compounds and minerals are insoluble in acids, however, even at high temperatures (298–353 K). The calorimetric study of solution in aqueous solutions of acids is therefore unsuitable for determinining the enthalpies of formation of refractory compounds or minerals. A much more effective method than acid calorimetry is provided by high-temperature solution microcalorimetry, where a liquid melt, having considerable solvent power at 1000–1200 K, is used instead of an aqueous acid solution. The procedure for carrying out the measurements was developed in 1960 [38] after the development of a high-temperature Tian–Calvet microcalorimeter with a special quartz device for studying the solution of specimens with a mass of 50–300 mg.[12,37] This procedure is used to determine the enthalpy change in the solution of a weighed specimen of a solid in a liquid solvent consisting of a melt with a definite composition.

A similar device for solution, made of a refractory ceramic and a heat-resistant alloy, has been described.[66] An advantage of this device is that it is possible to work with small specimens of the substances being studied, so that rare materials can be investigated (toxins, synthetic compounds, cosmic minerals). The enthalpies of solution in melts are generally about one tenth of the enthalpies of solution in aqueous acid solutions. This means that although the uncertainty of the determination of the enthalpy of solution in HTMC is ~1%,[18,52,136] whereas that for calorimetry involving solution in acids is ~0.1%, the uncertainty of the enthalpy of formation of a substance being studied will be the same in both cases (Table 1). The main advantage of the HMTC method for studying solution is that it is possible to measure the enthalpies of solution of refractory compounds

(oxides, chromites, ferrites, silicates, aluminosilicates, etc.) using specimens with a mass of 5–30 mg. A limitation of the method must be mentioned, however, namely the difficulty of studying hydrated compounds, including natural and synthetic minerals. Procedures for studying solution in melts have been examined in detail.[9,12,17,18,51,66,136–141]

Table 1. Comparative characteristics of calorimetric methods for determining the enthalpies of formation of silicates.[20,53]

Characteristics of the method	Calorimetry involving solution in acids (HF etc.)	High-temperature microcalorimetry involving solution in melts
Principle of the method	adiabatic calorimeter	Calvet microcalorimeter
Working temperature range, K	289–398 (depending on the type of calorimeter)	298–1800 (depending on the type of calorimeter)
Mass of specimen for one experiment	500–2000 mg	5–300 mg
Example of an experimentally determined quantity: $(\Delta H^0_T)_{solution(\alpha\text{-}SiO_2)}$, kcal mole^{-1}	−33.0±0.02	−1.01±0.05
Uncertainty of the determination (attainable) of $(\Delta H^0_T)_{solution}$, %	0.1	1
Uncertainty of the calculated enthalpy of formation of the silicate (ΔH^0_f), kcal mole^{-1}	0.1–0.2	0.1–0.2
Influence of dilution and change in the concentration of the solution on the value of ΔH^0_T, solution	considerable	slight
Solubility of the most important oxides (Al_2O_3, Cr_2O_3, MgO, SiO_2, etc.)	satisfactory or poor	good (at 1000–1300 K)
Work with hydrated compounds	possible	difficult

1. Oxide Solvents

As in classical solution calorimetry,[142] the main problem in the thermochemical study of the solution of substances in melts is the choice of the solvent melt. Up to the present, in spite of the accumulation of knowledge on the physical chemistry of melts and the equilibrium diagrams obtained, there is no scientifically based criterion for selecting a solvent melt in relation to the composition of the compounds being studied. The main requirements which must be satisfied in the choice of a solvent can be formulated as follows.

1. With allowance for the existing temperature limit of the measurements in the high-temperature microcalorimetric procedure, the melting point of the solvent should be comparatively low (900–1200 K), and the vapour pressure should be so low that the enthalpy of volatilisation does not distort the measurements being made.

2. The solvent should have a buffer capacity, that is it should have a concentration range in which the enthalpy of solution is practically independent of the composition of the solvent.

3. The solvent should be stable in the atmosphere in which the measurements are being made.

The most important characteristic of the solvent melt is its acid–base behaviour; the magnitude and sign of the enthalpy of solution are determined by the degree of acidic or basic character of the solvent.[12] The scale of basic strength of oxide solvent melts can be interpreted as a series of states of the oxygen ion between O^{2-} and O^- as a result of polarisation in the presence of metal cations.[143] The equilibrium for the acid–base behaviour in an oxide melt can then be written in the form:

$$\text{acid} + O^{2-} \rightarrow \text{base}$$

The greater the activity of the oxygen ion, the greater the basic strength of the melt.[144–146] For example, in the Na_2O–MoO_3 system, sodium oxide is a strongly basic oxide (base), and MoO_3 is a strongly acidic oxide (acid). Thus the solution of MoO_3 in melt rich in sodium oxide can be represented as the following chain of equilibria:

$$O^{2-}(\text{liquid}) + MoO_3(\text{crystalline}) \rightarrow MoO_4^{2-}(\text{liquid})$$
$$MoO_4^{2-}(\text{liquid}) + MoO_3(\text{crystalline}) \rightarrow Mo_2O_7^{2-}(\text{liquid})$$
$$MoO_3(\text{crystalline}) \rightarrow MoO_3(\text{liquid})$$

Solvents based on oxides, so-called oxide solvents, have been most widely used in high-temperature microcalorimetry. The possibility of using an oxide solvent (V_2O_5) to dissolve the oxides of a number of metals at 958 ± 5 K and lead vanadates at 953 K was first demonstrated by Yokokawa and Kleppa.[147,148] V_2O_5 was not used in other studies, since it does not show acid–base properties. The efforts of research workers were subsequently directed to the search for melts combining acidic and basic properties, since only these melts can fulfil the functions of a calorimetric solvent and give an acid–base equilibrium. The equilibrium diagram of the PbO–B_2O_3 system[149–151] showed a range of compositions (17–67% B_2O_3) existing in the liquid state at 973 K; a buffer capacity was detected for the composition $2PbO.B_2O_3$, and this was found to be suitable for dissolving many oxides (SiO_2, GeO_2, Fe_2O_3).[152] A less widely used melt for these oxides has the composition $9PbO.3CdO.4B_2O_3$, from the ternary PbO–CdO–B_2O_3 system.[153,154]

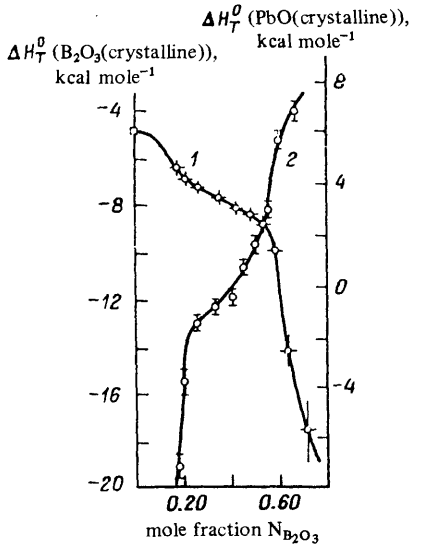

Figure 4. Dependence of the enthalpy of solution of PbO (*1*) and B_2O_3 (*2*) on the mole fraction of B_2O_3 in a PbO–B_2O_3 melt at 1173 K; *N* is the mole fraction.

The composition ranges of the PbO–B_2O_3 system corresponding to a buffer capacity of the solvent can be seen from Fig. 4, but oxides such as TiO_2, SnO_2, NiO, and their compounds are insoluble in these solvents. A so-called molybdate melt with the composition $3Na_2O.4MoO_3$ (75% Na_2MoO_4–25% MoO_3) (Fig. 5) has been proposed for these oxides;[155] because of its appreciable volatility, this melt is unsuitable at temperatures above 700 °C, and is unstable in

a reducing medium. A study of the acid–base properties of the K_2MoO_4–MoO_3 system[156] established that in the composition range 35–80 mole % MoO_3, this system has a lower melting point than Na_2MoO_4–MoO_3, and compositions with 40–50 mole % MoO_3 can be used as a calorimetric solvent at 820 K (Fig. 6).

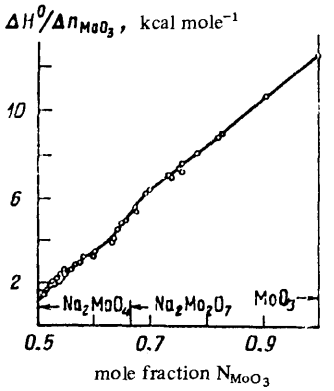

Figure 5. Dependence of the enthalpy of solution of MoO_3 on the mole fraction of MoO_3 (N_{MoO_3}) in an Na_2O–MoO_3 melt.

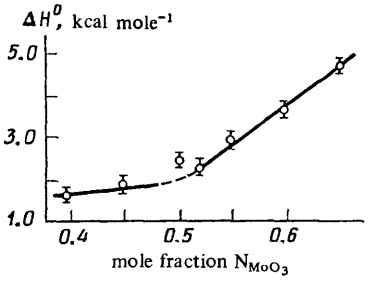

Figure 6. Dependence of the enthalpy of solution of MoO_3 on the mole fraction (N) of MoO_3 in a K_2O–MoO_3 melt.

To find new calorimetric solvents, the following oxide systems have been studied: PbO–SiO_2 at 1173 K,[157] PbO–GeO_2 at 1173 K,[158] Li_2O–B_2O_3 at 1213 K, and Na_2O–B_2O_3 at 1258 K.[159] A solvent with the composition 0.5 $LiBO_2$–0.5 $NaBO_2$, liquid at 940 K, was detected.[159] The ternary eutectic mixture with the composition Na_2O–B_2O_3–SiO_2, liquid at 1973 K, is a good solvent for dissolving SiO_2, Al_2O_3, MgO, CaO, FeO, and MnO in a reducing medium. This composition is hygroscopic, however, and this introduces a number of difficulties in its preparation and storage. Buffer properties have been detected for various compositions of the Na_2O–P_2O_5 system.[160] In the range 56–61 mole % Na_2O, the phosphates are liquid at 1116 K, and are of undoubted interest as promising calorimetric solvents. Up to the present, however, the phosphate melt has not found extensive application in high-temperature microcalorimetry. The main characteristics of the widely used and new solvent melts are summarised in Table 2. The practically unlimited possibilities in the further search for solvent melts are opening up extensive opportunities for using high-temperature microcalorimetry to study various classes of inorganic substance.

Table 2. Compositions and ranges of application of solvent melts used in high-temperature solution microcalorimetry.[17,20,249]

Composition of melt	Range of application K	Used to dissolve	Notes
$2PbO·B_2O_3$ or $9PbO·3CdO·4B_2O_3$ *	920–1170	SiO_2, GeO_2, Fe_2O_3, Cr_2O_3, MgO, CaO, NiO, CuO, ZnO, CdO, Cu_2O	not suitable for dissolving TiO_2, SnO_2, Mn_2O_3
$3Na_2O·4MoO_3$	870–1020	TiO_2, SnO_2, Mn_2O_3, MgO, CaO, NiO, ZnO, CdO Ln_2O_3	acidic oxides and SiO_2 do not dissolve well; volatile at T > 970 K
$0.35Na_2O·0.35B_2O_3·0.3SiO_2$	1070–1170	SiO_2, Al_2O_3, MgO, CaO, FeO **, MnO **	hygroscopic (special storage conditions)
$0.5Li_2O·0.5Na_2O·B_2O_3$ ($LiBO_2$+$NaBO_2$)	940	WO_3, FeO, MnO	new solvent, procedures not developed
$2.5Na_2O·1.5P_2O_5$ ($NaPO_3$+$Na_4P_2O_7$)	1120	WO_3	ditto

*Solvent with narrower range of application.
**A reducing medium is required.

2. Minerals and Silicate Systems

The enthalpies of formation of minerals are used for thermodynamic calculations when modelling the processes involved in natural and synthetic mineral formation.[161,162] High-temperature solution microcalorimetry has been developed for refractory natural and synthetic minerals.

Al_2O_3–SiO_2 system. The enthalpy of solution of the oxide Al_2O_3 was determined for the first time in 1964,[153,163] after which the enthalpies of solution of polymorphic forms of the compound Al_2SiO_5—the minerals andalusite, kyanite, sillimanite and mullite—in the ternary solvent $9PbO.3CdO.4B_2O_3$ at 968 ± 2 K was determined.[164,165] The calculated enthalpies of formation and other thermochemical constants (entropy, heat capacity) were used to construct the p–T diagram of the Al_2O_3–SiO_2 system over a wide range of temperatures and pressures.[166] Additional studies of the enthalpies of solution of minerals with the composition Al_2SiO_5 in molten $2PbO.B_2O_3$ at 974 + 2 K [167,168,169] made it possible to refine the p–T diagram, so that the coordinates of the triple point of the Al_2O_3–SiO_2 system coincided with published data.[170–173]

The measured enthalpies of solution of different forms of SiO_2 (quartz, cristobalite, coesite, stishovite, glass) in moltent $9PbO.3CdO.4B_2O_3$ at 970 ± 2 K, and the high-temperature enthalpies determined by mixing, were used to construct the p–T diagram giving the stability of the coesite–stishovite system, to calculate the thermodynamics of the polymorphic transformation[86] and the high-temperature equilibria for the forms of SiO_2, and to reach conclusions important for geology and seismology.[174] For sillimanite it was established that there is a difference in the enthalpies of solution of specimens[175] kept at different temperatures before the experiments (influence of the degree of ordering of the structure).

MgO–Al_2O_3–SiO_2 system. The stability fields of the solid phases in the MgO–Al_2O_3–SiO_2 system are usually studied using apparatus for high and superhigh pressures and temperatures.[176,177] The technical difficulties and the time

required for this experimental method, and the lack of published thermochemical data for the thermodynamic analysis of the stability fields of the solid phases on the $p-T$ diagrams, led to the development of the thermochemical study of the minerals in molten $2PbO.B_2O_3$ at 1000–1300 K [178–181] (Tables 3 and 4). The enthalpies of formation and heat capacities calculated in this way, and the known entropy values, can be used to carry out calculations for many reactions which are models for processes taking place in the earth's crust and upper mantle and used in silicate technology. The differences observed in the enthalpies of solution of natural compounds and their synthetic analogues indicate that the data obtained for a synthetic system cannot be transferred uncritically to a natural system, even when the compositions of the phases are similar.

Table 3. Enthalpies of solution of oxides in high-temperature solvents based on boric oxide (ΔH_T^0, kcal mole^{-1}).

Oxide	T, K	ΔH_T^0	Refs.	T, K	ΔH_T^0	Refs.
	$9PbO\cdot3CdO\cdot4B_2O_3$			$2PbO\cdot B_2O_3$

Measurement of the enthalpies of solution of magnesium silicates and aluminates in molten $2PbO.B_2O_3$ at 973 K [180] and $MgAl_2O_4$ in $9PbO.3CdO.4B_2O_3$ [181,182] showed that the solution of MgO takes place slowly and is not quantitative at 973 K, and is characterised by two thermal effects: a large exothermic effect is first observed, followed by a small endothermic effect. This two-stage solution was attributed[181] to the formation of an intermediate compound (exothermic effect), followed by its solution (endothermic effect). At 1173 K the solution of MgO is complete and takes place at a high rate, and the exothermic effect almost disappears; [183–186] the results of the determination of the enthalpy of formation of magnesium silicate show good agreement with the data obtained by calorimetry involving solution in acids (see Table 11 below). Thus the study of magnesium

Table 4. Enthalpies of solution [$(\Delta H_T^0)_{solution}$, kcal mole^{-1}] of silicates in molten $2PbO.B_2O_3$ and enthalpies of formation from the oxides (ΔH_f^0, kcal mole^{-1}); the number of experiments is given in brackets.

compounds in melts must be carried out at temperatures not lower than 1173 K.[136,187] Measurement of the enthalpies of solution of sapphirine in $2PbO.B_2O_3$ at 973 K showed the influence of temperature on the stability of natural ordered and synthetic disordered sapphirines.[188,189]

$CaO-MgO-Al_2O_3-SiO_2$ system. The enthalpies of formation of the solid phases of this system, determined from the enthalpies of solution in molten $2PbO.B_2O_3$ at 970 K, have been determined[137,190] (see Tables 4 and 5). The dependence of the values obtained for the enthalpy of solution on the size of the anorthite specimen was determined;[155] no significant change in the enthalpies of solution was observed for specimens weighing 43.72–34.90 mg. The enthalpy of solution of natural garnets (grossular, andradite, and pyrope) in molten $2PbO.B_2O_3$ at 973 K has been determined experimentally.[191] The phase relationships for pyrope and minerals of granulite and eclogite facies have been examined by the Schreinemakers method on coordinates $p-T$.[192,193] The thermochemical data for grossular $Ca_3Al_2(SiO_4)_3$, andradite $Ca_3Fe_2(SiO_4)_3$, and uvarovite $Ca_3Cr_2(SiO_4)_3$ have been analysed, and the most reliable experimental data on the $p-T$ equilibria have been used to calculate the Gibbs free energy.[194]

The thermochemical properties of the most important phases of the $CaO-MgO-SiO_2$ system have also been studied[195] by high-temperature solution microcalorimetry in molten $2PbO.B_2O_3$ at 1000–1300 K,[183,184] and the properties of $MgSiO_3$ have been studied at 965 ± 2 K in two solvents: $2PbO.B_2O_3$ and $9PbO.3CdO.4B_2O_3$ (Table 4).

New data on the enthalpy of the $\alpha \rightarrow \beta$ phase transformation of $CaSiO_3$ have been obtained from the enthalpies of solution of the two phases in molten $2PbO.B_2O_3$ at 973 K.[196] Improvements in the experimental technique for high-temperature solution microcalorimetry[137,198,199] made it possible to increase the accuracy of the determination of the enthalpies of solution of the phases and solid solutions of the $CaO-MgO-SiO_2-Al_2O_3$ system. Thus for a number of minerals of this system, synthesised at high temperatures and pressures, the enthalpies of solution of the extreme members in $2PbO.B_2O_3$ (970 K) have been determined, and the results have been used to study the thermochemistry of the solid solutions.[198–201]

The enthalpies of solution in $2PbO.B_2O_3$ (970 K) of the extreme members of the olivine system Mg_2SiO_4 (forsterite)–Fe_2SiO_4 (fayalite) made it possible to study a model of the molecular activity of silicate minerals#, of considerable importance for carrying out calculations for natural systems.[202–204] The determination of the enthalpies of solution in $2PbO.B_2O_3$ (1036 K) of minerals of the pyroxene group ($MgCaSi_2O_6$, $NiCaSi_2O_6$, $MnSiO_3$) and the enthalpies of fusion of $CaMgSi_2O_6$ (diopside) and $CaMgSi_2O_6$ (diopside glass),[205] and also the enthalpies of solution of cobalt silicates (α-Co_2SiO_4, β-Co_2SiO_4, γ-Co_2SiO_4), synthesised at a high pressure, made it possible to construct the $p-T$ diagrams for SiO_2-MO silicate systems.[206] The thermochemistry of the glasses and solid and liquid phases in the systems $CaMgSi_2O_6$–$CaAl_2Si_2O_8$–$NaAlSi_3O_8$, SiO_2–$CaAl_2Si_2O_8$–$NaAlSi_3O_8$, SiO_2–Al_2O_3–CaO–Na_2O, and $NaAlSi_3O_8$–$KAlSi_3O_8$ [determination of

Notes. [a] solvent V_2O_5; [b] quartz structure; [c] solvent $2.5Na_2O.1.5P_2O_5$, mole fraction $N_{Na_2O} = 0.5–0.61$; [d] solvent $2PbO.B_2O_3$, tetragonal structure; [e] solvent $2PbO.B_2O_3$, hexagonal structure; [f] solvent $2PbO.B_2O_3$, vitreous; [g] rutile; [h] solvent $0.5LiBO_2 + 0.5NaBO_2$; [i] solvent $3Na_2O.4MoO_3$.

The enthalpies of formation of the solid solutions of the Mg_2SiO_4–Fe_2SiO_4 system were studied by measuring the enthalpies of solution in molten $LiBO_2$–$NaBO_2$ in a medium of argon at 1180 K.[220]

the enthalpies of solution in $2PbO.B_2O_3$ (970 K, 986 K) and the heat content $H_T - H_{298}$ (mixing in HTMC)] has been studied.[140,207,208] The results obtained were used to carry out a thermodynamic study of models of the phase equilibria for the liquid surfaces of the ternary systems and general models of the structures of geological magma.[209,210,211,212]

The extensive accumulation of material on the high-temperature microcalorimetry of silicate and oxide systems has made it possible to distinguish the corresponding mineral associates of practical importance in geochemistry, petrology, geothermometry, and silicate technology.[213,214,215,216,217] The use of thermochemical data to construct $p-T$ diagrams has been reviewed.[218] At present, high-temperature solution microcalorimetry is used to study "dry" systems. The problem of the study of hydrated chemical compounds (minerals) is at an initial stage of development. Thus an attempt has been made[219] to measure the enthalpies of aqueous solutions at a pressure of 2 kbar and 1073 K by a combined method involving high-temperature microcalorimetry and the use of high-pressure ampoules. The difficulties in studies of this kind are associated with various technical problems in the construction of the calorimetric apparatus.

3. Chemical Compounds

A second direction taken by studies in high-temperature solution microcalorimetry arose in connection with the need to determine the thermochemical characteristics of refractory substances,[197,213,221,229] which cannot be studied by other thermochemical methods. From the methodological viewpoint, the two directions, that is the thermochemistry of minerals and the thermochemistry of inorganic substances, represent a single whole, since they use similar procedures (the same measurement temperature, solvent composition, thermochemical cycle, etc.), and the materials studied as models of minerals are often products of the chemical industry. The difference between these two directions is determined only by the purposes of the studies.

Since the separate aims of the thermochemistry of inorganic substances are fairly varied, the results of the studies have been systematised in the present work on the basis of the method of study used. The main problem in the development of a procedure is the choice of solvent, in which the enthalpy of formation is determined by measuring the enthalpies of solution of the compound being studied and its components under identical conditions (solvent composition, temperature of the experiment, and concentration of dissolved substances). For example, for complex oxides (chromites, silicates, tungstates, molybdates, gallates, manganates, aluminates, ferrites, etc.), the thermochemical cycle is as follows:

$$MWO_4(\text{crystalline}) + (\text{solvent}) \rightarrow M^{2+}(\text{liquid}) + WO_4^{2-}(\text{liquid}) + (\Delta H_T^0)_1 \quad (1)$$

$$MO(\text{crystalline}) + WO_3(\text{crystalline}) + (\text{solvent}) \rightarrow M^{2+}(\text{liquid}) + WO_4^{2-}(\text{liquid}) + (\Delta H_T^0)_2 \quad (2)$$

$$MO(\text{crystalline}) + WO_3(\text{crystalline}) \rightarrow MWO_4(\text{crystalline}) + (\Delta H_T^0)_2 - (\Delta H_T^0)_1 \quad (3)$$

The known values of the enthalpies of formation of the oxides and the values obtained for $(\Delta H_T^0)_1$ and $(\Delta H_T^0)_2$ are used to calculate the enthalpy of formation of the compound. A similar procedure is used in the study of the thermochemistry of solid solutions or isomorphous mixtures, but instead of oxide mixtures [reaction (2)], a mixture of the compounds forming the required solid solution is used.[224]

Vanadium(V) oxide (V_2O_5). Kleppa[225] used molten vanadium(V) oxide as a solvent to measure the enthalpies of solution of PbO and lead vanadates with the compositions $Pb_2V_2O_7$, $Pb_3(VO_4)_2$, and $Pb_8V_2O_{13}$ at 953 K to determine the enthalpies of formation of the vanadates from the oxides. The enthalpies of solution of the oxides of the alkaline earth metals and various transition metals were measured in the samel solvent[147] at 958 ± 5 K (Tables 3 and 5).

Table 6. Enthalpies of solution of oxides (ΔH_T^0, kcal mole^{-1}) in high-temperature solvents based on B_2O_3 and MoO_3.

Notes: [a]T = 965 K; [b]T = 973 K; [c]solvent $9PbO.3CdO.4B_2O_3$.

A solvent melt with the composition $2PbO.B_2O_3$ was proposed by Kleppa[152] for the study of the enthalpies of solution of MgO, α-Al_2O_3, and $MgAl_2O_4$, and has since been widely used (Tables 5–9). The enthalpies of formation of magnesium silicates and aluminates at 973 K and 1173 K [180] and of magnesium, nickel, copper, zinc, and cadmium chromites with the composition MCr_2O_4 at 1173 ± 2 K,[183] determined from the measured enthalpies of solution of the compounds and the original oxides, have been used to study the thermodynamic and crystal-chemical characteristics of the formation of chromite spinels[226] and the acid–base properties of transition metal oxides.

The energy characteristics and stability of the structures of silicates and germanates of the transition metals (Co, Ni, Zn) and magnesium,[197] the alkaline earth metals (Ca, Sr, Ba) and cadmium,[221] and minerals based on them have been studied by measuring the enthalpies of solution of the silicates, germanates, and corresponding oxides at (965–967) ± 2 K. A lead borate solvent has been used successfully by a number of authors to study the thermochemistry of the phases formed in the systems $PbO–SiO_2$ ($PbSiO_3$, Pb_2SiO_4, Pb_4SiO_6),[223] $CuO–GeO_2$ ($CuGeO_3$),[227] and $CoO–B_2O_3$ ($Co_3B_2O_6$, $Co_2B_2O_5$, CoB_4O_7)[228] in the thermochemistry of solid solutions.[140,224,229]

The thermochemistry of ferrites, borates, aluminates, and gallates with the composition§ $LnMoO_3$ (Ln represents a lanthanide, yttrium, or scandium) at 974, 975, and 1075 K [216,230–233] and aluminates[234,235] with the compositions $LnAlO_3$ and $Ln_3Al_5O_{12}$ at 875 K has been studied by measuring the enthalpies of solution of the compounds and the corresponding oxides of the lanthanides, iron, boron, aluminium, and gallium. The enthalpies of solution of sodium and potassium aluminates and carbonates at 975 K have been used to determine the enthalpies of formation of $NaAlO_2$ and $KAlO_2$.[236]

§ In the compounds $LnMO_3$. M represents Fe, B, Al, or Ga.

Table 9. Enthalpies of solution of compounds of the lanthanides in melts based on B_2O_3 or MoO_3 [216,230,234,244,245,246,243] (ΔH^0_T, kcal mole^{-1}).

Notes: [a]solvent $3Na_2O.4MoO_3$; [b]solvent $2PbO.B_2O_3$; T = 974 K or 975 K; [c]solvent $3Na_2O.4MoO_3$; T = 1075 K; [d]aluminate with the composition $Ln_3Al_5O_{12}$; [e]forms of $LnBO_3$ or $Gd_2(MoO_4)_3$.

Molten $9PbO.3CdO.4B_2O_3$. Beryllium aluminates and silicate (and also BeO, Al_2O_3, SiO_2) dissolve more readily in a melt with the composition $9PbO.3CdO.4B_2O_3$.[237] This solvent was therefore used[197] to refine the results of the study of the solution of MgO and various metal silicates and germanates, and also for a thermochemical study of the aluminates, ferrites, gallates, and germanates of bi- and tervalent metals.[222]

Molten $3Na_2O.4MoO_3$. A number of solvent melts based on MoO_3 are known.[139,155,156,238,239] The most widely encountered is the melt with the composition $3Na_2O.4MoO_3$, first used by Navrotsky and Kleppa.[155] The enthalpies of solution of simple and complex oxides of the transition metals in this melt were measured in a cycle of studies to determine the enthalpies of formation of the titanates M_2TiO_4 [222,240] and manganates M_2MnO_4 [222] with the spinel structure, and the isostructural tungstates MWO_4;[154,241] the thermodynamic data were compared with the mechanism of spinel formation by the titanates and manganates, and the thermodynamic characteristics of the tungstates were compared with the data for the sulphates, carbonates, and silicates of the same metals.

A systematic study of the thermochemistry of lanthanide molybdates has been carried out.[242–247] The enthalpies of formation of simple and double lanthanide molybdates were determined for the first time by measuring the enthalpies of solution of the oxides Ln_2O_3, Pr_6O_{11}, and MoO_3 and the molybdates $Ln_2(MoO_4)_3$, and $NaLn(MoO_4)_2$, and Na_2MoO_4 at 973 ± 0.5 K and of $Na_4La(MoO_4)_4$ at 897 K. The enthalpies of formation of magnesium borates were determined[248] from data on the composition of the compounds formed in the $MgO–B_2O_3$ system and the enthalpies of solution of the

borates $Mg_3B_2O_6$, $Mg_2B_2O_5$, and MgB_4O_7 and the oxides MgO and B_2O_3, measured at 973 ± 2 K.

Molten $NaPO_3$–$Na_4P_2O_7$. A relatively new solvent melt with the composition $2.5Na_2O.1.5P_2O_5$, proposed by Ko and Kleppa,[160] has been used to measure the enthalpies of solution of WO_3 in the presence of Na_2O (1116 K). There are no published data on other studies with this solvent.

Molten $LiBO_2$–$NaBO_2$. The enthalpies of formation of the solid solutions formed by manganese and iron tungstates have been determined[249,250] by measuring the enthalpies of solution of the solid solutions and oxides of tungsten(VI), iron(II), and manganese(II) in a solvent with the composition $0.5LiBO_2 + 0.5NaBO_2$ at 940 K¶.

Molten KCl–LiCl. A eutectic melt of lithium and potassium chlorides has been used[251] to measure the enthalpies of solution of the double chlorides of caesium and the transition metals (and calcium) at 728 K, to determine the enthalpies of formation (Table 9) and to study the stability of the ions in the melts. The enthalpy of the reaction of lead oxide (PbO) with liquid cadmium in the working cell at 800 K, measured by mixing, was −39.58 ± 0.89 cal mole^{-1} PbO.[252] Concentrated sulphuric acid has been used as solvent.[253] The authors cited measured the enthalpies of solution of copper and cadmium selenochromites and Cu(Cd) + Cr + Se mixtures at 475 K, and calculated the enthalpies of formation of the selenochromites, which have the spinel structure. The results, together with the data for other transition metal sulphides and selenides,[253] were used to study the energies of formation in oxide–sulphide–selenide series and to examine the characteristic features of the formation of chalcogenide spinels. The results of the measurements of the enthalpies of solution of the oxides are given in Tables 5 and 6, and the enthalpies of the chemical compounds in Tables 7–10.

Table 10. Enthalpies of solution of chlorides in a high-temperature solvent (ΔH^0_T, kcal mole^{-1}).

4. Phase Transformations

High-temperature solution microcalorimetry can be used to study the enthalpies of phase transformations by successively dissolving the two phases of the same chemical compound (mineral) under identical conditions (temperature, solvent composition, solute concentration). The enthalpy of a phase transformation is generally small (often <0.5 kcal mole^{-1}), and since it is determined from the difference between the large values of the enthalpies of solution of the two phases, the uncertainty is high,[86,196,254] and amounts to ~0.2 kcal mole^{-1}. Much better results can be obtained by the direct determination of the enthalpy of the transformation by simultaneously dissolving the two phases in the two cells of a differential HTMC.[229,255] These methods have been used to study the enthalpies of polymorphic transformations, phase transformations, and fusion, the enthalpies of formation of solid solutions, and the enthalpies of processes involving the disordering of solid phases, by dissolving the appropriate specimens in melts with the compositions $3Na_2O.4MoO_3$,[256,257,229] $2PbO.B_2O_3$,[181,196,205,254,258–265] $9PbO.3CdO.4B_2O_3$,[86,104,164,266] and $LiBO_2$–$NaBO_2$ [220] (Table 12).

IV. THERMOCHEMICAL STUDY OF GAS–SOLID REACTIONS

High-temperature microcalorimetry can be used to measure the enthalpies of heterogeneous solid + gas chemical reactions. Procedures for measuring the enthalpies of oxidation were examined in detail in a study of the oxidation of niobium.[267] The influence of the oxygen pressure and the temperature of the experiment on the form of the heat-liberation curve was studied, and the thermal effects of the successive stages of the oxidation: the dissociation and adsorption of oxygen, diffusion, and the formation of compounds on the surface, were examined. The results of this study were used to develop a method for the microcalorimetric study of heterogeneous reactions of solids with gases to give new solid compounds.

The calorimeter for the study of M + O_2 systems is calibrated from the known enthalpy of oxidation to give an oxide with a definite composition, or from the enthalpy of another chemical reaction.[268] Since the calibration constant may change from one experiment to another (for example, $K_1 = 100$, $K_2 = 120$, $K_3 = 130$), but remains constant during a given experiment, the HTMC are calibrated immediately before the experiment or immediately after it.[93] The enthalpy of the oxidation of thorium to ThO_2 has been recommended[93] for calibration. In the study of M + H_2 systems, the calibration is carried out either electrically or by mixing, since the partial enthalpies of solution of hydrogen are ~10 kcal, and in this case the quantity $0.5RT \cong 0.7$ kcal mole^{-1} cannot be neglected; it can be neglected, however, for the enthalpies of solution of oxygen (oxidation), amounting to ~80 kcal[268] ($0.5RT \cong 1.3$ kcal mole^{-1}).

The procedure involving the study of gas + solid reactions was used to measure the enthalpies of the oxidation of metals by oxygen.[95] Kleppa and co-workers[269–272] measured the enthalpies of the oxidation of tungsten, vanadium, niobium, and tantalum and the lower oxides of tungsten, vanadium, and titanium to give WO_3, V_2O_5, NbO_x, and TiO_2 respectively at temperatures of ~1100 K, and the heat of solution of O_2 in the non-stoichiometric phase TiO_x at 1323 K has been measured.[273] A similar procedure was used[274,275] to measure the enthalpies of oxidation of the lower oxides of praseodymium and terbium at 713 K and of the lower oxides of cerium ($CeO_{1.5}$–$CeO_{1.95}$) at 1353 K,[94] plutonium ($PuO_{1.5}$–$PuO_{1.71}$), and uranium[277,276,97] to give CeO_2, $PuO_{1.61}$, PuO_2, and U_3O_8 respectively. The enthalpies of oxidation of cerium oxides[94] have been compared with the results obtained by studying the equilibrium $CeO_{1.5} + O_2 \rightleftharpoons CeO_2$; the difference in the enthalpies of oxidation for the composition $CeO_{1.86}$ is less than 3 kcal. The uncertainty of the measurements of the enthalpies of oxidation of plutonium oxides[278] was 2%. The enthalpies of oxidation of non-stoichiometric iron oxides (FeO_{1+x}) were studied at 1073 K for $x = 1.05$–1.109 and at 1348 K for $x = 1.040$–1.140.[96,98,279] The partial enthalpies of solution of oxygen were measured; for the compositions FeO_{1+x} ($x = 0.040$–0.140), the enthalpies of mixing were 120.2–133.6 kcal mole^{-1}, and the values given for ΔH^0_{0x} increase linearly with increase in Δx.

The enthalpy of the chemisorption of oxygen on zinc powder has been determined[280] at 303.7 K and 451.1 K. The values obtained from the results of 15 experiments at 303.7 K (165–170 kcal mole^{-1} O_2) and at 451.1 K (166.0–176 kcal mole^{-1} O_2) are close to the standard enthalpy of formation of ZnO ($\Delta H^0_{f\,298} = -167.6$ kcal mole^{-1} O_2). The results confirm that it is possible in principle to use high-temperature microcalorimetry to study gas–solid reactions, and also that the method is suitable for the study of sorption processes and the reactions involved in the formation of non-stoichiometric compounds.

The adequate reliability of the measurements of the enthalpies of oxidation of "comparatively simple materials" (metals and oxides) enabled a number of authors to use the same procedure to study the oxidation of more complex oxygen compounds. Thus the enthalpy of oxidation of titanium oxide nitride at 1500 K according to the scheme:

$$TiO_xN_y + 0.5\,x\,O_2 \rightarrow TiO_2 + 0.5\,y\,N_2$$

has been determined.[281] Since the procedure is fairly complicated, the uncertainty of the experiment was estimated as 5%, which is greater than that of other microcalorimetric procedures, for example that involving the measurement of enthalpies of solution. The enthalpy of oxidation of cerium orthoferrite by atmospheric oxygen according to the equation:

$$CeFeO_3 + 0.25\,O_2 \rightarrow CeO_2 + 0.5\,Fe_2O_3$$

was measured at 975 K [282] by dropping the specimens, brought to constant temperature at 298 K, into the calorimeter cell. A similar procedure was used[258,283] to determine the enthalpies of oxidation of double sulphides of cobalt, iron, molybdenum, gallium, and copper. The enthalpies of the reactions of the type:

$$CoCr_2S_4 + 7\,O_2 \rightarrow CoCr_2O_4 + 2\,SO_2 + 2\,SO_3 \quad (975\ K)$$
$$Ga_{2/3}Mo_2S_4 + 9.5\,O_2 \rightarrow 1/3\,Ga_2O_3 + 2\,MoO_3 + 4\,SO_3 \quad (920\ K)$$

are given in Table 13. Non-stoichiometric iron sulphides have been studied by oxidising Fe.[284] The following reaction took place in the calorimeter cell at 555 K:

$$(1-0.4\,x)\,FeS + 0.4\,x\,O_2 \rightarrow Fe_{1-x}S + 0.2\,x\,Fe_3O_4$$

with enthalpy $\Delta H^0_{555} = -(23.1 \pm 1.4)x$, and the enthalpy of formation of the sulphides is:

$$\Delta H^0_{f\,555}\,(Fe_{1-x}S) = \Delta H^0_{f\,555}\,(FeS) + (10.0 \pm 1.8)\,x,\ x = 0 - 0.125$$

The results of the study of solid + oxygen reactions indicate the extensive possibilities provided by the procedure being considered for the thermochemical study of heterogeneous solid + gas chemical reactions. This is confirmed by studies of the high-temperature thermochemistry of M + H_2 systems, which from the calorimetric viewpoint are analogous to the reactions involved in the oxidation of metals. The solution of hydrogen and deuterium in metals, alloys, or solid solutions of M–H_2 or M–D_2 systems has been studied. The partial enthalpies have been measured[285,286] for the solution of hydrogen in lanthanum, yttrium, and their hydride phases at 917 K and 919 K, in vanadium, niobium, and tantalum and their solid solutions with hydrogen at 264, 300, and 437 K (V), 356 K and 440 K (Nb), and 700 K and 703 K (Ta), and in thorium at 700 K.[287–289] The thermodynamic properties of solutions of H_2 and D_2 in palladium at 770–970 K, in manganese at 550–700 K, and in the alloys Pd–Au (10.25% and 40% Au) and Pd–Cu (10.25% and 40% Cu) at 555 K and 700 K, and Pd–Ag and Pd_3Mn at 555–909 K have been measured.[290–297]

The temperature dependence of the enthalpy of solution of hydrogen has been measured in dilute PdH_x solutions at 555–712 K [238] and in Pd at 518–625 K and pressures up to 34 atm. The reaction of H_2 and D_2 with α-Zr has been studied,[299,300] and the enthalpies of solution determined. The solution of hydrogen in $LaNi_5$–$CaNi_5$ alloys at 298 K has been studied.[287]

Most studies showed that the enthalpies of solution are practically independent of the temperature at which the measurements are made. In a series of remarkable studies,[287,290–293] the microcalorimetric procedure was combined with a flow method for studying heterogeneous equilibria (gas–solid) to determine both ΔH^0 and ΔG^0 for the formation of hydride

phases. In these studies, as in other work,[288,289] good agreement was observed between the results of the measurements by two independent methods. The combination of the results of the microcalorimetric experiment (the enthalpy of the solid + gas reaction) with the results of the study of the equilibria in the same system (the Gibbs function) makes it possible to determine more accurately the fundamental thermodynamic functions of the solid–gas system and to use them to model the geological processes involved in the reaction of minerals with hot gas mixtures (H_2, O_2, N_2), in the study of sulphide equilibria and the solid phases in meteorites,[139,140] and to construct gas–metal equilibrium diagrams in metallurgy.[93–98] Table 14 compares the enthalpies of oxidation determined by high-temperature microcalorimetry with data obtained by combustion calorimetry in an oxygen bomb.

V. THE STUDY OF THE DISSOCIATION OF SOLIDS

Studies of the enthalpies of dissociation of solids are methodologically similar to microcalorimetric studies of solid + gas reactions. The dissociation, however, is accompanied by the liberation of the gaseous reaction product from the cell, with mass exchange between the contents of the cell and the surrounding medium and the removal of heat from the measurement zone. Thus in the study of dissociation it is important to take account of corrections for the removal of heat with the liberated gas. The use of an ampoule dropped into the calorimeter cell makes it possible to avoid mass transfer of gas and corresponding heat loss.

The largest number of studies using this procedure have been devoted to crystalline hydrates and metal carbonyls. The enthalpies of dehydration of the calcium aluminates $CaAl_2O_4.10H_2O$, $Ca_2Al_2O_5.8H_2O$, and $Ca_3Al_2O_6.6H_2O$,[303] and the dissociation of potassium hydrogen phosphates,[118] accompanied by the liberation of water:

$$K_2HPO_4 \rightarrow 0.5\,K_4P_2O_7 + 0.5\,H_2O\,(\text{gas})$$
$$2\,K_2HPO_4 + KH_2PO_4 \rightarrow K_5P_3O_{10} + 2\,H_2O\,(\text{gas})$$

have been studied. The enthalpies of the reactions are given in Table 15. The enthalpy of dissociation of lithium sulphate monohydrate at 328–348 K and p = 0.7–5 mmHg is 14.7 ± 0.7 kcal mole^{-1};[304] the dissociation of calcium iodate hexahydrate at 323 K and 423 K has been studied.[305]

The dissociation of transition metal carbonyls in a double HTMC at 514, 534, and 543 K in an argon atmosphere has been studied.[306–309] The measurements were made by dropping glass ampoules with and without the substance into the differential cell. The measurements made it possible to determine the enthalpies of dissociation of Mn, Mo, and Cr carbonyls, and also the enthalpies of the reactions of the carbonyls with iodine vapour (Table 13). The enthalpies of the reactions studied were used to calculate the M–CC bond energies, where M is a transition metal. Similar methods were used[310] to study the reduction and bromination of uranium(III) oxide to the tetrabromide. The enthalpy of dissociation of lithium orthotitanate

$$Li_4TiO_4 + CO_2 = Li_2CO_3 + Li_2TiO_3$$

has been used[311] to determine the enthalpy of formation of the orthotitanate. The value obtained at 860 K and p_{CO_2} = 1 atm was 104.1 ± 0.7 kJ mole^{-1}. The dissociation of the double caesium nickel chloride, which takes place in the

solid phase, has been studied at 718 K by mixing (by dropping an ampoule containing the original Cs_3NiCl_5 [312] and repeated measurements by mixing to determine the difference $H_T - H_{298}$). A noteworthy feature of the last two methods for measuring the enthalpies of solid-phase decomposition is that the absence of gas liberation eliminates the additional experimental errors.

VI. ENTHALPIES OF SYNTHESIS

A procedure analogous to that involving mixing in an HTMC can be used to study the enthalpies of formation of compounds during their preparation, for example during solid-phase synthesis. This method has not been widely used up to the present, however. In a study of the syntheses, the reaction of skinnerite with sulphur at 720 K to give the non-stoichiometric sulphides[313]

$$CuSbS_3 + x\,S \rightarrow CuSbS_{3+x}$$

and of liquid sulphur with FeS_x at 433 K [314] were studied. The results of the measurements [314] were used to determine the concentration dependence of the enthalpy of formation of iron sulphides, $\Delta H_{433}^0 = -22.2 \pm 11.8x$ kcal mole^{-1} for $0 \leq x \leq 0.095$ and also for $0 \leq x \leq 0.125$.

The enthalpies of formation of the double sulphides and selenides of gallium and thallium have been studied.[315] Stoichiometric mixtures of the sulphides (selenides), placed in an ampoule in the cell of an HTMC, were heated to 550—553 K for the sulphides and to 625 K for the selenides, and the enthalpy of the solid-phase synthesis on heating was determined:

$$Ga_2S_3 + Tl_2S_3 \rightarrow 2\,TlGaS_2,\ Ga_2Se_3 + Tl_2Se_3 \rightarrow 2\,TlGaSe_2$$

A similar procedure has been used to study the thermochemistry of the solid-phase reactions involved in the formation of manganese and boron carbides at 1320 K.[316,317]

VII. THERMOCHEMISTRY OF THE MIXING OF MOLTEN SALTS

The experimental study of the thermochemistry of molten salts was begun by Kleppa[38] with measurements of the enthalpies of mixing of melts of sodium and potassium nitrates at 619 K and 721 K. An ampoule containing a molten nitrate was placed in the cell of an HTMC containing the melt of the other nitrate (see Fig. 2*d*); the reaction began when the ampoule was broken using the manipulator. To increase the accuracy of the measurement, the effect of mixing was compensated by dropping specimens of gold, whose high-temperature enthalpy is known. This method was used to study the concentration dependence of the enthalpies of mixing in binary melts formed by the alkali metal nitrates[318] and in the mixtures $AgNO_3$–M^1NO_3,[319] M^1NO_3–$M^2(NO_3)_2$,[320—322] and $TlNO_3$–M^1NO_3,[323] where M^1 represents an alkali metal, and M^2 an alkaline earth metal. The enthalpies of mixing were also measured in the ternary systems formed by alkali metal nitrates with silver nitrate at $T < 723$ K.[324]

In all the systems studied, the values of the enthalpies of mixing increase regularly with increase in the differences in the sizes of the cations, but the sign of the effect shows no regularity. For most nitrate systems containing alkali metals, the enthalpies of mixing are negative. Some experimental data giving the dependence of the enthalpy of mixing on the mole fraction of a nitrate[38,318—324] are shown graphically in Fig. 7.

In spite of a theoretical treatment of the enthalpies of mixing, based on various assumptions,[325] and a review of experimental data,[318,319] regular features having "predictive power" could not be found. In accordance with the conformational theory of solutions, therefore, further studies of enthalpies of mixing were undertaken to examine the influence of the size and charge of the ions on the enthalpy of mixing.

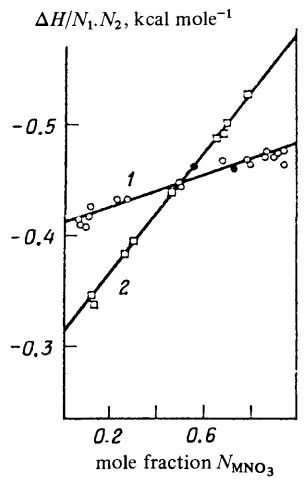

Figure 7. Dependence of the reduced enthalpy of reaction ($\Delta H/N_1.N_2$, kcal mole^{-1}) on the mole fraction of the nitrate (N_{MNO_3}) with the larger cation: *1*) KNO_3–$NaNO_3$, *2*) KNO_3–$AgNO_3$.

The enthalpies of mixing were studied for the halide systems MCl–M'Cl,[89–91,326,327] MCl–M'Cl–AgCl,[116,328] MCl–MCl_2,[329–333] MBr–MBr_2,[334] MCl_2–$M'Cl_2$,[335–338] and MI–M'I,[339] and the halide–nitrate systems MCl–MNO_3, MBr–MNO_3.[340–342] The use of halide melts, which are corrosive, made it necessary to modernise the HTMC to prevent the corrosive action of the halides. The inner metallic part of the calorimeter was protected by introducing a glass tube. Since the melting points of the halides are higher than those of the nitrates, the working temperature of the cell was increased to 1100 K,[320] or to ≥1300 K in the study of the fluorides.[343] The measurements were made in an atmosphere of nitrogen[319] or argon.[331] Before the experiment, the salts were placed in a quartz crucible and in a tube with an opening bottom (Fig. 8).

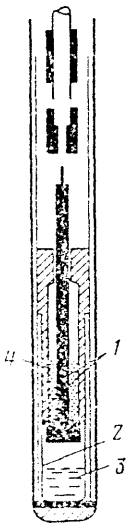

Figure 8. Reaction assembly for measuring the enthalpies of mixing of fluoride melts: *1*) ampoule with opening bottom, *2*) quartz cell, *3*) solvent (melt of the first component), *4*) melt of the second component.

For the study of molten alkali metal fluorides,[343,345] the inner parts of the HTMC were protected more thoroughly against corrosion.[343,344] The calorimeter cell containing the molten fluoride was made of platinum, and the melt of the second fluoride was placed in a platinum tube lowered into the first melt. The melts were mixed by displacing the melt from the tube by a graphite plunger (Fig. 9). This method was used to study the systems MF–M'F,[325,333] MF–MF_2,[344, 346–350] MF–AlF_3,[351,352] MF_2–MF_3,[351,352] MF–MCl, MF–MBr, and MF–MI.[353] The nature of the concentration dependence of the enthalpies of mixing of the fluorides differs from that for other halide systems (Fig. 10); there is considerable deviation from the linear relationship predicted by theory.[348] In the study of various chloride and more particularly fluoride systems, it was assumed that mixing leads to the formation of anionic complexes such as $PbCl_4^{2-}$, $PbCl_5^{3-}$,[329] MgF_4^{2-},[345] BeF_4^{2-}, and AlF_6^{3-}.[345,352]

The enthalpies of mixing have also been studied for oxygen-containing compounds such as carbonates,[354] sulphates,[355] metaphosphates,[160] and hydroxides,[357] and also WO_3(crystalline)–MWO_4(liquid),[358] Cs–CsCl,[359,360] LiF–Na_2SO_4, and Li_2SO_4–NaF.[361] A systematic analysis of experimental data was carried out by Kleppa,[22,342] and the data on binary salt melts was systematised.[363,364]

Thus high-temperature microcalorimetry has led to the accumulation of extensive experimental material with a high reliability. The influence of the size and charge of the ions (cation and anion) on the enthalpies of mixing of binary salt melts has been studied. Fig. 10 gives as an example the dependence of the reduced enthalpy of reaction $[\Delta H/N_1(1 - N_1)]$ on the mole fraction of the component with the smaller ion size.

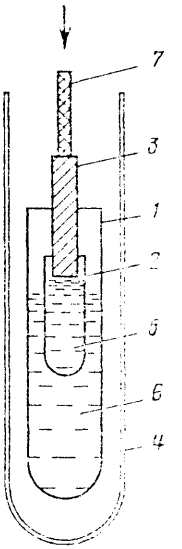

Figure 9. Reaction assembly for measuring the enthalpies of mixing of fluoride melts: *1*) platinum cell, *2*) platinum ampoule, *3*) graphite plunger, *4*) quartz cell, *5*, *6*) fluoride melts, *7*) plunger holder.

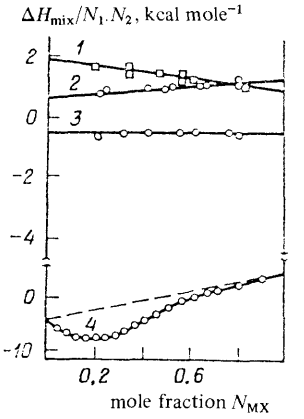

Figure 10. Dependence of the reduced enthalpy of reaction ($\Delta H/N_1.N_2$, kcal mole^{-1}) on the mole fraction (N_1) of the component with the smaller cation: *1*) LiCl–$PbCl_2$, *2*) LiBr–AgBr, *3*) $SrCl_2$–$BaCl_2$, *4*) LiF–BeF_2; N_1 is the mole fraction of the halide (MX) with the smaller cation, where X = chloride, bromide, or fluoride.

VIII. HIGH-TEMPERATURE ENTHALPIES AND ENTHALPIES OF PHASE TRANSFORMATIONS, DETERMINED BY MIXING

The high-temperature enthalpy of a chemical compound, mineral, or metal is determined by the classical thermochemical method of mixing calorimetry[365,366] by dropping a specimen with a mass of up to 20 g, heated in a furnace to the required temperature T, into a calorimeter cell at a constant standard temperature (298 K). The magnitude of the effect is determined by comparing with the values of the differences $H_T - H_{298}$ for standard substances (α-Al_2O_3, Pt, MgO, Au), used to calibrate the instrument.[135,367,368] This method is used to obtain the temperature dependence of $H_T - H_{298}$, and differentiation of this relationship with respect to T gives the temperature dependence of the mean heat capacity. When measurements are made by this method (hot → cold), sudden cooling (quenching) of the specimen is possible, and this may lead to the formation of metastable phases or structural defects and hence to errors which are eliminated only by additional measurments using other methods of study.

Cases of this kind were analysed in a study of the temperature dependence of the heat capacity of lithium ferrite,[348] where it was shown that the published values of $H_T - H_{298}$ for lithium ferrite, obtained by the classical method of mixing calorimetry, may contain a systematic error associated with the quenching of the specimen when it is dropped into the calorimeter cell.

In high temperature microcalorimetry, the specimen at the standard temperature of 298 K is dropped into the microcalorimeter cell heated to the required temperature T, after which the heat used to raise the temperature of the specimen is measured.[78,349] Thus in high-temperature microcalorimetry, the procedure (cold → hot) is the opposite of that in classical mixing calorimetry. High-temperature microcalorimetry makes it possible to eliminate the errors noted earlier. Another advantage of this method is the possibility of using specimens with a comparatively small mass (<1 g), thanks to the high sensitivity of the thermal detectors. The mass of the specimen is usually 100–300 mg.

*Defect spinel–ilmenite phase transformation.

The mixing method using HTMC began to be widely used after the publication of the first studies[86,370] and the development of an automatic device for dropping the specimens.[87] The accuracy of the results obtained by this method is higher when a compact specimen (crystal or tablet) is used. Powdered specimens are placed in a special ampoule made of Pt or Ag, and the heat capacity of the ampoule should not be greater than 15% of the total heat capacity of the specimen and the ampoule.

The improvement of the experimental procedure has made it possible to carry out measurements with extremely small specimen masses (2–10 mg) in the range 400–1100 K;[371,372] the use of a special device (see Fig. 1*b*) led to a marked increase in the sensitivity of the measurements. The heat-absorption time was decreased by a factor of 2, from 70 s to 25–30 s. When the temperature of the HTMC block is kept constant to within ±0.1 K, the uncertainty of the measurements is 2%.

As a consequence of these advantages, the method involving mixing using HTMC has been widely used, for example to determine the temperature dependence of the enthalpy and heat capacity of simple and double molybdates of the lanthanides and yttrium,[243–245,373–375] yttrium and lanthanum chromites,[376,377] yttrium and lathanide ferrites,[233,378,379] double sulphides of chromium, iron, cobalt, and copper,[283,380] quartz,[86] borosilicate and aluminosilicate minerals,[381,386] and a number of other substances and minerals.[40,162,349,387–392] The results of the experimental measurements, treated using the Mayer–Kelley equation and also using a special programme,[393] are given in Tables 16–18.

The method of mixing using HTMC also make it possible to study the energies of the transformations taking place when the dropped specimen is heated. Thus the enthalpy of the volatilisation of MoO_3 was measured by dropping MoO_3 (298 K) into an HTMC cell heated to 1086.1 K and 1119.4 K [373] and weighing after keeping for different time intervals; a similar method was used to determine the enthalpy of fusion of $NaBeF_3$.[349] The method of mixing from 298 K to 1083 K [391] was used to study the enthalpy of the defect spinel–ilmenite transformation in a $CoTiO_3$ specimen, and the phase transformation in TiO_2.[396] Most studies, however, have been devoted to the sublimation, volatilisation, or fusion of metals, for example the study of the enthalpy of the sublimation of zinc and tellurium at 1093 K [397,398] and of cadmium at 590 K;[399] an extremely large amount of experimental data has been obtained, and it cannot be examined in the present review.

---o0o---

While the present review was being prepared for publication, new papers appeared on the study of the theory[411] and practice[412,413,414] of high-temperature microcalorimetry, the thermochemical properties of lanthanide oxides, manganese borides, iron and aluminium vanadates, alkali metal perrhenates, lanthanide tungstates, and ferrite solid solutions,[415–420] and also on the thermochemistry of minerals.[421–423]

The Properties and Reactions of Ammonium Fluorides

E.G.Rakov and E.I.Mel'nichenko

The most important thermal properties of ammonium fluorides and fluorometallates, and the reactions of ammonium fluorides with elements, other simple fluorides, oxides, and salts have been reviewed.
The bibliography contains 379 references.

CONTENTS

I. Introduction 851
II. Properties of ammonium fluorides 851
III. Thermal properties of fluoro- and oxofluorometallates 852
IV. Reactions of ammonium fluorides 856
V. Conclusion 861

I. INTRODUCTION

Inorganic fluorides play an important role in modern technology. The principal methods for their preparation are based on the use of anhydrous hydrogen fluoride, fluorine, and hydrofluoric acid, and, on a smaller scale, halogen fluorides.[1] The original raw materials for the production of all these reagents are fluorite concentrates, which are treated with sulphuric acid to give hydrogen fluoride or hydrofluoric acid; hydrogen fluoride is decomposed electrolytically to give fluorine, and fluorine is used to synthesise halogen fluorides.[2]

This is not the only scheme, however. Phosphorite and apatite concentrates, which are raw materials for the phosphorus fertiliser industry,[3] are used in addition to fluorite concentrates as an industrial source of fluorine on every scale. A technical by-product (ammonium "fluoride–hydrogen fluoride"), consisting of a mixture of NH_4HF_2 and NH_4F, is now being obtained from the waste gases from the production of superphosphates.[4–8] Pure and technical grade ammonium fluorides can be used to obtain anhydrous hydrogen fluoride and hydrofluoric acid, and also directly for fluorination. They have been used, for example, to extract metals from beryl,[9] ilmenite,[10] pyrochlore,[11] monazite,[12] and scheelite,[13–15] to dissolve metals,[16] to purify fluorides,[17] and to obtain the fluorides of aluminium,[18] zinc,[19] cadmium,[20] and many other metals.

As a result of the exhaustion of rich fluorite deposits, the increase in the production of phosphoric acid and phosphorus fertilisers, and the need to obtain more complete utilisation of fluorine compounds, the volume of fluorides obtained from natural phosphorites, and the importance of ammonium fluorides as fluorinating agents, are increasing continuously.

Ammonium fluorides (anhydrous or in aqueous solution) react with many substances. These reactions are specific, and are accompanied by the formation of ammonium fluorometallates or oxofluorometallates. Increase in the temperature of synthesis or the action of heat on the fluorometallates lead to their thermal decomposition. The characteristic regular features of these reactions and the thermal properties of fluorometallates are important for optimising the conditions for the synthesis of fluorides using ammonium fluorides. Since published data on these topics have not been summarised before, the aim of the present review was to fill this gap.

A special section of the review is devoted to a brief description of the properties of ammonium fluorides, since these properties to a large extent determine the thermal characteristics of ammonium fluorometallates,[21] and it is necessary to supplement the last review, published about 10 years ago.[22]

II. PROPERTIES OF AMMONIUM FLUORIDES

Two compounds of ammonia with hydrogen fluoride, stable under ordinary conditions, are known: NH_4F and NH_4HF_2.

Ammonium fluoride is a colourless substance which forms hexagonal crystals with the wurtzite lattice (space group $P6mc$).[23–27] This distinguishes it from other ammonium halides, which have cubic structures, and is related to the formation of strong hydrogen bonds by NH_4F [28] and is responsible for the fact that the NH_4^+ groups are immobile in the crystal.[29,30] At 23°, the crystal lattice of NH_4F has the parameters: $a = 0.4439$ nm, $c = 0.7165$ nm, $z = 2$.[23,31] The measured and calculated values of the density are 1.002 g cm^{-3} and 1.006 g cm^{-3} respectively.[31]

The boiling point of NH_4F is not known. When heated, NH_4F decomposes according to the equation

$$2\,NH_4F(\text{crystalline}) \rightarrow NH_4HF_2(\text{crystalline}) + NH_3(\text{gas}) \qquad (1)$$

and this also distinguishes it from other ammonium halides. In the temperature range 343–383 K, the decomposition pressure (the equilibrium pressure of the gaseous products) is given by the expression[32]

$$\lg p\,[\text{mmHg}] = -8.82996 + 3022.966/T + 6.87415 \lg T$$

and in the range 404.2–438.9 K it is given by the equation:[33]

$$\lg p\,[\text{mmHg}] = 47.863 - 6582/T - 11.365 \lg T$$

The temperature at which the NH_3 pressure becomes equal to 760 mmHg is ~167 °C.[33–35]

The standard enthalpy of reaction (1), determined calorimetrically, is 19.7 kcal, and the value calculated from tensimetric data is 19.1 kcal.[36] The enthalpy of the reaction

$$NH_4F(\text{crystalline}) \rightarrow NH_3(\text{gas}) + HF(\text{gas})$$

at 298 K is 35.8 ± 0.9 kcal (calorimetry) or 35.1 ± 1.0 kcal (tensimetry).[36] The standard enthalpy of formation of NH_4F [37] is 110.8 ± 0.6 kcal mole^{-1}, and the Gibbs free energy $\Delta G^0_{\text{formation}}$ (298 K, NH_4F, crystalline) = −83.28 kcal mole^{-1}. The values were obtained assuming that $\Delta H^0_{\text{formation}}$ (298 K, HF, gas) = −64.8 kcal mole^{-1}, although the absolute value accepted at present is larger (−65.32 kcal mole^{-1}).[38]

The standard heat capacity and entropy of crystalline NH_4F are 15.60 ± 0.02 cal mole^{-1} K^{-1} and 17.20 ± 0.05 cal mole^{-1} K^{-1}.[39] The heat capacity data in Ref.40 do not agree with those in Ref.39, and are apparently erroneous.

Ammonium fluoride is readily soluble in water; its solubility at 25 ° is 45.38%.[41] It is unstable in aqueous solution, and when heated it decomposes with the liberation of NH_3, so that it cannot be obtained by evaporating its solutions;[4,6,7,41] NH_4F is readily soluble in liquid HF, and with NH_4HF_2 it forms a eutectic melting at 109.3°.[35,43]

Ammonium hydrogen fluoride (bifluoride) is a colourless slightly hygroscopic substance, which forms an orthorhombic crystal lattice with parameters $a = 0.840$, $b = 0.816$, $c = 0.367$ nm, $z = 4$, space group *Pman*, calculated density 1.505 g cm^{-3}.[23] The NH_4^+ group is joined to the F atom by hydrogen bonds: each fluorine atom forms two hydrogen bonds with nitrogen atoms, and one with another fluorine atom.[44] The melting point of NH_4HF_2 is 126.45°, and the enthalpy of fusion 4.564 ± 0.002 kcal mole^{-1}.[45]

The decomposition pressure of solid NH_4HF_2 at 343–383 K is given by the equation:[32]

$$\lg p\ [\text{mmHg}] = 5.42446 - 3424.363/T + 1.60995 \lg T$$

Over a wider temperature range (209–399.3 K), the decomposition pressure is given by the expression:[33]

$$\lg p\ [\text{mmHg}] = 6.723 - 3295/T + 6.915 \lg T - 0.00547\,T.$$

The decomposition pressure of liquid NH_4HF_2 in the range 392.5–411.7 K is given by the equation:[33]

$$\lg p\ [\text{mmHg}] = 20.809 - 4256/T - 3.6 \lg T + 0.00028\,T$$

The boiling point of NH_4HF_2 is ~238 °C.[6,7,33,35,46] Liquid NH_4HF_2 has an anomalously high compressibility, compared with the solid phase.[47]

The standard enthalpy of the reaction

$$NH_4HF_2(\text{crystalline}) \rightarrow NH_3(\text{gas}) + 2HF(\text{gas})$$

is 51.9 ± 0.2 kcal mole^{-1} [36] or 51.4 kcal mole^{-1} [48] from calorimetric data, or 51.1 kcal mole^{-1} [32,36] from tensimetric data. In Ref. 37, the value of $\Delta H^0_{\text{formation}}$ (298 K, NH_4HF_2, crystalline) was taken as −191 ± 1 kcal mole^{-1}. From calorimetric data, C_p^0(298 K) = 25.48 cal mole^{-1} K^{-1}, and S^0(298 K) = 27.61 cal mole^{-1} K^{-1}.[23,37,49]

Ammonium hydrogen fluoride is readily soluble in water. At 25° its solubility is 41.50 mass %[41] or 41.08 mass %,[48] and the enthalpy of solution to give a saturated solution is 5.12 ± 0.06 kcal mole^{-1}.[48] The soluion is accompanied by the absorption of heat. The density of the saturated solution at 25° is 1.1273 g cm^{-3}.[50] NH_4HF_2 is also readily soluble in liquid HF. In the NH_4HF_2–HF system, the compounds $NH_4H_3F_4$ and $NH_4H_5F_6$, which melt congruently (melting points 23.2° and −8.0°) and decompose readily with the liberation of HF, are formed.[43]

Thus ammonium hydrogen fluoride is of greatest interest as a fluorinating agent. Ammonium fluoride, when heated to medium temperatures, decomposes to ammonium hydrogen fluoride, and at temperatures above 165–170° it can exist only at an ammonia pressure greater than 1 atm. The "vapours" of ammonium fluorides, that is their thermal decomposition products, contain hydrogen fluoride, and can therefore take part in reactions characteristic of HF.

The properties of ammonium fluorides are such that in the thermal decomposition of ammonium fluorometallates, in addition to the absorption of heat as a result of decomposition to simple fluorides, at temperatures above 165–170° (and more particularly above 235–240°) absorption of heat takes place as a result of the highly endothermic decomposition of ammonium fluoride itself.

III. THERMAL PROPERTIES OF AMMONIUM FLUORO- AND OXOFLUOROMETALLATES

All the transition elements except the heavy actinides, and also beryllium, magnesium, and the non-transition elements of groups III–V except carbon and nitrogen, can form ammonium fluorometallates. Transition elements from the central part of the periodic system (mainly metals of groups V–VII), and also uranium and the non-transition elements of group V, also form oxofluorometallates.

Subsequent sections examine the compositions of the compounds and give the sequence of stages in the thermal decomposition, the temperatures of the separate stages, and the enthalpies of formation and other thermodynamic parameters of ammonium fluoro- and oxofluorometallates, except for the characteristics of the low-temperature phase transformations.

1. Compounds of Non-Transition Elements

Beryllium forms $(NH_4)_2BeF_4$, NH_4BeF_4, and $NH_4Be_2F_5$.[51–53] The tetrafluoroberyllate decomposes with the successive formation of NH_4BeF_3, $NH_4Be_2F_5$, and BeF_2; the minima of the endothermic effects on the differential thermal analysis (DTA) curves for the first two stages lie at 300° and 360°;[53] under isothermal conditions, the decomposition can be carried out at lower temperatures.[52] The standard enthalpy of formation of $(NH_4)_2BeF_4$ is −475.7 ± 1.5 kcal mole^{-1},[54,55] the Gibbs free energy $\Delta G^0_{\text{formation}} = 413.1$ kcal mole^{-1},[55] $S^0 = 59.8 \pm 0.6$ cal mole^{-1} K^{-1}, and $C_p^0 = 50.4 \pm 0.5$ cal mole^{-1} K^{-1}.[55,56]

Magnesium forms $MgF_2.2NH_4F.2H_2O$, $MgF_2.2NH_4F$, and $MgF_2.NH_4F$. Dehydration takes place at 110°;[57] $MgF_2.2NH_4F$ decomposes to $MgF_2.NH_4F$ and then to MgF_2 at 215–220° and 280–285° respectively.[57–59]

The fluoroborates NH_4BF_4 and $NH_4BF_4.NH_4F$,[60] and a large number of oxofluoro- and hydroxofluoroborates, for example $NH_4B(OH)_2F_2$, $NH_4B(OH)_3F$, NH_4BOF_4 or $(NH_4)_3B_3O_3F_{12}$, $(NH_4)_2BOF_3$, $(NH_4)_2B_3O_3(OH)F_4$, and $(NH_4)_2B_4OF_{12}$,[61,62] have been synthesised.

The thermogram of ammonium tetrafluoroborate shows endothermic effects with minima at 176 and 346°, corresponding to its polymorphic transformation and decomposition (sublimation).[61] According to Refs. 63 and 64, the temperature of the transformation is 205 ± 3°, and according to Ref. 65 it is 208 ± 2°. The enthalpy of the transformation is 2.4 ± 0.1 kcal mole^{-1}.[65] The decomposition pressure is given by the equation[66]

$$\lg p\ [\text{mmHg}] = 6.82 - 2469/T$$

so that the decomposition temperature is close to 354°, and the enthalpy of decomposition is close to 33.9 kcal mole^{-1}. The standard values of C_p^0 and S^0 for NH_4BF_4 are 32.09 cal mole^{-1} K^{-1} and 46.77 cal mole^{-1} K^{-1}.[67] According to Refs. 65 and 66 and the estimates of the present authors, $\Delta H^0_{\text{formation}}$ (298 K, NH_4BF_4, crysallline) ≦ −381.4 kcal mole^{-1}, $\Delta G^0_{\text{formation}}$ (298 K, NH_4BF_4, crystalline) ≦ −341 kcal mole^{-1}.

The reaction

$$(NH_4)_2B_3O_3(OH)F_4 \rightarrow NH_4BF_4 + B_2O_3 + NH_3 + H_2O$$

takes place at 200–250°.[68]

Aluminium, gallium and indium form higher fluorometallates with the same composition, $(NH_4)_3MF_6$. The hexafluoroaluminate decomposes in two stages with the successive formation of NH_4AlF_4 and γ-AlF_3.[69,72] It has been reported[7] that the thermal decomposition also gives the compound $NH_4AL_2F_7$, and

the compound $(NH_4)_2HAlF_6.H_2O$ has been described in a patent.[73]

The reactions

$$(NH_4)_3AlF_6(\text{crystalline}) \rightarrow NH_4AlF_4(\text{crystalline}) + 2NH_3(\text{gas}) + 2HF(\text{gas})$$
$$NH_4AlF_4(\text{crystalline}) \rightarrow \gamma\text{-}AlF_3 + NH_3(\text{gas}) + HF(\text{gas})$$

give endothermic effects at 305° and 450°; the equilibrium constants of these reactions are given by the equations:[71,72]

$$\lg K_p = 30.455 - 18182/T \quad (507 \leqslant T \leqslant 578\ \text{K})$$
$$\lg K_p = 17.240 - 13071/T \quad (663 \leqslant T \leqslant 731\ \text{K})$$

The mean enthalpies of decomposition of $(NH_4)_3AlF_6$ and NH_4AlF_4 are 83 ± 1 kcal mole^{-1} and 60 ± 1 kcal mole^{-1}, and the enthalpies of formation −731.3 kcal mole^{-1} and −496.6 kcal mole^{-1} respectively.[64]

According to Refs.74 and 75, $(NH_4)_2GaF_5.H_2O$ is dehydrated at 100–150°, and decomposes with the successive removal of two NH_4F molecules at 350° and 450°. Ammonium hexafluoroindate is converted at 280° into the pentafluoroindate, which then decomposes in two stages at 320° and 400°.[76] In Ref.77, much lower temperatures are given for the start of the separate stages (120, 170, and 185°). These data are less accurate, since if NH_4F were removed at such low temperatures, the thermograms would also have shown the effect at 238° corresponding to the "boiling" of NH_4HF_2. $(NH_4)_5In_3F_{14}$, $NH_4In_2F_7$, and $NH_4In_3F_{10}$ have been obtained directly from the simple fluorides.[78] $(NH_4)_2Ga(OH)_2F_3$ and $(NH_4)_2In(OH)_2F_3$ have also been described.[79]

Silicon forms the double salt $(NH_4)_2SiF_6.NH_4F$, which according to thermographic data decompose above 190°, and also ammonium hexafluorosilicate, which decompose above 300°.[80,81] The vapour pressure over $(NH_4)_2SiF_6$ at 532–592 K is given by the equation:[81]

$$\lg p\ [\text{mmHg}] = 9.94 - 4170/T$$

If it is assumed that $(NH_4)_2SiF_6$ decomposes to SiF_4, NH_3, and HF, the values of the enthalpies of decomposition and formation of $(NH_4)_2SiF_6$ from the elements are 95.4 kcal mole^{-1} and −633.1 kcal mole^{-1} respectively. The standard enthalpy of formation, determined calorimetrically, is −642.6 kcal mole^{-1}, the Gibbs free energy is −567.4 kcal mole^{-1}, $S^0 = 68.0$ cal mole^{-1} K^{-1}, and $C_p^0 = 59.25$ cal mole^{-1} K^{-1}.[82,83]

Germanium forms compounds similar to the silicon compounds: $(NH_4)_2GeF_6.NH_4F$ and $(NH_4)_2GeF_4$.[64] The hexafluorogermanate decomposes in a single stage with a minimum on the DTA curve at 400°.[85]

Tin(II) forms the fluorostannate $(NH_4)_2SnF_4.2H_2O$,[86] described as early as 1886, and also NH_4SnF_3 and $NH_4Sn_2F_5$.[87] The last two compounds decompose in an evacuated vessel at 160–200°.

Tin(IV) forms the fluorides $(NH_4)_4SnF_8$, $(NH_4)_2SnF_6$ (described in 1859),[86] $(NH_4)_2SnF_6.NH_4F$, $(NH_4)_2Sn(OH)F_5$, $(NH_4)_2Sn(OH)_2F_4.H_2O$, $(NH_4)_4Sn_2OF_{10}$, and $(NH_4)_3HSn_2OF_{10}$.[88] The thermal decomposition of $(NH_4)_2SnF_6.NH_4F$ takes place at 320°, and $(NH_4)_2SnF_6$ decomposes in two stages, at 410° and 500°[85] (according to Ref.89, the hexafluorostannate(IV) decomposes at 210°). The hydroxofluorostannates(II) decompose in three stages in the range 80–360°.[88]

Phosphorus(V) forms the fluoro-acids hexafluorophosphoric acid HPF_6, difluorophosphoric acid HPO_2F_2, and monofluorophosphoric acid H_2PO_3F, all of which form ammonium salts;[86] $NH_4PF_6.NH_4F$ has also been described.[90] Ammonium difluorophosphate and monofluorophosphate are thermally stable at 135°; the monofluorophosphate decomposes at 220° to NH_4HPO_3F, which melts at ~226°.[91,92]

Arsenic(V) gives similar compounds: NH_4AsF_6,[93] $NH_4As.(OH)F_5$, $NH_4As(OH)_2F_4$,[94] and $(NH_4)_2AsO_2F_2$.[95]

Antimony(III) gives the following compounds with alkali metal and ammonium cations: M_2SbF_5, $MSbF_4$, MSb_2F_7, and MSb_4F_{13};[96,97] *antimony(V)* forms M_2SbF_7 and $MSbF_6$. The compound $(NH_4)_2SbF_5$ undergoes phase transformations at temperatures between −23° and 17°.[98]

Bismuth(III) forms NH_4BiF_4.[86]

The melting point of NH_4SO_3F is 245°.[96]

2. Compounds of the Transition Elements

Copper(II) forms the compounds $(NH_4)_2CuF_4$ and NH_4CuF_3, which separate from aqueous solutions as the hydrates,[86] but which can also be obtained anhydrous.[99] The decomposition of NH_4CuF_3 gives a minimum on the DTA curve at 250°, and is accompanied by the absorption of 34.2 kcal mole^{-1}.[100]

Zinc and cadmium form the fluorides $(NH_4)_2ZnF_4.2H_2O$, $(NH_4)_2CdF_4.2H_2O$,[101] NH_4ZnF_3, NH_4CdF_3;[99,100] the anhydrous fluorides $(NH_4)_2CdF_4$ and $(NH_4)_3Cd_2F_7$ have also been described.[102] The decomposition temperatures of the trifluorometallates of zinc and cadmium are 250° and 205°, and the enthalpies of decomposition are 33.9 kcal mole^{-1} and 33.3 kcal mole^{-1} respectively.[100] As in the case of the fluorocuprate, the values obtained for the enthalpy of decomposition are lower than the value for the decomposition of NH_4F itself, so that they must be regarded with caution.

Scandium forms complex compounds with compositions corresponding to those of the aluminium compounds. Ammonium hexafluoroscandate decomposes at 260–290° and 340–350° with the successive formation of NH_4ScF_4 and ScF_3.[103–105]

The equilibria for the reactions

$$(NH_4)_3ScF_6(\text{crystalline}) \rightarrow NH_4ScF_4(\text{crystalline}) + 2NH_3(\text{gas}) + 2HF(\text{gas})$$
$$NH_4ScF_4(\text{crystalline}) \rightarrow ScF_3(\text{crystalline}) + NH_3(\text{gas}) + HF(\text{gas})$$

at 448–492 K and 563–605 K respectively are described by the equations:[106]

$$\lg K_p = 29.8 - 15400/T$$
$$\lg K_p = 16.0 - 10200/T$$

The mean enthalpies of decomposition of $(NH_4)_3ScF_6$ and NH_4ScF_4 are 70.5 kcal mole^{-1} and 46.7 kcal mole^{-1} respectively. Since they are independent of temperature, and $\Delta H^0_{\text{formation}}(298\ \text{K}, ScF_3, \text{crystalline}) = -394 \pm 2$ kcal mole^{-1},[107] the standard enthalpies of formation of the corresponding ammonium fluoroscandates can be found (−737 ± 7 kcal mole^{-1} and −517 ± 5 kcal mole^{-1}).

Yttrium forms the compound $NH_4Y_2F_7.NH_4F$, which decomposes in two stages, at 260° and 380°, to give $NH_4Y_2F_7$ and YF_3.[106] The equilibrium for the reaction

$$NH_4Y_2F_7(\text{crystalline}) \rightarrow 2YF_3(\text{crystalline}) + NH_3(\text{gas}) + HF(\text{gas})$$

at 601–653 K is described by the equation:

$$\lg K_p = 12.9 - 9000/T$$

Thus the mean enthalpy of decomposition is ~41 kcal mole^{-1}.

In the systems LnF_3–NH_4F–H_2O (Ln = lanthanum or a lanthanide), crystalline phases with the most varied compositions have been detected.[108,109] The compounds identified

most reliably are $(NH_4)_3LnF_6$, $(NH_4)_3Ln_2F_9$, NH_4LnF_4 (or $(NH_4Ln_2F_7.NH_4F)$, and $NH_4Ln_2F_7$.[110–114] According to Ref. 110, many lanthanides also form the compounds $(NH_4)_3Ln_2F_9.H_2O$. La, Pr, Nd, Sm, Eu, Gd, and Tb form tetrafluorometallates NH_4LnF_4, which decompose directly to LnF_3; Dy, Ho, Er, Tm, Yb, and Lu form $NH_4Ln_2F_7.NH_4F$ or $(NH_4)_3.Ln_2F_9$, which decompose at 250–270° to $NH_4Ln_2F_7$, and at 350° to LnF_3.[110,111]

Table 1. Characteristics of the decomposition of NH_4LnF_4.

Ln	T, K	$\lg K_p = A - B/T$		ΔH_T^0, kcal mole^{-1}
		A	B	
Pr	478—516	18.556	9 980	45.6
Nd	478—523	18.551	10 201	46.7
Sm	500—528	17.070	9 780	44.7
Gd	497—545	19.150	10 858	49.7

The decomposition pressures and enthalpies of decomposition of various Ln compounds are given in Table 1.[111]

The equilibrium for the reaction

$$NH_4Dy_2F_7(\text{crystalline}) \rightarrow 2DyF_3(\text{crystalline}) + NH_3(\text{gas}) + HF(\text{gas})$$

at 584–614 K is described by the expression:

$$\lg K_p = 32.003 - 20122/T$$

The enthalpy of the reaction is 46.0 kcal mole^{-1}.[111]

The thermal decomposition of NH_4EuF_4 takes place at 258° with the absorption of 21.8 ± 0.1 kcal mole^{-1}.[114] The enthalpy of the process was found in Ref.114 by differential scanning calorimetry, and is apparently too low.

The compounds $(NH_4)_3Ln_2F_9.H_2O$, where Ln = La, Pr, Sm, and Er, are dehydrated at 100°, and then decompose to $NH_4Ln_2F_7$ (at 200–215° for Sm and Eu) or to NH_4LnF_4 (at 170–185° for La and Pr). For the La Salt, the dehydration and the removal of NH_4F take place simultaneously.[109] According to Ref.109, the compounds $(NH_4)_2Ln_3F_{11}.H_2O$, where Ln = Dy, Ho, and Er, also exist, and at 60–120° decompose to $(NH_4)_2Ln_3F_{11}$ and then to $NH_4Ln_3F_{10}$ (at 204° for Ho) or to the trifluorides (at 159° for Dy and at 316° for Er). These data are apparently contradictory. For example, it is not clear why the trifluoride is formed from $(NH_4)_3Dy_2F_7$ at temperatures above 350°, but is formed from $NH_4Dy_3F_{10}$ even at 159°.

According to Ref.113, $(NH_4)_3NdF_6$ decomposes to NH_4NdF_4 at 350–400° and to NdF_3 at ~500°. The decomposition of $(NH_4)_3Ce_2F_9$ at 430° in a vacuum leads to the successive formation of NH_4CeF_4 and CeF_3.[115] According to Ref.116, NH_4CeF_4 decomposes to CeF_3 at 400–450°.

Cerium is unique among the lanthanides in its ability to form Ce^{IV} compounds. $(NH_4)_4CeF_8$, $(NH_4)_3CeF_7$, $(NH_4)_2CeF_6$, NH_4CeF_5, and $(NH_4)_7Ce_6F_{31}$ are known.[117–119] The decomposition of the most complex compounds begins at 108°, and is complete at 430° with the formation of CeF_3. Anhydrous CeF_4 may be formed at 300°.[118]

The actinides(IV) Th, Pa, U, Np, Pu, and Am have properties similar to those of Ce^{IV}. For each of these elements, the most complex ammonium fluorometallates are $(NH_4)_4AnF_8$ (where An = actinide), which decompose successively to $(NH_4)_2AnF_6$, $NH_4Th_2F_9$, $NH_4Th_2F_9.H_2O$,[125] and $7NH_4F.2ThF_4.H_2O$.[126]

Thorium forms $(NH_4)_4ThF_8$, which gives slightly different decomposition products. $(NH_4)_3ThF_7$,[124] $(NH_4)_2ThF_6$, $NH_4Th_2F_9$, $NH_4Th_2F_9.H_2O$,[125] and $7NH_4F.2ThF_4.H_2O$ [126] have been described.

Uranium forms the fluorometallate series $UF_6.nNH_4F$, $UF_5.nNH_4F$, and $UF_4.nNH_4F$. Ammonium oxofluorouranates(VI), or ammonium uranyl fluorides, are also known.

Only one ammonium fluorouranate(VI) has been obtained: NH_4UF_7.[124–126] According to Ref.127, its thermal decomposition takes place in three stages, involving the exothermic reduction of U^{VI} to U^V at 100–130°, the decomposition of NH_4F at 200–320°, and reduction to UF_4 at 350–450°. NH_4UF_6 is formed in the first stage.[128]

The UF_5–NH_4F system gives $(NH_4)_3UF_8$, $(NH_4)_2UF_7$, and NH_4UF_6.[128,129] According to Ref.130, the last compound is stable in a vacuum at 150°, although in Refs.131 and 132, vigorous exothermic decomposition is reported. In Ref.131, the mechanism of the decomposition was described by the equation

$$NH_4UF_6 \rightarrow UF_4 + NH_4F + 1/2\,F_2$$

which has not been rigorously proved, however, since fluorine and NH_4F are incompatible (see section IV).

U^{IV} compounds have been most extensively studied. Studies of the system UF_4–NH_4F and UF_4–NH_4F–H_2O [121,133,134] have made it possible to characterise $(NH_4)_4UF_8$, $(NH_4)_2UF_6$, $7NH_4F.6UF_4$, NH_4UF_5, and $NH_4F.3UF_4$. The reported[135] existence of anhydrous $(NH_4)_3UF_7$, $NH_4U_2F_9$, $NH_4U_4F_{17}$, and $NH_4U_6F_{25}$ is not sufficiently well-founded.

The octafluorouranate(IV) is stable in air to ~100°,[121] the hexafluorouranate(IV) to 225–250°, the pentafluorouranate(IV) to 350°, and $NH_4F.3UF_4$ to 450°.[136] In a vacuum, $(NH_4)_2UF_6$, NH_4UF_5, and $NH_4F.3UF_4$ decompose at 180, 290, and 400°.[121] The reported formation of HUF_5 from NH_4UF_5 at 320–360° [137] has not been confirmed.

The enthalpies of formation of $(NH_4)_4UF_8$, $(NH_4)_2UF_6$, $7NH_4F.6UF_4$, and $NH_4F.3UF_4$ are −941 ± 4, −413 ± 20, and −1510 ± 10 kcal mole^{-1}. The results[138] were calculated using the most reliable value for the standard enthalpy of formation of UF_4.[107]

The estimated values of the Gibbs free energy of formation of the compounds, given in Ref.119, are inaccurate. According to more reliable data,[139] for the formation of $(NH_4)_4UF_8$, $(NH_4)_2UF_6$, and $7NH_4F.6UF_4$ from the simple crystalline fluorides, the values of the change in the Gibbs free energy are −23.5, −20.9, and −97.1 kcal mole^{-1} respectively.

In the systems UO_2F_2–NH_4F–H_2O [140,141] and UO_3–NH_4F–H_2O,[142,143] the most stable complex compound is $(NH_4)_3UO_2F_5$. Its thermal decomposition takes place in two stages

$$(NH_4)_3UO_2F_5(\text{crystalline}) \rightarrow 1/2\,NH_4(UO_2)_2F_5(\text{crystalline}) + 5/2\,NH_3(\text{gas}) + 5/2\,HF(\text{gas})$$

$$1/2\,NH_4(UO_2)_2F_5(\text{crystalline}) \rightarrow UO_2F_2(\text{crystalline}) + 1/2\,NH_3(\text{gas}) + 1/2\,HF(\text{gas})$$

and the decomposition pressures are given by the equations:[144]

$$\lg p,\ [\text{atm}] = 8.01 - 4468/T \quad (516 \leqslant T \leqslant 558\ \text{K})$$

$$\lg p,\ [\text{atm}] = 6.927 - 4878/T \quad (647 \leqslant T \leqslant 703\ \text{K})$$

The mean enthalpies of decomposition are 102 ± 3 kcal mole^{-1} and 22 ± 2 kcal mole^{-1}.

The enthalpies of formation of $(NH_4)_3UO_2F_5$ and $NH_4.(UO_2)_2F_5$, found from tensimetric data,[144] are −749.4 kcal mole^{-1} and −918.0 kcal mole^{-1}, and coincide with the

calorimetric data (−748.9 ± 2.2 kcal mole^{-1} and −921.5 ± 2.8 kcal mole^{-1} from Refs.107 and 145, or −753 kcal mole^{-1} and −919 kcal mole^{-1} from Ref.138). The above values of the enthalpies of formation of oxofluorouranates(VI) were refined slightly by the present authors using published data[107] for UO_2F_2.

Under certain strictly defined conditions, ammonium oxofluorouranates(VI) can apparently sublime, and this has been made the basis of a method for extracting uranium from its ores.[146] These conditions cannot be determined from the thermal characteristics of salts and UO_2F_2 available at present.[147]

The hydrate $NH_4(UO_2)_2F_5.4H_2O$ melts at 64.5° and decomposes to give the trihydrate, which melts at 98.7° and decomposes to the anhydrous salt.[141] The enthalpies of formation of the hydrates have been measured.[148]

The data in Ref.149 on the formation of $NH_4UO_2F_3$ have not been confirmed experimentally by other workers, and are unreliable; the existence of an exothermic effect in the decomposition of pure $NH_4(UO_2)_2F_5$ [150] appears unlikely.

Neptunium forms fluorometallates in which the oxidation state of the metal is +4,[122] although the existence of neptunium(V) compounds is possible. The thermal decomposition begins at ~120° for $(NH_4)_4NpF_8$, 220° for $(NH_4)_2NpF_6$, 280° for $7NH_4F.6NpF_4$, and 300° for NH_4NpF_5. The most stable compound (up to ~600–650°) is $NH_3Np_3F_{13}$, which decomposes to the tetrafluoride.

Plutonium fluorides have properties similar to those of uranium fluorides. The thermal decomposition of ammonium octafluoroplutonate(IV) in air at 160° gives the hexafluoroplutonate, and at 210° the compound $7NH_4F.6PuF_4$; the latter is converted into NH_4PuF_5 in oxygen at 220°, into $NH_4F.3PuF_4$ in a vacuum at 290°, and into PuF_4 in a vacuum at 330°.[121] The formation of PuF_4 in the decomposition of ammonium fluoroplutonates(IV) has been confirmed;[151,152] the hydrate $NH_4PuF_5.2H_2O$ was not detected. Other workers,[119,153], however, report that the decomposition is complete with the formation of plutonium trifluoride. PuF_4 can apparently be reduced by ammonia, and the composition of the final product depends on the thermal decomposition conditions.

Published data[154] indicate that the thermal decomposition of ammonium fluorocurates(IV) also gives the trifluoride.

The transition metals of group IV in the oxidation state +4 do not form such a wide variety of fluorometallates as the actinides.

Titanium(IV) forms the compounds $(NH_4)_2TiF_6.NH_4F$,[155,156] $(NH_4)_2TiF_6$,[157] and NH_4TiF_5,[158] the first two of which were described in the middle of the last century by Marignac. Their decomposition in an inert medium is accompanied by the transfer of titanium to the gas phase (to the extent of 75% from published thermogravimetric curves,[85] 85% according to Ref.157, more than 95% according to Ref.158, and 100% according to Ref.159). The differences in the values obtained are due to differences in the moisture content of the gases surrounding the specimens, and the tendency of fluorotitanates to undergo hydrolysis.[160–162] Ammonium heptafluorotitanate decomposes slowly at temperatures above 150°, the hexafluorotitanate above 250°, and the pentafluorotitanate above 280°.

The enthalpy of formation of $(NH_4)_2TiF_6$ from the simple crystalline fluorides at 25° is −30.0 ± 1.0 kcal mole^{-1},[163] and that from the elements (using published data[164] for TiF_4) is −645.8 ± 2.6 kcal mole^{-1}.

Ammonium oxofluorotitanate $(NH_4)_2TiOF_4$,[158] peroxofluorotitanate $(NH_4)_3Ti(O_2)F_5$,[163,166] and fluorotitanate(III) NH_4TiF_4 also exist. The last compound decomposes to non-volatile titanium trifluoride at 600° in a stream of Ar or H_2.[167]

Zirconium(IV) and hafnium(IV) form $(NH_4)_3MF_7$, $(NH_4)_2MF_6$, and NH_4MF_5, whose thermal decomposition has been studied in detail.[157,168–173] The DTA curves show endothermic effects with minima at 315, 365, and 435° for $(NH_4)_3ZrF_7$, and at 300, 360, and 430° for $(NH_4)_3HfF_7$. Each minimum corresponds to the removal of 1 mole of ammonium fluoride. The equilibrium values of the decomposition pressures and enthalpies of decomposition of the zirconium and hafnium compounds are given in Table 2.

Table 2. Characteristics of the decomposition of Zr and Hf salts.[172]

Reactions	T, K	$\lg K_p = A - B/T$		ΔH^0_T, kcal mole^{-1}
		A	B	
3:1 → 2:1	525–567	13.79	8 330	38.1
2:1 → 1:1	578–625	12.72	8 500	38.8
1:1 → ZrF_4	640–687	14.42	10 500	48.1
3:1 → 2:1	518–565	16.28	8 710	44.4
2:1 → 1:1	578–625	14.60	9 750	44.6
1:1 → HfF_4	630–688	18.85	11 270	51.5

Note. 3 : 1, 2 : 1, and 1 : 1 represent respectively the formulae $(NH_4)_3MF_7$, $(NH_4)_2MF_6$, and MH_4MF_5, where M = Zr or Hf.

The enthalpies of the successive addition of crystalline NH_4F to crystallise ZrF_4, found from these values, are −12.9, −3.6, and 3.0 kcal mole^{-1}, which show satisfactory agreement with the calorimetric data (−13.5, −5.4, and −0.9 kcal mole^{-1}).[174] Thus the standard enthalpies of formation of $(NH_4)_3ZrF_7$, $(NH_4)_2ZrF_6$, and NH_4ZrF_5 −809.2 ± 0.7, −697.5 ± 0.7, and −581.2 ± 0.7 kcal mole^{-1} respectively. The Gibbs free energies are −703.6, −619.0, and −529.9 kcal mole^{-1} respectively (the absolute values of these quantities given in Ref. 164 are lower by ~5 kcal mole^{-1}).

For hafnium, the mean enthalpies of the successive addition of NH_4F to the tetrafluoride are −16.8, −9.4, and −8.6 kcal mole^{-1},[172] and the enthalpies of formation of $(NH_4)_3HfF_7$, $(NH_4)_2HfF_6$, and NH_4HfF_5 are −829.2, −709.6, and −589.2 kcal mole^{-1} respectively.

The enthalpy of the phase transformation of $(NH_4)_2ZrF_6$ at 138 °C is 1.7 kcal mole^{-1},[174,175] and the enthalpies of the transformations of $(NH_4)_2HfF_6$ at 140 °C and 240 °C are −1.39 kcal mole^{-1} and 1.18 kcal mole^{-1}.[175] The existence of the transformations influences the kinetics of the thermal decomposition.[173] The hydrate $NH_2ZrF_5.H_2O$ is also known; its standard enthalpy of formation is −651.97 ± 0.6 kcal mole^{-1}.[176]

The transition elements of group V have three characteristic oxidation states: +5, +4, and +3, so that in principle they can form compounds of the series $MF_5.nNH_4F$, $MOF_3.nNH_4F$, $MO_2F.nNH_4F$, $MF_4.nNH_4F$, $MOF_2.nNH_4F$, and $MF_3.nNH_4F$.

Vanadium forms compounds of all the series except $VF_4.nNH_4F$. Ammonium hexafluorovanadate(V) is very hygroscopic, and apparently thermally unstable.[177] Ammonium dioxotetrafluorovanadate is extremely unstable, and decomposes even at 50–60°. When this compound is heated,

$(NH_4)_2VO_2F_3$ is formed at 140°, $(NH_4)_3V_2O_4F_5$ at 160°, and $NH_4VO_2F_2$ at 180°.[178] The last compound begins to decompose at 150°[179] to give first an unidentified oxofluorovanadate, and then at 360° an oxide fluoride in which the oxidation state of vanadium is lower than +5[178] (the decomposition in air is complete with the formation of a product which does not contain fluorine).[180]

According to Ref.85, the oxofluorovanadate(IV) $(NH_4)_3VOF_5$ decomposes to give $(NH_4)_2VOF_4$, NH_4VOF_3, and VOF_2 successively at 250–300, 320–360, and 390–430°. The compound $NH_4V_3O_6F$ is also known;[181] the thermal decomposition of $(NH_4)_3VF_6$ begins at 250°, passes through stages involving the formation of $(NH_4)_2VF_5$, $VF_3.0.3NH_4F$, and VF_3, containing 0.1–1.5% NH_4^+, and is complete at 650–700° with the formation of the trifluoride.[182]

Niobium forms only ammonium oxofluoroniobates(V). The thermal decomposition of $(NH_4)_3NbOF_6$ gives $(NH_4)_2NbOF_5$, NH_4NbOF_4, and NbO_2F successively at 255, 320, and 420°.[183] It was also suggested[183] that the decomposition of NH_4NbOF_4 gives the oxide fluoride $NbOF_3$, which then decomposes to NbO_2F and NbF_5.

The most complex ammonium fluorometallate formed by tantalum is $(NH_4)_3TaF_8$, which is unstable even at 100°.[184] The more stable $(NH_4)_2TaF_7$ decomposes at 310° and 390° to give NH_4TaF_6, and then a mixture of TaF_5, NH_3, and HF.[184] The presence of water vapour leads to hydrolysis to TaO_2F and to a decrease in the quantity of tantalum volatilised. The enthalpies of formation of $(NH_4)_2TaF_7$ from the crystalline fluorides and from the elements at 298.15 K are −31.4 kcal mole^{-1} and −708.1 ± 0.4 kcal mole^{-1} respectively.[185]

According to Ref.183, the course of the thermal decomposition of $(NH_4)_3TaOF_6$ is similar to that described above for niobium, except that the separate stages take place at 175, 290, and 465°. It was suggested[183] that crystalline $TaOF_3$ exists in the temperature range 320–465°, but this appears unlikely, since attempts by other workers to isolate this compound have been unsuccessful. Heating moist NH_4TaOF_4 in air at 1000° gives mainly Ta_2O_5.[186] More complex oxofluoroniobates and oxofluorotantalates have also been isolated.[183]

Chromium forms NH_4CrO_3F,[187,188] $(NH_4)_3CrF_6$, $(NH_4)_2CrF_5.2H_2O$,[189,190] and NH_4CrF_4.[191] Ammines of chromium trifluoride are also known.[192]

Molybdenum forms the compounds NH_4MoF_7,[124,193,194] $NH_4Mo_2F_{13}$,[194] NH_4MoF_6, NH_4MoF_5, $(NH_4HF_2)_2MoF_5$,[196] NH_4MoOF_5,[194] $6NH_4F.7MoOF_4$,[195] $(NH_4)_3MoO_2F_5$, $(NH_4)_2MoO_2F_4$, $NH_4MoO_2F_3$,[196–199] $(NH_4)_3MoO_3F_3$, and $(NH_4)_2MoO_3F_2$.[200–201] The properties of many of the compounds have been reviewed.[202]

NH_4MoF_7 decomposes at 70, 145, and 380° according to the scheme:[203]

$$NH_4MoF_7 \rightarrow NH_4MoF_6 \rightarrow NH_4MoF_5 + MoF_5 + NH_4F \rightarrow MoF_3 + Mo_2N_3$$

The compound $6NH_4F.7MoOF_4$ (and probably NH_4MoOF_5) is stable up to 190°, although the most intense endothermic effect on the DTA curve is observed at 420°;[195] its decomposition products were not identified. The salt $(NH_4)_3MoO_2F_5$ is unstable, and decomposes even at 90–115° to give $(NH_4)_2.MoO_2F_4$; the latter is converted into $NH_4MoO_2F_3$ at 210° to 230°,[196] and at temperatures above 270–300° into a non-volatile molybdenum oxide fluoride containing 64.2% Mo, 10.9% F, and 2.0% N.[204]

Data on the thermal decomposition of $(NH_4)_2MoO_3F_2$ and $(NH_4)_3MoO_3F_3$ indicate that they have a high thermal stability; the first compound decomposes at 375°, and the second at 300°.[202]

Tungsten forms fewer ammonium fluorometallates than molybdenum. NH_4WF_7,[124] $(NH_4)_3WO_2F_5$, $(NH_4)_2WO_2F_4$, $(NH_4)_3W_2O_4F_7$,[197,198] $(NH_4)_3WO_3F_3$, $(NH_4)_2WO_3F_2$, $9NH_4F.5WO_3$, and NH_4WO_3F[205] have been characterised.

The thermal decomposition of $(NH_4)_3WO_2F_5$ gives $(NH_4)_2.WO_2F_4$, $(NH_4)_3W_2O_4F_7$, and $NH_4W_2O_2F_7$ successively at 240, 285, and 330°. The last compound decomposes at 380° to give an oxide fluoride, which was first assigned the composition WOF_2,[197,198] and then $W_2O_4F.n(N_mOF)$.[204,206] It is most probably an oxide fluoride bronze AW_2O_4F, in which the inserted cations A are NH_4^+, H_3O^+, and H_2F^+.[207]

Ammonium peroxofluoromolybdates(VI) and peroxofluorotungstates(VI) are also known.[208,209]

Manganese forms the fluorides $(NH_4)_3MnF_6$, $(NH_4)_2MnF_5$, and NH_4MnF_4,[210–212] and also NH_4MnF_3.[100] When heated, $(NH_4)_3MnF_3$ gives endothermic effects at 92, 115, and 203°. The last of these is due to decomposition to $(NH_4)_2MnF_5$, which in turn decomposes at 240–285° and 305–320° to NH_4MnF_4 and MNF_2. NH_4MnF_3 decomposes at 310° with the absorption of 38.5 ± 0.5 kcal mole^{-1}.[100]

Technetium and rhenium form the compounds $(NH_4)_2MF_6$, which decompose in an inert medium or in a vacuum at 300°.[213] The formation of nitride fluorides in the decomposition, postulated in Ref.213, was refuted by other workers.[214]

Stable compounds are formed by iron in two oxidation states: +3 and +2. The thermal decomposition of $(NH_4)_3FeF_6$ gives NH_4FeF_6 at 280°, and iron trifluoride at 410°.[69] In addition, the appearance of phases with the composition $(NH_4)_xFeF_{3+x}$, where x = 0.7–0.8 and 0.1–0.2, has been observed. The standard heat capacity of $(NH_4)_3FeF_6$ is 70.5 ± 1.7 cal mole^{-1} K^{-1}.[215]

The composition of ammonium hexafluoroferrate(III), isolated from aqueous solutions, does not correspond to the traditionally accepted formula. According to Ref.216, this compound has the composition $(NH_4)_{2.6}FeF_{5.6}.0.4H_2O$. The thermal properties of NH_4FeF_3[217,318] have not been studied. The existence of $NH_4Fe^{2+}Fe^{3+}F_6$ is possible.

The decomposition of $(NH_4)_2CoF_4$ gives an endothermic effect at 260°.[219] The NH_4CoF_3 formed decomposes at 290,[100] 310,[192] of 335°[219] to give CoF_2. The enthalpy of decomposition of NH_4CoF_3 is 30.4 ± 0.5 kcal mole^{-1}.[100]

Nickel forms the compounds $(NH_4)_2NiF_4$[219,220] and NH_4NiF_3. The first compound decomposes at 270°,[219] and the second at 290°[100] or 370°.[219] The enthalpy of decomposition of NH_4NiF_3 is 35.0 ± 0.5 kcal mole^{-1}.[100]

IV. REACTIONS OF AMMONIUM FLUORIDES

1. Reactions with Elements

The reactions with many elements can be described by the following equations:

$$E + nHF(gas) \rightarrow EF_n(crystalline) + \frac{n}{2}H_2 \quad (2)$$

$$E + \frac{n}{2}NH_4HF_2(crystalline) \rightarrow EF_n(crystalline) + \frac{n}{2}H_2 + \frac{n}{2}NH_3 \quad (3)$$

$$E + nNH_4F(crystalline) \rightarrow EF_n(crystalline) + \frac{n}{2}H_2 + nNH_3 \quad (4)$$

Table 3 shows that each of these reactions is probable for the alkali and alkaline earth metals, and also beryllium.

When the products are not simple fluorides, but fluorometallates, for example ammonium fluoroberyllates, the absolute values of ΔG^0 for the reactions are greater than those characteristic of reactions (2)–(4). The most negative values are observed for the reaction of a mixture of gaseous NH_3 and HF.

Table 3. Gibbs free energies ($-\Delta G^0$, kcal mole^{-1} for reactions (2)–(4) for non-transition elements of groups I and II (at 298 K).[23,55]

Reaction	Li	Na	K	Rb	Cs	Be	Mg	Ca	Sr	Ba
(2)	75.4	65.0	65.3	59.8	60.3	103.5	125.4	149.9	146.8	141.9
(3)	65.2	58.8	53.3	49.6	50.1	83.1	105.0	129.5	126.4	121.5
(4)	61.3	50.9	49.4	45.7	46.2	75.3	97.2	124.7	118.6	109.8

The results of the calculations given in Table 3 are confirmed by experimental data. Metallic beryllium is readily soluble in aqueous NH_4F solutions, and the rate of solution has the values 0.6 mg cm^{-2} min^{-1} and 2.4 mg cm^{-2} min^{-1} at 50° and 97°.[221] NH_4F solutions can be used to remove the beryllium coverings of fuel elements, and for the selective solution of beryllium from UBe_{13} alloy.[222]

With increase in the group number, the probability of reactions (2)–(4) for non-transition elements decreases (Table 4).

Carbon should obviously be inert with respect to all the reagents examined; phosphorus is probably stable to ammonium fluorides; arsenic and the group VI elements should also be inert.

Aluminium and silicon give high negative values of the Gibbs free energy. The formation of ammonium hexa- and tetrafluoroaluminates from a mixture of gaseous HF and NH_3 and crystalline NH_4HF_2 and NH_4F is highly exothermic. This is also true of the reactions

$$Si + 6HF(gas) + 2NH_3(gas) \rightarrow (NH_4)_2SiF_6(crystalline) + 2H_2$$
$$Si + 3NH_4HF_2(crystalline) \rightarrow (NH_4)_2SiF_5(crystalline) + 2H_2 + NH_3(gas)$$
$$Si + 6NH_4F(crystalline) \rightarrow (NH_4)_2SiF_6(crystalline) + 2H_2 + 4NH_3(gas)$$

for which the enthalpies at 298 K are −232, −81, and −22 kcal mole^{-1}, and the Gibbs free energies −168,0, −106.0, and −83.2 kcal mole^{-1}.[23,37,81,83] This explains why exothermic reactions of NH_4HF_2 with aluminium and silicon (at 120° and 80° respectively) were observed.[223] Since aluminium is kinetically relatively stable towards anhydrous HF,[224] NH_4HF_2 apparently dissolves the fluoride film on the metal surface. It is apparently because of these properties that mixtures containing NH_4HF_2 have been recommended for the cleaning and chemical polishing of aluminium and its alloys.[225–227]

Of the non-transition elements of groups VI and VII, oxygen and fluorine react with the ammonia present in ammonium fluorides. These reactions are used to isolate hydrogen fluoride[228,229] or nitrogen trifluoride.[230]

The regular features of the change in the probability of fluorination are slightly different for transition metals. Table 5 shows that reactions (2)–(4) are most probable for the elements of the central part of the periodic system, that is in groups III, IV, and V. Copper, silver, gold, mercury, molybdenum, tungsten, the group VII metals, and the platinum metals should be stable towards HF and ammonium fluorides. The values of ΔG^0 for the formation of Fe, Co, and Ni difluorides are −17.2 −17.8, and −15.3 kcal mole^{-1} respectively for reaction (2), and +11.0, +10.4, and +12.9 kcal mole^{-1} respectively for reaction (4).[23,164]

Table 4. Gibbs free energies (ΔG^0, kcal mole^{-1}) for reactions (2)–(4) for non-transition elements of groups III–VI (at 298 K).

Reaction	B	Al	In	C	Si	Ge	P	As	S	Se	Te
(2)	−71.9	−146.2	−34.1	48.9	−114.9	−13.6	−36.1	46.3	128.1	148.9	99.8
(3)	−41.3	−115.6	−3.5	89.7	−73.8	27.2	14.9	97.3	189.3	201.1	161.0
(4)	−29.6	−103.9	8.2	105.3	−58.2	42.8	34.4	116.8	212.7	233.5	184.4

Note. The calculation was carried out for the higher fluorides, which in all cases except Al and In were gaseous; the data from Refs.23, 37, 83, and 64 were used.

Table 5. Gibbs free energies (ΔG^0, kcal mole^{-1}) for reactions (2)–(4) for transitions elements (at 298 K).

Reaction	Cu^I	Ag^I	Zn	Cd	Hg	Sc	Y	La	Tl	Zr	Hf	V	Nb	Ta	Mo	W
(2)	9	20.4	−39.9	−24.6	42	−179	−197	−199	−111.4	−171.4	−176.2	−2.9	−79.5	−101	39.8	1.0
(3)	19	30.6	−19.5	−4.2	62	−148	−166	−168	−70.6	−130.6	−135.4	48.1	−28.5	−50	101.0	62.2
(4)	23	34.5	−11.7	3.6	70	−137	−155	−157	−55.0	−115.0	−119.8	67.6	−9.0	−31	124.4	85.6

Note. The calculation was carried out for the higher fluorides; the fluorides of V, Mo, and W were assumed to be liquid; the data from Refs.23, 107, and 164 were used.

The reactions of various transition metals may stop at the stage of lower fluoride formation. This is characteristic, for example, of titanium, which forms the trifluoride only on prolonged contact with gaseous HF in the absence of oxidising agents and moisture.[224,231]

The probability of fluorination increases if fluorometallates are formed. For the reaction

$$Zr + 6HF(gas) + 2NH_3(gas) \rightarrow (NH_4)_2ZrF_6(crystalline) + {}^3/_2H_2$$

$$Zr + 3NH_4HF_2(crystalline) \rightarrow (NH_4)_2ZrF_6(crystalline) + {}^3/_2H_2 + NH_3(gas)$$

$$Zr + 6NH_4F(crystalline) \rightarrow (NH_4)_2ZrF_6(crystalline) + {}^3/_2H_2 + 4NH_3(gas)$$

The absolute values of the standard free energies ΔG^0 are greater than those given in Table 5, and are −518, −230, and −135 kcal mole^{-1} (from Ref. 164 with allowance for the corrections described in section III of the present review). Thus the reaction with ammonium fluorides to give fluorometallates is unlikely only for copper, mercury, vanadium, molybdenum, and tungsten. The other transition metals of groups II–V (including scandium, yttrium, lanthanum, the lanthanides, and the actinides), in the absence of kinetic restrictions, can react readily under ordinary conditions with ammonium fluorides to give fluorometallates.

Thus NH_4HF_2 is used to etch zirconium and its alloys,[232] and aqueous NH_4F solutions can be used to dissolve titanium, zirconium, and hafnium.[233]

Niobium and tantalum dissolve in liquid NH_4HF_2 and react with it.[16] The enthalpies of the reactions

$$2M + 5NH_4HF_2(liquid) \rightarrow (NH_4)_2MF_7(crystalline) + 3NH_4F(crystalline) + MH_{0.8}(crystalline) + 2.1H_2$$

$$MH_{0.8}(crystalline) + {}^7/_2NH_4HF_2(liquid) \rightarrow (NH_4)_2MF_7(crystalline) + {}^3/_2NH_3(gas) + 2.9H_2$$

are close to −49 kcal mole^{-1} and −24 kcal mole^{-1} for niobium, and close to −64 kcal mole^{-1} and −54 kcal mole^{-1} for tantalum.[16] Niobium and tantalum react with gaseous hydrogen fluoride to form the pentafluorides,[234,235] so that their reactions with "gaseous" ammonium fluorides are quite problabe.

2. Reactions with Other Simple Fluorides

Many ammonium fluorometallates can be obtained by the direct reaction of the simple fluorides. Thus UF_4 and PuF_4 add on NH_4F at 80–130°,[121] UF_5 at 80–85°,[128,130] $TiOF_2$ at 80°,[158] and UF_6 at room temperature.[125] Stoichiometric mixtures of the simple fluorides have been used to obtain NH_4MgF_3,[58] NH_4CdF_3,[102] NH_4MnF_3,[211] $(NH_4)_2NiF_4$,[220] NH_4CoF_3,[236] and ammonium fluoroindates.[78] Compounds more highly saturated in NH_4F can be obtained by the reaction of the less saturated compounds with NH_4F. Thus heating equimolar mixtures of $(NH_4)_2SiF_6$ or $(NH_4)_2TiF_6$ with NH_4F at 90° to 95° gives the heptafluorometallates.[81,158]

Solid-phase syntheses using NH_4F are generally time-consuming, however (complete reaction takes from several hours to several days), and to avoid the loss of NH_3 and the partial loss of HF they must be carried out in closed vessels. To increase the reaction rates, mixtures of the powdered reagents can be compressed or heated under pressure[236] (liquid NH_4F is an ionic conductor[237]), but it is better to use solvents.

The most widely used solvent is water. The equilibrium solubility in metal fluoride (fluorometallate)–NH_4F–H_2O systems has been studied for BeF_2,[238,239] NH_4BF_4,[60] AlF_3,[240] GaF_3,[74,241] InF_3,[76] TlF,[242,243] $(NH_4)_2SiF_6$,[244] SnF_2,[87] CuF_2,[245] CdF_2,[246] CeF_4,[117] UF_4,[133,134] UO_2F_2,[140–142], CoF_2,[245] and NiF_2.[245] The NH_4BF_4–NH_4HF_2–H_2O system has been studied.[60]

Anhydrous HF,[194,247] ClF_3,[124] methanol,[99] polymerised trifluoroethylene,[248] etc. have also been used as solvents. HF, however, decomposes many fluorometallates, ClF_3 reacts with NH_4F (sometimes explosively) on slight heating, and the solubility of NH_4F in organic solvents is low (in Ref. 125, a suspension of NH_4F in trichloroethylene was used).

Table 6 gives the enthalpies of formation of fluorometallates, and shows that the maximum values of $-\Delta H^0_{formation}$ are observed for $(NH_4)_4UF_8$, $(NH_4)_2UF_6$, $(NH_4)_3AlF_6$, $(NH_4)_3HfF_7$, and $(NH_4)_2SiF_6$. If however the enthalpy is related to 1 mole of NH_4F, it decreases in a slightly different order: NH_4AlF_4, $(NH_4)_2UF_6$, NH_4HfF_5, $(NH_4)_2TaF_7$, $(NH_4)_2TiF_6$, etc., although in this case also the compounds of the elements of groups III–V are among the energetically most stable compounds. Comparison of the enthalpies of addition in the series $MF_n.nNH_4F$–$MF_2.nNH_4F$–$MF_3.nNH_4F$–$MF_4.nNH_4F$–$MF_5.nNH_4F$–$MF_6.nNH_4F$, where M represents a given metal in different oxidation states or metals from the same row of the periodic system, shows that the enthalpy tends first to increase and then to decrease.

Table 6. Enthalpies of formation of fluorometallates (at 298 K).

Substance	$-\Delta H^0_{formation}$, kcal mole^{-1}		Substance	$-\Delta H^0_{formation}$, kcal mole^{-1}	
	I	II		I	II
$(NH_4)_2BeF_4$	8.6	78.6	$(NH_4)_3UF_8$	39	109
NH_4BF_4	−1	33.9	$7NH_4F.6UF_4$	525	770
$(NH_4)_3AlF_6$	38	143	$NH_4F.3UF_4$	9.4	44
NH_4AlF_4	25	60	$(NH_4)_3UO_2F_5$	17.7	122.7
$(NH_4)_2SiF_6$	35	105	$NH_4(UO_2)_2F_5$	13.1	48
NH_4CuF_3	−1	34	$(NH_4)_2TiF_6$	31	101
NH_4ZnF_3	−1	34	$(NH_4)_3ZrF_7$	19.8	125
NH_4CdF_3	−2	33	$(NH_4)_2ZrF_6$	18.9	89
$(NH_4)_3ScF_6$	13	117	NH_4ZrF_5	13.5	48.5
NH_4ScF_4	12	47	$(NH_4)_3HfF_7$	36	141
$NH_4Y_2F_7$	6	41.2	$(NH_4)_2HfF_6$	26	96
NH_4PrF_4	10.6	45.6	NH_4HfF_5	17	51
NH_4NdF_4	11.7	46.7	$(NH_4)_2TaF_7$	31.4	101
NH_4SmF_4	9.7	44.7	NH_4MnF_3	4	39
NH_4GdF_4	14.7	49.7	NH_4CoF_3	−5	30
$NH_4Dy_2F_7$	11	46.0	NH_4NiF_3	0	35
$NH_4)_4UF_8$	40	180			

Note. I) from the simple crystalline fluorides; II) from MF_n(crystalline), HF(gas), and NH_3(gas). For references see Section III.

Fluorometallates with the maximum number of coordinated fluorine atoms have a lower thermal stability and a lower enthalpy of formation from the simple fluorides (calculated for 1 mole of NH_4F) than the compounds of the same metal with a smaller number of added NH_4F molecules.

NH_4HF_2 can also react with simple fluorides to give ammonium fluorometallates. $(NH_4)_2NiF_4$ has been obtained from NiF_2,[249] and $(NH_4)_2NiF_4$ and $(NH_4)_2CoF_4$ from NiF_2 and CoF_2 dihydrates.[219]

The reactions

$$MF_n(crystalline) + mNH_4HF_2(crystalline) \rightarrow (NH_4)_mMF_{n+m}(crystalline) + mHF(gas)$$

take place with a much smaller liberation of heat (by 15.4m kcal mole^{-1})[23] than the reactions

$$MF_n(crystalline) + mNH_4F(crystalline) \rightarrow (NH_4)_mMF_{n+m}(crystalline)$$

The difference in the Gibbs free energies for the reactions of NH_4HF_2 and NH_4F is smaller, and amounts to 8.8m kcal mole^{-1}. At the same time, the values of ΔH^0 and ΔG^0 for the

reactions of "gaseous" NH_4F and NH_4HF_2 should not be different. Thus the reactions

$$\underbrace{MF_n + mNH_3(gas) + 2mHF(gas)}_{\text{vapour over } NH_4HF_2} \rightarrow (NH_4)_mMF_{n+m}(\text{crystalline}) + mHF(gas)$$

can be used to obtain hydrogen fluoride from NH_4HF_2. This method was first patented by Sudarikov and co-workers;[250] silicon tetrafluoride is used, and the reaction is carried out at 140° with liquid NH_4HF_2 or at 200° with "gaseous" NH_4HF_2. A wider range of fluorides is listed in other patents,[251–253] which mention, in particular, the fluorides of copper, magnesium, calcium, zinc, aluminium, indium, thorium, germanium, tin, titanium, zirconium, vanadium, bismuth, chromium, iron, and nickel, and also fluorometallates not saturated in NH_4F. The preferred temperature range for carrying out the reactions is 125–200°.

Processes for obtaining hydrogen fluoride, based on the formation and thermal decomposition of alkali metal hydrogen fluorides, are of much greater practical importance. Usually, an aqueous solution of NH_4F and the sodium salt is heated to give $NaHF_2$, which is filtered off, dried, and heated. Ammonia, the mother-liquor, and sodium fluoride are returned to the same or another stage of the process. Sodium hydrogen fluoride can also be obtained by the reaction of anhydrous NH_4HF_2 and NaF, which begins at 105°.[254] Different versions of the method have been described and patented;[255–263] it can also be applied to potassium salts.[275, 264–267]

Ammonium hydrogen fluoride forms compounds and mixed crystals with the alkali metal hydrogen fluorides.[268–270]

The reaction of gaseous SiF_4 with NH_4F solution has been proposed for preparing $(NH_4)_2SiF_6$[271] and for trapping SiF_4 from gas streams.[4,8,272]

3. Reactions with Oxides and Hydroxides

Reactions with oxides and hydroxides, which are widely encountered in nature and are involved in many technological processes, are of considerable practical importance.

For the hydroxides of the alkali and alkaline earth elements (and also Be and Mg), the following reactions are of interest:

$$M(OH)_n(\text{crystalline}) + nHF(gas) \rightarrow MF_n(\text{crystalline}) + nH_2O(gas) \quad (5)$$

$$M(OH)_n(\text{crystalline}) + \frac{n}{2}NH_4HF_2(\text{crystalline}) \rightarrow MF_n(\text{crystalline}) + nH_2O(gas) + \frac{n}{2}NH_3(gas) \quad (6)$$

$$M(OH)_n(\text{crystalline}) + nNH_4F(\text{crystalline}) \rightarrow MF_n(\text{crystalline}) + nH_2O(gas) + nNH_3(gas) \quad (7)$$

The final products for the alkali metal hydroxides can apparently be hydrogen fluorides:

$$MOH(\text{crystalline}) + 2HF(gas) \rightarrow MHF_2(\text{crystalline}) + H_2O(gas) \quad (8)$$

$$MOH(\text{crystalline}) + NH_4HF_2(\text{crystalline}) \rightarrow MHF_2(\text{crystalline}) + H_2O(gas) + NH_3(gas) \quad (9)$$

$$MOH(\text{crystalline}) + 2NH_4F(\text{crystalline}) \rightarrow MHF_2(\text{crystalline}) + H_2O(gas) + 2NH_3(gas) \quad (10)$$

Table 7 shows that all these processes are probable. The same is true of many reactions involving the fluorination of oxides:

$$MO_{n/2}(\text{crystalline}) + nHF(gas) \rightarrow MF_n(\text{crystalline}) + \frac{n}{2}H_2O(gas) \quad (11)$$

$$MO_{n/2}(\text{crystalline}) + \frac{n}{2}NH_4HF_2(\text{crystalline}) \rightarrow MF_n(\text{crystalline}) + \frac{n}{2}H_2O(gas) + \frac{n}{2}NH_3(gas) \quad (12)$$

$$MO_{n/2}(\text{crystalline}) + nNH_4F(\text{crystalline}) \rightarrow MF_n(\text{crystalline}) + \frac{n}{2}H_2O(gas) + nNH_3(gas) \quad (13)$$

Table 7. Gibbs free energies (ΔG^0, kcal mole^{-1}) for reactions (5)–(7) for non-transition elements of groups I and II and for reactions (8)–(10) for the alkali metals (at 298 K).

Reaction	Li	Na	K	Be	Mg	Ca	Sr	Ba
(5)	−24.4	−28.1	−27.2	−18.3	−35.5	−43.4	−48.5	−46.1
(6)	−14.2	−17.9	−17.0	2.1	−15.1	−23.0	−28.1	−25.7
(7)	−10.3	−14.0	−13.1	9.9	−7.3	−15.2	−20.3	−14.9
(8)	−26.5	−26.8	−28.8	—	—	—	—	—
(9)	−6.0	−6.3	−8.3	—	—	—	—	—
(10)	1.7	1.4	−0.6	—	—	—	—	—

Note. The data from Refs. 23, 55, and 273 were used in the calculation.

Table 8. Gibbs free energies (ΔG^0, kcal mole^{-1}) for reactions (11)–(13) for non-transition elements of groups II–VI (at 298 K).

Reaction	Be	Mg	Ca	Sr	Ba	B	Al	C	Si	Ge	P	As	S
(11)	−19.7	−44.1	−59.1	−69.5	−71.5	−11.1	−138.9	33.8	−19.2	1.8	−13.5	1.3	40.9
(12)	0.7	−23.7	−38.7	−49.1	−51.1	20.6	−107.1	74.8	21.8	42.8	37.8	52.6	102.4
(13)	8.5	−15.9	−30.9	−41.3	−40.3	31.2	−96.6	90.2	37.2	58.2	57.0	71.8	125.5

Note. The calculation was carried out for the higher oxides and fluorides; the latter, for B, C, Si, Ge, P, As, and S were gaseous; the data from Refs. 23, 37, 64, 83, and 274 were used.

The data in Table 8 show that the reactions of the oxides of all non-transition elements of group II are probable. The higher oxides of the non-transition elements of groups III–V, except carbon, can react with HF to form higher fluorides, but with increase in the group number, the values of ΔG^0 for the reactions become more positive, and the reactions become less probable.

In many cases, the fluorination is characterised by larger absolute negative ΔG^0 values or smaller absolute positive ΔG^0 values, because of fluorometallate formation. Thus the reactions of α-quartz with crystalline NH_4HF_2 and NH_4F to give $(NH_4)_2SiF_6$ take place with $\Delta G^0 = -10.8$ kcal mole^{-1} and +12.3 kcal mole^{-1}.[83] There is also a high probability that oxide fluorides, and not fluorides, will be formed. For example, the values of ΔG^0 for the fluorination of P_2O_5 (crystalline) and SO_3 (gas) to gaseous POF_3 and SO_2F_2 are −18.5 kcal mole^{-1} and −29.5 kcal mole^{-1}.[23,37,274]

Many processes have been well studied by experimental methods. Thus BeO and moist $Be(OH)_2$ react with NH_4HF_2 on heating to 50–100°.[52,80,275] Different versions of the fluorination of alkali and alkaline earth metal oxides have been described.[276–281]

The fluorination of boric acid by anhydrous ammonium fluorides or their aqueous solutions gives NH_4BF_4,[61,62,65,282–284] but with a deficit of fluorinating agent and a short contact time the products are mixtures of $(NH_4)_2BOF_3$, $(NH_4)_3B_3O_3F_6$, and other ammonium oxo- and hydroxofluoroborates.[61,62,68,285]

A detailed study[286] showed that the reactions of $Al(OH)_3$ and Al_2O_3 with NH_4HF_2 begin at 20–130°, take place with considerable liberation of heat, and give $(NH_4)_3AlF_6$. Increase in the alumina heating temperature from 500° to 1200°, leads to a sharp decrease in its activity: a specimen obtained at 1200° is inert towards NH_4HF_2. Different versions of the process have been described.[287–291]

The reaction in a mixture of SiO_2 and NH_4HF_2 begins at a temperature of ~100° and takes place exothermally to give $(NH_4)_2SiF_6.NH_4F$.[80,81] Quartz dissolves relatively rapidly in aqueous NH_4HF_2 solutions.[292] Ammonium fluorides and their solutions have therefore been recommended for the removal of oxides from semiconductor surfaces[293] and for the removal of quartz from fluorite concentrates.[294–299] Silica is also soluble in alkaline and neutral NH_4F solutions,[300,301] and the rate of solution on heating is relatively high.[302] NH_4F solutions at 150–400° can be used for the hydrothermal preparation of single crystals of quartz and amethyst.[303]

The reaction of P_2O_5 with NH_4HF_2 or NH_4F takes place rapidly at 135° with the liberation of a large quantity of heat, to give $NH_4PO_2F_2$ or $(NH_4)_2PO_3F$.[91,304,305] Heating As_2O_3 with concentrated NH_4HF_2 solution for 1 h gives NH_4AsO_2.[94]

Table 9 shows that the regular features of the change in ΔG^0 for the fluorination of higher oxides to fluorides are slightly different for the transition elements than for non-transition elements. With increase in the group number, the probability of fluorination at first increases, reaching a maximum for the group III elements, and then decreases. In this case also, the reaction products for the metals of group V and VI may be oxide fluorides or ammonium oxofluorometallates, and this may lead to a considerable change in the ΔG^0 values.

Ammonium fluoride and more particularly ammonium hydrogen fluoride are fairly powerful fluorinating agents for many transition metal oxides. Thus ZnO reacts rapidly with molten NH_4HF_2 [278] or its "vapour" at 300°.[19]

The reaction of Sc_2O_3 with NH_4HF_2 begins at 60°, takes place with exothermic and endothermic effects, and is complete at 180° with the formation of $(NH_4)_3ScF_6$.[306] Y_2O_3 is fluorinated by ammonium hydrogen fluoride with an exothermic effect at 80° and an endothermic effect at 170°.[106,307,308] With an excess of NH_4HF_2, the initial product is $NH_4Y_2F_7.NH_4F$, which decomposes to YF_3. With a deficit of the fluorinating agent, yttrium oxide fluoride is formed.[309,310] It has also been suggested that the fluorination involves the formation of ammines of the trifluoride in intermediate stages.[309,310]

The fluorination is similar for La_2O_3, which is converted into NH_4LaF_4 or $NH_4La_2F_7$,[110,112,114] but which may also give the oxide fluoride or ammine.[309,310] The oxides of all the lanthanides are fluorinated with an exothermic effect at 80–180°; Eu_2O_3 is converted into NH_4EuF_4.[114] It has been concluded[110,112] that for Pr, Nd, Sm, and Gd, the first stage of the reaction gives the compounds NH_4LnF_4. According to Ref.111, Dy_2O_3 is first converted into $NH_4Dy_2F_7$, and according to Refs.110 and 112, the oxides of Dy, Ho, Er, Tm, Yb, and Lu give the compounds $(NH_4)_3Ln_2F_9$ in the initial stages of the fluorination. With a relatively small quantity of NH_4HF_2 at temperatures of 300–360°, hexagonal oxide fluorides were detected[111] in the fluorination products of the oxides of Pr, Nd, Sm, and Gd.

Table 9. Gibbs free energies (ΔG^0, kcal mole^{-1}) for reactions (11)–(13) for transition element (at 298 K).

Reaction	Cu^{II}	Ag^{I}	Zn	Cd	Hg	Sc	Y	La
(11)	−9.7	−9.5	−17.9	−24.4	1.0	−43.9	−62.0	−77.3
(12)	10.7	4.7	2.5	−4.0	21.4	−13.3	−31.4	−46.7
(13)	18.5	8.6	10.3	3.8	29.3	−1.6	−19.7	−35.0
	Tl	Zr	Hf	V	Nb	Ta	Mo	W
(11)	2.7	−31.4	−31.9	21.1	−15.2	−19.5	35.6	19.8
(12)	43.5	9.4	9.1	72.1	35.8	31.5	96.8	81.0
(13)	59.1	25.0	24.5	91.6	55.3	51.0	120.2	104.4

Note. The calculation was carried out for the higher oxides and fluorides; the latter, for V, Mo, and W, were liquid; the data from Refs.23 and 107 were used.

The fluorination of CeO_2 gives $(NH_4)_3CeF_7$ at 60° [117,118] and $(NH_4)_{0.6}CeF_{4.45}$ at 200°.[115]

NH_4F solutions at 200–300° can be used for the hydrothermal synthesis of single crystals of ammonium fluorometallates of erbium.[311]

The oxides of the light actinides (thorium, uranium, neptunium, plutonium, americium, and, apparently, protactinium) are fluorinated by ammonium fluoride or ammonium hydrogen fluoride at relatively low temperatures. Thus the conversion of $Th(OH)_4$ into ThF_4 by the action of NH_4F,[12] the fluorination of NpO_2,[122] the fluorination of PuO_2,[151–153] and the preparation of CmF_3 by the action of an excess of NH_4HF_2 on CmO_2 [154] have been described; in all cases, the reactions began at 110–125°. The fluorination of uranium dioxide has been studied in most detail. As early as 1943, it was shown that the reaction takes place at 150–200°;[312] higher temperatures are required to increase the degree of fluorination.[312–314] The reaction of UO_2 with NH_4HF_2 is exothermic[315] and takes place at 150–170° to give $(NH_4)_2.UF_6$.[136,316] The product of the reaction of UO_3 with concentrated NH_4HF_2 solutions is $(NH_4)_3UO_2F_5$.[142,143] UO_3 can also be fluorinated in the absence of a solvent.

The reaction of TiO_2 with NH_4HF_2 begins at a temperature of ~100° [158] to give $(NH_4)_2TiF_6.NH_4F$.

Zirconium dioxide reacts with NH_4HF_2 to give $(NH_4)_3ZrF_7$ [317] or $(NH_4)_2ZrF_6$.[160,318,319] The reaction is most vigorous after the NH_4HF_2 melts.[282,320,321] Treatment with ammonium hydrogen fluoride reduces the concentration of oxygen in ZrF_4 to 0.25%.[322]

NH_4F solution at temperatures of 450–700° and pressures of 800–3000 atm can be used to grow single crystals of TiO_2, ZrO_2, and HfO_2.[323]

The reaction of V_2O_3 with NH_4HF_2 in the ratio 1 : 8 or 1 : 2 at 185–200° for 2 h gives the green compound $(NH_4)_3VF_6$.[182] A mixture of V_2O_5 and NH_4HF_2 reacts at 95° to give $(NH_4)_3VO_2F_4$.[178]

Stoichiometric mixtures of Ta_2O_5 or TaO_2F with NH_4HF_2, with gentle heating, give $(NH_4)_2TaF_7$.[184] Under analogous conditions, the niobium compounds form $(NH_4)_3NbOF_6$.

According to Ref.324, the reaction of CrO_3 with NH_4F in aqueous solution gives $(NH_4)_2Cr_2O_7$ and HF.

The reaction of MoO_3 with NH_4HF_2 at a molar reagent ratio of 1 : 2 and a temperature of 105–110° leads to the exothermic formation of $(NH_4)_2MoO_2F_4$.[196,199] At lower temperatures, $(NH_4)_3MoO_2F_4$ is formed.[196] A stoichiometric mixture of WO_3 and NH_4HF_2 at 190–200° is converted into $(NH_4)_3WO_2F_5$.[197] The reactions of molybdenum and tungsten trioxides with aqueous NH_4F solutions give the salts $MO_3.nNH_4F$.[200,205]

The reaction of ReO_3 with NH_4HF_2 has been studied only qualitatively; its products are volatile oxide fluorides.[325]

The reaction of Fe_2O_3 with NH_4HF_2 takes place at 170° to give $(NH_4)_3FeF_6$.[69] NH_4HF_2 apparently reacts readily with other iron oxides, since ammonium fluorides have been recommended for the simultaneous removal of rust and sand from the surface of iron tubes.[326]

The higher oxides of other transition metals (manganese, cobalt, nickel, etc.) also apparently react with ammonium fluorides. Alumina heated at high temperatures is apparently the oxide most resistant to the action of ammonium fluorides. Oxides can be fluorinated using fluorometallates. This process has been described for Al_2O_3 [71,327] and BeO.[328]

The above data confirm the conclusions reached in Ref.329: NH_4HF_2 begins to react with oxides at 70–130°, the reactions are most vigorous after the NH_4HF_2 melts, and the reactivity of NH_4HF_2 (to give fluorometallates) is often greater than that of anhydrous hydrogen fluoride.

4. Reactions with Salts

A large number of reactions of ammonium fluorides with salts have been reported. For example, the conversion of calcium chloride into the fluoride by boiling an aqueous solution containing NH_4F,[330,331] of MgCl solution into $(NH_4)_2.MgF_4$,[58] of cadmium salt solutions into CdF_2,[20] and of solutions of lanthanide chlorides into the trifluorides[332] have been described. Phosphorus chlorides and oxide chlorides, and arsenic and silicon chlorides, although not salts, are fluorinated when boiled under reflux with NH_4F.[333]

The ammonium fluorometallates of many metals can be obtained by the reactions of the bromides or nitrates with NH_4F in methanol.[99,334,335] The conversion of $Th(NO_3)_4$ solution into ammonium fluorometallates[125] and the conversion of $NaNO_3$ into $NaHF_2$ [260] have been described.

Carbonates are often used as the starting materials for preparing fluorides. The carbonates and ammonium fluorides have been used to prepare lithium fluoride,[336] cerium trifluoride,[387] fluorides for luminophors,[338] and $(NH_4)_2MgF_4$,[58] and the hydroxide carbonates have been used to prepare fluoro-complexes of cobalt and nickel.[219] Treatment with anhydrous NH_4F or its solutions can be used to remove traces of $CaCO_3$ from CaF_2.[294,298] (The mechanism and kinetics of this process have been described.[338–341]) NH_4HF_2 can be used to obtain lanthanide fluorides from concentrates containing carbonates,[342] and also KHF_2 from K_2CO_3.[343]

Ammonium fluorides have also been used to fluorinate sulphates,[344–347] silicates,[9,348] phosphates,[349,350] magnesium acetate,[351] beryllium oxide acetate,[352] sodium aluminate,[346] ammonium vanadate,[178] ammonium tungstate,[197] calcium tungstate,[13–15] ammonium molybdate,[197] lithium hydroborate,[353] cerium(III) oxalate,[337] and various minerals and concentrates with complex compositions.[10–12,354]

The salts of most acids probably react with ammonium fluorides to give the corresponding fluorides. The formation of double salts is a somewhat unique phenomenon; they are few in number, however, and are known only for ammonium nitrate and perchlorate.[60,355–358]

V. CONCLUSION

In the research literature, including recent publications, it is still possible to find ammonium fluoride regarded as a complete analogue of other ammonium halides. Because of the formation of strong additional hydrogen bonds, however, many of the properties of ammonium fluoride differ sharply from those of compounds of NH_3–HX systems, where X = Cl, Br, or I. The most characteristic difference shown by the fluorides is the ability of the NH_3–HF system to form stable hydrogen salts: ammonium hydrogen fluoride even has a higher thermal stability than ammonium fluoride.

Ammonium fluorides also differ considerably from other ammonium halides in their reactivity, due to the specific properties of inorganic fluorides, namely the high strength of element–fluorine bonds (high enthalpy of bond rupture), and the consequent high values of the enthalpies and Gibbs free energies for many fluorination reactions.

In the series of traditional fluorinating agents (fluorine, halogen fluorides, anhydrous hydrogen fluoride, and hydrofluoric acid), ammonium fluorides, in particular ammonium hydrogen fluoride, occupy an intermediate position between fluorine and anhydrous hydrogen fluoride, often giving higher values than the latter for the equilibrium constants and rates of fluorination.

As shown above, ammonium fluorides can be used to fluorinate various elements, many oxides, and a very large number of salts (metallates).

The fluorination of the oxides of the non-transition elements of groups II–IV gives the higher fluorides or the corresponding fluorometallates, whereas the fluorination of the oxides of the non-transition elements of group V gives the oxide fluorides or oxofluorometallates. For the higher oxides of the transition metals, the "boundary" between the tendency to form completely fluorinated products (fluorides and fluorometallates) and the tendency to give oxide fluorides or oxofluorometallates corresponds to the centre of the periodic system; the oxides of the group IV metals form fluorometallates, and the oxides of the group VI metals form oxofluorometallates. An interesting feature is that V_2O_5, Nb_2O_5, and Ta_2O_5 under identical conditions react with NH_4HF_2 to give compounds of different types: $VO_2F.nNH_4F$, $NbOF_3.nNH_4F$, and $TaF_5.nNH_4F$. A decrease in the oxidation state of the metal in the oxide brings it closer to the elements of groups with a smaller number. Thus on fluorination, V_2O_3 behaves like a group III element and gives derivatives of VF_3; UO_3 is converted into $(NH_4)_3UO_2F_5$, resembling to some extent MoO_3 and WO_3, whereas the behaviour of UO_2 (which is converted into UF_4 derivatives) is closer to that of ZrO_2.

The thermal decomposition of fluoro-derivatives of Ce^{IV}, Mn^{III}, Pu^{IV}, and Cm^{IV}, and also oxofluoro-derivatives of V^{V}, Mo^{VI}, and W^{VI}, involves partial reduction in the last stages. This phenomenon should also be characteristic of salts of Cr^{IV}, Re^{VIII}, Re^{VI}, and other metals of group VII, and also of all the actinides following plutonium.

In an excess of NH_3, reduction may be accompanied by the ammonolysis of the simple fluorides. The question of the possibility of ammonolysis during thermal decomposition remains open. Heating simple fluorides in an ammonia atmosphere up to 300–900° gives nitrides or nitride fluorides.[359–364] A mixture of molybdenum nitride and trifluoride was detected in the thermal decomposition products of ammonium fluoromolybdate,[203] although these data require confirmation.

The behaviour of nitrogen in the last stages of the thermal decomposition has been little studied. The removal of small quantities even as ammonia is kinetically hindered (this is characteric, for example, of vanadium(III) [182]) because of mechanical blocking, the formation in a number of cases of solid solutions of the fluorometallates in the fluorides, or, as in the case of the lower oxide fluorides of tungsten and molybdenum, because of the introduction of ammonium ions into the cavities of the crystal lattice. These effects possibly also lead to erroneous conclusions about the formation of "new phases", with lower ammonium fluoride concentrations (see for example Refs.7 and 135). An increased concentration of residual nitrogen lowers the quality of the fluorides obtained, and is particularly undesirable when fluorides are used to prepare metals.

An interesting and little studied problem concerns the preparation of volatile fluorides using ammonium fluorides. The action of heat on many ammonium fluorometallates leads to the transfer of the metal fluorides (for example titanium, niobium, tantalum) to the gas phase, and the problem reduces to the separation of mixtures of these fluorides, ammonia, and hydrogen fluorides, which on simple cooling react again to re-form fluorometallates with the same or different compositions. The selective trapping of TiF_4 on CaF_2 at 300–350° has been proposed[365] for the separation of TiF_4 from its mixtures with NH_3 and HF.

The available published thermodynamic data on ammonium fluoro- and oxofluorometallates are unfortunately as yet insufficient for making any generalisations, predictions, or estimations.

Although various reactions of ammonium fluorides and properties of ammonium fluorometallates still require further study, it may be concluded that a fairly wide range of inorganic fluorides can be synthesised using ammonium fluorides.

The most urgent problems in further research in this direction are related primarily to the measurement of the enthalpies of formation, decomposition pressures, and heat capacities of fluoro- and oxofluorometallates, the study of the mechanism and kinetics of all the stages (particularly the last stages) of the thermal decomposition of fluoro- and oxofluorometallates, and the study of the reactions of ammonium fluorides with oxides, metallates, and minerals.

While the present manuscript was being prepared for publication, a number of publications related to its various sections appeared. Thus an indirect method has been used[366] to measure the degree of decomposition of NH_4F in the gas phase, and it has been shown that at 288.9 K, when the total vapour pressure is 0.40 Pa, the degree of decomposition is only 0.97. Strange as it may seem, even lower values were obtained for other ammonium halides. At the same time, a new measurement of the enthalpy of decomposition of NH_4HF_2[367] gave a result (about 51.5 kcal $mole^{-1}$) differing little from the value previously adopted.

The study of the fusion diagram of the NH_4F–HF system has been repeated, a number of new ammonium hydrogen fluorides have been detected, and the crystal structures of $NH_4H_3F_4$, $NH_4H_4F_5$, and $NH_4H_7F_8$ have been studied.[368] The enthalpies of solution of NH_4F and NH_4HF_2 in water have been measured again.[369]

Published calorimetric data on the enthalpies of formation of NH_4ZnF_3 and NH_4CdF_3 (−295.3 kcal $mole^{-1}$ and −286.8 kcal $mole^{-1}$) [370,371] make it possible to eliminate the contradiction noted in the text of the present review, and indicate that the results obtained in Ref.100 are too low. The enthalpies of the separate stages of the thermal decomposition of $(NH_4)_3WO_2F_5$ and the overall enthalpy of decomposition to W_2O_4F (109 kcal $mole^{-1}$) have been determined.[372]

Hydrothermal synthesis in NH_4HF_2 has been used to synthesise $NH_4Fe^{2+}Fe^{3+}F_6$, NH_4MnFeF_6, and NH_4MnCrF_6,[373–375] which are isostructural with one another and have a previously unknown structure. The thermal properties of these unusual fluorometallates have been studied.

New data on the reactions of ammonium fluorides have been published. Thus the reaction of an equimolar mixture of CrO_3 and NH_4HF_2 in the presence of small quantities of water has been used to synthesise NH_4CrO_3F;[376] the thermal decomposition of this compound is accompanied by the reduction of Cr^{6+} to Cr^{3+}.

The reaction of nickel and cobalt oxide carbonates and hydrated fluorides with ammonium fluorides has been studied in more detail.[377] The reactions of NH_4F with XeF_2, XeF_6, and KrF_2 [378] give N_2, HF, and Xe (or Kr). In the presence of metals (Fe, Cr), the compounds NH_4MF_4 are also formed.

According to Ref.379, the reaction of NH_4HF_2 with $NaVO_3$ and NH_4VO_3 gives $(NH_4)_2NaVO_2F_4.H_2O$ and $(NH_4)_3VO_2F_4.0.5H_2O$. The published[379] thermal decomposition schemes assume that the compounds give up NH_4F in three stages, but retain water of crystallisation. This does not agree with the general regular features of processes of this kind (ammonium fluorometallates have a higher thermal stability than the metal fluoride crystalline hydrates), X-ray diffraction data (the presence of water of crystallisation would change the structures of the compounds), and the results of earlier studies.[178,180] The process proposed in Ref.178, however, also requires refinement, with allowance for the observed[379] reversible phase transformation of $(NH_4)_3VO_2F_5$ (408 K; ~0.6 kcal $mole^{-1}$).

Mass Spectrometry of Saturated Hydrocarbons

L.S.Golovkina, G.V.Rusinova, and Al.A.Petrov

The decomposition by electron impact of saturated acyclic and cyclic (mono-, bi-, tri-, tetra-, penta-, and hexa-cyclic) hydrocarbons having condensed, bridged, and single-bonded structures is examined and the reaction mechanisms, the characteristics of the decomposition due to structural and stereochemical factors, and the possibilities for the identification of the hydrocarbons by analysing their mass spectra are discussed.
The bibliography includes 204 references.

I. INTRODUCTION

The basis on which mass spectrometry has been established as an analytical method has been its successful application in qualitative and quantitative analyses of hydrocarbon mixtures, in particular, petroleum and its processing products as well as the products of the petrochemical and organic synthesis. The subsequent stage in the development of this method was determined by the combined employment of highly effective procedures for the separation of mixtures and the automation of the interpretation of the mass spectrum which led to the development of fundamentally new mass-spectrometric analytical methods.

Chromato-mass-spectrometry has become irreplaceable in the analysis of hydrocarbons and their mixtures by virtue of the large amount of information derivable by this procedure, its sensitivity, and the speed and accuracy of the determinations. The advances in this field are based on the systematic study of the characteristics of the mass-spectrometric decomposition of individual hydrocarbons. In contrast to compounds with functional groups, where the heteroatom is generally the site of the preferential localisation of charge and hence determines which particular bond is ruptured preferentially, for a hydrocarbon molecule it is difficult to isolate such a decisive factor, i.e. it is difficult to interpolate the mass spectrum even within the limits of a narrow group of compounds. The low predictive power of the mass spectra of hydrocarbons (with the exception of n-alkanes), where the appearance of even one non-bonding interaction can lead to significant changes in the spectrum, the large number of isomeric and stereoisomeric structures, the monotonic variation of their mass spectra, and the associated difficulty of the computer search in their identification necessitate a detailed investigation and periodic systematic treatment of the mass spectra of hydrocarbons as well as the analysis and survey of the information in this field, which is constantly being renewed and expanded.

The review below is devoted to the characteristic features of the decomposition of saturated hydrocarbons under electron impact.

II. ALKANES

Alkanes constitute a large proportion of petroleum and their mass spectra have been described in the greatest detail.[1-7] The spectra of unbranched normal alkanes are very similar. The curve for the distribution of the peak intensities in their spectra (Fig.1) decreases smoothly from a maximum in the region of mass numbers of 43, 57, and 71 to the peak of the molecular ion (MI). The appearance of a maximum at any position on this curve implies the presence of a branch in the alkane molecule (Fig.2). The above features of the mass spectra of normal alkanes and alkanes substituted at different sites (including isoprenoid alkanes) are used for analytical purposes[8-13] although the information obtained from the consideration of the mass spectrum is insufficiently specific for the complete identification of any alkane.

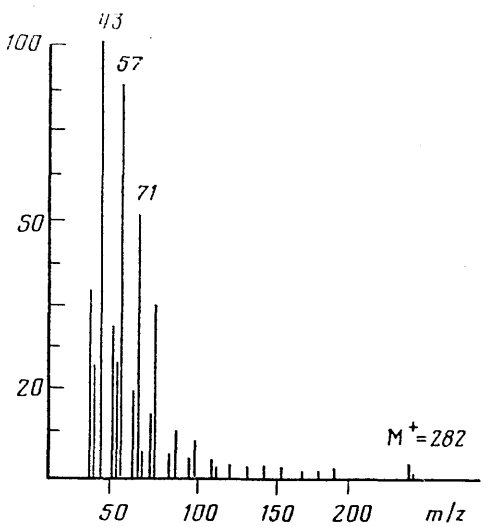

Figure 1. The mass spectrum of n-eicosane.[41]

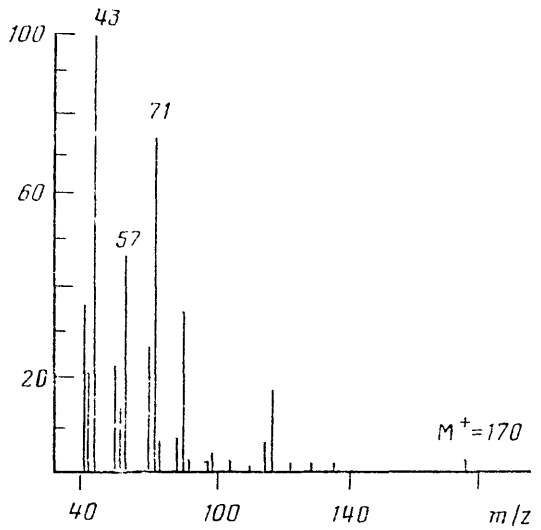
The intensity of the MI peaks of n-alkanes is low and decreases exponentially with increased molecular weight of the alkane.[14] The intensities of the MI peaks of branched alkanes depend on the number and relative positions of the methyl groups and decrease with increase in the degree of branching.[1,8,14]

A whole series of communications (among them also reviews),[9,15-29] including the analysis of the mass spectra of n-alkanes labelled with ^2H [15,17-19] and ^{13}C,[20-23] thermochemical data for the molecular and fragment ions,[24,25] low-temperature spectra,[29] ionisation efficiency curves,[5] reactions occurring on collision with a gas molecule,[16,23] etc. have been devoted to the structure and mechanism of the decomposition of molecular and fragment ions derived from n-alkanes. This analysis permitted the conclusion that the reactive configuration of the MI retains to a large extent the structure of the neutral molecule, while fragment ions decompose via complex skeletal rearrangements, which accounts for the observed loss of identity of the peaks of labelled ions in a series of mass spectra of lower n-alkanes.[15]



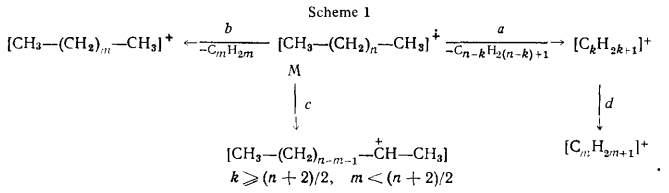


Figure 2. The mass spectrum of 4,7-dimethyldecane.[2]

The alkyl ions C_kH_{2k+1} are formed with the highest probability by simple rupture of the C–C bonds in the MI (Scheme 1, pathway *a*). This process is most favoured in the formation of large ions [$k \geq (n+2)/2$].[9,15,20]

Scheme 1

The study of the mass spectra of a large series of n-alkanes showed that there is a relation between the intensity of the peak of the alkyl ion C_kH_{2k+1} and the number of carbon atoms in the molecule (n) and fragment (k) ions.[9,15] The study of metastable transitions and ionisation efficiency curves[5] and comparison of the low-temperature mass spectra obtained for high (70 eV) and low ionisation energies[29] have shown that small alkyl ions are formed mainly via secondary processes, i.e. as a result of the decomposition of heavier primary alkyl ions (Scheme 1, pathway *d*). The few ions which are formed directly from the MI are produced from its central component (Scheme 1, pathways *b* and *c*) in the non-specific dissociation of the C–C bonds with recombination of the terminal methyl groups.[15,20] The contribution of this pathway increases with increasing chain length.

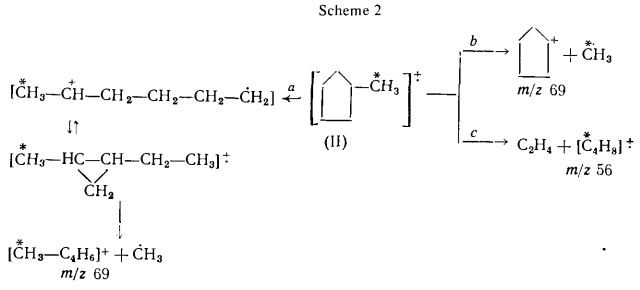
The probability of the loss of the methyl group is low and diminishes with increase in the n-alkane chain length.[22] The elimination of the CH_3 group proceeds to a large extent non-specifically: the formation of $[M-CH_3]^+$ is associated with the elimination of both terminal carbon atoms (pathway *a*) and the carbon atoms in the central component of the molecule (pathway *c*).[22] The formation of ions with an odd number of electrons is associated with the rearrangement of H atoms[28] or CH_3 groups.[18]

III. MONOCYCLIC SATURATED HYDROCARBONS

1. Unsubstituted Monocyclic Hydrocarbons

The mass spectra of unsubstituted monocyclic hydrocarbons having the general formula  are known for compounds with n = 3–14 and 24.[2,30-41] The character of the variation of the MI peak intensities in the series of C_3–C_{14} cycloalkanes is described by a curve[30] having maxima in the region of n = 3, 6, and 13 and a distinct minimum in the region of n = 9 and 10. The molecular ion of cyclopropane is the most stable in the series of cycloalkanes and its intensity is a maximum in the spectrum. A distinctive feature of this spectrum is the presence of a peak due to the ion $[M-3H]^+$,[2,32] whose high intensity can be explained by the aromatic character of the cyclopropenyl cation $[C_3H_3]^+$ formed.[33]

The study of the mechanisms of the fragmentation of cycloalkanes with the aid of deuterated analogues,[34,35] the measurement of the ionisation potentials and the heats of formation of their molecular ions,[36,37] and the study of the kinetics of the isomerisation of the MI [38,39] showed that, under the conditions of electron impact, the MI of cycloalkanes with three–five-membered rings undergo intensive isomerisation to linear ions, while the MI of hydrocarbons with six–eight-membered rings mainly retain the cyclic structure.



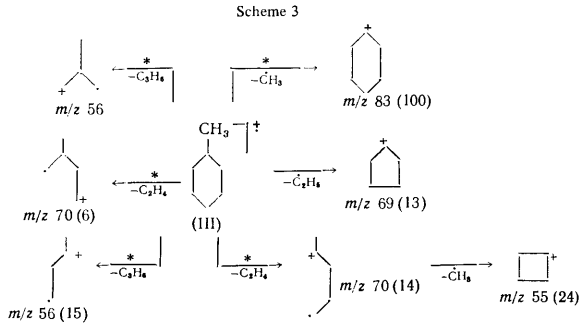
Despite the different structures of the MI of hydrocarbons with different ring sizes, the mass spectra of compounds with four–eight-membered rings are in many respects similar. They are characterised by the intense peak of the ion $[M-CH_3]^+$ and the peak for one of the odd-electron ions (m/z 56, 70, etc.) is the most intense in their spectra.[2,30,40] An increase of ring size alters appreciably the pattern in the decomposition of the MI and the character of the spectrum of the hydrocarbon containing more than eight carbon atoms in the molecule becomes similar to that of the spectrum of the corresponding alkane: the stability of the MI is low and the peaks of the even-electron ions (m/z 57, 71, etc.) predominate in the spectrum.[2,30,31] The high intensity of the MI peak in the spectrum of cyclotetracosane should be noted as an exception.[41]

2. Monosubstituted Monocyclic Hydrocarbons

The introduction of the methyl substituent into the cycloalkane molecule does not eliminate the differences noted between the structures of the molecular ions of unsubstituted

hydrocarbons. It has been suggested[40,42–44] that the ionisation of the MI of methylcyclopropane (I) and methylcyclopentane (II) entails the rupture of the endocyclic bond adjoining the methyl group and that, after the migration of the proton, an alkene ion with a straight-chain structure is formed [the n-butene ion for (I) and the n-hexane ion for (II)]. For methylcyclopropane, this conclusion has been confirmed by the identity of the spectra of compound (I) and its acyclic isomers.[42] Analysis of the spectra of methylcyclopentane and methylcyclohexane (III) analogues deuterated in all positions and labelled with ^{13}C permitted a detailed study of all the possible pathways leading to the formation of the fragment ions (Scheme 2; the ^{13}C isotope is marked with an asterisk) and also an estimate of the contribution of each pathway to the overall peak intensity of the ion having the given mass.[43–46]

Scheme 2



The data obtained for compound (II) show that the molecular ion decomposes with a higher probability via pathway *a*.[43–44]

Another intense process involving the decomposition of the molecule of compound (II) is the elimination of ethylene from the MI. The study of the mass spectra of the deuterated analogue of compound (II) showed[45] that the C_2H_4 molecule is ejected mainly from the cyclic component of the MI (Scheme 2, pathway *c*).

In methylcyclohexane, whose MI retains mainly the cyclic structure, the elimination of the methyl group takes place only from the side chain.[45] Scheme 3† presented below, constitutes the generalised result of a study which showed[46] that more than 90% of the primary fragment ions are formed on dissociation of the C–C bond at the tertiary carbon atom of the MI (the relative peak intensities expressed as percentages are indicated in brackets):

Scheme 3

The ratios $I_{[M]^+}/I_{[M-CH_3]^+} < 1$ have been obtained for methylcycloheptane and methylcyclo-octane, as for compound (II) and (III). On further increase of ring size, the $[M-CH_3]^+$ peak diminishes and is not observed at all in the spectra of methylcyclodecane, methylcyclododecane, and methylcyclotetracosane.[2,41]

The existence of the isomeric linear form of the MI has also been noted for ethyl and propyl derivatives of cyclopropane and cyclopentane,[45–47] although it has been shown for ethylcyclopentane[45] that the weakening of the bond between the ring and the substituent results in an equal probability of the two processes involving the abstraction of the substituent from the MI (pathways *a* and *b* in Scheme 2). The intensity of the MI peak in the spectra of monoalkylcyclopentanes [Alk = n-Pr, n-Bu, t-Bu, n-C_3H_{11}, iso-C_5H_{11}, n-$C_{16}H_{33}$, or $CH(C_9H_{19})_2$] and cyclohexanes (Alk = C_2H_5–$C_{10}H_{21}$, iso-Pr, s-Bu, iso-Bu, or t-Bu)[48] varies appreciably as a function of the length and structure of the substituting group.[48,49] The most intense peak in the spectra of monoalkylmonocyclanes is that of the ion $[M-R]^+$. The intense peak of the ion $[M-RH]^+$ accompanies it. This pair of peaks (*m/z* 83, 82 for alkylcyclohexanes and *m/z* 69, 68 for alkylcyclopentanes) is used for the qualitative and quantitative analyses of these two types of hydrocarbons in mixtures.[50–55] There are also literature data on the mass spectra of alkylcyclohexanes and alkylcyclopentanes obtained using different energies of ionising electrons.[50,51,56]

3. Polysubstituted Monocyclic Hydrocarbons

Among polysubstituted monocyclanes, alkylcyclopentanes (ACP) and alkylcyclohexanes (ACH) have been studied in greatest detail. Analysis of the mass spectra of the structural and geometrical isomers revealed the influence of ring size and the number, nature, and relative disposition of the substituents in the molecule on the mechanism of the decomposition of the MI.[57–68]

An increase of the number of methyl groups in the methylcycloalkane molecule as a rule decreases the peak for the ion $[M-CH_3]^+$ and increases the intensity of the peaks due to the ions formed on decomposition of the ring, but has little influence on the stability of the MI[68] (Table 1). The appearance in the molecule of a more stable group R entails a decrease of the intensity of the MI peak and an increase of the intensity of the peak due to the ion $[M-R]^+$.

Table 1. The peak intensities of the ions M^+ and $[M-R]^+$ in the mass spectra of alkylcyclopentanes (ACP) and alkylcyclohexanes (ACH).[68]

N	$I_{[M]^+}$		$I_{[M-CH_3]^+}$		$I_{[M-C_2H_5]^+}$	
	ACP	ACH	ACP	ACH	ACP	ACH
1	3.0–0	9.2–0.3	9.5	22.5	16.2	27.3

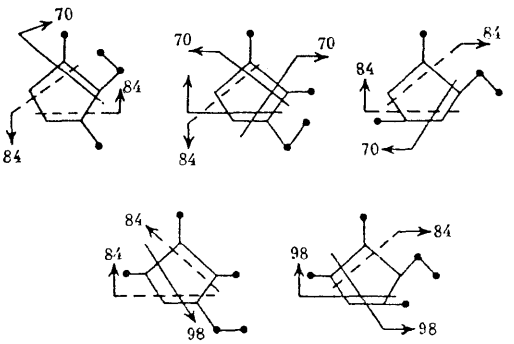
4	2.3–0.1	5.4–3.4	0.7–0.2	16.8–0.7	8.3–1.3	–
5	3.2–0.6	4.9–2.4	1.5–0.2	9.2–0.5	—	–
6	—	5.8–2.1	—	8.5–0	–	–
gem	2.4–0.1	2.8–0	15.0–3.0	31.6–5.5	—	30.9–18.0

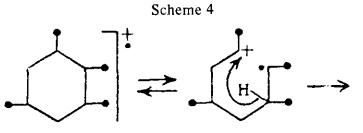
Remarks: R = CH_3 for the methyl-substituted derivatives and R = C_2H_5 for the ethyl and methylethyl-substituted derivatives; *N* is the number of substituents in the molecule. Here and henceforth the peak intensities are quoted as percentages of the total ion current.



The molecular ions of hydrocarbons of the cyclopentane series, whose molecules contain a ring more strained than in cyclohexanes, decompose via two competing pathways with

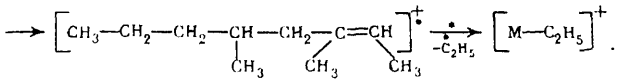
†In Scheme 3 and henceforth the asterisk denotes the presence of a peak due to a metastable ion (MSP).

equal probabilities: (1) abstraction of the alkyl substituent R from the molecular ion with subsequent decomposition of the ion $[M-R]^+$ formed; (2) decomposition of the cyclic component of the molecule. The decomposition of the cyclic component leads mainly to the formation of ions with an odd number of electrons (Scheme 2, pathway *c*).



The mass spectra of the structural isomers of dialkylcyclopentanes differ only in the intensities of the peaks due to ionic species M^+ and $[M-RH]^{+\cdot}$, the first peak being more intense in the spectra of 1,2-substituted derivatives and the second in those of the 1,3-substituted derivatives.[49,65]

The differences between the spectra of the structural isomers of tri- [57] and tetra-alkylcyclopentanes[58] are expressed mainly in the different intensities of the peaks for ions with *m/z* 70, 84, 98 formed on decomposition of the cyclic component of the molecule.



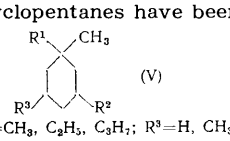
In contrast to alkylcyclopentanes, the decomposition of the cyclic components of the molecules of alkylcyclohexanes occurs only for structures having a vicinal disposition of the methyl groups in the molecule. It involves the formation of both odd-electron ions, for example, $[M-C_2H_4]^{+\cdot}$ and $[M-C_3H_6]^{+\cdot}$, and even-electron ions, for example, $[M-C_2H_5]^+$. The appearance of the latter can be explained by the decomposition of the isomeric linear form of the MI whose formation is initiated by the presence of vicinal substituents.[60,67,68] This also accounts for the appearance of the peak due to the ion $[M-C_2H_5]^+$ in the spectra of hydrocarbons with the MI (IV), which lack an unsubstituted dimethylene unit whose elimination together with the proton might also lead to the formation of the ion $[M-C_2H_5]^+$ (Scheme 4).[60]

Scheme 4

M, (IV)

Additional evidence for the existence of the isomeric form of the MI is provided by the absence of correlation between the stability of the MI and the relative stabilities# in the series of geometrical isomers as well as the presence of such correlation for the primary ions formed in the competing decomposition reactions of the isomeric forms of the MI.[60]

#Here and henceforth thermochemical stability (ΔH) is referred to.



In the series of structural isomers of di-, tri-, and tetramethylcyclohexanes the peak intensities of the ionic species formed on decomposition of the cyclic component of the molecule, namely $[M-C_2H_5]^+$ and $[M-C_3H_6]^{+\cdot}$, increase and the intensity of the ion $[M-CH_3]^+$ formed in a competing process falls as the stability of the isomer diminishes.[60] For the 1,3- and 1,4-dimethyl- and 1,3,5-trimethyl-cyclohexanes, which have no vicinal methyl groups in the molecule, the MI decomposes only via the first pathway. They are characterised by the maximum intensity of the peak due to the ion $[M-CH_3]^+$ in the series of structural isomers.

The quantitative differences between the spectra of the structural isomers of di-, tri-, tetra-methylcyclohexanes, reflecting the contribution of a particular pathway in the decomposition of the MI, make it possible to identify each isomer, with the exception of 1,3-, and 1,4-dimethylcyclohexanes, on the basis of the criteria presented (Table 2).[68]

Table 2. Diagnostic features of the mass spectra of structural isomers of di-, tri-, and tetra-methylcyclohexanes.

Di-	I_{70}/I_{83}	Tri-	I_{84}/I_{83}	I_{97}	Tetra-	I_{84}/I_{97}	I_{98}/I_{97}
1,2-	$\geqslant 1$	1,2,3-	$\leqslant 1$	8,6—2,2	1,2,4,5-	>1	>1
1,3-	$\leqslant 1$	1,2,4-	>1	5,0—1,2	1,2,3,5-	$=1$	$\leqslant 1$
1,4-	$\leqslant 1$	1,3,5-	$\leqslant 1$	0,7—0,5	1,2,3,4-	<1	$\geqslant 1$

For cyclohexanes having a substituent R other than the methyl group, the decomposition of the MI take place mainly in accordance with the first pathway. The differences between the spectra of these structures are associated solely with the intensity of the peaks for the ionic species M^+, $[M-R]^+$, and $[M-RH]^{+\cdot}$ and as a rule have no diagnostic value.[60] However, the position of the group R in the molecules of geminal-substituted cyclohexanes (V) can be readily determined mass-spectrometrically.[2,68] The spectra of geminally substituted cyclopentanes have been little studied.[2]

(V)

R^1, R^2=CH_3, C_2H_5, C_3H_7; R^3=H, CH_3

Systematic study of the mass spectra of monocyclic hydrocarbons has shown no possibility for an unambiguous assignment of the hydrocarbon to the cyclopentane or cyclohexane series solely on the basis of one characteristic feature. However, when the molecule contains at least one methyl substituent, this can be achieved on the basis of a number of features which are proposed in Table 3. The same data permitted conclusions concerning the number *N* of substituents in the ring.

The presence of two and more substituents in the ring implies the possibility of the existence of stereoisomers. Under these conditions, in the case of compounds without heteroatoms, the influence of the steric structure on the decomposition of the molecule can be very considerable and in a number of instances[68] can swamp the effect of structural isomerism. This influence is natural if one takes into account the absence of a site of preferential localisation of the charge in the saturated hydrocarbon molecule—a factor which is as a rule of decisive importance in the decomposition of heteroatomic compounds. Thus only the energy state of the molecules of isomeric hydrocarbons, determined by the

number of non-bonding interactions, determines the mass-spectrometric properties.

The idea of a relation between the relative stabilities of the stereoisomers and the differences between their spectra was put forward by Biemann[69] as early as 1962 and was then developed in a whole series of studies by Natalis and co-workers.[70-74] Subsequently Meyerson[75] related these differences to the thermochemical stabilities, i.e. the enthalpies of the ground states of the ions, which determine the ease of the fragmentation reactions, and not to the thermodynamic stability of the isomer—a factor which is significant for the relative proportions of the isomers under equilibrium conditions. This conclusion is consistent with the ionisation energies (IE) and appearance energies (AE).[71,76]

Table 3. Diagnostic features in the mass spectra of hydrocarbons of the cyclopentane and cyclohexane series and the values of m/z for the peak with maximum intensity.

5	84	—	—	—

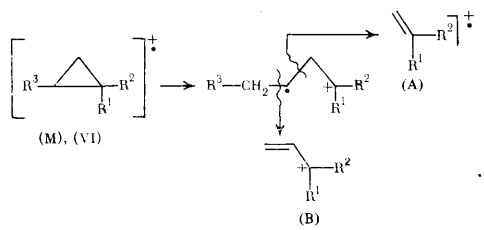
*The spectrum of 1,2,3-trimethylcyclohexane is an exception, but for this spectrum $I_{83}>I_{84}$, in contrast to the spectra of trialkylcyclopentanes.

**The spectrum of 4-ethyl-1,2-dimethylcyclohexane is an exception. It resembles the spectra of the series of stereoisomers of tetramethylcyclohexane.

Measurements performed with the aid of photoionisation for a series of 1,2-dimethylcyclopentanes and cyclohexanes have shown[71] that the IE of the stereoisomers do not differ, while the AE of the ions $[M-CH_3]^+$ {for dimethylcyclopentanes, also the ions $[M-C_2H_4]^+$, $[M-C_2H_5]^+$, $[M-C_3H_5]^+$, and $[M-C_3H_6]^+$} change by 0.1 eV on passing from the *cis*- to the *trans*-isomer. Within the limits of experimental error, this difference is in each case equal in magnitude (but opposite in sign) to the difference between the heats of formation of the stereoisomer. Somewhat different values but showing the same type of variation as a function of the relative positions of the substituents have been obtained for the stereoisomers of 1,2-dimethylcyclohexane by other methods.[77,78]

The interrelation of the stereochemistry of the molecule and of the characteristic features of its decomposition under electron impact has been traced in detail and systematically for almost all the stereoisomers in the series of polymethylcyclopentanes and polymethylcyclohexanes.[2-5,49,57-68] The character of the variation of the quantitative characteristics of the spectrum remains the same as in the series of structural isomers: the intensity of the peaks due to the ions $[M-R]^+$ is a maximum in the spectrum of the isomer showing the highest thermochemical stability and decreases with decrease of the stability in the series of stereoisomers; there is a simultaneous increase of the intensities of the peaks due to the ions formed on decomposition of the cyclic component of the molecule.

The differences between the quantitative characteristics of the spectra of the stereoisomers are greater the larger the difference between the stabilities of their molecules. In a number of instances these differences are of diagnostic value.[57-60] The spectra of stereoisomers whose stabilities are similar are virtually identical.



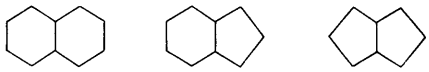
The available information about the decomposition of substituted cycloalkanes C_nH_{2n} (where $n\neq 5$ or 6) under electron impact is limited to data concerning alkylcyclopropanes. In the spectra of geminally (R^1=R^2=CH_3, R^3=H) and vicinally (R^1=R^3=CH_3, R^2=H) substituted dimethylcyclopropanes (VI)[132] the peak for the ion $[M-CH_3]^+$ shows the highest intensity. The absence of appreciable differences between their spectra has been attributed to[32] the pseudo-ethylenic character of the bonds in the cyclopropane ring. This hypothesis is supported by the large number of peaks due to doubly charged ions.[69]

The mass spectra of isomeric cyclopropanes differing in the lengths of the alkyl substituents R^1 and R^2 (i.e. in the position of the cyclopropane ring in the aliphatic chain) also proved to be similar.[79] The absence of differences between the spectra of dialkylcyclopropanes (VI) and the corresponding olefins (there are differences only in the stabilities of the MI) demonstrates the possibility of the isomerisation of the MI compound (VI) to an ion having a linear structure.

A distinctive feature of the spectra of the hydrocarbons (VI) is the presence of intense peaks of the ions formed on dissociation of the C—C bonds in the ring at one of the carbon atoms [ions of types (A) and (B), Scheme 5].

The peaks for the ions (A) and (B) are characterised by having the maximum intensity in the majority of spectra.[79]

Scheme 5



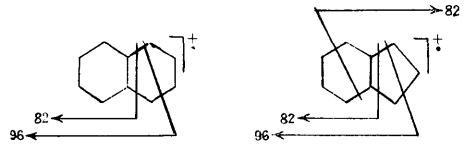
Analysis of the spectra of deuterated analogues of compound (VI) permitted the conclusion that the formation of the ions (A) and (B) involves the ionisation of the most highly substituted cyclopropane bond with localisation of the positive charge on the most substituted carbon atom.[79]

IV. BICYCLIC SATURATED HYDROCARBONS

1. Hydrocarbons with a Condensed Type of Junction between the Rings

(a) Unsubstituted hydrocarbons. In the series of compounds of this type attention has been concentrated on the mass spectra of hydrocarbons consisting of five- and/or six-membered rings belonging to the bicyclo[4.4.0]decane (VII),

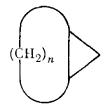
bicyclo[4.3.0]nonane (VIII), and bicyclo[3.3.0]octane (IX) series.[2,31,80–86] Data have been published also for the spectra of hydrocarbons with cyclopropane (X) and cyclobutane (XI) rings.[86–93]



(VII) (VIII) (IX)

The stability of the MI of the bicycloalkanes considered decreases in the sequence (VII) > (VIII) > (IX) in parallel with the increased strain in the molecules.[80–82] In contrast to the spectra of unsubstituted monocyclic hydrocarbons, the intensity of the peak due to the ion $[M-CH_3]^+$ in the spectra of compounds (VII)–(IX) is low. In the case of compounds (VIII) and (IX) the abstraction from the molecular ion of a fragment containing two carbon atoms takes place mainly in the form of the ethylene molecule. This process is not characteristic of compounds (VII). The ratio of the ionic species $[M-C_3H_6]^{+\cdot}$ and $[M-C_3H_7]^+$ is influenced by the number of methylene units in the ring. Thus the presence of only cyclopentane rings in the molecules of compounds (IX) entails the preferential elimination of a three-carbon fragment in the form of the propyl radical; the intensity of the peak for the ion $[M-C_3H_7]^+$ becomes a maximum§, much greater than the intensity of the peak in the ionic species $[M-C_3H_6]^{+\cdot}$. In the case of the hydrocarbon (VII), containing only cyclohexane rings, there is a high probability of the elimination of a propene molecule and the ratio of the intensities of the above peaks changes ($I_{[M-C_3H_6]^{+\cdot}} > I_{[M-C_3H_7]^+}$). On the other hand, for the molecules of compounds (VIII), consisting of five- and six-membered rings, the peaks of the ionic species $[M-C_3H_6]^{+\cdot}$ and $[M-C_3H_7]^+$ (*m/z* 82 and 81 respectively) have similar intensities and their ratio depends on the type of junction between the rings: $I_{82} > I_{81}$ for *trans*-(VIII), while the opposite relation obtains for *cis*-(VIII).

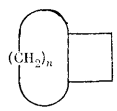
The differences between the thermochemical stabilities of the *cis*- and *trans*-isomers of compounds (VII) and (VIII) [compounds (IX) exist solely as the *cis*-isomers[94]] are clearly reflected in their spectra.[80–84] Thus a much higher intensity of the MI peak and a lower intensity of the peaks due to the primary ions are observed in the spectra of the more stable *trans*-isomers of compounds (VII) and (VIII) compared with the spectra of the *cis*-isomers. With decrease in the energy of the ionising electrons, the above differences become more pronounced.



Interesting results have been obtained from the comparison of the IE and AE of the *cis*- and *trans*-isomers. The IE of the molecular ions for the two isomers proved identical but the AE of some of the ions (*m/z* 96, 82) are higher for the *trans*-isomers, while those for other ions (*m/z* 95, 68, 67) are higher for the *cis*-isomers. The AE measured with a high accuracy can be used to determine the differences between the enthalpies of formation of the *cis*- and *trans*-isomers of compounds (VII) and (VIII).[95] The difference between the ΔH of the stereoisomers should then be correlated quantitatively to the differences between the AE of only those ions which are formed from the MI in a single stage as a result of simple bond rupture. From this standpoint, the ions with *m/z* 96 and 82 are of greatest interest:

(VII) (VIII)

The equality of the differences between the AE and ΔH for the stereoisomers of compounds (VII) and (VIII) is observed only for the ion with *m/z* 96. The absence of such clear-cut quantitative correlation for the ion with *m/z* 82 can be associated with the difference between the pathways leading to its formation on decomposition of the stereoisomers, while for other ions it can be associated with the fact that they are in the nature of rearrangements (*m/z* 109, 95, 81) or with the multistage character of their formation (*m/z* 67. 68).[95]



The differences between the spectra of hydrocarbons of type (X) are associated with the size of the polymethylene ring:[87–91]

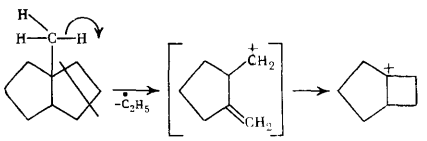
(X); n = 3-10

The stability of the MI decreases from 11 to 0.5% with increase of the size of this ring from $n = 3$ to $n = 8$ and then increases slightly. The decomposition of the MI of hydrocarbons (X) takes place as a result of the simultaneous occurrence of two processes—the contraction of the polymethylene ring and the opening of the cyclopropane ring.[87] The intensity of the peak due to the ion $[M-CH_3]^+$ is a maximum in the spectrum of bicyclo[3.1.0]hexane and diminishes with increase of the size of the larger ring. Comparision of the spectra of compounds (X) and their halogeno-derivatives suggests[87] that the methyl radical split off from the MI is derived from a methylene unit of the three-membered ring. The peak of the ion $C_5H_7^+$ with *m/z* 67 shows the maximum intensity in the majority of the spectra.

Bicyclo[*n*.2.0]alkanes (XI) are characterised by a low stability of the MI (1.6–0.2%) and, in contrast to bicyclo-[*n*.1.0]alkanes (X), the stability of their MI is independent of the size of the larger ring of the molecule.[92,93]

(XI); n = 2–6

On the other hand, the intensity of the peak due to the ion $[M-CH_3]^+$ diminishes with increase in the size of the above ring. The MI of the bicycloalkanes (XI) decompose with the preferential cleavage of the C–C bonds in the cyclobutane ring, while the intensity of the peak of the radical-ion $[M-C_2H_4]^{+\cdot}$, formed as a result of this process, is a maximum in the majority of the spectra.

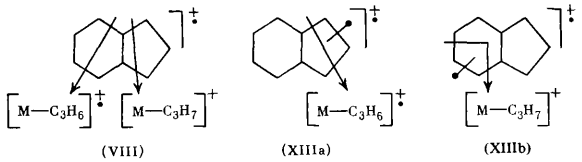


(b) Monosubstituted hydrocarbons. The mass spectra of a large number of structural and geometrical isomers of the methyl derivatives of compounds (VII)–(IX) have been described in the literature.[65,85,86,96,97] It has been observed that the MI of methylbicyclo[4.4.0]decanes (XII) are more resistant to electron impact than the MI of methylbicyclo-[4.3.0]nonanes (XIII) and methylbicyclo[3.3.0]octanes (XIV). In the series of structural isomers of compounds (XIII) and (XIV) the greatest stability of the MI is observed for the

§There is a possibility of a two-stage pathway to the formation of the ion $[M-C_3H_7]^+$—from the radical-ion $[M-C_2H_4]^{+\cdot}$ or the ion $[M-CH_3]^+$.

angular position of the methyl group.[85,86] The spectra of compounds (XII) with angular substituents have not been described.

The introduction of the methyl group into the molecules, of the unsubstituted hydrocarbons (VII)–(IX) does not entail significant changes in the intensity of the MI peak. The intensity of the peak of the ion $[M-CH_3]^+$ in the spectra of compounds (XII)–(XIV) is higher compared with that observed in the spectra of compounds (VII)–(IX), the only exception being 7-methylbicyclo[4.3.0]nonane. The intensity of the $[M-CH_3]^+$ peak then changes markedly as a function of both the position of the substituent and the stereochemistry of the molecule.



The abstraction from the MI of a fragment consisting of two carbon atoms takes place in the case of hydrocarbons (XIII)–(XIV) mainly in the same manner as in the unsubstituted structures—in the form of the ethylene molecule. The fact that the elimination of the ethyl radical from structures with angular substituents is favoured by energy factors has been explained[85,86] by the disposition of the methyl group convenient for the migration of a proton:

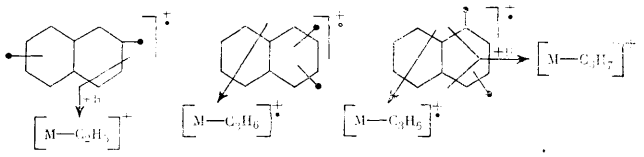
(XIV) *m/z* 95

The abstraction of a two-carbon fragment from the molecular ion is not characteristic of compounds (XII).

The main pathways leading to the fragmentation of the MI of methylbicycloalkanes (XII)–(XIV) are associated with the rupture of the bond at the tertiary (quaternary) carbon atoms.[85,86,96] The peaks of the ionic species $[M-C_4H_8]^{+\cdot}$, $[M-C_4H_9]^+$, $[M-C_5H_{10}]^{+\cdot}$, and $[M-C_5H_{11}]^+$ are the most intense in the spectra of compounds (XII), while the $[M-C_3H_6]^{+\cdot}$ and $[M-C_3H_7]^+$ peaks are the most intense in the spectra of compounds (XIII)–(XIV). The ratio of the latter peak intensities depends on the position of the methyl group in the cyclopentane or cyclohexane ring of the molecule: for structures with the substituent in the cyclopentane ring [structures (XIIIa)], a propene molecule is eliminated preferentially, while the presence of a substituent in the cyclohexane ring [structures (XIIIb)] promotes the ejection of a propyl radical from the MI¶. As a consequence, the ratio $I_{[M-C_3H_6]^{+\cdot}}/I_{[M-C_3H_7]^+}$ becomes diagnostic: it is greater than unity for compounds (XIIIa) and less than unity for compounds (XIIIb).

(VIII) (XIIIa) (XIIIb)

The differences between the spectra of the *cis*- and *trans*-isomers of compounds (XII)–(XIV) are correlated with their relative stabilities.[85,86,96] Thus a more stable MI is formed also in the case of the more stable bicycloalkane stereoisomers. The abstraction of the methyl substituent from the MI proceeds as a rule also more vigorously for the more stable stereoisomers, while an increase of strain in the molecules entails an increase of the contribution by the competing dissociation of endocyclic bonds. The attempt to explain these differences for the stereoisomers of compounds (XII) as a consequence of the stronger decomposition of the ion $[M-CH_3]^+$ in the case of the less stable isomer[65] appears little justified, since the difference between the enthalpies of the stereoisomers influences mainly the rates of the primary and not secondary MI decomposition reactions[98]—those which can result in an excess of internal energy, which is characteristic of the less stable isomer. The features discussed above are more likely to be a consequence of differences between the energy relations of the competing MI decomposition reactions. For the less stable isomer with an axial methyl group, the decomposition of the cyclic system consuming less energy obtains more readily, while in the case of the more stable stereoisomers with an equatorial substituent the probability of the rupture of the exocyclic bond increases, which results in an increase of the peak intensity of the ion $[M-CH_3]^+$ in its spectrum. If the radial abstraction process were energetically more favourable than the cleavage of the ring, the peak of the ion $[M-R]^+$ in the spectrum of the stable isomer would have had a greater intensity.



In order to confirm this hypothesis, studies were made of the mass spectra of ethylbicyclo[4.4.0] decanes,[98] because the dissociation energy of the $C-C_2H_5$ exocyclic bond is much lower than that of the $C-CH_3$ bond. Indeed the peak intensity of the ion $[M-C_2H_5]^+$ in the spectra of ethylbicyclo[4.4.0]decanes is much higher than the peak intensity of the ion $[M-CH_3]^+$ in the spectra of compounds (XII) and the differences between their intensities in the spectra of the stereoisomers are reduced, as was to be expected. Nevertheless, this peak still remains more intense in the spectrum of the stereoisomer with an equatorial ethyl group.

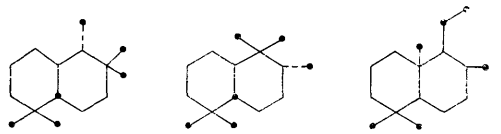
The measurements of the IE and AE for the ions of 2- and 3-methylbicyclo[4.4.0]decanes with a *trans*-junction between the rings also failed to throw light on the above equation.[97]

(c) Disubstituted hydrocarbons. The spectra of dimethylbicycloalkanes have been studied in detail only for compounds (VII).[99–101] In addition, the spectra of 7,7-, and 7,9-, and 1,9-dimethyl derivatives of compounds (VIII)[85,102] and the 1,2-, 1,3-, 2,4-, and 3,7-dimethyl derivatives of compounds (IX)[86] have been described. The stability of the MI of dimethylbicycloalkanes with angular substituents is higher than that of the MI of all the methyl-substituted compounds (XII)–(XIV), while for the remaining dimethyl derivatives it is lower than for compounds (XII)–(XIV). The peak intensity of the ion $[M-CH_3]^+$ varies within broad limits. The presence of a geminal group leads to a sharp increase in the intensity of this peak, with the exception of 7,7-dimethylbicyclo[4.3.0]nonane, while the angular position of one of the methyl groups has little influence on its magnitude.

The decomposition of the cyclic system takes place preferentially via the rupture of the bonds at the tertiary and quaternary carbon atoms. The abstraction of a two-carbon fragment from the MI of dimethylbicyclo[4.4.0]decane (XV) takes place mainly in the form of a radical from the substituted ring of the molecule, while the peak intensity of the ion $[M-C_2H_5]^+$ is greatest in the spectra of structures of type (XVa) in which the disposition of the substituents is favourable for this purpose. On the other hand, the peak of the ion $[M-C_2H_5]^+$ is virtually absent from the mass spectra of compounds (XV) with angular and geminal substituents:

¶ The opposite ratio of the intensities of these peaks has been observed for unsubstituted structures on decomposition of the rings in compounds (VIII).

M, (XVa) M, (XVb) M, (XVc)



C_9 ions are present in the spectra of all dimethylbicyclo-[4.4.0]decanes. For structures of type (XVb), where both substituents are in the same ring, the peak intensities of these ions are comparatively low and that of the radical-ion $[M-C_3H_6]^+$ is somewhat greater than that of the ion $[M-C_3H_7]^+$, as in the spectra of unsubstituted compound (VII). It has been suggested[100] that the formation of the radical-ion $[M-C_3H_6]^+$ is associated with the cleavage of the unsubstituted ring. This hypothesis is supported by the higher peak intensity of the ion $[M-C_3H_7]^+$ compared with that of $[M-C_3H_6]^+$ in the spectra of 2,4- and 2,5-dimethylbicyclo[4.4.0]decanes (XVc), which also have one unsubstituted ring, but the disposition of the methyl groups in the second ring is favourable for the elimination of the C_3H_6 and C_3H_7 fragments.

The formation of C_8 (m/z 109, 110) and C_7 (m/z 95, 96) ions takes place most vigorously for the hydrocarbons (XV); the corresponding peaks have as a rule the maximum intensity in the spectra. Geminally substituted structures, in the spectra of which the peak of the ion $[M-CH_3]^+$ predominates, are an exception. Structures of type (XVb) are distinguished by a higher peak intensity of the ions $[M-C_4H_9]^+$ compared with those of $[M-C_4H_8]^+$ ($I_{109} \gg I_{110}$). For hydrocarbons with a different disposition of the methyl groups in the molecule, the ratio of these peaks is reversed to a marked extent ($I_{109} \ll I_{110}$). The peaks of C_7 ions have a high intensity in the spectra of all the structural isomers with the exception of 2,5-dimethylbicyclo[4.4.0]decane, for which their formation in a single stage is impossible without skeletal rearrangement.[99]

As a consequence of the limited number of spectra of dimethyl derivatives of compounds (VIII) and (IX), it is difficult to isolate any group characteristics of the structural isomers.[82,85] One can only note that the presence or absence of an angular methyl group in the molecule can be inferred from the ratio of the peak intensities of the ionic species $[M-C_3H_7]^+$ (m/z 95) and $[M-C_3H_6]^+$ (m/z 96) in the spectra of dimethyl derivatives of compound (IX): $I_{95}/I_{96} > 1$ for the 1,2- and 1,3-dimethyl derivatives and $I_{95}/I_{96} < 1$ in the absence of a substituent at C(1).

In the series of dimethylbicycloalkane stereoisomers examined the same dependence of the MI intensity on the stability of the molecule is observed as for the monosubstituted structures: in the mass spectrum of the sterically less hindered stereoisomer the peaks of the ionic species M^+ and $[M-CH_3]^+$ are as a rule more intense than those observed in the spectra of the more hindered isomer. The differences between the peak intensities of the primary ions in the series of stereoisomers of certain hydrocarbons are then found to be sufficiently large to be employed for diagnostic purposes.[85,86,99-102]

(d) Polyalkyl-substituted hydrocarbons. The mass spectra of compounds having more than two substituents in the molecule are known only for the most stable bicyclo[4.4.0]decane system—compounds (XV)–(XVII).[103-105]

(XVI) (XVII) (XVIII)

The difference between the positions of the geminal and methyl groups in the molecules of the structural isomers of compounds (XVI) and (XVII) does not affect the character of the decomposition of their molecular ions—the spectra of compounds (XVI) and (XVII) proved to be similar:[103] they are both characterised by a low-intensity peak of the molecular ion (m/z 208) and the maximum peak intensity of the ion $[M-CH_3]^+$. Fragments corresponding to the abstraction of two and three carbon atoms from the molecular ion are absent. Despite the presence of the geminal group in the molecule of compound (XVIII), its mass spectrum is characterised by a small peak due to the ion $[M-CH_3]^+$ and an intense MI peak (m/z 222).[105] The peak intensity for the ion $[M-C_2H_5]^+$ is also high and the peak for the ion with m/z 123 has the highest intensity.

2. Hydrocarbons with a Bridge Type of Junction between the Rings

(a) Unsubstituted hydrocarbons. The vast majority of the mass spectra quoted in the literature[91,106-119] refer to hydrocarbons consisting of five–six-membered rings [compounds (XIX)–(XXII)]. The only exception is bicyclo[1.1.1]-pentane (XXIII),[120] whose mass spectrum contains, apart from the MI peak with the maximum intensity, also the peak of the ion $[M-H]^+$. The study of the decomposition of the deuteriated analogue of compound (XXIII) led to the conclusion that hydrogen is eliminated not only from the methylene but also from the methylidyne unit. The peak intensities of the remaining fragment ions are low.

(XIX) (XX) (XXI) (XXII) (XXIII)

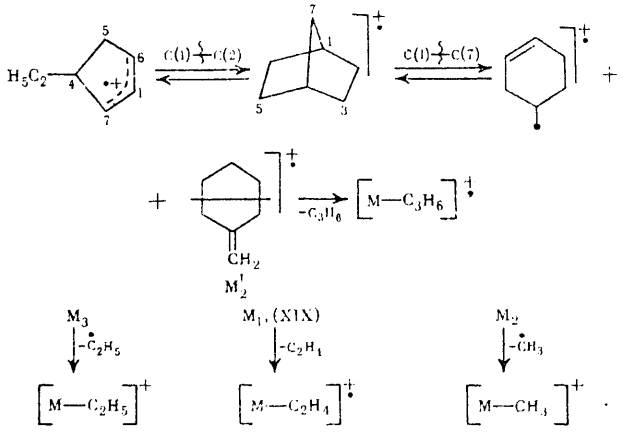


Table 4.

Compound	$I_{[M]^+}$	$I_{[M-CH_3]^+}$
(XIX)	3.8	14.7
(XX)	7.5	3.9
(XXI)	11.9	0.5
(XXII)	12.3	3.3

The stability of the MI and the ion $[M-CH_3]^+$ in the spectra of the unsubstituted bicycloalkanes (XIX)–(XXII) varies within wide limits (Table 4).[106,108,117,119] A molecule of the hydrocarbon (XIX) is subject to an intense strain arising as a consequence of the distortion of the C(1)–C(7)–C(4) angle (~90°) and an appreciable "Pitzer" interaction between the hydrogen atoms [C(2), C(3) and C(5), C(6)], which is characteristic of a six-membered ring in the boat conformation. Under the conditions of electron impact, these difficulties initiate the formation of isomeric forms of the molecular

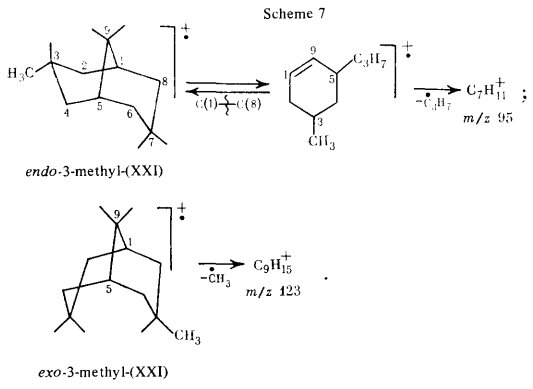
ion (M_2 and M_3, Scheme 6), whose subsequent decomposition leads to the appearance of the intense peaks of $[M-CH_3]^+$ and $[M-C_2H_5]^+$ (maximum peak).[117,118] The decomposition of the form M_1 leads to the appearance of the intense peak of the radical-ion $[M-C_2H_4]^{+\cdot}$.

Scheme 6

In the spectra of the hydrocarbons (XX) and (XXII), whose molecules also contain the dimethylene bridge, the peak of the ion $[M-C_2H_5]^+$ is one of the most intense. In the spectra of compounds (XX)–(XXII) the maximum intensity is shown by the peak of the ion $[M-C_3H_7]^+$. For compound (XX), the formation of this ion is attributed to the successive elimination of a methyl radical and an ethylene molecule from the MI,[106] in the case of compound (XXI) it is believed to arise as a consequence of the ejection of a propyl radical from the monocyclic form of the MI,[119] while for compound (XXII) the formation of the ion is believed to be due to the contributions of both decomposition pathways.[108]

Table 5. The peak intensities of the characteristic ions in the spectra of monomethylbicycloalkanes.[106,108,117–119]

Ions	(XIX)	(XX)	(XXI)	(XXII)
M^+	2.0—4.2	1.5—6.7	5.0—8.6	10.1—11.1
$[M-CH_3]^+$	5.8—9.8	2.7—12.8	3.2—18.1	4.3—10.8
$[M-C_2H_5]^+$	10.6—32.5	3.7—28.6	0.4—5.4	13.8—22.5
$[M-C_3H_7]^+$	9.5—16.6	3.2—24.3	3.8—32.2	7.3—12.8
$[M-C_4H_9]^+$	—	6.3—14.6	7.3—14.9	9.8—14.3

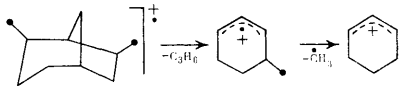


(b) Monosubstituted hydrocarbons. The introduction of the methyl substituent into the molecules of compounds (XIX)–(XXII) lowers somewhat the stability of their MI. The highest stability of the MI is then shown for bicyclo[2.2.2]octanes (Table 5), which makes it possible to distinguish them from the isomeric bicyclo[3.2.1]octanes.[106–108,112,117–119] The peak intensity of the ion $[M-CH_3]^+$ derived from the methyl derivative of compound (XXII) is higher compared with the unsubstituted structure; nevertheless the ratio $I_{[M]^+}/I_{[M-CH_3]^+}$ remains greater than unity. For the remaining members of the series, the ratio of the intensities of these peaks is determined by the position of the methyl group in the molecule.

The decomposition of the cyclic components of the bridged bicyclo-octanes takes place preferentially with the abstraction from the molecular ion of fragments containing two and three carbon atoms. A two-carbon fragment is ejected mainly as a result of the decomposition of the unsubstituted dimethylene bridge. This process proceeds very vigorously for the methyl derivatives of compounds (XIX), (XX), and (XXII), with the exception of 6-methylbicyclo[3.2.1]octane, but is not characteristic of compounds (XXI) (Table 4). A distinctive feature of the spectra of the 6- and 8-methyl derivatives of compound (XX), in which the substituent is attached to the most strained part of the molecule, is the prominance of the peak due to the primary odd-electron ionic species, namely $[M-C_3H_6]^{+\cdot}$ and $[M-C_2H_4]^{+\cdot}$ respectively, whose intensity in the spectra of the remaining structural isomers does not exceed 50% of the maximum value.

The monosubstituted hydrocarbons (XIX)–(XXI) exist in the form of two (*exo*- and *endo*-) geometrical isomers, apart from compounds (XIX)–(XXI) substituted in the angular position. As a consequence of the high symmetry of the molecule of hydrocarbon (XXII), its monosubstituted derivatives have no geometrical isomers. The stereochemical characteristics of the molecules are reflected in the spectra of the stereoisomers differing greatly in their thermochemical stabilities. These differences are particularly clear in the spectra of the *exo*- and *endo*-isomers of the 3-methyl derivative of compound (XXI).[119] The molecule of compound (XXI) exists in the "chair–chair" conformation, in which there is a strong *trans*-annular interaction with the axial hydrogen atoms at C(3) and C(7) and for this reason the additional interactions in the molecule, arising following the introduction of substituents [in particular, the interaction of the 3-*endo*-methyl group with the hydrogen atom at C(7) in the molecules of 3-methyl substituted derivatives], force one of the rings to adopt the boat conformation.

Thus the decomposition of the MI of the *endo*-epimer is determined by the removal of the "bowsprit" interactions, which is achieved, according to the authors,[119] by the efficient formation of the isomeric monocyclic form of the MI. The subsequent decomposition of this form yields the ion with *m/z* 95, the peak intensity of which is a maximum in the spectrum. The main pathway in the decomposition of the *exo*-epimer involves the elimination of the methyl group. The peak of the ion $[M-CH_3]^+$ in its spectrum has the maximum intensity (Scheme 7).



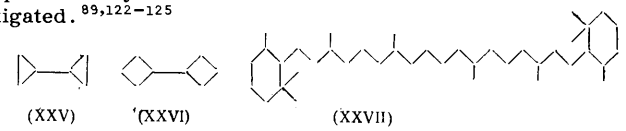
Scheme 7

(c) Disubstituted hydrocarbons. The introduction of a second methyl group into the molecules of compounds (XIX)–(XX) and (XXII) reduces somewhat the stability of the MI.[106,108,117] In the case of compound (XXI) it hardly changes.[119] On the other hand, no regularity is observed in the variation

of the peak intensity of the ion $[M-CH_3]^+$ and the ratio $I_{[M]^+}/I_{[M-CH_3]^+}$ in a series of structural isomers. The peaks of the ionic species $[M-C_2H_5]^+$, $[M-C_3H_7]^+$, and $[M-C_4H_8]^{+\cdot}$ are the most intense in the spectra of the dimethyl derivatives of compounds (XIX)–(XXI) and one of these actually has the maximum intensity. Analysis of the mass spectra of structural isomers available in the literature does not allow unambiguous conclusions about the structural elements of the molecule (such as the structure of the bicyclic skeleton, substitution in one or different rings, and vicinal or geminal disposition of the methyl groups).

However, the spectra of hydrocarbons (XIX) and (XX) substituted in the angular position stand out somewhat. They are as a rule characterised by a considerable predominance of one [the 1,2-, 1,6-, and 1,7-dimethyl derivatives of compound (XX) and the 1,4-dimethyl derivative of compound (XIX)] or two [the 1,3-, 1,4-, and 1,5-dimethyl derivatives of compound (XX) and the 1,2- and 1,3-dimethyl derivatives of compound (XIX)] decomposition pathways as a result of the preferential rupture of the bond at the quaternary carbon atom. The intensities of the peaks of the remaining ions under these conditions do not exceed 25% of the intensity of the main peak. An exception is provided by the 1,8-dimethyl derivative of compound (XX), which is characterised by an intense decomposition of the molecular ion to an equal extent via all the pathways as a consequence of the considerable strain in the molecule. For the remaining dimethyl derivatives of hydrocarbon (XX), each having three tertiary carbon atoms, the fragmentation of the molecular ion proceeds with equal probability via several pathways; according to some investigators[106] the methyl substituents are retained in the charged fragments and their subsequent abstraction leads to the strong formation of secondary ions.

In the series of geometrical isomers of dimethylbicyclooctanes the spectrum of the most stable stereoisomer of each structure also exhibits the most intense peaks of the ions M^+ and $[M-CH_3]^+$. In other respects the spectra of the stereoisomers are very similar.[106,108,117–119]

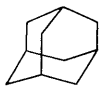


3. Other Bicyclic Systems

(a) Spiran hydrocarbons. Spiropentane (XXIV) is the only representative of this class whose mass spectrum has been described.[2,121]

(XXIV)

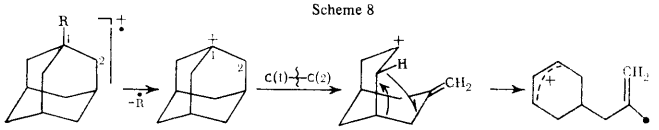
It is of interest that at 70 eV the peak of the ion $(M-H)^+$ is the most intense in the spectrum of compound (XXIV), while at 15 eV the peak of the radical-ion $(M-C_2H_4)^{+\cdot}$ is the most intense. The intensity of the peak for the ion $(M-CH_3)^+$ is low in both spectra.



(b) Hydrocarbons with single-bonded rings. The mass spectra of hydrocarbons of this class have been little investigated.[89,122–125]

(XXV) (XXVI) (XXVII)

The MI peak in the spectra of compounds (XXV)–(XXVII) is insignificant. The strongest peak in the spectra of bicyclopropyl (XXV) [89] and bicyclobutyl (XXVI) [122] {the radical-ions $[M-C_2H_4]^{+\cdot}$ and $[M-C_3H_6]^{+\cdot}$} corresponds to the ionic species formed on dissociation of endocyclic bonds at a tertiary carbon atom. The strongest peak in the spectrum of perhydro-β-carotene (XXVII) is that of the secondary ion with m/z 69.[123–125] The height of the peak due to the ion $[M-CH_3]^+$ is considerable (90% of the maximum value) only in the spectrum of compound (XXV).



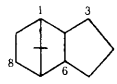
V. TRICYCLIC SATURATED HYDROCARBONS

The greatest number of studies on the mass spectrometry of tricyclic hydrocarbons have been devoted to compounds of the adamantane series. Adamantane (XXVIII) itself is the first among tricyclic hydrocarbons to have been identified in petroleums; much attention has been devoted to hydrocarbons of the adamantane series in the chemistry of petroleum.[126] The adamantane system is the most stable among tricyclic systems, which is due to the absence of any internal strains, since all three rings have the chair conformation. In the spectrum of compound (XXVIII) the MI peak has the maximum intensity. The easiest decomposition reaction of the MI of adamantane involves the elimination from it of fragments containing three and four carbon atoms, but the peak intensities of the ions formed do not exceed 50% of the maximum value:[127]

(XXVIII)

Regardless of the energy of the ionising electrons, the decomposition of the MI of alkyladamantanes leads to the formation of the adamantyl ion $C_{10}H_{15}^+$ with m/z 135 [Scheme 8, ion (C)] from the monoalkyl derivative of compound (XXIX) [128–132] or of its homologues from polyalkyladamantanes.[132–134] The peaks of these ions have the maximum intensity. It has been suggested[130,133] that the ion (C) does not retain the tricyclic structure with a positive charge on the carbon atom at the bridgehead but actually undergoes an extensive rearrangement to the cyclic allyl ion (D) which accounts for its high stability.

Scheme 8

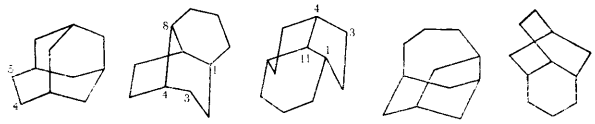


Examination of the mass spectra of 1- and 2-alkyladamantanes demonstrated a considerable decrease in the stability of the MI with increase in the length of the substituent group[128,129,132] and, for the same length of the substituent group, the stability of the MI is higher for the 2-substituted structures than for the 1-substituted structures. As a result, the ratio $I_{[M]^+}/I_{[M-R]^+}$ can be used as a criterion in determining the position of the substituent in the adamantane nucleus: it is 5–7 times higher for the 2-substituted derivatives than for the 1-substituted derivatives.

An increase in the number of substituents in the adamantane molecule leads to a decrease of the stability of the MI and an increase of the peak intensity of the ion $[M-R]^+$.[129, 132,133] In contrast to the spectra of monomethyladamantanes, the peaks of the ions $[M-C_2H_5]^+$ appear in the spectra of the tri- and tetrasubstituted derivatives, which indicates,

according to the authors,[129] the additional elimination of the CH_2 fragment from the other methyl group. The peak intensity of the above ion increases with increased number of methyl groups in the molecule.

Apart from the mass spectrum of adamantanes, a detailed study has been made of the spectrum of the isomeric tricyclo[5.2.1.$0^{2,6}$]decane (XXX) and its methyl and ethyl derivatives,[135,136] for which the IE have been measured.[137]



(XXX)

The peak for the ion $[M-C_3H_5]^+$ with *m/z* 95, formed following the abstraction of the CH_2=CH−CH_2 fragment from the MI, has the maximum intensity in the spectra of the *exo*- and *endo*-isomers of compound (XXX).

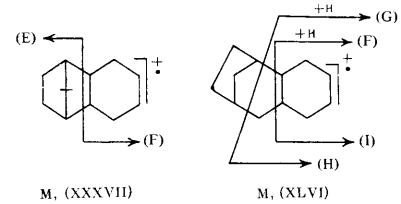
The introduction of a substituent into the molecule of compound (XXX) (the 3-, 4-, 8-, and 10-methyl derivatives have been studied) decreases the stability of the MI. On the other hand, the peak intensity of the ion $[M-CH_3]^+$ increases relative to that noted for the unsubstituted structure. The peak for the ion $[M-C_2H_5]^+$ has the maximum intensity only in the spectrum of 10-methyltricyclo[5.2.1.$0^{2,6}$]-decane. Apparently it arises in the spectrum of this compound via a mechanism analogous to that described for 7-substituted bicyclo[2.2.1]heptanes.[118] In all the remaining spectra the peaks of the secondary ions have the maximum intensities.[135,136]

As regards tricyclic hydrocarbons having the composition $C_{11}H_{18}$ (tricycloundecanes), there exist literature data for a fairly large number of structures,[138–145] many of which have been identified in petroleum.[146] The mass spectrum of homoadamantanes (XXXI) resembles that of adamantane—the MI peak is more than twice as intense as the remaining peaks in the spectrum.[138] The main difference between the spectra of compounds (XXVIII) and (XXXI) is associated with the presence in the latter of the intense peak of the ion $[M-CH_3]^+$. The spectra of the hydrocarbon labelled with ^{13}C have shown[139] that each atom in the C(4)−C(5) dimethylene bridge is involved in the abstraction of the methyl group from the MI to the extent of ~25%.

(XXXI) (XXXII) (XXXIII) (XXXIV) (XXXV)

The maximum intensity of the MI peak is observed in the spectrum of tricyclo[5.4.0.$0^{4,8}$]undecane (XXXII),[140] but a high intensity of the main fragment ions is also characteristic of this compound. The decomposition of the MI of tricyclo[5.3.1.$0^{4,11}$]undecane (XXXIII) takes place with the preferential ejection of an ethylene molecule.[140] The molecule of 4-homoprotoadamantane (XXXIV), containing the cycloheptane ring, decomposes via many pathways under electron impact.[141] The peak of the secondary ion $[C_6H_7]^+$ with *m/z* 79 has the maximum intensity in its spectrum.

Among the hydrocarbons having the composition $C_{11}H_{18}$, the most interesting is tricyclo[5.3.1.$0^{3,8}$]undecane—homoisotwistane (XXXV).[142–144] This hydrocarbon is the only one among the tricycloundecanes investigated which is formed solely from six-membered rings and the valence angles in its molecule are completely undistorted. The characteristics of the structure of homoisotwistane are reflected in its high thermal stability[104] and the high intensity of the MI peaks in its spectrum, which exceeds by a factor of almost two the intensities of the remaining peaks. The maximum intensity of the MI peak persists also in the spectrum of 1-methyltricyclo[5.3.1.$0^{3,8}$]undecane,[145] which is not characteristic of methyl-substituted saturated hydrocarbons.



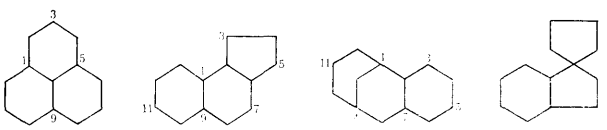
Systematic mass-spectrometric studies of a series of unsubstituted tricycloundecanes[144] and tricyclododecanes,[147] made up of five- and six-membered rings, demonstrated the possibility of identifying structural and in many instances also geometrical isomers. The mass spectra of tricyclo-[6.3.0.$0^{2,6}$]undecane (XXXVI), tricyclo[6.2.1.$0^{2,7}$]undecane (XXXVII), tricyclo[5.2.2.$0^{2,6}$]undecane (XXXVIII), tricyclo-[5.3.1.$0^{2,6}$]undecane (XXXIX), tricyclo[6.2.1.$0^{2,6}$]undecane (XL), tricyclo[5.3.1.$0^{3,7}$]undecane (XLI), tricyclo-[6.2.1.$0^{1,6}$]undecane (XLII), tricyclo[5.2.2.$0^{1,5}$]undecane (XLIII), tricyclo[6.3.0.$0^{1,5}$]undecane (XLIV), tricyclo-[7.3.0.$0^{3,8}$]dodecane (XLV), tricyclo[7.2.1.$0^{2,7}$]dodecane (XLVI), tricyclo[6.3.1.$0^{2,6}$]dodecane (XLVII), tricyclo-[6.2.2.$0^{2,7}$]dodecane (XLVIII), tricyclo[6.3.1.$0^{4,12}$]dodecane (XLIX), tricyclo[7.2.1.$0^{1,6}$]dodecane (L), tricyclo[6.3.1.$0^{1,6}$]-dodecane (LI), tricyclo[6.3.1.$0^{1,5}$]dodecane (LII), and tricyclo[5.3.1.$1^{4,11}$]dodecane (LIII) have been investigated.

The stability of the MI of the tricyclanes investigated varied within wide limits (1.8–13.3%) and is lower the greater the number of cyclopentane rings in the molecule. The mass spectra of all the tricyclanes contain the peaks of the ions $[M-CH_3]^+$ and $[M-C_2H_5]^+$, the intensity of the latter being particularly high in the spectra of compounds containing the dimethylene bridge. The abstraction of a three-carbon fragment from the MI takes place strongly only in the decomposition of tricyclododecanes.

All the hydrocarbons (XXXV)–(LIII) investigated can be divided into two groups according to the absence (group 1) or presence (group 2) of a carbon atom common to all three rings. The quantitative differences between the spectra of the hydrocarbons in groups 1 and 2 reflect the fundamental difference between the pathways in the decomposition of their MI.

The first significant difference for tricycloundecanes consists in the peak intensity for the ion $C_5H_7^+$ with *m/z* 67 [ion (E), Scheme 9], which is more than twice as high in the spectra of the group 1 hydrocarbons (XXXVI)–(XL) as in the spectra of the group 2 compounds (XLI)–(XLIV). This is apparently associated with the fact that the formation of the ion (E) from compounds (XXXVI)–(XL) requires the rupture of two C−C bonds (Scheme 9, on the left), while in compounds (XLI)–(XLIV) three such bonds must be broken, which is less probable.

Scheme 9



M, (XXXVII) M, (XLVI)

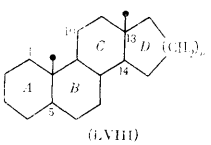
The second difference is the absence from the spectra of group 2 hydrocarbons of the peak of the ion $C_6H_{11}^+$ with *m/z* 83 [ion (F)]. In the case of group 1 hydrocarbons this ion is formed directly from the molecular ion. Among group 2 hydrocarbons, its formation requires, apart from the rupture of the C−C bonds, the migration of at least one hydrogen atom to the C_6 fragment. The impossibility of such migration for steric or other reasons apparently leads

to the absence of the peak of the ion (F) from the spectra of group 2 hydrocarbons.

The spectra of group 1 tricyclododecanes (XLV)–(XLVIII) contain intense peaks for the ionic species $C_6H_{11}^+$ (m/z 83), $C_7H_{13}^+$ (m/z 97), $C_7H_{12}^+$ (m/z 96), and $C_6H_{10}^+$ (m/z 82) [ionic species (F), (G), (H), and (I), Scheme 9, on the right], whereas in the spectra of group 2 hydrocarbons the first two peaks are missing and the intensities of the last two are insignificant. The above differences are associated with the impossibility of the formation of these ions as a result of the simple rupture of two bonds in the molecules of group 2 hydrocarbons. Their formation following the dissociation of three bonds, is firstly, less favourable on energy grounds and, secondly, requires the migration of at least one hydrogen atom.

The mass spectra of tricyclic hydrocarbons having the composition $C_{13}H_{22}$ have been obtained for tricyclo[7.3.1.$0^{5,13}$]-tridecane (LIV),[107] tricyclo[7.4.0.$0^{2,6}$]tridecane (LV),[148] tricyclo[7.3.1.$0^{2,7}$]tridecane (LVI),[149] and 1,2-tetramethylene-spiro[4,4]nonane (LVII).[148]

(LIV) (LV) (LVI) (LVII)



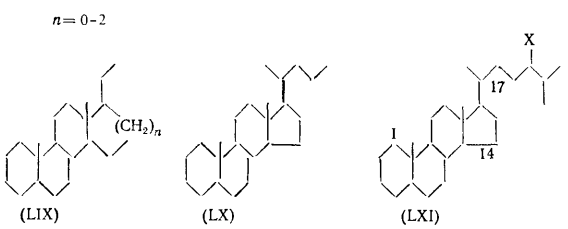
The intensity of the MI peak for the first three compounds is high, while that of the peaks for the ions $[M-CH_3]^+$ and $[M-C_2H_5]^+$ is insignificant. The main pathway in the decomposition of the MI of compounds (LIV)–(LVIII) involves the abstraction of fragments containing three carbon atoms: in the spectra of compounds (LV) the peak of the ion $[M-C_3H_7]^+$ has the maximum intensity. The mass spectrum of the hydrocarbon (LVII) is characterised by a high peak intensity of the ion $[M-C_4H_9]^+$ greatly exceeding that observed for the remaining peaks in the spectrum.

VI. HYDROCARBONS WITH FOUR AND MORE RINGS IN THE MOLECULE

The decomposition of the molecule of a polycyclic compound of this type under electron impact conditions has been examined in greatest detail for hydrocarbons of the steroid and triterpenide types, which is due primarily to their widespread occurrence in nature and the important role which they play in the solution of many geochemical problems.[150]

1. Tetracyclic Hydrocarbons of the Steroid Type

The extensive experimental data obtained in the mass-spectrometric study of the hydrocarbons (LVIII)–(LXI) with the aid of ^{13}C-labelled and deuteriated analogues made it possible to formulate the main pathway leading to the decomposition of the MI and to determine the mechanism of the formation and the structure of the main fragment ions as well as the type of A/B and C/D junctions between the rings in molecules of compound (LXI).[151–156]

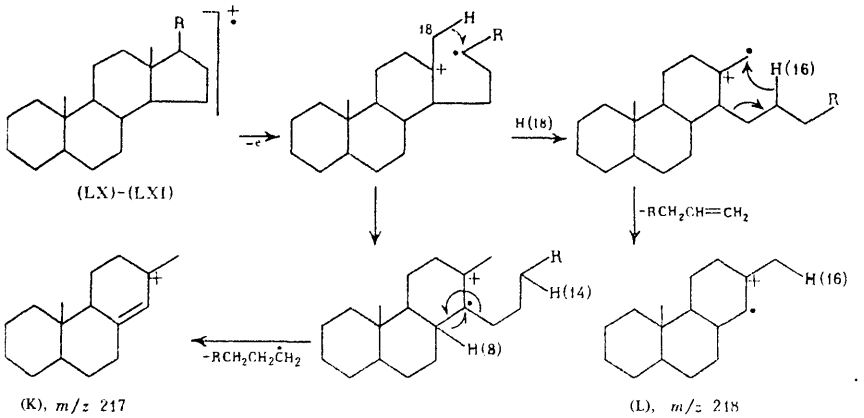


(LVIII)

(LVIIIa): n = 0 (D-norandrostane); (LVIIIb): n = 1 (androstane); (LVIIIc): n = 2 (D-homoandrostane); (LVIIId): n = 3 (D-bishomoandrostane)

The principal pathway in the decomposition of the unsubstituted structure (LVIII) is determined by the structure of the D ring.[41,151,153] The MI peak is intense in the spectra of all the compounds with the exception of compound (LVIIIa). The peak intensity of the ion $[M-CH_3]^+$ in the spectra of compound (LVIII, a, c, and d) is approximately half the maximum value, while in the spectrum of compound (LVIIIb) this is the main peak.

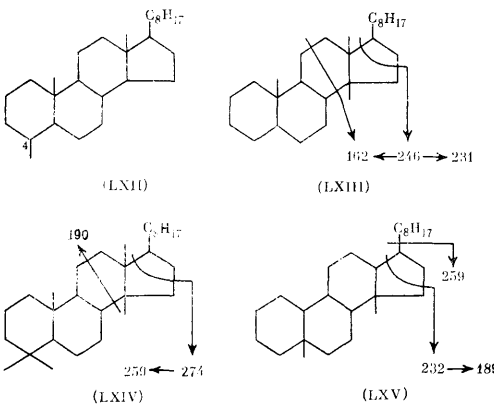
The decomposition of the cyclic component of the molecule of compound (LVIII) takes place with the preferential rupture of the C–C bonds in the A and D rings. Studies of the deuteriated analogues have shown[41,151] that the decomposition of the A ring in compound (LVIIIb) predominates over the decomposition of the D ring, while in compounds (LVIII, a and d) the opposite behaviour obtains. In the case of compounds (LVIII, a, c, and d) this leads to the preferential formation of ions with m/z 217 and 218 [(K) and (L), Scheme 10], while in the case of compound (LVIIIb) ions with m/z 203 and 204 are formed preferentially. The appearance in the D ring of a substituent at the carbon atom adjoining C(13) [pregnanes (LIX), cholanes (LX), and steranes (LXI) have also been investigated][151,156–162] promotes the preferential rupture of the bond between these two atoms, as a result of which the peaks for the ions with m/z 217 and 218 have the maximum intensity in the spectra of compounds (LIX)–(LXI)†.



(LIX) (LX) (LXI)

(LVIIIa): (cholestane); (LXIb): X = CH_3 (ergostane); (LXIc): X = C_2H_5 (sitostane)

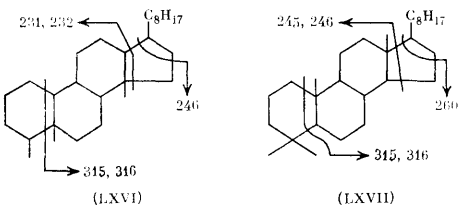
Attempts to determine structures of this type have been frequently made,[158,159] but only by the analysis of the spectra of deuteriated compounds was it possible to formulate a mechanism of the formation of these ions and to determine their structure (Scheme 10).[151,157]



†The presence in the spectra of steranes of intense peaks due to the ions with m/z 217 and 218 makes it possible to determine unambiguously their presence in complex mixtures, which is widely used in the chromato-mass-spectrometric analysis of petroleum fractions.[163–173]

Scheme 10

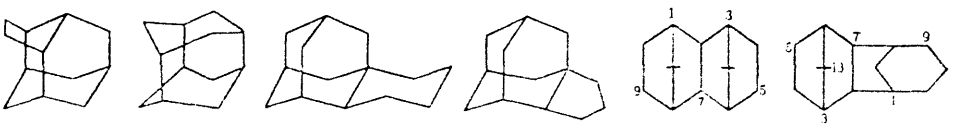
The ratio of the peak intensities for the ions with m/z 217 and 218 and also the ions with m/z 149 and 151, formed on cleavage of the C ring,[156] plays an important role in the determination of the stereochemical features of molecules of the steranes (LXI, a–c). Thus the first of these characterises the type of C/D junction between the rings (*trans*-junction for $I_{217}/I_{218} > 1$ and *cis*-junction for $I_{217}/I_{218} < 1$), while the second characterises the type of A/B junction between the rings (*cis*-junction for $I_{149}/I_{151} \geq 1$ and *trans*-junction for $I_{149}/I_{151} < 1$).[150]



Apart from the hydrocarbons (LVIII)–(LXI) examined above, studies have been made of the spectra of a large group of compounds retaining the skeleton of the molecule of cholestane (LXI), but having methyl groups in other positions in the molecule.

The study of the 4α-methylcholestane (LXII) fragmentation pathway showed[172–174] that the appearance of an additional substituent in the A ring does not alter the principal pathways leading to the decomposition of the molecular ion and characteristic of steranes, merely displacing the mass numbers of the fragment ions incorporating the A ring by 14 a.m.u. towards higher values.

On the other hand, the presence of a substituent at C(14) in 14α-methylcholestane (LXIII) and lanostane (LXIV) [172] alters significantly the MI decomposition pattern. The study of the (LXIII) and (LXIV) fragmentation pathways with the aid of deuteriated analogues showed[175] that the ion with the maximum peak intensity in their spectra [with m/z 231 for (LXIII) and m/z 259 for (LXIV)] is formed from the fragment ions and not from the MI as in the case of cholestane.



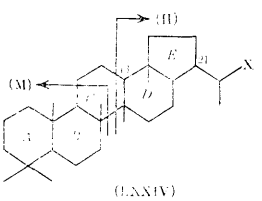
The mass spectra of the stereoisomers of the rearranged cholestane (LXV) are characterised by a high peak intensity of the ions with m/z 189 and 259.[176] The methyl group in the C(5) position in the molecule of compound (LXV) not only shifts by 14 a.m.u. the mass number of the fragments containing the A ring, as in the case of compound (LXII), but also alters sharply the quantitative picture of the spectrum.[174] A characteristic feature of the spectra of the rearranged 4-methylcholestanes (LXVI) is the presence of the intense peaks for the ions with m/z 315 and 316 formed on degradation of the A ring. As for compound (LXV), this is accompanied by the decomposition of the D ring with formation of ions having m/z 232, 231, and 246.

The decomposition of 4,4-dimethylcholestanes (LXVII) under electron impact resembles the decomposition of cholestanes.[175] The mass number of the ions incorporating the A ring is displaced by 28 a.m.u. relative to the corresponding peaks in the spectrum of compound (LXI). Ions which do not incorporate the A ring have the same mass number as for compound (LXIa). For the hydrocarbons (LXV)–(LXVII), there is a possibility, as for cholestane, of the mass-spectrometric determination of the type of A/B and C/D junctions between the rings.[174,176]

2. Other Tetracyclic Hydrocarbons

The molecule of tetracyclo[6.3.1.$0^{2,6}$.$0^{5,10}$]dodecane (LXVIII) can be regarded as the molecule of adamantane having an ethane bridge in the 2,5-positions.

(LXVIII) (LXIX) (LXX) (LXXI) (LXXII) (LXXIII)



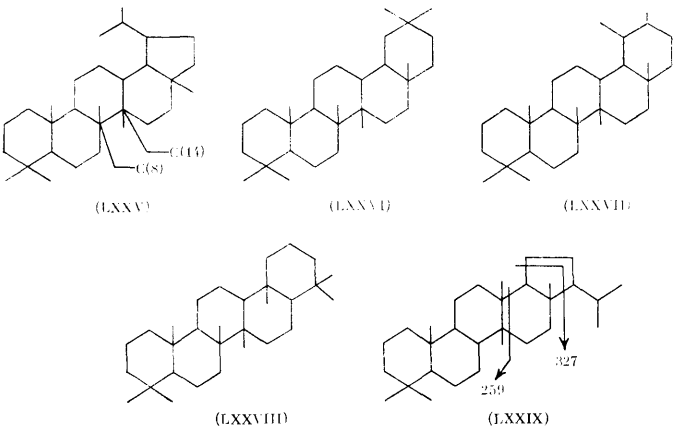
This modification of the adamantane structure does not alter the decomposition of its MI.[177] The MI peak again has the maximum intensity in the spectrum of compound (LXVIII), while the peak of the ion $[M-C_2H_5]^+$ is insignificant. The replacement of the dimethylene bridge by the methylene bridge, as in tetracyclo[5.3.1.$1^{2,6}$.$0^{4,9}$]dodecane, is also hardly reflected in the character of the fragmentation of the MI and the spectrum of compound (LXIX) retains the features characteristic of that of adamantane.[178]

The MI peak intensity remains a maximum also in the spectra of the hydrocarbons (LXX) and (LXXI).[179] However, the stability of the parent ion is greatly reduced compared with its stability in the adamantane spectrum.

The decomposition of the molecules of tetracyclo[6.2.1.$0^{2,7}$.$1^{3,6}$]-dodecane (LXXII) and tetracyclo[6.3.1.$0^{2,7}$.$1^{3,6}$]tridecane (LXXIII) proceeds with formation of the ionic species M^+, $[M-C_2H_4]^+$, $[M-C_2H_5]^+$, and $[M-C_3H_7]^+$, which correspond to intense peaks.[180] The peaks of the secondary ions [*m/z* 80, 121 for (LXXII) and *m/z* 41 for (LXXIII)] have the maximum intensity in the spectra of compounds (LXXII) and (LXXIII).

3. Pentacyclic Hydrocarbons of the Triterpane Series

The study of the fragmentation of hydrocarbons of the triterpane series (LXXIV) (the hopane series) under electron impact showed[172,181,182] that it proceeds with the preferential formation of ions of two types—(M) and (H).

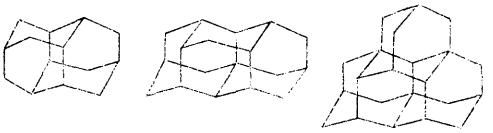


(LXXIV)

(LXXIVa): X = H (adiantane); (LXXIVb): X = CH_3 (hopane); (LXXOVc): X = C_2H_5 (homohopane)

In the case of hopane these ions have equal masses (*m/z* 191). The presence in the spectra of pentacyclic hydrocarbons of the peaks due to the ions (M) and (H), whose intensity greatly exceeds that of the remaining peaks in the spectrum {the peaks of the ions M^+ and $[M-CH_3]^+$ have as a rule low intensities}, has been widely used for the identification of compounds of the "hopane series" in petroleum.[152,183-193] On the other hand, the ratio of the intensities of these peaks is diagnostic for the type of *D/E* ring junction—$I_{(M)}/I_{(H)} > 1$ for the *trans*-junction and $I_{(M)}/I_{(H)} < 1$ for the *cis*-junction.

A change in the position of the substituent in the *E* ring of the hopane molecule does not entail any changes in the spectrum of compound (LXXV).[181,183,184]

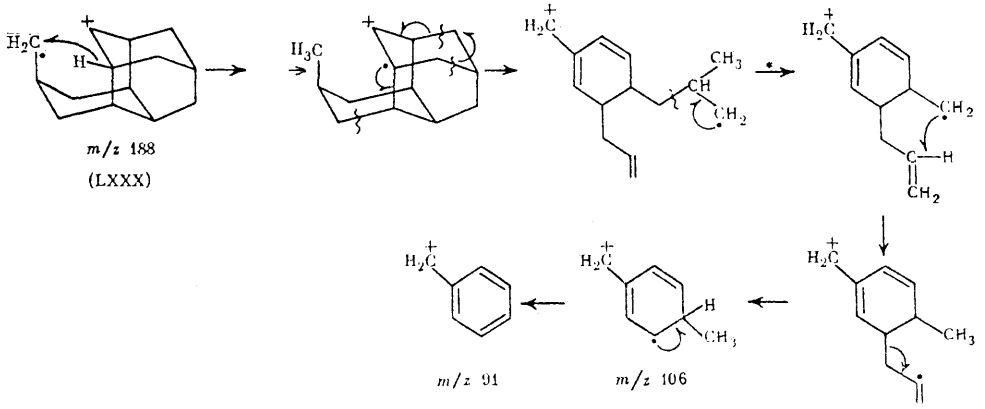


(LXXV) (LXXVI) (LXXVII) (LXXVIII) (LXXIX)

The rupture of the C(8)–C(14) bond is the main process also for compounds with a six-membered *E* ring [oleanane (LXXVI), ursane (LXXVII), and gammacerane (LXXVIII)][181,185] which retain the methyl groups C(8) and C(14).

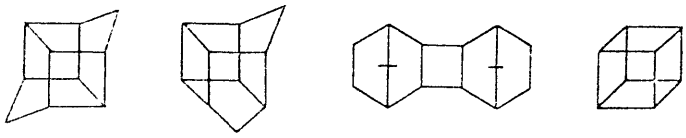
The transfer of the methyl group from the C(8) position to the C(13) position in structures of type (LXXIX) leads to a sharp decrease of the peak intensity for the ion with *m/z* 191.[172,181] Intense peaks due to the ions with *m/z* 259 and 327, which are absent from the spectra of compounds (LXXIV)–(LXXIX), then appear and there is also a sharp increase of the intensity of the peaks in the region of low masses, which in fact attain maximum values (*m/z* 69, 81, 109).

4. Other Hydrocarbons with Five and More Rings in the Molecule



Polycyclic hydrocarbons having adamantane-like structures (LXXX)–(LXXXII) have been studied in detail. As in the spectrum of adamantane, the maximum intensity in their spectra is that of the molecular ion.[193-200]

(LXXX) (LXXXI) (LXXXII)



In the diamantane (LXXX) spectrum the intensity of the MI peak is a maximum, being approximately five times greater than that of any other peak.[194,195] The study of the metastable ion peaks in the spectrum of compound (LXXX) showed[196] that the ion with *m/z* 91 which has the next largest peak is not primary, but is formed as a result of a multistage decomposition of the MI and apparently has the structure of the phenylalkyl cation (Scheme 11).

Scheme 11

The spectra of 1-, 3-, and 4-methyldiamantanes retain the type of behaviour in the decomposition of the MI described previously for alkyladamantanes.[197,198] The ratio $I_{[M]^+}/_{[M-CH_3]^+}$ can also be used in this instance for the determination of the position of the methyl group in the diamantane nucleus: it is greater for 3-methyldiamantane than for the 1- and 4-methyldiamantanes.

The decomposition of the MI into two symmetrical fragments with dissociation of the bonds in the cyclobutane rings is characteristic of two pentacyclic hydrocarbons—pentacyclo-[5.3.0.$0^{2,6}$.$0^{3,9}$.$0^{4,8}$]decane (LXXXIII) and pentacyclo-[5.3.0.$0^{2,6}$.$0^{3,9}$.$0^{5,8}$]decane (LXXXIV).[201] The ion with the cyclopentadiene structure (m/z 66) formed under these conditions exhibits the maximum intensity for both compounds, which is much higher than for the remaining peaks in the spectrum (more than 50% of the total ionic current).

(LXXXIII) (LXXXIV) (LXXXV) (LXXXVI)

The possibility of the symmetric cleavage of the molecule into two fragments of equal mass (with m/z 91) has also been discussed in connection with the dissociation of pentacyclo-[8.2.1.$1^{4,7}$.$0^{2,9}$.$0^{3,8}$]tetradecane (LXXXV).[202] However, consideration of the metastable transitions and the spectra of deuteriated analogues showed that the ion $C_7H_7^+$ with m/z 91 is formed as a result of the successive ejection also of C_2 and C_5 fragments from the MI.[202] The ion does not then retain the norbornane structure, but isomerises to a tropylium ion.

The spectrum of "cubane" (LXXXVI), a hexacyclic hydrocarbon with four carbon atoms in the rings, proved to be interesting.[203] The peak for the ion $(M-H)^+$ shows the maximum intensity (this had been observed earlier only in the spectrum of spiropentane[121]).

Mass-spectrometric study of linked-ring adamantane derivatives, containing two adamantyl groups, namely biadamantyls (R–Ad–Ad–R) and diadamantylethanes (Ad–CH_2–CH_2–Ad), showed[204] that the dissociation of the bond between the adamantyl residue Ad and the carbon chain is accompanied by the formation of the radical-ion $[M-AdH]^+$ having an intense peak is characteristic of diamantylethanes, while in the case of biadamantyls the most intense peak in the spectrum corresponds to the rupture of the bond between the adamantyl residues {the $[RAd]^+$ ion}. The above differences persist also for the alkyl derivatives of these structures.

In conclusion one must note yet again that the characteristic features of the decomposition of saturated hydrocarbons under electron impact, mentioned in the present review, necessitate much caution in the approach to the interpretation of the mass spectra and the identification of compounds of this class on that basis. The data available to us do not allow unambiguous conclusions concerning individual structural elements of the molecule, such as the presence (or absence) of a substituent, of a quaternary or tertiary carbon atom, and of bridge type, condensed, or single bond type of connection between the rings in the molecule of the polycyclic hydrocarbon. The solution of these problems is so far possible only in some cases and within the limits of groups of compounds which have been studied systematically.

Alkoxycarbenium Ions

D.L.Rakhmankulov, R.T.Akhmatdinov, and E.A.Kantor

The method of synthesis, NMR spectra, and chemical properties of alkoxycarbenium ions are examined and the influence of the medium, temperature, and the structure of the ions on their stability are discussed.
The bibliography includes 99 references.

CONTENTS

I. Introduction 888
II. Methods of synthesis of alkoxycarbenium ions 888
III. The structure and properties of alkoxycarbenium ions 894

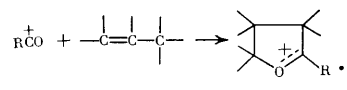
I. INTRODUCTION

Alkoxycarbenium ions are intermediate in the reactions of organic compounds of many classes: acetals, α-halogenoethers, vinyl ethers, unsaturated ketones, etc. In many respects they determine the reactivity of these compounds and the mode of their reactions. The interest in these compounds is therefore entirely legitimate; since the 1960s, a considerable number of original communications, reflecting particular aspects of the chemistry of alkoxycarbenium ions, have appeared in the literature. Particularly marked progress in this field has been achieved in connection with the development of NMR spectroscopy and the practical applications of the results of research into superacids, which permit the generation of various cations, including alkoxycarbenium ions, and the investigation of their properties under "long life" conditions.

The majority of the reviews and monographs[1-5] devoted to the chemistry of oxonium and in particular alkoxycarbenium ions were published more than ten years ago and reflect inadequately the present advances in this field. In addition, the reviews hardly describe the work of Soviet investigators.

The present review deals with the methods of synthesis of alkoxycarbenium ions, their structure and chemical properties, and the mode of their reactions as a function of the structure of the ions, the reaction conditions, and the character of the nucleophile.

II. METHODS OF SYNTHESIS OF ALKOXYCARBENIUM IONS



The methods of synthesis of alkoxycarbenium ions are fairly varied. In terms of the principles underlying the synthesis, the methods can be divided into seven groups:

1. Alkylation of the carbonyl group:

$$\rangle C{=}O + R^+ \rightarrow \rangle C^{+}\!\cdots\!OR \ .$$

Cyclic alkoxycarbenium ions are mainly obtained by this procedure as a result of the intramolecular alkylation of the carbonyl groups of aldehydes and ketones containing other functional groups.

2. Acylation of olefins and cyclopropanes:

3. Protonation of vinyl ethers:

$$-\overset{|}{C}{=}\overset{|}{C}-OR + H^+ \rightarrow -\overset{|}{C}H-\overset{|}{C}^{+}\!\cdots\!OR \ .$$

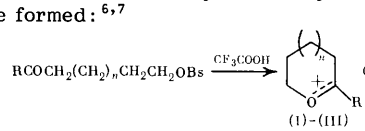
4. Abstraction of the halide anion from α-halogenoethers:

$$R_2C(X)-OR' \xrightarrow{-X^-} R_2C^{+}\!\cdots\!OR' ;$$
X=Cl, Br, I.

5. Abstraction of the alkoxy-group from acetals by protic or aprotic acids:

$$ROCOR \xrightarrow{+H^+} ROC^{+}OR \xrightarrow{-ROH} -\overset{|}{C}^{+}\!\cdots\!OR \ .$$
H

6. The formation of the carbenium centre at a site in the molecule remote from the oxygen atom with subsequent hydride or alkyl shift:

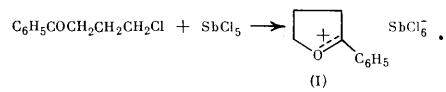


$$-\overset{+}{C}-\left(-\overset{|}{C}-\right)_n-\overset{|}{C}R-OR' \longrightarrow -\overset{|}{C}R-\left(-\overset{|}{C}-\right)_n-\overset{|}{C}^{+}\!\cdots\!OR' ;$$
n=0, 1; R=H, Alk.

7. Isomerisation of oxenium ions:

$$-\overset{|}{C}R-\overset{+}{O} \longrightarrow -\overset{|}{C}^{+}\!\cdots\!OR \ .$$

1. Alkylation of the Carbonyl Group

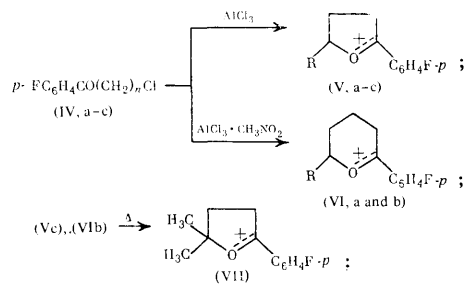


The intramolecular alkylation methods differ in the procedure used to generate the alkyl cation attacking the carbonyl group. The solvolysis of brosylates or the elmination of a halogen are the most convenient for the generation of primary alkyl cations. Thus, when the brosylates of γ- and δ-hydroxyketones are dissolved in trifluoroacetic or formic acid, five- and six-membered cyclic alkoxycarbenium ions (I)–(III) are formed:[6,7]

(I)-(III)

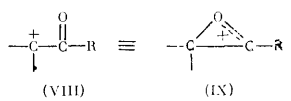
(I) $n=0$, $R=C_6H_5$; (II) $n=0$, $R=CH_3$;
(III) $n=1$, $R=C_6H_5$; OBs = p-$BrC_6H_4SO_2O$.

Unambiguous evidence supporting the formation of the ion (I) is provided by the identity of the ^1H NMR spectrum with that of a solution of the salt obtained by treating γ-chlorobutyrophenone with antimony pentachloride in SO_2 or acetonitrile:[7]



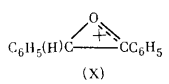
(I)

The chloride ion can also be removed by treatment with silver salts:[8]



Analogous ions are formed on interaction of ω-chlorophenones (IV, a–c) with aluminium chloride.[9,10] It is of interest that, on treatment with free $AlCl_3$, only the five-membered cyclic ion (Vb) is formed from the ketone (IVb), while on treatment with the complex $AlCl_3.CH_3NO_2$, a mixture of five-membered (V, b and c) and six-membered (VI, a and b) cyclic alkoxycarbonium ions is formed with the five-membered ions predominating. On heating, the ions (Vc) and (VIb) are converted into the more stable ion (VII):

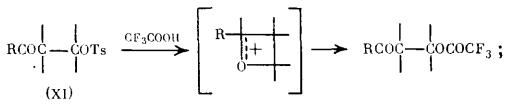
(IV): $n = 3$ (a), 4 (b), 5 (c); (V), (VI): R = H (a), CH_3 (b), C_2H_5 (c).



Thus five-membered cyclic alkoxycarbenium ions are more stable than the six-membered ions.

Three- and four-membered cyclic alkoxycarbenium ions are apparently unstable. It has been suggested[11] that α-acylcarbenium ions can have the cyclic structure as a result of the interaction of a vacant orbital with the unshared electron pairs of the carbonyl oxygen atom:

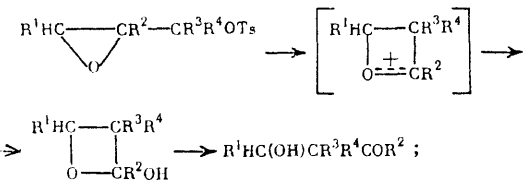
(VIII) (IX)



Quantum-chemical calculations have shown[12] that structure (IX) should be more stable than structure (VIII). At −75 °C signals due to the first representative of three-membered cyclic alkoxycarbenium ions (X) were detected in ^1H and ^{13}C NMR spectra:[12]

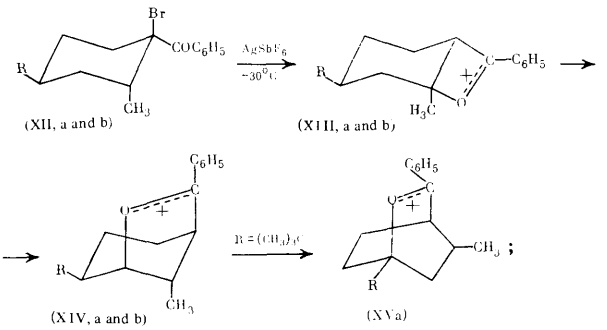
(X)

α-Acylcarbenium ions have been in many instances suggested as intermediates.[8,11–17]



The formation of four-membered cyclic alkoxycarbenium ions has been postulated in a number of studies.[18–21] In particular, their formation is indicated by the results of the solvolysis of compounds of type (XI) in trifluoroacetic acid:[18,19]

(XI)

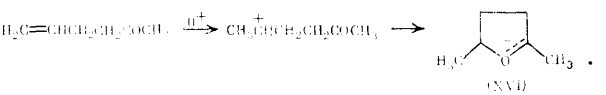


R = p-$CH_3OC_6H_4$, p-$NO_2C_6H_4$, C_6H_5, CH_3.

The study of the kinetics and stereochemistry of the products of the solvolysis of oxiranylmethyl toluene-*p*-sulphonates also led to the conclusion that such ions are formed:[20]

$R^1 - R^4$ = H, CH_3.

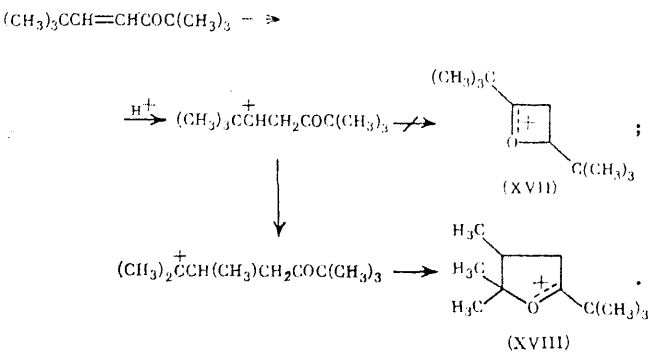
Four-membered cyclic alkoxycarbenium ions were first detected by NMR after the elimination of the bromide anion from α-bromoketones.[12,13] The ions (XIII, a and b) were detected following the interaction of the ketones (XII, a and b) with $AgSbF_6$ at −30 °C:



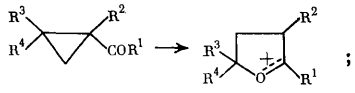
(XII)–(XV): R = $(CH_3)_3C$ (a), H (b).

When the temperature is raised to 25 °C, the ions (XIII, a and b) isomerise to the more stable five-membered ions (XIV, a and b), and t-butyl-substituted ions (XIVa) can isomerise in their turn to the six-membered ions (XVa).

When the reaction is carried out at room temperature, five- and six-membered cyclic alkoxycarbenium ions are formed immediately.[14–16]



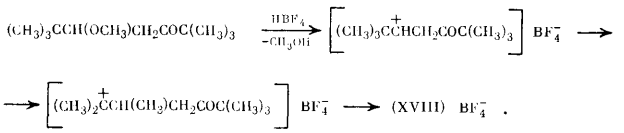
The most convenient method of synthesis of cyclic alkoxycarbenium ions involves the protonation of unsaturated ketones. When the protonation leads to the formation of a carbenium centre in the γ- or δ-position relative to the carbonyl group, the cations cyclise and give rise to five- and six-membered cyclic ions respectively,[22–32] for example:



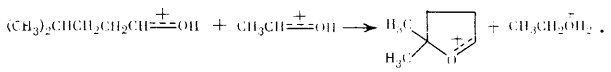
(XVII)

The cyclisation takes place under the influence of both various superacids[22,27–30] and also weaker acids such as HBF_4,[31] $HClO_4$,[32] concentrated sulphuric acid,[23,24] and dilute sulphuric acid.[25] This method of synthesis has been used to determine the heats of formation of alkoxycarbenium ions.[23,24]

If the protonation leads to the formation of a carbenium centre in the β-position relative to the carbonyl group, the corresponding four-membered alkoxycarbenium ions (XVII) are not formed and instead a rearrangement takes place (provided that it is feasible), which leads to the formation of five-membered cyclic alkoxycarbenium ions (XVIII).[31–33]

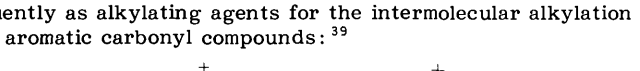


Cyclic alkoxycarbenium ions are also formed on protonation of cyclopropryl ketones in 75–96% H_2SO_4:[34,35]

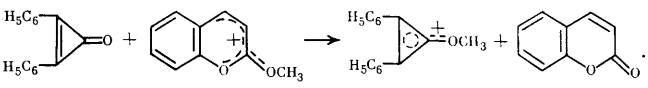


R^1–R^4 = H, CH_3, C_6H_5, cyclo-C_3H_5.

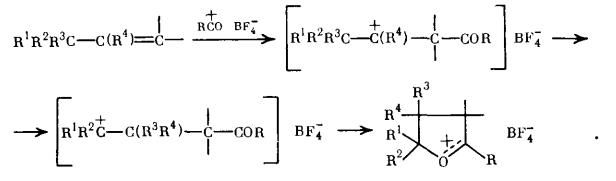
In some cases the abstraction of the alkoxy-group by strong acids has been used to generate the alkyl cation alkylating the carbonyl group:[31]



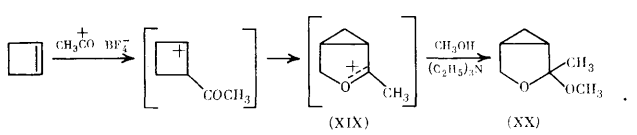
The carbenium centre attacking the carbonyl group can be created also by abstracting a hydride ion from the γ- and δ-positions relative to the carbonyl group. Thus, when 4-methylvaleraldehyde reacts with acetaldehyde in the 9 : 1 HF–SbF_5 system, the protonated acetaldehyde acts as the acceptor of the hydride ion. The dication formed from the protonated 4-methylvaleraldehyde abstracts a proton from the oxygen atom and is converted into a cyclic ion:[36]



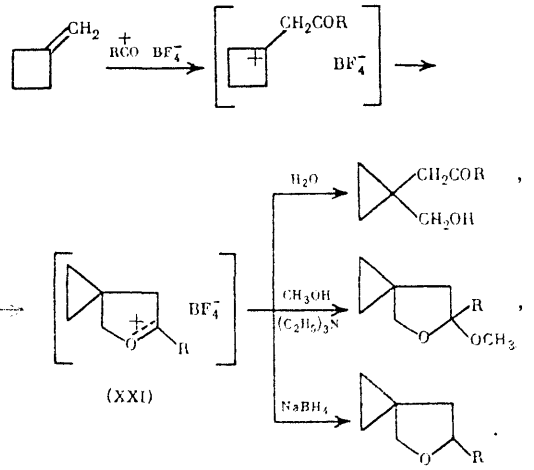
The ethanol formed is protoned in this medium. Only aromatic carbonyl compound readily undergo intermolecular alkylation. The majority of aliphatic aldehydes and ketones undergo the aldol condensation under alkylation conditions,[1,37] but, on treatment with $CH_3F.SbF_5$ in SO_2 at −78 °C, it is possible to methylate also aliphatic ketones:[38]



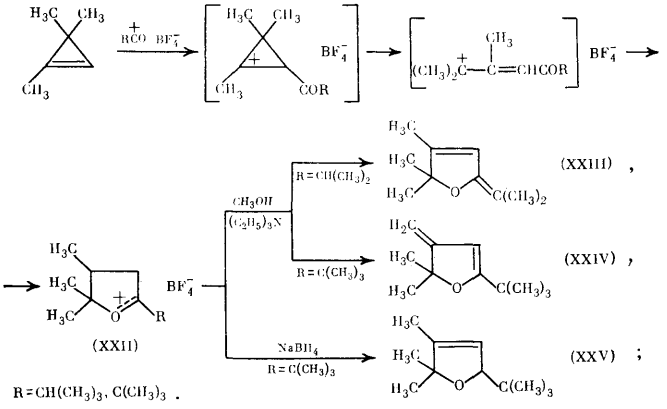
Trialkyloxonium or dialkoxycarbenium ions are used frequently as alkylating agents for the intermolecular alkylation of aromatic carbonyl compounds:[39]



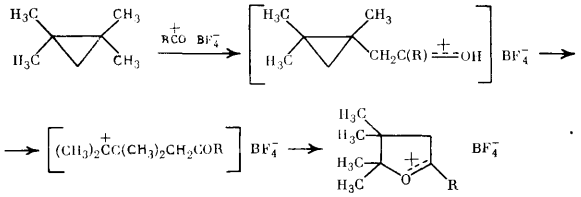
2. Acylation of Olefins and Cyclopropanes



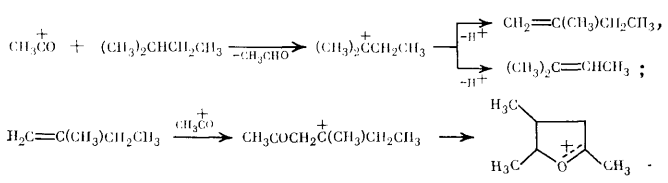
A novel method for the simultaneous introduction of the carbonyl group and the generation of the carbonium ion leading to the formation of cyclic alkoxycarbenium ions involves the acylation of olefins:[40–46]



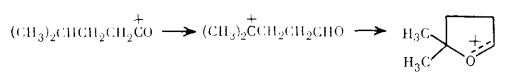
Both acylic and cyclic olefins enter into this reaction.[40–42] After the addition of the acyl cation, a 1,2-hydride or 1,2-alkyl shift and cyclisation take place. In the acylation of cyclobutene the ring contracts and the bicyclic cation (XIX) is formed.[43] Its treatment with a methanol solution of triethylamine leads to the formation of the acetal (XX):



In the acylation of methylenecyclobutane cyclic alkoxycarbenium ions are formed only when pivaloyl and isobutyryl tetrafluoroborates are used.[44,45] Ring contraction also takes place in this instance. The formation of the alkoxycarbenium ion (XXI) has been confirmed by its subsequent reactions:

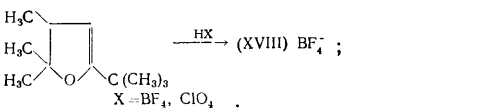


Alkoxycarbenium ions (XXII) of the dihydrofuran series are formed on acylation of 1,3,3-trimethylcyclopropene with pivaloyl or isobutyryl tetrafluoroborate:[46]

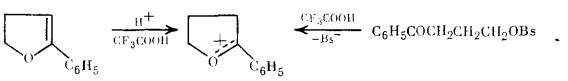


Analogous results have been obtained also on acylation of cyclopropanes.[47] The reaction of acyl cations with 1,1,2,2-tetramethylcyclopropane is somewhat unusual. Using tracer atoms, it has been shown that the ring is not attacked directly by the acyl cation; the authors proposed the following reaction mechanism:[47]

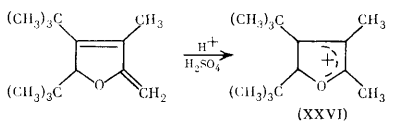
Cyclic alkoxycarbenium ions can be obtained by the reaction of acylcations with alkanes containing a tertiary carbon atom. The acyl cation then abstracts a hydride ion and is reduced to an aldehyde. The tertiary alkyl cation formed is converted into an olefin, which reacts with yet another acyl cation to form an alkoxycarbenium ion:[48]



An example of an intramolecular reaction of this kind is provided by the isomerisation of acyl cations to alkoxycarbenium ions in superacid media:[36,49]

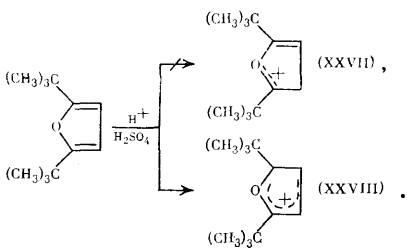


3. Protonation of Vinyl Ethers



Alkoxycarbenium ions can be obtained by protonating vinyl ethers. Thus, when 2-t-butyl-4,5,5-trimethyl-4,5-dihydrofuran is mixed in the cold with an ethereal solution of HBF_4[31] or with $HClO_4$,[32] the salt of the corresponding cation (XVIII) is formed:

The addition of a proton on dissolution of 2-phenyl-4,5-dihydrofuran in trifluoroacetic acid has been used to identify the ion (I) formed on solvolysis of γ-hydroxybutyrophenone brosylate in trifluoroacetic acid:[6,7]



When 4,5-di-t-butyl-3-methyl-2-methylene-2,5-dihydrofuran is dissolved in sulphuric acid, the ion (XXVI), where the positive charge is distributed over four atoms, is formed:[50]

(XXVI)

It is remarkable that only the more stable ion (XXVIII) is formed when 2,5-di-t-butylforan, whose protonation can result in the formation of the two ions (XXVII) and (XXVIII):[50]

4. Abstraction of a Halide Anion from α-Halogenoethers

α-Halogenoalkyl ethers are themselves incapable of ionising with elimination of a halide anion. The ionisation is promoted by the binding of the halide, for example, in a complex anion on treatment with certain metal polyhalides. Antimony pentachloride or pentafluoride is most frequently used for this purpose. Thus the interaction of α-chloroethers with $SbCl_5$ at −75 °C results in the formation of hexachloroantimonates of the corresponding cations:[51]

When α-halogenoethers are treated with a solution of SbF_5 in SO_2, the alkoxycarbenium ions formed remain in solution, which makes it possible to investigate them by NMR:[52–54]

(XXIX)

Alkoxycarbenium ions are formed particularly readily from α-halogenoallyl ethers:[55]

A convenient method for the synthesis of alkoxycarbenium ions from α-halogenoethers involves treatment of the latter with silver salts such as $AgSbF_6$, $AgBF_4$, or $AgOSO_2C_6H_2(NO_2)_3$,[56–61] for example:

(XXIX)

The halide anions can also be bound by protonation on treatment with strong acids. For example, when chloromethyl methyl ether is treated with a mixture of HF and SbF_5, methoxycarbenium hexafluoroantimonate (XXIX) is formed in quantitative yield:[62]

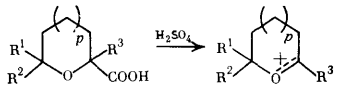
(XXIX)

Interesting results have been obtained in the study of this reaction by ^1H NMR in the HSO_3F–SbF_5–SO_2 system at low temperatures.[63] When α-halogenoethers are dissolved in this mixture at −80 °C, the oxygen atom is protonated with the consequent formation of oxonium ions:

On raising the temperature to −60 °C, the oxonium ions slowly split off HCl and are converted into alkoxycarbenium ions:

The formation of alkoxycarbenium ions from alkoxyacetic acid chlorides can also be regarded as an application of this method. When methoxyacetic acid chloride is dissolved in the HF–SbF_5 mixture at −60 °C, the oxocarbenium ion (XXX) is formed:[62]

(XXX)



On raising the temperature, the ion (XXX) slowly splits off a molcule of carbon monoxide and is converted into the methoxycarbenium ions (XXIX):

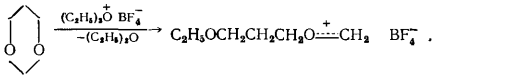
(XXIX)

Decarboxylation of carboxylic α-alkoxyacids also constitutes a procedure closely resembling the above method. Thus, when tetrahydrofuran- and tetrahydropyran-2-carboxylic acids are

dissolved in 96% H_2SO_4, the carboxy-group is split off and five- and six-membered cyclic alkoxycarbenium ions are formed respectively:[64]

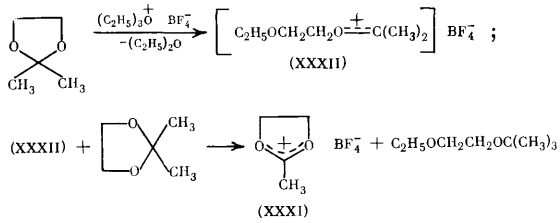
$R^1-R^3 = H, CH_3$; $p = 0.1$.

The six-membered ions are in equilibrium with the isomeric five-membered ions.



5. The Synthesis of Alkoxycarbenium Ions from Acetals

Like α-chloroethers, acetals are extremely convenient precursors for the generation of alkoxycarbenium ions. The alkoxy-group is a much more powerful nucleophile than the halide anion and its elimination from the acetal molecule therefore requires preliminary electrophilic attack on the oxygen atom.



One of the first method described in the literature for the preparation of alkoxycarbenium ions and acetals involves treatment of the latter by trialkyloxonium salts:[65]

$$(CH_3)_3CC(CH_3)(OCH_3)_2 \xrightarrow[-2(CH_3)_2O]{(CH_3)_2\overset{+}{O}BF_4^-} (CH_3)_3CC(CH_3)\overset{+}{=}OCH_3BF_4^- .$$

Under the influence of trialkyloxonium salts, the ring in cyclic acetals is cleaved, which entails the formation of alkoxycarbenium ions:[66-68]

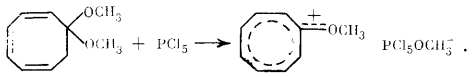
When cyclic ketals are treated with trialkyloxonium salts, cyclic dioxolenium ions (XXXI) are formed. It has been suggested[69] that acyclic alkoxycarbenium ions (XXXII) are formed initially and then abstract an alkyl anion from a second ketal molecule, for example:

(XXXII)

(XXXI)

The same reactions take place when cyclic ketals are treated with other electrophiles, such as dialkoxycarbenium ions, Lewis acids, and RHal–$AgBF_4$ mixtures.[69]

BF_3 or $SbCl_5$ are most often used as the Lewis acids.[70] Thus, when BF_3 interacts with benzaldehyde dimethyl acetal, salts (tetrafluoroborates) are formed. The mechanism of their formation can be described schematically as follows:[70]



$$C_6H_5CH(OCH_3)_2 + BF_3 \rightarrow \underset{\text{(XXXIII)}}{C_6H_5CH\overset{+}{=}OCH_3} \quad BF_3OCH_3^- ;$$

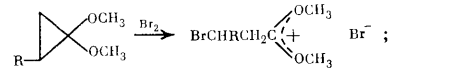
$$3BF_3OCH_3^- + BF_3 \rightarrow 3BF_4^- + B(OCH_3)_3 .$$

The anion $BF_3OCH_3^-$ formed initially is unstable and its interaction with the excess BF_3 converts it into the stable anion BF_4^-, which reacts with the cation (XXXIII) to form the salt $C_6H_5\overset{+}{C}H{-}OCH_3BF_4^-$, which is insoluble in the reaction mixture.

It is noteworthy that, when this reaction is carried out in $CDCl_3$ as the solvent, the anion $BF_3OCH_3^-$ does not disproportionate and the salt remains in solution, which makes it possible to investigate this reaction by ^1H NMR.[71,72] The introduction of electron-accepting groups in the *para*-position in the benzene ring reduces the reactivity of the acetal and *p*-nitrobenzaldehyde dimethyl acetal does not react with BF_3 at all.[72]

Weaker Lewis acids have also been used to obtain more stable alkoxycarbenium ions. Thus treatment of a solution of 7,7-dimethoxycyclo-octa-1,3,5-triene in liquid SO_2 with PCl_5 or $SOCl_2$ at −20 °C results in the formation of the 1-methoxycyclo-octatrienylium ion:[73]

Molecular bromine can also be used as the electrophile for the abstraction of the alkoxy-group.[74,75] When 2,2-dimethoxypropane reacts with bromine in SO_2 at −60 °C, the methoxydimethylcarbenium ion (XXXIV) is formed:



$$(CH_3)_2C(OCH_3)_2 + Br_2 \rightarrow \underset{\text{(XXXIV)}}{(CH_3)_2C\overset{+}{=}OCH_3}\ Br^- + CH_3OBr .$$

Benzaldehyde, acetophenone, benzophenone, cyclohexanone, cycloheptanone, and cyclobutanone dimethyl acetals behave analogously.[75]

The ions formed from acetaldehyde and formaldehyde acetals are unstable under these conditions and, having combined with the Br^- counterion, are converted into the corresponding α-bromoethers:

$$RCH(OCH_3)_2 \xrightarrow[-CH_3OBr]{Br_2} [RCH\overset{+}{=}OCH_3]Br^- \rightarrow RCHBrOCH_3 ;$$
$$R = H,\ CH_3 .$$

In cyclopropanone dimethyl acetals, the cyclopropane ring is more reactive in relation to bromine, which leads to the formation of β-bromoethyldimethoxycarbenium ions:[75]

$R = H, C_6H_5$.

The simplest method of synthesis of alkoxycarbenium ions from acetals involves treatment of the latter with strong acids. This method is also convenient because in this instance the ions are in solution and can be investigated by ^1H NMR. Depending on the stability of the alkoxycarbenium ions, acids of different strengths must be used for their generation. For example, the simplest alkoxycarbenium ion, namely the methoxycarbenium ion, has been obtained in an acid as strong as the equimolar mixture of HSO_3F and SbF_5 diluted with liquid SO_2 to reduce its viscosity:[54]

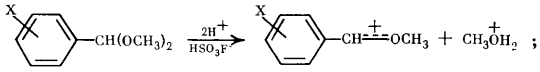
$$CH_2(OCH_3)_2 \xrightarrow[HSO_3F-SbF_5]{2H^+} \underset{\text{(XXIX)}}{CH_2\overset{+}{=}OCH_3} + CH_3\overset{+}{O}H_2 .$$

The methanol split off is protonated in this medium. At −60 °C there is almost no proton exchange with the medium. The splitting of the signal due to the methyl group of the protonated methanol into a triplet is observed in ^1H NMR spectrum (as a consequence of the spin–spin coupling with the protons of the $\overset{+}{O}H_2$ groups), which permits an unambiguous assignment of the signals of the methyl groups of methanol and methoxycarbenium.

The presence of substituents at the acetal carbon atom increases the stability of the ions formed from the acetals and they become stable in less acid media. Thus the methoxydimethylcarbenium ion (XXXIV) can be obtained at room temperature in 30% oleum:[76]

$$(CH_3)_2C(OCH_3)_2 \xrightarrow[H_2SO_4-SO_3]{H^+} \underset{\text{(XXXIV)}}{(CH_3)_2C\overset{+}{=}OCH_3} + CH_3OH .$$

The alkoxycarbenium ions derived from ketone and benzaldehyde acetals at −60 °C can be obtained even on treatment with HBr:[74]



$$RR^1C(OCH_3)_2 \xrightarrow[-60°C]{HBr} RR^1C^{+}{-}OCH_3 + CH_3\overset{+}{O}H_2 ;$$
$$R=R^1=CH_3;\quad R=R^1=C_6H_5;\quad R=H,\ R^1=C_6H_5;\quad R=CH_3,\ R^1=C_6H_5 .$$

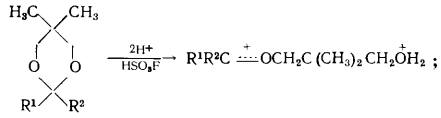
Under these conditions, the methanol is also present in the protonated form.

HSO_3F is most often employed to obtain alkoxycarbenium ions from acetals. The possibility of the generation and the stability of alkoxycarbenium ions in HSO_3F depend on the structure of the acetal and temperature. The dissolution of ketals even at room temperature leads to the formation of alkoxycarbenium ions:[77]

$$C_6H_5C(CH_3)(OCH_3)_2 \xrightarrow[HSO_3F]{2H^+} C_6H_5C(CH_3)\overset{+}{-}OCH_3 + CH_3\overset{+}{O}H_2 .$$

As in the $HSO_3F-SbF_5-SO_2$ mixture, methanol is present in the protonated form, as shown by the identity of the chemical shifts of the signals of the methyl protons in the two media. However, owing to the rapid proton exchange with the medium, there is no splitting of the signal into a triplet. The protonated methanol is therefore a convenient internal standard. The dimethyl acetals of substituted benzaldehydes give rise to alkoxycarbenium ions on dissolution in HSO_3F at −60 °C:[71,72,78]

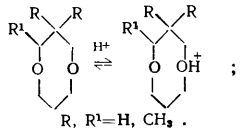
X = H, 4-CH_3, 4-OCH_3, 4-Cl, 4-Br, 4-F, 3-F, 2-CH_3, 2-OCH_3, 4-NO_2 .



It was noted above that the corresponding ion cannot be obtained from the dimethyl acetal of *p*-nitrobenzaldehyde on treatment with BF_3. In HSO_3F this ion is formed readily.

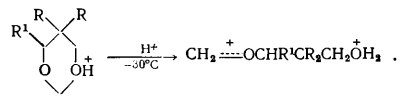
Furthermore, the corresponding dications $CH_3O\overset{+}{-}CHC_6H_4.\overset{+}{C}H{-}OCH_3$ have been obtained from the bis(dimethyl acetals) of *o*-, *m*-, and *p*-phthaladehydes.[72,78] All the ions obtained are stable when the temperature is raised to 36 °C. The dissolution of the acetals of aliphatic aldehydes in HSO_3F at −70 °C results in the formation of alkoxycarbenium ions, whose stability depends on temperature:[79-81]

$$RCH(OR^1)_2 \xrightarrow[HSO_3F]{2H^+} RCH\overset{+}{-}OR^1 + R^1\overset{+}{O}H_2 ;$$
$$R=H,\ CH_3,\ C_2H_5;\ R^1=CH_3,\ C_2H_5,\ C_3H_7,\ CH(CH_3)_2 .$$



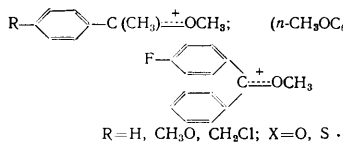
When R = alkyl, the ions are fairly stable at room temperature and appreciable changes in the ^1H NMR spectrum are observed only over a period of 2–3 h. When R = H, the ions are stable in the range between −70° and −30 °C.

The behaviour of cyclic acetals and ketals in HSO_3F does not differ from that of their acyclic analogues. At −70 °C the ring is opened, which entails the formation of the corresponding dications,[82,83] for example:



$R^1=R^2=CH_3;\quad R^1=H,\ R^2=C_6H_5 .$

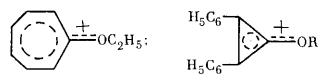
In their response to treatment with HSO_3F, cyclic formals differ from all the acetals described previously. The point is that the formation of alkoxycarbenium ions from acetals is a two-stage process. In the first stage the acetal is protonated with formation of an oxonium ion. The alkoxycarbenium ion is formed after the subsequent elimination of an alcohol molecule from the oxonium ion. However, when the acetals described previously were allowed to react with acids, the intermediate oxonium ions were not detected. Only on dissolution in HSO_3F of certain cyclic formaldehyde acetals at −70 °C was it possible to detect oxonium ions by ^1H NMR:[83,84]



R, R^1=H, CH_3 .

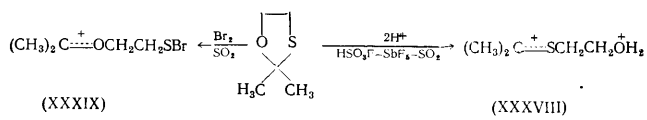
The ^1H NMR spectrum indicates the retention of the ring at temperatures between −70 °C and −40 °C, although the signal of the oxonium proton is not observed as a consequence of the rapid proton exchange.[84] Above −40 °C, ring opening takes place:

However, the alkoxycarbenium ions formed are unstable and rapidly undergo further reactions.[84]



In less acidic media the alkoxycarbenium ions derived from acetals can be obtained and detected only in exceptional cases. Thus in solution in 96–100% H_2SO_4 the following ions derived from the corresponding acetals were detected by ^1H NMR at room temperature:[85]

R = H, CH_3O, CH_2Cl; X = O, S .



In more dilute H_2SO_4 solutions the formation of alkoxycarbenium ions from acetals cannot be detected by NMR.[85]

The ions (XXXV)–(XXXVII) have been detected by ultraviolet spectroscopy under conditions where the rate of their formation exceeds the rate of their hydrolysis:[86]

(XXXV) (XXXVI): R = CH_3; (XXXVII): R = C_2H_5 .

In the presence of various heteroatoms in the acetal molecule the direction of attack depends on the nature of the attacking reagent. Thus, when 2,2-dimethyloxathiolan is dissolved in the $HSO_3F-SbF_5-SO_2$ mixture at −60 °C, the alkylthiocarbenium ion (XXXVIII) is formed, while the interaction with bromine in SO_2 at −80 °C leads to the alkoxycarbenium ion (XXXIX):[87]

(XXXIX) (XXXVIII)

The authors[87] explained these results by the lower basicity but greater nucleophilicity of the sulphur atom compared with the oxygen atom.

6. Rearrangement of Oxygen-containing Carbenium Ions

When a positive charge is generated in the molecules of ethers on a carbon atom not adjoining the oxygen atom, a rearrangement leading to alkoxycarbenium ions is frequently

observed. For example, when 2-halogeno-3-methoxy-2,3-dimethylbutane is dissolved in the SbF_5-SO_2 or $HSO_3F-SbF_5-SO_2$ mixture at −60 °C, the t-butylmethoxymethylcarbenium ion is produced:[88]

$$(CH_3)_2CXC(CH_3)_2OCH_3 \xrightarrow[-SbF_4X]{SbF_5} [(CH_3)_2\overset{+}{C}C(CH_3)_2OCH_3] \rightarrow (CH_3)_3CC(CH_3)=\overset{+}{O}CH_3;$$
X=Cl, Br, I.

The dissolution of alkoxyalcohols in the $HSO_3F-SbF_5-SO_2$ mixture at −60 °C leads to oxonium dications. On raising the temperature, some of them are dehydrated with formation of alkoxycarbenium ions,[53] for example:

$$CH_3OCH_2CH(CH_3)OH \xrightarrow[-60°C]{2H^+} CH_3\overset{+}{O}(H)CH_2CH(CH_3)\overset{+}{O}H_2 \xrightarrow[-10°C]{-H_2O,\ -H^+} \longrightarrow CH_3O\overset{+}{=}CHCH_2CH_3;$$

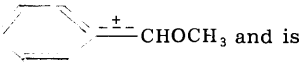
$$C_2H_5O(CH_2)_3OH \xrightarrow[-60°C]{2H^+} C_2H_5\overset{+}{O}(H)(CH_2)_3\overset{+}{O}H_2 \xrightarrow[0°C]{-H_2O,\ -H^+} C_2H_5O\overset{+}{=}CHCH_2CH_3.$$

7. Isomerisation of Oxenium Ions

The isomerisation of unstable oxenium ions formed in certain reactions constitutes a fairly unusual method for the formation of alkoxycarbenium ions. Thus, when t-alkyl hydroperoxides are dissolved in superacids, alkoxydialkylcarbenium ions (XXXIV) are formed:[89,90]

$$(CH_3)_3COOH \xrightarrow{H^+} [(CH_3)_3C\overset{+}{O}OH_2] \xrightarrow[-H_2O]{} [(CH_3)_3C-\overset{+}{O}] \rightarrow (CH_3)_2C=\overset{+}{O}CH_3.$$
(XXXIV)

The formation of alkoxycarbenium ions via the isomerisation of intermediate oxenium ions has been observed in the oxidation with ozone in superacids of stable t-alkyl cations,[91] branched hydrocarbons,[92,93] and alcohols,[94] in the oxidation of hydrocarbons in superacids with hydrogen peroxide,[93,95] and on dissolution of t-alkyl esters of peracids in superacids.[96]



III. THE STRUCTURE AND PROPERTIES OF ALKOXYCARBENIUM IONS

It follows from the analysis of the methods of synthesis of alkoxycarbenium ions presented above that almost all these ions are stable at low temperatures in weakly nucleophilic media such as HSO_3F and $HSO_3F-SbF_5-SO_2$. With increase of temperature and of the nucleophilicity of the medium, the stability of the alkoxycarbenium ions falls. The cyclic ions are more stable than the acyclic ions; many cyclic alkoxycarbenium ions exist at room temperature in H_3SO_4 [23,24] and in trifluoroacetic acid in the absence of trifluoroacetate anions.[6,7]

The stability of acyclic alkoxycarbenium ions depends to a large extent on the presence of electron-donating substituents at the carbenium carbon atom. Alkoxycarbenium ions without substituents at the carbenium centre are stable in HSO_3F only at temperatures not exceeding −30 °C, while their methyl-substituted analogues are stable even at room temperature.[44,45,49] Electron-accepting substituents destabilise alkoxycarbenium ions. Thus the methoxy-4-*p*-nitrophenylcarbenium ion is not formed from the corresponding acetal on treatment with BF_3, although the dimethyl acetals of other substituted benzaldehydes are converted into methoxyarylcarbenium ions under the same conditions.[71,72] The use of a less nucleophilic medium (HSO_3F), which tends to increase the stability of the ions, makes it possible to obtain not only the nitrophenyl-substituted cation but also the dications.[72,78]

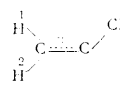
Protons at the carbenium carbon atom give rise to signals in the ^1H NMR spectra of alkoxycarbenium ions in a very low field (Table 1), which indicates their carbenium character. This is also indicated by the downfield shift of the signals of the α-protons of the substituents at the carbenium centre. The chemical shifts of the benzyl protons in the ^1H NMR spectra of aryl-substituted alkoxycarbenium ions depend on the positions and character of the substituents (Table 2) and are better correlated with the δ^+ constants of the substituents ($\delta_{H_\alpha} = 0.588\delta^+ + 9.078$, $r = 0.972$) [72] than with the σ constants ($r = 0.852$), which is a consequence of the carbenium character of the ions.

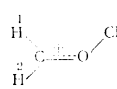
The substitution of the chemical shifts for the benzyl protons in the *meta*- and *para*-dications in the correlation expression made it possible to determine the σ^+ constants for the substituent $-CH=\overset{+}{O}CH_3$ ($\sigma_m^+ = 0.916$; $\sigma_p^+ = 1.074$).[72] It follows from these values that the $-CH=\overset{+}{O}CH_3$ group is a stronger electron acceptor than the nitro-group.

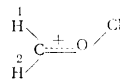
The carbenium centre is conjugated with the aromatic ring, which hinders rotation about the partially double bond  and is manifested by some non-equivalence of the protons in the aromatic ring in the *para*-substituted ions.[71]

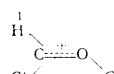
On the other hand, alkoxycarbenium ions also have some oxonium character, which is indicated, for example, by the correlation between the chemical shift of the protons of the methoxy-groups and the σ^+ constants of the substituents in aryl-substituted alkoxycarbenium ions.[72] In the oxonium form of the ions the bond between the oxygen and the carbon should be double:

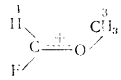
This leads to the non-equivalence of the substituents R^1 and R^2 (when $R^1 = R^2$) and the existence of two isomers of the ions for $R^1 \neq R^2$. The chemical shifts of the methylene protons in the ^1H NMR spectrum of the methoxycarbenium ion (XXIX) at −60 °C differ by 0.12 p.p.m. In addition, these protons interact with one another, the corresponding constant being $J = 20.79$ Hz, and with the protons of the methoxy-group, the corresponding constants being $J = 0.83$ and 0.97 Hz. An analogous fact has been established also for the chloromethoxycarbenium ion (XL) (Table 1).[54]

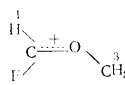












Recent analysis of the ^{17}O NMR spectra showed that the degree of π-bonding in the methoxydimethylcarbenium ion (XXXIV) is ~60%.[38]

The partially double bond is retained even at room temperature. Thus the chemical shifts of the signals of the methyl groups at the carbenium centre in the ^{13}C NMR spectrum of the ion (XLIa) are different at −60 °C (32.6 and 27.8 p.p.m.),[94] while for the analogous ion (XLIb) the difference is maintained even at room temperature (32.6 and 28.4 p.p.m.):[82]

(XLI, a and b)
R=H (a), CH_3 (b).

The majority of the alkoxycarbenium ions with different substituents at the carbenium carbon atom exist only in the form of one isomer, which can be explained by the difference between the thermodynamic stabilities of the two isomers.[53] However, the simplest ions, such as the chloromethoxycarbenium ions (XLII) and the fluoromethoxycarbenium ion (XLIII), each form two isomers, which have different ^1H NMR spectra (Table 1). The isomers have been identified on the assumption that the *cis*-allyl constant is higher than the *trans*-constant. The ratio of the isomers (XLIIa) and (XLIIb) is 81 : 19, while that of (XLIIIa) and (XLIIIb) is 70 : 30.[52]

Table 1. Characteristics of the ^1H NMR spectra of alkoxycarbenium ions in superacids.

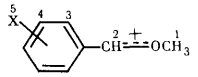
Notation. Solvent: A = HSO_3F; B = HSO_3F–SbF_5–SO_2; C = SbF_5–SO_2; D = H_2SO_4–SO_3 (30%). Multiplicity: s = singlet; d = doublet; t = triplet; qr = quartet; qn = quintet; sp = septet; m = multiplet.

*The values of δ in H_2SO_3F have been determined relative to the internal standard CH_2Cl_2 (δ = 5.33 p.p.m.) and have been recalculated relative to TMS; in the remaining cases the recalculation has been relative to an external TMS standard.

**The parameters 1.67; t (7.0) correspond to the signal of the H^4 proton.

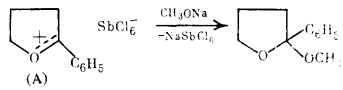
***The parameters 1.70; t (7.0) correspond to the signal of the H^4 proton.



The carbenium and oxonium characters of alkoxycarbenium ions determine their dual reactivity. In most cases, alkoxycarbenium ions react as carbenium ions. For example, the interaction of a solution of the methoxycarbenium ion (XXIX) in the SbF_5–SO_2 mixture with methanol in the presence of K_2CO_3 at −78 °C results in the formation of dimethoxymethane:[52]

$$\underset{\text{(XXIX)}}{CH_2\overset{+}{=}OCH_3} + CH_3OH \xrightarrow[-H^+]{} CH_3OCH_2OCH_3 .$$

An analogous formation of an acetal takes place when a salt of the alkoxycarbenium ion (XLIV) is treated with sodium ethoxide in benzene:[55]



$$\underset{\text{(XLIX)}}{[ClCH\overset{+}{=}C(CH_3)\overset{+}{=}CHOC_2H_5]^+ SbCl_6^-} \xrightarrow[-NaSbCl_6]{C_2H_5ONa} ClCH=C(CH_3)-CH(OC_2H_5)_2 .$$

Table 2. The chemical shifts (δ, p.p.m.) in the ^1H NMR spectra of aryl-substituted alkoxycarbenium ions in HSO_3F at 34 °C (relative to a TMS external standard).[72]

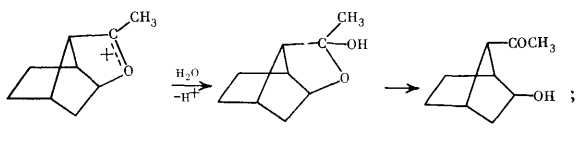
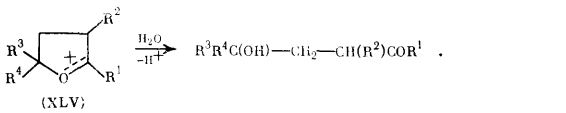
On treatment with alkoxide anions, cyclic alkoxycarbenium ions also give rise to acetals. When 2-phenyl-2-tetrahydrofurylium hexachloroantimonate was treated with sodium methoxide in methanol, 2-methoxy-2-phenyltetrahydrofuran was obtained:[7]

(A)



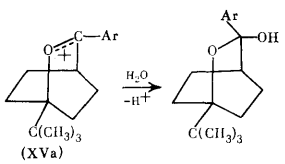
In many cases acetals are formed also when alkoxycarbenium salts are treated with alcohols:[40]



****The parameters 5.30; s correspond to the signal of the H^4 proton.

*****The parameters 5.51; qr (7.0) correspond to the signal of the H^4 proton and the parameters 1.70; t (7.0) correspond to that of the H^5 proton.

Alkoxycarbenium ions react with water also as carbenium ions. The reaction products are unstable hemiacetals, which are then converted into carbonyl compounds:[40,41]

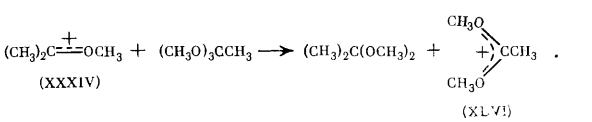


(XLV)

When solutions of alkoxycarbenium ions (XLV) are poured into an aqueous solution of NaOH, γ-hydroxycarbonyl compounds are produced.[34,35]

In some cases, hemiacetals have been isolated and characterised:[17]

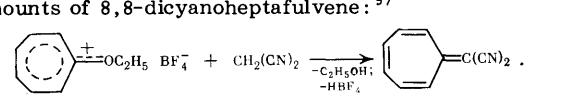
(XVa)



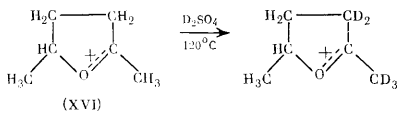
The rate of hydrolysis of alkoxycarbenium ions varies within wide limits depending on their structure.[85]

Alkoxycarbenium ions can react also with weaker nucleophiles such as acetals and orthoesters. Thus, it was noted above that, when acetals are treated with an excess of bromine in SO_2 at −60 °C, alkoxycarbenium ions are formed. In the presence of a deficiency of bromine, the chemical shifts observed in the ^1H NMR spectrum assume intermediate values between those of the acetal and the ion; within the limits of the bromine : acetal ratios from 0 to 1, they vary linearly with the bromine content, but, on further increase of the latter, remain unchanged, which shows that the following rapid equilibrium exists in solution even at −60 °C:[74]

(XXXIV) (XXXIV)



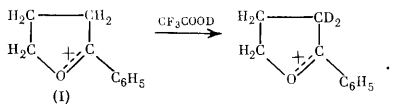
The interaction of the same ion (XXXIV) with methyl orthoacetate leads irreversibly to the formation of the more stable dimethoxymethylcarbenium ion (XLVI) and an acetal:[74]



(XXXIV) (XLVI)

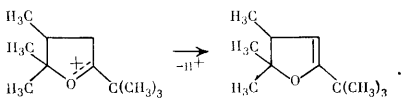
The methoxycarbenium ion adds smoothly to double and triple bonds in various compounds.[56–61]

Alkoxycarbenium ions can react with compounds containing an activated methylene group. For example, ethoxytropylium tetrafluoroborate reacts with malonodinitrile in the presence of bases, and together with tropone, gives rise to considerable amounts of 8,8-dicyanoheptafulvene:[97]



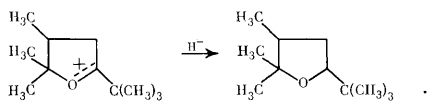
Like other carbenium ions, alkoxycarbenium ions can be stabilised by splitting off a proton from the β-position. Experiments with deuterated sulphuric acid established that the hydrogen atom in the β-positions relative to the carbenium centre in the 2,5-dimethyl-2-tetrahydrofuryl cation (XVI) are substituted by deuterium at 120 °C:[25]

(XVI)

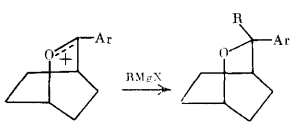


In the analogous cations (XLV) in solution in 96% D_2SO_4 the H–D exchange takes place at 70–100 °C, but is hardly observed at 25 °C. However, on reducing the D_2SO_4 concentration to 80%, the exchange proceeds at an appreciable rate also at 30 °C.[34] Such exchange is effected via deprotonation with the intermediate formation of vinyl ether and its subsequent deuteration.

In a less acidic medium (trifluoroacetic acid) deuterium exchange is observed even at room temperature:[6,7]



(I)



The deprotonation of sterically hindered alkoxycarbenium ions with formation of vinyl ethers becomes the dominant pathway even in reactions such as hydrolysis[32] or interaction with an alkoxide anion:[31,32]

On treatment with hydride ion donors[17,40,41,47] or on catalytic hydrogenation in the presence of Pd/C,[32] alkoxycarbenium ions are reduced to ethers:

On treatment with Grignard reagents, alkoxycarbenium ions are alkylated:[17]

Under suitable conditions, alkoxycarbenium ions can abstract on alkyl anion from cyclic ketals. It has been suggested that this reaction is responsible for the formation of cyclic dialkoxycarbenium ions (XXXI) on treatment of cyclic ketals with trialkyloxonium salts[69] (see the scheme above).

The most striking manifestation of the carbenium character of alkoxycarbenium ions is their capacity for isomerisation. When ethoxycarbenium hexachloroantimonate (XLVII) and propoxycarbenium hexachloroantimonate (XLVIII) were dissolved in water, considerable amounts of methanol and acetaldehyde or propionaldehyde were formed apparently as a result of the isomerisation of the ions (XLVII) and (XLVIII) via the 1,3-hydride shift to the methoxymethylcarbenium ion (XLIX) or the ethylmethoxycarbenium ion (L), together with the hydrolysis products—formaldehyde and ethyl or propyl alcohol:[98]

(XLVII), (XLVIII) (XLIX), (L)

(XLVIII), (XLIX):R=CH_3; (XLVIII), (L):R=C_2H_5 .

The study of the behaviour of the alkoxycarbenium ions obtained by dissolving formaldehyde acetals in HSO_3F at −70 °C[80,81] showed that ethoxy- and propoxycarbenium ions are stable in HSO_3F up to −30 °C. At higher temperatures signals due to the presence in solution of methanol and also

of the ions (XLIX) and $CH_3CH{=}\overset{+}{O}CH_2CH_3$ (LI) or (L) and $C_2H_5CH{=}\overset{+}{O}C_3H_7$ (LII) appear in the ^1H NMR spectra.

The characteristic signal of the fragment $CH_3O{=}\overset{+}{C}-$ has been detected also in the ^1H NMR spectra of the cyclic formaldehyde acetals in HSO_3F at temperatures above −30 °C.[83]

The ion (XLIX) could be formed from the ion (XLVII) not only via an internal 1,3-hydride shift but also as a result of intermolecular hydride transfer. The abstraction of a hydride ion from the ethyl alcohol present in solution should lead to the formation of ethyl methyl ether and protonated acetaldehyde:

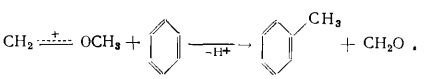
$$\underset{\text{(XLVII)}}{CH_2{=}\overset{+}{O}CH_2CH_3} + CH_3CH_2OH \rightarrow CH_3OCH_2CH_3 + CH_3CH{=}\overset{+}{O}H .$$

Next, the transfer of the hydride ion from the α-position in the ethyl group of ethyl methyl ether to the protonated acetaldehyde or the ethoxycarbenium ion would lead to the methoxymethylcarbenium ion and ethyl alcohol or ethyl methyl ether:

$$CH_3OCH_2CH_3 + CH_3CH{=}\overset{+}{O}H \rightarrow \underset{\text{(XLIX)}}{CH_3O{=}\overset{+}{C}HCH_3} + CH_3CH_2OH ;$$

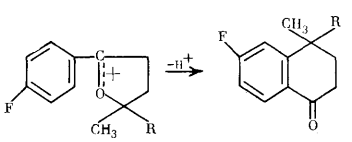
$$CH_3OCH_2CH_3 + \underset{\text{(XLVII)}}{CH_3CH_2O{=}\overset{+}{C}H_2} \rightarrow \underset{\text{(XLIX)}}{CH_3O{=}\overset{+}{C}HCH_3} + CH_3CH_2OCH_3 .$$

However, specially formulated experiments showed that under these conditions diethyl ether does not react with protonated acetaldehyde or the methoxycarbenium ion:[81]



$$CH_3CH_2OCH_2CH_3 + CH_3CH{=}\overset{+}{O}H \not\rightarrow$$

$$CH_3CH_2OCH_2CH_3 + \underset{\text{(XXIX)}}{H_2C{=}\overset{+}{O}CH_3} \rightarrow \underset{\text{(LI)}}{CH_3CH_2O{=}\overset{+}{C}HCH_3} + CH_3OCH_3 .$$

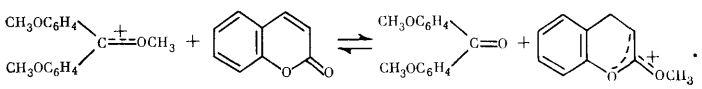


On this basis, it was concluded that the ion (XLVII) is converted directly into (XLIX) via an internal 1,3-hydride shift.[81]

Whereas the 1,3-hydride shift in the ethoxycarbenium ion leads to an energy gain since the ion (XLIX) is more stable to the extent of 46 kJ mol^{-1} than the ion (XLVII),[99] the analogous process in the methoxycarbenium ion is degenerate. The study of the temperature-induced changes in the ^1H NMR spectra and experiments with deuterated dimethoxymethane species showed that the 1,3-hydride shift in the methoxycarbenium ions takes place at 40 °C.[81]

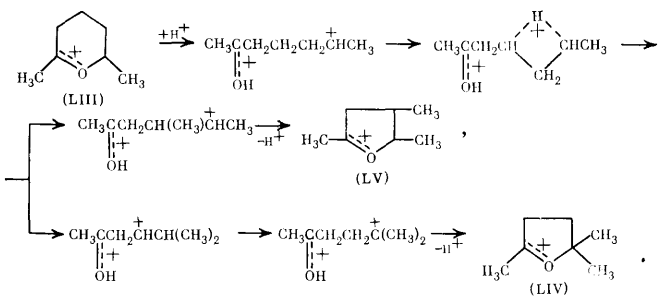
Alkoxycarbenium ions can react as oxonium ions, splitting off an alkyl cation or transferring it to nucleophiles. Thus a methoxycarbenium salt methylates aromatic hydrocarbons:[62]

An example of the intramolecular alkylation of an aromatic ring can be provided by the conversion of the ions (Vb) and (VII) into the corresponding tetralones:[9]

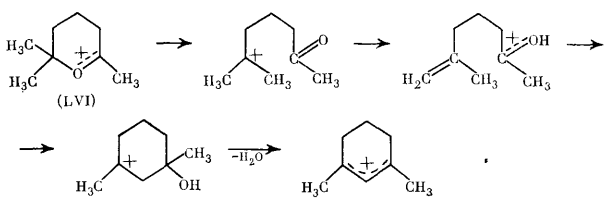


R = H (Vb), CH_3 (VII)

The interaction of alkoxycarbenium ions with iodides results in the alkylation of the iodide ion:[37]

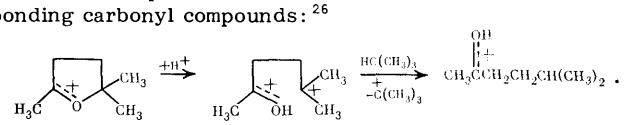


Alkoxycarbenium ions can alkylate also certain oxygen-containing compounds. For example, the interaction of the methoxydi(*p*-methoxyphenyl)carbenium ion with coumarin leads to the formation of an equilibrium mixture:[39]

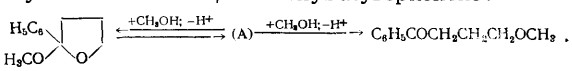


The possibility of the reaction of alkoxycarbenium ions as oxonium ions depends also on the strength of the nucleophile. For example, the cyclic 2-phenyl-2-tetrahydrofuryl cation is stable in trifluoroacetic acid. When sodium trifluoroacetate is added to the solution, the cation reacts with the trifluoroacetate ion to form γ-trifluoroacetoxybutyrophenone:[6]

$$(A) + CF_3COO^- \rightarrow C_6H_5COCH_2CH_2CH_2OCOCF_3 .$$

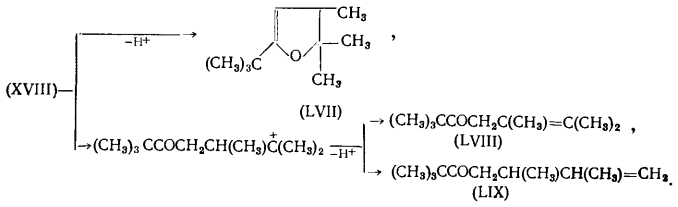


In the absence of nucleophiles the oxonium character of alkoxycarbenium ions is manifested by the possibility of their dealkylation. Thus the ion (LIII), which is stable in superacids at room temperature, is converted into a mixture of the ions (LIV) and (LV) on heating to 100 °C. It has been suggested[28] that this reaction proceeds in accordance with the following scheme:



The 6,6-dimethyl-substituted analogue (LVI) is still less stable. In 96% H_2SO_4 the ring is opened in the course of 5 min even at room temperature and a series of reactions lead ultimately to the cyclic allyl cation:[84]

Five-membered cyclic alkoxycarbenium ions without substituents at the carbenium centre undergo an analogous dehydration.[49] In superacid media cyclic alkoxycarbenium ions can abstract a hydride ion from hydrocarbons such as isobutane or isopentane and can be reduced to the corresponding carbonyl compounds:[26]



In certain cases the carbenium and oxonium properties of alkoxycarbenium ions are manifested simultaneously. In the reaction of the ion (A) with methanol, the product formed initially is 2-methoxy-2-phenyltetrahydrofuran, which is gradually converted into γ-methoxybutyrophenone:[7]

Such behaviour is due to the fact that in an acid medium the first reaction is reversible and its rate is higher than that of the second reaction. In the initial instant the main product is therefore 2-methoxy-2-phenyltetrahydrofuran—the product of the reaction occurring under the conditions of kinetic control. After a time, the product resulting from thermodynamic control, namely γ-methoxybutyrophenone, accumulates in the mixture.

Three products, compounds (LVII), (LVIII), and (LIX) in the proportions 9 : 2 : 3, have been obtained on heating a mixture of 2-t-butyl-4,5,5-trimethyl-2-tetrahydrofurylium tetrafluoroborate with potassium t-butoxide: [31]

The formation of the first proton (LVII) is due to the carbenium character of the initial ion, while the formation of the other two products (LVIII) and (LIX), is due to its oxonium character.

---o0o---

Thus alkoxycarbenium ions have now been transformed from hypothetical intermediates into entirely real objects available for study by physical methods. Nevertheless, one cannot claim that these ions have been adequately investigated. The study of alkoxycarbenium ions by modern methods such as ^{1}H, ^{13}C, and ^{17}O NMR, ion-cyclotron resonance, and quantum-chemical calculations will yield more detailed information about their structure and properties, which will in its turn enable chemists to predict their reactivity and to control appropriately the reactions in which they are formed.

New Trends in the Hydration of Nitriles

E.N.Zil'berman

The advances in the hydration of nitrile ligands in complexes with various central ions, in the employment of complexes as homogeneous catalysts of the hydration of nitriles, and in the addition of water to the nitrile group in the presence of manganese(IV) oxide and other metal oxides as well as catalysts containing metallic copper and other metals are examined. The conditions in the synthesis of amides, the influence of the structure of the starting materials on the mode of reaction and on the side reactions accompanying hydration, the reaction mechanisms, and the practical value of individual pathways leading to the conversion of nitriles into amides are discussed.
The bibliography includes 123 references.

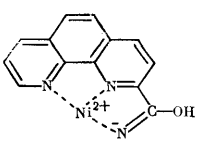
I. INTRODUCTION

The hydration of nitriles is frequently used to prepare the corresponding carboxylic acid amides. The classical hydration procedures are based on the interaction of nitriles with water and hydrogen chloride, sulphuric acid, or other inorganic acids and also on the reaction of nitriles with hydrogen peroxide in aqueous alkali. These and certain other methods have been considered in detail in a monograph[1] covering the literature mainly up to 1970 and have still not lost their importance. However, during the past 10–12 years a number of fundamentally new procedures for the conversion of nitriles into amides have been proposed and have developed rapidly. Thus, advances have been made in the hydration of coordinated nitriles, homogeneous-catalytic hydration using catalysts, mainly complexes, has been achieved and is being improved, and particularly significant results have been obtained in liquid-phase heterogeneous-catalytic hydration of nitriles in the presence of certain metal oxides or metals, which made it possible, in particular, to organise the large-scale manufacture of acrylamide by the hydration of acrylonitrile in the presence of catalysts containing metallic copper.[2]



This review deals with the present state of these problems mainly on the basis of the literature up to 1982.

II. HYDRATION WITH FORMATION OF COORDINATED AMIDES

The chemistry of complexes containing nitrile molecules in the inner sphere has attracted much attention.[3] In these complexes the nitriles are as a rule n-coordinated to the central ion but π-complexes are also formed in some cases. The coordination of nitriles results in a sharp increase of their electrophilic reactivity.[3]

The hydration of coordinated nitriles leading to the formation of coordinated amides was first investigated in relation to pyridine derivatives containing the cyano-group in the 2-position, evidently because the amides formed, behaving as bidentate ligands, give rise to relatively stable complexes with many ions, including bivalent cobalt, nickel, copper, and zinc ions; on the other hand, the complexes of these ions with monodentate amide ligands are extremely unstable.

The hydration of 2-cyano-1,10-phenanthroline is greatly accelerated by copper(II) as well as nickel(II) and zinc ions even at room temperature.[4] 1,10-Phenanthroline-2-carboxamide can be isolated quantitatively from the reaction products by treatment with the disodium salt of ethylenediaminetetra-acetic acid. The kinetics and mechanism of the hydration reaction in the presence of salts have been studied and it has been shown that it is of first order with respect to the metal ion complex with the substrate and with respect to hydroxide ions. The second-order rate constant for the reaction catalysed by Ni^{2+} is ~10^7 times greater than for the hydration in the same basic medium but in the absence of metal ions. This acceleration is caused by the appreciable alteration of the entropy of activation (from -50 J mol^{-1} K^{-1} in the absence of nickel to $+59$ J mol^{-1} K^{-1} in its presence). According to the mechanism proposed, the nitrile and Ni^{2+} form a complex in which the CN group is located close to the metal ion but is not coordinated to it; this group is attacked by the OH^- ion with formation of a complex in which Ni^{2+} now interacts with three nitrogen atoms:

The positive entropy of activation is probably associated with the fact that a coordinated water molecule is displaced from the initial nickel complex on formation of the transition state and appreciable desolvation of the nucleophile takes place. The above mechanism is preferred over the alternative mechanism according to which the nitrile group is subjected to the nucleophilic attack by the hydroxo-group coordinated to the central ion and not by a free OH^- ion.[4,5] It is noteworthy that the subsequent hydrolysis of the 1,10-phenanthroline-2-carboxamide formed is also accelerated in the presence of copper(II), nickel(II), and zinc salts but to a much lesser extent than the hydration of the nitrile.[4]

2-Cyanopyridine, coordinated to copper(II) or nickel(II), is rapidly hydrated to pyridine-2-carboxamide on heating in aqueous solutions, the carboxamide remaining bound to the metal ion the form of a chelate compound.[6] The hydration of

2-cyano-8-hydroxyquinoline complexes of nickel(II), cobalt(II), and copper(II) proceeds analogously. In terms of its kinetic features, the reaction differs little from the hydration of coordinated 2-cyano-1,10-phenanthroline examined above. Here too the sharp increase of rate on passing from the free to the coordinated nitrile is associated with the increase of the activation entropy—from −113 to −4 J mol^{-1} K^{-1} in the nickel complex and to −13 J mol^{-1} K^{-1} in the cobalt complex (while the enthalpy of activation remains unaltered).[7,8]

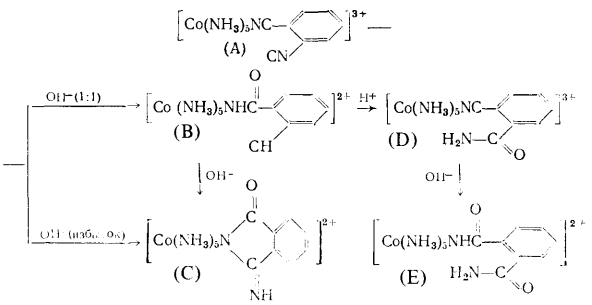
The nitrile group of the *o*-cyanobenzyl ligand coordinated as a bidentate species to platinum(II) [9] and palladium(II) [10] in complexes of the type

$$\left[L_2Pd\begin{matrix}CH_2C_6H_4CN\\NCC_6H_4CH_2\end{matrix}PdL_2\right]^{2+}(BF_4^-)_2\ ,$$

where L_2 = $2PPh_3$, 1,2-bis(phenylphosphino)ethylene, or 1,2-bis(phenylphosphino)ethane, is hydrated at 50 °C in solution in aqueous acetone. It is believed[9] that the reaction begins with the nucleophilic substitution of the coordinated cyano-group by water, after which the water coordinated to the central ion interacts intramolecularly with the ligand containing the cyano-group and occupying the *cis*-position. The *o*-toluidide and complexes of the type PtL_2Cl_2 have been obtained by treating the dimeric carboxamide-complexes with hydrochloric acid.

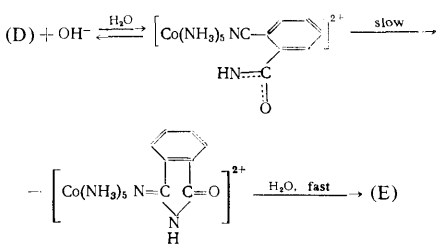
Cobalt(III) forms with amides much more stable complexes than the bivalent metals examined above. Even complexes with amides without groups capable of forming an additional coordinate bond with the central ion are distinguished by an appreciable stability; different nitrile complexes based on cobalt(III) are therefore conveient objects for a detailed study of hydration. The reaction was first achieved[11] with pentamminecobalt complexes containing benzonitrile and 3- and 4-hydroxybenzonitriles as ligands:

$$[Co(NH_3)_5NCR]^{3+} + OH^- \rightarrow [Co(NH_3)_5NHC(=O)R]^{2+}\ .$$



In an acid medium these complexes are reversibly protonated:

$$[Co(NH_3)_5NHC(=O)R]^{2+} + H^+ \rightleftarrows [Co(NH_3)_5NH_2C(=O)R]^{3+}\ .$$



The reaction proceeds analogously also when pentamminecobalt complexes of 3-cyano-, 4-cyano-, 4-acetyl-, 3-formyl-, and 4-formyl-benzonitriles and even 2-, 3-, and 4-cyanopyridines are used.[12,13] The kinetics of the hydration reaction are described by a second order equation—of first order with respect to the complexes and of first order with respect to hydroxide ions. (In the hydration of coordinated formylbenzonitriles the hydration kinetics are complicated by the reversible reaction involving the addition of OH^- ions to the carbonyl group, which takes place simultaneously.[12]) The *n*-coordination of benzonitriles to Co^{3+} makes it possible to increase the rate constants for their hydration by a factor of 10^6–10^7. The rate constants then increase also with increase of the electron-accepting capacity of the substituents in the benzonitrile. The activation parameters for the hydration of coordinated benzonitriles are as follows:[11,12] $\Delta H^{\neq}$ = 51.5–69.1 kJ mol^{-1} and $\Delta S^{\neq}$ = −31–+21 J mol^{-1} K^{-1}. These values of $\Delta S^{\neq}$ are much greater than the $\Delta S^{\neq}$ for the hydration of non-coordinated benzonitriles.

The nitrile group is hydrated under mild conditions and with low yields also in the pentamminecobalt(III) complexes of acetonitrile[14] and acrylonitrile.[15]

The neighbouring functional groups can exert a significant influence on the hydration of the nitrile coordinated to a transition metal. In particular, interesting results have been obtained in the hydration of 1,2-dicyanobenzene coordinated to cobalt(III).[16] The pentamminecobalt complex of the dinitrile (A) reacts with a stoichiometric amount of a base to form the cyanobenzamide complex (B), which cyclises in the presence of an excess of the base to the 3-imino-1-oxoisoindoline complex (C). Coordination, which sharply accelerates the reaction (A) + OH^- – (B), has very little influence on the rate of cyclisation. In an acid medium the complex (B) undergoes an intramolecular rearrangement with formation of the complex (D), in which the nitrile group is coordinated to the cobalt atom, while the amide group is free. In the presence of a base, this nitrile complex is hydrated to the phthalamide complex (E). The rate constant for the last reaction is 10^3 times greater than the rate constant for the reaction (A) + OH^- → (B).

Detailed study of the kinetics of the hydration of coordinated dicyanobenzenes and 2-cyanobenzamide made it possible to refine the mechanism of the catalysis of the hydration of the nitrile group under the influence of the neighbouring carboxamide group in the complex (D).[17] Since the rate of hydration of 1,2-dicyanobenzene is only ~3 times greater than the rate of hydration of 1,3- and 1,4-dicyanobenzenes, it was concluded that the *o*-nitrile group influences the reactivity of the coordinated CN group in the complex (A) solely by virtue of its electron-accepting capacity. On the other hand, the appreciable increase of the rate of reaction in the complex (D) under the influence of the less electron-accepting *o*-carboxamide group shows that the latter influences the hydration via another mechanism. The entropy of activation for hydration in the complex (A) (+4 J mol^{-1} K^{-1}) is of the same order of magnitude as for other complexes of the nitriles in the inner sphere (−31–+21 J mol^{-1} K^{-1}), while the activation entropy for hydration in the complex (D) is unusually high (+184 J mol^{-1} K^{-1}). On the basis of these data and bearing in mind that the hydration of the CN group and the complex (D) is catalysed specifically by OH^- ions, a reaction mechanism has been proposed according to which the amide group is initially deprotonated and this is followed by the inner-sphere nucleophilic attack on the CN group with formation of an isoindole heterocycle, which hydrolyses to compound (E):

According to Balahura and Purcell,[17] the high value of $\Delta S^{\neq}$ is due to the desolvation of both the OH^- ion and the carboxamide anion together with the partial neutralisation of the

charge on cyclisation. Thus the high rate of hydration of the CN group in the complex (D) can be explained by the combination of the effects of coordination and catalysis by the o-carboxamide group.

The coordination of nitriles leads not only to an increase of the electrophilic reactivity of the CN group but also to an appreciable increase of the mobility of the α-hydrogen atoms of the nitrile ligand. Under the conditions of the hydration of coordinated acetonitrile is an alkaline medium, this is expressed by the simultaneous exchange of the protons of the methyl group.[14] The coordination of malononitrile, cyanoacetic acid, and its ethyl ester to pentamminecobalt(III) leads to such a sharp increase of the acidity of these compounds that in aqueous alkaline solutions equilibrium is rapidly established between the initial complexes and complexes containing the deprotonated methylene group. In these systems the initial complexes are hydrated through both OH^- ions and water while in the coordinated carbanions an electron is displaced with formation of the cobalt(II) ion and the corresponding free radical:[15,18]

$$[Co(NH_3)_5(NCCH_2CN)]^{3+} \begin{cases} \xrightarrow{OH^-} [Co(NH_3)_5(NHCCH_2CN)]^{2+}, \\ \xrightarrow{H_2O} [Co(NH_3)_5(NHCCH_2CN)]^{2+} + H^+, \\ \xrightarrow[-H_2O]{OH^-} [Co(NH_3)_5(NCC^-HCN)]^{2+} \rightarrow Co^{2+} + 5NH_3 + NC\dot{C}HCN. \end{cases}$$

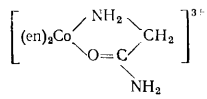
The free radicals formed as a result of the reaction of the ligands in a non-aqueous medium initiate the polymerisation of acrylic monomers and styrene.[15]

The hydration of nitriles bound as ligands to the central ion in the pentammine complexes of platinum group metals has been described in a number of studies.[19–21] In weakly alkaline solutions the reaction proceeds at a high rate, which is proportional to the concentrations of both the complex and OH^- ions. The pentammineruthenium(III) complexes of acetonitrile and benzonitrile are hydrolysed ~10^8 times faster than the free nitriles and ~10^2 times faster than the pentamminerhodium(II) complexes of the same nitriles. In the corresponding ruthenium(II) complex of acetonitrile the reaction is ~10^6 times slower than in the ruthenium(III) complex. The high reactivity of the ruthenium(III) complex can be explained by the fact that the ruthenium(III) ion, which is a powerful π-electron acceptor, stabilises the negative charge formed on the ligand as a result of attack by the hydroxide anion on the carbon atom of the nitrile group. The comparatively low reactivity of the ruthenium(II) complex is associated with the fact that in this instance the central ion is a weak π-electron acceptor. It has been found that in hydration in a weakly alkaline medium (pH 8–9) the complex $[Ru(NH_3)_5NCPh]^{3+}$ undergoes a side reaction to a slight extent, namely the disproportionation to the ruthenium(II) and ruthenium(IV) complexes.[20] According to Diamond and co-workers,[22,23] ethyl cyanoacetate and αβ-unsaturated nitriles coordinated to ruthenium(III) are also hydrated to the corresponding amides.

The rate constants for the reactions of the pentamminerhodium(III) and pentammineiridium(III) complexes of benzonitrile with OH^- ions have been determined.[21] Comparison with the reaction of the corresponding cobalt(III) complex under analogous conditions[11] showed that the rate constants decrease in the sequence Co > Rh > Ir, i.e. in the homologous series of complexes with the same central ion electron configuration completion the reactivity decreases with increasing the ionic radius. This confirms the significant influence of the electrostatic attraction between the central ion and the nitrile ligand on the ability of the latter to be subjected to nucleophilic attack.[21]

As a consequence of the high stability of cobalt(III), ruthenium(III), and other tervalent metal complexes[22–25] of carboxylic acid amides, the isolation of the free amides requires the reduction of the central ion in these complexes to the II-state, which gives much less stable complexes. A method has also been proposed[22–24] for the preparation of amides from pentammineaquoruthenium(II) trifluoroacetate and nitriles in accordance with the scheme

$$[Ru(H_2O)(NH_3)_5]^{2+} + RCN \xrightarrow[-H_2O]{} [Ru(NH_3)_5NCR]^{2+} \xrightarrow[-e]{} [Ru(NH_3)_5NCR]^{3+} \xrightarrow{H_2O} \rightarrow$$



$$\rightarrow [Ru(NH_3)_5NH_2\overset{O}{\overset{\|}{C}}R]^{3+} \xrightarrow{+e,H_2O} [Ru(NH_3)_5(H_2O)]^{2+} + RCONH_2.$$

The addition of water to acetonitrile and benzonitrile coordinated to platinum(II) in the *trans*-acetonitrilebis(triphenylphosphino)methylplatinum cationic complex in an alkaline medium has been described.[26] Analogous results were obtained later[27] starting with similar complexes having other tertiary phosphine ligands:

$$[PtMe(NCMe)L_2]^+ \xrightarrow{H_2O,OH^-} PtMe(\overset{O}{\overset{\|}{H}}NCMe)L_2.$$

The interaction of $[PtCl_4]^{2-}$ with acetonitrile combined with the oxidation of the central ion by oxygen leads to the formation of the acetamide complex of platinum(IV). It has been suggested[28] that the reaction proceeds via the intermediate formation of the complexes $[Pt(NCMe)Cl_3]^-$ and $Pt(H_2O)\cdot(NCMe)Cl_2$.

Studies of the hydration of the nitrile group incorporated in the inner sphere of a complex but not linked directly to the central ion are of interest. It has been shown[29] that the CN group of the aminoacetonitrile ligand in the complex *cis*-$[Co(H_2O)(en)_2(H_2NCH_2CN)]^{3+}$ is hydrated in neutral and alkaline media with formation of a five-membered chelate compound:

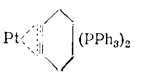
The reaction is regarded as a process within the complex involving hydration by the water molecule coordinated to the cobalt ion. In the analogous complex based on 3-aminopropionitrile hydration does not occur under these conditions and the corresponding six-membered chelate compound is not therefore formed. In an acid medium the complexes of both nitriles are hydrated, but the rate of hydration of the first is ~10^5 times greater. The presence of mercury(II) ions makes it possible to increase the rate of hydration of the aminoacetonitrile and 3-aminopropionitrile ligands to the same extent (by a factor of ~10^7). The different types of behaviour during hydration of aminoacetonitrile and 3-aminopropionitrile incorporated in complexes shows that the presence of the nitrile and water in the same coordination sphere is not a sufficient condition for hydration within the complex; the appropriate disposition of the reacting groups in space is also necessary (in the case considered there must be a possibility of the formation of a five-membered chelate compound). The combination of the accelerating effect induced by the possibility of chelation and of the presence of mercury ions permits, overall, an increase in the rate of hydration in a neutral medium by a factor of 10^{15}–10^{18}. The catalysis by mercury(II) ions can be explained by the fact they they form a complex with the nitrile group, withdrawing electron density to themselves: this facilitates nucleophilic attack by the hydroxide ion and the formation of an unstable Hg^{2+} complex with the amide group.[30] The Ag^+ ion is a less effective catalyst of hydration within the complex, but it is in its turn greatly superior to Zn^{2+} and Cd^{2+}.[29]

The hydration of the nitrile group in the presence of mercury(II) ions in the complexes *cis*-$[Co(en)_2(H_2NCH_2CH_2CN).X]^{2+}$, where X = Cl or Br, is based on the removal of a halide ion under the influence of Hg^{2+}, the occupation of the liberated coordination site by the OH^- ligand, and subsequent catalysis by the Hg^{2+} ion of the nucleophilic attack by the OH ligand on the nitrile group within the complex and the formation of a chelate compound. In the analogous complexes based on aminoacetonitrile the hydration also proceeds partly via this mechanism.[25,29,31]

In the absence of Hg^{2+}, the complexes $[Co(en)_2(H_2NCH_2CN).X]^{2+}$ (at pH 7.3 and above) are not hydrated; instead, rapid intramolecular addition of the deprotonated amino-group, located *trans* to the halide ion and to the non-coordinated nitrile group takes place and complexes in which the amidine substituent has a coordination capacity of three are obtained: $\{Co(en)[H_2NCH_2C(NH_2)=NCH_2CH_2NH_2]X\}^{2+}$. The reaction is of first order with respect to both the initial aminoacetonitrile complex and OH^- ions.[31,32]

III. HOMOGENEOUS-CATALYTIC HYDRATION

It was stated above that bivalent cobalt, nickel, and copper chelate complexes of pyridine-2-carboxamide and other amides with similar structure are extremely stable under the conditions of their synthesis. However, conditions have been found under which the amide ligands in these complexes are substituted by nitriles, which makes it possible to employ such complexes as hydration catalysts.



Bivalent nickel, copper, and cobalt complexes of picolinic acid or its amide[33–35] proved to be effective and highly selective catalysts of the hydration of 2-cyanopyridine (pH 5.5 to 8.5, reaction temperature 60 °C and above). In most cases the catalysts remained unchanged after the reaction. The same complexes showed no catalytic activity when an attempt was made to hydrate 3- and 4-cyanopyridines. On the other hand, 2-cyanopyridines are not hydrated in the presence of cobalt(III) and platinum(IV) complexes, although the former reacts with 2-cyanopyridine on heating in aqueous solution.[35] The catalysis of the hydration of 2-cyanopyridine is evidently based on the displacement of the 2-carboxypyridine or pyridine-2-carboxylate ligand from the complex by a 2-cyanopyridine molecule, the subsequent hydration of the coordinated nitrile, and the repeated substitution of the amide ligand formed by the nitrile.[35]

The complex used as the hydration catalyst can be formed in the reaction mixture *in situ*. It is obtained using as the starting material the salts of metals† capable of giving rise to complexes with 2-carboxypyridines and their derivatives. Thus, when aqueous solutions of 2-cyanopyridine[33] and also 4-substituted 2-cyanopyridines[38] were heated with a large excess of nickel(II) or copper(II) chloride, chelates were obtained in which two molecules of the corresponding pyridine-2-carboxamide were present as ligands for each central ion. In the presence of a smaller amount of metal chloride, free amides are also produced together with the chelate complexes. The formation of a chelate complex which catalyses hydration directly also accounts for the conversion of 2,6-dicyanopyridine into pyridine-2,6-dicarboxamide when a mixture of this dinitrile and water is boiled in the presence of catalytic amounts of cobalt(II) acetate.[39]

A study of the hydration of substituted 2-cyanopyridines in the presence of the complex $[Cu(H_2O)(en)_2]Cl_2$ in a nearly neutral medium established that the reactivity decreases in the sequence[38] 2-cyano-4-methylpyridines > 2-cyanopyridine > 2,4-dicyanopyridine. Since an electron-donating substituent in the 4-position promotes and an electron-accepting substituent hinders hydration, it can be assumed that the rate-limiting stage of the process is the nucleophilic reaction involving the incorporation of the nitrile in the inner sphere of the complex. 2-Cyanoquinoline proved to be much less reactive than 2-cyanopyridine, apparently because of the lower capacity of the nitrogen atom of the pyridine ring to form a coordinate bond with the central ion. Whereas the 2-cyano-group in 2,4-dicyanopyridine is selectively hydrated while the 4-cyano-group is inert, in 2,6-dicyanopyridine both cyano-groups react and the product is pyridine-2,6-dicarboxamide. It is noteworthy that an increase of temperature (up to boiling of the reaction mixture) and of the duration of heating of aqueous solutions of nitriles and complex catalysts leads to the hydrolysis of pyridinecarboxamides and the formation of the corresponding carboxylic acids.[38]

Thus the hydration of nitriles with the cyano-group in the 2-position in the pyridine ring in the presence of certain bivalent metal complexes can be used to synthesise the corresponding amides. There is so far little information about the successful homogeneous catalytic hydration of other nitriles in the molecules of which there are no groups capable of chelating the ligands.

In the presence of catalytic amounts of zerovalent platinum complexes of phosphines and cyclohexyne, for example,

acetonitrile is converted into acetamide in a low yield after prolonged heating.[26,40] Benzonitrile is hydrated analogously.[40] It has been suggested that a coordinated hydroxo-group, appearing in the platinum complex under the reaction conditions, is responsible for the catalysis. Phenylacetonitrile,[26] which is a stronger CH acid than acetonitile, is not hydrated under these conditions and is merely incorporated in the inner sphere of the complex $Pt(C_6H_9)[CH(CN)Ph](PPh_3)_2$. When non-ionic phosphonocyclohexyne complexes of platinum react with αβ-unsaturated nitriles, the complexes exhibit a capacity to catalyse the addition of water to the C=C bond. Mainly di(2-cyanoethyl) ether and 3-hydroxyproprionitrile and only 8% of acrylamide have been obtained from acrylonitrile.[26]

The strong hydroxo-bases, formed when zerovalent platinum complexes of phosphines, for example $[Pt(P(t\text{-}Bu)_2Ph]_2$ and $Pt[P(iso\text{-}Pr)_3]_3$, are treated with water, were found to catalyst nitrile hydration.[41] After the reaction, the catalysts are isolated and changed. It has been suggested that complexes containing nitriles coordinated to platinum in the corresponding amido-complexes formed from them as a result of attack by OH^- ions are intermediates in the reaction. The degree of conversion of the initial nitriles is low and in the hydration of αβ-unsaturated nitriles the addition of water is not regioselective; in a number of cases the hydration of the C=C bond predominates. Under the conditions of acrylonitrile hydration, the dimer $CH_2=C(CN)CH_2CH_2CN$ was also formed.

† The metal salts are not usually catalysts of nitrile hydration, although it has been reported that various amides have been obtained from nitrile complexes with $PdCl_2$ on boiling with water[36] and also on treatment of solutions of nitriles in acetic acid with $TiCl_4$ and water.[37] However, it is noteworthy that the mechanisms of these reactions have not been studied, so that it is not clear to what extent the complexes and the hydrogen chloride, produced by the hydrolysis of $PdCl_2$ and $TiCl_4$ are each responsible for the hydration.

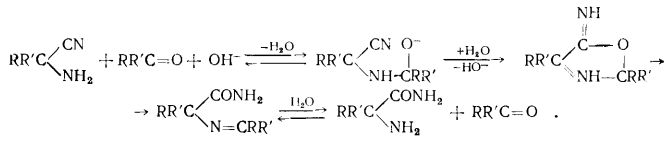
The hydration of acetonitrile at 80 °C in the presence of different hydroxophenyl and hydroxomethyl complexes $PtRL_2(OH)$ and the analogous acetamido-complexes $PtRL_2$. .(NHCOMe) has been described.[42] The phenyl complexes are more active than the methyl complexes. When R = Ph, the activity of the complexes decreases in the following sequence as a function of the nature of the ligand L:

$$PEt_3 > P(t\text{-}Bu)Me_2 > PPh_3 \simeq PMe_2Ph > P(t\text{-}Bu)_2Me \gg P(C_6H_{11})_3 .$$

When the catalytically most active complex $PtPh(PEt_3)_2(OH)$ was used, 173 moles of acetamide per mole of the catalyst were obtained for a low degree of conversion of acetonitrile (~11%). Under the same conditions, acrylonitrile gives rise to products of the hydration of both the C≡N and C=C bonds. Higher saturated aliphatic nitriles and benzonitriles are hydrated to a lesser extent than acetonitrile, partly because of the inhomogeneity of the reaction medium. Methyl cyanoacetate reacts with the above hydroxo-complexes, forming methoxycarbonyl(keten imino)- or cyanomethoxycarbonylmethyl complexes, for example:

$$PtPh(PEt_3)_2(N{=}C{=}CHCOOMe) \text{ or } Pt(Me)(dppp)[CH(CN)COOMe] ,$$

where dppp = 1,3-bis(diphenylphosphino)propane.



The catalytic hydration of benzonitrile has been carried out also in the presence of the cationic complex $[cis\text{-}Pt(PPh_3)_2.(o\text{-}CH_2C_6H_4CONH_2)]_2(BF_4)_2$. However, not more than 5 moles of benzamide were then obtained per mole of the catalyst. It has been shown[9] that the loss of catalytic activity in the given system is associated with the conversion of the initial complex into the complex $[cis\text{-}Pt(PPh_3)_2(o\text{-}CH_2C_6H_4CONH)]_2$.

The phosphine complexes of zerovalent rhodium and iridium, *trans*-$Rh(CO)(PPh_3)_2(OH)$ and *trans*-$Ir(CO)(PPh_3)_2(OH)$, are more active in the hydration of acetonitrile than the analogous phosphine complexes of platinum. In the presence of the iridium complex, nitriles such as phenylacetonitrile, acrylonitrile, and crotononitrile are also hydrated to the amides.[40]

An appreciable increase of the yields in the homogeneous-catalytic hydration has been achieved in a number of studies.[43–45] The authors began with the results of a study[46] according to which acetonitrile is hydrated to acetamide in a satisfactory yield and with a high selectivity in the presence of sodium chloropalladate and 2,2′-bipyridyl (bipy) at pH 10.4. It was shown[43] that a number of products of the reaction of sodium chloroplatinate [chloropalladate?] and 2,2′-bipyridyl, among which the neutral complex $Pd(bipy)Cl_2$ proved to be a most active catalyst of the hydration reaction are formed under the reaction conditions. Treatment of this complex with an equivalent amount of hydroxide ion yielded the complex $Pd(H_2O)(bipy)(OH)Cl$, which exhibits an even higher catalytic activity. The latter is retained when the chloride ion in the palladium complex is replaced by other anions ($MeCOO^-$, Br^-, OH^-) and bipyridyl is replaced by other bidentate nitrogen-containing ligands.[44] The hydration (at 76 °C and pH 5.5) of acetonitrile and butyronitrile in the presence of an excess of water and catalytic amounts of the above complexes afforded the amides in yields of 70–84% for a selectivity of 100%. The yields of adipamide, benzamide, and phenylacetamide in the hydration of the corresponding nitriles are low. Acrylamide is formed in 80% yield from a heterogeneous mixture of acrylonitrile and water at 60 °C in the presence of a catalytic amount of the complex $Pd(H_2O).(bipy)(OH)_2$ soluble in the nitrile.[45] In order to isolate the amide from the reaction mixture, the catalyst was decomposed with acid, the precipitated complex of the palladium salt of this acid and bipyridyl was filtered off, and the filtrate was evaporated. Study of the hydration kinetics of acetonitrile has established[44] that the amide formed inhibits the addition of water to the nitrile group. The results also support the view that the hydration involves the intramolecular attack by the OH group on the coordinated CN group.

Dichlorobis(η-cyclopentadienyl)zirconium apparently catalyses the hydration of α-hydroxyisobutyronitrile.[118]

Hydration specific to α-aminonitriles, which proceeds in an alkaline medium and is catalysed by carbonyl compounds, has been described. The reaction has been studied in relation to a series of α-aminonitriles with the amino-group at a secondary or tertiary carbon atom, acetaldehyde, isobutyraldehyde, acetone, etc. being used as the carbonyl compounds.[47–49] A carbonyl compound can be formed directly in the reaction mixture together with ammonia and hydrocyanic acid as a result of the hydrolytic decomposition of the α-aminonitrile. The hydration reaction proceeds in accordance with the following mechanism:

Its rate is determined by the rates of the reversible formation of the geminal aminoalkoxide anion and subsequent cyclisation to a substituted 5-imino-oxazolidine. The rate of cyclisation (in the presence of isobutyraldehyde as the catalyst) is then ~10^8 times higher than the rate of nucleophilic attack by OH^- ions on the nitrile group, which is the reason for the catalytic effect of carbonyl compounds.[49] Hydrolysis of the reaction mixtures (without the isolation of the α-aminoamides) makes it possible to obtain α-aminoacids in almost quantitative yields.[50]

IV. HETEROGENEOUS-CATALYTIC HYDRATION

The heterogeneous-catalytic hydration of nitriles can take place in the presence of acids or bases insoluble in the reaction mixture. Anion-exchange resins were frequently used previously as catalysts and 3- and 4-cyanopyridines were hydrated. Under these conditions, 85–96% of 3-cyanopyridine is converted into the amide. The subsequent hydrolysis results in the simultaneous formation of 3-carboxypyridine bound chemically to the catalyst (up to 5–10%), which lowers its activity and necessitates its periodic regeneration.[1,51–55] Attention is concentrated below on new trends in the hydration of nitriles in the presence of heterogeneous catalysts whose action is not based on their acidity and basicity (or not solely on these factors) but on other properties.

1. Hydration in the Presence of Metal Oxides

Among metal oxides, manganese(IV) oxide is the most effective catalyst of the hydration of nitriles. As early as 1934, the formation of benzamide was observed when benzonitrile came into contact with active MnO_2 at room temperature.[56,57] It was suggested[57] that the reaction proceeds by virtue of the water bound to MnO_2 and that the yield of the amide (~3%) is limited by its content. Subsequently the hydration was carried out in methylene chloride[58] and dioxan[59] in the presence of a large amount of MnO_2 containing sufficient bound water to satisfy the stoichiometry of the reaction. It was not until the 1970's that it was established that manganese(IV) oxide is the catalyst and that there is no necessity for its preliminary "saturation" with water for effective hydration.[60,61]

The study of the hydration of benzonitrile in the presence of the β- and γ-modifications of MnO_2 showed that the activity of the catalyst is not determined by its crystal lattice type but by its specific surface,[62] which is usually 30–80 $m^2 g^{-1}$. The catalytic activity of MnO_2 depends on its method of preparation[55] in so far as the conditions of the synthesis influence the surface area of the oxide. The catalyst is used in a powdered or pelleted form. Because of the low degree of coverage of the manganese(IV) oxide surface by the nitrile in the hydration reaction,[63] the yield of the amide per unit mass of the catalyst and per unit time is low and for this reason a comparatively large amount of MnO_2 is used to synthesise the amides, its mass in the hydration reaction carried out by the periodic method usually exceeding severalfold the mass of the nitrile.

Aromatic nitriles, including *o*-substituted nitriles, and water, taken in molar proportions of 1 : 1.2 at 100–140 °C in the presence of MnO_2, form amides in high yields. Hydrolysis takes place to a very slight extent (1–2%),[60,64] but on raising the temperature the yield of the acid increases (it reaches 28% in the reaction with benzonitrile at 200 °C). Aromatic nitriles are hydrated extremely smoothly also in organic solvents—methylene chloride[58] and dioxan.[59]

Halogenoacetonitriles are hydrated to the amides in the presence of MnO_2 in high yields and with a high selectivity at temperatures below 100 °C. At higher temperatures side reactions play a significant role. Thus the hydration of trichloroacetonitrile yielded, together with the amide, appreciable amounts of ammonia, hydrogen chloride, carbon dioxide, and chloroform. The formation of the last compound can be accounted for by the hydrolysis of trichloroacetamide, the decarboxylation of the trichloroacetate anion, and the reaction of the trichloromethyl anion with water.[64]

The hydration of aliphatic nitriles in the presence of MnO_2 in the presence of small amounts of water proceeds to an appreciable extent only on heating to 140–170 °C.[60,64] This results in low yields of amides contaminated by products of side reactions—hydrolysis and oxidation.[65] (The simultaneous reduction of Mn^{4+} to Mn^{2+} leads to the deactivation of the catalyst.) The formation of NH_3 and CO_2 on hydration of acetonitrile is caused mainly by the hydrolysis of acetamide and subsequent "oxidative decarboxylation"[66] of acetic acid:

$$MeCN \xrightarrow{H_2O} MeCONH_2 \xrightarrow[-NH_3]{H_2O} MeCOOH \xrightarrow[-H_2O]{O} [HOOCCOOH] \xrightarrow{O} 2CO_2 + H_2O .$$

Slow acetamide and acetonitrile oxidation reactions also take place and the oxidation of acetonitrile results in the formation of hydrogen cyanide and carbon dioxide. In the hydration of isobutyronitrile the main side products are hydrogen cyanide and acetone, which are formed via α-hydroxyisobutyronitrile; acetone is also formed in the oxidation and decarboxylation of α-hydroxyisobutyric acid.[65]

Satisfactory yields of amides derived from unsubstituted and β-hydroxy- and β-methoxy-substituted aliphatic nitriles are achieved as a result of hydration in the presence of MnO_2 under mild conditions (60–80 °C) in dilute aqueous solutions.[61,67]

When the nitriles are sparingly soluble in water, the initial reaction mixtures are homogenised by organic solvents or the reaction is carried out in the presence of emulsifying agents.

The hydration of succinonitrile in dilute aqueous solutions results in the initial formation of 3-cyanopropionamide, which then combines with a water molecule and is converted into succinamide. Conditions have been found under which each of these compounds is obtained in a high yield.[67] At 60 °C, the rate constants for the addition of the first (activation energy 56 kJ mol^{-1}) and second water molecules are in the ratio 4 : 1. This ratio shows that the influence of the substituents in both reactions is based mainly on the inductive effect. On the other hand, the direct influence of the neighbouring $CONH_2$ group, which leads to a significant alteration of the rate (as for 2-cyanobenzamide coordinated to cobalt[16]), and what is more to a change in the reaction pathway (as in the hydration of succinonitrile in the presence of a copper-containing catalyst[68]), is not observed. At the same time the influence of substituents in the molecules of nitriles on their reactivity is not caused solely by polar effects.[63,67] Thus the effective rate constants (at 60 °C) for the hydration of 3-cyanopropionamide, 3-hydroxypropionitrile, and 3-methoxypropionitrile are in the proportions 2.1 : 1.3 : 1, although the polar constant $\bar{\sigma}^*$ for all three substituents are similar (1.75, 1.60, and 1.73).[69] The causes of the above ratios will be examined below in the discussion of the hydration mechanism.

Under the influence of MnO_2 both in the presence of small amounts of water and in its absence, acrylonitrile and methacrylonitrile partially polymerise via the C=C bonds. In the macromolecules of the polymer based on methacrylonitrile, amide groups as well as short conjugated segments $(\rangle C{=}N{-})_n$ were identified together with the nitrile groups. It has been suggested[64] that the polymerisation proceeds via a radical mechanism and is initiated directly by the free radicals formed as a result of the oxidation of organic compounds by manganese oxide.[70] Acrylamide has been obtained as the main reaction product (70%) from acrylonitril in aqueous solution in the presence of a radical reaction inhibitor, but under these conditions, too, side reactions involving oxidation by manganese oxide take place, which leads to the rapid deactivation of the oxide.[71]

The nitrile groups of polyacrylonitrile in an aqueous solution of potassium thiocyanate at 80 °C are hydrated in the presence of MnO_2 (a degree of conversion of 50% has been achieved).[72]

3-Cyanopyridine in aqueous solution at 85 °C in the presence of MnO_2 is converted into nicotinamide, a product of practical importance, in a high yield (96%). Under the proposed conditions, the reaction takes place in the kinetic region and is described satisfactorily by a first order equation.[62] Similar results were later obtained in other studies[55,73] for the hydration of 3-cyanopyridine in the presence of MnO_2. The cyano-group of cyanamides is hydrated in aqueous solutions in the presence of the same oxide.[74,75]

When phenyl- and diphenyl-acetonitriles were heated with water and MnO_2, the corresponding amides were not obtained because the oxidation reactions predominated.[76] A polymer, soluble in organic solvents, whose molecules incorporated the conjugated (C=N−) chains as well as amide, nitrile, and carboxy-groups, was formed from phenylacetonitrile in the presence of MnO_2 at 80–125 °C (the reaction mechanism has been published[76]). Oxidation of diphenylacetonitrile, having only one hydrogen atom in the α-position, with manganese oxide afforded a high yield of tetraphenylsuccinonitrile.[76]

α-Hydroxynitriles whose OH groups are located at a primary or secondary carbon atom are hydrated selectively and in high yields to α-hydroxyamides in dilute aqueous or aqueous dioxan solutions at room temperature in the presence of MnO_2.[77] An increase of reaction temperature promotes the hydrolysis of the amides formed. Attention has been drawn to the appreciable adsorption of α-hydroxyamides on manganese(IV) oxide. The reactivity of the α-hydroxynitriles RCH(OH)CN decreases in the following sequence in terms of the substituent R: H > Me > Et > n-Pr > iso-Pr. The hydration of α-hydroxynitriles which are tertiary alcohols proceeds in a more complex manner. The hydroxynitriles undergo simultaneous dehydrocyanation under the reaction conditions,[78] which lowers the yield of α-hydroxyamides.

Since α-hydroxyisobutyramide, formed on hydration of α-hydroxyisobutyronitrile, can be used as the starting material for the synthesis of methacrylic monomers,[79–81] most attention has been devoted to the study of the reactions of this nitrile.[63,82,119] It has been found that dehydrocyanation, which is reversible in the absence of MnO_2, becomes almost irreversible in the presence of this oxide. The hydrocyanic acid formed is rapidly adsorbed on the surface of manganese(IV) oxide and is then comparatively slowly oxidised to cyanogen, which gives rise to oxamide on hydration. Under dehydration conditions, dehydrocyanation proceeds until the attainment of equilibrium over a period shorter than 5 min. In the course of approximately the same time, adsorption equilibrium is established between the dissolved hydrocyanic acid and the hydrocyanic acid on the surface of MnO_2. The hydration of α-hydroxyisobutyronitrile as well as the oxidation of HCN take place much more slowly, i.e. the dehydrocyanation and adsorption period in the main separated in time from the hydration and oxidation period. In the hydration of α-hydroxyisobutyronitrile in an aqueous medium the yield of amide does not therefore exceed 70%. When the reaction is carried out in a less polar medium (in aqueous dioxan solutions), where the dehydrocyanation is appreciably retarded, it is possible to increase the yield of α-hydroxyisobutyramide. The addition of acetone to the reaction medium, which shifts the equilibrium towards hydrocyanation with reformation of the starting material, is even more effective. An important feature of the hydration in the presence of acetone is the presence of an extremum in the relation between the effective rate constants and the water content in the aqueous acetone mixture (there is a minimum at a water mole fraction of 0.8), which can be attributed to a change in the internal structure of the water–acetone mixture.[82] The optimisation of the process taking into account its inhibition by the α-hydroxyisobutyramide formed (adsorption on MnO_2) revealed the conditions (45 °C, 1.3 M nitrile, 3.4 M acetone, 7–8 h) under which α-hydroxyisobutyramide is obtained in 95% yield with a selectivity of 96% in the presence of the catalyst specimen employed. The shift of the dehydrocyanation equilibrium by the introduction into the reaction mixture of the ketone formed as a result of the reaction is effective also in the hydration of other α-hydroxynitriles unstable in water.[63,82]

In aqueous solutions in the presence of manganese(IV) oxide, α-aminoisobutyronitrile is converted into α-aminoisobutyric acid, α-aminoisobutryamide, α-hydroxyisobutyramide, acetone, ammonia, hydrocyanic acid, and its oxidation products. Evidently the hydration of α-aminoisobutyronitrile is accompanied by the hydrolysis of both this compound and of the hydration product as well as secondary reactions of the hydrolysis products:[63]

$$Me_2C(NH_2)CN \left\{ \begin{array}{l} \xrightleftharpoons[-NH_3]{H_2O} Me_2C{=}O + HCN \rightleftarrows Me_2C(OH)CN \xrightarrow{H_2O,\,MnO_2} Me_2C(OH)CONH_2, \\ \xrightarrow[MnO_2]{H_2O} Me_2C(NH_2)CONH_2 \xrightarrow{H_2O,\,MnO_2} Me_2C(NH_2)COOH + NH_3. \end{array} \right.$$

The replacement of α-aminoisobutyronitrile in the above system by its hydrochloride rules out hydrolysis almost completely and appreciably accelerates the hydration, which leads to a virtually quantiative yield of α-aminoisobutryamide hydrochloride (45 °C, 1 h). The subsequent binding of the hydrogen chloride by a strong base and an increase of the temperature of the reaction mixture to 90 °C make it possible to achieve with the same yield the hydrolysis of the resulting amide, catalysed by manganese(IV) oxide, to α-aminoisobutyric acid. 2-Amino-2-methylbutyramide and 2-amino-2-methylbutyric acid are formed analogously from 2-amino-2-methylbutyronitrile.[63]

Data on the kinetics and mechanism of the hydration of nitriles in the presence of manganese(IV) oxide are of interest. S-Shaped kinetic curves for the hydration of benzonitrile in the presence of MnO_2 and small amounts of water, the acceleration of the reaction by the preliminary treatment of the catalyst with benzonitrile, its retardation as a result of a similar treatment with water, and other kinetic features of the hydration reaction suggested that the first stage of the process is the formation of an intermediate complex of the nitrile with MnO_2, which is then subjected to nucleophilic attack by water.[83] It follows from the relations presented above between the rate of hydration and the polar properties of the substituents in the nitrile molecules that, in the hydration in the presence of an excess of water, the rate-limiting stage is the second.[63,67] Kinetic data have shown[63] that the complex of the nitrile with MnO_2 is then attacked by water from the bulk phase.

In the reactions of hydroxynitriles the hydroxy-group as well as the nitrile group can react with the catalyst surface, for example, via the formation of hydrogen bonds. Under the conditions of the hydration α-hydroxynitriles with a tertiary OH group, such interaction is probably the cause of the acceleration of the dehydrocyanation side reaction in the presence of manganese oxide, which was mentioned above.

In view of the appreciable electron-accepting capacity of the group $\alpha\text{-}\overset{+}{N}H_3$, it was to be expected that the hydration of α-ammonianitrile, like the hydrolysis of α-ammonia-amide, will proceed at a higher rate than the corresponding reactions of the α-amino-compounds. However, as shown above, this happens only in the case of the hydrolysis. The opposite behaviour in the hydration reaction can be attributed to the fact that the α-aminonitrile is adsorbed on the acid centres of the catalyst via the highly basic NH_2 groups; since both σ-bonds in the group $C{-}C{\equiv}N$ are colinear,[1] contact between the CN group in the adsorbed α-aminonitrile, whose position is to a large extent fixed, and the surface of the catalyst is hindered for geometrical reasons with a consequent retardation of its reaction with water. In the hydration of α-ammonianitrile adsorbed on the catalyst via the nitrile group such steric hindrance does not arise.

Depending on their position in the nitrile molecule, the same functional groups have exerted the opposite influence on the reactivity of the nitrile group. Whereas substituents in the α-position in the nitrile capable of interacting with the catalyst play a negative role in the hydration, the β-substituents accelerate the hydration as a result of their interaction with the catalyst. Presumably the higher reactivity of 3-aminocarbonyl- and 3-hydroxy-propionitriles compared with 3-methoxypropionitrile (see above) is due to the interaction of both the $CONH_2$ or OH group and the CN group with the surface of the catalyst, which leads to the formation of energetically favourable closed structures and to an increase of the surface concentration of the substrate.

It is striking that hydrocyanic acid is not hydrated in the presence of MnO_2 and is instead oxidised to cyanogen. This may be a consequence of the formation of the hydrogen bond between the hydrogen atom of HCN and the oxygen-containing groups on the surface of the catalyst with subsequent elimination of the hydrogen atom from the HCN molecule.[63]

Despite the fact that manganese(IV) oxide proved to be a highly active catalyst of the hydration of nitriles, in some cases its application is limited, as shown above, by its high oxidising capacity, as a result of which the addition of water to the nitrile group is not always the main pathway in the

reaction between reactants. Hydration in the presence of other metal oxides is therefore of interest.

Numerous oxides proposed as hydration catalysts are inactive or their activity is low[120] in the temperature range where hydration takes place in the presence of MnO_2. The study of the interaction of benzonitrile with water in the presence of various oxides under comparable conditions[84] showed that hydration proceeds at an appreciable rate as a rule only at 175–225 °C. Hydration is induced by almost all transition metal oxides, but, not counting MnO_2, the oxides of the iron subgroup elements proved to be the most active. Results of practical interest have been obtained with iron(III) oxide. At 225 °C benzamide has been obtained in 71% yield (the yield of benzoic acid was 7.5%); when Fe_2O_3 is re-used, its activity does not fall. In contrast to MnO_2, iron(III) oxide proved to be an extremely effective catalyst of the hydration of readily oxidisable nitriles such as phenylacetonitrile and diphenylacetonitrile. It has been shown that the hydration of nitriles in the presence of Fe_2O_3, as in the presence of MnO_2, is preceded by the interaction of the catalyst with the CN group.[84] Cobalt(III) and nickel(III) oxides are no less active in the hydration of benzonitrile than Fe_2O_3, but, under the conditions investigated (Co_2O_3 at 225 °C and Ni_2O_3 already at 175 °C), they interact to an appreciable extent with the reaction products, which rules out their reuse. After prolonged refluxing of aqueous solutions of 3- and 4-cyanopyridines in the presence of NiO, high yields of the amides were obtained.[33] On the other hand, in the reaction of 2-cyanopyridine under the same conditions, the amide obtained hydrolyses to 2-carboxypyridine, which forms a chelate compound with a catalyst. It has been suggested that the geminal positions of the nitrogen atoms of the pyridine ring and of the amide group of this compound are responsible for their simultaneous and specific adsorption on the same catalytic surface centre, which is the cause of the ready hydrolysability of the amide group.[33] At the same time the hydration of 2,4- and 2,6-dicyanopyridines to the corresponding dicarboxamides has been achieved in another study[38] in the presence of NiO.

In the hydration of benzonitrile (at 225 °C) copper(II) and zinc oxides proved to have activities similar to those of the oxides of the iron subgroup elements. However, in the presence of CuO the reaction products interact with the catalyst, while in the presence of ZnO the hydration is accompanied to a large extent by the hydrolysis of the benzamide formed.[84] Under milder conditions (refluxing of the aqueous solutions), copper(II) oxide proved to be a weak catalyst of the hydration of 3- and 4-cyanopyridines, but, like NiO, it induces appreciable hydrolysis of 2-cyanopyridine and the formation of a chelate compound.[33] Zinc oxides accelerates slightly the hydrolysis of stearonitrile at 180 °C.[85]

The analogues of zinc oxide in the subgroup, namely the cadmium and mercury(II) oxides, undergo irreversible changes in the course of the reaction.[84] It has been shown[86] that cadmium oxide is bound in the form of a salt to the benzoic acid formed. The interaction of benzonitrile and of *p*-substituted benzonitriles with water and CdO has been directed towards the formation of diamminecadmium benzoates in quantitative yields:

$$2RC_6H_4CN + 3H_2O + CdO \rightarrow (RC_6H_4COO)_2Cd\cdot 2NH_3.$$

The reactions catalysed by metal oxides are frequently catalysed also by the sulphides of the same metals. In the presence of copper(II) sulphide 25% of benzamide has been obtained from benzonitrile at 225 °C. The instability of CuS in the presence of water was also manifested under these conditions.[87]

The activity of the oxides of Group IIA elements proved to be low and approximately the same.[84] Among the oxides of Group III elements, alumina proved to be a weak but extremely selective hydration catalyst.[84] The adsorption of nitriles on this oxide is accompanied by their partial conversion into amides.[88,89] High yields of aromatic and saturated aliphatic amides have been obtained[90] on refluxing solutions of the corresponding nitriles in t-butyl alcohol in the presence of alumina modified by treatment with potassium fluoride.[91] The water required for hydration is present in the catalyst. Alumina and potassium fluoride taken separately do not induce an appreciable hydration of the nitriles, other conditions being equal.

Among the oxides of Group IV elements, a satisfactory yield of benzamide (59%) is obtained in the presence of lead(II) oxide. Zirconium and germanium(IV) oxides exhibit a weak catalytic activity, while titanium(IV) and silicon oxides are almost inactive. Among the oxides of Group V elements, a tendency has also been observed towards an increase of activity with increase of the atomic weight. In the presence of Bi_2O_3 and V_2O_5 benzamide has been obtained in almost identical satisfactory yields and both oxides also give rise to an appreciable hydrolysis of benzamide.[84] (The hydrolysis of amides in the presence of V_2O_5 at 150–180 °C has been used as a preparative method of synthesis of carboxylic acids.[92]) The activity of the oxides of Group VI metals increases in the sequence $Cr_2O_3 < MoO_3 < WO_3$. In the presence of the last oxide 41% of benzamide was obtained at 225 °C (with a selectivity of 95%).[87]

Comparison of the hydrating capacities of various higher and lower oxides of the same metals showed that in all cases the higher oxides are more active. A relation between the activities of various oxides and their acid–base properties has not been discovered. Thus the activities of Bi_2O_3 and V_2O_5, the first of which has basic properties and the second has acid properties, are similar.[84] Nor has it been possible to correlate the activities of various metal oxides with the electronic configurations of the corresponding cations. Overall, the oxides of transition metals with moderate acid–base properties proved to be the most active and selective in the reaction considered.

2. Hydration in the Presence of Metal-Containing Catalysts

Among the known metal-containing catalysts, the most active in the hydration of nitriles are those based on copper. It is known that metallic copper is a catalyst of the alkaline hydrolysis of polyacrylonitrile.[93] However, the first attempts at the hydration of nitriles in the presence of catalysts based on metallic copper were described subsequently.[33,94,95] The best results were achieved in the hydration of 2-, 3-, and 4-cyanopyridines in aqueous solutions: the yield of the amides reached 50% for a low selectivity. Later the first patent was published[96] on the hydration of acrylonitrile and other nitriles in the presence of catalysts incorporating, together with copper salts, which the authors erroneously assumed to be the main carriers of catalytic properties, also zerovalent copper. Since then numerous versions of copper catalysts for the hydration of nitriles (copper on oxide and organic polymeric carriers,[97] Raney copper, and powdered copper with a high surface area) have been described mainly in the patent literature.[2] The catalysts are obtained in the usual way, i.e. by reducing mixtures of finely dispersed copper(II) oxide and other oxides, for example the Atkins catalyst, prepared beforehand. Copper(II) oxide is usually reduced at 170–250 °C with hydrogen, the activity of the catalyst increasing with decrease of the hydrogen content in

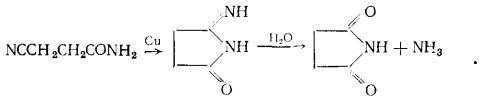
its mixture with nitrogen or another inert gas.[98] At a reduction temperature of 210 °C the optimum hydrogen content in the hydrogen–nitrogen mixture is 3 mole %. The rate of hydration increases with increase of the degree of reduction of CuO, but the presence of small amounts of CuO and Cu_2O in the copper catalyst does not exert an appreciable influence on its activity.[99,100] The rate of hydration is influenced also by inorganic salts present as admixtures in the liquid component of the reaction mixture and in the catalyst.[121,122]

In order to obtain active copper powders, copper salts (sulphates, chlorides, acetates, etc.) are also reduced by metal hydrides, alkali metal tetrahydroborates, metals, hydrazine, formaldehyde, and other reductants.[2] As a rule, there is no direct relation between the activity of the catalysts and their surface area (10–120 $m^2\ g^{-1}$). The nature of the carrier has a greater influence on the activity.

After prolonged use in continuous processes, copper containing hydration catalysts are gradually deactivated, which is accounted for by the oxidation of copper by the traces of atmospheric oxygen dissolved in the reaction mixture and by the blocking of the catalyst surface by copper(II) oxide. The regeneration of oxide catalysts consists in their reduction, in the first place by hydrogen, as described above. Additional oxidation of the partly spent catalyst by atmospheric oxygen before its reduction may prove useful.

The efficiency of the regeneration of catalysts which have lost their activity depends to a large extent on the nature of the carrier. Thus the catalyst obtained by the thermolysis (in the presence of hydrogen) of copper formate deposited on the cross-linked copolymer of 4-vinylpyridine and 1,4-divinylbenzene contains finely dispersed copper and exhibits a high initial activity in the hydration reaction.[97] However, after its deactivation, it is impossible to restore fully its activity by passing hydrogen, while less dispersed copper catalysts obtained under the same conditions on metal oxides are readily regenerated. It has been suggested[97] that the finely dispersed copper on the polymeric carrier becomes partially aggregated on contact with atmospheric oxygen. It is also possible that the carrier undergoes chemical changes in the course of the high temperature reduction and this is responsible for the alteration of its influence on the activity of copper.

One of the ways of increasing the lifetime of copper-containing catalysts involves the introduction of halide ions into the reaction mixture,[101] in particular of potassium bromide.[102] The catalytic activity of the oxidised copper is almost fully restored after it has been treated with potassium iodide.[103]



Aromatic and unsubstituted aliphatic nitriles are hydrated with a high selectivity in the presence of various copper-containing catalysts; appreciable amounts of side products have not been detected. The yields of aliphatic amides at 100–110 °C are close to theoretical values.[104] The synthesis of benzamides with a substituted amino-group in the 2-position from 2-chlorobenzonitrile and piperidine or another cyclic base in the presence of a bronze is apparently based on the hydration of aromatic nitriles in the presence of copper.[105]

The kinetics of the hydration of aromatic nitriles for a molar ratio of water and the nitrile of 1.5 : 1 in dioxan in the presence of the Cu–MgO catalyst are described by a second-order equation. The effective specific rate constants for the hydration increase with increase of the electron-accepting capacity of the substituent in the benzene ring of the nitrile. A satisfactory correlation has been established between these constants and the Hammett σ constants (ρ = +0.33).[104] The kinetics of the hydration of aliphatic nitriles in an excess of water in the presence of the Cu–MgO catalyst obey a first-order equation. A satisfactory correlation between the effective specific rate constants and the Taft σ^* constants (ρ = +1.78) has been observed for the hydration of acetonitrile, propionitrile, butyronitrile, 3-hydroxypropionitrile, and acrylonitrile. The low absolute reaction constants show that the polarity of the transition state in the hydration of nitriles in the presence of copper catalysts is low.[104]

In the presence of the Cu–MgO catalyst chloroacetonitrile partly undergoes side reactions with evolution of hydrogen chloride, which interacts with the catalyst. On lowering the hydration temperature to room temperature, it was possible to suppress to a large extent the formation of HCl and to obtain a high yield of chloroacetamide. In the presence of this catalyst 3-chloropropionitrile undergoes dehydrochlorination together with hydration, which leads to the formation of acrylamide as the main reaction product.[104]

In contrast to 2-hydroxynitriles, 3-hydroxypropionitrile is hydrated smoothly in the presence of copper (activation energy E_a = 60 kJ mol^{-1} at 90–110 °C).[104,106] 2-Methoxyisobutyronitrile is also hydrated, although the reaction is very slow owing to steric hindrance.[107]

The hydration of the nitriles of dibasic aliphatic acids in an excess of water in the presence of the Cu–ZnO–Al_2O_3 catalyst has been described.[68] Adiponitrile is hydrated, as in the presence of manganese(IV) oxide, initially to 5-cyanovaleramide, which is then converted into adipamide. The hydration of succinonitrile involves the formation of 3-cyanopropionamide and succinimide (instead of succinamide as in the presence of MnO_2). Malononitrile is hydrated to 2-cyanoacetamide and at the same time is partly converted into a polymeric product. In the presence of an excess of water the ratios of the rate constants for the addition of the first water molecule to adipo-, succino-, and malono-nitriles are 1.35 : 1 : 9. The highest reactivity of malononitrile can be naturally accounted for by the mutual activation of the two cyano-groups. However, the lower rate constant for succinonitrile than in the hydration of adiponitrile is unexpected, since the negative polar effect of the 2-cyanoethyl group of succinonitrile is somewhat greater than that of the 4-cyanobutyl group of adiponitrile. Presumably the hydration of succinonitrile is preceded by the interaction of the active centres of the catalyst, in close proximity, with both cyano-groups of the dinitrile with formation of a cyclic complex, in which at least one cyano-group is π-bonded to the metal. On the other hand, in the hydration of adiponitrile such a cyclic complex would be strained and in this case electron-donating properties are therefore shown only by the *n* electrons of the cyano-group, which is the reason for the higher reactivity of adiponitrile. The unusual interaction of succinic acid derivatives with the copper catalyst may be responsible also for the fact that 3-cyanopropionamide is not hydrated but undergoes cyclisation in an aqueous solution in the presence of zerovalent copper:

It is noteworthy that the rate constant for the hydration of adiponitrile is greater by a factor of ~1.7 than for 5-cyanovaleramide.[68] A greater reactivity of the cyano-group in the adiponitrile molecule than in the compound where one cyano-group has already reacted has been observed also in a number of other reactions of adiponitrile.[1]

The hydration of acrylonitrile in the presence of copper-containing catalysts has been studied more thoroughly than for any other nitrile. The numerous varieties of catalysts based on zerovalent copper described have been proposed primarily for the hydration of acrylonitrile. In the presence

of copper-containing catalysts acrylamide is formed in high yields. In the presence of the $Cu-Cr_2O_3$ catalyst at temperatures not exceeding 120 °C up to 90% of acrylonitrile is converted into acrylamide when the catalyst is used repeatedly.[108] The Cu–MgO and $Cu-ZnO-Al_2O_3$ catalysts as well as Raney copper also exhibit a high activity in the hydration of acrylonitrile.[97,108,109] After prolonged hydration in the presence of the $Cu-SiO_2-MgO$ catalyst, the yield of acrylamide is 85%.[97] Certain technological aspects of the hydration of acrylonitrile in the presence of $Cu-ZnO-Al_2O_3$ in an excess of water and, in particular, the quantitative dependence of the rate of hydration in a continuous process on temperature, the linear flow rate in the reactor, and the initial concentration of acrylonitrile in the reaction mixture, as well as the phase equilibria in the systems formed by the initial nitrile, the amide, water, and other substances have been examined.[71,108,110,111] The hydration of acrylonitrile in the presence of Raney copper in a flow-circulation system has been described[112] and the same paper also presents an empirical equation for the process kinetics.

The hydration of acrylonitrile in the presence of copper-containing catalysts is not fully regioselective. Together with the hydration of the cyano-group, water adds to the C=C bond under the reaction conditions with formation of 3-hydroxypropionitrile, which then partially reacts with a second acrylonitrile molecule or undergoes hydration. This leads to the formation of di(2-cyanoethyl) ether and 3-hydroxypropionamide.[106] These reactions have been studied quantitatively in the hydration reaction in the presence of the $Cu-ZnO-Al_2O_3$ catalyst.[106] It has been found that, by virtue of their occurrence in the temperature range 80–120 °C, the selectivity of the hydration to acrylamide is 97–93%. At 100 °C in a continuous process the selectivity increases to 99.5% (for a degree of conversion of acrylonitrile of 90%) as a consequence of the elution from the catalyst of traces of alkali, which catalyse the addition of water to the C=C bond. The hydration of the double bonds is also accelerated by copper(II) oxide, which is incorporated to a greater or lesser extent in the catalysts based on metallic copper.[123] However, the possibility of the side reaction involving the formation of 3-hydroxypropionitrile depends not only on the admixture in the catalyst but also on the structure of the latter. Whereas in the hydration reaction in the presence of Raney copper carefully washed with water acrylamide is virtually the only reaction product, when catalysts deposited on certain carriers are employed 3-hydroxypropionitrile is formed in appreciable amounts; under these conditions, the more basic the carrier the lower the selectivity of the hydration to acrylamide (for example, water adds to the C=C bond particularly vigorously in the presence of the Cu–MgO catalyst).[71,97] The replacement of the basic MgO by the SiO_2-MgO carrier, which exhibits acidic properties, made it possible to suppress to a large extent the formation of 3-hydroxypropionitrile: under comparable conditions in the preparation of the catalysts and their tests, the selectivity in the formation of acrylamide increased from 75% to 97%.[97] It is therefore undesirable to employ catalysts containing basic components for the hydration of the C≡N group in unsaturated nitriles capable of combining with water via the C=C double bond, although these catalysts may be entirely suitable for the synthesis of amides from other nitriles.

Small amounts of other side products are also formed in the hydration of acrylonitrile. Thus traces of acrylamide hydrolysis products, namely, acrylic acid and ammonia, have been found in the reaction mixture.[106,113] Only above 120 °C are these admixtures formed in more appreciable amounts.[108] Microadmixtures of a number of unsaturated amides, namely heptatrienamide, pentadienamide, and 5-cyanopent-2-enamide, which may be the products of the catalytic hydration of the corresponding nitriles present as admixtures in the initial acrylonitrile, have been detected in acrylamide.[114] Under the conditions of the hydration reaction in the presence of Raney copper containing adsorbed hydrogen, there is a possibility of side reactions involving the hydrogenation of acrylonitrile, which leads to the appearance of admixtures of n-propylamine in acrylamide.[2]

The kinetics in the initial period of the hydration of acrylonitrile in an excess of water are described by an equation which is of first order with respect to the nitrile ($E_a = 75.8–86.7$ kJ mol^{-1}).[100,108] In an excess of acrylonitrile the reaction is also of first order with respect to water.[100] In the hydration of acrylonitrile as well as other nitriles in an excess of water up to high degrees of conversion the reaction kinetics do not obey the equation derived for the initial period of the hydration process, which can be explained by the inhibition of the reaction by the amides formed, through preferential adsorption of acrylamide on the catalyst surface.[71,97,100,109,122] Calculation based on the kinetic data for high degrees of conversion using different copper catalysts on carriers[97] showed that the ratios of the adsorption coefficients for a number of amides and the corresponding nitriles are 10 : 1–50 : 1. It has been shown recently that acrylamide is not the only reaction product inhibiting the hydration of acrylonitrile. The acrylic acid formed in the hydrolysis of acrylamide in an amount as much as 0.7 mole % of the initial nitrile reduces the rate of hydration under comparable conditions by more than a factor of two. Under the influence of acrylamide, the same effect is attained when its content is ~15%. Another side product, namely 3-hydroxypropionitrile, does not affect the rate of hydration of acrylonitrile.[100]

Under conditions of the hydration of methacrylonitrile in the presence of copper-containing catalysts, side reactions do not occur to an appreciable extent, in contrast to acrylonitrile; methacrylamide (96%), which is an industrial monomer, and the nitrile which has failed to react have been isolated from the reaction products. The first order reaction rate constant diminishes during hydration with increase of the content of the amide in the reaction mixture. The activation energy in the temperature range 61–90 °C is 55.7 kJ mol^{-1}.[115]

Raney copper has been used as the catalyst of the hydration of the cyano-groups of polyacrylonitrile in a saturated aqueous solution of potassium thiocyanate. A polymer containing up to 34% of acrylamide elementary units was obtained. Polymerisation via the cyano-groups with formation of azapolyene sections in the macromolecules also occurs under the hydration conditions.[71,72]

The data for the hydration of nitriles in the presence of oxide catalysts (see above) suggest that the hydration in the presence of copper includes a stage in which the nitrile interacts with the catalyst (activation of the cyano-group) with subsequent addition of water. The data presented above for the kinetics of the hydration of dinitriles[68] agree with the hypothesis that the cyano-group interacts with the catalyst surface. Important evidence in support of this is provided by the polymerisation via the cyano-groups of polyacrylonitrile under the influence of a hydration catalyst, i.e. the occurrence on copper of a reaction in which water is not involved. The positive reaction constants ρ in the Hammett and Taft equations presented above show that the rate of hydration of nitriles is limited by the rate of nucleophilic attack by water on the CN group.[104] If the interaction of the catalyst with the nitrile, for example the formation of a complex, were the rate-limiting stage, then the constant ρ would have had the opposite sign. The mechanism proposed by Elsemongy and Onsager,[109] according to which the catalyst

activates both the nitrile and water, is also inconsistent with the observed correlations. Thus the sequence of the principal stages of the hydration process is apparently clear. However, it has been shown[100] that, in order to refine the reaction mechanism, it is necessary to carry out additional studies on the adsorption and other processes occurring during hydration.

An attempt has been made to hydrate the thiocyanate group in organic compounds in the presence of a copper catalyst.[116] However, when an aqueous solution of methyl thiocyanate was heated in the presence of Raney copper, only insignificant amounts of *S*-methyl thiocarbamate were found in the reaction products. It was discovered that the main reactions of methyl thiocyanate involve the hydrolysis of the SCN and $SCONH_2$ groups at the sulphur–carbon bond and the homolytic reactions of the SCN group induced by the presence of copper.

Catalysts based on metallic nickel have also been used for the hydration of nitriles.[33,94,95,117] Urushibara nickel (nickel on a zinc carrier) and Raney nickel proved to be the best catalysts. The hydration was carried out by prolonged refluxing of nitriles with an excess of water in the presence of these catalysts. The amides have been obtained in high yields from benzonitrile, a series of *p*-substituted benzonitriles, and 3-, 4-, and 2-cyanopyridines. *o*-Substituted benzonitriles and aliphatic nitriles have been converted into amides in moderate yields. The hydration of nitriles entails the simultaneous formation of acids and amines (the latter evidently as a consequence of the hydrogenation by the hydrogen adsorbed on the catalyst). The hydration of amino- and nitro-benzonitriles is accompanied by side reactions of the resulting amides with the catalyst. Only nickel and zinc complexes have been obtained in the case of *p*-hydroxy- and *o*- and *p*-cyano-benzonitriles, *p*-cyanobenzoic acid, ethyl *p*-cyanobenzoate, and *p*-cyanobenzaldehyde. The introduction of pyridine into the reaction mixture increases the yield of the amides, while the introduction of thiophen and organic acids lowers their yield. It has been suggested[95] that the hydration is preceded by the adsorption of the cyano-groups on nickel, mainly on its basic centres.

The studies of the hydration reaction in the presence of the nickel catalysts examined above were carried out in the 1960's. In view of major practical advances achieved in the employment of copper as a hydration catalyst, subsequently nickel catalysts attracted little attention.[55]

Among other metallic catalysts, mention has been made of "activated iron"[55] and iron–zinc[2] and platinum[1] catalysts.

---o0o---

Thus the present review shows that the advances in various new aspects of the hydration of nitriles are not all of equal value. Significant results have been obtained in the homogeneous hydration of coordinated nitriles. It has been established that coordination is responsible for a very considerable increase of the rate of hydration (by a factor up to $\sim 10^{18}$). Considerable experimental data have now accumulated on the synthesis in these reactions of amides (coordinated to different ions) in high yields. In a number of instances the study of the hydration kinetics made it possible to examine in detail the reaction mechanism and to put forward entirely feasible mechanisms for the reactions of the initial complexes. It has also been found that the coordinated nitriles also enter into other reactions in aqueous solutions, the latter being determined by the structure of the nitriles and sometimes by the reaction conditions. At the same time there have been no systematic studies of the hydration of a sufficiently wide range of nitriles and of the influence of the structure of the initial complexes on the characteristic features of the hydration process. The preparative value of the hydration reaction under consideration is as a rule limited, because the isolation of the free amides requires the chemical modification or even the decomposition of the amide-containing complexes obtained.

The homogeneous-catalytic hydration of nitriles in the presence of complexes as catalysts, which leads to the formation of amides not linked chemically to the complexes present in the reaction mixture, has so far been comparatively little studied. There have been as yet no kinetic investigations of the reaction and high rates of hydration and degrees of conversion approaching quantitative values have not been achieved. However, the proposed fundamental mechanism of the catalytic action of complexes appears to be correct. Apparently the main task in this field is the choice of new catalytically more active complexes and the develoment of conditions for the isolation of the amides formed, which will make it possible to increase the preparative values of the method.

The best practical results have so far been achieved in the heterogeneous-catalytic hydration of nitriles. This hydration method has undoubted advantages over other considered in this review and also those described previously[1] in view of its simplicity, high yields of the amides, and also because reactants other than nitriles are hardly consumed in the synthesis of the amides. All these factors have served as a basis for the employment of heterogeneous-catalytic hydration of nitriles in industrial organic synthesis. During the last 5–10 years, studies have been made of the kinetics and mechanism of the hydration reaction and many of its features in the presence of manganese(IV) oxide and copper-containing and other catalysts have become understood, which made it possible to propose reliable reaction mechanisms, but these require a certain amount of experimental confirmation and specification in greater detail. In view of the similarity of the characteristics of the hydration of certain substituted nitriles under the conditions of heterogeneous catalysis and in a homogeneous medium containing complexes with the same nitriles as ligands and also in view of the weak dependence of the activation energies for the hydration of nitriles on the method of hydration, it is to be expected that the achievements in the study of the mechanism of homogeneous hydration will promote the solution of urgent problems in the heterogeneous-catalytic hydration of nitriles.

The Development of Circulation Gas Chromatography

M.P.Zabokritskii, V.P.Chizhkov, and B.A.Rudenko

The present state of circulation gas chromatography, and its principal regular features and apparatus, have been examined. A highly effective version of circulation gas chromatography has been proposed. It has been shown possible to achieve a high efficiency in the separation of organic compounds with similar structures and properties (several tens of thousands of theoretical plates with a specimen of up to 1 g).
The bibliography contains 159 references.

I. INTRODUCTION

In recent years, as a result of the intensified study in the field of present-day organic chemistry, it has become necessary to carry out the fine preparative separation of organic compounds showing extremely small differences in their structures and properties (for example, similar structural and spatial isomers). Attempts to solve this problem using the classical methods encountered in laboratory practice (distillation, extraction, crystallisation, etc.) do not always give the desired results. Moreover, the restricted nature of the possibilities provided by these methods becomes increasingly apparent with the increased complexity of the task of fine preparative separation. The difficulty of separating isomers is also increased by the fact that newly synthesised organic compounds are often available only in very small quantities. At the same time, the extremely marked differences in the chemical properties and biological activities of a number of isomeric molecules make the problem of their separation and individual study extremely important.

The present-day level of gas-chromatographic procedures and techniques makes it possible to separate substances with extremely similar structures and properties. In most cases, however, chromatographic methods, which have a high efficiency of separation, have an extremely low productivity, making it possible to work only with specimens with masses of 10^{-3}–10^{-6} g. These systems — capillary columns, very long (up to 100 m) packed columns with a small diameter, and short packed columns included in a circulation scheme — are used successfully to separate multicomponent mixtures, similar structural and spatial isomers, and isotopes and isotopically substituted compounds. The efficiency of the preparative separation of specimens of a mixture of substances, however, even in amounts corresponding to several tenths of a gram, is usually much lower, and rarely exceeds 3–5 thousand theoretical plates (t.p.). At the present time, in gas chromatography, the only methodological version making it possible to separate gram quantities of substances with an efficiency of about 30–50 thousand t.p. is apparently preparative circulation chromatography.

Since the publication of the first reviews of circulation gas[1] and liquid[2] chromatography, new papers have been published, developing the theory and extending the range of application of this method.

The present review examines chiefly development circulation gas chromatography (CGC), which is not, however, the only method of circulation separation. Versions of the circulation method have found application in heat-dynamic gas,[3] liquid,[4-29] and thin-layer[30] forms of chromatography. The preparative separation of a number of substances has been described.[31-34] Capillary circulation chromatography appears promising for some cases of extremely fine separation.[35,36]

II. VERSIONS OF THE CIRCULATION METHOD AND APPARATUS

The idea of circulating the specimen to be separated in a closed cycle with a layer of sorbent, suggested by Martin,[37,38] found practical application in two different types of technical apparatus. In the first case, the circulation of the specimen and the mobile phase is carried out in a single cycle by the action of a circulating pump. In the second version, recirculation of the mobile phase does not take place, and the circulation of the band of compounds being separated is brought about by a periodic change in the direction of the gas stream by means of special tap or valve switching devices.

In 1959–1960, Porter and Johnson[39-41] described the first circulation apparatus consisting of a closed circuit with two chromatographic columns, detector, input device, and peristaltic circulation pump. A similar apparatus, differing only in the replacement of the peristaltic pump by a piston pump, was later used.[42,43] With apparatus of this type, considerable broadening of the chromatographic peaks was observed, because of the mixing action of the pump and the large dead volumes in the closed system, and this made it impossible to obtain a high efficiency of separation. Moreover, the temperature range of operation of these circulation pumps was found to be extremely restricted.

In the period 1960–1970, circulation apparatus with a periodic action and switching devices appeared,[44-50] in which the band of chromatographic compounds circulated without passing through the pump. This made it possible to increase the efficiency of the separation. The turning of the taps, however, leads to marked pneumatic disturbance, associated with the redistribution of the pressures in the column. This leads to additional broadening of the chromatographic band, and a large number of cycles cannot be carried out. In a

comparison of the two systems described, preference was given[49] to the circulation scheme with a pump in the main cycle.

Circulation chromatography developed considerably by the use of gas stream switching devices in various circulation schemes with a semi-continuous or continuous action, designed mainly for preparative and industrial chromatography. Among the semi-continuous systems, mention may be made of an apparatus in which portions of the mixture to be separated are introduced in each half-cycle into the middle section of the circulation band, and the separated products are removed by cutting off the end sections of the chromatographic zones of each component.[51,52] Systems with a continuous action include circulation apparatus in which the specimen is introduced by the alternate opening and closing of taps arranged round the circumference of a toroidal column, with stationary columns,[53-55] and apparatus in which the supply section remains stationary as a result of the rotation or reciprocating movement of the columns.[56-62] These versions of toroidal circulating assemblies can also operate under periodic conditions.[63,64] Circulation assemblies based on the use of frontal chromatography have also been developed.[65-67] Although they have a high productivity, these assemblies have not solved the problem of the highly effective preparative separation of similar structural and spatial isomers or isotopically substituted compounds, which represents the most difficult problem for the organic chemist and technical engineer.

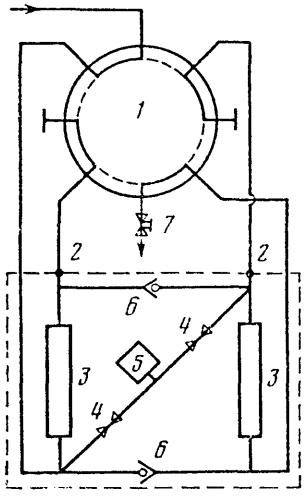

Figure 1. Circulation apparatus with unheated switching device: *1*) circulation tap, *2*) input devices, *3*) chromatographic columns, *4*) pneumatic resistance, *5*) detector, *6*) stream chopper valves, *7*) valve.

An unsatisfactory feature of many circulation schemes with gas stream switching devices is that the mixture being separated passes through the channels of the switching taps or valves. This makes it necessary to heat the switching assemblies, and this decreases their reliability of operation and the temperature range of application of the method, increases the dead gas volumes, and prevents the elimination of possible degradation of heat-sensitive compounds when they come into contact with the heated metal surfaces. In these schemes it is difficult to use pieces of apparatus made of glass.

To overcome these disadvantages, circulation schemes in which the switching tap is brought out of the thermostat have been proposed. In this case, the temperature restrictions are determined only by the thermal stability of the stationary liquid phase. The removal of the switching tap from the circulation circuit, however, led to considerable non-productive losses of the carrier gas and the substances being separated; these were lost to the atmosphere through the chokes connecting the column inlets and outlets,[68-70] or through auxiliary columns with a high resistance to the gas stream.[71,72] Further progress in CGC was achieved by using check valves or gate valves with a forced action to divide the gas stream,[73-75] replacing the economically unsuitable chokes. One possible form of circulation scheme with removal of the switching tap from the heated zone is shown in Fig.1.

The development of the circulation method of separation has been reflected in a number of Soviet (LKhP-4, LKhP-71, LKhM-9) and imported instruments. The universal attachments, developed by the Special Design Office of the Institute of Organic Chemistry of the Academy of Sciences of the USSR, with manual control or with programming and automatic switching of the circulation tap, PTsU-1 and PTsU-2, and attachments for chromatography in water vapour and for switching columns, P-1 and P-2, have made it possible readily to combine various versions of a circulation scheme with analytical and preparative gas chromatographs, for example LKhM-8MD, LKhP-51, etc. A specialised capillary circulation gas chromatograph, Biokhrom-27, is being developed at present (Special Design Office, Institute of Organic Chemistry of the Academy of Sciences of the USSR).

III. PRINCIPAL THEORETICAL REGULAR FEATURES OF CIRCULATION GAS CHROMATOGRAPHY

1. Dependence of the Efficiency of Separation on the Number of Chromatographic Cycles Carried Out

Early theoretical studies of the dependence of the efficiency of separation on the number of cycles carried out in the circulation scheme assumed a linear increase in the number of theoretical plates with increase in the number of columns through which the specimen passed.[47,76,77] Experiments showed, however, that the rate of increase in the efficiency of the separation usually decreases with increase in the number of columns passed through. A similar decrease in efficiency was noted in Ref.49. Sakodynskii and co-workers[32,78,79] observed a considerable fall-off in the increase in efficiency with increased number of cycles in a circulation preparative assembly; to make fuller use of the possibilities provided by the circulation scheme, the end zones of the peaks were removed without waiting for their complete separation.

A similar fall-off in the rate of the increase in the efficiency of separation with each new cycle was demonstrated in Refs.80 and 81. The observed effect was attributed to the influence of non-stationary regions in the gas stream, produced when the circulation tap was turned. As a result of the sharp redistribution of pressure in the columns when the tap is turned, part of the specimen in the gas phase is rapidly compressed, and moves forward relative to that part of the specimen present in the sorbed state in the stationary phase; for a finite rate of mass transfer, this leads to additional broadening of the chromatographic band.

Under the conditions described above, it was found appropriate to use long columns (10 m or longer),[33] which make it possible to reduce the number of times the circulation tap is turned and hence to decrease the rate of broadening of the chromatographic bands of the compounds being separated throughout the entire length of the column. Similar considerations apparently led other workers[82-85] to use columns with a length of 8–15 m for the separation of isotopically substituted compounds.

The limitations in the efficiency of separation attainable using circulation chromatography, which appeared at this stage of its development, produced in some workers a certain scepticism,[86] which was overcome only after an extensive analysis of the effects of pulse contraction and broadening of the chromatographic zones.

2. Effect of Pulse Contraction of the Chromatographic Zone

The effect of pulse contraction[88-90] of the chromatographic zone received its name by analogy with the pulse thermal enrichment[87] of the chromatographic zone. The essential features of this effect are as follows. If in the first chromatographic column of the circulation scheme through which the carrier gas moves, the linear velocity of the mobile phase is greater than that in the second column (as a consequence of the presence of the stream divider), then in the first column the trailing edge of the zone after a time t passes through a distance

$$l_1 = tu_1/(1 + k')$$

and the leading edge of the zone in the second column after the same time t passes through a distance

$$l_2 = tu_2/(1 + k')$$

where u_1 and u_2 are the linear velocities of the carrier gas in the first and second columns, and k' the extraction coefficient. As a result of the removal of part of the carrier gas between the columns, $u_1 > u_2$, that is $l_1 > l_2$. Thus the transfer of the band from one column to the other is accompanied by a contraction of the chromatographic zone in the ratio

$$b = l_2/l_1 = u_2/u_1 = 1 - a/100$$

where a is the mass fraction of the carrier gas removed between columns 1 and 2, expressed as a percentage. Thus the turning of the circulation tap will lead to a contraction of the chromatographic zone.

For columns consisting of a large number of identical sections, the width of the peak ν_m, the distance between the maxima of the peaks Δn_m, and the degree of separation R_m alter with change in the number m of columns passed through, as follows:

$$\nu_m = \nu_1 (m)^{1/2} \quad (1)$$

$$\Delta n_m = \Delta n_1 \cdot m \quad (2)$$

$$R_m = R_1 (m)^{1/2} \quad (3)$$

where ν_1, Δn_1, and R_1 are the parameters of the chromatographic band after its passage through the first column. Eqns.(1)–(3) describe the linear increase in the efficiency of separation with increase in the number of columns passed through.

Under pulse conditions, the width of the zone at the start of the second column is $\nu_1^0 = b\nu_1$. As a result of the broadening of the zone on passage through the second column, the width will be

$$\nu_2 = (b^2 + 1)^{1/2} \nu_1$$

After the transfer of the zone to the third column, the width of the band is reduced to

$$\nu_2^0 = (b^4 + b^2)^{1/2} \nu_1$$

after which it increases to the following value:

$$\nu_3 = (b^4 + b^2 + 1)^{1/2} \nu_1$$

As a result of the alternate contraction and broadening of the band, the width of the chromatographic zone after passage through m colums will be

$$\nu_m = [b^{2(m-1)} + b^{2(m-2)} + \ldots + b^2 + 1]^{1/2} \nu_1 = \left(\frac{1 - b^{2m}}{1 - b^2}\right)^{1/2} \nu_1 \quad (4)$$

Thus the broadening of the zone of a chromatographic compound in the circulation zone with removal of some of the gas between the columns is less than that given by Eqn.(1). The increase in the width of the zone is restricted to the limit

$$\nu_\infty = (1 - b^2)^{-1/2} \nu_1$$

reached as $m \to \infty$.

Similar arguments can be used to examine the change in the distance between the maxima of the bands of two chromatographic compounds. After the zone has passed through m columns, the distance between the maxima of the bands will be:

$$\Delta n_m = \frac{1 - b^m}{1 - b} \cdot \Delta n_1 \quad (5)$$

From this equation it follows that in a circulation scheme with removal of gas, the increase in Δn_m is less than that expected from Eqn.(2). The value of Δn_m as $m \to \infty$ will be

$$\Delta n_\infty = \frac{1}{1 - b} \cdot \Delta n_1$$

that is the distance between the band maxima in a circulation scheme with removal of gas is restricted to a certain limiting value.

Eqns.(4) and (5) give

$$R_m = \left(\frac{1 + b}{1 - b} \cdot \frac{1 - b^m}{1 + b^m}\right)^{1/2} R_1 \quad (6)$$

It follows from Eqn.(6) that the increase in the degree of separation is also restricted to the limiting value:

$$R_\infty = \left(\frac{1 + b}{1 - b}\right)^{1/2} R_1$$

The theoretical ideas about pulse chromatographic conditions were verified experimentally[89] using a model mixture of benzene and cyclohexane. The relationships obtained are given in Fig.2. When part of the gas stream is removed, the chromatographic zone eventually reaches an equilibrium state in which there is practically no further broadening of the zone, and simultaneously no further change in the values of ν_m, Δn_m, and R_m. The lack of agreement between the experimental curves and the curves corresponding to the theoretical equations (4), (5), and (6) is attributed to the effect of the pulse broadening of the zone.

3. Effect of Pulse Broadening of the Chromatographic Zone

The effect of pulse broadening of the chromatographic zone[90,91] is the opposite of the effect examined above, and is due to the existence of a gradient in the linear velocity of the carrier gas in the columns of the circulation scheme.

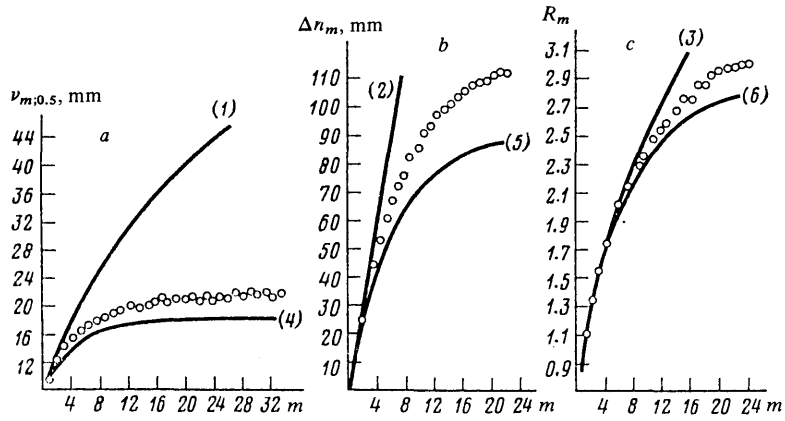

Figure 2. Dependence of the peak width at half-height $\nu_{m;0.5}$ (*a*), the distance between the maxima of the peaks Δn_m (*b*), and the degree of separation R_m (*c*) on the number of half-cycles m; the numbering of the curves corresponds to the numbering of the equations, and the points correspond to the experimental data. Conditions: two 4 m × 4 mm columns containing 5% Apiezon L, inlet pressures p_{in} = 1.1 MPa, outlet pressure p_{out} = 1.0 MPa, gas removal kept at a level of 12–13%.

The essential features of this effect are as follows. When there is no removal of gas between the columns, the linear velocity of the carrier gas in the columns increases continuously. The leading edge of the zone will move in the second column at an average velocity which is greater than that of the trailing edge remaining in the first column. The difference in the rates of movement of the edges of the zone, combined with the subsequent pulse redistribution of the velocities, will lead in each half-cycle to additional broadening of the bands of the chromatographic compounds, which increases from one cycle to another. Thus the movement of the chromatographic zone through the entire length of the column of the circulation scheme will take place slightly earlier than indicated by Eqns.(1) and (2).

The changes in the principal chromatographic characteristics with variation of the number m of columns passed through, with allowance for the effect of pulse broadening of the chromatographic zone, are given by the following equations:

$$b_0 = \bar{u}_2/\bar{u}_1$$

$$\nu_m = \left(\frac{b_0^{2m}-1}{b_0^2-1}\right)^{1/2} \nu_1 \qquad (7)$$

$$\Delta n_m = \frac{b_0^m - 1}{b_0 - 1} \cdot \Delta n_1 \qquad (8)$$

$$R_m = \left(\frac{b_0+1}{b_0-1} \cdot \frac{b_0^m-1}{b_0^m+1}\right)^{1/2} R_1 \qquad (9)$$

Here, b_0 is the zone broadening factor for the chromatographic compounds ($b_0 > 1$), and u_1 and u_2 the average linear velocities of the carrier gas in the first and second columns along the path of the gas.

According to Eqn.(9), the increase in R_m is restricted to the limiting value:

$$R_\infty = \left(\frac{b_0+1}{b_0-1}\right)^{1/2} R_1$$

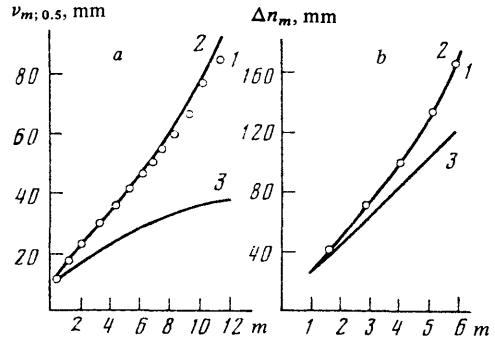

Figure 3. Dependence of the peak width at half-height $\nu_{m;0.5}$ (*a*) and the distance between the maxima of the peaks Δn_m (*b*) on the number of half-cycles m; *1*) experimental points; *2* and *3*) theoretical curves corresponding to Eqns. (7), (8) and (1), (2) respectively. Conditions: two 3 m × 4 mm columns containing 20% Apiezon L, p_{in} = 0.57 MPa, C = 1.24, no removal of gas.

The factor b_0 depends on the ratio C of the pressure at the inlet to the pressure at the outlet of the circulation assembly. For $C \leq 1.4$, it may be assumed that

$$\bar{u}_1 = (u_{out}/C + u_{1/2})/2$$
$$\bar{u}_2 = (u_{out} + u_{1/2})/2$$
$$u_{out}/u_{1/2} = [(C^2+1)/2]^{1/2}$$

where $u_{1/2}$ is the local linear velocity of the carrier gas at the outlet from the first column in the path of the gas. Thus b_0 is given by the expression

$$b_0 = \frac{[(C^2+1)/2]^{1/2}+1}{[(C^2+1)/2]^{1/2} \cdot \frac{1}{C}+1} \approx C^{1/2}$$

It follows from this equation that a decrease in C (for a constant pressure drop) leads to a decrease in the influence of the pulse effect in broadening the chromatographic zone. This conclusion has been confirmed experimentally.[92–95]

The dynamics of the change in the chromatographic parameters were studied using a circulation assembly with an eight-way tap in a scheme with two columns. The materials studied were the same as in the first case. Fig.3 shows that the above theoretical ideas about the pulse effect in broadening the chromatographic zone are confirmed qualitatively and quantitatively by the experiments. Only six half-cycles could be carried out without cutting off components.

Fig.4 gives the experimental dependence of the number of theoretical plates n on the number of half-cycles m under conditions of different ratios of the inlet and outlet pressures with no removal of gas between the columns (curves *1* and *2*).

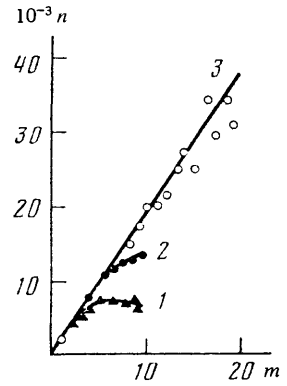

Figure 4. Dependence of the number of theoretical plates n on the number of half-cycles m: *1*) curve obtained at $C = 1.24$ (without gas removal) under the conditions described in Fig.2; *2*) curve obtained at $C = 1.06$ (without gas removal) under the following conditions: $p_{in} = 0.99$ MPa; *3*) straight line obtained under non-pulse chromatographic conditions for $C = 1.24$ ($a = 9.1\%$) at $p_{in} = 0.57$ MPa.

4. Non-pulse Circulation Gas Chromatography

The effect of pulse broadening of the chromatographic zone can be eliminated completely by compensating it by the effect of pulse contraction. This gives the optimum conditions of "non-pulse chromatography".†[90,91,96]

The optimum value, required to create these conditions, of the gas removal factor between the columns of the circulation scheme a can be estimated approximately from the material balance equation

$$S_1 u_1 d_1 = S_2 (u_2 d_2 + a u_1 d_1)$$

where S_1 and S_2 are the areas of the cross-section of the columns, occupied by the gas in the first and second columns of the circulation system, and d_1 and d_2 the densities of the gas in the chosen sections. When the sections of the columns are equal at points situated in the middle of the length of the columns, the following relationship will be observed:

$$a = 1 - u_2 d_2 / u_1 d_1$$

For non-pulse chromatographic conditions, $u_1 = u_2$, so that

$$a_{opt} = 1 - d_2/d_1 = 1 - p_2/p_1$$

since the density of the gas is proportional to the pressures p_1 and p_2 in the middle sections of the first and second columns.

For small values of a and C, the pressure in the columns decreases from p_{in} to p_{out} by an almost linear law. Under these conditions, taking the total length of the two columns of the circulation scheme as equal to unity, it is possible to write approximately:

$$p_1 = p_{in} - (p_{in} - p_{out})/4 = (3C/4 + 1/4)\, p_{out}$$
$$p_2 = p_{in} - 3(p_{in} - p_{out})/4 = (C/4 + 3/4)\, p_{out}$$

This gives

$$a_{opt} = 2(C - 1)/(3C + 1) \qquad (10)$$

Thus increase in the pressures at the inlet and outlet of the circulation scheme for a given pressure drop makes it possible to achieve values of C close to unity, leading to a corresponding decrease in the factor b_0. Complete elimination of the effect of pulse broadening of the chromatographic zone is achieved, however, by the pulse contraction of the zone, taking place when part of the gas stream is removed after the first column of the circulation scheme.

These ideas were verified[91] using a circulation scheme with controlled gas removal. The dependence of n on m, recorded under these conditions, was linear (straight line in Fig.4) over a fairly wide range of values of m (up to 19 half-cycles).

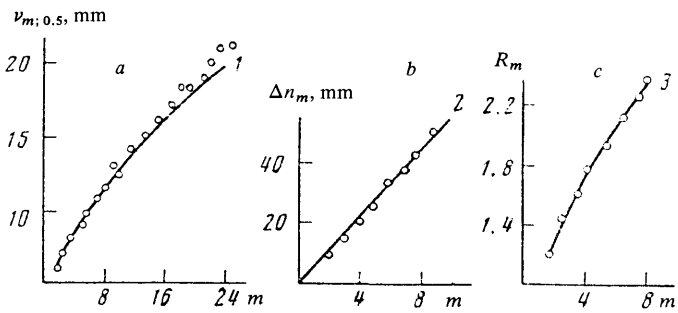

Figure 5. Dependence of the peak width at half-height $\nu_{m;0.5}$ (a), the distance between the maxima of the peaks Δn_m (b), and the degree of separation R_m (c) on the number of half-cycles m: *1*, *2*, *3*) theoretical curves corresponding to Eqns.(1), (2), and (3); the experimental points are marked with circles. Conditions: the column parameters are the same as those in Fig.2; $p_{in} = 0.82$ MPa, $C = 1.29$, $b_0 = 1.01$ for $a_{opt} = 12\%$.

Fig.5 gives the dependence of ν_m, Δn_m, and R_m on m, obtained for $b_0 = 1.01$ and $a_{opt} = 12\%$. The experimental points were found to be close to the theoretical curves *1* and *3* for ν_m and R_m, constructed using Eqns.(1) and (3), and to the theoretical curve *2* for Δn_m, constructed from Eqn.(2).

†The term "non-pulse chromatography" is possibly not entirely appropriate, since when the carrier gas moves from one column to another, its velocity undergoes an abrupt change at the moment when the tap is turned, that is the pulses are preserved. The term "non-pulse chromatography" reflects the fact that the pulse effects, which altered the principal regular features characteristic of the chromatographic process with circulation, disappear.

A decrease in the value of a_{opt} is extremely important in preparative chromatography. According to Eqn.(10), for $C = 1.06$ the value of a_{opt} would be reduced to 3%. On preparative columns[97] with dimensions 3 × 10 mm containing 20% Apiezon L at $p_{in} = 0.63$ MPa and $C = 1.068$ ($a_{opt} = 2.81 \pm 0.15\%$), a linear relationship was obtained between the number of theoretical plates n (with respect to hexane) and the number of columns m through which the chromatographic zone passed. Under these conditions, the preparative circulation apparatus can be regarded as a system of m columns with identical parameters, connected in series.

The losses ϕ of substance during circulation with removal of part of the gas stream between the columns are given by:[90]

$$\varphi, \% = [1 - (1 - a_{opt}/100)^{m-1}] \cdot 100 \qquad (11)$$

These losses can be eliminated almost completely either by the removal and repeated separation of the material removed, or by using hydrogen or a mixture of nitrogen and hydrogen as carrier gas, combined with a palladium separator.[98,99] The contraction of the chromatographic zone brought about by the pneumatic pulses arising when the circulation tap is turned can to some extent replace the use of thermal pulses.[100,101]

Table 1. Comparison of the parameters of the fine separation of benzene and hexadeuteriobenzene at $k' = 2$ in a long packed column (pc), the columns of a circulation assembly (pcc), and a capillary column with a thick layer of sorbent on the walls (c).

Parameter	Nitrogen			Helium		
	pc	pcc	c	pc	pcc	c
Diffusion coefficient in the gas phase at atmospheric pressure $10D_{g,0}$, $cm^2 s^{-1}$	1.06	1.06	1.06	4.14	4.14	4.14
Viscosity of the gas $10^{10}\eta$, kg s cm^{-2}	2.19	2.19	2.19	2.40	2.40	2.40
Diameter of carrier particles d_p, cm	0.02	0.02	0.02	0.02	0.02	0.02
Diffusion coefficient in the gas phase $10^2 D_g$, $cm^2 s^{-1}$	1.40	2.60	2.10	2.70	5.13	4.20
Permeability coefficient $10^7 K^0$, cm^2	3.95	14.04	16.20	3.95	14.58	16.20
Height equivalent to a theoretical plate HETP, cm	0.118	0.118	0.118	0.118	0.118	0.118
Column length l, cm	10620	425	10620	10620	425	10620
Mean linear velocity of the carrier gas $\bar{u}$, cm s^{-1}	1.40	2.60	3.55	2.70	5.13	7.08
Number of theoretical plates n	90000	3600	90000	90000	3600	90000
Number of half-cycles m	—	25	—	—	25	—
Separation time t_R, h	6.33	3.41	2.42	3.28	1.72	1.25
Duration of a half-cycle Δt, min	—	8.19	—	—	4.13	—
Inlet pressure p_{in}, MPa	1.12	0.47	0.70	2.34	0.97	1.49
Guiochon factor j_{pc}	0.81	1.00	0.84	0.78	1.00	0.80
HETP/$\bar{u}$, s^{-1}	0.084	0.045	0.032	0.043	0.023	0.016
$t_R/(t_R)_c$	2.62	1.41	1.00	2.62	1.38	1.00

Notes: separation factor of the components of the mixture 1.02, separation temperature 338 K, capillary column diameter 0.025 cm, fraction of the cross-section occupied by the gas in the capillary column $\kappa = 0.4$, attainable degree of separation $R = 1$.

Thus the ideas developed above about the effects of the pulse contraction and broadening of chromatographic zones, confirmed experimentally, can be used to estimate the place and importance of CGC relative to other chromatographic methods with similar efficiencies.

5. Comparison of the Parameters of Fine Separation in the Filled Columns of a Circulation Scheme and in Columns of Equivalent Length

Comparison of the parameters of fine separation (separation factor $\alpha - 1 \ll 1$) in circulation chromatography and in long packed columns[102-106] showed[107-109] that for a given degree of separation, the time taken for the analysis of a binary mixture is smaller by a factor of approximately 2–3 in the first case. This advantage of circulation chromatography increases as α approaches unity. Compared with long packed columns, circulation chromatography requires a pressure at the inlet to the column which is smaller by a factor of 3.5–4, and the length of the column can be reduced by a factor of 25–30.

Table 1[109] compares various parameters of fine separation in long packed columns, columns of a circulation assembly, and a capillary column with a thick layer of sorbent on the walls.[110,111] The rates of separation for the last two systems are similar. This is due to the relatively high permeability of a hypothetical column with separating power and analysis time equivalent to those of the columns of the circulation system. The slight increase in the HETP in the range of high velocities, observed in circulation chromatography, is much less than that in long columns. As a result of these factors, it is possible to achieve extremely high values of the efficiency of separation in capillary circulation chromatography on columns with a length of 7.5 m.[35,36]

Thus the method examined has extremely significant advantages over separation in long columns from the viewpoint of the total efficiency, separation time, magnitude of the pressure required, quantity of sorbent used, and necessary column length.

IV. THE EFFICIENCY OF THE COLUMNS IN PREPARATIVE CIRCULATION GAS CHROMATOGRAPHY AND METHODS FOR INCREASING THEIR PRODUCTIVITY

The expression for the HETP of a preparative column can be written as follows[112]

$$\text{HETP} = A^0 + \frac{2\gamma \cdot D_g}{\bar{u}} + \frac{8}{\pi^2}\left(\frac{k'}{1+k'}\right)^2 \frac{d_p^2}{D_g}\bar{u} + \frac{2k'}{3(1+k)^2}\frac{d_l}{D_l}\bar{u} + \frac{C_0 d^2}{4D_g}\bar{u}$$

where A^0 is the constant in the Van Deemter equation, γ the sinuosity coefficient, d_l the thickness of the liquid film, D_l and D_g the diffusion coefficients in the liquid and gas phases respectively, C_0 a constant, and d the column diameter.

For preparative columns containing 1–5% or less of the liquid phase,[113] by analogy with analytical columns, it is possible to write

$$\text{HETP} = \frac{2\gamma D_g}{\bar{u}} + \left\{\frac{\frac{C_0}{4}\left(\frac{d}{d_p}\right)^2 + \frac{C_0}{2}\left(\frac{d}{d_p}\right)^2 k' + \left[\frac{C_0}{4}\left(\frac{d}{d_p}\right)^2 + 0.81\right](k')^2}{(1+k')^2}\right\}\frac{d_p^2}{D_g}\bar{u} \qquad (12)$$

When the columns are carefully filled, the efficiences of preparative columns with relatively small diameters are comparable to those of analytical columns. If it is assumed that

$$\frac{C_0}{4}\left(\frac{d}{d_p}\right)^2 = 0.9$$

Eqn.(12) gives

$$\text{HETP} = \frac{2\gamma D_g}{\bar{u}} + \frac{0.9 + 1.8k' + 1.71(k')^2}{(1+k')^2} \cdot \frac{d_p^2}{D_g}\bar{u}$$

The form of the equation obtained is similar to that of the equation for analytical columns.[109]

It has been shown[114] that

$$\bar{u}_{pc} = 0.3\frac{\alpha-1}{d_p}[K^0(D_{r,0})_{pc}(p_{out})_{pc}/\eta]^{1/2}\{(k')^2/[0.9+1.8k'+1.71(k')^2]\}^{1/2} \quad (13)$$

where the subscript "pc" refers to the packed column. Substituting Eqn.(13) in the equation[115]

$$\Pi \approx 5\cdot 10^{-2}\left[\frac{d(\alpha-1)}{R}\right]^2 \varkappa c_g \bar{u}\frac{k'}{1+k'}$$

where Π is the productivity of the preparative chromagraphic assembly, and c_g the equilibrium concentration of the first and second components in the gas phase, gives

$$\Pi_{pc} \approx 1{,}5\cdot 10^{-2}\left[\frac{d(\alpha-1)}{R}\right]^2\frac{\alpha-1}{d_p}\varkappa c_g[K^0(D_{g\,0})_{pc}(p_{out})_{pc}/\eta]^{1/2}[\chi(k')]_{pc}$$

where

$$[\chi(k')]_{pc} = \{(k')^3/(1+k')^2[0.9+1.8k'+1{,}71(k')^2]\}^{1/2}$$

For the circulation system (subscript "pcc")

$$\Pi_{pcc} \approx 1{,}5\cdot 10^{-2}\left[\frac{d(\alpha-1)}{R}\right]^2\frac{\alpha-1}{d_p}\varkappa c_g\left[\frac{K^0_{pce}(D_{g\cdot 0})_{pc}(p_{out})_{pc}}{\eta}\right]^{1/2}[\chi(k')]_{pc}$$

where K^0_{pce} is the permeability coefficient of a hypothetical column equivalent to that used in the circulation system.

With allowance for the loss of substance during circulation (Eqn.(11)), the ratio of the productivities of the circulation system and the long packed column is given by

$$\left[\frac{\Pi_{pcc}}{\Pi_{pc}} = \frac{1}{[C_{pcc}]^{(n-1)/2}}\frac{1}{2.12}\left[\frac{C_{pcc}-1}{C_{pcc}+1}\frac{1}{j_{pc}(\alpha-1)}\frac{1+k'}{k'}\right]^{1/2}\right.$$

where j_{pc} is the Guiochon factor.[116]

These arguments show that for a given total efficiency and similar parameters of the columns used for the separation of substances with very similar properties ($\alpha = 1.02$), the productivity of long columns[117-119] is 2–2.5 times that of a circulation system. The productivity per unit volume of the sorbent,[47,120] however, is ~5 times greater for separation using circulation. This last feature is of considerable importance, since a decrease in the volume of sorbent is not only economical but also leads to a decrease in the volume of the apparatus and the expenditure of work and time in the preparation of the columns.

The efficiency and separating power of columns with length 2–4 m and diameter 10 mm in the preparative separation of mixtures with $1.02 < \alpha < 1.07$ by CGC have been studied.[121] Under conditions in which the removal of gas between the columns was negligibly small (~0.1% of the main stream), increase in the pressure at the outlet from the columns leads to an increase in the overall efficiency n and to an increase in the number of possible half-cycles m. At the same time there is an increase in the time taken for circulation, so that the productivity of the system for a constant volume of specimen added $M_0 = \text{const}$ decreases. Increase in M_0 leads to a decrease in the number of half-cycles and the number of theoretical plates.

Under the conditions of non-pulse circulation chromatography, the removal of gas leads to an additional decrease in productivity. In this case, however, there is a marked increase in the overall efficiency of the separation and an increase in the possible number of cycles. For large volumes of the added specimen and $C_{pcc} = 1.1$, the effect of the pulse broadening of the zone is of secondary importance, and a decisive contribution to the decrease in the overall efficiency is made by the influence of the volume of the specimen added.

The results show that it is appropriate to use CGC to separate compounds with very similar properties under non-pulse circulation conditions.

The decrease in the productivity of the circulation assembly compared with long columns can be avoided by the periodic introduction of the original mixture and removal of the separated components in semi-continuous circulation systems. This method has been used[4,122-124] to separate the alkali metals and various isotopes by ion-exchange chromatography.

For gas chromatography, a method for the semi-continuous separation of mixtures has been proposed,[51] in which, as the specimen is transferred from one column to another during circulation, a fresh portion of the mixture being separated is introduced each time into the supply section, situated between the maxima of the peaks of the components being separated. Subsequently, beginning from the moment when the total width of the zone becomes equal to the length of the chromatographic column, the ends of the chromatographic band are cut off, and the pure components are collected. The overall distribution curve of the component streams with periodic additional supply shows a clearly defined maximum, whose position coincides with the supply section (as a consequence of the superposition of a large number of Gaussian curves).

Circulation chromatography in which the enriched ends of the chromatographic band are cut off is characterised by a high purity of the products obtained. For the usual method of removing the separated zones of the chromatographic compounds, this quantity is given by the equation[125]

$$X_p = 1 - \frac{1}{2(2\pi R)^{1/2}}e^{-2R^2} \quad (14)$$

The value $R = 1$ from Eqn.(14) corresponds to the value $X_p \times 100 = 97.3\%$. The same quantity for circulation chromatography in which the enriched ends of the chromatographic band are cut off is given by the expression[97,126]

$$X'_p = e^{8R(R+1)}/(1+e^{8R(R+1)})$$

For $R' = 1$ the value obtained is $X'_p \times 100 = 99.99998\%$.

For $X_p = X'_p = 99.97\%$, the values obtained are $R \cong 2.8$ and $R' \cong 0.65$ using a column approximately ten times shorter in the circulation scheme.[97]

Thus a brief theoretical examination of the application of the circulation method with periodic additional supply, in which the ends of the chromatographic band are cut off, shows not only an increase in productivity but also the possibility of using this form of CGC to obtain substances with a high purity (≥99.97%).

V. SEPARATION OF ISOTOPICALLY SUBSTITUTED COMPOUNDS

In gas chromatography, the separation of isotopically substituted compounds is one of the most complex problems, requiring the use of highly efficient columns. Unfortunately, an increase in the separation factor by the use of selective liquid phases is almost impossible in this case, because of the extremely small magnitude of the isotope effects in the solution process.[127-129] In other words, change in the nature of the absorbent or liquid phase and the associated change in the adsorptive or solvent power cannot ensure success in the separation of compounds containing different isotopes of a given element.[130] Thus in the search for ways of solving this problem, the need to increase the efficiency of the chromatographic columns used is the most important feature to be considered.

In gas–liquid and gas–adsorption capillary chromatography, the efficiency of the columns can be increased by modifying the inner surface of the walls of the capillaries in different ways, or by depositing sorptive layers of different materials on the walls.[130]

Isotopically substituted compounds can be separated without using long capillary and packed columns of small diameter, by using short packed columns included in a circulation assembly. In the early stages of the development of circulation chromatography, fairly long columns were used. This made it possible to decrease the rate of broadening of the chromatographic band throughout the entire length of the column when the circulation tap was turned. The first isotopic separations[82] of methane, n-butane, cyclobutane, and their deuteriated and tritiated analogues were carried out on 15 m columns at atmospheric pressure at the outlet.

Columns with length 8 m, containing a solution of silver nitrate in ethylene glycol as stationary phase, have been used[83,84] for the gas-chromatographic separation of the isotopically substituted ethylenes C_2H_4, C_2H_3D, and $C_2H_2D_2$. The analysis using the circulation technique was more rapid than that using one long column; this is particularly important in the gas chromatography of isotopic molecules containing radioactive isotopes with short half-lives.

An attempt has been made[85] to separate the isotopes of carbon (^{12}C and ^{13}C) and sulphur (^{32}S and ^{34}S) as their volatile fluorides. The separation was carried out with Maxwell's circulation scheme[44] using two 8 m columns containing Porapak. Appreciable enrichment of the isolated fractions in the individual isotopes was achieved. Compounds labelled with radioactive isotopes (^{14}C, ^{35}S) were later analysed[131] on an automatic circulation gas radiochromatograph.

Table 2. Principal characteristics of the preparative gas-chromatographic separation of various isotopically substituted organic compounds by CGC on columns with dimensions 4 m × 23 mm.

Mixture being separated	Stationary phase	v, ml	w, %	L, m	α	$10^{-3}n$	HETP, mm	R
CH_3COCH_3—CD_3COCD_3	LAC-3R-728	0.90	39.9	108	1.012	35.5	3.0	0.56
C_6H_{12}—C_6D_{12}	LAC-3R-728	0.85	50.4	84	1.014	44.5	1.9	0.74
$C_6H_5CH_3$—$C_6D_5CD_3$	DC-550	0.50	44.0	84	1.013	44.0	1.9	0.68
C_6H_6—C_6D_6	DC-550	0.55	40.3	92	1.011	48.0	1.9	0.60
$C_6H_5C_2H_5$—$C_6D_5C_2H_5$	DC-550	0.50	28.7	128	1.006	74.5	1.7	0.41

Symbols: v is the volume of the specimen added, w the yield of separated products, and L the total column length traversed by the zones.

The separation of the carbon isotopes ^{12}C and ^{13}C as the oxide on molecular sieves, and the separation of the neon isotopes ^{20}Ne and ^{22}Ne, have been carried out;[132] appreciable enrichment in the isotopes was again achieved. Two columns with lengths of 0.5 m containing molecular sieves have been used[77] to separate the o- and p-isomers of H_2 and D_2. The separation factors were 1.032 for o- and p-hydrogen, 1.024 for protium deuteride and deuterium, and 1.019 for o- and p-deuterium.

The effects of pulse broadening and contraction of the chromatographic zones and the related increase in the efficiency of the process made it possible to separate benzene and hexadeuteriobenzene, and also benzene and trideuteriobenzene,[133] on columns with dimensions 4 m × 4 mm containing squalane as liquid stationary phase. In the last case, the compounds being separated passed through a total column length equivalent to 100 m, and the efficiency of the separation was ~120 thousand t.p. This high efficiency of separation was made possible by using non-pulse circulation chromatography conditions, characterised by a linear relationship between the number of theoretical plates and the number of columns passed through. The analytical separation of a number of oxygen-containing isotopically substituted organic compounds has been carried out:[69,134] C_2H_5OH–C_2D_5OD, CH_3COCH_3–CD_3COCD_3, iso-C_3H_7OH–iso-C_3D_7OD, under non-pulse CGC conditions.

The possibilities provided by preparative CGC for separating isotopically substituted organic compounds have been studied by the present authors.[135–137] The principal characteristics of the preparative gas-chromatographic separation of the mixtures studied by CGC are given in Table 2,[138] which shows that the efficiency of preparative separation by CGC reached several tens of thousands of t.p., which is 10–20 times the efficiency of long packed columns (dimensions 20 m × 9 mm),[113] and is comparable with the possibilities provided by capillary chromatography. Mass-spectrometric analysis showed that the purity of the fractions obtained was not lower than 95–97%. Fig.6 gives fragments of the chromatogram obtained in the preparative separation of toluene and perdeuteriotoluene.

As already noted, the productivity of circulation gas-chromatographic systems used to separate compounds with similar properties, requiring a highly efficient process, depends to a large extent on the quantity of eluate removed to maintain non-pulse chromatographic conditions. For the preparative separations listed in Table 2, this quantity was 2.0–2.4% of the total carrier-gas volume for a ratio of the

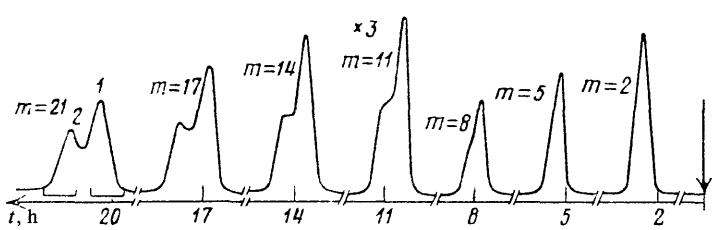

Figure 6. Fragments of the chromatogram for the preparative CGC separation of a mixture of octadeuteriotoluene (*1*) and toluene (*2*) on 4 m × 23 mm columns filled with DC-550 (15%). Conditions: temperature of the columns 105 °C, p_{in} = 0.64 MPa, C = 1.04, carrier-gas (nitrogen) velocity 400 ml min^{-1}, fraction of gas removed ~2%, initial loading 0.5 ml, yield of separated products 44%.

inlet and outlet pressures $C = 1.04-1.05$ and a pressure at the column inlet not exceeding 0.64 MPa. A decrease in the quantity C as a result of an increase in the inlet and outlet pressures (for the same given pressure drop) makes it possible to decrease the quantity of gas removed between the columns and hence to increase the productivity of the circulation assembly. Thus an increase in the pressure at the inlet into the system to, for example, 1.33 MPa (keeping the rate of supply of carrier gas at the outlet from the system unchanged) decreases the value of C to 1.023. This in turn makes it possible to decrease the quantity of gas removed between the columns and to decrease the loss during the separation of the above mixtures by 13–17%.

VI. SEPARATION OF ORGANIC COMPOUNDS WITH SIMILAR STRUCTURES AND PROPERTIES

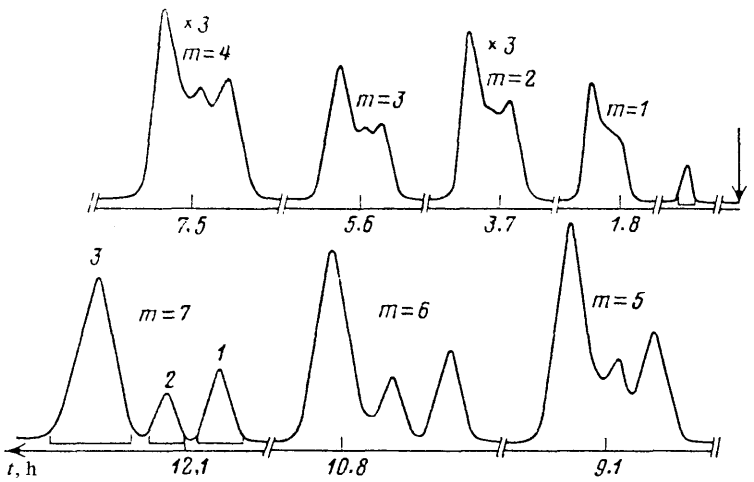
A field in which circulation chromatography is irreplaceable is the fine preparative separation of the isomers of volatile organic compounds. In a number of cases, the similarity in the properties of these isomers is even closer than that for isotopic molecules. The difficulties of separating isomers are also increased by the fact that newly synthesised organic compounds are often available only in very small quantities, corresponding to fractions of a gram or milligrams.

The problem of determing the isomeric composition of newly synthesised organic compounds is now being solved using highly efficient capillary chromatography, but the problem of the preparative separation of isomers with similar properties still remains one of the most difficult unsolved problems in organic chemistry. At the same time, the high efficiency of separation characteristic of CGC makes it possible to solve the problem of both the analytical and the preparative separation of isomeric structures for the resolution of a wide range of problems encountered in present-day organic chemistry.

Thus the composition of the products of the intramolecular acylation of ω-(5-methylthienyl-2)-alkanoic acids with side chains of different length has been studied[139] by the chromatographic analysis of the isomeric macrocyclic ketones with a thiophene ring. The isomeric cyclic thienones were separated on 3 m × 4 mm columns with a sorbent containing 3% SE-30 at a temperature of 235 °C, a carrier-gas velocity of 55 ml min^{-1}, $p_{in} = 0.89$ MPa, and $C = 1.25$. Twelve half-cycles in 2 h gave the value $R = 1.04$ for $\alpha = 1.023$. The efficiency of separation amounted to ~64 thousand t.p. Good results have been obtained in the separation of the geometric isomers of high-boiling saturated aliphatic acids on columns containing 5% Apiezon L.[94] Methyl oleate and methyl elaidate were separated at 220 °C after 11 half-cycles at $p_{in} = 0.70$ MPa and $p_{out} = 0.62$ MPa. The isomeric methyl linoleates were separated under similar conditions. The overall efficiency of separation in these experiments reached ~83 thousand t.p.

The *cis*- and *trans*-isomers of 1-ethyl-4-isopropylcyclohexane, 2-t-butyltetrahydrofuran, and 3-t-butylcyclopentanol have been separated on columns with length 3.5 m and diameter 10 mm, filled with the carrier Chezasorb with 5% XE-60.[70] An efficiency of separation of 3–8 thousand t.p. was achieved using a 20 mg specimen after 8–9 half-cycles. The same authors carried out the analytical separation of a mixture of the methyl esters of 1,3-dimethylcyclohex-3-ene-1-carboxylic and 1,4-dimethylcyclohex-3-ene-1-carboxylic acids — the isomeric products of a diene synthesis — with $\alpha = 1.044$. An efficiency of ~23.5 thousand t.p. with a separation factor of 1.04 was achieved after 8 half-cycles in 1.5 h.

A mixture of propylene oxide and propionaldehyde has been separated[140] by circulation gas chromatography on a column with Chromosorb W containing 30% dinonyl phthalate. The same author separated *m*- and *p*-xylenes after 3 half-cycles on two 45 cm columns filled with a sorbent containing 7.5% bentone-34 and 14.25% MS-555 silicone oil. The micropreparative separation of the isomeric tetramethylbenzenes



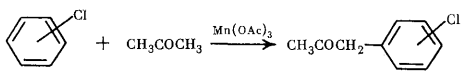


Figure 7. Fragments of the chromatogram of the preparative CGC separation of a mixture of *p*- (*1*), *m*- (*2*), and *o*-chlorobenzyl methyl ketones (*3*) on 4 m × 20 mm columns filled with LAC-3R-728 polyester (12%). Conditions: temperature of the columns 220 °C, $p_{in} = 0.58$ MPa, $p_{out} = 0.54$ MPa, carrier-gas (nitrogen) velocity 380 ml min^{-1}, removal of gas between columns 3.0%, original loading 0.5 ml, yield of separated products 83%.

durene and isodurene with an efficiency of separation of 26 thousand t.p. has been described.[115]

One of the advantages of CGC is its universal nature. As a result of the high efficiencies achieved by repeating the separation cycle, it is possible to obtain good results without using highly selective stationary liquid phases. Thus mixtures of the isomeric aromatic hydrocarbons: *m*- and *p*-xylenes, *p*-xylene and ethylbenzene,[137] and isomeric tetramethylbenzenes[115] were separated equally successfully by preparative methods on stationary phases which are not highly selective (LAC-3R-728, DC-550, and PEG-6000 respectively).

Circulation chromatography has also been used to study the kinetics of chemical reactions in reaction gas chromatography. Thus in a study of the kinetics of the Diels–Alder reaction between isoprene and maleic anhydride, the latter was deposited on Chromosorb P as stationary phase in the form of a solution in tricresyl phosphate. The change in the concentration of the volatile component isoprene was followed from the change in the area of the peaks recorded during circulation.[141]

To study the products of homolytic substitution in chlorobenzene by acetonyl radicals generated in the acetone–$Mn(OAc)_3$–AcOH redox system at 70 °C according to the published scheme,[142] the present authors[138] carried out the preparative separation of the mixtures of isomers formed, using highly efficient CGC.

The separation was carried out in an all-glass assembly with a gas-stream separating tap placed outside the thermostat.[75] Fragments of the chromatogram obtained are shown in Fig.7. Practically complete separation of all three isomers with an efficiency of separation of 12.5 thousand t.p. for the *p*-isomer was achieved after seven half-cycles, which corresponds to a total path length of the zones through the column of 28 m. The separation factors of the isomers according to the analytical chromatograms were 1.046 for *m*- and *p*-chlorobenzyl methyl ketones and 1.051 for the *o*- and *m*-structures.

A series of preparative separations of stereoisomeric derivatives of 1,3-dioxolane was described by the present authors.[143] These five-membered cyclic acetals are of interest as model systems for the study of the stereochemistry of various natural physiologically active substances. Calculations of the thermodynamic parameters of solution[143] showed that the diastereoisomers of 2,4,5-tri-isopropyl-, 2-phenyl-4,5-di-isopropyl-, and 2-phenyl-2-methyl-4,5-di-isopropyl-1,3-dioxolanes, synthesised by the acid-catalysed condensation of *meso*- and *dl*-2,5-dimethylhexan-3,4-diols with the corresponding carbonyl compounds, have extremely similar properties. The similar di- and trialkyl(aryl)-derivatives of 1,3-dioxolane also have similar properties,[144–147] and this made it necessary to use preparative columns with lengths of 20 m and 7.5 m. Examples of the preparative CGC separation of 2-substituted 4,5-di-isopropyl-1,3-dioxolanes are shown in Fig.8. The separation was carried out on a circulation assembly with the valve switching system described in Ref.137. The separation factor for the *syn*- and *anti*-isomers of 2-phenyl-4,5-di-isopropyl-1,3-dioxolane, according to the analytical chromatogram, was 1.048. The efficiency of the preparative separation at the seventh half-cycle reached 14.5 thousand t.p. (with respect to the *syn*-isomer). The separation of the *syn*- and *anti*-isomers of 2,4,5-tri-isopropyl-1,3-dioxolane, for which the differences in the free energies of solution in the temperature range 110–140 °C do not exceed 38–55 J $mole^{-1}$ (that is $\alpha = 1.011$–1.019), required an efficiency of more than 50 thousand t.p.

In the experiments described above, the quantity of products being separated simultaneously was 0.5–1.0 g, which corresponds to the scale of the laboratory studies usually carried out in synthetic organic chemistry at the present time. CGC may also find extensive application, however, in special preparative studies involving the accumulation of large quantities of individual isomers for a more detailed study of their physicochemical properties, for use in subsequent synthetic studies, or for carrying out biological tests.

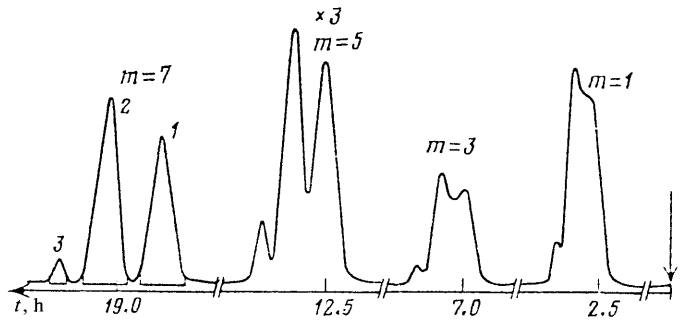

Figure 8. Fragments of the chromatogram of the preparative CGC separation of a mixture of *cis-anti*- (*1*), *cis-syn* (*2*), and *trans*-2-phenyl-4,5-di-isopropyl-1,3-dioxolanes (*3*) on 4 m × 23 mm columns filled with DC-550 polyphenylsiloxane oil (15%). Conditions: temperature of the columns 210 °C, $p_{in} = 0.64$ MPa, $p_{out} = 0.59$ MPa, carrier-gas (nitrogen) velocity 480 ml min^{-1}, removal of gas between columns 3.3%, original loading 0.6 ml, yield of separated products 79.5%.

The present authors used a semi-continuous version of highly efficient CGC to separate a mixture of the *cis*- and *trans*-isomers of 2,5-dimethyl-1,3-octathiane.[138] The preparative assembly operated at an inlet pressure of 0.59 MPa and an outlet pressure of 0.56 MPa, the quantity of carrier gas removed was 2%, the temperature of the columns 140 °C, the carrier-gas (nitrogen) velocity 300 ml min^{-1}, and the magnitude of the original specimen 0.65 ml. The stationary phase was Carbowax-20M (10%) in columns with dimensions 4 m × 23 mm. Beginning from the eighth half-cycle, when the band of chromatographic compounds had spread throughout the entire length of the column, the circulation was continued under non-pulse chromatographic conditions. The introduction of fresh portions of the mixture being separated and the removal of the enriched ends of the chromatographic band were carried out in each half-cycle in quantities of 50 μl. By the seventeenth half-cycle, ten additional quantities of the mixture had been introduced, and ~0.5 ml of separated products had been collected, corresponding to 43% of the total loading. Analysis of the collected fractions by capillary chromatography (column length 40 m, efficiency 70 thousand t.p. with respect to benzene) showed that the compounds were practically pure, containing not less than 99.6% of the individual components.

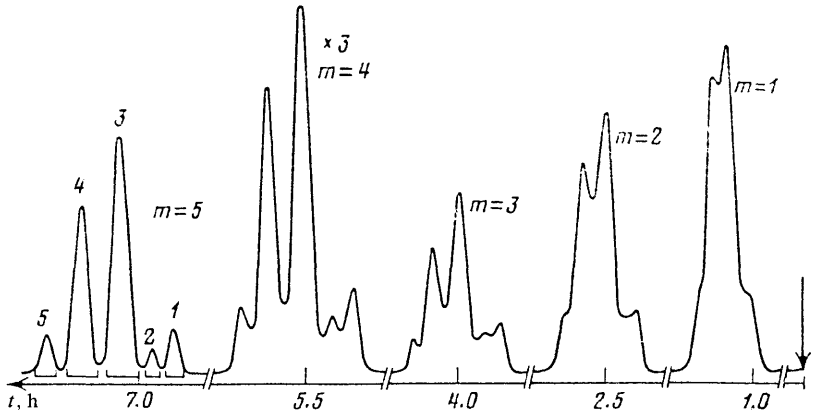

Figure 9. Fragments of the chromatogram of the preparative CGC separation of the high-boiling fraction of the distillate of the light oil, purified from phenol, of the tar from the semi-coking of Cheremkhovo coal on 4 m × 23 mm columns filled with DC-550 polyphenylsiloxane oil (15%). Conditions: temperature of columns 235 °C, p_{in} = 0.64 MPa, p_{out} = 0.58 MPa, carrier-gas (nitrogen) velocity 450 ml min^{-1}, removal of gas between columns 3.7%, original loading 0.5 ml; *1*) benzothiophene, *2*) methylbenzothiophene, *3*) β-methylnaphthalene, *4*) α-methylnaphthalene, *5*) biphenyl; efficiency of separation after the fifth half-cycle 12.5 thousand t.p. (with respect to β-methylnaphthalene); yield of separated products 84%.

Highly efficient preparative CGC has also been used to study the composition of various products of the treatment of coal. The importance of the complete and rational utilisation of the products of the processing of coal is making it necessary to develop accessible methods for separating and analysing the compounds originating from coal. The present authors and the Technological Laboratory of the Institute of Organic Chemistry of the Academy of Sciences of the USSR have studied the composition of the light oil, purified from phenol, with boiling point up to 250 °C, obtained as a fraction of the tar from the medium-temperature coking of coal from the Cheremkhovo deposit (Irkutsk coalfield).[138] The results obtained in the course of this study showed the promising possibilities provided by the use of preparative CGC at the stage involving the separation of the substances being studied from the semi-coking products. CGC showed that the light oil from the tar obtained in the medium-temperature coking of Cheremkhovo coal contains normal saturated, cyclic, and aromatic hydrocarbons, heterocyclic sulphur-containing compounds of the thiophene and benzothiophene series, and also condensed aromatic hydrocarbons, mainly of the naphthalene series. Fig.9 gives a chromatogram for the preparative separation of one of the narrow fractions of light oil from the tar obtained in the thermal degradation of Cheremkhovo coal.

Until recently, the separation of enantiomers of α-aminoacids by gas–liquid chromatography on optically active stationary phases was carried out using highly efficient capillary columns. Thanks to the availability of highly selective chiral liquid phases,[148] the number of which has increased considerably in recent years,[149–153] it has been possible to use for this purpose not only capillary columns but also fairly efficient short packed columns.[154–157] In this connection, promising possibilities are provided by the preparative separation of racemates using short packed columns with a selective chiral stationary phase included in a circulation scheme.

CGC has been used[158] to separate the enantiomers of alanine (Fig.10), valine, norvaline, leucine, norleucine, alloisoleucine, and isoleucine as the isopropyl esters of the N-trifluoroacetyl derivatives of N-stearyl-L-valine t-butylamide as liquid phase. The experiments were carried out as models for the subsequent preparative separation of the optically active compounds from the racemic mixtures, and it was shown[158] that the proposed chiral separating agent successfully combines a fairly high thermal stability (≧170 °C) with a high separating power. Even when the chiral diamide was mixed with achiral polyethylene glycol in the ratio 1 : 1, it was possible to achieve the practically complete separation of the enantiomers of a number of aminoacids.

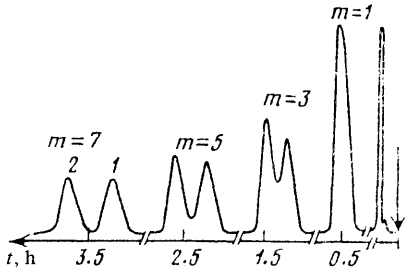

Figure 10. Fragments of the chromatogram of the CGC separation of the racemic isopropyl ester of N-trifluoroacetylalanine. Conditions: 2 m × 3 mm columns, N-stearyl-L-valine t-butylamide (4.6%) and PEG-20 M (4.4%) on N-Super Chromaton, temperature of columns 137 °C, p_{in} = 0.69 MPa, p_{out} = 0.65 MPa, carrier-gas (helium) velocity 35 ml min^{-1}, removal of gas between columns 2.5%, specimen volume 1 μl, *1* and *2*) *D*- and *L*-isomers respectively.

Subsequently, columns with dimensions 2.5 m × 8 mm with a sorbent containing 10% of the pure chiral stationary phase were used for the preparative separation of the racemates of a number of α-aminoacids.[159] Fig.11 gives fragments of t

chromatogram of the preparative separation of the racemate of norvaline by CGC. The optical purity of the separated enantiomers was followed from the dispersion of the optical rotation of the fractions collected and the pure *L*- or *D*-forms of the standard in solutions with similar concentrations, and it was shown that there was good agreement between the dispersion curves of the standard specimens and the corresponding separated fractions of the racemates, and also between the enantiomer pairs themselves. For a loading of the original racemate of 90–120 mg, the yield of the fractions separated, with allowance for the losses associated with the removal of part of the gas stream to achieve non-pulse chromatography conditions, is 70–90%. The productivity of the circulation assembly used, based on a standard LKhM-8MD gas chromatograph, corresponded to 0.4–0.6 g of racemate per day. A number of methods are available for increasing the productivity of the preparative separation of enantiomers, for example by the use of semi-continuous circulating systems. The above data make it possible to regard the preparative CGC of optically active substances as a new method for separating racemic mixtures, which has not been used before in organic chemistry and which may find a place in practical studies in fine organic synthesis and biochemistry.

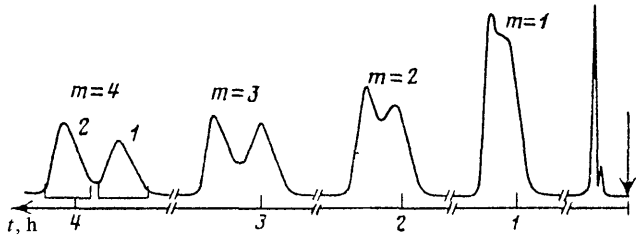

Figure 11. Fragments of the chromatogram of the preparative CGC separation of the racemic isopropyl ester of N-trifluoroacetylnorvaline on 2.5 m × 8 mm columns filled with N-stearyl-L-valine t-butylamide (10%) on Chromaton N-AW DMCS. Conditions: temperature of the columns 170 °C, p_{in} = 0.66 MPa, p_{out} = 0.60 MPa, carrier-gas (nitrogen) velocity 70 ml min^{-1}, removal of gas between columns 3.7%, original loading 90 mg; *1* and *2*) *D*(-) and *L*(+) isomers respectively; yield of separated products 90%.

---oOo---

The ideas developed in the last ten years on the effects of the pulse contraction and broadening of chromatographic zones, the optimum conditions of non-pulse circulation chromatography established on this basis, and the new apparatus and procedures for carrying out circulation chromatography have laid the foundations for the use of this method for the highly efficient preparative separation of compounds with extremely similar properties.

Preparative circulation chromatography under non-pulse conditions, characterised by a linear increase in the number of theoretical plates with increase in the number of cycles, makes it possible to achieve an efficiency of separation comparable with that of capillary chromatography, using specimens which are larger by factors of 10^6–10^7. This makes it possible, within an acceptable time, to obtain the pure separated components in quantities sufficient for subsequent physical, chemical, and biological studies.

The extension of theoretical knowledge and the improvement of circulation techniques and procedures are opening up extensive possibilities for the further development of the circulation method in various forms of chromatography — gas, vapour-phase, liquid — as a method for the physicochemical study, analysis, accumulation, and preparative separation of compounds with similar structures and properties.

The Temperature Jump Method and Its Application in the Study of Complex Formation

V.I.Pogonin and A.K.Chibisov

The present state of the apparatus used in the temperature jump method (methods for rapid heating, recording concentration changes, and collecting and processing experimental data) has been described. The formal kinetics of chemical relaxation on complex formation (relaxation times and amplitudes) have been examined. The mechanisms of complex formation by metal ions with various ligands, based on data obtained by the temperature jump method, have been discussed.
The bibliography contains 118 references.

I. INTRODUCTION

In the last twenty years, considerable progress has been made in the study of fast reactions, due primarily to the development of methods for studying them.[1,2] With the development of pulse, relaxation, flow, electrochemical, radiofrequency spectroscopic, and other methods,[2] it has now become possible to study intermediate short-lived products (excited molecules and complexes, ions, radicals, etc.), and also to study the kinetics and mechanism of reactions taking place in times of down to 10^{-14} s.

Among chemical relaxation methods, which are widely and successfully used to study the kinetics of reversible reactions in which equilibrium is established rapidly, an important place is occupied by the temperature jump method. The relative simplicity of the method makes it widely accessible for the study of redox and protolytic reactions, complex formation, enzyme reactions, hydrolysis, etc.

The present review examines the temperature jump method and its application in the study of complex formation in solution. The latest experimental techniques are described, and the formal kinetics of chemical relaxation on complex formation are examined. There is practically no information on these topics in the Soviet literature.

As an illustration of the application of the temperature jump method in the study of fast reactions, the process of complex formation by metal ions with various ligands is examined (the last review in this field was published in 1968 [3]).

II. THE TEMPERATURE JUMP METHOD

The temperature jump method is based on the temperature dependence of the equilibrium constant of a reaction. In accordance with the Van't Hoff isobar equation, the change in the equilibrium constant produced by change in temperature

is revealed by a corresponding change in the equilibrium concentrations of the reagents and reaction products. If the temperature of a system in equilibrium is increased rapidly (temperature jump), a relaxation process involving the establishment of new equilibrium concentrations begins to take place in the system. The rate of this process and the magnitude of the change in concentration are determined by the properties of the system being studied. Various methods for rapidly increasing the temperature, and methods for recording the concentration changes and for processing the experimental data, are examined below.

1. Methods for Rapidly Increasing the Temperature

The internal energy of a system is determined by the sum of the translational, rotational, vibrational, and electronic energies. Each of the components of the internal energy can be expressed in terms of the distribution of the populations of the corresponding levels and determines the corresponding temperature of the system: translational, rotational, vibrational, and electronic, which are equal to one another at thermodynamic equilibrium. An increase in one of these temperatures is brought about by a selective change in the distribution of the populations of the corresponding energy levels, but as a result of rapid internal relaxation and exchange of energy between the molecules in the liquid phase, temperature equilibrium is re-established in a time of <1 ns.[4]

Thus the temperature of a system can be increased rapidly and effectively by introducing energy in any of the above forms into the system. Thus different methods are available for rapidly increasing the temperature: a) Joule heating and a heat-exchange temperature jump (excitation as a result of a change in the rate of translational movement of the molecules); b) microwave heating (rotational excitation); c) laser temperature jump (vibrational excitation); and d) pulse ultraviolet irradiation (electronic excitation).

Joule heating is the simplest and most widely encountered method for obtaining a temperature jump. The heating is brought about by the discharge of a high-voltage condenser through the electrolyte solution. The discharge is usually controlled by a discharger or thyratron. The use of Joule heating makes it possible to obtain a temperature jump of 3–10 K in 1–10 μs in a system with a volume of 0.1–25 ml.[2] Decreasing the heating time is a technically difficult problem. A temperature jump apparatus has been described,[5] which can heat 0.2 ml of solution through 3 K in 300 ns by using a low-induction condenser, gas-filled dischargers of the "krytron" type, and a specially designed cell. A coaxial line, matched with the cell, is also used as condenser, to obtain a temperature jump of 10 K in 50 ns.[6] Decrease in the length of the coaxial line, and suppression of stray effects of electro-luminescence and electrodichroism, produced in solutions at electric field intensities greater than 60 kV cm^{-1}, made it possible to decrease the heating time to 10 ns.[7]

The heat-exchange temperature jump method uses two water-baths, kept at different constant temperatures.[8] The temperature jump can be made fairly large, and both heating and cooling of the system being studied are possible. The heat-exchange temperature jump method makes it possible to study relaxation processes with times of 0.5 s or more.

The temperature jump method is usually employed to study systems in equilibrium at normal atmospheric pressure. Temperature jump apparatus with Joule heating, in which the cell design makes it possible to study chemical relaxations at a pressure of up to 3×10^8 Pa, have also been described.[9–11]

Microwave heating, or heating as a result of the dielectric relaxation of a liquid, is achieved by using a pulse superhigh-frequency (SHF) generator. For water, as for most polar solvents, the maximum absorption of microwave energy takes place at ~10 GHz. Apparatus with SHF heating[12–15] usually employs magnetrons, operating under pulse conditions with an output energy of up to 0.5 J; the solution is heated through 0.2–2 K in 0.25–5 μs.

Rapid heating of a solution can be achieved by the absorption of the light pulse of, for example, a neodymium or ruby laser (laser temperature jump), for which the wavelength of the radiation is 1.06 μm or 0.694 μm respectively. For most solvents, however, the absorption at these wavelengths is extremely small, so that it is impossible to obtain a significant temperature jump. Thus when a neodymium laser operating under free lasing conditions[16,17] or under modulated Q conditions,[18,19] was used, the temperature jump for aqueous solutions was ≤ 0.6 K. A temperature jump of more than 1 K using a neodymium laser with modulated Q is prevented both by the plasma produced when the powerful laser radiation is focussed and by the two-photon processes excited in the system being studied.[20]

One method for increasing the efficiency of laser heating is by introducing into the system substances (absorbers) which strongly absorb the laser radiation. These substances should be chemically inert with respect to the solvent and the system being studied, should be transparent in the range of the spectrum where the changes in absorption are being recorded, and should effectively transform the absorbed light energy into heat during the laser pulse.[16] The absorbers proposed for use with a ruby laser include copper nitrate and Naphthol Green B for aqueous solutions,[16,21] and also vanadyl phthalocyanine for aprotic solvents.[22] The temperature jump achieved by this method was 2–5 K. The heating time was determined by the duration of the laser pulse and amounted to 300–500 μs. The heating time cannot be decreased using a laser with modulated Q, because of the bleaching of the absorber at high laser energy densities.

A temperature jump of 3–10 K has been obtained using lasers with modulated Q by employing Raman neodymium lasers. The radiation of the neodymium laser, operating under modulated Q conditions, is transformed into radiation of longer wavelength by passing through an appropriate Raman medium. A laser temperature jump apparatus using liquid nitrogen ($\lambda_{rad} = 1.41$ μm) as Raman medium has been described.[23–29] In this case, 0.1 ml of aqueous solution was heated through 5–9 K in 30 ns. A laser temperature jump apparatus using gaseous hydrogen ($\lambda_{rad} = 1.89$ μm) at a pressure of 8×10^6 Pa as Raman medium has been described.[30–32] The temperature jump was 2–3 K in 18–50 ns. The use of hydrogen does not require cryogenic techniques, as in the case of liquid nitrogen. 24 different media for Raman lasers, and also a laser temperature jump apparatus using liquid nitrogen, with subnanosecond resolution (heating time 180 ps), have been described.[33] The possible use of excimer lasers to achieve a temperature jump has been examined.[24] An iodine laser ($\lambda_{rad} = 1.315$ μm)[34–36] and a neodymium laser operating at 1.32–1.36 μm without additional transformation[37] have also been described.

The use of laser heating also makes it possible to study relaxation processes at pressures of up to $(2–3) \times 10^8$ Pa.[16,17]

Pulse ultraviolet lamps, whose radiation is readily absorbed by solvent molecules, can also be used to heat solutions rapidly. A spiral pulse ultraviolet lamp, through which a condenser with a capacity of 10 μF, charged to a voltage of 15 kV, is discharged, has been described.[38] In temperature

jump apparatus with ultraviolet irradiation, an aqueous solution has been heated through 1 K in 5 μs.

The characteristics of different methods for obtaining a temperature jump are compared in Table 1.

2. Methods for Recording Changes in Concentration

The most convenient and widely used method for recording the changes in the concentrations of the reagents or reaction products is the spectrophotometric method. In this method, a light beam (usually monochromatic) is passed through the cell containing the solution being heated, and falls on a photoreceiver (for example a photomultiplier instrument), whose output is transferred to an oscillograph, which records the change with time in the transmission in the cell. Methods for supplying the photomultiplier instrument, and the amplifiers and integrating and differentiating filters used in fast-action absorption spectrophotometry, have been described in detail.[2,39]

When an equilibrium between reagents and reaction products is displaced, their concentrations change by an amount Δc_i, leading to a change in the optical density of the system D in accordance with the Lambert–Beer law:

$$\Delta D = \sum_i \varepsilon_i \Delta c_i l$$

where ε_i is the molar absorptivity of the absorbing species, and l the optical path length of the cell. If $\Delta D \ll D$, the relative change in the light intensity is given by

$$\frac{\Delta I}{I_0} = -2.304 \frac{\Delta D}{D} \cdot D \cdot 10^{-D}$$

Differentiating this expression with respect to D and assuming that the ratio $\Delta D/D$ is constant gives the value of the optical density $D = 0.434$ corresponding to the maximum change in intensity ΔI. The maximum signal/noise (S/N) ratio for a system in which particles of only one kind absorb is observed at $D = 0.868$.[40] These conclusions apply to systems whose composition is fixed. For systems with varying composition, usually studied by the temperature jump method, the calculation of the optimum values of the S/N ratio is extremely complicated. The calculation has been carried out using a computer for the single-stage protolytic reaction of Methyl Orange (pH indicator).[41] The calculation showed that the conditions under which the highest values of the intensity of the photometric signal and the S/N ratio are reached depend on the absorption by the particles $\varepsilon_i l$, the pH of the solution, and the analytical concentration of the reagent. The optimum value of the optical density is approximately half that given in Ref. 40.

The sensitivity limit of a temperature jump apparatus with spectrophotometric recording is usually 10^{-3}–10^{-4} optical density units, and is determined by the S/N ratio. This ratio in turn depends on the transmission band Δf of the recording scheme, the quantum efficiency of the photo-receiver, and the intensity of the probing light source. The transmission band is usually controlled during the experiment by integrating and differentiating filters, and is kept in the following range:

$$(3-10)\,\tau_f^{-1} > \Delta f > (0.1-0.3)\,\tau_s^{-1}$$

where τ_f and τ_s are the relaxation times of the fastest and slowest of the processes being studied. The photo-receiver is usually a photomultiplier, for which the quantum yield of the photo-cathode is 1–30%. A silicon photo-diode, combined with a low-noise amplifier, has been used.[42] This apparatus makes it possible to record changes in absorption in the range 1 μs–5 ms with a better S/N ratio than a photomultiplier.

The S/N ratio can be increased by increasing the brightness of the probing light source. Increasing the brightness of a halogen lamp by a factor of ~5 with an increase in the supply voltage from 12 V (nominal conditions) to 16 V (forced conditions) in a time of 300 ms has been proposed.[43] Xenon arc lamps are usually supplied from stabilised current sources; by applying rectangular pulses of increased current with a duration reaching 1 ms, it is possible to obtain an increase in the brightness of the lamp by a factor of 50–700 in the blue and ultraviolet ranges of the spectrum.[44–46] This method makes it possible to improve the S/N ratio by a factor of $(I_f/I_{st})^{1/2}$, where I_f and I_{st} are the intensities of the emission from the lamp under forced and stationary conditions respectively. With pulse supply of the probing lamp, it is necessary to use special active schemes to compensate automatically the constant component of the output current of the photomultiplier[47] or a high-frequency passive filters.[48]

Table 1. Comparison of methods for obtaining a temperature jump.

Heating method	τ_h, s	ΔT, K	V_{min}, ml	Solvent requirements	Possibility of using conductometric recording	Possibility of operating under frequency conditions with accumulation and averaging	Possibility of application to heterogeneous systems	Technical simplicity of heating apparatus	Notes
Joule	10^{-8}–10^{-5}	5–10	0.1–10	polar, ionic strength 0.05–0.5 M	no	no	no	simple, particularly for the range 10^{-6}–1 s	side reactions with electrolysis products and the salts added to create the required ionic strength are possible
SHF	10^{-6}	0.2–2	0.07–0.2	polar, any ionic strength	yes	yes	yes	complex	—
Laser	10^{-8}–10^{-11}	2–9	0.01–0.1	none	yes	yes	yes	complex, particularly when liquid N_2 is used as the Raman medium	requires a laser with wavelength in the range of infrared absorption by the solvent; cavitation is possible; heating is non-uniform
Ultraviolet	$5 \cdot 10^{-6}$	5	5	none	yes	—	—	simple	simultaneous photochemical reactions are possible

Notes: τ_h = heating time; V_{min} = minimum solution volume.

In temperature jump apparatus with spectrophotometric recording, the reaction cell is usually illuminated by a monochromatic light beam, and this makes it possible to record the relaxation process at only one wavelength in one experiment. A series of experiments is necessary to record the spectrum of relaxation amplitudes. An apparatus using a polychromator has been described,[49] which makes it possible to record the kinetic curves at several wave-lengths simultaneously. The output from the polychromator passes to 10–30 photo-electronic multipliers, connected to digital memory blocks, in which the information is recorded simultaneously in the course of one experiment. A similar apparatus using a dissector instead of a set of photomultipliers has been described.[50] Spectrophotometric recording has a high selectivity, and this is of considerable importance in the study of multi-equilibrium systems.

Conductometric recording is used in addition to spectrophotometric recording in the temperature jump method. In conductometric recording, two planar inert electrodes (usually of platinum or gold), to which a probing voltage is applied, are placed in the reaction cell. Slow relaxation processes are observed using a constant current,[51] and fast processes using rectangular current pulses,[52] which makes it possible to decrease the polarisation effects at the electrodes. Best results are obtained, however, using a varying probing voltage; in this case, a high-frequency Wheatstone bridge is used to increase the sensitivity. The bridge is supplied from the generator of a variable (usually sinusoidal) voltage with a frequency of from 100 kHz to 10 MHz, and a narrow-band amplifier and oscillograph are connected to its diagonals. On temperature perturbation of the reaction system, the bridge is unbalanced; the change in the amplitude of the high-frequency voltage reflects the relaxation process.

Conductometric recording is used with microwave heating,[12–14] optical heating using lasers,[16,18] and pulse ultraviolet lamps.[38] Conductometric recording has a higher sensitivity (reaching 0.001%) than spectrophotometric recording, and, other conditions being equal, it makes it possible to obtain a better S/N ratio.[52]

Recording changes in fluorescence can be an extremely effective method for observing chemical relaxation in the temperature jump method. A temperature jump method with Joule heating, using recording of the changes in concentration both from the absorption and from the intensity of the fluorescence, has been described.[53] The cell had four optical windows, two of which were used for the spectrophotometric recording, and the other two were used to record both the polarised and the non-polarised fluorescence emission. An apparatus of this kind can also be used to record changes in the light scattering.

3. The Collection and Processing of the Experimental Data

In the general case, the kinetic curve obtained in temperature jump experiments represents the sum of several exponents:

$$S(t) = \sum_i A_i \, e^{-t/\tau_i}$$

where A_i and τ_i are the initial amplitude and time of the relaxation of the ith equilibrium. The traditional method for processing the kinetic curves involves photographing the curve on the oscillograph screen and then transforming it to a semilogarithmic scale. If the relaxation process is characterised by a single relaxation time, the transformed line is strictly linear. If there is a set of relaxation times, the transformed line is a curve. In this case, graphical separation of the terms included in the sum $S(t)$ is possible with the condition that the values of τ_i differ by factors of not less than 2–3.

The question of the accuracy of the graphical separation of two or more exponential curves has been discussed.[54,55]

Since the graphical procedure described above is extremely laborious, other methods have been proposed for determining relaxation times. Thus a method has been proposed[56] for processing a kinetic curve characterised by a single relaxation time. The photographic image of the curve is projected on to the screen of an oscillograph, and an exponentially damping voltage, produced by means of an RC-circuit, is supplied to the oscillograph input. The values of R and C are varied to achieve superposition of the curves and hence find the relaxation time $\tau = RC$. A scheme has been proposed,[57] in which the voltage from the output of the temperature jump apparatus is applied to the input Y of the oscillograph, and the voltage from the generator of the exponentially quenching voltage is applied to the input X. When the parameters are equal, a Lissajou figure in the form of a straight line is observed on the oscillograph screen. The uncertainty of the determination of the relaxation time by the two methods is 10%.

A widely encountered method for collecting and processing the experimental data involves the use of a computer. The signal being studied is transformed into digital form by means of an analogue–digital transformer and recorded in the memory of the computer, which processes the kinetic curve using special programs. A method involving the use of a digital oscillograph connected to a mini-computer has been described.[58] With a large number of breakdown points (up to 4000), the subsequent mathematical treatment to a large extent makes it possible to avoid periodic and random noise in the signal, to improve considerably the signal/noise ratio, and to determine the parameters of the relaxation process with a high accuracy.

Digital recording readily makes it possible to accumulate and average the signals from a large number (N) of repeat experiments, leading to an increase in the S/N ratio by a factor of $(N)^{1/2}$. This method, combined with preliminary analogue integration of the signal,[59] makes it possible to increase the accuracy of the processing of the experimental data. Accumulation and averaging of the signal are particularly easily carried out in apparatus with microwave[12,14,15] and laser[37] heating, since the excitation sources used in these methods operate under frequency conditions. Using accumulation of the data, it has been possible to achieve a sensitivity of 0.01% in the microsecond time range and of 0.1% in the nanosecond range.

The digital information is usually processed by the least-squares method for non-linear curves, and various methods for doing this on a computer have been described.[60–62]

III. THE KINETICS OF CHEMICAL RELAXATION ON COMPLEX FORMATION

In the general case, complex formation between metal ions $M^{m+}(aq)$ and a ligand $L^{n-}(aq)$ is a multi-stage reversible reaction:

$$M^{m+}(aq) + L^{n-}(aq) \rightleftharpoons ML^{(m-n)+} \qquad (1)$$

If the equilibrium constants of the reactions (1) depend on temperature, heating displaces the equilibrium. If the system is in equilibrium at an initial temperature T_1, then a rapid change (jump) in temperature by δT leads to the production of non-equilibrium conditions. The time taken to reach the new equilibrium state corresponding to the final temperature

T_2 (the relaxation time τ) in general depends on the rate constants of the stages of reaction (1) and on the equilibrium concentrations of the reagents. The change in the equilibrium concentrations of the reagents (the relaxation amplitude), reached at the moment when the new equilibrium state is established, depends on the magnitude and sign of the enthalpy changes of the separate stages of the reaction, and also on the equilibrium constants and the equilibrium concentrations of the reagents. Expressions for the relaxation times and relaxation amplitudes in complex formation reactions with different degrees of complexity are given below.[63,64]

1. Relaxation Time and Relaxation Amplitudes in a Single-Stage Reaction

In the simplest case, complex formation can be represented as a single-stage reversible reaction:

$$M^{m+}(aq) + L^{n-}(aq) \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} ML^{(m-n)+} \qquad (2)$$

The expression for the relaxation time is obtained from the equation describing the kinetics of the reaction after the temperature jump (or after any other short-lived perturbation of the system, leading to displacement of its equilibrium).[63] The expression for the rate of reaction (2)†

$$-d[M]/dt = k_{12}[M][L] - k_{21}[ML]$$

written in terms of the equilibrium (at the final temperature) concentrations $[\bar{M}]$, $[\bar{L}]$, and $[\overline{ML}]$ and in terms of the small changes in the concentrations $\delta[M]$, $\delta[L]$, and $\delta[ML]$, due to the displacement of the equilibrium, has the form:

$$-\frac{d[\bar{M}]}{dt} - \frac{d\,\delta[M]}{dt} = k_{12}[\bar{M}][\bar{L}] - k_{21}[\overline{ML}] + k_{12}\delta[M][\bar{L}] + k_{12}\delta[L][\bar{M}] + k_{12}\delta[M]\delta[L] - k_{21}\delta[ML] \qquad (3)$$

For small deviations from the equilibrium position, it is possible to neglect the term $k_{12}\delta[M]\delta[L]$ in Eqn.(3). The material balance equation

$$\delta[M] + \delta[ML] = 0;\ \delta[L] + \delta[ML] = 0 \qquad (4)$$

gives

$$-\frac{d\,\delta[M]}{dt} = k_{12}([\bar{M}] + [\bar{L}])\,\delta[M] + k_{21}\delta[M] \qquad (5)$$

Thus the expression for the relaxation time has the form

$$\tau = \{k_{12}([\bar{M}] + [\bar{L}]) + k_{21}\}^{-1} \qquad (6)$$

The values of the rate constants k_{12} and k_{21} of the forward and back reactions are found from the graphical plot of τ^{-1} against $[\bar{M}] + [\bar{L}]$. Since the values of $[\bar{M}] + [\bar{L}]$ are usually unknown, k_{12} and k_{21} are determined by the widely used technique in which one of the reagents, for example L, is taken in excess. In this case

$$\tau^{-1} = k_{12}[L]_0 + k_{21} \qquad (7)$$

where $[L]_0$ is the initial concentration of the ligand, and $[L]_0 \gg [M]_0$.

To find k_{12} and k_{21}, it is also convenient to use the expression

$$\tau^{-2} = k_{12}^2([M]_0 - [L]_0)^2 + 2k_{12}k_{21}([M]_0 + [L]_0) + k_{21}^2 \qquad (8)$$

obtained from Eqn.(6). In this case, the values $k_{12}k_{21}$ are found from the graphical plot of τ^{-2} against $[M]_0 + [L]_0$ for a fixed value of the difference $[M]_0 - [L]_0$. In the particular case where $[M]_0 = [L]_0$, expression (8) is simplified to

$$\tau^{-2} = 4k_{12}k_{21}[M]_0 + k_{21}^2 \qquad (9)$$

and when $[L]_0 \gg [M]_0$ it becomes Eqn.(7).

Eqn.(6) leads to an important conclusion about the conditions for achieving the extremal value of τ (τ resonance). Expressing the equilibrium concentrations $[M]$ and $[\bar{L}]$ in terms of the initial concentrations $[M]_0$ and $[L]_0$ and the equilibrium constant $K = k_{12}/k_{21}$ and using Eqn.(6) gives

$$\tau k_{12} = \{([M]_0 - [L]_0 + K^{-1})^2 + 4K^{-1}[L]_0\}^{-1/2} \qquad (10)$$

From Eqn.(10) it follows that τk_{12} has a maximum value for $[M]_0 = [L]_0$ (Fig.1):

$$\tau_{max} k_{12} = (K^{-2} + K^{-1}[L]_0)^{-1/2} \qquad (11)$$

Eqn.(11) can also be obtained from Eqn.(9), which is simplified when $K^{-1} \ll [M]_0$, $[L]_0$ (for a strongly bonded complex)

$$\tau_{max} k_{12} = \frac{1}{2}\left(\frac{K}{[L]_0}\right)^{1/2}$$

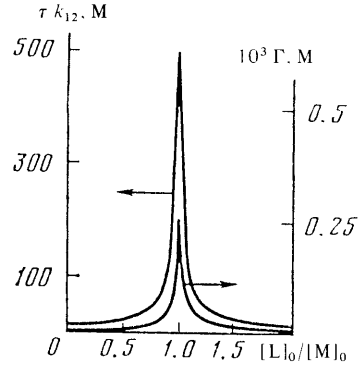

Figure 1. Resonance of τ and Γ for a strongly bonded complex, $K = 10^5$ litre mole^{-1}; $[M]_0 = 0.1$ M.[63]

The relationship between the relaxation amplitude and the parameters of reaction (2) can be established as follows. From the expression for the equilibrium constant

$$K = [\overline{ML}]/[\bar{M}][\bar{L}] \qquad (12)$$

it follows that

$$\frac{\delta K}{K} = \frac{\delta[ML]}{[\overline{ML}]} - \frac{\delta[M]}{[\bar{M}]} - \frac{\delta[L]}{[\bar{L}]} \qquad (13)$$

The material balance equation (4) and Eqn.(13) gives:

$$\frac{\delta K}{K} = \delta[ML]\left(\frac{1}{[\bar{M}]} + \frac{1}{[\bar{L}]} + \frac{1}{[\overline{ML}]}\right)$$

On the other hand, the Van't Hoff isobar equation

$$\left(\frac{\partial \ln K}{\partial T}\right)_p = \frac{\Delta H}{RT^2}$$

gives:

$$\frac{\delta K}{K} = \frac{\Delta H}{RT^2}\delta T$$

Thus the relaxation amplitude is given by the expression

† For simplicity, the indices $m+$, $n-$ and $(m-n)+$ for M, L, and ML are omitted.

$$\delta[ML] = \Gamma \frac{\Delta H}{RT^2} \delta T \qquad (14)$$

where $\Gamma = (1/[\bar{M}] + 1/[\bar{L}] + 1/[\overline{ML}])^{-1}$ is the transfer function of reaction (2).

Thus the change in the concentration of the complex (or the reagents) is directly proportional to the product of the enthalpy of the reaction, the change in temperature as a result of heating, and the value of the transfer function. The values of the relaxation amplitudes are important for finding the change in the enthalpy of the reaction. It follows from Eqn.(14) that the enthalpy of the reaction can be determined from direct measurements of $\delta[ML]$ (or $\delta[M]$, $\delta[L]$, the quantity δT, and the value of Γ.

A knowledge of the value of Γ is of considerable importance for finding the optimum conditions for measuring the relaxation amplitude. Using Eqn.(12), it is possible to write the expression for Γ as:

$$\Gamma = \frac{K[\bar{M}][\bar{L}]}{1 + K([\bar{M}] + [\bar{L}])} \qquad (15)$$

In the particular case where $[\bar{M}] = [\bar{L}]$, Eqn.(15) becomes

$$\Gamma = \frac{K[\bar{M}]^2}{1 + 2K[\bar{M}]} \qquad (16)$$

Introducing the parameter $\alpha = [\bar{M}]/[M]_0$ gives from Eqn.(16)

$$\Gamma = \frac{\alpha(1-\alpha)}{2-\alpha}[M]_0$$

from which the maximum value of $\Gamma/[M]_0 = 0.173$ for $\alpha = 0.586$.

The transfer function Γ can be expressed in terms of the initial concentrations $[M]_0$ and $[L]_0$. For this purpose, the expression for Γ is written in the form:

$$\Gamma = \frac{[\overline{ML}]K^{-1}}{[\bar{M}] + [\bar{L}] + K^{-1}}$$

obtained from Eqns.(12) and (15). Expressing $[\overline{ML}]$ in terms of $[M]_0$, $[L]_0$ and K gives:

$$\Gamma = \frac{1}{2K} \cdot \frac{[M]_0 + [L]_0 + K^{-1}}{\{([M]_0 - [L]_0)^2 + 2K^{-1}([M]_0 + [L]_0) + K^{-2}\}^{1/2}} - 1 \qquad (17)$$

Particular cases give the following results:

1) for $[M]_0 \gg [L]_0$

$$\Gamma = \frac{1}{2K}[([M]_0 + K^{-1})^{1/2} - 1] \qquad (18)$$

2) for $[M]_0 = [L]_0 \neq K^{-1}$

$$\Gamma = \frac{1}{2K}\left[\frac{2[M]_0 + K^{-1}}{(4K^{-1}[M]_0 + K^{-2})^{1/2}} - 1\right] \qquad (19)$$

3) for $[M]_0 = [L]_0 = K^{-1}$

$$\Gamma = 0.6K^{-1} \qquad (20)$$

Eqns.(18)–(20) can be used to calculate Γ, which is necessary to find ΔH for the reaction.

It is of interest to examine the case where a strongly bonded complex is formed, $[M]_0 + [L]_0 \gg K^{-1}$; in this case, from Eqn. (17):

$$\Gamma = \frac{1}{2K}\left(\frac{[M]_0 + [L]_0}{[([M]_0 - [L]_0)^2 + 2K^{-1}([M]_0 + [L]_0)]^{1/2}} - 1\right)$$

If the initial concentrations are equal, $[M]_0 = [L]_0$ (resonance of Γ), it follows that:

$$\Gamma \simeq {}^1/_2([M]_0/K)^{1/2}$$

It is obvious that the value of Γ for $[M]_0 = [L]_0$ is much greater than the limiting values of Γ for $[M]_0 \gg [L]_0$ or $[L]_0 \gg [M]_0$, that is for a given value of $[M]_0$ the plot of Γ against $[L]_0/[M]_0$ passes through a maximum, which is reached at $[L]_0/[M]_0 = 1$ (see Fig.1).

2. Relaxation Times and Relaxation Amplitudes in Two-Stage Reactions

A two-stage reaction (for example the formation of a unidentate complex) is described by the equation:

$$\underset{(I)}{M^{m+}(aq) + L^{n-}(aq)} \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} \underset{(II)}{M^{m+}(aq)L^{n-}} \underset{k_{32}}{\overset{k_{23}}{\rightleftharpoons}} \underset{(III)}{ML^{(m-n)+}} \qquad (21)$$

where $M^{m+}(aq)L^{n-}$ and $ML^{(m-n)+}$ are the outer-sphere and inner-sphere complexes. Stage (I) → (II) involves the loss of a water molecule from the hydration layer of the ligand, whereas stage (II) → (III) involves the loss of a water molecule from the hydration layer of the metal cation.

An approach to the derivation of an expression for the relaxation times in the case where the rates of reactions (I) ⇌ (II) and (II) ⇌ (III) are close to one another[63] is examined below. For small departures from the equilibrium position, the rate of reaction (21) is described by the system of equations #:

$$\begin{cases} -\dfrac{d\delta[M]}{dt} = k_{12}\delta[M]([\bar{M}] + [\bar{L}]) - k_{21}\delta[M(aq)L] \\ \dfrac{d\delta[ML]}{dt} = k_{23}\delta[M(aq)L] - k_{32}\delta[ML] \end{cases}$$

which with allowance for the material balance equation

$$\delta[M] + \delta[M(aq)L] + \delta[ML] = 0 \qquad (22)$$

becomes

$$\begin{cases} \dfrac{d\delta[M]}{dt} + \{k_{12}([\bar{M}] + [\bar{L}]) + k_{21}\}\delta[M] + k_{21}\delta[ML] = 0 \\ \dfrac{d\delta[ML]}{dt} + k_{23}\delta[M] + (k_{23} + k_{32})\delta[ML] = 0 \end{cases} \qquad (23)$$

The solution of this system of differential equations has the form:

$$\begin{cases} \delta[M] = \delta[M]^0 e^{-t/\tau} \\ \delta[ML] = \delta[ML]^0 e^{-t/\tau} \end{cases} \qquad (24)$$

Substituting Eqns.(24) in Eqns.(23) gives the relaxation times τ_1 and τ_2, $\tau_1 < \tau_2$, in the form:

$$\tau_1^{-1} = \frac{1}{2}\{\Sigma k + [(\Sigma k)^2 - 4\pi k]^{1/2}\} \qquad (25)$$

$$\tau_2^{-1} = \frac{1}{2}\{\Sigma k - [(\Sigma k)^2 - 4\pi k]^{1/2}\} \qquad (26)$$

where

$$\Sigma k = \tau_1^{-1} + \tau_2^{-1} = k_{12}([\bar{M}] + [\bar{L}]) + k_{21} + k_{23} + k_{32}$$
$$\Pi k = \tau_1^{-1}\tau_2^{-1} = k_{12}(k_{23} + k_{32})([\bar{M}] + [\bar{L}]) + k_{21}k_{32}$$

The values of the rate constants of reaction (21) are found graphically from the linear dependence of the sum $\tau_1^{-1} + \tau_2^{-1}$ on $([\bar{M}] + [\bar{L}])$ and the linear dependence of the product $\tau_1^{-1}\tau_2^{-1}$ on $([\bar{M}] + [\bar{L}])$.

It is important to examine the expressions for τ_1^{-1} and τ_2^{-1} for the following particular cases:

1) $k_{12}([\bar{M}] + [\bar{L}] + k_{21} \gg k_{23}, k_{32}$,
that is reaction (I) ⇌ (II) is more rapid than reaction (II) ⇌ (III) In this case the expression for the relaxation times have the form

$$\tau_1^{-1} = k_{12}([\bar{M}] + [\bar{L}]) + k_{21}$$
$$\tau_2^{-1} = k_{23}\frac{K_1([\bar{M}] + [\bar{L}])}{1 + K_1([\bar{M}] + [\bar{L}])} + k_{32}$$

where $K_1 = k_{12}/k_{21}$;

2) $k_{21} + k_{23} \gg k_{12}([\bar{M}] + [\bar{L}])$, k_{32},
that is the state of the complex M(aq)L can be regarded as

For simplicity, the indices $m+$, $n-$, and $(m-n)+$ for M, L, and ML are omitted.

stationary. In this case,

$$\tau_1^{-1} = k_{21} + k_{23}$$
$$\tau_2^{-1} = \frac{k_{12}k_{23}([\bar{M}] + [\bar{L}])}{k_{21} + k_{23}} + \frac{k_{21}k_{32}}{k_{21} + k_{23}} \quad (27)$$

Eqn.(27) can also be obtained by the method of stationary concentrations. It is simplified in the limiting cases where $k_{21} << k_{23}$ and $k_{21} >> k_{23}$. For $k_{21} << k_{23}$, that is when the formation of the inner-sphere complex ML is more rapid than the dissociation of the outer-sphere complex M(aq)L to the solvated ions,

$$\tau_2^{-1} = k_{12}([\bar{M}] + [\bar{L}]) + \frac{k_{21}k_{32}}{k_{23}}$$

In the opposite situation, when $k_{21} >> k_{23}$, Eqn.(27) becomes

$$\tau_2^{-1} = k_{23}K_1([\bar{M}] + [\bar{L}]) + k_{32}$$

3) $k_{23} + k_{32} >> k_{12}([\bar{M}] + [\bar{L}])$, k_{21}, that is reaction (II) ⇌ (III) is more rapid than reaction (I) ⇌ (II). In this case,

$$\tau_1^{-1} = k_{23} + k_{32}$$
$$\tau_2^{-1} = k_{12}([\bar{M}] + [\bar{L}]) + k_{21}k_{32}/(k_{23} + k_{32})$$

Table 2 gives expressions for the relaxation times in two-stage reactions taking place by different mechanisms. Thus the reaction

$$\begin{cases} LH^+ \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} L + H^+ \\ L + M \underset{k_{32}}{\overset{k_{23}}{\rightleftharpoons}} ML \end{cases} \quad (A)$$

corresponds to the typical case of complex formation involving a ligand L present in equilibrium with the protonated form LH^+. In the reaction

$$\begin{cases} L' \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} L \\ L + M \underset{k_{32}}{\overset{k_{23}}{\rightleftharpoons}} ML \end{cases} \quad (B)$$

the ligand is the reactive tautomer L, present in equilibrium with the tautomer L′ which does not form complexes. In the reaction

$$\begin{cases} M + L_1 \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} ML_1 \\ ML_1 + L_2 \underset{k_{32}}{\overset{k_{23}}{\rightleftharpoons}} ML_1L_2 \end{cases} \quad (C)$$

successive addition of the two ligands L_1 and L_2 takes place.

It is convenient to examine the expressions for the relaxation amplitudes for the example of the two-stage reaction (21) with the condition that there is an excess concentration of one of the reagents, for example the ligand ($[L]_0 >> [M]_0$).[63] In this case, from the expressions for the equilibrium constants, defined as

$$K_1 = \frac{k_{21}}{k_{12}[L]_0} = \frac{[\bar{M}]}{[\overline{M(aq)L}]}; \quad K_2 = \frac{k_{23}}{k_{32}} = \frac{[\overline{ML}]}{[\overline{M(aq)L}]}$$

it follows that the maximum changes in the concentrations $\delta[M]^0$ and $\delta[ML]^0$ can be written as

$$\delta[M]^0 = K_1\delta[M(aq)L]^0 + \delta K_1[\overline{M(aq)L}] \quad (28)$$

$$\delta[ML]^0 = K_2\delta[M(aq)L]^0 + \delta K_2[\overline{M(aq)L}] \quad (29)$$

The material balance equation (22) and Eqns.(28) and (29) give the following expressions for the relaxation amplitudes

$$\delta[M]^0 = [\bar{M}]\frac{(1 + K_2)\cdot\delta K_1/K_1 - K_2\cdot\delta K_2/K_2}{1 + K_1 + K_2} \quad (30)$$

$$\delta[ML]^0 = [\overline{ML}]\frac{(1 + K_1)\cdot\delta K_2/K_2 - K_1\cdot\delta K_1/K_1}{1 + K_1 + K_2} \quad (31)$$

$$\delta[M(aq)L]^0 = -[\overline{M(aq)L}]\frac{K_1\cdot\delta K_1/K_1 + K_2\cdot\delta K_2/K_2}{1 + K_1 + K_2} \quad (32)$$

Since the relative changes in the equilibrium constants K_1 and K_2 are proportional to the enthalpies of the reactions

$$\delta K_1/K_1 = (\Delta H_1/RT^2)\delta T,\ \delta K_2/K_2 = (\Delta H_2/RT^2)\delta T$$

where ΔH_1 and ΔH_2 are the enthalpies of reactions (II) ⇌ (I) and (II) ⇌ (III), it follows that the expressions for the relaxation amplitudes (30)–(32) represent essentially the dependence of these amplitudes on the enthalpies ΔH_1 and ΔH_2.

Table 2. Expressions for the relaxation times for the two-stage reactions (A)–(C) for different relationships between the rate constants of the separate stages; $K_1 = k_{12}/k_{21}$, $K_2 = k_{32}/k_{23}$.

Reaction	Conditions	τ_1^{-1}	τ_2^{-1}
(A)	$k_{12} + k_{21}([\bar{L}] + [\bar{H}^+]) \gg k_{23}([\bar{L}] + [\bar{M}]),\ k_{32}$	$k_{12} + k_{21}([\bar{L}] + [\bar{H}^+])$	$k_{23}\left([\bar{L}] + [\bar{M}]\frac{K_1 + [\bar{L}]}{K_1 + [\bar{L}] + [\bar{H}^+]}\right) + k_{32}$
	$k_{23}([\bar{L}] + [\bar{M}]) + k_{32} \gg k_{12},\ k_{21}([\bar{L}] + [\bar{H}^+])$	$k_{23}([\bar{L}] + [\bar{M}]) + k_{32}$	$k_{12} + k_{21}\times\left([\bar{L}] + [\bar{H}^+]\frac{K_2 + [\bar{L}]}{K_2 + [\bar{L}] + [\bar{M}]}\right)$
(B)	$k_{12} + k_{21} \gg k_{23}([\bar{L}] + [\bar{M}]),\ k_{32}$	$k_{12} + k_{21}$	$k_{23}\left([\bar{L}] + \frac{K_1[\bar{M}]}{1 + K_1}\right) + k_{32}$
	$k_{23}([\bar{L}] + [\bar{M}]) + k_{32} \gg k_{12},\ k_{21}$	$k_{23}([\bar{L}] + [\bar{M}]) + k_{32}$	$k_{12} + k_{21}\frac{K_2 + [\bar{L}]}{K_2 + [\bar{L}] + [\bar{M}]}$
(C)	$k_{12}([\bar{M}] + [\bar{L}_1]) + k_{21} \gg k_{23}([\overline{ML_1}] + [\bar{L}_2]),\ k_{32}$	$k_{12}([\bar{M}] + [\bar{L}_1]) + k_{21}$	$k_{23}\left([\overline{ML_1}] + [\bar{L}_2]\times\frac{K_1[\bar{M}] + K_1[\bar{L}_1]}{1 + K_1([\bar{M}] + [\bar{L}])}\right) + k_{32}$
	$k_2([\overline{ML_1}] + [\bar{L}_2]) + k_{32} \gg k_{12}([\bar{M}] + [\bar{L}_1]),\ k_{21}$	$k_{23}([\overline{ML_1}] + [\bar{L}_2]) + k_{32}$	$k_{12}([\bar{M}] + [\bar{L}_1]) + k_{21}\frac{K_2 + [\overline{ML_1}]}{K_2 + [\overline{ML_1}] + [\bar{L}_2]}$

In particular, if complex formation is conjugated with the protonation of the ligand, then for a definite value of the ratio $\Delta H_1/\Delta H_2$, a change in the sign of the relaxation amplitudes (a bicipital phenomenon[65–67]) with change in the pH of the medium is possible.

Thus the following reaction can be considered:

$$\begin{matrix} M + L \overset{\Delta H_1}{\rightleftharpoons} ML \\ L + H^+ \overset{\Delta H_2}{\rightleftharpoons} LH^+ \end{matrix} \quad (33)$$

Assuming that the stage involving the protonation of the ligand L is more rapid than the stage involving the formation of the complex ML, and also that complex formation takes place in an excess concentration of the metal, $[M]_0 >> [L]_0$, it follows that the relaxation amplitudes $\delta[H^+]^0$, $\delta[L]^0$, and $\delta[ML]^0$ can be expressed as follows in terms of the transfer function Γ of reaction (33), where $\Gamma^{-1} = [\bar{L}]^{-1} + [\bar{H}^+]^{-1} +$

$[\overline{LH^+}]^{-1}$, and the enthalpies ΔH_1 and ΔH_2:

$$-\delta[H^+]^0 = \Gamma \frac{\Delta H_2}{RT^2}\delta T$$
$$\frac{\delta[ML]^0}{[\overline{ML}]} - \frac{\delta[L]^0}{[\overline{L}]} = \frac{\Delta H_1}{RT^2}\delta T$$

The material balance equation

$$\delta[L]+\delta[ML]+\delta[LH^+]=0$$

gives

$$\delta[ML]^0 = \frac{[\overline{L}][\overline{ML}]}{[\overline{L}]+[\overline{ML}]}\left(\Delta H_1 - \frac{\Delta H_2}{1+\beta}\right)\frac{\delta T}{RT^2} \quad (34)$$

where

$$\beta = \frac{1}{K[\overline{H^+}]} + \frac{[\overline{L}]}{[\overline{H^+}]}, \quad K = [\overline{LH^+}]/[\overline{L}][\overline{H^+}] \quad (35)$$

It follows from Eqns.(34) and (35) that if $\Delta H_2/\Delta H_1 > 1$, then the relaxation amplitude $\delta[ML]^0$ changes sign when

$$[\overline{H^+}] = \frac{K^{-1}+[\overline{L}]}{\Delta H_2/\Delta H_1 - 1}$$

Eqns.(30)–(32) represent the total changes in the concentrations of M, ML, and M(aq)L in reaction (21). Expressions are given below for the relaxation amplitudes in the stages (I) ⇌ (II) (provisionally taken as fast, subscript A) and (II) ⇌ (III) (provisionally taken as slow, subscript B) of reaction (21):

$$\delta[M]^0_A = [\overline{M}]\frac{1}{1+K_1}\cdot\frac{\delta K_1}{K_1}$$
$$\delta[M(aq)L]^0_A = -[\overline{M(aq)L}]\frac{K_1}{1+K_1}\frac{\delta K_1}{K_1}$$
$$\delta[M]^0_B = [\overline{M}]\frac{K_2(K_1\cdot\delta K_1/K_1 - \delta K_2/K_2 - K_1\cdot\delta K_2/K_2)}{(1+K_1)(1+K_1+K_2)} \quad (36)$$

$$\delta[M(aq)L]^0_B = [\overline{M(aq)L}]\frac{K_2(K_1\cdot\delta K_1/K_1 - \delta K_2/K_2 - K_1\cdot\delta K_2/K_2)}{(1+K_1)(1+K_1+K_2)} \quad (37)$$

The amplitude $\delta[ML]^0_B = \delta[ML]^0$ is given by Eqn.(31).

It follows from Eqns.(31), (36), and (37) that to observe stage (II) ⇌ (III) by the temperature jump method it is not necessary that the enthalpy of this stage have a finite value ($\Delta H_2 \sim \delta K_2/K_2 \neq 0$). It follows from Eqn.(31) that for $\Delta H_2 = 0$,

$$\delta[ML]^0 = -[\overline{ML}]\frac{K_1\cdot\delta K_1/K_1}{1+K_1+K_2}$$

that is the relaxation amplitude $\delta[ML]^0$ is determined essentially by the enthalpy ΔH_1 of the stage (I) ⇌ (II). This feature is of considerable practical importance; small relaxation amplitudes can be increased considerably by selecting a stage (I) ⇌ (II) with a high rate of establishment of equilibrium and a high enthalpy value.

3. Relaxation Times in Multi-Stage Reactions

In the general case, the kinetics of multi-stage reactions involving $n+1$ states can be described by a system of n linear differential equations[63]

$$\frac{d[x_i]}{dt} + \sum_{j=1}^{n} a_{ij}[x_j] = 0, \text{ where } i, j = 1, 2, \ldots, n \quad (38)$$

Here, $[x_j] = \delta[c_j] = [c_j] - [\bar{c}_j]$ is the change in the concentration of the jth state for a small displacement of the equilibrium, and a_{ij} is a parameter which depends on the rate constants and the equilibrium concentrations of the states of the multi-stage reaction.

The solution of the system of equations (38) is a set of n exponents of the form:

$$[x_i] = \sum_{j=1}^{n}[x_i]^0_j e^{-t/\tau_j}, \text{ where } i, j = 1, 2, \ldots, n \quad (39)$$

The relaxation times (relaxation spectrum) are found by solving the system of algebraic equations obtained by substituting Eqn.(39) in Eqn.(38).

The most general example of a reaction involving more than two stages is the three-stage reaction of complex formation with a bidentate ligand:

$$M^{m+}(aq) + L^{n-}(aq) \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} M^{m+}(aq)L^{n-} \underset{k_{32}}{\overset{k_{23}}{\rightleftharpoons}} ML^{(m-n)+} \underset{k_{43}}{\overset{k_{34}}{\rightleftharpoons}} M{=}L^{(m-n)+} \quad (40)$$
(IV) (V) (VI) (VII)

which compared with reaction (21) includes the additional stage (VI) ⇌ (VII) involving the formation of the bidentate complex $M{=}L^{(m-n)+}$, associated with the loss of a second water molecule from the hydration layer of the metal cation. In accordance with the scheme for the solution of Eqns.(38) and (39), the three values of the relaxation times characterising the three-stage reaction (40) are the roots of the cubic equation

$$(1/\tau)^3 + A_1(1/\tau)^2 - A_2(1/\tau) + A_3 = 0$$

where

$$A_1 = k_{12}([\overline{M}]+[\overline{L}]) + k_{21} + k_{23} + k_{32} + k_{34} + k_{43}$$
$$A_2 = (k_{21}+k_{12}([\overline{M}]+[\overline{L}]))(k_{23}+k_{32}) + (k_{23}+k_{32})(k_{34}+k_{43}) + (k_{21}+k_{12}([\overline{M}]+[\overline{L}]))(k_{34}+k_{43}) - k_{21}k_{23} - k_{32}k_{34}$$
$$A_3 = (k_{21}+k_{12}([\overline{M}]+[\overline{L}]))(k_{23}+k_{32})(k_{34}+k_{43}) - (k_{21}+k_{12}([\overline{M}]+[\overline{L}]))k_{32}k_{34} - (k_{34}+k_{43})k_{21}k_{23}$$

The corresponding concentration dependence of the relaxation times τ_1, τ_2, and τ_3, obtained experimentally, and the relationships

$$A_1 = \tau_1^{-1} + \tau_2^{-1} + \tau_3^{-1}$$
$$A_2 = \tau_1^{-1}\tau_2^{-1} + \tau_1^{-1}\tau_3^{-1} + \tau_2^{-1}\tau_3^{-1}$$
$$A_3 = \tau_1^{-1}\tau_2^{-1}\tau_3^{-1}$$

can now be used to determine the values of all six rate constants of reaction (40).

In complex formation, the stages of the reaction often differ considerably in the rates at which equilibrium is established. In this case, the analysis of the relaxation spectrum is much easier. Table 3 gives expressions for three relaxation times, corresponding to fast, medium, and slow stages in the reaction.

A frequently encountered particular case is complex formation (A) (R.p.1612) not accompanied by spectral changes. The kinetics of the establishment of equilibrium can then be followed using an acid–base indicator added to the system. The set of coupled equilibria is represented by the scheme:[2]

$$M + L \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} ML$$
(VIII) (IX)
$$H^+ + L \rightleftharpoons LH^+$$
$$H^+ + Ind \rightleftharpoons Ind\,H^+$$

If the formation of ML is slow compared with the rapid protonation of the ligand L and the indicator Ind, the establishment of equilibrium (VIII) ⇌ (IX) after the temperature jump is followed from the change in the colour of the indicator. The relaxation time is given by the expression

$$\tau^{-1} = k_{12}\left(\frac{[\overline{M}]}{1+\gamma} + [\overline{L}]\right) + k_{21}$$

where

$$\gamma = \frac{[\overline{H^+}]}{K_{LH^+} + \chi[\overline{L}]}; \quad \chi = \frac{K_{IndH^+} + [\overline{H^+}]}{K_{IndH^+} + [\overline{H^+}] + [\overline{Ind}]};$$
$$K_{LH^+} = [\overline{H^+}][\overline{L}]/[\overline{LH^+}]; \quad K_{IndH^+} = [\overline{H^+}][Ind]/[\overline{IndH^+}]$$

If the values of K_{LH^+} and K_{IndH^+} are known, the value of γ can be calculated for any value of the pH of the solution, and this in turn makes it possible to determine graphically the values of k_{12} and k_{21} from the experimentally determined value of τ.

Table 3. Expressions for the relaxation times in the system

$$M(aq) + L(aq) \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} M(aq)L \underset{k_{32}}{\overset{k_{23}}{\rightleftharpoons}} ML \underset{k_{43}}{\overset{k_{34}}{\rightleftharpoons}} M\text{-}L$$

for different ratios of the reaction rate constants*.

Conditions	τ_1^{-1} (fast stage)	τ_2^{-1} (medium stage)	τ_3^{-1} (slow stage)
$k_{12}([\overline{M}]+[\overline{L}])$, $k_{21} \gtrsim k_{23}$, $k_{32} \gtrsim k_{34}$, k_{43}	$k_{12}([\overline{M}]+[\overline{L}])+k_{21}$	$k_{23}\frac{K_1([\overline{M}]+[\overline{L}])}{1+K_1([\overline{M}]+[\overline{L}])}+k_{32}$	$k_{34}\frac{K_1([\overline{M}]+[\overline{L}])K_2}{1+K_1([\overline{M}]+[\overline{L}])(1+K_2)}+k_{43}$
$k_{12}([\overline{M}]+[\overline{L}])$, k_{21}, k_{23}, $k_{32} \gtrsim k_{34}$, k_{43}	see Eqn. (25)	see Eqn. (26)	$k_{34}\frac{K_1([\overline{M}]+[\overline{L}])K_2}{1+K_1([\overline{M}]+[\overline{L}])(1+K_2)}+k_{43}$
$k_{12}([\overline{M}]+[\overline{L}])$, k_{21}, k_{34}, $k_{43} \gtrsim k_{23}$, k_{32}	$k_{12}([\overline{M}]+[\overline{L}])+k_{21}$	$k_{34}+k_{43}$	$k_{23}\frac{K_1([\overline{M}]+[\overline{L}])}{1+K_1([\overline{M}]+[\overline{L}])}+k_{32}\frac{1}{1+K_3}$

* $K_1 = k_{12}/k_{21}$, $K_2 = k_{23}/k_{32}$, $K_3 = k_{34}/k_{43}$.

IV. THE APPLICATION OF THE TEMPERATURE JUMP METHOD IN THE STUDY OF COMPLEX FORMATION

Studies of the kinetics of complex formation carried out in the early stages of the development of the chemistry of complex compounds made possible an arbitrary division into inert and labile complexes.[68,69] For inert complexes, substitution takes place in minutes or longer, whereas for labile complexes the half-reaction time is much less than one second.[69] A very large number of labile complexes, formed by the ions of the alkali, alkaline earth, and transition metals with various inorganic and organic ligands, are now known.[3,70–77] The study of labile complexes has become possible only with the development of methods for studying fast reactions, in particular the temperature jump method.

A large number of studies have been devoted to complex formation between a hydrated metal ion $M^{m+}(aq)$ and a unidentate ligand $L^{n-}(aq)$. The most general scheme for a reaction of this kind is given below:[63–64]

$$\underset{(X)}{M^{m+}(aq) + L^{n-}(aq)} \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} \underset{(XI)}{M^{m+}(aq)\,(aq)\,L^{n-}} \underset{k_{32}}{\overset{k_{23}}{\rightleftharpoons}} \underset{(XII)}{M^{m+}(aq)L^{n-}} \underset{k_{43}}{\overset{k_{34}}{\rightleftharpoons}} \underset{(XIII)}{ML^{(m-n)+}} \quad (41)$$

The initially solvated (hydrated) ions of the metal and the ligand, as a result of diffusion, form an encounter complex (XI), or an ion pair, in which the ions are separated from one another by not more than two monolayers of solvent molecules. The stage of ion pair formation is diffusion controlled, and therefore very fast. The rate constant k_{12} of the diffusion approach of the ions can be calculated from the expression[64,78]

$$k_{12} = \frac{4\pi Na}{1000}(D_+ + D_-)\left(\frac{\alpha}{e^\alpha - 1}\right)$$
$$\alpha = \frac{mne_0^2}{\varepsilon akT}\left(\frac{1}{1+\varkappa a}\right)$$
$$\varkappa = \left(\frac{8\pi e_0^2 NI}{1000\varepsilon kT}\right)^{1/2}$$

where D_+ and D_- are the diffusion coefficients of the cation and the anion, N Avogadro's number, a the distance of closest approach in the encounter complex; e_0 the charge of the electron, ε the dielectric constant of the medium, I the ionic strength, and k the Boltzmann constant.

The value of k_{12} for an encounter complex, for example with the 1:1 composition and $a = 0.7$ nm in an aqueous solution at $I = 0.01$ and 25 °C, is 1.1×10^{10} litre mole^{-1} s^{-1}.

The rate constant k_{21} for the diffusion separation of an encounter complex is given by the expression:[78,79]

$$k_{21} = \frac{3(D_+ + D_-)}{a^2}\frac{\alpha e^\alpha}{e^\alpha - 1}$$

The value of k_{21} for the same conditions is 6×10^9 s^{-1}.

The next stage (XI) ⇌ (XII) reflects the formation of the outer-sphere complex (XII), in which two ions are separated by only one monolayer of solvent molecules. Since the interaction between the ligand anion and the water molecule is weaker than that between the metal cation and the water molecule, the formation of the outer-sphere complex is accompanied by the loss of a water molecule from the hydration layer of the ligand. The stage (XI) ⇌ (XII) is also fast (k_{23}, $k_{32} \cong 10^8$–10^9 s^{-1}). The temperature jump method cannot distinguish stages (X) ⇌ (XI) and (XI) ⇌ (XII). Their existence follows from ultrasonic absorption data; three relaxation processes have been established for aqueous solutions of $CoSO_4$, $NiSO_4$, and $ZnSO_4$.[80]

The final stage (XII) ⇌ (XIII), that is the replacement of a water molecule from the inner coordination sphere of the metal ion by a molecule (ion) of the ligand, is the slowest stage, and gives the inner-sphere complex (XIII). Thus the stage (XII) ⇌ (XIII) is the limiting stage, and this makes it possible to simplify the reaction scheme (41) to the form given by scheme (21). The applicability of scheme (21) is confirmed by the experimental detection of two relaxation times. Thus the slow relaxation time is given by the expression

$$\tau^{-1} = K_1 k_{23}\frac{[\overline{M}]+[\overline{L}]}{1+K_1([\overline{M}]+[L])} + k_{32}$$

which can be used to find the value of k_{32} and the product $K_1.k_{23}$. The values of the product $K_1.k_{23}$ obtained in this way for complex formation by Ni^{2+} with various unidentate ligands ($CH_3PO_4^{2-}$, CH_3COO^-, NCS^-, F^-, HF, NH_3, C_5H_5N, etc.) have been published.[73] If K_1 is known, the rate constant for the formation of the inner-sphere complex k_{23} can also be determined.

The equilibrium constant K_1 can be estimated from the expression[81,82]

$$K_1 = \frac{4\pi Na^3}{3000}e^{-\alpha} \quad (42)$$

For some reactions, independent estimates of the values of K_1 have been obtained from spectral, polarometric, NMR, and EPR measurements.[69,74,83] These estimates show fairly good agreement with the values calculated from Eqn. (42) (see

Table 4), if it is assumed that $a = 4-5$ Å, as in the estimation of the distance of the closest approach in an encounter complex.[74]

Table 4. Values of the equilibrium constant K_1 for the formation of the outer-sphere complex in the system $M(aq)^{m+} + L(aq)^{n-}$.

System	K_1, litre mole^{-1}	
	calculation	experiment
$Ni(H_2O)_6^{2+} + CH_3PO_4^{2-}$	14 [69]	4 (Refs. 84, 85)
$Ni(H_2O)_6^{2+} + NH_3$	0.15 [69]	0.15 (Ref. 69)
$Ni(H_2O)_6^{2+} + CH_3COO^-$	3 [73]	—
$Ni(H_2O)_6^{2+} + C_5H_5N$	0.15 [73]	—
$Cr(H_2O)_6^{3+} + Cl^-$	13 [75]	—

Thus the temperature jump method and other methods for studying fast reactions can be used to find the values of the rate constants for the formation and dissociation of an inner-sphere complex.

1. Complex Formation With Unidentate Ligands

The extensive experimental material obtained in the study of the mechanism of fast reactions of complex formation has made it possible to separate the metals studied into three groups, depending on the magnitude of the rate constant of the inner-sphere replacement of a water molecule for different metal aquo-ions.[72] Fig. 2 gives characteristic values of the rate constants for this reaction. The first group consists of the alkali and alkaline earth metals (Ca^{2+}, Sr^{2+}, and Ba^{2+}). For the ions of these metals, the value of the rate constant for the exchange of coordinated water is greater than 10^7 s^{-1}.[86] In this case the limiting stage of the reaction is the attack by the ligand, and the observed reaction rate constant for complex formation is close to the diffusion value.

Table 5 gives the values of the rate constant of the replacement of coordinated water for the aquo-ions of the alkali metals, and shows that the rate of replacement depends on the nature of the ligand. The difference in the rates of substitution observed in each series can be explained simply by the difference in the electrostatic potentials (that is the charge/size ratios) of the metal ions.

The ions Zn^{2+}, Cd^{2+}, and Hg^{2+} react at the same high rates as Ca^{2+} (Fig. 2), but the rates do not depend significantly on the nature of the ligand. Thus for example for the Zn^{2+} ion the rate constant k_{23} for the replacement of water by SO_4^{2-} is 3×10^7 s^{-1},[87,88] and is close to the value 3.2×10^7 s^{-1} corresponding to complex formation by Zn^{2+} with oxalic acid.[71]

The second group contains the ions Fe^{3+}, Al^{3+}, and Be^{2+}, for which the rate of the exchange of a water molecule from the inner coordination sphere of the metal ion is lower than the rate of hydrolysis. The following mechanism of complex formation has been proposed for these ions. After the formation of the outer-sphere complex, hydrolysis takes place, followed by the formation of the inner-sphere complex, involving attack by a protonated ligand molecule:[78]

$$Fe^{3+}(aq) + L^-(aq) \rightleftharpoons (H_2O)_5Fe^{3+}(H_2O)L^- \rightleftharpoons$$
$$\rightleftharpoons (H_2O)_5FeOH^{2+}HL \rightleftharpoons (H_2O)_5FeL^{2+} + H_2O$$

According to this mechanism, the rate of complex formation depends on the nature of the ligand, and in particular on its basic strength. The mechanism of complex formation by Fe^{3+} with various ligands has been confirmed by the pressure jump method[89] and other methods for studying fast reactions.[90–92]

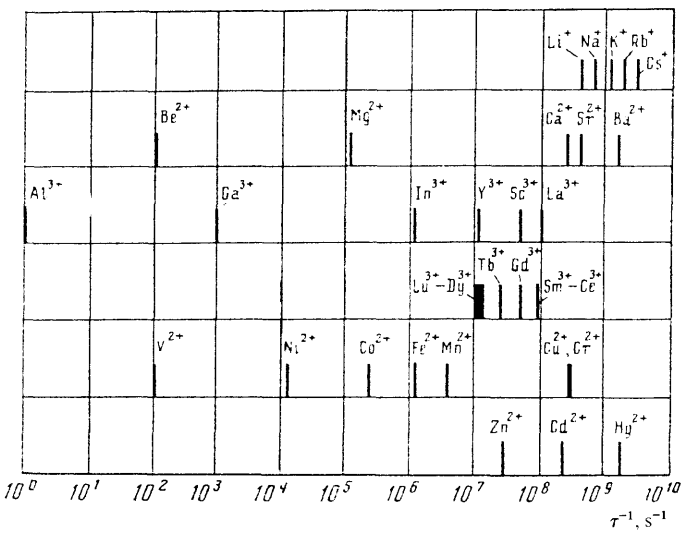

Figure 2. Characteristic rate constants (s^{-1}) of the inner-sphere replacement of a water molecule for various aquo-ions.[72]

Table 5. Values of the rate constants (10^{-7} τ^{-1}, s^{-1}) of substitution for alkali metal ions in water.[78]

Cation	$EDTA^{4-}$	NTA^{3-}	IDA^{2-}
Li^+	4.8	4.7	25
Na^+	4.7	8.8	25
K^+	7.5	15	—
Rb^+	14	23	—
Cs^+	21	35	—

Notation: NTA = nitrilotriacetate, IDA = iminodiacetate.

The third group consists of the ions of transition metals, and also metals of the main sub-groups of the periodic system, for which the rate constant for the exchange of coordinated water is less than 10^7 s^{-1}. A primary characteristic of these ions is that the rate constant for complex formation k_{eff} is practically independent of the nature of the ligand. Table 6 gives the values of k_{eff} obtained by the temperature jump method. A more complete summary of k_{eff} values obtained by other methods for studying fast reactions has been published.[74] The fact that k_{eff} is independent of the nature of the ligand is related to the fact that the limiting stage of the reaction is the removal of water molecules from the inner coordination sphere of the metal ion. The values of k_{eff} obtained experimentally and the values of K_1 calculated from Eqn. (42) can be used to determine k_{23}. For example, for complex formation by Ni^{2+} with CH_3COO^-, NH_3, and C_5H_5N,

$k_{23} = 3 \times 10^4$ s^{-1}.[73] On the other hand, the value of k_{23} practically coincides with the value of the rate constant for the exchange of coordinated water in metal aquo-ions.[74]

Table 6. Values of the rate constant k_{eff} for complex formation.

Metal ion	Ligand	lg k_{eff}, litre mole^{-1}s^{-1}	Refs.
Mg^{2+}	4,5-dihydroxybenzene-1,3-disulphonic acid	6.5	[93]
Mg^{2+}	8-quinolinol	5.5	[94]
V^{2+}	SCN^-	1.2	[95]
Fe^{2+}	SO_4^{2-}	3.6	[96]
Fe^{3+}	$Fe(CN)_6^{3-}$	3.2	[97]
Co^{2+}	SO_4^{2-}	5.3	[96]
Co^{2+}	NH_3	5.0	[98]
Co^{2+}	L-carnosine	5.6	[99]
Co^{2+}	α-alanine	5.8	[100]
Co^{2+}	β-alanine	4.8	[100]
Co^{2+}	4,5-dihydroxybenzene-1,3-disulphonic acid	6.0—6.6	[93]
Ni^{2+}	NH_3	3.2	[98]
Ni^{2+}	α-alanine	4.3	[100]
Ni^{2+}	α-aminobutyrate	4.0	[101]
Ni^{2+}	Murexide	3.5	[102]
$Ni(en)^{2+}$	NH_3	4.1	[103]
Cu^{2+}	L-carnosine	6.5	[104]
Cu^{2+}	Murexide	7.7	[105]
Zn^{2+}	Murexide	6.9	[105]
Cd^{2+}	pyridine-2-azodimethylaniline	7	[106]
Cd^{2+}	Murexide	8.1	[102]

Thus the results of kinetic measurements carried out chiefly by the temperature jump method, together with thermodynamic data (entropy and enthalpy of activation),[107] indicate that complex formation takes place by a dissociative mutual exchange mechanism (*Id* mechanism).[69,76] A large number of kinetic measurements have shown that the rate constant k_{23} depends markedly on the size and charge of the cation and other factors.[72] On the whole, the rate of replacement is lower, the greater the charge of the ion and the smaller its size. For example, the rate of complex formation by $Mg^{2+}(aq)$ with CrO_4^{2-}, ATP^{4-}, and ADP^{3-} is lower by 10^2—10^3 than that for $Ca^{2+}(aq)$.[72]

2. Complex Formation With Bidentate Ligands

The mechanism of complex formation by metal ions with bidentate ligands on the whole is analogous to the mechanism examined above for unidentate ligands. For bidentate ligands there is an additional stage of ring closure. The reaction scheme is given below:

$$\underset{\text{(XIV)}}{M^{m+}(aq) + L^{n-}(aq)} \underset{k_{21}}{\overset{k_{12}}{\rightleftharpoons}} \underset{\text{(XV)}}{M^{m+}(aq)L^{n-}} \underset{k_{32}}{\overset{k_{23}}{\rightleftharpoons}} \underset{\text{(XVI)}}{M{-}L^{(m-n)+}} \underset{k_{43}}{\overset{k_{34}}{\rightleftharpoons}} \underset{\text{(XVII)}}{M{=}L^{(m-n)+}}$$

where the stages (XV) ⇌ (XVI) and (XVI) ⇌ (XVII) describe the formation of unidentate and bidentate inner-sphere complexes respectively. The last stage involves the replacement of a second water molecule from the inner coordination sphere of the metal ion and closure of the ring.

In complex formation involving a bidentate ligand, two cases are possible: 1) ring closure takes place at a higher rate than the formation of the encounter complex from the unidentate complex, that is $k_{34} \gg k_{32}$; this case corresponds to "normal" substitution;[73,100] 2) the stage of ring closure is slower, and is therefore the limiting stage in complex formation. These substitution reactions belong to the class of "sterically controlled" reactions.[100] The study of complex formation involving bidentate ligands by the temperature jump method has made it possible to observe two stages (two values of the relaxation time), corresponding to the replacement of two water molecules. Table 7 gives the values of the rate constants for different stages of complex formation by Ni^{2+} with various bidentate ligands.

Table 7. Rate constants for complex formation by Ni^{2+}.[73,108]

Aquo-ion	Ligand	K_1k_{23}, litre mole^{-1}s^{-1}	k_{32}, s^{-1}	k_{34}, s^{-1}	k_{43}, s^{-1}
$Ni(H_2O)_6^{2+}$	diaminoethylene	$4.0 \cdot 10^5$	$4.5 \cdot 10$	$9 \cdot 10^2$	$1.4 \cdot 10^{-1}$
$Ni(H_2O)_6^{2+}$	bipyridyl	$1.5 \cdot 10^3$	$4.5 \cdot 10$	$3 \cdot 10^3$	$3.4 \cdot 10^{-3}$
$Ni(H_2O)_6^{2+}$	maleate	$8.5 \cdot 10^5$	$3.5 \cdot 10^3$	$4.5 \cdot 10^3$	$1 \cdot 10^2$
$Ni(en)_2(H_2O)_6^{2+}$	diaminoethylene	$5.5 \cdot 10^6$	$1.2 \cdot 10^5$	$2.2 \cdot 10^5$	$8.7 \cdot 10$
$Ni(H_2O)_6^{2+}$	pyridine-2-azodimethyl-aniline	$1.5 \cdot 10^3$	$1.4 \cdot 10^4$	$2.9 \cdot 10^4$	$3 \cdot 10^{-1}$

An experimental criterion for distinguishing "normal" and "sterically controlled" substitution reactions is the magnitude of the volume of activation $\Delta V^{\neq}$.[109] Values of $\Delta V^{\neq}$ equal to 5—8 cm^3 mole^{-1} indicate that the reaction is a "normal" substitution reaction. For "sterically controlled" reactions, the values of $\Delta V^{\neq}$ are ~3 cm^3 mole^{-1}. The values of $\Delta V^{\neq}$ for complex formation by $Ni^{II}L$ with pyridine-2-azodimethylaniline (PAA) have been determined.[110] The measurements were made by the laser temperature jump method at pressures of up to 3 kbar. The reaction took place by the "normal" substitution mechanism when the ligand L was nitrilotriacetate, ethylenediaminediacetate, and diethylene-triamine, and by the "sterically controlled" reaction mechanism when L was 2,2',2''-triaminotriethylamine and triethylene-tetramine. The volumes of activation have also been determined for the reactions of Co^{II}, Cu^{II} and Zn^{II} with NH_3, PAA, glycinate, and Murexide.[77] In all cases the values of $\Delta V^{\neq}$ were positive, as is characteristic of the exchange-dissociative mechanism of complex formation.[17,109,111]

Convincing evidence in support of the "normal" substitution mechanism was obtained by complex formation by Ni^{2+} with PAA.[108,112] The laser photo-excitation method made it possible to observe directly the fast stage of five-membered ring closure.

In complex formation by Ni^{II} and Co^{II} with α-alanine, the limiting stage is the loss of the first water molecule from the inner coordination sphere of the metal ion, whereas for complex formation with β-alanine, the limiting stage is the ring closure.[113] The stage of ring closure probably also limits the rate of complex formation by the lanthanides of the cerium sub-group with the dye Xylenol Orange.[114] The values of the reaction rate constants given in Ref.114 are appreciably lower than the rate constants for the exchange of water in lanthanide ions.[74] It is suggested that the low rate of formation of the chelate compound compared with the rate of formation of the unidentate inner-sphere complex is related to the difficulty of the formation of six- and seven-membered chelate compounds.

Complex formation in micellar solutions has been studied.[115,116] For the reaction of Ni^{II} with PAA in the presence of sodium dodecylsulphate, the maximum reaction rate is achieved close to the critical micelle concentration, and the reaction takes place by an Id mechanism.

The ions of transition metals and other multivalent cations can form complexes with more than one ligand. On the whole, the rate of complex formation by a metal with a second and subsequent ligands is greater than that with the first ligand. Since the ligands are generally stronger electron donors than the water molecule, it follows that on complex formation with the first ligand, the effective charge of the metal cation is decreased, and the radius increases, and there is an overall increase in the exchange rate.[74]

The study of the kinetics of complex formation in non-aqueous media has established that reactions with unidentate ligands take place by an *Id* mechanism. For bidentate ligands, the organic solvent has a specific influence,[107] in that complex formation is either slower or faster than normal substitution in aqueous solutions. The study of the role of the solvent has shown that for bidentate ligands, for which in the case of the normal substitution reaction in water the relationship $k_{eff} = K_1k_{23}$ applies, the ratio k_{eff}/K_1k_{23} deviates considerably from unity. This deviation is due to the influence of the solvent on all three stages of complex formation represented by scheme (43). The nature of the solvent influences the stability of the outer-sphere complex and the orientation of the ligand in the outer sphere.[77] These factors are also influenced by ion–dipole interaction and the formation of H-bonds.[117] For example, the mechanism of the formation of $BeSO_4$ in a water–dimethyl sulphoxide mixture is much more complex than that in aqueous solution,[118] as indicated by the experimental observation of five values of the relaxation times.

---o0o---

Thus the temperature jump method has proved to be extremely promising for the study of the kinetics and mechanism of complex formation. The further development of experimental technique should create the conditions for the development of this method and its extensive introduction in the study of various types of chemical transformation, and the temperature jump method will occupy an important place among other physical methods for studying fast reactions.

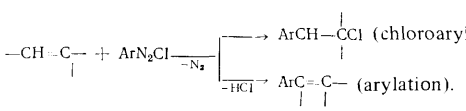
The Development and Synthetic Applications of the Meerwein Reaction

A.V.Dombrovskii



The development of the study of the Meerwein reaction is described and the reactions involving the anion-arylation and arylation of unsaturated compounds by aromatic diazo-compounds and catalysed by transition metal salts are examined and surveyed. The modern ideas about the mechanisms of these reactions and the possibility of their employment in organic synthesis are discussed.
The bibliography includes 144 references.

IV. The latest data on the Meerwein reaction 945

I. INTRODUCTION

Meerwein[1] described in 1939 the copper(II) chloride-catalysed reaction of unsaturated compounds with arenediazonium chlorides (ADC), which results in the elimination of the nitrogen of the diazo-group and the hydrogen attached to the sp^2-carbon atom is substituted by the aryl group or the aryl group and the chlorine atom add to the multiple bond. Subsequently these reactions were called arylation and chloroarylation respectively:[2]

The Meerwein reaction proved to be an extremely valuable synthetic method whereby it is possible to obtain aliphatic-aromatic olefins and polyfunctional compounds in a single step at low temperatures from a very large number of readily available, cheap, unsaturated compounds and aromatic amines. The olefins can be used in their turn in many reactions in organic synthesis to obtain substances of practical interest.

The subsequent development of this reaction involved the improvement of methods and expansion of the range of saturated and aromatic diazo-compounds employed, containing the anions Cl^-, Br^-, CN^-, HO^-, BF_4^-, $MeCOO^-$, SO_4H^-, NO_3^-, etc. Chloroarylation can be regarded as a special (albeit the commonest) case of the general reaction involving the anion-arylation of unsaturated compounds by aromatic diazo-compounds. Subsequently, it was found that, apart from $CuCl_2$, the reaction is catalysed by CuCl and other salts, mainly transition metal halides.

Since the discovery of the Meerwein reaction, several hundreds of publications, both experimental and theoretical, concerning chloroarylation and arylation of unsaturated compounds have appeared, mainly in the Soviety Union. The first survey of the reactions of unsaturated compounds with aromatic diazo-compounds was published by the present author.[3] Subsequently other reviews appeared,[4-6] covering the literature mainly up to 1970, in which the results obtained were not fully described. This review suggests and surveys the literature data up to 1983. The results of earlier studies are quoted only in so far as it is necessary.

II. THE REACTION MECHANISM

The mechanism of the Meerwein reaction has been discussed for a long time. It was not clear whether the reaction is of the ionic or radical type. The question of what is in actual fact the catalyst, $CuCl_2$ or CuCl, has been controversial; in the absence of these salts, neither chloroarylation nor arylation occurs in most cases. There was a need for theoretical and experimental explanations of a number of side reactions and products accompanying the chloroarylation and arylation reactions. Different versions of the mechanism of this reaction, based on theoretical and experimental studies performed with different degrees of scientific expertise, have been proposed at different times. The polar mechanism proposed by Meerwein[1] and other investigators[2-4] proved unacceptable for a number of reasons. In both early and later studies the majority of investigators of this reaction concluded that, like the Sandmeyer reaction, the Meerwein reaction is catalysed by copper(I) halides and has a radical mechanism.[7,8]

The Meerwein reaction should probably be regarded as an extended version of the Sandmeyer reaction, which in this case occurs in the presence of an unsaturated compound. In the Sandmeyer reaction the aryl radicals and halogen atoms combine to form aryl halides. On the other hand, in the presence of an unsaturated compound, these species interact with the multiple bonds to form chloroarylation and arylation products. The involvement of the molecules of the unsaturated compound, interacting with the arenediazonium ion and the catalyst, apparently leads to the appearance of a ternary reaction complex in the simplest case,[9] which in its turn modifies the mechanism of the entire process.

It is known that transition metal halides, including copper-halides, react with arenediazonium chlorides to form complexes (double salts),[10-14] which are relatively stable in aqueous organic solutions in the cold and at room temperature but begin to decompose after the addition of an unsaturated compound. It has been demonstrated by ultraviolet and infrared spectroscopy[15] that there is a chemical bond between the metal ions and the nitrogen of the diazo-group in double salts of this kind. On the other hand, it is known that copper(I) halides form π-complexes with many olefins even in an aqueous medium. Such complexes react with the ADC to form the product of the Meerwein reaction. The stability of the complexes diminishes in the sequence CuCl > CuBr > CuI; the cyanide CuCN does not form complexes and does not catalyse the Meerwein reaction.[16] The Meerwein reaction and

the catalytic effect of copper halide on the latter should therefore be regarded as radical oxidation-reduction addition to olefins[17] whose mechanism includes a series of consecutive elementary reactions leading to the main and side products. The most logical and experimentally demonstrated mechanism of the interaction of the ADC–copper chloride–unsaturated compound system has been proposed by Schrauzer[18] [reactions (1)–(8)].

Under the classical conditions of the Meerwein reaction, an aqueous acetone solution of $CuCl_2$, whose reduction by acetone to CuCl is well known[19] [reaction (1)], is used. The CuCl generated at the instant of reaction is apparently more reactive than the preparation obtained beforehand. The CuCl formed during the reaction or introduced as such forms a double salt with the ADC [reaction (2)], in which the diazo-group is coordinated to the complex anion $CuCl_2^-$; such complexes are known for transition metal chlorides.[20] The double salt then forms a ternary reaction complex with the olefin (–CH=C<), in which the diazo-group and the olefin are linked to the copper ion in conformity with the coordination number, which is two [reaction (3)]. The details of the binding and of the geometry of the species within the ternary complex are so far unknown.

The onset of reaction is signalled by the evolution of nitrogen (as a result of its elimination from the diazo-group), which begins only after the addition of the olefin. Under the influence of the polarising action of the copper ion and the olefin, the arenediazonium cation is reduced to the radical Ar·. The electrochemical reduction of arenediazonium salts at copper, iron, and other metal cathodes in the presence of unsaturated compounds has demonstrated[21] that this involves the generation of aryl radicals, which interact with the π-bond of the olefin. In this case the diazonium cation is initially reduced via a one-electron mechanism to the arenediazonium radical, which then decomposes to the radical Ar· and free nitrogen:[21–23]

$$[PhN_2]^+ + e \rightarrow PhN_2^{\cdot} \rightarrow Ph^{\cdot} + N_2 .$$

Without being released into the bulk of the medium, the radical Ar· reacts with the olefin to form an aliphatic-aromatic radical [reaction (4)] whose interaction with $CuCl_2$ entails the formation of the chloroarylation product as a consequence of the transfer of the radical species Cl· [reaction (5)]. If there is a hydrogen atom at the α-carbon atom in the aliphatic component of the aliphatic-aromatic radicals, the latter can be eliminated together with a chlorine atom in the form of HCl [reaction (5a)], which constitutes one of the interpretations of the arylation mechanism.[6] One cannot rule out the possibility that the hydrogen atom in the olefin or another ligand can be substituted by the radical Ar· directly:

$$2CuCl_2 + Me_2CO \rightarrow 2CuCl + MeCOCH_2Cl + HCl , \quad (1)$$

$$ArN_2^+Cl^- + CuCl \rightleftarrows ArN_2^+CuCl_2^- , \quad (2)$$

$$ArN_2^+CuCl_2^- \underset{\leftarrow}{\overset{-HC\equiv C<}{\rightarrow}} \left[ArN_2^+CuCl_2^- \cdot \begin{matrix} -C- \\ \| \\ -CH \end{matrix} \right] , \quad (3)$$

$$\left[ArN_2^+CuCl_2^- \cdot \begin{matrix} -C- \\ \| \\ -CH \end{matrix} \right] \xrightarrow{-N_2} [ArCH-\dot{C}-\cdots Cu^{\cdot}Cl_2] , \quad (4)$$

$$[ArCH-\dot{C}-\cdots Cu^{\cdot}Cl_2] \xrightarrow{-CuCl} \begin{cases} \rightarrow ArCH-C(Cl)- , & (5) \\ \xrightarrow{-HCl} ArC(=)C- , & (5a) \end{cases}$$

$$Ar^{\cdot} + Cu^{\cdot}Cl_2 \rightarrow ArCl + CuCl , \quad (6)$$

$$Ar^{\cdot} + Me_2CO \rightarrow ArH + MeCO\dot{C}H_2 , \quad (7)$$

$$ArN_2Cl + H_2O \rightarrow ArOH + HCl + N_2 , \quad (8)$$

$$ArCH-\dot{C}H-\cdots CuCl_2 \xrightarrow[-CuCl]{-HC\equiv C-} Ar(CH=\dot{C}-)_2Cl , \quad (9)$$

$$2ArC(\cdot)-\dot{C}- \rightarrow \left(ArC(-)-C- \right)_2 . \quad (10)$$

Thus, under the conditions of "cuprocatalysis", the chloroarylation proceeds as a redox-initiated free radical addition via stage involving the formation of intermediate complexes of the catalyst with the diazo-compound and with the unsaturated compound.

If for any reason the radical species Ar· and Cl· leave the inner sphere of the reaction complex, side reactions take place, in the first place the formation of ArCl (the Sandmeyer reaction), aromatic hydrocarbons and phenols reaction (6)–(8). The Meerwein reaction is also accompanied by the formation of resins, telomers, and additive dimers. The telomers are formed if the aliphatic-aromatic radical reacts with the next molecule of the monomeric olefin and then the $CuCl_2$ radical [reaction (9)]. As in the polymerisation of unsaturated compounds in the presence of variable-valence catalysts, telomers appear in this instance and under certain conditions can be the main reaction products.[24–29] Additive dimers arise as a consequence of the recombination of the same aliphatic-aromatic radicals [reaction (10)].[30,31]

Arylation formally involves the substitution of a hydrogen atom at a carbon atom involved in the multiple bond by the aryl group of the diazo-compound. Arylation should apparently be regarded in most cases as an addition–elimination process, which can be demonstrated by purely chemical means. It has been shown[32] that, on interaction with the ADC, α-chlorostyrene gives rise smoothly and in satisfactory yields to the α-chlorostilbenes PhCCl=CHAr (Ar = Ph, 4-MeC_6H_4, or 4-$O_2NC_6H_4$). If α-bromostyrene is used in the reaction, then the same α-chlorostilbenes are obtained in virtually quantitative yields:[33]

$$PhCBr=CH_2 + ArN_2Cl \xrightarrow[-N_2]{CuCl_2} [PhCBrCl-CH_2Ar] \xrightarrow[-HBr]{} PhCCl=CHAr .$$

Consequently, the arylation of α-halogenostyrenes proceeds via a stage involving the addition of the Ar group and the Cl atom of the arenediazonium cation to the ethylenic bond. Since the C–Cl bond in the adduct obtained from α-bromostyrene is stronger than the C–Br bond, HBr and HCl are split off on spontaneous decomposition of the unstable intermediate adduct and α-chlorostilbene is obtained as a result.

III. FACTORS DETERMINING THE EFFECTIVENESS OF THE REACTION

The effectiveness of the reaction, i.e. the yields of the chloroarylation and arylation products, depends on a series of factors, the most important of which are as follows.

The unsaturated component (olefin). The vinyl monomers $H_2C=CH-X$ and $H_2C=CX_2$, in which the ethylenic bond has been activated by one or two electron-accepting groups (X = Cl, CN, Ar, $-C=CH_2$, COR, COOH, COOAlk, etc.) usually react satisfactorily. Because copper halides are capable of transferring radical chains very effectively, such monomers do not give rise to high-molecular-weight compounds. Ethylene, acetylene, and their substituted derivatives, containing electron-donating groups, react poorly. The unsaturated compounds RHC=CHR in which the double bond has been blocked also react with difficulty.

The arenediazonium component. ADC (concentrated or even saturated aqueous solutions are used for the reaction), which are capable of forming complexes with copper halides,

give the best results in most cases. Arenediazonium salts containing other anions usually give rise to lower yields of chloroarylation and arylation products.

The best yields of products are obtained when the *para*-position in the aromatic ring contains a substituent, regardless of the electronic effect which it exhibits; *ortho*- and *meta*-substituted derivatives give rise to lower yields.

Apart from arenediazonium salts (including tetrafluoroborates[34,35]), other compounds forming aryl radicals, for example, benzoyl peroxide, arylhydrazone peroxides, 1-aryl-3,3-dimethyltriazenes, *N*-nitrosoacetanilides, diazoaminobenzene, and diaryliodonium salts, have been proposed for the arylation of olefins;[6] aryl radicals generated by the electrochemical reduction of diazonium salts have also been used.[21] However, with the exception of arylpalladium reagents,[36,37] such sources of aryl radicals have given lower yields of arylation products and in most cases initiated the polymerisation of the olefins.[6]

Catalysts. Apart from copper halides, the salts $FeCl_2$,[30,31,38] $HgCl_2$,[39] $LiPdCl_3$,[40] and Pd(0) (obtained *in situ*)[41] and the $CuSO_4 + FeSO_4$, $Cu(NO_3)_2 + Cu$, and $Cu(NO_3)_2 + Fe$ systems[30] have been used for chloroarylation and arylation. However, $CuCl_2$ and CuCl, used in an amount equivalent to 10–20 mole % per mole of the ADC, still remain the best catalysts. An increase of the catalyst concentration promotes the occurrence of the Sandmeyer reaction, while at lower concentrations ArH is formed.[2,6]

The catalytic capacity of copper halides, iron(II) salts, and certain other redox initiators, can be explained by the comparatively low oxidation-reduction potentials E of the ions of these metals; for example, $E = 0.16$ eV for the $Cu^+ \rightarrow Cu^{2+}$ system and $E = 0.77$ eV for $Fe^{2+} \rightarrow Fe^{3+}$.

The potentials E for the metal ions in the salts $FeCl_3$, $AlCl_3$, $ZnCl_2$, $CdCl_2$, $CoCl_2$, $MnCl_2$, and $NiCl_2$, which do not catalyse or only weakly catalyse chloroarylation and arylation, are significantly higher.[31] Cases are known where arylation takes place in the absence of catalysts, for example, in the reactions of arenediazonium salts with coumarin,[1] quinones, and ferrocene,[2] which can be accounted for by the fairly low oxidation-reduction potentials of these compounds.[31]

Solvents. The chloroarylation and arylation reactions usually take place in aqueous organic media with vigorous stirring. In the absence of water, the reactions hardly begin. In those cases where the arenediazonium and olefinic components dissolve in water, the reactions have been achieved successfully in aqueous media.[2,6] The nature of the organic solvent has a significant influence on the effectiveness of the reaction. The most important requirement which this organic solvent must meet is that it is miscible with water without binding the catalyst chemically at the same time. Solvents such as tetrahydrofuran (THF), 1,4-dioxan, ether, dimethylformamide (DMF), dimethyl sulphoxide (DMSO), and pyridine, which apparently bind copper halides and other catalysts in complexes removing them from the reaction sphere thereby, proved to be ineffective.[2,6,42]

Acetone, acetonitrile, and sulpholan proved to be the most suitable solvents. A water–acetone mixture, the volume ratios of the components of which are varied in the range 3 : 1–7 : 10, is usually employed for the reactions.

The pH of the medium. Media close to neutrality (pH 4–6) are optimal in reactions with arenediazonium salts containing electron-donating substituents in the aromatic ring. In the presence of electron-accepting substituents in the ring a high acidity of the medium is required (pH 1–2). It has been suggested that MeCOONa, CaO, $Ca(OH)_2$, and $NaHCO_3$ be added to the reaction mixture in order to maintain and regulate the necessary pH.[2]

Temperature. The chloroarylation and arylation reactions proceed under mild conditions as regards temperature (from −5 to +30 °C). In a few instances the evolution of nitrogen begins at −10 °C. If the temperature is not regulated, then the interaction becomes vigorous, the temperature rises rapidly, and nitrogen is evolved in abundance; in such cases the Sandmeyer reaction and resin formation predominate.

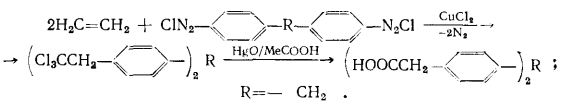
IV. THE LATEST DATA ON THE MEERWEIN REACTION

Studies devoted to the reactions of olefins and their derivatives with arenediazonium salts, which have not been included in previous reviews,[2,3,6] are discussed below. In a number of instances the applications of the products of the anion-arylation and arylation reactions in organic synthesis are indicated.

1. Alkenes, Halogenoalkenes, and Certain Vinyl Monomers

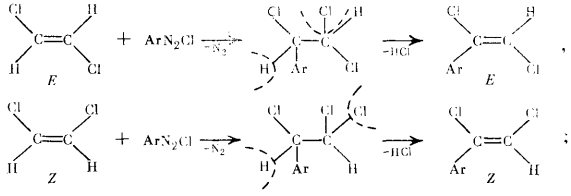
The simplest alkenes, namely ethylene and propene, react with difficulty even with the most reactive ADC. Only under comparatively severe conditions in an autoclave, does ethylene react with diazotised 4-nitroaniline to form 1-chloro-2-(4-nitrophenyl)ethane (45–50%),[43] which is quantitatively converted into 4-nitrostyrene on dehydrochlorination:[2]

$$H_2C{=}CH_2 + 4\text{-}O_2NC_6H_4N_2Cl \xrightarrow[42^\circ C;\ 70\text{–}75\ atm\ N_2]{CuCl_2} \rightarrow 4\text{-}O_2NC_6H_4CH_2CH_2Cl \xrightarrow[-NaCl]{NaOH} 4\text{-}O_2NC_6H_4CH{=}CH_2 .$$



Halogenoalkenes with halogen atoms attached to the sp^2-carbon atom give rise to chloroarylation products on interaction with ADC; the mode of addition to the multiple bond is then consistent with the Markovnikov rule. The vinyl chloride gives rise to 1,1-dichloro-2-arylethanes (60–70%),[44–46] which have served as starting materials for the synthesis of 4-nitrophenylacetaldehyde,[47] β-chlorostyrenes,[48] 1,4-bis-(β-chlorovinyl)benzene, and 1,3-dioxolan-4-ylphenylenediacetaldehyde:[46]

$$H_2C{=}CHCl + ArN_2Cl \xrightarrow[-N_2]{CuCl_2} ArCH_2CHCl_2 ;$$
$$Ar{=}Ph,\ 4\text{-}MeC_6H_4,\ 4\text{-}MeOC_6H_4,\ 4\text{-}BrC_6H_4,$$
$$2,4\text{-}Cl_2C_6H_3,\ 4\text{-}O_2NC_6H_4 .$$



Vinylidene chloride reacts particularly effectively with ADC to form 2,2,2-trichloroarylethanes (~80%),[49] which proved to be convenient starting materials for the synthesis of arylacetic acids[50] and 1,4-bis(ββ-dichlorovinyl)benzene:[51]

$$H_2C{=}CCl_2 + ArN_2Cl \xrightarrow[-N_2]{CuCl_2} ArCH_2CCl_3 ;$$
$$Ar\text{-}4\text{-}MeC_6H_4,\ 4\text{-}ClC_6H_4,\ 4\text{-}MeOC_6H_4,$$
$$4\text{-}O_2NC_6H_4,\ 4\text{-}Cl_3CH_2C_6H_4 .$$

Biphenyl-4,4′-bisdiazonium chloride reacts via both diazo-groups with two molecules of vinylidene chloride to form 4,4′-bis(2,2,2-trichloroethyl)biphenyl (30%), which is converted into biphenyl-4,4′-diacetic acid after hydrolysis. Vinylidene chloride reacts analogously with tetrazonium chloride containing a bridging group between the benzene rings:[52]

The symmetrical dichloroethylene reacts poorly with ADC. The reactivity of the *E*-isomer is twice as high as that of the *Z*-isomer. The reaction results in the formation of 2-aryl-1,1,2-trichloroethanes (two conformers), which are converted into the *E*- and *Z*-aryl-1,2-dichloroethylenes on alkaline dehydrochlorination. HCl is eliminated as a result of the abstraction of the α-hydrogen atom and the chlorine atom from the transoid β-position:[53]

Ar = Ph, 4-ClC_6H_4.

1,3-Dichlorobut-2-ene reacts with benzenediazonium chloride to form $MeCCl_2CH(Ph)CH_2Cl$ in a low yield (~30%),[54] while trichloroethylene gives rise to moderate yields (~50%) of aryl-1,1,1,2-tetrachloroethanes, which are smoothly dehydrochlorinated by an alcoholic solution of alkali to give α,β,β-trichlorostyrenes:[55]

$$ClHC{=}CCl_2 + ArN_2Cl \xrightarrow[-N_2]{CuCl_2} ArCHClCCl_3 \xrightarrow[-HCl]{KOH} ArCCl{=}CCl_2;$$
Ar = Ph, 4-MeC_6H_4, 4-BrC_6H_4, 4-$O_2NC_6H_4$

Fluorine-containing olefins react with ADC in the usual way, forming adducts, which are converted on dehydrochlorination into the corresponding fluorine-containing aryl derivatives,[56] for example:

$$F_2CHCF_2CH{=}CH_2 + 4\text{-}RC_6H_4N_2Cl \xrightarrow[N_2]{CuCl_2,\ 33^\circ C} \rightarrow$$
$$\rightarrow F_2CHCF_2CHClCH_2C_6H_4R\text{-}4 \xrightarrow[-KCl,\ -H_2O]{KOH/MeOH} F_2CHCF_2CH{=}CHC_6H_4\text{-}R\text{-}4;$$
R = Cl, NO_2, COOH (28—50%).

$F_2CHCF_2C(Me){=}CH_2$, $F_2CH(CF_2)_3CF{=}CF_2$, $CF_3(CF_2)_4CF{=}CF_2$, and $C_4H_9CF{=}CFCl$ react analogously; chlorotrifluoroethylene gives rise to the adducts $ArCF_2CFCl$ (27%) only under comparatively severe conditions (40–50 °C, in an autoclave), while $H_2C{=}CF_2$ and $F_2C{=}CF_2$ hardly react even with the most reactive ADC.[56]

1,1,1-Trifluoropropene reacts with 4-nitrobenzenediazonium halides to form adducts (yield 30–40%), which are also readily dehydrohalogenated and give almost quantitative yields of 2-(4-nitrophenyl)-1-trifluoromethylethylenes:[57]

$$F_3CCH{=}CH_2 + ArN_2X \xrightarrow[MeCOONa]{CaX_2,} F_3CCHXCH_2Ar \xrightarrow[-HCl]{Et_3N} F_3CCH{=}CHAr;$$
Ar = 4-$O_2NC_6H_4$; X = Cl, Br.

The reactions of ADC (catalysed by $CuCl_2$) with vinylsilanes, vinylphosphonate, and vinyl sulphones also involve the addition of chlorine and the aryl groups in the α- and β-positions respectively to the vinyl component. Vinylsilane $Ph_3SiCH{=}CH_2$ gives rise to 15–37% yields of the compounds $Ph_3SiCHClCH_2Ar$ (Ar = 4-ClC_6H_4, 4-BrC_6H_4, 4-$HOCOC_6H_4$, or 3- and 4-$O_2NC_6H_4$);[2] the reactions of $(EtO)_2P(O)CH{=}CH_2$ result in 45% yields of the compounds $(EtO)_2P(O)CHClCH_2Ar$ (Ar = Ph or 4-ClC_6H_4).[58]

Vinyl sulphones react analogously with ADC to form β-aryl-α-halogenoethyl sulphones (yields up to 45%), which are converted on dehydrochlorination into styryl sulphones in high yields:[59–61]

$$RSO_2CH{=}CH_2 \xrightarrow[-N_2]{ArN_2X,\ CuCl_2} RSO_2CHXCH_2Ar \xrightarrow[HX]{base} RSO_2CH{=}CHAr;$$
R = Me, Et, CF_3, 4-MeC_6H_4; X = Cl, Br;
Ar = Ph, 4-FC_6H_4, 4-ClC_6H_4, 3- and 4-$O_2NC_6H_4$, 4-$HOCOC_6H_4$.

2. Acetylenes

The C≡C bond is less reactive in the reactions with ADC than the C=C bond. Like ethylene, acetylene itself undergoes the Meerwein reaction with 4-nitrobenzenediazonium chloride to form a low yield (~20%) of the chloroarylation product, which is wholly dehydrochlorinated by an alcoholic solution of alkali and is converted into 4-nitrophenylacetylene. Substituted acetylenes are more reactive. Thus phenylacetylene is chloroarylated to α-chlorostilbenes in satisfactory yields (46–70%) and the latter have been converted on dehydrochlorination into tolanes (yield 85%):[2]

$$R{-}C{\equiv}CH + ArN_2Cl \xrightarrow[-N_2]{CuCl_2} R{-}CCl{=}CH{-}Ar \xrightarrow[-HCl]{KOH/\ dioxan} R{-}C{\equiv}C{-}Ar;$$
R = H, Ph; Ar = Ph, 4-$O_2NC_6H_4$.

Vinyl- and isopropenylacetylenes react with ADC via the ethylenic bond to form chloroarylbutynes, which are converted into arylbutenynes on dehydrochlorination. Allene derivatives have been detected in small amounts together with the chloroaryl derivatives:[62–64]

$$H_2C{=}CR{-}C{\equiv}CH + ArN_2Cl \xrightarrow[-N_2]{CuCl_2} ArCH_2CCl(R){-}C{\equiv}CH \xrightarrow[-HCl]{KOH} \rightarrow$$
$$\rightarrow ArCH{=}CR{-}C{\equiv}CH;$$
R = H, Me; Ar = Ph, 4-ClC_6H_4, 4-$MeOC_6H_4$.

Tetrazonium chloridee based on 4,4′-diaminobiphenyl, 4,4′-diamino-3,3′-dimethoxybiphenyl, di(4-aminophenyl) sulphone, and di(4-aminophenyl) ether react via the acetylenic bond with propargyl alcohol, propargylic acid, and phenylacetylene (in the presence of CuCl as the catalyst) with evolution of nitrogen from both diazo-groups, forming bischloroarylation products (46–58%):[65]

$$2HC{\equiv}CR + R''[{-}C_6H_3(R')N_2Cl]_2 \xrightarrow[2N_2]{CuCl_2} [{-}C_6H_3(R')CH{=}CClR]_2R'';$$
R = MeO, COOH, Ph; R′ = H, MeO;
R″ = —, CH_2, SO_2, O.

3. Arylethylenes

Arylethylenes in which the aryl group is conjugated with the ethylenic bond have been widely used in the anion-arylation and arylation reactions. Arylethylenes with a terminal $>C{=}CH_2$ group exhibit an enhanced reactivity. Apart from the electronic effects, steric factors have an effect in this case.

Styrene reacts with ADC at pH ~ 5 ($CuCl_2$, aqueous acetone solution of MeCOONa) to form stilbenes;[2] however, in an acidic medium (pH 1–2) chloroarylation takes place and 2-aryl-1-chloro-1-phenylethanes are formed in satisfactory yields and are readily dehydrochlorinated and converted almost quantitatively into substituted stilbenes:[66–68]

$$PhHC{=}CH_2 + ArN_2Cl \xrightarrow[-N_2]{\begin{cases} \xrightarrow[-HCl]{pH\sim5} PhHC{=}CHAr, & (a) \\ \xrightarrow{pH\ 1\text{-}2} PhHCClCH_2Ar \xrightarrow[-HX]{base} PhHC{=}CHAr; & (b) \end{cases}}$$
(a) Ar-4-ClC_6H_4, 4-$MeOC_6H_4$;
(b) Ar = 4-MeC_6H_4, 4-$MeOC_6H_4$, 4-ClC_6H_4, 4-BrC_6H_4, 4-$EtOCOC_6H_4$, 4-$Et_2NC_2H_4OCOC_6H_4$, 2-$O_2NC_6H_4$, 3-$O_2NC_6H_4$, 4-$O_2NC_6H_4$.

Arylethylenes containing electron-donating substituents in the aromatic ring or at the ethylenic bond are as a rule readily arylated. The reaction is one of the practically convenient methods of synthesis of substituted stilbenes, frequently in high yields; examples are presented below (the yields expressed as percentages are indicated in brackets):

$$RR^1C{=}CHR^2 + ArN_2Cl \xrightarrow{-N_2} RR^1C{-}CR^2Ar + HCl;$$

R = Ph, 4-MeC_6H_4, 4-$MeOC_6H_4$; R^1 = H, Me, F, Cl, Ph; R^2 = H, Et; Ar = Ph, 4-MeC_6H_4, 4-ClC_6H_4, 2-$O_2NC_6H_4$, 3-$O_2NC_6H_4$, 4-$O_2NC_6H_4$, 4-$HOCOC_6H_4$, 4-$MeOC_6H_4$, 4-NCC_6H_4, 4-$MeCOC_6H_4$, 4-$HOSO_2C_6H_4$, 4-$H_2NSO_2C_6H_4$, 4-$Et_2NC_2H_4C_6H_4$, 4-$Et_2NC_2H_4OCOC_6H_4$ [2, 33, 68, 69]

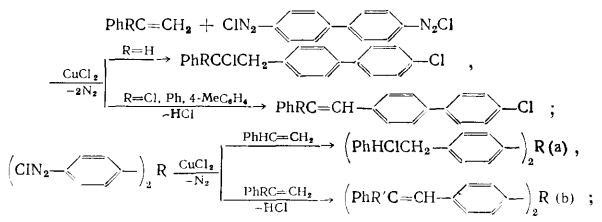
Styrene enters into the copper salt-catalysed anion-arylation reaction with benzenediazonium salts in the presence of sodium nitrite or sulphide:[70]

$$PhHC{=}CH_2 \xrightarrow[-N_2]{PhN_2Cl,\ CuCl_2} \begin{cases} \xrightarrow{NaNO_2} PhCH(NO_2)CH_2Ph & (20\%), \\ \xrightarrow{Na_2S} (PhCH_2CHPh)_2S & (25\%). \end{cases}$$

Anion-arylation of styrenes. Styrene reacts with arenediazonium sulphates in an acetic acid–acetone solution saturated with sulphur(IV) oxide in the presence of thiocyanate anions and copper(I) thiocyanate. It is assumed that arenediazonium thiocyanates are formed in the reaction and then generate Ar$^{\cdot}$ radicals. The latter react with SO_2 to form arenesulphonyl radicals, which add together with thiocyanate radicals to the ethyleneic bond of styrene. This results in the formation of 2-(arenesulphonyl)-1-phenyl-1-thiocyanatoethanes (in ~60% yields):[47]

$$ArN_2SO_4H + NH_4SCN \rightleftarrows ArN_2SCN + NH_4HSO_4,$$

$$ArN_2SCN \xrightarrow[-N_2]{SO_2,\ CuSCN} [ArSO_2^{\cdot} + {\cdot}SCN] \xrightarrow{PhHC{=}CH_2} PhHC(SCN)CH_2SO_2Ar;$$

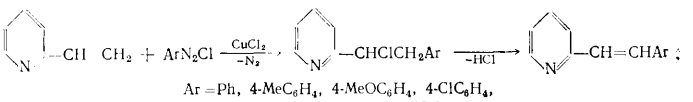


Ar = Ph, 4-MeC_6H_4, 4-$MeOC_6H_4$, 2-$O_2NC_6H_4$, 3-$O_2NC_6H_4$, 4-$O_2NC_6H_4$.

Under analogous conditions but in the presence of chloride, bromide, *O,O*-diethyl phosphorodithioate, or xanthate anions and catalytic amounts of copper ions, styrene reacts with aromatic diazo-compounds, forming crystalline anion-sulphonylation products (in yields of ~80%): 2-(arenesulphonyl)-1-chloro-1-phenylethanes, 2-(arenesulphonyl)-1-bromo-1-phenylethanes, 2-(arenesulphonyl)-1-(*O,O*-diethylphosphorodithioato)-1-phenylethanes, and 2-(arenesulphonyl)-1-(*O*-ethyl dithiocarbonato)-1-phenylethanes:[48]

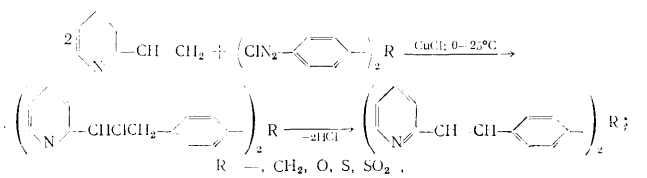
$$PhHC{=}CH_2 + ArN_2X + SO_2 + MHal \xrightarrow{CuHal} PhHC(Hal)CH_2SO_2Ar;$$

X = Cl, Br, SO_4H; M = Na, K; Hal = Cl, Br, $(EtO)_2PS_2$, EtOC(S)S; Ar = Ph, 4-MeC_6H_4, 4-ClC_6H_4, 4-$O_2NC_6H_4$.



Styrene reacts with biphenyl-4,4'-bisdiazonium chloride with evolution of nitrogen from both diazo-groups, one of which undergoes the Sandmeyer reaction, while the other chloroarylates one styrene molecule to form 4-chloro-4'-(2-chloro-2-phenylethyl)biphenyl in 57% yield. α-Substituted styrenes (R = Ph, Cl or 4-MeC_6H_4) gives rise to products of arylation involving one diazo-group, while the other diazo-group is substituted by chlorine (yields ~50%):[52]

(a) R = S (40), CH_2 (67);
(b) R = S; R' = Cl (33), Ph (49); R = CH_2; R' = Cl (54), Ph (49).



It has been stated[71] that styrene is arylated by bisdiazotised benzidine to form 4,4'-distyrylbiphenyl (yield 14%). Tetrazonium chlorides with a bridging S atom or CH_2 group between the benzene rings react with styrene via both diazo-groups. In reaction (a) the diazo-groups of di(4-diazoniaphenyl)-sulphide chloride and di(4-diazoniaphenyl)methane chloride react with two molecules of styrene to form chloroarylation products. In reaction (b) α-substituted styrenes react with the same tetrazonium chlorides to form arylation products[52] (the yields expressed as percentages are given in brackets). Numerous biphenyl, diphenyl sulphide, and diphenylmethylene derivatives have been synthesised from compounds obtained by chloroarylating and arylating various styrenes by tetrazonium chlorides.[52]

Like styrene, 2-vinylpyridine reacts with ADC to form 2-aryl-1-chloro-1-(2'-pyridyl)ethanes (in 50–60% yields), which are readily converted into 2-stilbazoles on dehydrochlorination (80–96%):[72]

Ar = Ph, 4-MeC_6H_4, 4-$MeOC_6H_4$, 4-ClC_6H_4, 4-BrC_6H_4, 2-$O_2NC_6H_4$, 4-$O_2NC_6H_4$.

2-Vinylpyridine is also readily chloroarylated by tetrazonium chlorides, giving rise to bisadducts, which are converted into bis-stilbazoles (in 80% yield) on treatment with an alcoholic solution of alkali:[73]

R = —, CH_2, O, S, SO_2.

4. Conjugated Dienes

Conjugated dienes react extremely vigorously with aromatic diazo-compounds, evolving nitrogen from the diazo-group and giving rise to arylation, chloroarylation, and anion-arylation products, which are formed readily when the reaction is catalysed by both $CuCl_2$ and CuCl.

In order to explain the mechanism of the chloroarylation of conjugated dienes, it has been assumed,[8] on the basis of data obtained from conductimetric measurements in the ArN_2Cl–CuCl-buta-1,4-diene system, that the chlorine atom in the double salt of arenediazonium and copper(I) chlorides is substituted by the diene. The resulting ternary complex decomposes with evolution of nitrogen from the diazo-group as a consequence of a redox process within the complex and with participation of the copper ion, accompanied by the simultaneous addition of the aryl radicals and chlorine atoms formed to the diene in the 1- and 4-positions. This leads to the formation of 1-aryl-2-chlorobut-2-enes:

$$ArN_2Cl + CuCl \rightleftarrows [ArN_2CuCl]^+Cl^- \xrightarrow{diene} [ArN_2{\cdot}diene{\cdot}Cu^-]^{2+}\ 2Cl^-;$$

$$[Ar{:}N_2{:}diene{\cdot}Cu]^{2+}2Cl^- \xrightarrow{-N_2} ArCH_2CH{-}CHCH_2Cl + CuCl;$$

diene = $CH_2{-}CH{=}CH{-}CH_2$.

The mechanism proposed also makes it possible to account for the chloroarylation of unsaturated monomers and the formation of the products of the side reactions (ArCl, telomers, additive dimers, etc.).[52]

Numerous reactions of buta-1,4-diene with ADC and other anion-substituted arenediazonium compounds have been carried out. In most cases *trans*-chloroarylbutenes are obtained in satisfactory yields (50–80%):[2,8,74,75]

$$CH_2=CH-CH=CH_2 + ArN_2Cl \xrightarrow[-N_2]{CuCl_2} ArCH_2CH=CHCH_2Cl\ ;$$

Ar=Ph, 2-MeC_6H_4, 3-MeC_6H_4, 4-MeC_6H_4, 4-$HalC_6H_4$ (where Hal=F, Cl, Br, I), 2,4-$Cl_2C_6H_3$, 2,4-$Br_2C_6H_3$, 2-, 3- and 4-$O_2NC_6H_4$, 4-$MeOC_6H_4$, 4-$H_2NSO_2C_6H_4$, 4-$Et_2N(CH_2)_2OCOC_6H_4$,

Divinyl sulphone, in which there is virtually no conjugation between the vinyl groups, reacts with ADC to form adducts involving both one and two vinyl groups (in yields of ~50%):[76]

$$(H_2C=CH)_2SO_2 \xrightarrow[-N_2]{ArN_2Cl,CuCl_2} \begin{cases} \longrightarrow ArCH_2CHClSO_2CH=CH_2 \\ \longrightarrow (ArCH_2CHCl)_2SO_2 \end{cases};$$

Ar=Ph, 4-ClC_6H_4, 4-$O_2NC_6H_4$.

Isoprene is chloroarylated in the 1- and 4-positions with formation of 1-aryl-4-chloro-2-methylbut-2-enes (yields 65–70%):[2,75]

$$H_2C=C(Me)-CH=CH_2 + ArN_2Cl \xrightarrow[-N_2]{CuCl_2} ArCH_2C(Me)=CHCH_2Cl\ ;$$

Ar=Ph, 4-MeC_6H_4; 4-$HalC_6H_4$ (where Hal=F, Br, I), 4-$MeOC_6H_4$, 4-$Et_2N(CH_2)_2OCOC_6H_4$.

Mono- and dichloro-substituted conjugated dienes react analogously with ADC, giving satisfactory yields of 1,4-adducts:[2,77–80]

$$H_2C=CH-CCl=CH_2 + ArN_2Cl \xrightarrow[-N_2]{CuCl_2} ArCH_2CH=CClCH_2Cl,$$

$$H_2C=CH-CH=CHCl + ArN_2Cl \xrightarrow[-N_2]{CuCl_2} ArCH_2CH=CHCHCl_2,$$

$$H_2C=CCl-CCl=CH_2 + ArN_2Cl \xrightarrow[-N_2]{CuCl_2} ArCH_2CCl=CClCH_2Cl\ ,$$

$$H_2C=CCl-C(Me)=CH_2 + ArN_2Cl \xrightarrow[-N_2]{CuCl_2} ArCH_2CCl=C(Me)CH_2Cl\ .$$

In its reaction with ADC piperylene combines in all cases with the Ar$^{\cdot}$ radical at the methylene group. However, the chlorine atom of the diazo-compound adds in both 2- and 4-positions of the conjugated system, forming a mixture of arylchloropentenes (overall yield 60–70%). The latter are so unstable that they lose HCl already during their isolation or purification; 1-arylpenta-1,3-dienes are obtained on a preparative scale when the above chloro-derivatives interact with bases:[81]

$$H_2C=CH-CH=CHMe + ArN_2Cl \xrightarrow[-N_2]{} \begin{cases} \longrightarrow ArCH_2CHClCH=CHMe \\ \longrightarrow ArCH_2CH=CHCHClMe \end{cases} \xrightarrow[-HCl]{} ArCH=CH-CH=CHMe\ ;$$

Ar=Ph, 4-MeC_6H_4, 4-BrC_6H_4, 4-$MeOC_6H_4$, 4-ClC_6H_4, 4-$O_2NC_6H_4$.

Bi-isopropenyl is chloroarylated to 4-chloro-2,3-dimethylbut-2-enes (in yields of 50–58%):[82]

$$H_2C=C(Me)-C(Me)=CH_2 + ArN_2Cl \xrightarrow[-N_2]{} ArCH_2C(Me)=C(Me)CH_2Cl\ ;$$

Ar=Ph, 4-MeC_6H_4, 4-ClC_6H_4, 4-$MeOC_6H_4$.

The chloroarylation of conjugated dienes catalysed by $FeCl_2$ has been described. The yields of the chloroarylbutenes obtained thereby are somewhat lower (~55%); in this case the reaction is accompanied by the formation of considerable amounts of the products of the Sandmeyer reaction, telomers, and the products formed as a result of the additive dimerisation of the initial monomers.[30,31]

Tetrazonium chloride based on benzidine and diamines containing bridging R^2 groups between the benzene rings chloroarylate conjugated dienes with participation of both diazo-groups (yields 50–60%):[83–85]

$$2H_2C=CR-CH=CH_2 + \left(ClN_2-C_6H_3(R^1)-\right)_2R^2 \xrightarrow[-2N_2]{CuCl_2} \left(ClCH_2CR=CHCH_2-C_6H_3(R^1)-\right)_2R^2\ ;$$

R=H, Me, Cl; R^1=H, Me, MeO; R^2=—, S, CH_2.

Chloroarylbutenes are compounds exhibiting different types of reactivity which have been used as the starting materials for the synthesis of many new substances which are otherwise difficult to obtain. Chloroarylbutenes are readily dehydrochlorinated by bases, being converted thereby into α-arylbutadienes. In particular, a convenient method has been developed for the dehydrochlorination of chloroarylbutenes by heating in dioxan with KOH or NaOH powder, which makes it possible to obtain very satisfactory yields of α-arylbutadienes with various substituents in the benzene ring and in the side chain:[2,77]

$$ArCH_2CR=CR^1CH_2Cl \xrightarrow[-HCl]{base} ArCH=CR-CR'=CH_2\ ;$$

R=R′=H; R=Me, R′=H; R=Cl, R′=H; R=R′=Me; R=Ph, R′=H; Ar=Ph, 4-MeC_6H_4, 4-ClC_6H_4, 4-$O_2NC_6H_4$ etc.

The reactions involving the substitution of the allyl chlorine atom in chloroallylbutenes are widely used for the synthesis of 1-alkyl-4-arylbut-2-enes,[2] 1-alkoxy- and 1-amino-4-arylbut-2-enes,[79,86] the corresponding quaternary ammonium salts,[74] *N*-arylbutenyldiethanolamines,[87] *N*-arylbutenylsulphonamides,[88] and diethyl 4-arylbut-2-enylphosphonates.[89] The aldehydes $ArCH_2CH=CHCH_2CHO$, which are difficult to obtain, have been synthesised from chloroarylbutenes by the Sommelet reaction.[90] The chloroarylbutenes undergo the Vilsmeier reaction with formation of penta-2,4-dienals.[91] A novel method has been developed recently for the synthesis of diaryloctatetraenes containing substituents in the aromatic rings and in the aliphatic chain.[31]

1,4-Di(4′-chlorostyryl)- and 1,4-di(4′-nitrostyryl)-benzenes were obtained by the interaction of diazotised *p*-chloro- or *p*-nitro-aniline with 4,4′-divinylbenzene followed by the dehydrochlorination of the chloroarylation products (in yields of 14 and 30%):[71]

$$H_2C=CH-C_6H_4-CH=CH_2 + 2(4-RC_6H_4N_2Cl) \xrightarrow[-2N_2]{CuCl_2} \rightarrow 4-RC_6H_4CH_2CHCl-C_6H_4-CHClCH_2C_6H_4R\text{-}4 \rightarrow \xrightarrow[-2HCl]{KOH/C_2H_5OH} 4-RC_6H_4CH=CH-C_6H_4-CH=CHC_6H_4R\text{—}4;$$

R=Cl, NO_2.

The reaction of ADC with conjugated arylbutadienes catalysed by copper chloride is of special interest. In this case arylation takes place, namely substitution of the terminal hydrogen atom in the aliphatic chain by the aryl group of the diazo-compound. This results in the formation of conjugated 1,4-diarylbutadienes:[2,92,93]

$$4-RC_6H_4CH=CR^1-CR^2=CHR^3 + ArN_2Cl \xrightarrow[-N_2,-HCl]{CuCl_2} 4-RC_6H_4CH=CR^1-CR^2=CR^3Ar;$$

R=H, Me, Cl, NO_2; R^1=R^2=R^3=H, Me, Cl, Ar=Ph, 4-MeC_6H_4, 4-ClC_6H_4, 4-$O_2NC_6H_4$.

The interaction of α-arylbutadienes with biphenyl-4,4′-bisdiazonium chlorides entails the evolution of nitrogen from both diazo-groups. One diazo-group is involved in arylation and the other in the Sandmeyer reaction (yield ~ 35%):[94,95]

$$4-RC_6H_4CH=CR'-CH=CH_2 + ClN_2C_6H_4-C_6H_4N_2Cl \xrightarrow[-2N_2,-HCl]{CuCl_2} \rightarrow 4-RC_6H_4CH=CR'-CH=CH-C_6H_4-C_6H_4Cl\ ;$$

R=H, Me, Cl; R′=H, Me, Cl.

Apart from the reactions with ADC, the interaction of conjugated dienes with arenediazonium salts containing other anions has been described. Buta-1,4-diene reacts with benzenediazonium bromide (in the presence of $CuBr_2$ as the catalyst), giving a low yield (~20%) of $PhCH_2CH=CHCH_2Br$;[2] chloroprene is bromoarylated with satisfactory yields (50 to 58%):[96]

$$H_2C=CCl-CH=CH_2 + 3-RC_6H_4N_2Br \xrightarrow[-N_2]{} 3-RC_6H_4CH_2CCl=CHCH_2Br;$$

R=H, Me, MeO.

The interaction of buta-1,4-diene with arenediazonium sulphates and nitrates catalysed by $CuSO_4$ and $Cu(NO_3)_2$ respectively in the presence of added copper or iron powder leads to the formation of a mixture of 1,2- and 1,4-hydroxyarylbut-2-enes (in proportions of 1 : 4 and in an overall yield of ~25%). The same hydroxyarylbutenes (in proportions of 1 : 7 and in an overall yield of ~40%) are also obtained in the reaction of buta-1,4-diene with arenediazonium tetrafluoroborates in the presence of $(MeCOO)_2Cu$ as the catalyst:

$$H_2C=CH-CH=CH_2 + 4\text{-}RC_6H_4N_2X \xrightarrow[-N_2]{pH\ 5-7} \rightarrow 4\text{-}RC_6H_4CH_2CH(OH)-CH=CH_2 + 4\text{-}RC_6H_4CH_2CH=CHCH_2OH;$$
$$X = HSO_4,\ NO_3,\ BF_4;\ R = H,\ Me,\ MeO,\ NO_2.$$

The products of anion-arylation are apparently formed initially and are then hydrolysed to hydroxyarylbutenes under the reaction conditions (in an aqueous acetone medium).[97]

Buta-1,4-diene is anion-arylated by arenediazonium acetates to give 1-acetoxy-4-arylbut-2-enes (25–30%), which are smoothly converted into 1-aryl-4-hydroxybut-2-enes on alkaline hydrolysis:[98]

$$H_2C=CH-CH=CH_2 + 4\text{-}RC_6H_4N_2OCOMe \xrightarrow[-N_2]{(MeCOO)_2Cu} \rightarrow 4\text{-}RC_6H_4CH_2-CHCH_2OCOMe \xrightarrow[-MeCOOH]{H_2O} 4\text{-}RC_6H_4CH_2CH=CHCH_2OH;$$
$$R = H,\ Me,\ MeO.$$

Buta-1,4-diene and isoprene react with arenediazonium tetrafluoroborates in aqueous alcoholic media to form 1-alkoxy-4-arylbut-2-enes (in yields of 30–50% for primary alcohols); secondary alcohols give low yields (~15%), while tertiary alcohols hardly react:[99]

$$H_2C=CR-CH=CH_2 + 4\text{-}R'C_6H_4N_2BF_4 \xrightarrow[-N_2,\ -HF,\ -BF_3]{AlkOH,\ (MeCOO)_2Cu} \rightarrow 4\text{-}RC_6H_4CH_2R'C=CHCH_2OAlk,$$
$$R = H,\ Me;\ R' = H,\ Me,\ Cl;\ Alk = Me,\ Et,\ Pr,\ iso\text{-}Pr,\ Bu,\ PhCH_2.$$

In the presence of ethylene glycol the above dienes are alkoxylated with participation of both hydroxyls and give 35–57% yields of the ethers $(4\text{-}R'C_6H_4CH_2CR=CHCH_2OCH_2)_2$.[99]

On interaction with arenediazonium sulphates, nitrates, and tetrafluoroborates in the presence of sodium nitrate, sodium halides, or sodium salts of carboxylic acids and with catalysis by $(MeCOO)_2Cu$, the same dienes combine with the aryl groups of the diazo-compounds and the anions of the corresponding sodium salts at the ends of the conjugated system to form anion-arylation products (25–45%):[100]

$$H_2C=CR-CH=CH_2 + ArN_2X \xrightarrow[-N_2,\ -NaX]{NaHal} ArCH_2CR=CHCH_2Hal;$$
$$R = H,\ Me;\ X = SO_4H,\ NO_2,\ BF_4;$$
$$Hal = NO_2,\ F,\ Cl,\ Br,\ MeCOO,\ EtCOO,\ PrCOO;$$
$$Ar = Ph,\ 4\text{-}MeC_6H_4,\ 4\text{-}ClC_6H_4.$$

On interaction with arenediazonium tetrafluoroborates or sulphates in the presence of potassium salts of *O,O*-dialkyl or *O,O*-diphenyl phosphorodithioates, buta-1,4-diene and isoprene give rise to 1,4-adducts (in 66–80% yields):[101]

$$H_2C=CR-CH=CH_2 + 4\text{-}R^1C_6H_4N_2X \xrightarrow[-N_2,\ -KX]{(R^2O)_2P(S)SK,\ CuCO_3(OH)_2} \rightarrow 4\text{-}R^1C_6H_4CH_2CR=CHCH_2SP(S)(OR^2)_2;$$
$$R = H,\ Me;\ X = BF_4,\ HSO_4;\ R^2 = Me,\ Et,\ Pr,\ iso\text{-}Pr,\ Bu,\ iso\text{-}Bu,\ Ph.$$

5. Vinyl Ethers and αβ-Unsaturated Aldehydes and Ketones

Vinyl acetate results with ADC[102] (and also with arenediazonium tetrafluoroborates[103]) to form 1-acetoxy-2-aryl-1-chloroethanes (in yields of 30–50%), which readily hydrolyse on steam distillation, giving high yields (~90%) of arylacetaldehydes:[104]

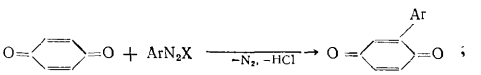
$$MeCOOCH=CH_2 + ArN_2X \xrightarrow[-N_2]{CuCl_2} MeCOOCHClCH_2Ar \xrightarrow[-HCl,\ -MeCOOH]{H_2O} ArCH_2CHO;$$
$$Ar = Ph,\ 4\text{-}MeC_6H_4,\ 4\text{-}MeOC_6H_4,$$
$$2\text{-}\text{ и }4\text{-}ClC_6H_4,\ 4\text{-}BrC_6H_4;\ X = Cl,\ BF_4.$$

A method of synthesis of α-arylketones by the reaction of ADC with enol acetates has been proposed. For this purpose, enol acetate (or enol benzoate or disulphide) is obtained from the initial ketone. On interaction with ADC, the acetate is arylated in the α-position in the ethylene group. After the removal of the acetyl group (by hydrolysis), the α-arylketone is obtained. $ArCH_2COMe$ (from acetone), $ArCH_2COPh$ (from acetophenone), ArPhCHCOPh (from benzyl phenyl ketone), etc. have been obtained in this way:[103,105]

$$RCOMe \xrightarrow[-AcOH]{Ac_2O} RC(OAc)=CH_2 \xrightarrow[-N_2,\ -HCl]{ArN_2Cl,\ CuCl} RC(OAc)=CHAr \xrightarrow[-AcOH]{H_2O+} RCOCH_2Ar,$$
$$R = Me,\ PhCH_2;\ Ar = 4\text{-}ClC_6H_4.$$

Acrolein and crotonaldehyde are chloro- and bromophenylated, combining with the halogen and the $Ph^{\cdot}$ radical at the ethylenic bond in the α- and β-positions respectively. Best results (yields of 20–50%) are achieved when the reaction is carried out at 0–2 °C and pH ~ 7 (Dombrovskii[2]):

$$RHC=CHCHO + PhN_2X \xrightarrow[-N_2]{CuX_2} RCH(Ph)CHXCHO;$$
$$R = H,\ Me;\ X = Cl,\ Br.$$



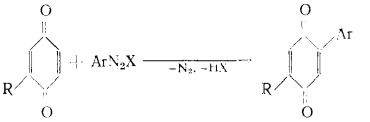
Methyl vinyl ketone is chloroarylated analogously, forming α-chloro-substituted aliphatic-aromatic ketones (yields 20 to 40%):[2]

$$MeCOCH=CH_2 + RC_6H_4N_2Cl \xrightarrow[-N_2]{CuCl_2} MeCOCHClCH_2C_6H_4R;$$
$$R = 4\text{-}Cl,\ 4\text{-}O_2N,\ 4\text{-}COOH.$$

Aryl vinyl and aryl isopropenyl ketones react in the same way, forming unstable aryl β-aryl-α-chloroethyl ketones (yields 25–40%); some of these are dehydrochlorinated even on vacuum distillation and are converted into chalcones:[106]

$$Ar'COCR=CH_2 + ArN_2Cl \xrightarrow[-N_2]{CuCl_2} Ar'COCRClCH_2Ar \xrightarrow{-HCl} Ar'COCR=CHAr;$$
$$R = H,\ Me;\ Ar = Ph,\ 4\text{-}O_2NC_6H_4;$$
$$Ar' = Ph,\ 4\text{-}MeC_6H_4,\ 2,4\text{-}Me_2C_6H_3,$$
$$4\text{-}Cl\text{- and }4\text{-}BrC_6H_4$$

Quinones undergo a vigorous arylation reaction with arenediazonium salts, a distinctive feature of which is that it proceeds in the absence of catalysts owing to the low redox potential of the quinonoid system.[31] The arylation of *p*-benzoquinone has been widely investigated. This reaction constitutes an excellent method of synthesis of numerous monoaryl-*p*-benzoquinones, whose yields frequently reach 80–90%:[2,6]

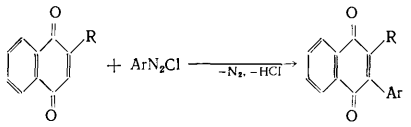


$$+ ArN_2X \xrightarrow[-N_2,\ -HCl]{}$$

;

Ar = Ph, 2- and 4-MeC_6H_4, 2-, 3- and 4-ClC_6H_4, 2,6-$Cl_2C_6H_3$, 2-BrC_6H_4, 2,6-Me_2-4-BrC_6H_2, 4-HOC_6H_4, 2- and 4-$MeOC_6H_4$, 2,4-$(MeO)_2C_6H_3$, 2-, 3- and 4-$O_2NC_6H_4$, 4-$MeCOC_6H_4$, 4-$HOCOC_6H_4$, 3-$MeOCOC_6H_4$, 2-PhC_6H_4, 4-PhC_6H_4, 4-$H_2NSO_2C_6H_4$, 1- and 2-$C_{10}H_7$; $X = HSO_4^-,\ Cl^-,\ Br^-,\ PO_4^{3-}$.

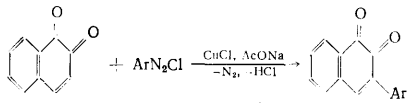
Monosubstituted *p*-benzoquinones are arylated predominantly in the 5-position for steric reasons, forming 2-R-5 aryl-*p*-benzoquinones in satisfactory yields:[2,6]



$$+ ArN_2X \xrightarrow[-N_2,\ -HX]{}$$

;

R = Me, Cl, Ph, 4-ClC_6H_4, 2-$O_2NC_6H_4$, 4-$MeOCOC_6H_4$; Ar = Ph, 3- and 4-ClC_6H_4, 2- and 3-BrC_6H_4, 2,- 3- and 4-$O_2NC_6H_4$, 4-$MeOC_6H_4$, 4-$MeOCOC_6H_4$, 1- and 2-$C_{10}H_7$; X = HSO_4, Cl.



2,3-, 2,5-, and 2,6-Disubstituted *p*-benzoquinones are effectively arylated by diazo-compounds (the 2,3-derivatives in the 5-position and the 2,5- and 2,6-derivatives in the 3-position).[2,6]

1,4-Naphthoquinone and its 2-substituted derivatives are arylated to 2-aryl-1,4-naphthoquinones and 2-R-3-aryl-1,4-naphthoquinones respectively (in moderate yields):[2,6]

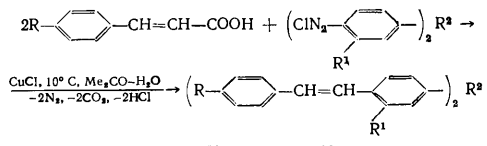
R=H, Me, OH, MeO; Ar=Ph, 2- and 4-MeC_6H_4, 4-ClC_6H_4, 4-$MeOC_6H_4$, 3- and 4-$O_2NC_6H_4$, 4-HOC_6H_4, 4-$HOSO_2C_6H_4$, 3-HO-4-$HOCOC_6H_4$, 2-$C_{10}H_7$.

1,2-Naphthoquinone is arylated in the presence of the CuCl catalyst in acetate buffer, giving low yields (5–37%) of 3-aryl-1,2-naphthoquinones:[107]

Ar = 2-, 3- and 4-ClC_6H_4.

6. αβ-Unsaturated Acids and Their Derivatives

The reactions of αβ-unsaturated carboxylic acids their derivatives with ADC have been investigated and described fairly completely. A survey of the available data shows that the reactions of αβ-unsaturated carboxylic acids in which the carboxyl is conjugated with electron-accepting groups proceed with substitution of the vinyl α-hydrogen atom by the Ar· radical derived from the diazo-compound with simultaneous decarboxylation and elimination of HCl.



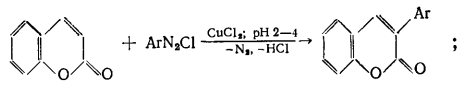
Thus the reactions of β-arylacrylic (cinnamic) acids with ADC proceed via this pathway and constitute the basis of a convenient and simple method of synthesis of numerous stilbenes, whose yields are in most cases good or entirely satisfactory:[2,6]

$$RCX{=}CHCOOH + ArN_2Cl \xrightarrow[-N_2,\,-CO_2,\,-HCl]{CuCl_2 \text{ or } CuCl} RCX{=}CHAr;$$

X = H, Ph, or other aryl groups;
Ar = Ph or other aryl groups.

Fluorine-containing stilbenes 4-$HOC_6H_4CH{=}CHC_6H_4CF_3$ and 4-$EtOCOC_6H_4CH{=}CHC_6H_4CF_3$-4 have been obtained in this way from diazotised fluoroanilines and cinnamic acid derivatives (yields of 60 and 33%).[108]

On interaction with tetrazonium chlorides, i.e. the chlorides of diphenylbisdiazonium, 3,3'-dinitrobiphenylbisdiazonium, methylenebis(benzenediazonium), oxybis(benzenediazonium), and bis(diazoniaphenyl) sulphone, cinnamic acid give rise to the corresponding bis-stilbenes (in ~50% yield), which exhibit a semiconductor type sensitivity to light:[109]



R=H, MeO, NO_2, Me_2N;
R^1=H, NO_2; R^2=—, O, SO_2, CH_2

β-Aroylacrylic acids react analogously with ADC, forming as a rule chalcones in high yields, which constitutes an effective method of synthesis of these compounds:[2,6,110]

$$RCOCH{=}CHCOOH + ArN_2Cl \xrightarrow[-N_2,\,-CO_2,\,-HCl]{CuCl_2} RCOCH{=}CHAr;$$

R = Ph or other aromatic groups;
Ar=2-, 3- and 4-$HalC_6H_4$ (where Hal=Cl, Br), or 2- 3- and 4-$O_2NC_6H_4$

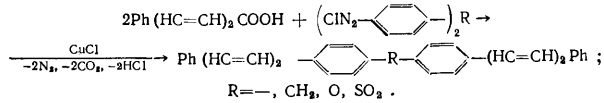
Coumarin and unbelliferone are arylated in the α-position relative to the carbonyl group, forming 3-arylcoumarins (in yields up to 80%):[2,6,42]

Ar=4-ClC_6H_4, 2-, 3- and 4-$O_2NC_6H_4$ etc.

In the reactions of ADC with maleic acid one of the COOH groups is split off and cinnamic acids are obtained as a result (in yields of ~60%):

$$\begin{matrix} HC{-}COOH \\ \| \\ HC{-}COOH \end{matrix} + ArN_2Cl \xrightarrow[-N_2,\,-CO_2,\,-HCl]{CuCl_2} ArCH{=}CHCOOH;$$

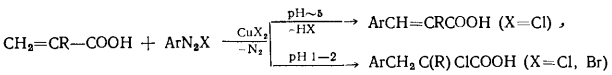
Ar=2-, 3- and 4-ClC_6H_4, 2.6-$Cl_2C_6H_3$ etc.



In the arylation of citraconic or bromomaleic acid the COOH group adjoining the methyl group or the bromine atom respectively is split off.[2,6]

Under the conditions of the Meerwein reaction, sorbic and cinnamylideneacetic acids are arylated at the α-carbon atom with simultaneous decarboxylation. This results in the formation of 4-aryl-1-methyl- and 1,4-diaryl-buta-1,3-dienes (for the latter, this reaction is one of the effective methods of synthesis):[2,6]

$$R(CH{=}CH)_2COOH + ArN_2Cl \xrightarrow[-N_2,\,-CO_2,\,-HCl]{CuCl_2} R(CH{=}CH)_2Ar;$$



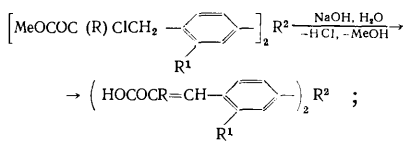
R=Me, Ph; Ar=2-, 3- and 4-ClC_6H_4, 2- and 4-$MeOC_6H_4$, 3- and 4-PhC_6H_4.

Cinnamylideneacetic acid reacts also with aromatic tetrazonium chlorides forming bisbutadienes (in yields up to 64%):[109]

R=—, CH_2, O, SO_2.

In media close to neutrality acrylic and crotonic acids are arylated at the β-carbon atom with retention of the carboxy-group, while in acid media they are halogenoarylated also with retention of the carboxy-group:[2,111]

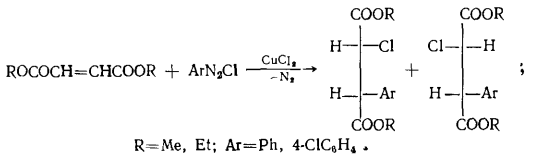
R=H, Me; Ar=2- and 4-MeC_6H_4, 2-, 3- and 4-ClC_6H_4, 2-, 3- and 4-BrC_6H_4, 2-, 3- and 4-$O_2NC_6H_4$, 2- and 4-$MeOC_6H_4$, 1-$C_{10}H_7$.



Methyl acrylate and methacrylate react with ADC, combining with a chlorine atom in the α-position and with the aryl radical derived from the diazo-compound in the β-position. This results in the formation of chloroarylation products (the yields reach 70%).[2,112,113] The products obtained from acrylic acid and its derivatives are valuable starting materials for the synthesis of substituted cinnamic acids and their esters and, after aminolysis, they serve as a source of phenylalanines with various substituents in the benzene ring:[2,6]

$$H_2C{=}CRCOOMe + ArN_2Cl \xrightarrow[-N_2]{CuCl_2} ArCH_2C(R)ClCOOMe \xrightarrow[H_2O]{NH_3} \rightarrow ArCH_2CR(NH_2)COOH;$$

R=H, Me, Cl, Br; Ar=Ph etc.



The reactions of methyl acrylate and methacrylate with bisdiazotised 4,4'-diaminobiphenyls, di(4-aminophenyl)-methane, and di(4-aminophenyl) ether proceed via two

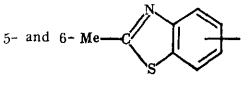
pathways: chloroarylation with participation of both diazo-groups (the main reaction with yields of products of 42–62%) and chloroarylation with participation of only one diazo-group and the replacement of the second diazo-group by a chlorine atom via the Sandmeyer reaction (yields 5–21%). The reactions are catalysed by both $CuCl_2$ and $FeCl_2$, but the latter promotes the formation of telomers. The bischloro-arylation products are smoothly dehydrochlorinated and hydrolysed by alkali, being converted into the corresponding biscinnamic acids:[114]

R=H, Me; R^1=H, MeO, NO_2; R^2=O, CH_2.

The reactions of maleate and fumarate esters with ADC proceed mainly as *trans*-addition of the Ar$^{\cdot}$ radical and a chlorine atom to the ethylenic bonds in fumarate esters, to which the maleate esters also isomerise under the reaction conditions.[115] This results in the formation of a mixture of the *erythro*- and *threo*-forms in proportions of 72 : 28:[115,116]

R=Me, Et; Ar=Ph, 4-ClC_6H_4.

Acrylamide undergoes the chloroarylation reaction and gives satisfactory yields (60–70%) of β-aryl-α-chloropropion-amides, whose dehydrochlorination by organic bases results in their smooth conversion into β-arylacrylamides, which is also of synthetic interest:[117]

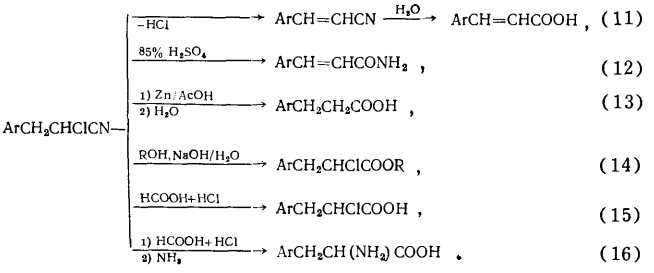


$$H_2C{=}CHCONH_2 + ArN_2Cl \xrightarrow[-N_2]{CuCl_2} ArCH_2CHClCONH_2 \xrightarrow[-HCl]{Et_3N} ArHC{=}CHCONH_2;$$

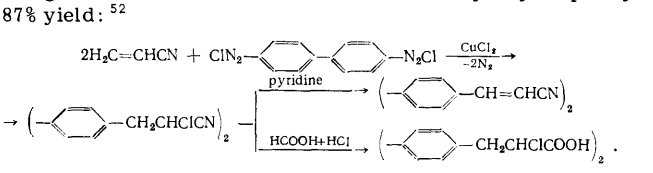
Ar=Ph, 4-MeC_6H_4, 4-$MeOC_6H_4$, 4-ClC_6H_4, 2-, 3- and 4-$O_2NC_6H_4$.

Acrylonitrile, the most important derivative of an αβ-unsaturated acid, is widely used in reactions with numerous ADC, which results in good yields (up to 90%) of β-aryl-α-chloropropionitriles. The reactions are catalysed by $CuCl_2$, CuCl, and other catalysts:[2,6,18,19,118,119]

$$H_2C{=}CHCN + ArN_2Cl \xrightarrow[-N_2]{} ArCH_2CHClCN;$$



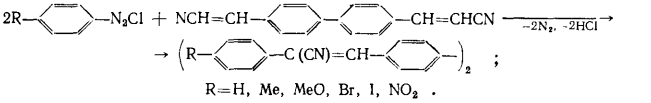
Ar=Ph, 2-, 3- and 4-MeC_6H_4, 2-, 3- and 4-ClC_6H_4, 2.4-$Cl_2C_6H_3$, 2-, 3- and 4-BrC_6H_4, 2-, 3- and 4-$O_2NC_6H_4$, 2.4-$(O_2N)_2C_6H_3$, 4-$MeOC_6H_4$, 4-NCC_6H_4, 4-$HOSO_2C_6H_4$, 1- and 2-$C_{10}H_7$,



α-Methyl- and α-chloro-acrylonitriles form analogously β-aryl-α-chloroisobutyronitriles $ArCH_2C(Me)ClCN$ [120] and β-aryl-αα-dichloroacrylonitriles $ArCH_2CCl_2CN$ [121] respectively in yields of 50–70%:

(Ar=Ph, 4-MeC_6H_4, 4-Cl and 4-BrC_6H_4, 4-$MeOC_6H_4$, 2-, 3- and 4-$O_2NC_6H_4$).

Arylchloropropionitriles have served as starting materials for the synthesis of new compounds which are otherwise difficult to obtain. Thus they are readily dehydrochlorinated by bases, being converted almost quantitatively into the nitriles of cinnamic acids, whose hydrolysis give rise to the corresponding acids [reaction (11)],[2,118,119] or their amides [reaction (12)].[122] The successive reduction and hydrolysis of chloropropionitriles make it possible to obtain hydro-cinnamic acids [reaction (13)],[2] while alkaline hydrolysis in aqueous alcohol gives rise to esters of α-chlorohydrocinnamic acids [R = Me or Et; reaction (14)].[2] It has been suggested that the ester 4-$ClC_6H_4CH_2CHClCOOMe$ be used to eradicate wild oats in wheat fields.[123,124] The hydrolysis of chloro-propionitriles with a mixture of concentrated formic and hydrochloric acids gives rise to β-aryl-α-chloropropionic acids in ~95% yields [reaction (15)];[2] hydrolysis with the same mixture of acids followed by treatment with ammonia or urotropine results in the formation of D,L-arylalanines and their derivatives from arylchloropropionitriles [reaction (16)]:[2,125]



Biphenyl-4,4′-bisdiazonium chloride reacts with acrylo-nitrile with evolution of nitrogen from both diazo-groups and produces 4,4′-bis(2-chloro-2-cyanoethyl)biphenyl in 78% yield. The latter is readily dehydrochlorinated and con-verted into 4,4′-bis(2-cyanoethylene)biphenyl in 71% yield and on heating with a mixture of concentrated HCOOH and HCl it gives rise to 4,4′-bis(2-chloro-2-carboxyethyl)biphenyl in 87% yield:[52]

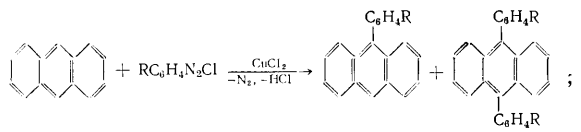
Acrylonitrile gives rise analogously to the chloroarylation products $X(C_6H_4CH_2CHClCN)_2$, where X = CH_2 or S, on reaction with methylenebis(benzenediazonium) and thiobis-(benzenediazonium)chlorides (yields 44 and 66% respec-tively).[52]

In reactions with ADC, 4,4′-bis(2-cyanovinyl)biphenyl is arylated in the α-position relative to the CN group (reactant ratio 1 : 2, catalyst CuCl, pH 2–4, aqueous acetone medium), giving rise to bisarylation products–4,4′-di(cyanostyryl)-biphenyls (yields 33–52%):[126]

R=H, Me, MeO, Br, I, NO_2.

The anion-arylation of acrylonitrile by the diazonium salts $ArN_2^+A^-$ also proceeds with addition of the anion A^- and the radical derived from the diazo-compound in the α- and β-positions of the ethylenic bond respectively. It has been shown that the interaction of acrylonitrile with arenediazonium sulphates in the presence of thiocyanate ions and catalytic amounts of copper(I) thiocyanate leads to β-aryl-α-thio-cyanatopropionitriles (in yields of ~60%).[47] In this case considerable amounts of ArSCN (up to 35%) are also obtained.[127] Arenediazonium thiocyanates are apparently

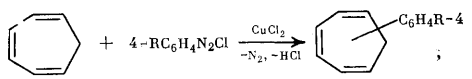
formed initially in the exchange reaction and then react further with acrylonitrile in accordance with a familiar mechanism:



$$ArN_2HSO_4 + NH_4SCN \rightleftarrows ArN_2SCN + NH_4HSO_4,$$
$$H_2C{=}CHCN + ArN_2SCN \xrightarrow[-N_2]{CuSCN} ArCH_2CH(SCN)CN;$$
Ar = Ph, 4-MeC_6H_4, 4-ClC_6H_4, 2-$O_2NC_6H_4$.

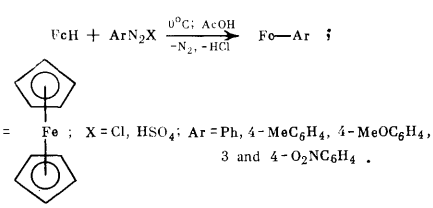
β-Aryl-α-(*O*-ethyl dithiocarbonato)propionitriles have been obtained analogously in the presence of potassium and copper(I) ethylxanthates,[128] while in the presence of sodium and copper(I) diethyl phosphorodithioates the products are β-aryl-α-(*O*,*O*-diethyl phosphorodithioato)propionitriles (in yields of 40–72%):[129]

$$H_2C{=}CHCN + 4\text{-}RC_6H_4N_2HSO_4 \xrightarrow{-N_2}$$
$$\rightarrow \begin{cases} \xrightarrow[EtOC(S)SCu]{EtOC(S)SK} 4\text{-}RC_6H_4CH_2CH[SC(S)OEt]CN, & (a) \\ \xrightarrow[(EtO)_2P(S)SCu]{(EtO)_2P(S)SNa} 4\text{-}RC_6H_4CH_2CH[SP(S)(EtO)_2]CN; & (b) \end{cases}$$
(a) R = H, NO_2; (b) R = NO_2.



7. Aromatic Systems

In conclusion we shall consider data on the arylation of aromatic systems under the conditions of the Meerwein reaction or similar conditions. Benzene, toluene, xylenes, halogenobenzenes, and nitrobenzenes are apparently hardly arylated under the conditions of this reaction. However, certain polycyclic aromatic systems enter into the arylation reaction. Thus anthracene is arylated by ADC, forming mixtures of 9-aryl- and 9,10-diarylanthracenes, whose yields vary from 7 to 54%:[130]



R = H, 4-Cl, 4-MeO, 2-NO_2, 4-NO_2.

Cyclohepta-1,3,5-triene is also arylated, giving low yields (7–29%) of arylcycloheptatrienes (the position of the Ar group has not been established):[131]

R = H, Cl, NO_2.

It has been shown in the studies of Nesmeyanov, Perevalova, and co-workers[132–134] that ferrocene is arylated by arenediazonium salts in the absence of catalysts, giving satisfactory yields (~60%) of arylferrocenes:

Among heteroaromatic compounds, substituted furans proved to be the most reactive in relation to ADC. Furan itself is arylated in the α-position with low yields.[135,136] α-Substituted furans, namely furfural, 2-acetylfuran, furan-2-carboxylic acid, and furyl-2-nitroethylene, are arylated in the 5-position on interaction with various ADC (in the presence of $CuCl_2$ or CuCl as the catalysts), giving rise to 5-aryl-2-substituted furans, whose yields vary from 6 to 80%:

R = CHO, Ar = 3-$O_2NC_6H_4$, 4-HOC_6H_4, 4-PhC_6H_4, 4-(4-$MeOC_6H_4$)C_6H_4 137—139; R = COMe, Ar = 4-ClC_6H_4, 4-BrC_6H_4, 4-$O_2NC_6H_4$ 140; R = COOH, Ar = 3- and 4-ClC_6H_4, 4-BrC_6H_4, 3- and 4-$O_2NC_6H_4$ 141, 142; R = COOAlk (Alk = Me, Et, Pr), Ar-2-, 3- and 4-ClC_6H_4, 2- and 3-$O_2NC_6H_4$, 2,4-$(O_2N)_2C_6H_3$ 136, 142; R = COCOOH, Ar = 4-BrC_6H_4 143; R = CH=$CHNO_2$, Ar = 4-ClC_6H_4, 4-BrC_6H_4, 4-$O_2NC_6H_4$ 144.

The data described show that the scope of the reactions of unsaturated compounds with aromatic diazo-compounds has not been exhausted. There is apparently no doubt about the radical mechanism of the reactions catalysed by transition metal salts and in the first place by copper chlorides. There is a need for further studies in order to elucidate the details of the mechanism of the conversion of the olefin–catalyst–aromatic diazo-compound complex, which results in the formation of anion-arylation and arylation products. The latter is apparently a process involving the addition-elimination of the elements of arenediazonium at the multiple bond of the unsaturated compound.

Further expansion of the range of unsaturated compounds and aromatic diazo-compounds used in the Meerwein reaction in order to obtain aliphatic-aromatic compounds containing several reaction centres is of undoubted interest for organic synthesis. The improvement of the anion-arylation and arylation methods will make it possible to reduce to a minimum the competing reactions, which will reduce the amount of side products.

The Reactions of Azines on Treatment with 1,3-Bifunctional Nucleophiles

V.N.Charushin and O.N.Chupakhin

The literature data on the *o*-cyclisation reactions of azines with 1,3-bifunctional nucleophiles, which make it possible to annelate furan, pyrrole, imidazole, and other five-membered rings to an aromatic aza-ring are surveyed and described systematically. The cyclisation reactions leading to *m*-linked cyclic adducts or products of the transformation of azines via the intermediate formation of cyclic *m*- and *p*-adducts are also examined.
The bibliography includes 152 references.

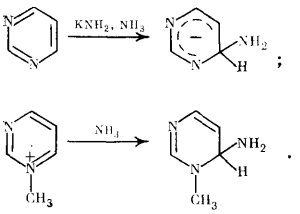
I. INTRODUCTION



The reactions of azines with simple nucleophiles have been considered in fair detail in a whole series of books, monographs, and reviews.[1-12] Rules have been established for the nucleophilic substitution in the series of azines which make it possible to predict the rates of these reactions as a function of the number of aza-groups and their positions in the ring, the influence of other substituents, benzoannelation, the nature of the leaving group, and other factors.[1-3, 10,11] The characteristics of the nucleophilic substitution of hydrogen[7-9] as well as the wide variety of transformdtions of azines and azinium salts under the influence of ammonia, potassium amide, hydrazine, and other simple nucleophiles have been investigated.[4-6]

An increasing number of communications concerning the reactions of azines with 1,3-bifunctional nucleophiles have been published in recent years; as a rule, these reactions are more complex, more varied, and sometimes also unexpected, The present review is devoted to the rules governing these reactions and their characteristic features. Before discussing the reactions of azines with 1,3-dinucleophiles, we shall consider briefly certain reactions of azines with simple nucleophiles.

II. CHARACTERISTIC FEATURES OF REACTIONS OF AZINES WITH SIMPLE NUCLEOPHILES

1. σ-Adducts of Azines

It is nowadays considered as generally recognised that the first stage in many reactions of azines with nucleophiles is the formation of σ-adducts. The σ-adducts are understood to be both anionic σ-complexes of azines, which are close analogues of Meisenheimer complexes, and uncharged dihydrocompounds, which are formed as a result of the addition of neutral nucleophiles to an uncharged aromatic aza-ring or in reactions of azinium cations with anionic and neutral reagents.[13-42]. The anionic σ-complex of pyrimidine with potassium amide[33] and the neutral amino-adduct formed on dissolving an *N*-methylpyrimidinium salt in liquid ammonia[31] can serve as examples.

The development and application of the ^1H and ^{13}C NMR spectroscopic methods made it possible to accumulate during the last 10–15 years extensive factual data on the direct detection of anionic σ-complexes and neutral σ-adducts for the majority of azines (pyridine,[18-20] quinoline and isoquinoline,[18,21,22] acridine,[23,24] pyrimidine,[17,25-32] other diazines and benzodiazines,[17,18,33-36] triazines,[15,16] pteridine,[37-39] naphthyridines,[40,41] *s*-tetrazine,[42] as well as a series of aromatic polynitro-compounds related to the above substances in terms of a series of chemical properties[43-46]). For example, the series of *N*-adducts attained in the reactions of azines with liquid ammonia or with potassium amide in liquid ammonia is fairly varied and representative (Table 1). The *O*-adducts formed in the reactions involving the covalent hydration of *N*-alkylazinium cations[13] and the products of the *C*-addition of the cyanide anion to acylazinium salts (Reissert's compounds)[14] have also been fairly thoroughly investigated.

The data presented in Table 1 make it possible to compare the spectroscopic characteristics of the anionic and neutral amino-adducts of azines and also to trace their variation as a function of the position of the aza-group relative to the sp^3-carbon atom. A characteristic feature of the ^1H NMR spectra of both anionic and neutral σ-adducts is the signal in the range 3.7–5.5 p.p.m. (Table 1), i.e. the signal displaced upfield by 3.5–5.0 p.p.m. compared with the signals of the initial substrates, which has been assigned to the proton at the tetragonal carbon atom. In the anionic σ-complexes of pyridine, quinoline, and isoquinoline the proton at the sp^3-carbon atom (H_α) absorbs in weaker fields, while that at the neighbouring carbon atom ($H\beta$) absorbs in stronger fields compared with the corresponding signals of the uncharged *N*-methyl analogues (Table 1). It is also seen from the examples presented that the constants for the spin–spin interaction (CSSI) between the corresponding protons of the

heterocycle are reduced by ~1 Hz on passing from neutral σ-adducts to the anionic adducts, but overall their ^{1}H NMR spectra are extremely similar.

Table 1. ^{1}H NMR spectra of the anionic and neutral σ-adducts of azines in liquid ammonia.

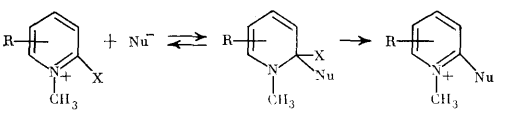
The formation of σ-adducts as the primary σ-linked products of the interaction is characteristic of various types of reactions of azines with simple nucleophiles: nucleophilic substitution of hydrogen,[7,8,23,24,32,40] substitutions via the $S_N(ANRORC)$† mechanism,[6] reactions leading to transformations of the heterocyclic systems,[4,5] and other reactions.

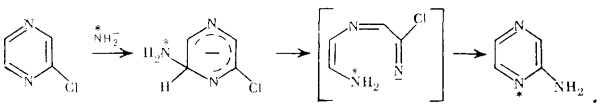
2. The Polydentate Nature of Azines



The outcome of the reactions of azines with nucleophiles and in general with 1,3-dinucleophiles in particular is in many respects determined by the properties of the σ-adducts, their stability, and the subsequent reactions which they undergo. The situation is complicated by the fact that many azines are polydentate and form two or even several types of σ-adducts with simple nucleophiles with respect to different positions in the heterocycle (Table 1). On the basis of the chemical shifts of the protons and the values of the CSSI in the ^{1}H NMR spectra of the σ-adducts, it is possible to determine accurately the reaction centre, i.e. the carbon atom which forms a covalent bond with the nucleophile. Since the values of CSSI characteristic of addition to a particular position in the azine ring change insignificantly as the substituent at the sp^3-carbon atom is varied, the data in Table 1 for the amino-adducts can be used to analyse the composition of the reaction mixtures of azines with other nucleophiles.

In cases of competitive addition of a nucleophile to two positions in the heterocycle an important factor is how the reaction is controlled under the given conditions—kinetically or thermodynamically. As a rule, the *o*-position relative to the heteroatom, i.e. the C(2) carbon atom, is more vulnerable to nucleophilic attack, while under the conditions of thermodynamic control more stable σ-adducts involving the C(4) position are formed. The formation of C(2)- and C(4)-linked σ-adducts in the reactions of pyridinium[19,20] and quinolinium[22] salts with *C*-nucleophiles as well as the formation of 2- and 4-amino-adducts of 1,5-naphthyridine[40] and 5-nitropyrimidine[32] in reactions with liquid ammonia (Table 1) may be quoted as examples of compounds obtained in recent years.

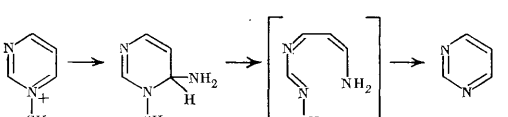
†Addition of the nucleophile, ring opening, and ring closure.



3. Chemical Reactions of the σ-Adducts

The stability of the σ-adducts depends both on the conditions of their formation and on the structure of the azines and varies within wide limits. The pathways whereby they can be stabilised are also varied. One of these pathways is the aromatisation of the σ-adducts as a result of the elimination of the substituent X, which represents overall aromatic nucleophilic substitution (S_NAE):

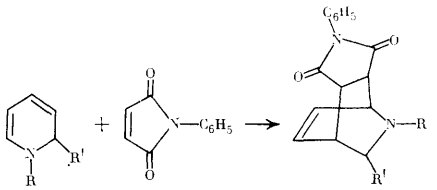
If X is a group which can be readily eliminated, then aromatisation usually proceeds so rapidly that the σ-adducts cannot be detected. This is true both of the series of azines and of the anionic σ-complexes of aromatic polynitrocompounds.[43–46] When X = H, the σ-adducts formed are relatively more stable and nucleophilic substitution of hydrogen is then known to require an oxidant.[7,8] The knowledge of the conditions governing the formation of the σ-adducts and the choice of a suitable oxidant make it possible to achieve successfully reactions involving the nucleophilic substitution of hydrogen in the series of azines. A number of recently published studies on the low-temperature oxidation of the σ-adducts of azines with ammonia demonstrate how attractive and promising is this direct amination method.[32,47,48]



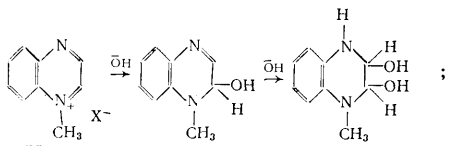
Another possible reaction pathway for the azine σ-adducts involves the opening of the heterocycle with subsequent formation of a new cyclic system; these are the so-called recyclisation reactions. The studies by Dutch chemists, namely van der Plas and co-workers,[4–6] have played a major role in the study of the recyclisation reactions of azines and other heterocyclic systems. These investigations showed that many outwardly simple nucleophilic substitution reactions of azines in reality proceed via the $S_N(ANRORC)$ mechanism.[4–6] The substitution of chlorine in 2-chloropyrazine on treatment with potassium amide in liquid ammonia can serve as an example of a reaction which takes place to the extent of 100% via the $S_N(ANRORC)$ mechanism:[49]

(I) (II)

Here and henceforth $\overset{*}{N}$ represents nitrogen enriched in the ^{15}N isotope.

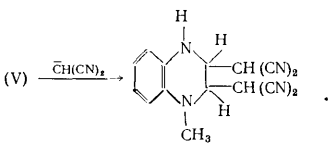


The observation of the demethylation of *N*-methylpyrimidinium salts in liquid ammonia[31] led to the concept of the so-called degenerate transformations of heterocycles,[5] i.e. reactions in which the initial heterocyclic system is restored as a result of recyclisation:



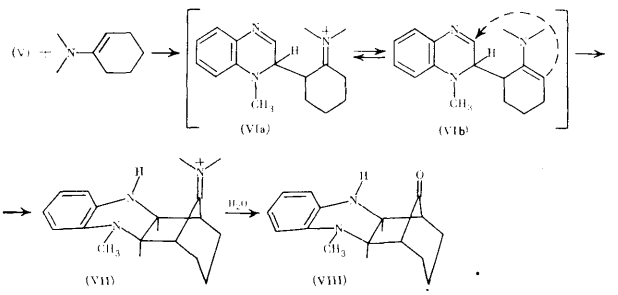
(III) (IV)

If the formation of the σ-adducts can be detected by NMR, then in the majority of studies on the recyclisation of azines[4-6] this is regarded as a stage preceding the opening of the heterocycle. The opening of the ring in the σ-adducts (I) and (III), formed in these and similar recyclisation reactions, is usually postulated on the basis of the results of experiments using ^{15}N isotope labels. It has been suggested[5] that the opening of the ring in the dihydropyrimidines (III) proceeds most probably as a thermally allowed $[\pi 4_s + \sigma 2_s]$-electrocyclic disrotary reaction. However, it must be emphasised that direct evidence for the involvement of the non-cyclic intermediates of type (II) and (IV) in the above reactions of the heterocycles has not so far been obtained.



As regards the σ-adducts of azines, they have long ceased to be merely hypothetical intermediates. Studies whose authors were enabled by the knowledge of the structure and conditions of the formation of the σ-adducts to employ them as starting materials for further syntheses are being published at an increasing frequency. Examples of such an approach have been quoted in a review[50] devoted to advances in the chemistry of dihydropyridines. The addition of nucleophiles to pyridines and pyridinium salts is regarded in this review as one of the methods of synthesis of 1,2- and 1,4-dihydropyridines. The σ-adducts formed can be used further as the starting materials in [4 + 2]- and [2 + 2]-cycloadditions, *N*-alkylation and *N*-acylation reactions, and other transformations:[50]

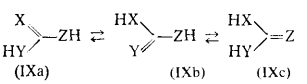
Yet another reaction pathway involving the σ-adducts is the secondary addition of a nucleophile with formation of bis-adducts. The presence of electron-accepting groups in the aromatic ring creates in many instances a structural situation where the remaining double bond (or bonds) of the σ-adduct is activated for secondary nucleophilic attack. Among azines, the tendency towards the formation of bis-adducts is most characteristic of compounds containing the pyrazine ring: pyrazines,[51] quinozalines,[18,35,51,52] pyrido[2,3-*b*]pyrazines,[53-55] and pteridines.[37-39] Thus the quinoxalinium salts (V) combine twice with both heteroanions[35] and carbanions:[52]



(V)

The bis-adducts formed in the reactions of pyrazines with heteroatomic nucleophiles usually exist in solution in equilibrium with the monoadducts, but are detected in the ^1H NMR spectra from the characteristic absorption of the H(2) and H(3) protons in the range 3.8–5.4 p.p.m. and the low values of the vicinal CSSI (Table 2). An important factor increasing the stability of the bis-adduct is the presence of an aromatic ring or an aromatic aza-ring condensed with the tetrahydropyrazine ring. It is not fortuitous that all the examples presented in Table 2 refer to bicyclic 1,4-diazines and the presence of a positive charge in the pyrazine ring in the initial substrates is not an obligatory condition for the formation of the bis-adducts (Table 2). Monocyclic pyrazines react with heteroatomic nucleophiles to form monoadducts (Table 1), but the more stable products of the addition of two *C*-nucleophile residues to pyrazines have been obtained on a preparative scale.[51] Bis-adducts with *C*-nucleophiles have also been obtained in the reactions of quinoxalinium[52] and pyrido[2,3-*b*]pyrazinium[53-55] cations.

It is readily seen that reactions involving diaddition to 1,4-diazines create conditions also for the formation of cyclic adducts when the reactant contains two nucleophilic centres. Thus, for example, the enamines derived from cyclic ketones, which exhibit the properties of 1,3-dicarbanionic reagents, react with quinoxalinium salts to form the cyclic adducts (VII) and (VIII):[59,60]

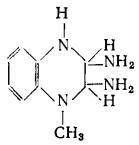


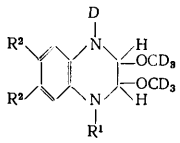
It has been suggested that the cyclisation takes place stepwise via a stage involving the formation of the σ-adduct (VI). Depending on the nature of the reactants, the reactions of azines with dinucleophiles can also proceed via other mechanisms (see below).

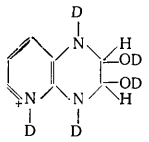
Bifunctional nucleophiles are usually classified in terms of the atoms which function as the nucleophilic centres (C,C-; C,N-; C,O-; N,N-; etc.) and also of their relative positions (1,2-, 1,3-, and 1,4-dinucleophiles). Analysis of the literature data shows that the 1,3-dinucleophiles are used most frequently because their cyclisations with azines lead to the formation of unstrained five- and six-membered rings.

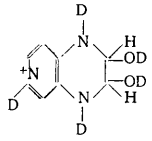
In the present review an attempt has been made to summarise the data published during the last ten years on the cyclisations of azines with 1,3-dinucleophiles which make it possible to annelate to an aromatic aza-ring various carbocyclic and heterocyclic fragments; in addition, the cyclisation leading to *m*- and *p*-linked bicyclic adducts as well as the products of the transformation of azines under the influence of 1,3-dinucleophiles are examined.

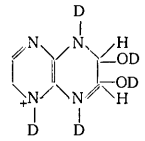
III. 1,3-BIFUNCTIONAL NUCLEOPHILES

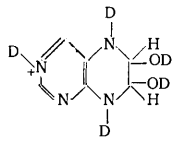


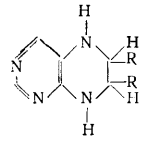












Ketones,[61,62] ketone enamines,[59,60,63,64] β-diketones and their derivatives,[65-71] ureas, thioureas, and guanidines,[72-74] amidines,[75,76] α-substituted acetamidines[76-79] and iminoesters,[80-82] CH-active acetamides,[70,74,83] and other reagents described by formulae (IX, a–c) have been used as 1,3-dinucleophiles in reactions with azines;

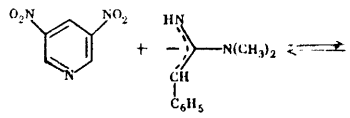
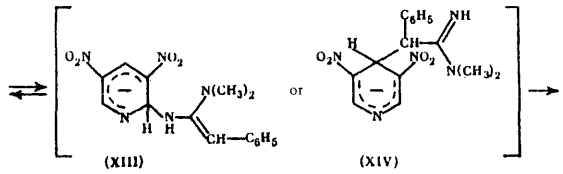
1. Tautomerism and Ambident Nature

A common structural feature of the 1,3-dinucleophiles considered is the presence of a double bond conjugated with a heteroatom having an unshared electron pair. A characteristic of such three-centre unsaturated systems is their capacity for prototropic tautomerism. The keto–enol,[84] thione–thiol, imino–enamine, lactim–lactam, and other types of triad tautomerism are known.[85] Certain types of tautomeric transformations, in particular, the existence of acetamidines (Xa) in the form of keten *N,N*-acetals (Xb), have been confirmed experimentally quite recently:[77,78]

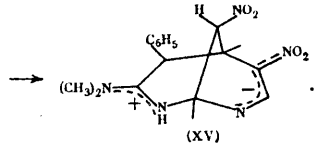
(Xa) (Xb)



Many reactions of azines with 1,3-dinucleophiles take place only in the presence of bases. Tautomeric systems which exist solely in two forms give rise to the ambident anions (XI) on treatment with bases; in the case of three tautomeric forms, there is a possibility of the existence of the tautomeric anions (XII, a–c):

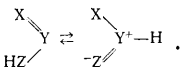


(XI) (XIIa) (XIIb) (XIIc)

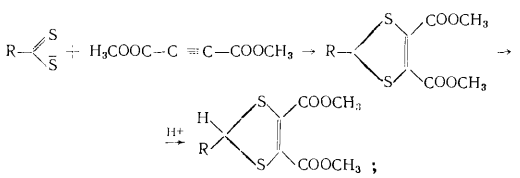


In the anions (XI) and (XII, a–c) the negative charge is distributed between the atoms of the triad and each of the terminal atoms can participate in the formation of a bond with the electrophile. Classical examples of 1,3-ambident anions are, for example, the enolates of β-diketones which form both *C*- and *O*-alkylation products.[86,87]

Thus the 1,3-ambident nature of nucleophiles combined with the behaviour of azines as polydentate species permits the formation of several types of mono-adducts which differ both in the site of the addition of the nucleophile to the azine nucleus and in the terminal atoms of the 1,3-anionic system involved in the formation of the bond. 1,3-Ambident systems are capable of reacting not only via each of its nucleophilic centres separately but also simultaneously via both such centres, which is the reason for the possibility of the formation of rings. Thus the reaction of 3,5-dinitropyridine with *N,N*-dimethyl-α-phenylacetamidine leads to the bridged cyclic adduct (XV)[88] and both the *N*- and *C*-adducts (XIII) and (XIV) can be regarded as probable intermediates:



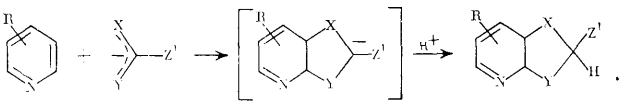
(XIII) (XIV)



(XV)

2. Anionic and Dipolar Cycloaddition Reactions

It has been suggested in the literacture[89] that any triatomic systems of the type $\bar{Z}-X=Y$ and $\ddot{Z}-X=Y$, where Z is an atom with a free electron pair, are potential 1,3-dipoles. It has also been shown in a number of studies[90-94] that systems of the type X=Y−ZH are sources of 1,3-dipoles as a result of prototropic tautomerism:

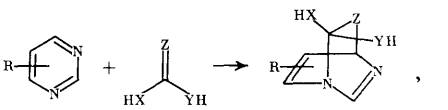


A number of studies have been published in recent years on the cycloaddition reactions with participation of heteroallyl anions.[68,69,80-82,95-108] For example, it has been found that the anions of dithiocarbamic[104] and also dithiocarbonic acid[101] react with a typical dipolarophile, namely dimethyl acetylenedicarboxylate, to form the 1,3-dithiols (XVI, a and b):

(XVI, a and b):

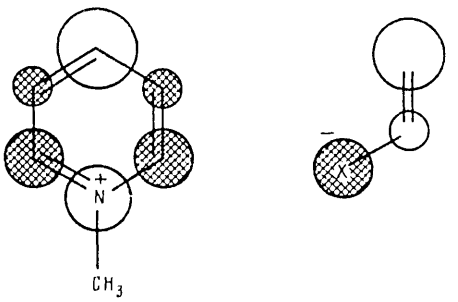
(a) R = $N(C_2H_6)_2$; (b) R = C_6H_5 .

Many of the dinucleophiles examined above conform to the principles, formuldted by Petrov et al.,[104] of the construction of systems capable of anionic cycloaddition. In the light of these requirements, we believe that the possibility of the concerted cycloaddition of 1,3-ambident anions to a double bond of the aromatic aza-system is entirely realistic.



(XVII)

We shall consider the simplest case—the reaction of pyridine (pyridinium ion) with the 4π-electron heteroallyl system from the standpoint of the theory of molecular frontier orbitals.[109] The form of the highest occupied molecular orbitals (HOMO) of the heteroallyl anion and the lowest unoccupied molecular orbitals (LUMO) of the pyridinium cation, presented in the Figure, shows that the anionic cycloaddition at the C(2) and C(3) positions in the pyridine ring is prohibited owing to the phase incompatibility of the frontier orbitals but is possible at the C(3) and C(4) positions.

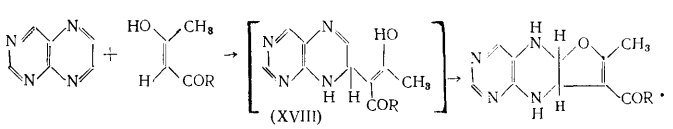


Apart from the limitations imposed by the theory of frontier molecular orbitals, the reaction via the anionic cycloaddition mechanism requires the stabilisation of the anionic intermediate (XVII), for example, as a result of protonation.[95] Furthermore, in the course of the anionic cycloaddition reactions the aromaticity of the azine ring is lost and the operation of this mechanism is therefore possible only for azines with an extremely low degree of aromaticity. Apparently, because of all these factors, clear-cut examples of anionic cycloaddition involving azines have not so far been found.

3. The Diels–Alder Reaction with Reverse Electronic Requirements

A number of 1,3-ambident nucleophiles contain a double bond enriched in electrons and can be regarded as 2π-components in reactions involving cycloaddition to the electron-deficient azadiene system of azines (the Diels–Alder reaction with reverse electronic requirements).[110,111] In a general form, such cyclisation can be described schematically as follows:

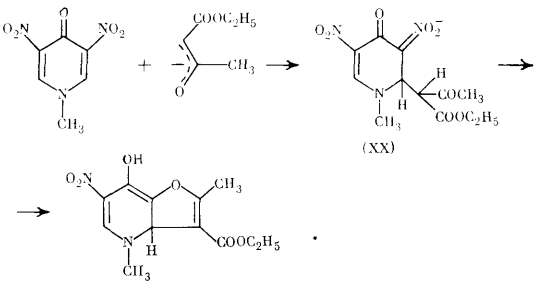
where XH and YH are electron-donating groups. Such reactions are at present known for azines containing at least two aza-groups in the *meta*-positions and yet another acceptor: nitropyrimidines, triazines, and tetrazines.



Schematic representation of the lowest unoccupied molecular orbital of the pyridinium cation and of the highest occupied molecular orbital of the heteroallyl anion.[109] The diameters of the circles are proportional to the coefficients of the atomic orbitals and cross-hatching indicates a change in the sign of the wave functions.

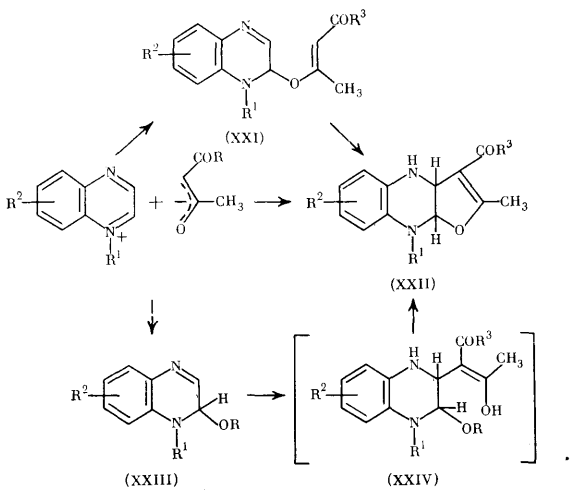
IV. THE CYCLISATION REACTIONS OF AZINES WITH 1,3-DINUCLEOPHILES

The reactions of azines with 1,3-dinucleophiles can in general lead to bicyclic systems with an *o*-, *m*-, or *p*-linked aza-ring. Despite a number of common features and the identity of the reagents capable of inducing all three types of cyclisation, the mechanisms of the formation of *o*-, *m*-, and *p*-linked cyclic adducts are different and merit separate consideration.



1. *ortho*-Cyclisations

One of the first examples of the *o*-cyclisations of azines with 1,3-dinucleophiles is the reaction of pteridine with β-dicarbonyl compounds.[71] The authors[71] suggested a stepwise cyclisation mechanism involving the intermediate formation of the monoadduct (XVIII). It is noteworthy that the structure of the cyclic adducts (XIX) has not been rigorously demonstrated and one cannot rule out the possibility of the reverse regio-orientation of the furan ring:

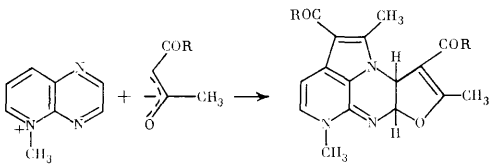


(XVIII) (XIX)

A similar mechanism with the initial formation of Michael adducts (XX) has also been proposed for the reactions of 3,5-dinitro-4-pyridone,[112] 3-bromo-4-nitropyridine *N*-oxide,[113] and 2,3,5,6-tetrachloropyrazine[114] with the anions of β-dicarbonyl compounds in which the furan ring is annelated as a result of the successive nucleophilic substitution of the halogen atoms or the nitro-group#:

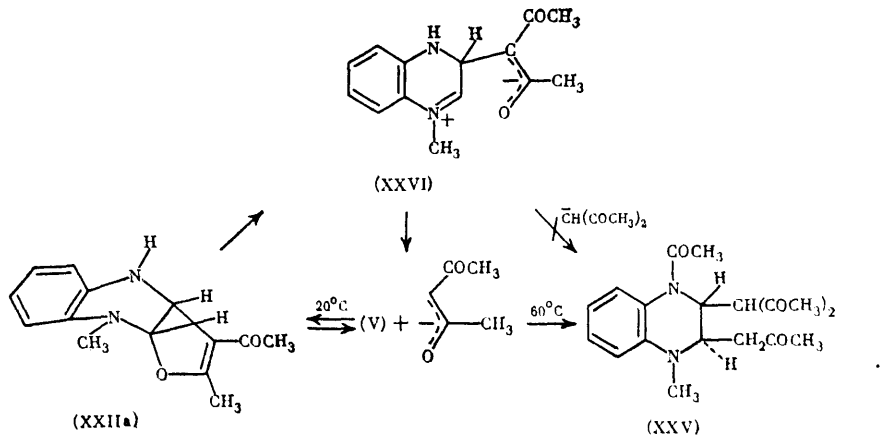
(XX)

The mechanisms discussed in a number of studies[71,112-114] are inapplicable to the outwardly similar cyclisations of quinoxalinium salts with the enolates of β-dicarbonyl compounds in which the furan ring is also annealed but the C(2) atom, which is the most electrophilic in quinoxolinium salts, is linked during the reaction to the enolate oxygen. The reverse orientation of the furan ring presupposes either the initial formation of a C—O bond (charge control) in the stepwise course of the reaction via the σ-adduct (XXI) or the concerted formation of the C—O and C—C bonds via the anionic cycloaddition mechanism.[67-69] If the reaction is carried out in an alcoholic medium and is catalysed by bases, one cannot rule out also a mechanism in which the lyate complex (XXIII) is formed initially. Next there is a possibility either of the displacement of the OR group from the σ-adduct (XXIII) by the enolate anion, which leads to the formation of compound (XXI), or of the *C*-addition of the enolate to the 3-position. The complex (XXIII) can be detected in the ^{1}H NMR spectra and its conversion into the cyclic adduct (XXII) has been confirmed experimentally.[36]



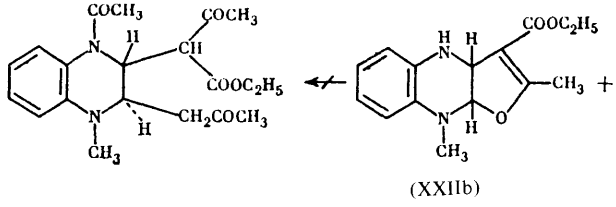
(XXI) (XXII) (XXIII) (XXIV)

#The cyclisations of azines with 1,3-dinucleophiles which take place as a result of the substitution of readily removed groups, as well as the cyclisations involving side groups, have their specific features and are not considered in this review.

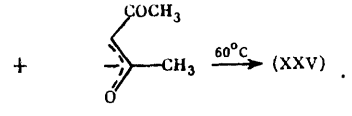


It has been shown by ^{1}H NMR and X-ray diffraction that, under the conditions of kinetic control, the reaction is highly regioselective and stereoselective and leads exclusively to the cyclic adducts (XXII) with the *endo*-configuration and *cis*-orientation of the bridgehead hydrogen atoms.[68] Quinoxalinium salts substituted in the benzene ring, including benzo[*g*]- and benzo[*f*]-annelated cations, react with the enolates to form cyclic adducts (XII) of analogous structure.[69]

The pyrido[2,3-*b*]pyrazinium cation reacts with the enolates in a more complex manner.[69] Apart from the annelation of the furan ring to the uncharged (as in pteridines[71]) pyrazine ring, in this case the second diketone residue undergoes *C*-addition to the *p*-position of the pyridinium ion with subsequent intramolecular cyclisation to the pyrrole ring:[69]



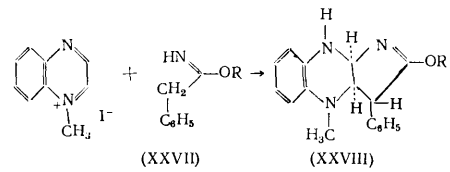
The question how the *o*-cyclisations discussed above take place—stepwise or as concerted pericyclic reactions—is common to these processes and is of fundamental importance. It is known[115-118] that the *cis*-principle is one of the main criteria of pericyclic reactions. The regiospecificity and stereospecificity of the cyclisation of β-diketones with aromatic 1,4-diaza-salts as well as their occurrence in conformity with the *cis*-principle constitute, as it were, arguments in support of anionic [3$^-$ + 2]-cycloaddition. However, it was noted above that the anionic cycloaddition at the C(2) and C(3) positions in the pyridinium ion is prohibited by the phase incompatibility of the frontier orbitals. Since it is difficult to expect a qualitative change in the properties of the LUMO on passing from the pyridinium to the pyrazinium (quinoxalinium) cation in view of their topological similarity, the question of the mechanism of the cyclisations considered remains open and requires both more profound quantum-chemical analysis and additional experimental data.



The experimental data demonstrating the concerted nature of the reverse cyclodecomposition reaction may serve as an additional argument in support of the concerted mechanism of the cyclisation of the enolates with quinoxalinium salts.[119] It has been shown that furo[2,3-*b*]quinoxaline (XXIIa) is formed only under the conditions of kinetic control at temperatures below 20 °C, but at 60 °C the reaction of *N*-methylquinoxalinium with acetylacetonate leads to the diadduct (XXV) with the *trans*-orientation of the hydrogen atoms located at the C(2) and C(3) atoms of the tetrahydropyrazine ring:[119]

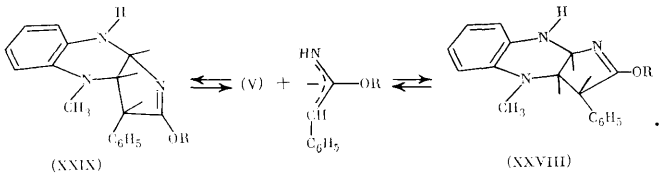
Compound (XXV) is also formed when a solution of the cyclic adduct (XXIIa) in ethanol, heated to 60 °C, is treated with a second mole of acetylacetonate. The stepwise mechanism of this reaction via the intermediate (XXVI) in accordance with the scheme (XXIIa) → (XXVI) → (XXV) has been disproved by an experiment in which acetylacetonate was added at 60 °C to a solution of the cyclic adduct (XXIIb) having the ethoxycarbonyl group in the furan ring, which led to the diadduct (XXV) without the ester group:[119]

(XXIIb)



The result of this experiment demonstrates the reversibility of the cyclisation of the cation (V) with the enolates and also that the rupture of both σ-bonds (C–O and C–C) in the dissociation of the cyclic adduct (XXIIa) to give the starting materials most probably takes place via a concerted mechanism. The base-catalysed cycloreversions of tetrahydrofurans,[120] which have been discussed as concerted reactions,[118] constitute a fairly close analogy.

However, one cannot rule out fully the stepwise mechanism of the dissociation of the cyclic adduct (XXIIa) in accordance with the scheme (XXIIa) → (XXVI) → (V) + diketone. The absence of the reaction (XXVI) → (XXV), demonstrated by the experiment involving the transformation of compound (XXIIb) into (XXV), can be accounted for by the unduly short lifetime of the intermediate (XXVI) and its much faster dissociation compared with the rate of addition of the second diketone residue.

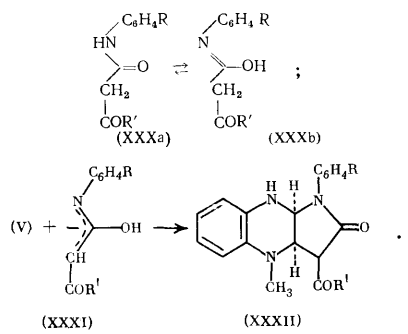


It is noteworthy that the cyclisation reactions of pyrazines with β-ketoenolates merit attention as a method of synthesis of furo[2,3-*b*]pyrazines regardless of the mechanism.

The annelation of the pyrrole ring to pyrazines is achieved in the reactions with N, C-dinucleophiles such as α-substituted acetiminoesters (XXVII),[80–82] acetamides, and β-ketoacid amides:[121]

(XXVII) (XXVIII)

Under the conditions of thermodynamic control, the interaction of quinoxalinium salts with iminoesters takes place regioselectively and stereoselectively and leads to the cyclic adduct (XXVIII) having the *exo*-structure.[81] In base catalysis the rate of cyclisation increases and two types of stereoisomeric cyclic adducts (XXVIII) and (XXIX) have been detected in the reaction mass by ^{1}H NMR. They have also been isolated on the preparative scale in the form of crystals:[80]

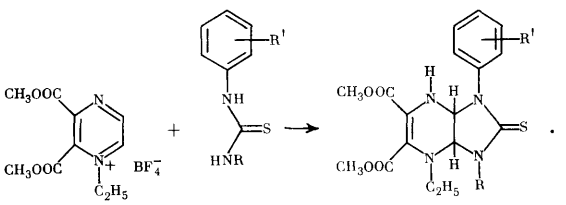


(XXIX) (XXVIII)

It has been shown chemically and spectroscopically that the *endo*-adducts (XXIX) are formed at a high rate in the initial period but under the reaction conditions the *endo*-adducts rearrange irreversibly to the more stable *exo*-isomers (XXVIII). It has been established that the rearrangement proceeds via a cycloelimination stage, i.e. via the decomposition of the *endo*-isomers to the starting materials.[80]

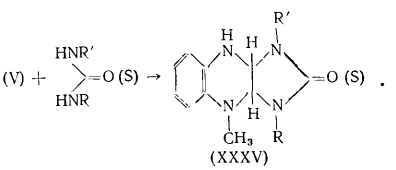
The above characteristics of the cyclisation of quinoxalinium salts with iminoesters repeat in broad outline the characteristics of the cycloaddition reactions[115–118] and, in particular, the anionic cycloaddition reactions.[95,97] It therefore appeared quite justifiable to regard these reactions as anionic [3$^-$ + 2]-cycloaddition of heteroallyl anions to the conjugated C=C bond of the pyrazine ring.[80]

The anilides of β-ketoacids (XXX) in the potentially tautomeric form (XXXb) are in essence analogues of iminoesters. They too react with quinoxalinium salts (V) to form the cyclic adducts (XXXII) containing the pyrrole ring:[121]



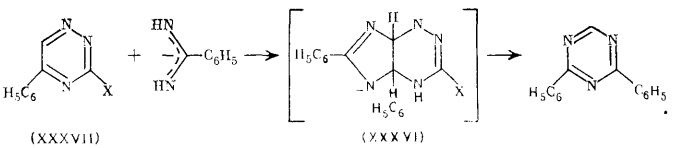
(XXXa) (XXXb)

(XXXI) (XXXII)



The high regioselectivity and stereoselectivity of the cyclisation is noteworthy. Despite the fact that the mesomeric anion (XXXI) participates in the reaction, no appreciable amounts of furo[2,3-*b*]quinoxalines or other cyclic adducts are formed.[121]

The annelation of the imidazole ring, leading to derivatives of imidazo[4,5-*b*]pyrazine (XXXIV), takes place in the reactions of pyrazinium salts with *N*-mono- and *N*,*N*′-di-aryl-substituted thioureas (XXXIII):[122]

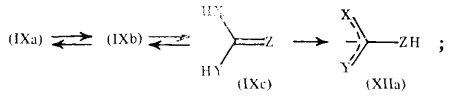


(XXXIII) (XXXIV)

Ureas and thioureas also behave as N,N′-dinucleophiles in reactions with quinoxalinium salts (V), giving rise to the products (XXXV):[122]

(XXXV)

The bicyclic adducts (XXXVI) with the annelated imidazole ring have also been regarded as the most probable intermediates in the transformation of 1,2,4-triazines (XXXVII) into 2,4-diphenyl-1,3,5-triazine, which has a fairly complex mechanism:[123]

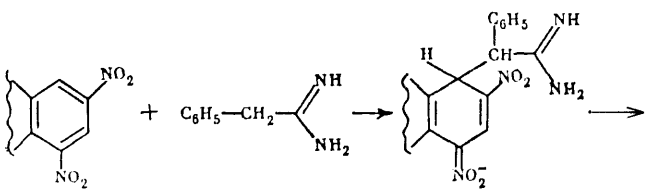


(XXXVII) (XXXVI)

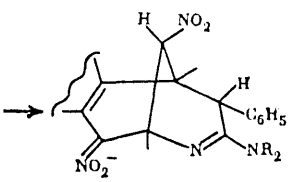
We may mention again that the presence of the pyrazine fragment in the triazines (XXXVII) is structurally favourable for *o*-cyclisations.

A characteristic feature of the ^{1}H NMR spectra of all the cyclic adducts of pyrazinium and quinoxalinium salts with 1,3-dinucleophiles mentioned above is fairly high values of the vicinal CSSI between the protons at the bridgehead carbon atoms (^3J = 7–10 Hz), which indicates a *cis*-junction between the five-membered heterocycles and the pyrazine ring.[68,69,80,81,121,122]§ As already mentioned above, other vicinal constants $^3J_{2,3}$ = 2.5–3.5 Hz (Table 2), corresponding to the *trans*-orientation of the protons in the tetrahydropyrazine ring, are characteristic of the acyclic diadducts of pyrazines and quinoxalines.

If an attempt is made to formulate the empirical principles of the selection of 1,3-dinucleophiles (IX) capable of *o*-cyclisation, it is found that a common feature of different combinations of the heteroatoms X and Y remains, on the one hand, the presence of substituents stabilising the 1,3-ambident anions (XIIa) formed (this is frequently the phenyl or keto-group) and, on the other hand, the presence at the central atom of a triad of electron-donating groups of the type NR_2, OR, SR, or the methyl group, which activate these systems with respect to interaction with electron-deficient azines.



§ The ^{1}H NMR spectra of tetrahydroquinoxalines condensed with five-membered heterocycles have been discussed in detail by V.N.Charushin, A.I.Chernyshov, N.N.Sorokin, and O.N.Chupakhin, Org.Magnet.Resonance, 1984 (in the Press).

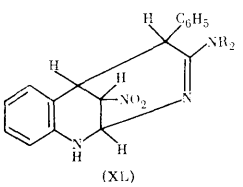


X, Y = N, O, S, CH, NH, NAr, CHAr, CHCOR;
ZH = NR_2, OR, SR.

2. *meta*-Cyclisations

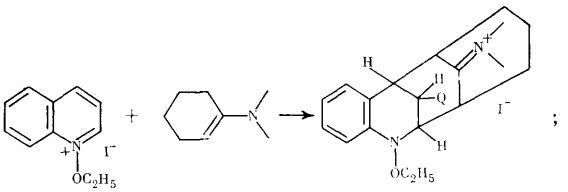
The characteristic features of *m*-cyclisations with 1,3-dinucleophiles were first formulated clearly by Strauss in a series of studies of the reactions of aromatic polynitro-compounds with enamines, α-phenylacetamidines, and urethanes:[124-130]

(XXXVIII)



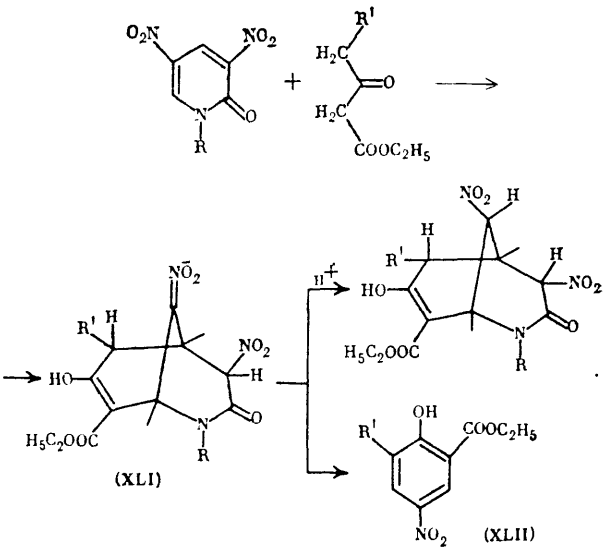
(XXXIX)

Cyclisations of this type, which have been called *meta*-bridging reactions,[124] immediately attracted attention as a direct and convenient method of synthesis of complex polycyclic structures. In particular, Strauss[126] demonstrated the applicability of these reactions to the direct synthesis of benzomorphans—potential antagonists of narcotic drugs.



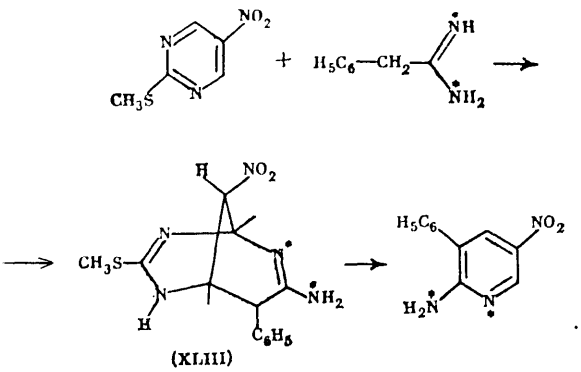
It has been suggested[124] that *m*-cyclisations take place in two stages via the intermediate formation of the anionic σ-complexes (XXXVIII), which can not only be detected spectroscopically but in a number of instances can be isolated, after which the second stage of the reaction can be carried out—the cyclisation of the σ-complexes (XXVIII) to *m*-linked cyclic adducts (XXXIX).[130]

The *m*-bridging reactions were subsequently extended to the aza-analogues of aromatic polynitro-compounds such as 3,5-dinitropyridine and 3-nitroquinoline.[88]



(XL)

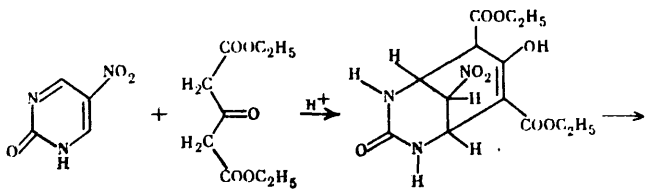
The formation of the cyclic adducts (XV) and (XL) has been detected by ^{1}H NMR, but they could not be isolated.[88] This is due to the lower stability of the *m*-linked adducts of azines with 1,3-dinucleophiles compared with their nitro-analogues or with the *o*-annelated azines. In addition, the *m*-adducts undergo various chemical reactions. Thus the *m*-cyclisation of *N*-ethoxyquinolinium salts with enamines is accompanied by the addition of a second molecule of the initial cation:[61,64]



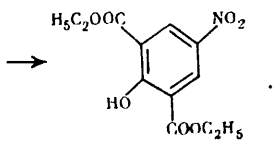
Q = 2-quinolinyl.

However, the most common reactions of the cyclic *m*-adducts are apparently their transformations into other heterocyclic systems. The sodium salts of β-ketoesters, for example, induce the transformation of 3,5-dinitropyridones into the nitrophenols (XLII) via the intermediate formation of bicyclic adducts (XLI), which can also be isolated on acidification of the medium:[66]

(XLI) (XLII)

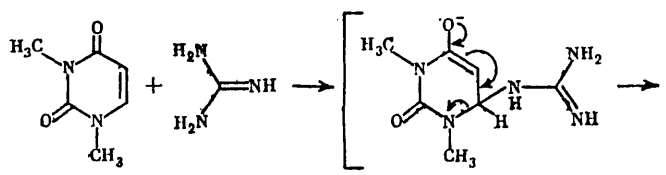


The formation of *m*-linked adducts has been postulated also in the transformation of 5-nitropyrimidines on treatment with the carbanions of keto-reagents[62] and also acetamidines[76]; however, experimental data confirming the feasibility of this mechanism of the transformation have been obtained quite recently.[78]

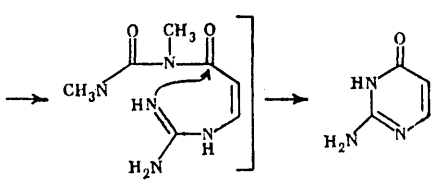


(XLIII)

The formation of the cyclic *m*-adducts (XLIII) in the reaction of 2-methylthio-5-nitropyrimidine with α-phenylacetamidine has been detected by ^{1}H NMR and its involvement in the rearrangement is not inconsistent with experimental data obtained using [^{15}N]amidine.[78]

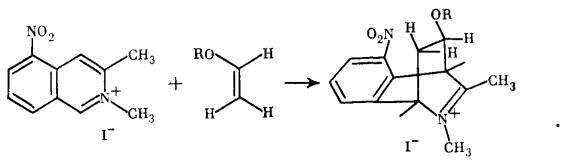


The involvement of bridged *m*-linked cyclic adducts (XLIV) in the transformations of 5-nitro-2*H*-pyrimidinone into nitrophenols on treatment with keto-reagents has been recently reported:[61]

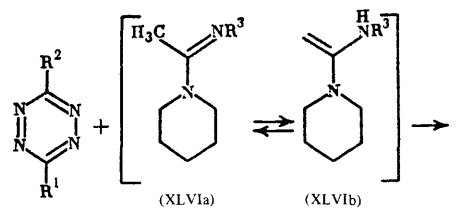


(XLIV)

We may note that earlier in the majority of their investigations of similar transformations of uracils under the influence of 1,3-ambident nucleophiles American and Japanese chemists were inclined to adopt the *ANRORC* mechanism involving an acyclic intermediate of type (XLV):[70,72-74]

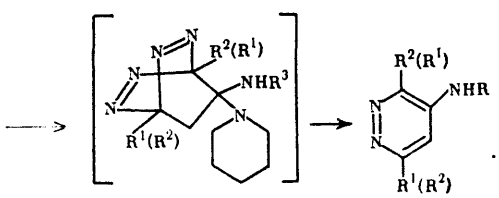


(XLV)

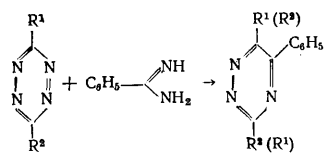


The question of the mechanism of the transformations of pyrimidines under the influence of 1,3-dinucleophiles still remains open, although studies in recent years have shown that the formation of bridged bicyclic intermediates in such reactions is extremely real.[61,66,78] Whereas the bridged cyclic adducts can nevertheless be detected in a number of instances,[61,66,78] the difficulties associated with the detection of the σ-adducts of azines with 1,3-dinucleophiles and even more so of the acyclic intermediates are evident. The σ-adducts formed on monoaddition of a 1,3-dinucleophile to azines with the *meta*-disposition of the electrophilic carbon atoms are extremely unstable, because their further reactions are greatly favoured by thermodynamic factors: they involve either the opening of the ring with rapid recyclisation or *m*-cyclisations with subsequent decomposition of the bridged cyclic adduct, leading to the transformation products.

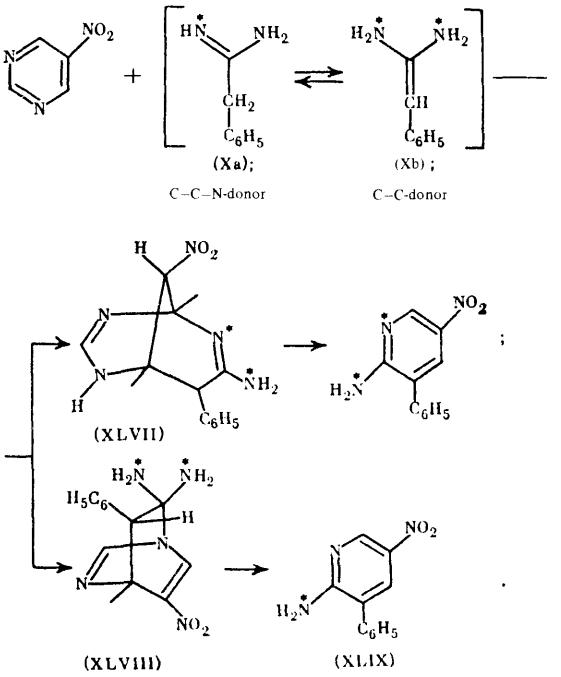
3. *para*-Cyclisations



The most widely used method of synthesis of bicyclic systems with a bridge connecting the *p*-positions in the initial azine ring is the Diels–Alder reaction with reverse electronic requirements, in which the 4π-electron fragment of the azine system plays the role of the diene, while a wide variety of unsaturated compounds containing a double bond enriched in electrons are employed as dienophiles.[110,111] In conformity with the predictions of the theory of frontier orbitals, cyclisations of this type become energetically favourable only when several aza- or other electron-accepting groups have accumulated in the azine molecule or in the presence of a cationic centre, which all adequately reduce the energies of the lowest unoccupied molecular orbitals.[109,110,111,118] Derivatives of 1,2,4-triazine and 1,2,4,5-tetrazine,[111,131] as well as isoquinolinium and acridizinium cations, which readily enter into the cationic [4⁺ + 2]-cycloaddition reactions,[132-142] therefore show an extremely great tendency towards the formation of cyclic [4 + 2]-adducts:

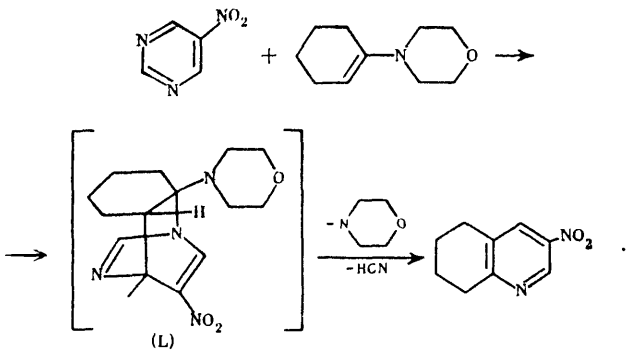


Many 1,3-ambident nucleophiles contain an electron-enriched double bond capable of participating in cycloaddition reactions with azadienes. Although there is no point in this connection to consider the manifestation of ambident properties by nucleophiles, these reactions nevertheless should be regarded as constituting another possibility for the involvement of 1,3-ambident systems in reaction with azines. This is particularly valid because the mode of many cyclisations is determined by tautomeric transformations characteristic precisely of 1,3-ambident systems and impossible in the case of isolated double bonds. Thus the acetamidines (XLVI) enter into reactions involving cycloaddition to tetrazines in the form of the enediamines (XLVIb) and it has been noted that the participation of acetamidines as C=C dienophiles is the first experimentally observed manifestation of the acetamidine–enediamine tautomerism.[77]

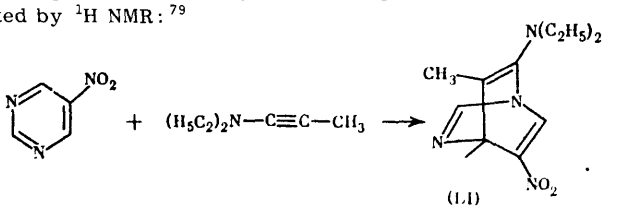


(XLVIa) (XLVIb)

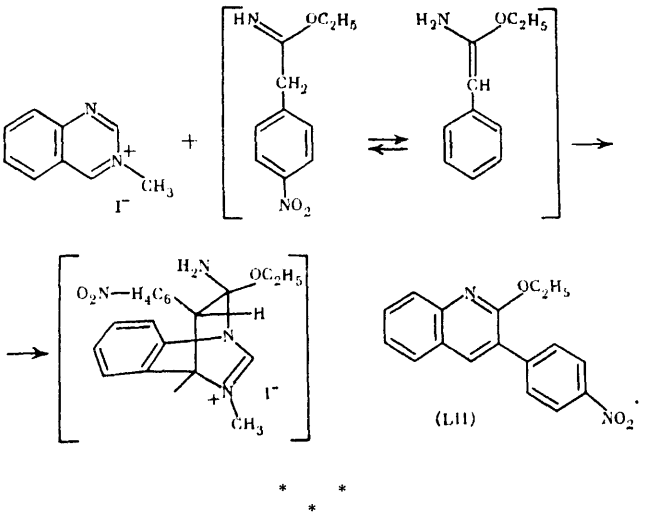
In the absence of N,C-prototropic tautomerism, which obtains only in the presence of an active α-methylene group, amidines are capable of cyclising with tetrazines as C=N dienophiles:[143]



In some cases amidines are capable of exhibiting in their reactions with azines both the properties of 1,3-dinucleophiles and the functions of reverse dienophiles. It has been shown with the aid of ^{15}N isotope labels that the transformations of 5-nitropyrimidines on treatment with α-phenylacetamidines proceed via several mechanisms involving the formation of both bridged *m*-linked intermediates (XLVII) and *p*-linked cyclic adducts (XLVIII):[78]

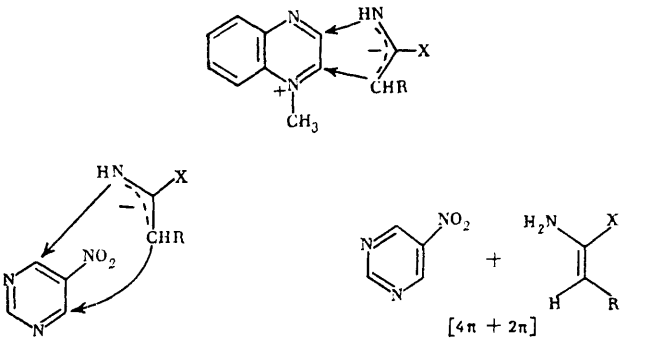


In the latter case the electron-enriched C=C bond of the enediamine (Xb) participates in the cyclisation, the enediamine thus behaving as a donor of the C–C fragment to the final transform5tion product, namely the pyridine (XLIX), which does not contain the ^{15}N isotope label in the ring.[78]

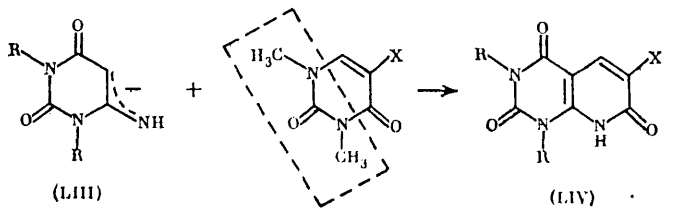


The transformations of pyrimidines based on the Diels–Alder reactions with reverse electronic requirements have been further confirmed and developed in a study[79] of the transformations of 5-nitropyrimidine on treatment with keten *O,O*- and *N,N*-acetals, enamines, and ynamines:

The postulated intermediates in these transformations, namely cyclic [4 + 2]-adducts of type (L), are unstable; on the other hand, in the case of *N,N*-diethylaminopropyne the stable cyclic adduct (LI) is formed as a result of addition to the 1,4-positions of the pyrimidine ring and has been detected by ^{1}H NMR:[79]

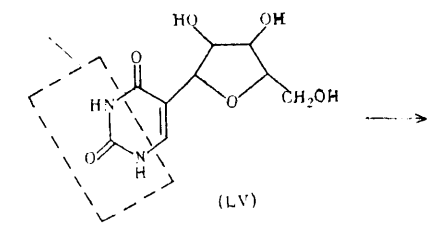


It is noteworthy that, whereas the formation of cyclic [4 + 2]-adducts with a *p*-linked 1,2,4-triazine or 1,2,4,5-tetrazine ring as intermediates in the transformations of the latter into other azine systems is generally accepted.[111,131] Charushin and van der Plas[78,79] were the first to conclude that systems with two heteroatoms can also participate in transformations proceeding via cyclic [4 + 2]-adducts. This result provides a more reasonable explanation of the previously described transformations of quinazolinium salts into the quinolines (LII) on treatment with methyl *p*-nitrophenylacetimidate[82] without resorting to open-chain intermediates and to *ANRORC* mechanisms usually postulated in such cases. This has been considered by Chupakhin et al.[82]



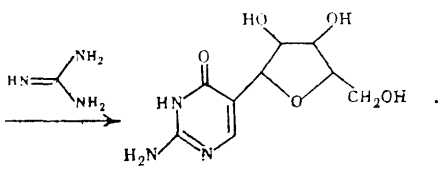
* * *

Thus the reactions of azines with ambident 1,3-nucleophiles are extremely varied and proceed via different pathways determined by the nature of the reactants, the structural and electronic factors, and the reaction conditions. The examples examined above show that, in reactions with ambident C,N-nucleophiles, such as, for example, acetamidines (acetimidates), there is a possibility of the formation of all three types of cyclic adducts: *ortho*-, *meta*-, and *para*-, the last two types of adducts being unstable and leading to the formation of transformation products.



The data of Chupakhin et al.[82] for the reactivities of four isomeric benzodiazinium cations, namely quinoxalinium, cinnolinium, phthalazinium, and quinazolinium, with respect to *p*-nitrophenylacetimidate demonstrate a specific character of the *o*-, *m*-, and *p*-cyclisations rather than their common features.

The knowledge of the characteristics of the reactions of azines with ambident 1,3-nucleophiles and of the features of their occurrence in structurally different series of azines makes it possible to design new syntheses of azine systems and of annelated heterocycles based on them. Examples of such specific employment of cyclic ambident 1,3-nucleophiles (LIII) in the syntheses of pyrido[2,3-*d*]pyrimidines (LIV) have been described.[144,145] In the example presented in the scheme below the N–C–N fragment of 1,3-dimethyluracil is substituted by the C–C–N group of the 1,3-dinucleophile:[144]



(LIII) (LIV)

A striking example of the practical use of the transformations of azines under the influence of 1,3-dinucleophiles has been given in a study[72] in which degenerate transformations of the pyrimidine ring were used for the modification of pyrimidine nucleosides. Thus pseudouridine (LV) can be converted under the influence of guanidine into pseudoisocytidine (LVI), which exhibits antileukaemic activity:[72]

(LV)

(LVI)

Further investigations of the cyclisation reactions and the transformations of azines on treatment with 1,3-dinucleophiles will make it possible to develop new easy methods of synthesis of practically useful compounds.

During the preparation of the manuscript for the press, a further series of studies on the cyclisation and transformations of azines under the influence of bifunctional 1,3-nucleophiles were published.[146–152] Among these, mention should be made of a novel one-stage method of synthesis of the familiar antitumour preparation 5-fluorouracil based on the transformation of 1,3-dimethyl-1,3,5-triazine-2,4-dione on treatment with fluoroacetamide.[147] This method undoubtedly merits attention, because transformations of this type can find applications also in the syntheses of other fluorinated heterocyclic compounds. We may also mention a review[150] of the Diels–Alder reactions of azadienes, which contains many examples of the participation of electron-deficient azines in cyclisations involving the *p*-position in the azine ring.

The Reactivity of Organosilicon Derivatives of Phosphorus in Addition Reactions

G.A.Kutyrev and R.A.Cherkasov

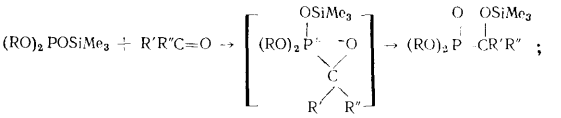
The results of studies of the reactivity of organosilicon derivatives of tricoordinate and tetracoordinate phosphorus containing the P-X-Si (X = O, N, or S) groups in reactions involving addition to various unsaturated systems are examined and surveyed. Attention has been concentrated on the elucidation of the specific influence of the trialkylsilyl group on the character of the reaction of phosphorus-silicon compounds.
The bibliography includes 137 references.

CONTENTS

I. Introduction 971
II. Organosilicon derivatives of tervalent phosphorus 971
III. Organosilicon derivatives of tetracoordinate phosphorus 982

I. INTRODUCTION

During the last one and a half decades, organosilicon derivatives of phosphorus have been vigorously investigated in many world laboratories. The interest in these compounds is caused primarily by the possibility of synthesising on their basis a wide range of new organoelemental structures, many of which have important practical applications. The combination of phosphorus and silicon atoms in a single molecular system has its specific manifestation in the character of the chemical behaviour of phosphorus–silicon reagents, which differs from that of the corresponding organophosphorus or organosilicon analogues. The determination of the interrelation between the structure and chemical reactivity of such two-element compounds and the elucidation of the specific role of the phosphorus- and silicon-containing fragments in the molecule are of undoubted theoretical interest for organoelemental chemistry.



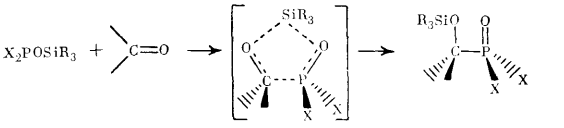
In the literature there are almost no reviews devoted to the reactivity of phosphorus–silicon compounds. Data concerning the synthesis of organosilicon derivatives of phosphorus and certain reactions of silyl phosphites, which may be used for the synthesis of phosphorus compounds, are summarised in the monograph of Voronkov and co-workers[1] and in publications of Japanese investigators.[2]

The present review deals with the reactivity of organosilicon derivatives of tervalent and quinquevalent phosphorus containing the P–X–Si group (X = O, N, or S) in addition reactions. Wherever possible, the reactivities of silylated phosphorus systems and phosphorus compounds of analogous structures without organosilicon groups have been compared in order to discover the factors which control the processes under discussion.

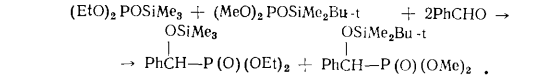
II. ORGANOSILICON DERIVATIVES OF TERVALENT PHOSPHORUS

1. Reactions with Aldehydes and Ketones

The silyl esters of tervalent phosphorus acids readily add to the carbonyl groups of aldehydes and ketones with formation of α-trialkylsiloxyalkylphosphonates:[3-10]



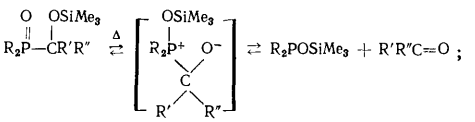
(I)



R' = Alk, Ar; R'' = H, Alk, Ar.

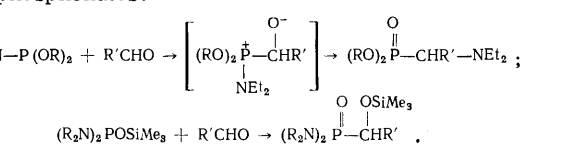
It has been suggested[6,9-11] that the reaction begins with nucleophilic attack by the phosphorus atom on the carbonyl carbon atom with formation of an intermediate dipolar ion (I). This mechanism is supported by the fact that the more nucleophilic trimethylsilyl dibutylphosphinite adds to acetaldehyde more readily than trimethylsilyl diethyl phosphite and the interaction of the same phosphinite with trifluoroacetone proceeds much faster than with acetone.[9]

At the same time, in contrast to trialkyl phosphites,[12] for phosphorus–silicon reagents one cannot rule out the possibility of a concerted 1,2-addition mechanism,[10] because the trialkylsilyl group can migrate as a result of frontal substitution at the silicon atom with retention of its configuration:[13,14]



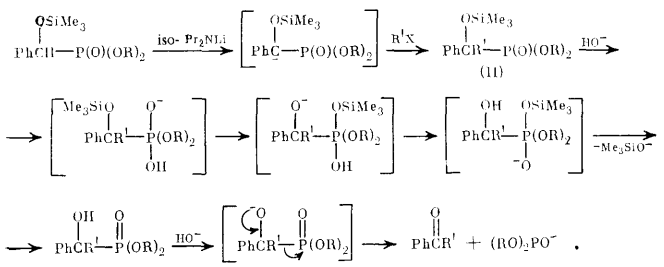
The results of a "cross-experiment" with participation of equimolar amounts of diethyl trimethylsilyl phosphite, t-butyldimethylsilyl dimethyl phosphite, and two equivalents of benzaldehyde confirm the intramolecular character of the migration of the silicon atom:[10]

With increasing steric hindrance at the silicon atom, the rate of addition diminishes under these conditions. The insertion of trialkyl phosphites in the carbonyl group takes place as a result of intermolecular alkyl transfer.[12]

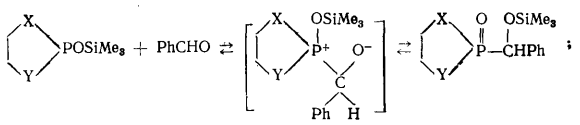


The adducts obtained by the interaction of silyl phosphites with aromatic aldehydes and ketones are thermally unstable and decompose on heating into the initial compounds.[15] The decomposition of α-trimethylsiloxyphosphonates via a pathway which is the reverse of the

Arbuzov reaction is accelerated with increasing nucleophilicity of the phosphoryl oxygen and with enhancement of the polarisation of the Si–O bond as a result of the electron-accepting influence of the substituents at the α-carbon atom:

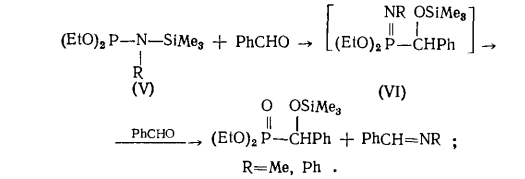


R=Bu, MeO, EtO; R′=H, Me; R″=Ph, COOEt, P(O)(OMe)$_2$.

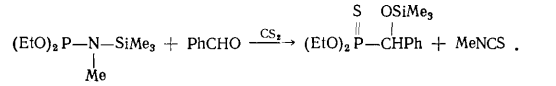


In contrast to dialkyl phosphoramidites, which react with aldehydes to form α-aminophosphonates,[16] trimethylsilyl *N,N,N′,N′*-tetra-alkylphosphorodiamidites give α-trimethylsiloxyphosphonates:[11,17,18]

The adducts of silyl phosphites with aldehydes have been recently used widely in the synthesis of asymmetric ketones.[19–21] The ready dissociation of the P–C bond in compound (II), obtained by alkylating the comparatively acidic α-hydrogen atom in α-trimethylsiloxybenzylphosphonate, is promoted by the sigmatropic migrations of the Me_3Si group in the course of the nucleophilic attack by the hydroxide anion on the phosphorus atom:

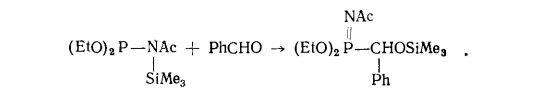


The P–N bond is cleaved and 1,4,2-oxazaphosphorinanes are formed on interaction of 2-alkoxy(alkyl)-1,3,2-oxazaphospholans with carbonyl compounds.[22] In contrast to this, the cyclic fragments are retained in the reactions of 2-siloxy-derivatives of 1,3,2-diheterophospholans with benzaldehyde. The reaction is reversible and on heating α-trimethylsiloxyphosphonate decomposes into the starting materials:[23]

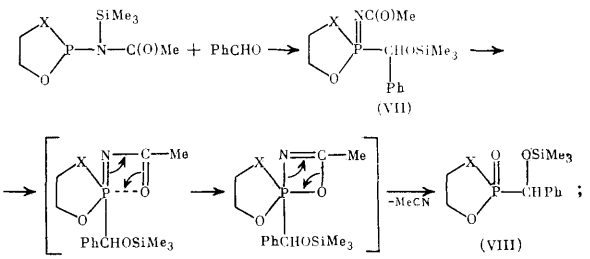


(a, X=Y=O; (b) X=NMe, Y=O; (c) X=NPh, Y=O; (d) X=Y=NBu .

Two versions of the relative orientations of the benzaldehyde and oxazaphospholan molecules in the intermediates (III, b and c) determine the formation of diastereoisomeric cyclic α-trimethylsiloxybenzylphosphonates (IV).

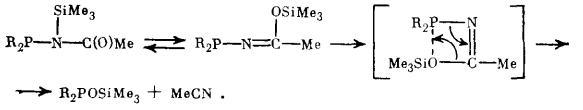


The interaction of phosphorous acid *N*-trimethylsilylamides (V) with benzaldehyde proceeds differently.[24,25] The phosphonimidate (VI), formed as a result of the nucleophilic addition of the phosphoramidite to the carbonyl group, reacts vigorously with a second benzaldehyde molecule, which leads to α-trimethylsiloxybenzylphosphonate and benzylideneamine:



In the presence of carbon disulphide the intermediate phosphonimidate (VI) is converted into a phosphonothioate:[24]

The introduction of the electron-accepting acetyl group at the nitrogen atom of *N*-silylphosphoramidite stops the reaction at the stage of the formation of the phosphonimidate:[23]



In the case of 2-(*N*-trimethylsilylacetamido)-1,3,2-diheterophospholans the reaction with benzaldehyde leads to the formation of the cyclic α-trimethylsiloxybenzylphosphonate:[23]

X=O, NMe .

The process involves the initial formation of *N*-acetylphosphonimidates (VII), which are converted into the phosphonates (VIII) by nucleophilic attack by the carbonyl oxygen at phosphorus. The ease of the intramolecular rearrangement depends significantly on the nature of the substituents at the phosphorus atom. In the series of 1,3,2-diheterophospholans the replacement of oxygen in the ring by the more electron-donating nitrogen reduces the electrophilicity of the phosphimide phosphorus and thereby stabilises the phosphonimidate structure (VII) (X = NMe). The interaction of 3-methyl-2-(*N*-trimethylsilylacetamido)-1,3,2-oxazaphospholan with benzaldehyde leads to the phosphonimidate (VII), which is stable under the usual conditions and is converted on heating to 65 °C into the phosphonate (VIII). In the series of dioxaphospholan derivatives (X = O) the phosphonimidate cannot be detected even at a low temperature.[23] A similar rearrangement of diethyl α-trimethylsiloxybenzylacetylphosphonimidate has been achieved only at 135 °C.

Acetyl and trimethylsilyl substitution at the nitrogen atom reduces significantly the thermal stability of the phosphoramidite. The migration of the Me_3Si group in *N*-acetyl-*N*-trimethylsilylphosphoramidite to the carbonyl oxygen promotes intramolecular nucleophilic substitution at the phosphorus atom and the formation of silyl phosphites and acetonitrile:[26,27]

The decomposition of *N*-silylated acetamido-derivatives of tervalent phosphorus depends on the nature of the substituents R at the electrophilic centre and, according to the results of the differential thermal analysis, is retarded with increase of their electron-donating capacity[27] (Table 1).

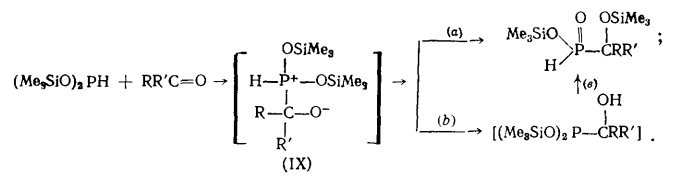


Table 1. The effect of substituents at the phosphorus atom on the rate of decomposition of the compounds $R_2P-N-SiMe_3$.[27]

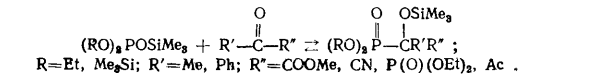
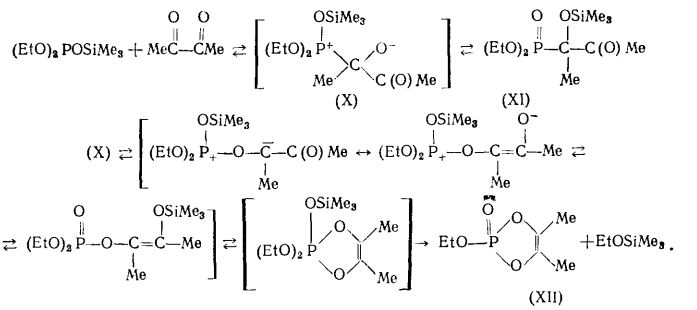
	AC	
R_2	T_i, °C	T_m, °C
$-OCH_2CH_2O-$	35	88
$-OCH_2CH_2CH_2O-$	52	128
$-OCH_2CH_2N(Ph)-$	65	108
$-OCH_2CH_2N(Me)-$	70	130
$(EtO)_2$	95	135
Et_2*		

Notation: T_i is the temperature of the onset of the effect and T_m is the temperature of the maximum effects.

*Stable up to 200 °C.

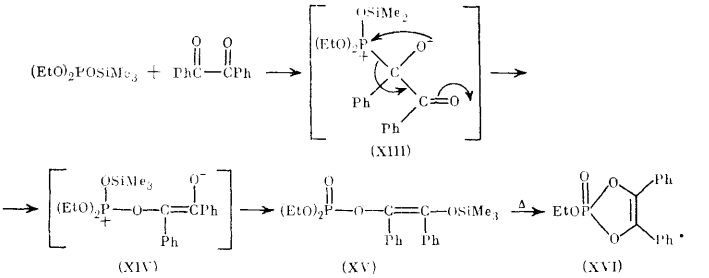


The addition of bis(trimethylsilyl) hypophosphite to aldehydes and ketones leads to bis(trimethylsilyl) alkylphosphonites with the retention of the P–H bond.[28,29] The dipolar ion (IX) formed initially can be stabilised by the migration of the Me_3Si group, which leads to the final reaction product [pathway (*a*)]; there is also a possibility of the intramolecular proton transfer [pathway (*b*)] and subsequent rearrangement of the intermediate bis(trimethylsilyl) α-hydroxyalkylphosphonite via pathway *c*:[29]

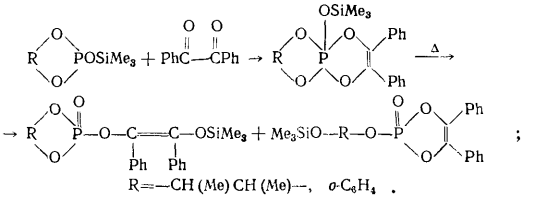


2. The Interaction with Carbonyl Compounds Containing Electron-Accepting Substituents

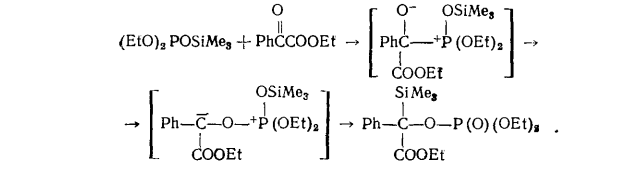
The introduction of electron-accepting substituents at the carbonyl group not only increases the reactivity of the carbonyl compounds in reactions with organosilicon derivatives of tervalent phosphorus but also in many cases influences significantly the mode of their interaction.



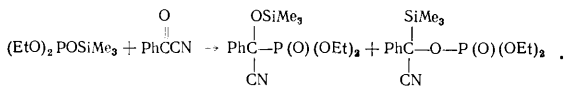
Silyl phosphites add vigorously to the esters and nitrile of pyruvic acids,[30] acetyl phosphonates,[31] benzoyl phosphonates,[32] and diacetyl[33–35] with formation of the corresponding α-trimethylsiloxyphosphonates:



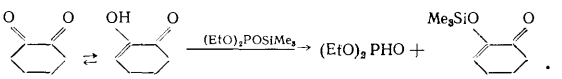
These reactions are as a rule reversible. However, after prolonged heating of the adducts, other processes can also occur. Thus, dioxaphospholen (XII) and ethoxysilane (XXXV) are formed from diethyl trimethylsilyl phosphite and diacetyl as a result of silotropic transformations and the phosphonate–phosphate rearrangement:[35]



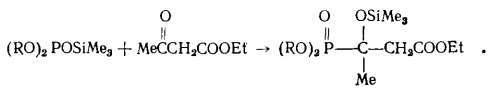
The dipolar intermediate can be stabilised by the intramolecular transfer of the trimethylsilyl or phosphoryl group. The ratio of the rates of these competing processes depends on the structure of the carbonyl reagent. For the diacetate, the α-siloxyphosphonate (XI) is the kinetically controlled product. In the reactions of silyl phosphites with benzil the phosphonate–phosphate rearrangement (XIII) → (XIV) is faster than the migration of the silyl group and the only product of the interaction is 2-trimethylsiloxy-1,2-diphenylvinyl phosphate (XV), which is converted into the dioxaphospholen (XVI) on heating:[34,36]



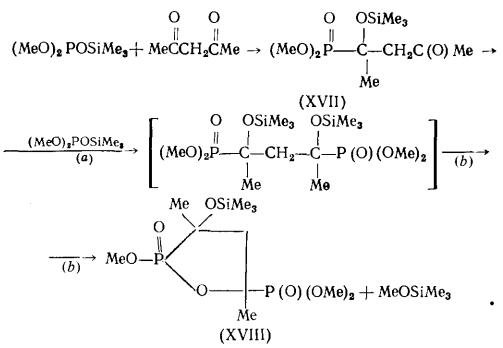
The formation of spiro-phosphorane structures, which is characteristic of the interaction of 1,3,2-diheterophospholans with dicarbonyl compounds,[37,38] is also observed in the reaction of 2-trimethylsiloxy-1,3,2-dioxaphospholans with benzil.[39] Silylated spiro-phosphoranes are formed at a low temperature (between −40 °C and −50 °C) and on heating are fully transformed into the corresponding cyclic phosphates:



A product with a phosphate structure has also been isolated in the reaction of silyl phosphites with benzoylformic acid ester:[30]

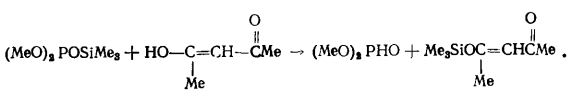


Both pathways leading to stabilisation, namely the migration of the Me_3Si group and the phosphonate–phosphate rearrangement, are realised in the reaction with the nitrile of benzoylformic acid:[30]

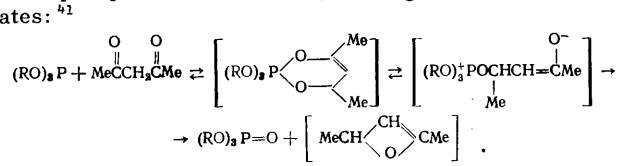


The attempt to obtain the products of the addition of diethyl trimethylsilyl phosphite to cyclohexane-1,2-dione was unsuccessful. The reaction results in the quantitative formation of diethylphosphorous acid and 2-trimethylsiloxycyclohexenone, i.e. the diketone reacts in the enolic form:[40]

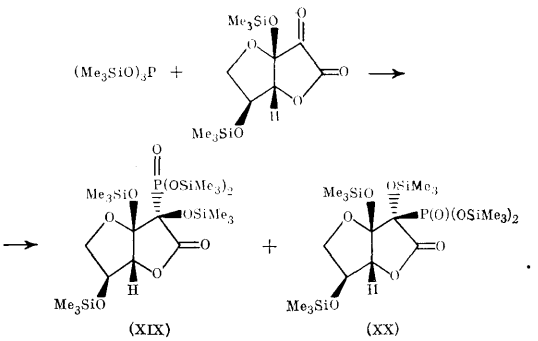
The involvement of the enolic form also in the reaction of silyl phosphites with acetoacetic ester might have been expected, but in this case the product of addition to the C=O group is formed exclusively:[5,41]



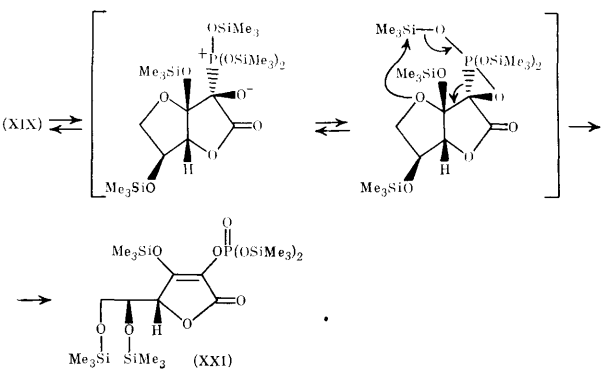
The reaction of acetylacetone resulted in the isolation of 5-dialkylphosphoryl-1,2-oxaphospholan (XVIII) together with α-siloxyphosphonate (XVII):[41]



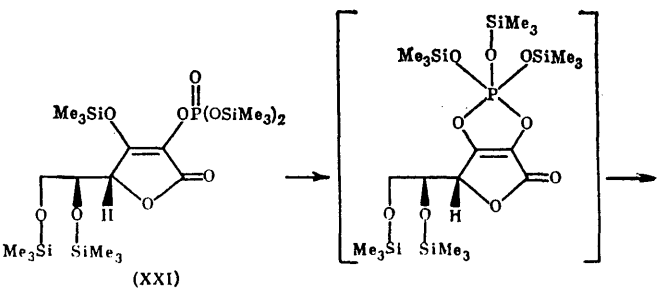
The preferential formation of only one diastereoisomer of 1,2-oxaphospholan (XVIII) has been explained[41] by the stereospecificity of the attack by silyl phosphite on the carbonyl group of the 1:1 adduct [stage (*a*)] and also by the stereospecificity of the cyclisation reaction (*b*), because there are three bulky groups at the interacting atoms in the transition state: two dialkylphosphoryl groups and one trimethylsilyl group.



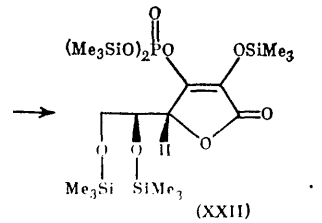
Another reaction pathway, namely the silylation of the enol of acetylacetone, has also been noted:



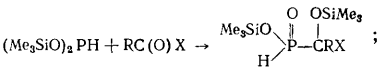
In contrast to silyl phosphites, trialkyl phosphites react with acetylacetone and acetoacetic ester via the intermediate phosphorane structures, forming trialkyl phosphates:[41]



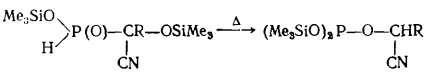
The conformational characteristics of bicyclic α-ketolactones are responsible for the possibility of the formation of the diastereoisomeric phosphorates (XIX) and (XX) as a result of the nucleophilic attack by silyl phosphite on the carbonyl carbon atom from different sides of the plane of the lactone ring:[42]



The adducts (XIX) and (XX) isomerise to the 2-*O*-phosphate (XXI) on heating. The diastereoisomer (XIX), which is a product of the attack by silyl phosphite on the carbonyl group from the rear of the plane of the ring, then undergoes a thermal rearrangement at a higher rate than the isomer (XX), which is caused by favourable conditions for the formation of a six-membered cyclic transition state:

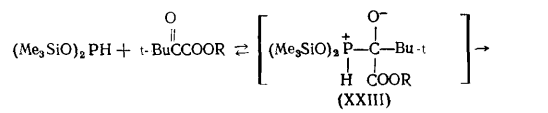


The transformation of the phosphonate (XX) into the 2-*O*-phosphate (XXI) evidently includes the decomposition of compound (XX) into the initial compounds and subsequent formation of the diastereoisomer (XIX), whose pyrolysis leads to the phosphate (XXI). The 2-*O*-phosphate (XXI) also isomerises to the 3-*O*-phosphate (XXII) via the intramolecular migration of the phosphoryl group during the thermal rearrangement:

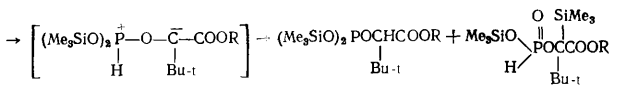


(XXII)

Bis(trimethylsilyl) hypophosphites add to the carbonyl group in ketophosphonates, ketonitriles, and acetoacetic ester with retention of the P–H bond: [29]

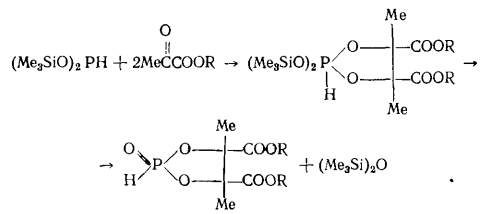


R=Me, t-Bu; X=P(O)(OEt)$_2$, CN, CH_2COOMe .

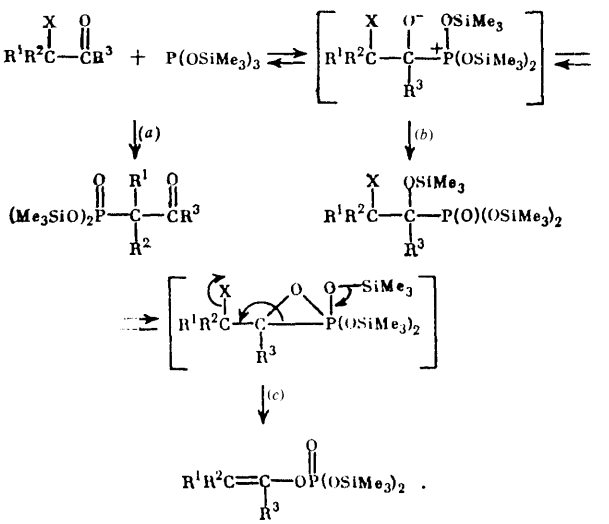


The products formed in this process are thermally unstable and decompose into a series of compounds on heating. α-Cyanoalkyl bis(trimethylsilyl) phosphites are formed from trimethylsilyl α-cyano-α-trimethylsiloxyalkylphosphonites: [29]

Increasing steric hindrance of the carbonyl carbon atom in trimethylpyruvic acid esters, combined with the electron-accepting influence of the alkoxycarbonyl group, promotes the rearrangement of the intermediate dipolar ion (XXIII) with a P–C bond to the ion (XXIV) with a P–O–C bond. The intermediate is then stabilised via the migration of a proton or Me_3Si group to the carbanionic centre: [29]

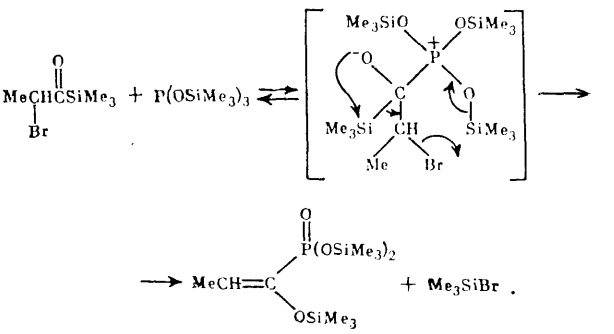


(XXIII)



(XXIV)

The interaction of silyl hypophosphite with pyruvic acid esters leads to 4,5-dialkoxycarbonyl-2-hydro-4,5-dimethyl-2,2-bis(trimethylsiloxy)-1,3,2-dioxaphospholans with a pentacoordinate phosphorus atom, which are slowly converted into 4,5-dialkoxycarbonyl-2-hydro-4,5-dimethyl-2-oxo-1,3,2-dioxaphospholans: [29]

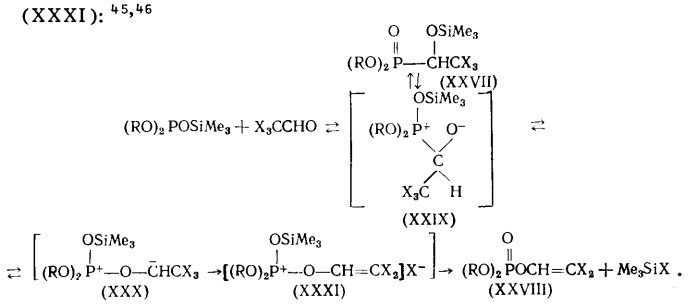


3. Interaction with Halogen-Containing Carbonyl Compounds

The reactions of trialkyl phosphites with α-halogeno-substituted carbonyl compounds result in the formation of either the enol phosphate esters (the Perkow reaction) or of 2-oxophosphonates (the Arbuzov reaction). [12] The ratio of the products depends on the structure of the carbonyl compound and the experimental conditions. A different pathway is characteristic of organosilicon derivatives of tervalent phosphorus in their reactions with α-halogeno-substituted aldehydes and ketones, namely addition to the C=O group with formation of α-trimethylsiloxyalkylphosphonates [pathway (*b*)]. [43,44] At the same time the products of the Arbuzov reaction [pathway (*a*)] and the Perkow reaction [pathway (*c*)] have been isolated in the reactions involving phenacyl halides, α-halogenoacetates, and esters of α-halogenopyruvic acid: [36,43,44]

A general reaction mechanism has been proposed, [43] including the initial formation of a dipolar intermediate and a subsequent rapid intramolecular transfer of the Me_3Si group to the *O*-anionic centre. Electron-accepting substituents (Ph, COOR) at the C=O group promote the phosphonate–phosphate rearrangement and the formation of the products of the Perkow reaction. The electron-donating alkoxy-group in α-halogenoacetates suppresses the addition of silyl phosphites to the carbonyl group—only the direct substitution of the halogen with the formation of alkoxycarbonylalkylphosphonates (the Arbuzov reaction) takes place.

An interesting result has been obtained in the reaction of α-bromoethyl trimethylsilyl ketone with tris(trimethylsilyl) phosphite. [44] The rapid 1,2-migration of the trimethylsilyl group to the negatively charged oxygen atom of the dipolar intermediate (XXV) overtakes the 1,4-silylotropic transition and the phosphonate–phosphate rearrangement. The subsequent β-elimination of the bromide ion leads to a mixture of the *Z*- and *E*-phosphonates (XXVI):



Z-, *E*-(XXVI)

A characteristic feature of the chemical behaviour of silyl phosphites in reactions with various carbonyl compounds, including α-halogeno-derivatives, is their capacity to add readily to the C=O group. As shown above, this constitutes a significant difference between silyl phosphites and trialkyl phosphites. One of the causes of such reactivity of silyl phosphites in carbonyl addition reactions is the possibility of formation of a five-membered cyclic transition state in the stage involving the transfer of the trimethylsilyl group to the *O*-anionic centre of the dipolar intermediate with formation of α-trimethylsiloxyalkylphosphonates. At the same time, according to Sekine et al.,[44] the electron-donating properties of the Me_3SiO substituent, which are more pronounced than those of the RO groups, may play an important role in this reaction pathway. The electron-donating effect promotes the stabilisation of the phosphonium centre of the intermediate and hinders the phosphonate–phosphate rearrangement. The successive introduction of trimethylsilyl groups into the phosphite molecule alters the reaction pathway: carbonyl addition becomes dominant even in the case of ethyl bis(trimethylsilyl) phosphite.[44] The tendency towards the addition to the carbonyl group of chloroacetone is more marked than in the reaction with bromoacetone (Table 2).

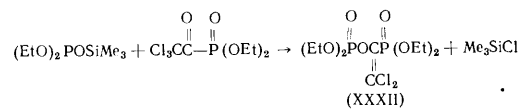


Table 2. The relative ease of various pathways in the interaction of phosphorus(III) derivatives with halogenoacetones (Ad = addition to the carbonyl group, A = Arbuzov reaction, P = Perkow reaction[44]).

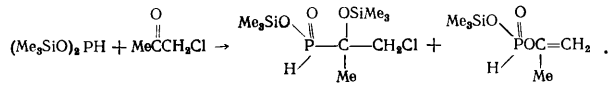
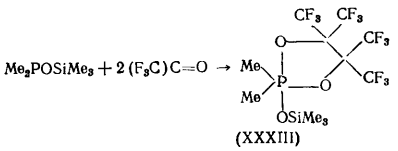
$XCH_2C(O)Me$	$(EtO)_3P$	$(EtO)_2POSiMe_3$	$EtOP(OSiMe_3)_2$	$P(OSiMe_3)_3$
X=Cl	A< P	Ad	Ad	Ad
X=Br	A∼P	A< P	Ad	Ad

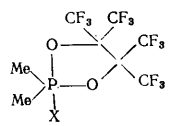


In those cases where there is a possibility of the formation of α-siloxyphosphonates and vinyl phosphates, the addition to the carbonyl group is the kinetically controlled process and the Perkow reaction takes place under the conditions of thermodynamic control. Thus the interaction of silyl phosphites with trihalogenoacetaldehyde leads initially to the formation of the phosphonates (XXVII), which decompose on prolonged heating into vinyl phosphates and a halogenosilane via a pathway involving the formation of the zwitter-ionic intermediates (XXIX) to (XXXI):[45,46]

The reaction of diethyl trimethylsilyl phosphite with trichloroacetylphosphonate takes place via an analogous mechanism and leads to the unsaturated phosphoryloxyphosphonate (XXXII):[47]

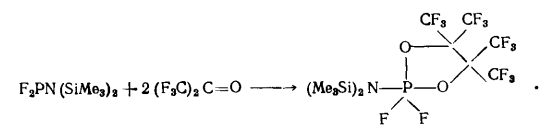


Bis(trimethylsilyl) hypophosphite reacts with chloroacetone to form α-siloxyphosphonate and vinyl phosphate:[29,48]

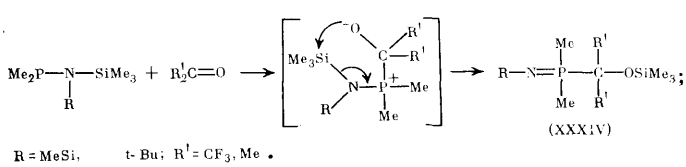


Various reaction pathways have been noted also for the reactions of diethyl trimethylsilyl phosphite and trimethylsilyl dimethylphosphinite with hexafluoroacetone. In the former case the authors[15] detected the formation of the intermediate diethyl hexafluoro-α-trimethylsiloxypropylphosphonate, which is converted into vinyl phosphate at a high temperature (160 °C) in 3 h:

Trimethylsilyl dimethylphosphinite reacts with two moles of hexafluoroacetone even at −78 °C with the quantitative formation of the thermally highly stable λ^5-1,3,2-dioxaphospholan (XXXIII):[49]



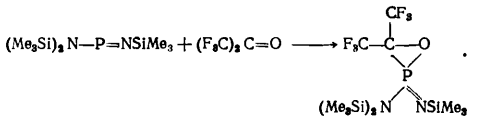
The presence of the mobile Me_3SiO group in compound (XXXIII) makes it possible to synthesise readily a number of derivatives of pentacoordinate phosphorus:



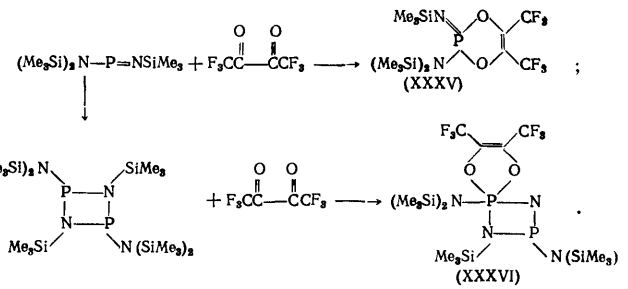
X=F, Cl, NMe_2, N_3, MeO .

Bis(trimethylsilyl)aminodifluorophosphine reacts similarly with hexafluoroacetone:[50]

However, on passing to *N*-alkyl-*N*-silylaminodialkylphosphines, the process develops differently. Nucleophilic attack by the phosphorus atom of the aminophosphine on the carbonyl carbon atom is accompanied by the 1,4-transfer of the Me_3Si group from nitrogen to oxygen and leads to the adduct (XXXIV) having the imino-structure:[51]

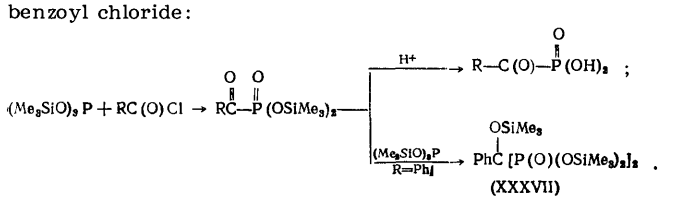


R = MeSi, t-Bu; R' = CF_3, Me .

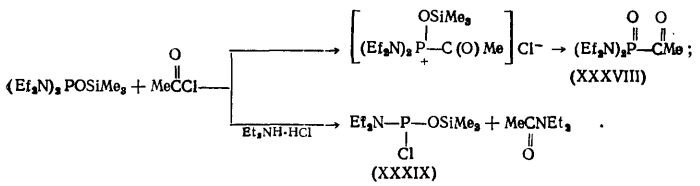


Thus the variation of the nucleophilic properties of the phosphorus(III) centre combined with the high lability of the Si–N bond in silylaminophosphines is reflected significantly in the character of the interaction with carbonyl

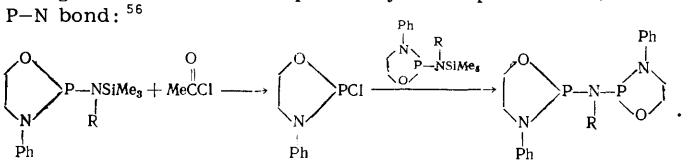
reagents, permitting the synthesis of various types of organophosphorus compounds with functional group substituents.



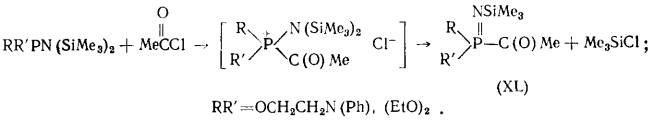
The reaction of the *N*-silylated amide of phosphenimidous acid with hexafluoroacetone is unusual. The [1 + 2]-cycloaddition yielded a new three-membered cyclic adduct, namely 2-[bis(trimethylsilyl)amino]-3,3-bis(trifluoromethyl)-2-trimethylsilylimino-1,2-λ^5-oxaphosphiran: [52]



The reactions of the phosphenimidous amide and its dimer with hexafluorodiacetyl lead to the [1 + 4]-cycloaddition products (XXV) and (XXXVI) respectively: [52]

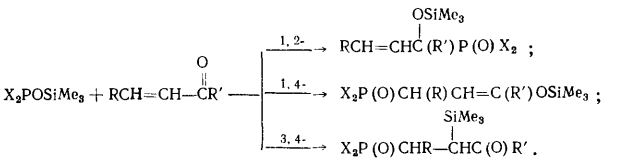


Like trialkyl phosphites, silyl phosphites give rise to the corresponding acylphosphonates on interaction with acyl halides. [53,54] The use of tris(trimethylsilyl) phosphite in this reaction makes it possible to synthesise readily the free acylphosphonic acids; the silylated α-hydroxybenzyldiphosphonate (XXXVII) can be obtained by reaction with benzoyl chloride:

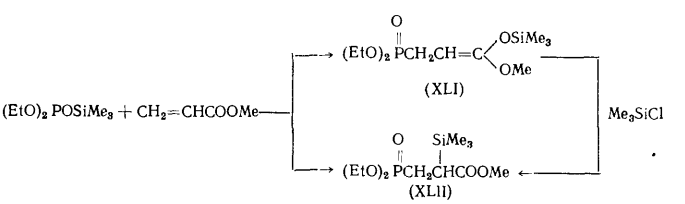


Trimethylsilyl *N,N,N',N'*-tetra-alkylphosphorodiamidites react with acetyl chloride to form the Arbuzov reaction products (XXXVIII) and the products (XXXIX) resulting from the substitution of the amino-group: [55]

The interaction of monosilylated 2-amino-1,3,2-oxazaphospholans with acetyl chloride proceeds with involvement of the nitrogen atom and is accompanied by the rupture of the P–N bond: [56]



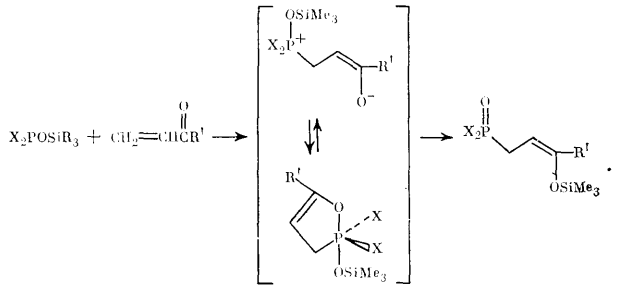
The introduction of a second Me_3Si group results in a change of the reaction centre—*N*-trimethylsilylacetylphosphonimidates (XL) are formed in the reaction: [56]



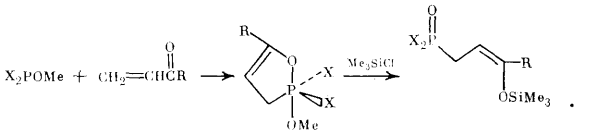
Thus the character of the interaction of the organosilicon derivatives of tervalent phosphorus with halogenocarbonyl compounds depends on the nature of the substituents in the reactant. In most cases the reactions apparently proceed via a nucleophilic mechanism; a dipolar ion with a P–C bond is formed initially and can be stabilised in different ways: (1) by the 1,4-transfer of the Me_3Si group to the oxygen ion with formation of α-siloxyphosphonates; (2) by the Perkow reaction with elimination of a halogenosilane; (3) by the addition of a second molecule of the carbonyl compound and the formation of 1,3,2-dioxaphospholans. Other reaction pathways are also possible, particularly those involving organosilicon reagents containing the P(III)–N–Si fragment.

4. Reactions with αβ-Unsaturated Carbonyl Compounds

The reactions involving addition to unsaturated carbonyl compounds occupy an important place in the chemistry of phosphorus–silicon compounds containing the P(III)–X–Si (X = O or N) group. The possibility of the involvement of the carbonyl and vinyl centres of the unsaturated reactant in these processes determines the simultaneous occurrence of three competing reactions: addition to the 1,2-, 3,4-, and 1,4-positions of the enone; their ratios are determined by the nature of the substituents in the initial compounds:



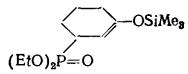
Dialkyl trimethylsilyl phosphites react vigorously with unsaturated aldehydes via the 1,2- and 1,4-addition pathways in the absence of catalysts, [5,10,11,18–20] while silyl phosphoramidites form exclusively the 1,2-adducts. [11] The interaction of trialkylsilyl phosphites and trialkylsilyl phosphoramidites with vinyl ketones takes place under more severe conditions and is accompanied by the preferential formation of 1,4-adducts. [10,11,19,57] The introduction of electron-donating alkoxy-substituents at the carbonyl centre (esters of αβ-unsaturated carboxylic acids) renders only the 1,4- and 3,4-addition reactions energetically favourable. [4,5,58] The phosphorylated derivatives of alkyltrimethylsilylketen acetals (XLI) rearrange to the *C*-silylated phosphonates (XLII) on treatment with halogenosilanes: [7]

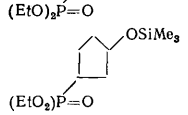


The study of the stereochemical characteristics of the reactions of silyl phosphites with unsaturated carbonyl compounds and the elucidation of the factors determining

the composition of the reaction products resulted in two pathways leading to the formation of 1,2- and 1,4-adducts being proposed.[19] The first is analogous to the mechanism of the addition of silyl phosphites to the carbonyl groups of unsaturated aldehydes and ketones examined above. The mechanism of the 1,4-addition is presented below:

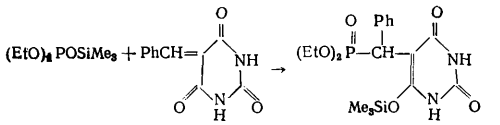
(XLIIIa)





The preferential formation of the *Z*-adduct as well as the absence of the interaction of the silyl phosphite with an equimolar amount of cyclohexene (100 °C, 52 h) shows that the cisoid geometry of the enone promotes the 1,4-addition. It is believed that[19] the intermediate formation of the oxaphospholen (XLIIIa) in this reaction is probable, because the silylation of the methoxy-analogues (XLIIIb) also results in phosphorylated *Z*-silylenols:

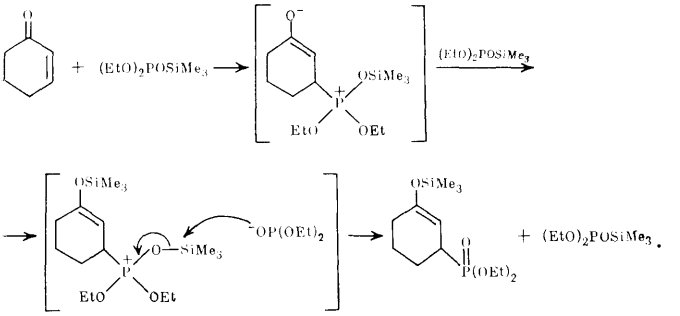
(XLIIIb)



The independent occurrence of the 1,2- and 1,4-addition reactions is confirmed by the finding that the corresponding adducts are thermally stable and do not isomerise to one another (200 °C, 24 h).[19] The low sensitivity of the ratio of the 1,2- and 1,4-adducts to changes in the solvating properties of the medium indicates only a small charge separation in the transition states of the rate-determining stages of both addition reactions.

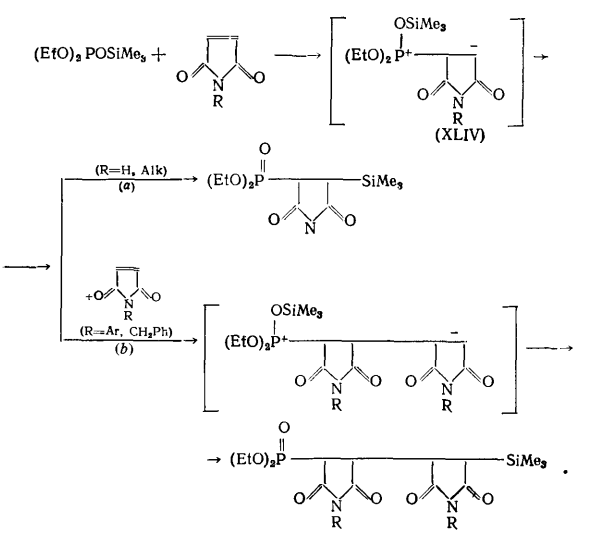
Table 3. Reactions of cyclic enones with $(EtO)_2POSiMe_3$.[60]

Initial enone	Main product	*T*, °C	τ, h	α
		80 180	75 12	8:1 16:1
		80 180	12 12	100:1 100:1
		80 180	200 18	1:3 1:19



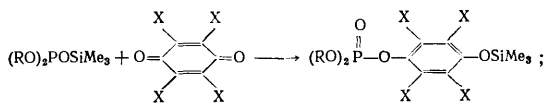
Notation: *T* is the reaction temperature, τ the reaction time, and α the ratio of the 1,4- and 1,2-adducts.

The reaction of diethyl trimethylsilyl phosphite with 5-benzylidenebarbituric acid apparently also proceeds by the 1,4-shift mechanism:[59]



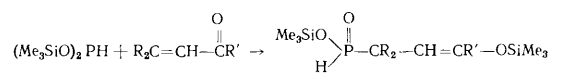
The rigid fixation of the *s-trans*-conformation of the unsaturated carbonyl compound alters the mechanism of the addition reaction. Cyclic enones form stable 1,4- and 1,2-adducts with diethyl trimethylsilyl phosphite only after prolonged heating of the reactants.[60] The ratio of the 1,4- and 1,2-adducts depends significantly on the experimental temperature and on the steric accessibility of the β-carbon atom of the unsaturated cyclic ketone (Table 3).

The mechanism of the formation of 1,4-adducts from cyclic enones presupposes the intermolecular transfer of the Me_3Si group with participation of a second silyl phosphite molecule:



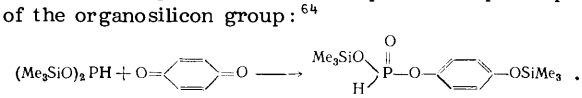
The appreciable acceleration of the reaction in the presence of an excess of silyl phosphite and the high sensitivity to changes in the dielectric properties of the medium (the reaction with $CHCl_3$ is much slower than that with MeCN), which confirms the formation of intermediate dipolar structures, are evidence in support of the mechanism proposed by the authors.[60]

The stabilisation of the intermediate (XLIV) in the reactions of silyl phosphites with maleimides, which also have the *s-trans*-configuration of the C=C and C=O bonds, can be achieved in different ways depending on the nature of the substituents R at the nitrogen atom:[61,62]



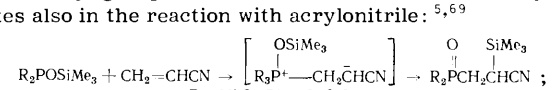
In order to elucidate the causes of the different types of chemical behaviour of *N*-substituted maleimides, measurements were made of the half-wave potentials of the polarographic reduction of these substances.[61] The values of $E_{\frac{1}{2}}$ for compounds with R = Ph, CH_2Ph, or p-ClC_6H_4, determined in dimethylformamide (DMF), proved to be greater than the corresponding values for the imides with R = H or Bu, which indicates more pronounced electrophilic properties of the *N*-aryl and *N*-benzyl structures. Maleimides containing electron-accepting substituents readily add to the carbanionic centre of the intermediate zwitter-ion (XLIV) [pathway (*b*)] and this reaction is faster than the 1,4-shift of the trimethylsilyl group [pathway (*a*)]. The stabilisation of the intermediate (XLIV) by electron-accepting groups in maleimide, which increases the lifetime of the intermediate compound and thereby favours the intermolecular addition of a second molecule of the unsaturated reactant [pathway (*b*)] plays an important role in the formation of adducts having the 1:2 composition. On the other hand, a decrease of the nucleophilicity of the carbanion in the 1:1 intermediate lowers the rate of the competing silylotropic process.

The interaction of silyl phosphites with p-quinones proceeds differently. The addition is at the 1,6-positions of the quinonoid system and leads to products having the phosphate structure:[34,63]



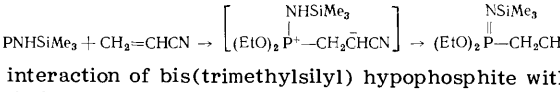
X=H, Cl .

Mainly 1,4-adducts are formed in the reactions of bis(trimethylsilyl) hypophosphite with unsaturated carbonyl compounds by migration of an Me_3Si group to carbonyl oxygen:[29]



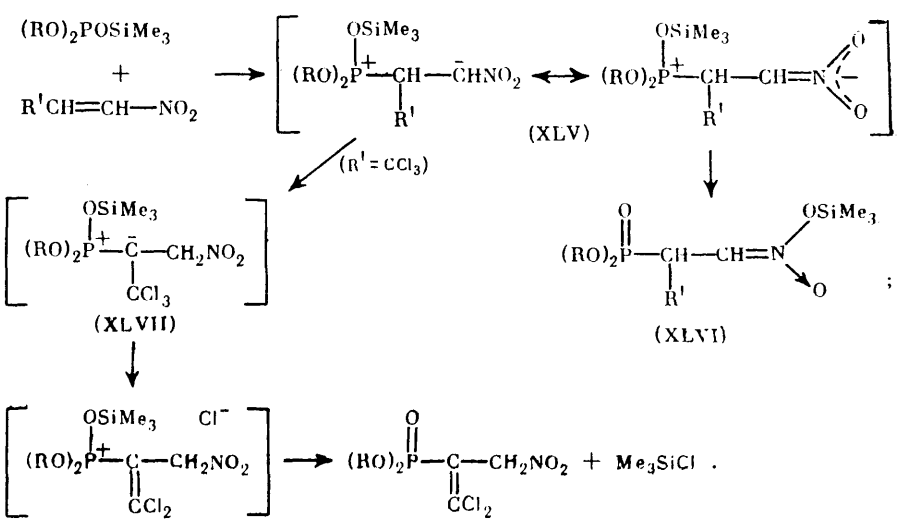
The addition to p-quinones also takes place with participation of the organosilicon group:[64]

The character of the interaction of silyl phosphites with nitro-olefins is in many respects similar to that of reactions involving 1,4-addition to unsaturated carbonyl compounds. The nucleophilic attack by the phosphorus atom on the β-carbon atom of the ethylenic bond results in the formation of the intermediate dipolar ion (XLV), which rapidly isomerises to the silyl ester of the phosphorylated nitronic acid (XLVI).[65,66] In the reaction of 3,3-trichloro-1-nitroprop-1-ene the dipolar intermediate can be stabilised not only by the transfer of the Me_3Si group but also by the prototropic transition (XLV) → (XLVII) with the subsequent elimination of chlorosilane from the unsaturated quasi-phosphonium intermediate (XLVIII).[67]
Trialkyl phosphites under the same conditions form esters of alkylenephosphonic acids and alkyl nitrites.[68]

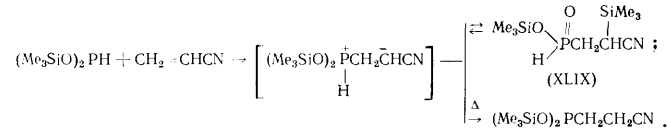


5. Reactions with Other Unsaturated Compounds

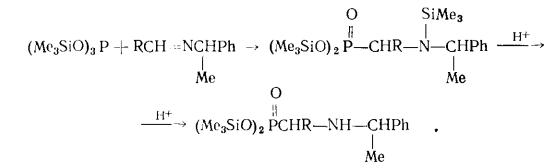
Organosilicon derivatives of tervalent phosphorus are capable of reacting with various unsaturated compounds containing the C=C, C=N, C=S, N=O, and S=O bonds and heterocumulene fragments. An example, namely the addition to maleimides, was examined above. The mechanism, involving the initial addition of silyl phosphites to the β-carbon atom of the activated double bond and the subsequent migration of the silyl group to the carbanionic centre, evidently operates also in the reaction with acrylonitrile:[5,69]



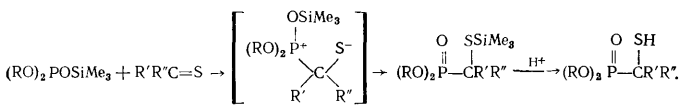
R=AlkO, Ph, Me_3SiO .



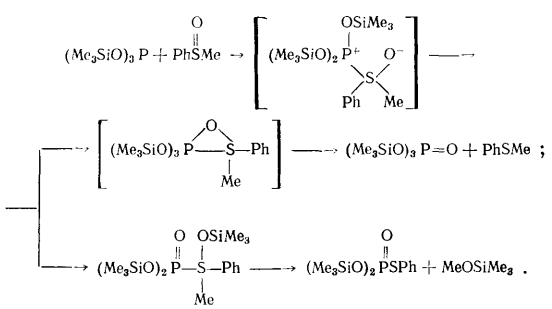
Diethyl *N*-trimethylsilylphosphoramidite also readily reacts with acrylonitrile. As a result of the prototropic transition, diethyl *N*-trimethylsilyl-β-cyanoethylphosphonimidate is formed under these conditions:[70]



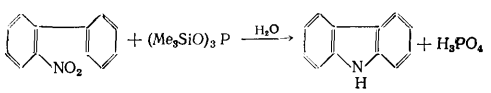
The interaction of bis(trimethylsilyl) hypophosphite with acrylonitrile and styrene leads to substituted bis(trimethylsilyl) ethylphosphonites.[71,72] It has been established by low-temperature ^{31}P NMR [72] that the reaction of the hypophosphite with acrylonitrile involves the initial formation, as a result of the migration of the Me_3Si group, of monosilyl phosphonite (XLIX), which isomerises at a higher



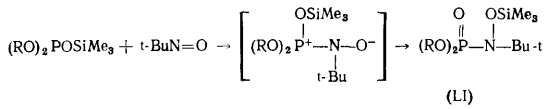
temperature to a thermodynamically controlled product—the disilyl phosphonite (L):



Tris(trimethylsilyl) phosphite is capable of adding to the C=N bond in aldimines: [73]

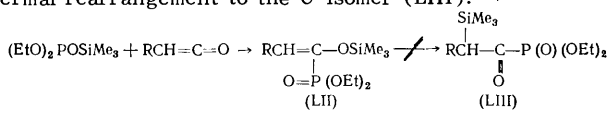


The reactions of silyl phosphites with cyclohexanethione and ethyl methyl thioketone lead readily to the dialkyl esters of α-trimethylsilylthioalkylphosphonic acid: [74]

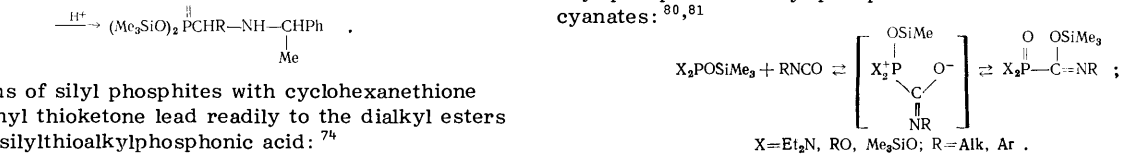


Tris(trimethyl silyl) phosphite exhibits a very high deoxygenating activity in interaction with sulphoxides and nitro-compounds. [75] In the reaction with methyl phenyl sulphoxide the main products are a sulphide and a silyl phosphate. However, the decomposition of the dipolar intermediate arising in the first stage takes place apparently also via the 1,4-migration of the organosilicon group and leads to *S*-phenyl phosphorothioate via a phosphorylated sulphurane:

The deoxygenation of nitro-compounds can lead to nitrogen-containing heterocycles: [75]



Nitroalkanes react with silyl phosphites like carbonyl compounds: the initial step in the interaction is nucleophilic attack by the phosphorus atom on the nitrogen atom of the nitroso-group; the subsequent 1,4-silylotropic shift leads to stable adducts having the phosphoramidate structure (LI): [76]

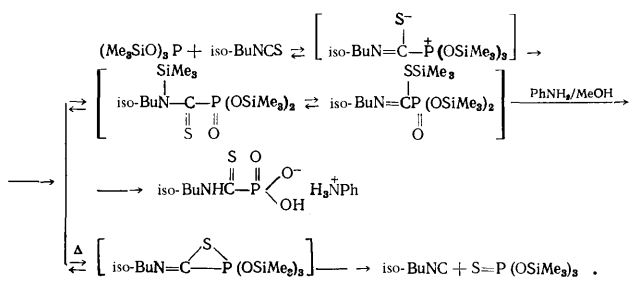


Trialkyl phosphites are oxidised by nitrosoalkanes to phosphates. [77]

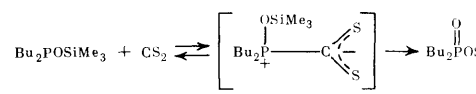
A characteristic feature of the interaction of silyl phosphates with heterocumulenes is the possibility of the involvement in the reaction of one or several reaction centres of the unsaturated system. The addition of silyl phosphites to keten leads to the quantitative formation of the *O*-silyl derivative (LII), which does not undergo a thermal rearrangement to the *C*-isomer (LIII): [78,79]

An analogous addition to the carbonyl fragment of a heterocumulene has also been observed in the reactions of silyl phosphites or silyl phosphoramidites with isocyanates: [80,81]

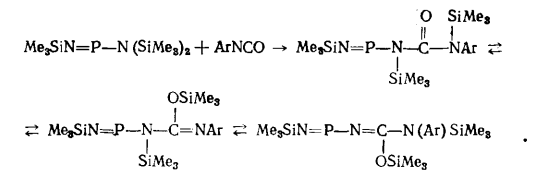
On heating, the reaction products decompose into the initial compounds. The thermal stability of the adducts with phenyl isocyanate is much higher than that of the adducts with the alkyl analogues by virtue of the conjugation of the C=N bond with the aromatic ring. [81]



The interaction of phosphorus–silicon reagents with isothiocyanates does not proceed quite so unambiguously. Silyl phosphoramidites readily add to the C=N bond of phenyl isothiocyanate with formation of the amides of *N*-phenyl-*N*-trimethylsilylthiocarbamoylphosphonic acids: [80]



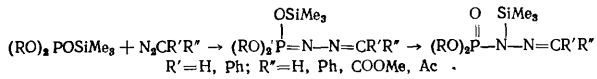
In the case of tris(trimethylsilyl) phosphite the Me_3Si group migrates to the sulphur atom of the isothiocyanate: [81]



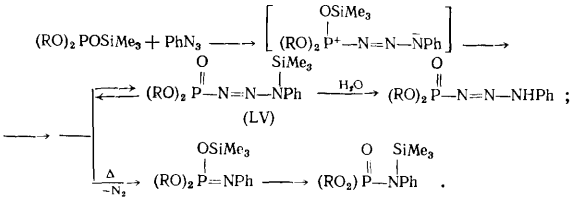
The mode of reaction of silyl phosphite with isobutyl isothiocyanate is determined by the experimental temperature. At room temperature a 1:1 adduct is formed and has been isolated in the form of the monoanilinium salt of *N*-isobutylthiocarbamoylphosphonic acid (LIV). Heating of the reaction mixture at 100 °C is accompanied by the desulphurisation of the isothiocyanate: [81]

The mechanism of the formation of phosphorothioates in this reaction is apparently analogous to the mechanism of the interaction of silyl phosphinites with carbon disulphide: [82]

The addition of the *N*-silylated amide of *N*-(trimethylsilyl)phosphenimidous acid to aryl isocyanates leads to an equilibrium mixture of adducts;[83] the phosphorus atom remains dicoordinate under these conditions:

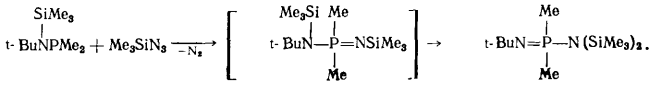


The complexity of the signals due to the Me_3Si group in the ^1H NMR spectrum and its dependence on temperature and the nature of the solvent demonstrate, according to the authors,[83] the occurrence of the amide–imide tautomerism and the 1,3-migration of the silyl group in the N=P–N triad.

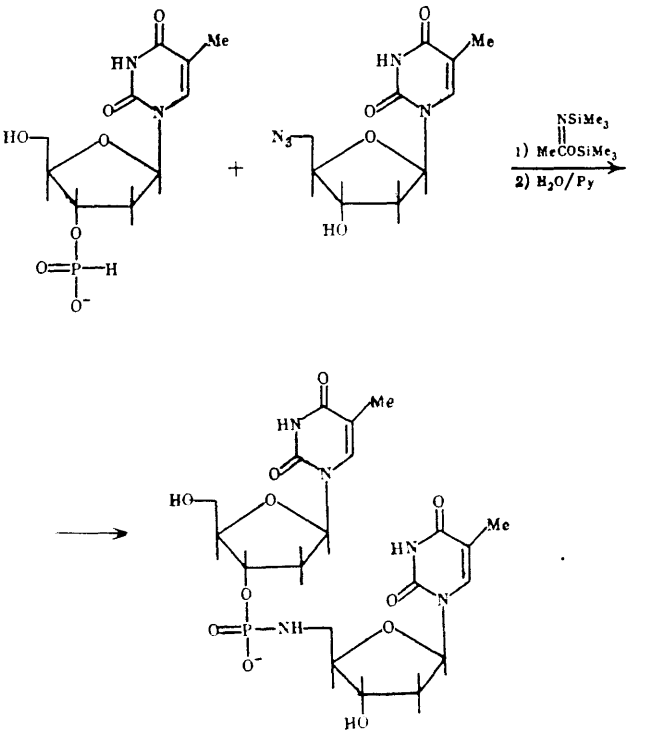


Trialkyl phosphites are known[84] to react with isocyanates and isothiocyanates under severe conditions (150–180 °C) with formation of isonitriles:

The first stage of the reaction of silyl phosphites with diaza-compounds involves the formation of phosphazenes, which isomerise to phosphorohydrazidates even at room temperature:[85,86]



When silyl phosphite reacts with phenyl azide, the kinetically controlled product is 1-dialkylphosphoryl-3-phenyl-3-silyltriazene (LV), which is readily hydrolysed by atmospheric moisture. With increase of temperature, conditions are attained for the irreversible decomposition of the intermediate betaine with evolution of nitrogen and formation of *N*-silylphosphoramidate:[87]

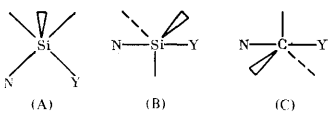


An increase of steric hindrance at the nitrogen atom in the phosphimine prevents the O → N migration of the Me_3Si group:[88,89]

The imination of *N*-t-butyl-*N*-trimethylsilylaminodimethylphosphine with trimethylsilyl azide results in the formation of a phosphimine with the sterically most favourable disposition of the bulky groups:[90]

The silyl phosphite–azide method of synthesis of phosphoramidates can be applied successfully to the synthesis of biologically important compounds:[88]

The data on the reactions involving the addition of organosilicon derivatives of tervalent phosphorus to various unsaturated compounds examined in this Section show that in the majority of the processes, as in the case of systems containing the P–X–C fragment, the initial step of the interaction is attack by the phosphorus(III) atom on the electrophilic centre of the other reactant. Consequently the replacement of the organic substituent in the phosphorus-containing reactant by the trialkylsilylgroup does not have a significant influence on the nucleophilic character of the phosphorus atom.



Extensive experimental and theoretical data showing that the overall electronic effect of the R_3Si group consists of the inductive and mesomeric interactions have accumulated in the literature.[91–98] The inductive effect is quantitatively expressed by the σ^* constants.[99] The electron-accepting influence of the R_3Si group [conjugation of the $(p-d)_\pi$, $(\sigma-4s)$, and $(\sigma-3d)_\sigma$ types] depends both on the nature of the heteroatom X in the fragment $\overset{\frown}{Si-X}-R$ and on the competing interaction $\overset{\frown}{X-R}$.[93,100] The replacement of the alkyl substituent at the oxygen or nitrogen atom by the trimethylsilyl group in isotypical compounds leads to a decrease of electron density at the heteroatom. The basicity of silyl ethers and silylamines is lower than that of their carbon analogues.[101–105]

The available literature data concerning comparative estimates of the nucleophilic properties of organosilicon derivatives of tervalent phosphorus are contradictory. Qualitative comparison of the reactivities of trialkyl and silyl phosphites shows, in the view of a number of investigators,[19,106,107] that the introduction of the Me_3SiO substituent at the phosphorus atom increases the nucleophilic reactivity of the phosphorus(III) system. On the other hand, the half-wave potentials $E_{1/2}$ (in volts) of the full esters of phosphorous acids, determined at a platinum electrode in acetonitrile[108,109] [1.60 for $(EtO)_3$; 1.66 for

$(MeO)_3P$; 1.74 for $(EtO)_2POSiMe_3$; 1.78 for $(MeO)_2$. $.POSiMe_3$; 1.96 for $(Me_3SiO)_3P$] indicate the electron-accepting influence of the organosilicon group.

Spectroscopic study of the hydrogen-bonded complexes of dialkyl and bis(trimethylsilyl) phosphites with phenol demonstrated approximately identical basicities of the oxygen atom in the P=O group in the two compounds.[110]

All these factors suggest that the unusual chemical behaviour of systems incorporating the P(III)–X–Si group is determined not only, and even not so much, by the change in electron density at the phosphorus atom as by the specific role of the trialkylsilyl group in stabilising the dipolar intermediates formed. Nucleophilic substitution at the silicon atom requires a low activation energy and can proceed via two transition states of types (A) and (B) having similar energies.[111–113] Depending on the structure of the intermediate compound and the experimental conditions, a particular version of the silylotropic transition obtains:

(A) (B) (C)

In the case of alkyl derivatives of tervalent phosphorus the only possible way in which the nucleophile can approach the sp^3-carbon atom leads to a trigonal bipyramidal structure of the transition state (C) with an axial disposition of the entering (N) and leaving (Y) groups. The distance between the nucleophilic centres should then be 3.5–4.5 Å.[113] All this increases sharply the energy barrier to the intramolecular transfer of the alkyl group and is responsible for the intermolecular reaction mechanism.

The driving force of the Ad† reactions of silyl phosphites with unsaturated compounds is in our view the thermodynamic ease of the formation of the phosphoryl group; for *N*-silylphosphoramidates, both the differences between the energies of the N–P(III) and N–P(IV) bonds and the greater strength of the Si–O bond compared with the Si–N bond play an important role in stabilising the adducts.

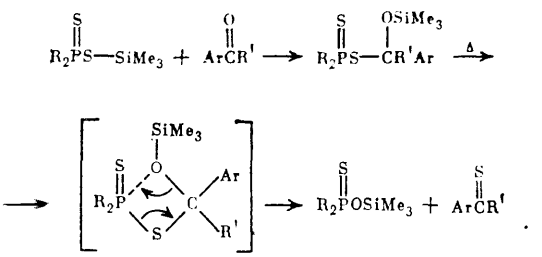
III. ORGANOSILICON DERIVATIVES OF TETRACOORDINATE PHOSPHORUS

The reactivity of organosilicon derivatives of tetracoordinate phosphorus has been studied to a much lesser extent than that of the corresponding phosphorus(III) compounds. It is known that the systems containing the P(IV)–X–Si (X = O, N, or S) group are capable of splitting off the trialkylsilyl group readily on treatment with proton-donating reagents,[1,114] acid halides,[115] and certain metal salts.[114] The reactions of silyl phosphates and their thio- and seleno-analogues with iodotrimethylsilane have been surveyed in a review.[116] There are no literature data concerning the addition of silyl phosphates or *N*-silylphosphoramidates to unsaturated compounds but the Ad processes involving *S*-trimethylsilyl phosphorodithioates have been studied in fair detail. The cause of this situation will be discussed below.

†Addition to carbonyl group—see Table 2 (Ed.of Translation).

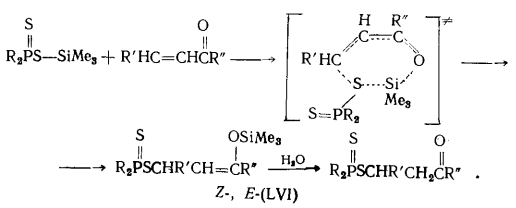
We have analysed the reactivity of *S*-trimethylsilyl phosphorodithioates in addition reactions in comparison with phosphorodithioic acids, because *S*-organyl phosphorodithioates do not enter into Ad reactions. Such comparison of the chemical reactivities of phosphorodithioates containing the S–Si and S–H bonds makes it possible to elucidate clearly the specific features of the reactions of silicon-containing phosphorus systems.

1. Interaction with Carbonyl Compounds and Nitro-Compounds



S-Trimethylsilyl esters of phosphorodithioic acids readily add to aliphatic aldehydes in the absence of a catalyst with formation of *S*-(α-trimethylsiloxy)-alkyl ethers:[117]

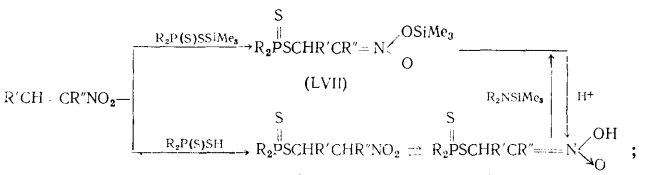
$$R_2P(S)S—SiMe_3 + R'CHO \rightarrow R_2P(S)S—CHR'—OSiMe_3;$$
R=AlkO, Alk, Ar; R' Alk .



Under analogous conditions, phosphorodithioic acids form bis(dialkylphosphinodithioyl)alkanes:[118]

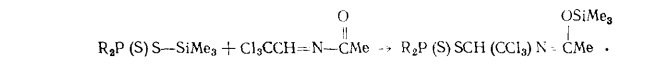
$$2R_2P(S)SH + R'CHO \rightarrow [R_2P(S)S]_2CHR' .$$

The adducts of silyl phosphorodithioates with aromatic aldehydes and ketones are unstable and decompose on heating via an O,S-exchange process,[117] noted previously for phosphorodithioic acids:[119]



Unsaturated aldehydes and ketones combine vigorously with silyl phosphorodithioates with formation of a mixture of *Z*- and *E*-isomers of phosphorylated silylenols (LVI).[120] The hydrolysis of the adducts leads to 3-oxoalkyl phosphorodithioates obtained from the corresponding phosphorodithioic acids:

Z-, *E*-(LVI)



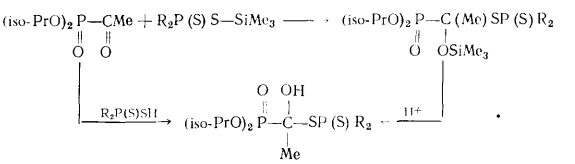
The appreciable, and in the case of acrolein preferential, formation of the *Z*-isomers can be due to the cyclic character of the transition state in the reaction. A similar structure of the activated complex has been proposed for the analogous reactions of phosphorodithioic acids.[121]

The interaction of silyl phosphorodithioates with nitroolefins leads to the formation of 1,4-adducts (LVII, a and b); the hydrolysis of the adduct (LVIIa) gives rise to a mixture of isomers—the nitro-compound (LVIIIa) and the *aci*-nitro-compound (LIXa):[117]

(a) R=MeO, R′=Ph, R″=Me; (b) R=MeO, R′=CCl_3, R″=H.

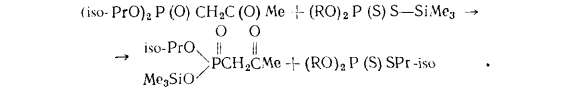
The silyl esters of phosphorodithioic acids do not add to acrylonitrile, alkyl acrylates, vinyl sulphones, alkyl vinyl ethers, and benzylideneaniline, while phosphorodithioic acids readily form 1,2-adducts with these compounds.[121,122] At the same time silyl phosphorodithioates react vigorously with *N*-acetyltrichloroaldimine:[117]

Thus silyl phosphorodithioates and phosphorodithioic acids show many features in common in their interaction with aromatic aldehydes and ketones but differ in their reactions with aliphatic aldehydes. Comparison of the ways in which the phosphorodithioates react with unsaturated carbonyl compounds and nitro-compounds suggests that the phosphorus-containing addend adds to the terminal positions of the unsaturated system. In the case of silyl phosphorodithioates the 1,4-adducts formed are thermodynamically stable. The addition of phosphorodithioic acids is in most cases accompanied by prototropic isomerisation.[121]



The fact that, in contrast to systems with a P(III)–X–Si group, silyl phosphorodithioates do not add to the C=C bond in unsaturated carbonyl reagents is apparently associated with the necessity for the 1,4-orientation of the silicon-containing phosphorodithioates in the course of the interaction. The driving force of such orientation is the high energy of the Si–O bond (89.3 kcal mol^{-1}) compared with the Si–C (69.3 kcal mol^{-1}) and Si–S (60.9 kcal mol^{-1}) bonds.[123] The coordination of the silicon and oxygen atoms in the transition state also promotes an increase of the nucleophilicity of the sulphur atom of the phosphorodithioate fragment. All these features significantly lower the activation energy for the Ad process.

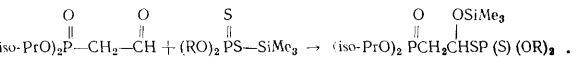
The reactions of silyl phosphites begin with the nucleophilic attack by the phosphorus atom on the sp^2-carbon atom of the ethylenic bond of the unsaturated reactant.[107] The migration of the Me_3Si group to the basic centre of the intermediate takes place in the second stage of the reaction. The factor determining the reactivity of silyl phosphites is the thermodynamic ease of formation of the P=O bond.



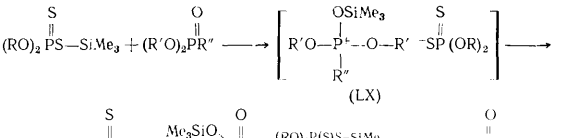
Hence it is clear why phosphorus–silicon reactants containing the P(IV)–O–Si group are incapable, in contrast to silyl phosphites, of adding to various unsaturated systems, including carbonyl systems. This applies to a large extent also to *N*-silylphosphoramidates, although in this instance the deliberate search for suitable reagents may lead to the occurrence of the Ad interaction.

2. Reactions with Organophosphorus Compounds Containing the C=O Group

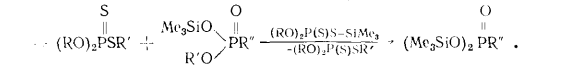
The mode of reaction of silyl phosphorodithioates with phosphorus-containing carbonyl compounds depends significantly on the structure of the latter. Di-isopropyl acetylphosphonate combines with silyl phosphorodithioates via the carbonyl group, forming siloxy-derivatives. The hydrolysis of the adducts lead to phosphorylated carbinols, also obtained by specific synthesis—by the reaction of phosphorodithioic acid with α-ketophosphonates:[124]



Under these conditions, *O*,*O*-di-isopropylphosphorylacetone undergoes dealkylation:

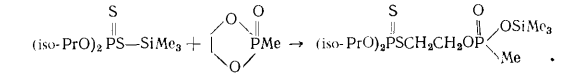


When an excess of silyl phosphorodithioate is used and when methoxy- or ethoxy-groups are introduced at the phosphorus atom of phosphorylacetone, complete silylation of the phosphonate is observed.[124]

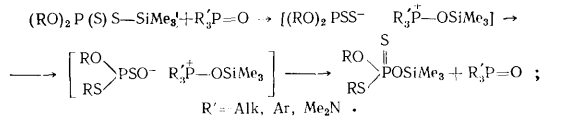


It is noteworthy that *O*,*O*-di-isopropylphosphorylacetaldehyde, which is alkylated with greater difficulty and contains a more reactive carbonyl group, reacts with silyl phosphorodithioates to form adducts via the C=O group:[124]

The dealkylation of phosphonates by silyl phosphorodithioates is a common feature:[124]

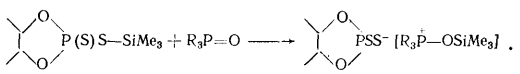


(LX)



Initially the Me_3Si group of the phosphorodithioate migrates to the phosphoryl oxygen atom with formation of the intermediate quasi-phosphonium compound (LX). The phosphorodithioate anion attacks next the alkyl group of the phosphonium ion, forming the corresponding *S*-alkyl ester of the phosphorodithioic acid and alkyl trimethylsilyl phosphonate. In the case of dimethyl and diethyl phosphonates and in the presence of an excess of silyl phosphorodithioate the dealkylation reaction develops further.

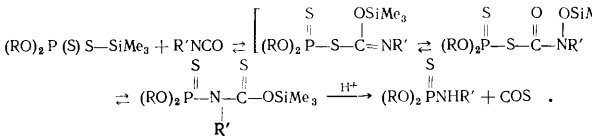
The use of cyclic phosphonates in this reaction makes it possible to synthesise readily compounds with two phosphorus atoms:[124]



The reaction of silyl phosphorodithioates with organophosphorus systems in which the dealkylation process is impossible (phosphines, phosphine oxides, and hexamethylphosphoramide) does not stop at the stage involving the formation of quasi-phosphonium structures: the isomerisation of the phosphorodithioate anion and subsequent silylation result in the formation of *O*-alkyl *O*-trimethylsilyl *S*-alkyl phosphorodithioates:[124]

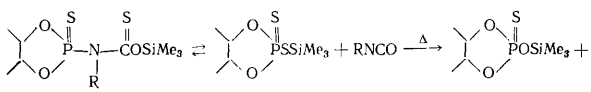
R′ = Alk, Ar, Me_2N.

Stable quasi-phosphonium compounds have been isolated in the reaction of a cyclic *S*-silyl phosphorodithioate with phosphine oxides and hexamethylphosphoramide (HMP):

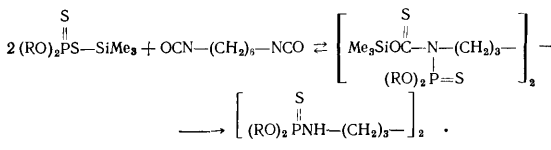


Phosphorodithioic acids react with phosphoryl compounds to form hydrogen-bonded complexes.[125]

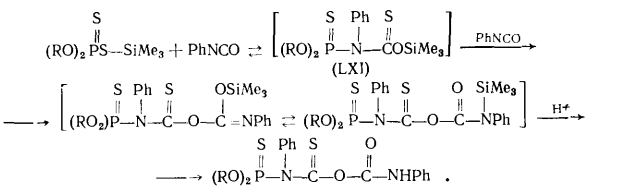
3. Reactions with Heterocumulenes



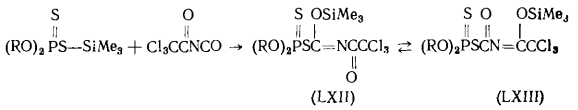
It is known that phosphorodithioic acids add vigorously to the C=N bond in isocyanates to form *N*-organylcarbamoyl phosphorodithioates:[122]



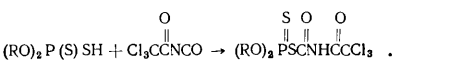
The reactions of silyl phosphorodithioates with various isocyanates have been widely investigated.[126] In the reactions with alkyl isocyanates the products of addition to the N=C=O group of the heterocumulene are formed initially and then rearrange to *N*-thiophosphorylated thiocarbamates via the intermolecular S → N migration of the thiophosphoryl group. The adducts are stable under the usual conditions, but on vacuum fractionation they decompose into the starting materials. This demonstrates the reversibility of the addition reaction and of the phosphorodithioate—phosphoramidothioate rearrangement. The hydrolysis of the reaction product leads to phosphoramidothioates and carbon oxide sulphide:[126]



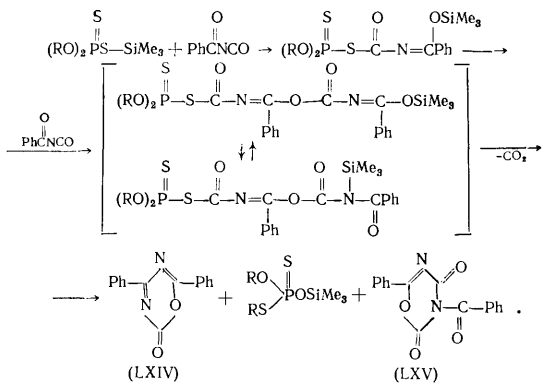
In the reactions involving cyclic silyl phosphorodithioates the products are *N*-thiophosphorylthiocarbamates, which are stable at room temperature, but on heating the O,S-exchange process takes place:



The reactions of the silyl esters of phosphorodithioic acids with hexamethylene di-isocyanate can proceed, depending on the reactant ratio, with participation of one or both isocyanate groups:[126]



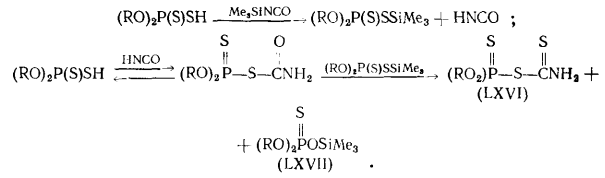
The replacement of the alkyl group in the isocyanate by the phenyl group reduces the reactivity of the heterocumulene—the reaction proceeds at a higher temperature. Two phenyl isocyanate molecules are then involved in the process: the electronic effect of the aromatic ring promotes the nucleophilic addition of the intermediate (LXI) to a second molecule of the unsaturated reactant:[126]



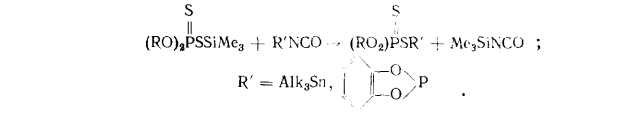
Trichloroacetyl isocyanate readily combines with silyl phosphorodithioates to form the (LXII) ⇌ (LXIII) equilibrium mixture, whose existence is associated with the reversible 1,5-migration of the trimethylsilyl group:

The reaction with phosphorodithioic acids leads to the product of addition to the C=N bond:[126]

In the interaction of silyl phosphorodithioates with benzoyl isocyanate the formation of adducts having the 1 : 2 composition is followed by the intramolecular substitution of the phosphorodithioate fragment under the influence of the siloxane or silazane groups. In the former case the cyclisation is accompanied by decarboxylation and leads to 6-oxo-2,4-diphenyl-1,3,5-oxadiazine (LXIV)—this is the main pathway. In the latter case the product is the benzoyl isocyanate dimer (LXV). The phosphorodithioate anion isomerises and is converted into the corresponding *S*-alkyl ester:[126]

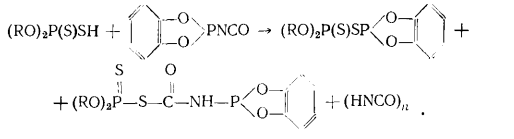


Cyclic silyl phosphorodithioates react with aryl and acyl isocyanates via the mechanism of the O,S-exchange process:[126]

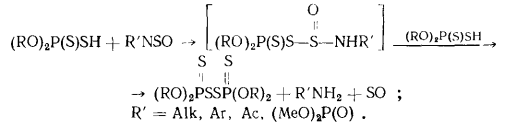


R = Ph, $Cl_3CC(O)$, PhC(O) .

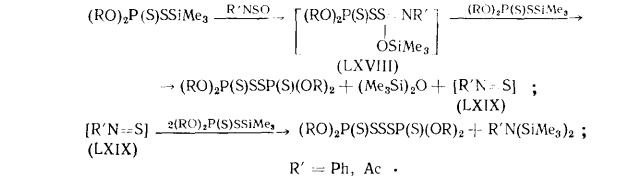
Silyl phosphorodithioates do not add to isocyanatosilanes; apparently the steric and electronic influences of the trimethylsilyl group in the heterocumulene prevent the stabilisation of the adduct via the S → N migration of the thiophosphoryl group.



Phosphorodithioic acids readily rupture the Si–N bond in the trimethylsilyl isocyanate molecule and the subsequent reactions result in the formation of *S*-thiocarbamoyl phosphorodithioate (LXVI) and *O*-silyl phosphorothioate (LXVII):[127]



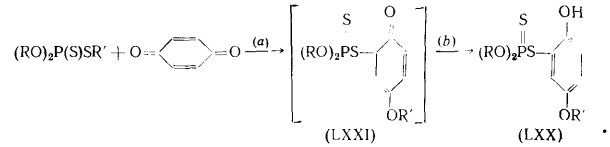
The interaction of silyl phosphorodithioates with other organoelemental isocyanates, namely isocyanatostannanes and phosphoroisocyanatidites, proceeds with cleavage of the element–nitrogen bond:[128]



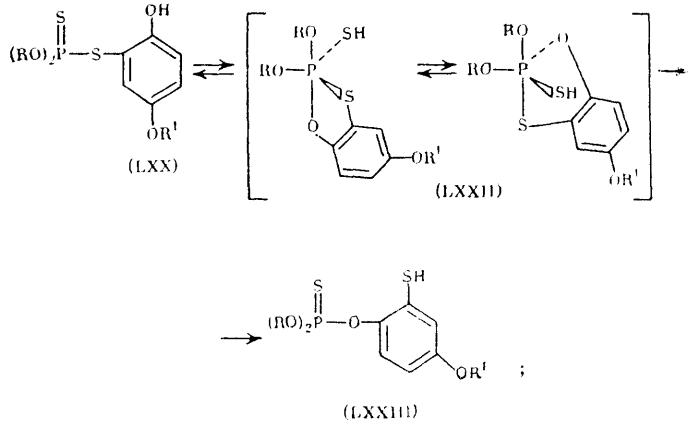
Both addition and substitution take place in the reactions of phosphorodithioic acids with *o*-phenylene phosphoroisocyanatidite:[128]

Significant differences in the chemical behaviour of silyl phosphorodithioates and phosphorodithioic acids have been observed also in their reactions with sulphinylamines. The reactions with phosphorodithioic acids result in the formation of bis(dialkylthiophosphoryl) disulphide, sulphur monoxide, and the corresponding amino-derivative:[129]

Silyl phosphorodithioates initially add to the S=O bond of the sulphinyl amine. The resulting intermediate (LXVIII) interacts with a second molecule of the phosphorodithioate to form bis(dialkylthiophosphoryl) disulphide, hexamethyldisiloxane, and an unstable intermediate (LXIX) having the thionitroso-structure, which reacts with two molecules of the silyl phosphorodithioate to form bis(thiophosphoryl) trisulphide and a disilylated amine:[130]



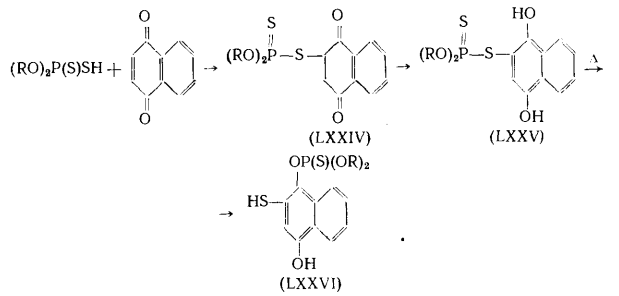
Thus the differences in the mode of reaction of silyl phosphorodithioates and phosphorodithioic acids with sulphinylamines are associated primarily with the different structures of the intermediates formed initially: phosphorodithioic acids form adducts involving the S=N bond, while silyl phosphorodithioates add to the S=O bond of the heterocumulene molecule.



4. Reactions with *p*-Quinones

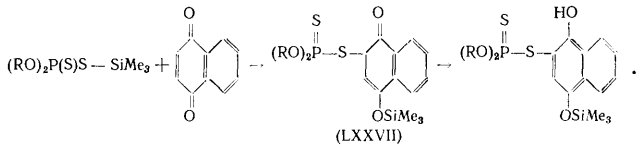
Like phosphorodithioic acids,[122] *S*-trimethylsilyl phosphorodithioates[131] are capable of adding readily to *p*-quinones, having a rigidly fixed *s*-transdisposition of the C=C and C=O bonds. The reactions with *p*-benzoquinone proceed vigorously in the absence of catalysts and are accompanied by the quantitative formation of *S*-aryl phosphorodithioates.

Kinetic study of these processes in various solvents using deuterated reactants showed[132] that both phosphorodithioic acids and their silyl esters initially react with *p*-benzoquinone to form 1,4-adducts (LXX). In non-polar weakly basic media the first stage of this reaction (*a*) determines the rate of the entire process ($k_H/k_D = 1$ for *p*-benzoquinone) and phosphorodithioic acids are therefore more reactive than silyl phosphorodithioates. With increase of the degree of nucleophilicity of the solvents, the proton transfer from the aromatic ring of the intermediate (LXXI) to the carbonyl group [stage (*b*); k_H/k_D is much greater than unity] becomes rate-limiting. The rates of reaction of phosphorodithioates (R′ = H or $SiMe_3$) are approximately the same under these conditions:



On vacuum distillation or heating, *S*-aryl phosphorodithioates (LXX) isomerise to the corresponding phosphoromonothioates.[131,132] The mechanism of their rearrangement includes the intermediate formation of mercaptophosphoranes (LXII):

R = H, Me_3Si.



Kinetic study of the isomerisation,[132] occurring via a unimolecular mechanism, showed that the influence of the nature of the substituents at the phosphorus atom is determined by a set of electronic and steric factors and is described satisfactorily by the rules of the "hydroxyphosphorane concept".[133] The introduction of a phosphorus atom into the dioxaphospholan ring accelerates the isomerisation reaction so much that the phosphorodithioate adduct having the structure (LXX) cannot be isolated—the phosphoromonothioate (LXXIII) is formed immediately. This effect is associated with the low energy of the intermediate cyclic spiro-mercaptophosphoranes (LXXII) with R = $CH(CH_3)CH(CH_3)$. It is known[133–136] that spirocyclisation favours all prototropic processes involving the formation of hydroxyphosphoranes.

The interaction of phosphorodithioic acids and silyl phosphorodithioates with *p*-naphthoquinone proceeds via a mechanism formally analogous to that of the reaction with *p*-benzoquinone. However, detailed analysis of the changes in the infrared spectra of mixtures of solutions of *p*-naphthoquinone and a phosphorodithioic acid in CCl_4 as a function of time showed that the product of addition to the C=C bond of the quinone (LXXIV) is formed initially and is then gradually converted into the dithiophosphorylated dihydroxynaphthalene (LXXV).[137] Under severe conditions (100 °C), the phosphorodithioate isomerises to the phosphoromonothioate (LXXVI):[132]

(LXXIV) (LXXV) (LXXVI)

In the case of silyl phosphorodithioates the 1,4-adduct (LXXVII) is an intermediate, as in the reaction with *p*-benzoquinone:

(LXXVII)

Consequently the mechanism of the reactions of phosphorodithioic acids with *p*-quinones depends on the structure of the unsaturated reactant; silyl phosphorodithioates form initially 1,4-adducts in all cases.

---o0o---

Summarising the discussion of the reactivity of organosilicon derivatives of phosphorus in addition reactions, one should note that the introduction of the trialkylsilyl group into the molecule of a phosphorus-containing system introduces significant, sometimes radical, changes into the character of Ad processes. The knowledge and purposeful employment of the specific features of the chemical behaviour of phosphorus–silicon reagents makes it possible to synthesise successfully new types of organoelemental compounds, which promotes the development and interpenetration of the chemistry of phosphorus and the chemistry of silicon.

The Synthesis of Mono- and Sesqui-terpene Insect Pheromones

A.M.Moiseenkov, K.V.Lebedeva, and B.A.Cheskis

The review presents a critical discussion of the available information on the syntheses of isoprenoid insect pheromones. Attention is concentrated on modern methods for the construction of molecules with a specified carbon skeleton. The efficiencies of the synthetic schemes are compared on the basis of the number of stages and the overall yields of the desired products. A systematic account of the data is given in terms of the types of pheromones.
The bibliography includes 179 references.

I. INTRODUCTION

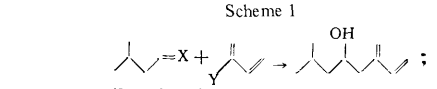
One of the most interesting and important fields in the modern science of life involves the study of insect pheromones. The term "pheromones" was proposed in 1959 [1] for chemical compounds "produced by living organisms, released into the environment, and inducing a specific response in individuals of the same biological species receiving them". Chemical signals ensuring intercommunications between insects may be individual compounds, but in most cases they are complex synergistic mixtures of substances whose biological activity can be reduced sharply following the removal of one of the components. The geometry and chirality of these components frequently exert a definite influence on the biological activity. The progress achieved recently in the determination of the absolute configurations of chiral pheromones has been possible by virtue of the employment of the most sophisticated methods of modern fine organic synthesis. Comparison of the spectroscopic characteristics and biological properties of the synthetic and natural specimens frequently permits a correct conclusion about the structure of the pheromone even in the presence of vanishingly small amounts of the latter.

Pheromones serve the most varied spheres in the vital activity of insects: sex and aggregation pheromones, fear pheromones, track pheromones, territorial markers, etc. are known. [2] The enormous interest by chemists and biologists in these copounds is associated not only and not so much with their purely scientific value as with the real possibility of their practical employment for the control of the size of the populations of harmful insects or as a method of fighting them by mass capture and, more rarely, by disorientation. At the present time there is a large number of reviews and monographs devoted to various questions concerning insect pheromones. [3-17] Correspondingly extensive factual data have accumulated on the syntheses of these compounds and are contained in a series of reviews, [13,18,19] which, being extremely extensive, nevertheless are not exhaustive, which has in turn led to the appearance of a series of small specialised reports on this topic. [20-23]

The present review is devoted to the synthesis of mono- and sesqui-terpene insect pheromones. Despite the fact that such data are partly contained in the communications noted above, there are no publications surveying the available information on this question. The present review contains data obtained mainly during the last ten years (up to July 1982 inclusive) and is concerned solely with regular and isomeric isoprenoid structures.

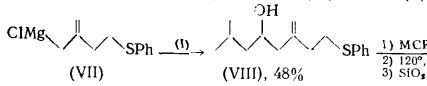
II. SEX AND AGGREGATION PHEROMONES

The sexual pheromones (SP) are produced by the insect in order to attract individuals of the opposite sex with the aim of subsequent coupling. Aggregation pheromones (AP) attract both sexes, which also as a rule precedes coupling. Since the purpose of the given group of substances is closely related to the propagation of the genus, they have in fact found extensive application in the protection of plants against insect pests and have therefore been studied at the present time on an extremely broad front.



Among the isoprenoid SP, the main place is occupied perhaps by the monoterpenols found in certain insects of the family *Scolytidae*, which are dangerous forest pests.

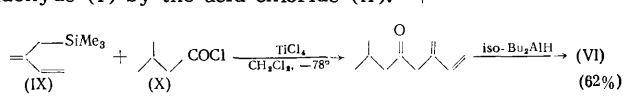
1. Ipsenol



Ipsenol (VI) is a pheromone or a component of the pheromone mixture in many species of bark beetles of the genus *Ips* [24-29] and scolytid beetles of the genus *Pityokteines*. [30,31] In many instances only the *S*-(-)-enantiomer is biologically active. [28,31,32] Very many studies have been devoted to the synthesis of compound (VI). Here and henceforth we shall consider initially the preparation of the racemic product and then of the chiral derivative.

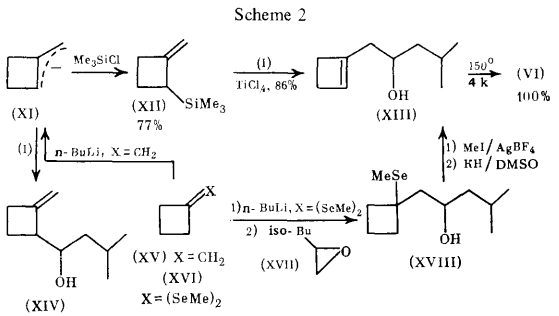
The majority of the methods of synthesis of compound (VI) are based on the construction of the whole C_{10} molecule from two C_5-synthones, one of which is isovaleraldehyde (I) or its dithioacetal (II) (Scheme 1).

Scheme 1



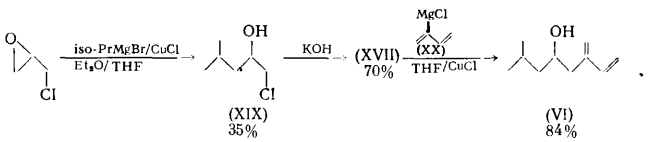
(I) X=O, (II) X = $S(CH_2)_2S$, (III) Y = H, (IV) Y = Br, (V) Y = $SnMe_3$;

Thus the deprotonation of the latter compound and subsequent alkylation with the bromide (IV) give rise to a product, which is converted into the required compound



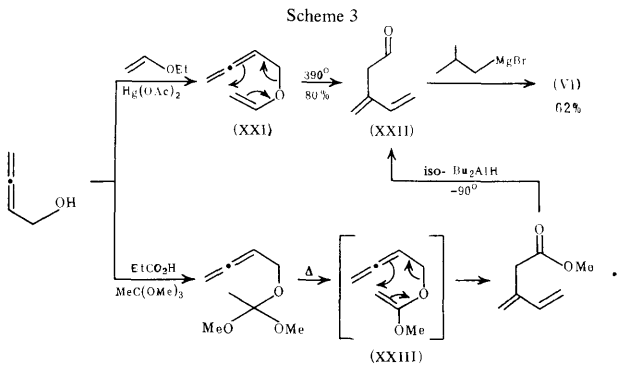
(VI) after the removal of the protecting dithio-group and hydride reduction.[24,33]

The bromide (IV) could not be converted into the magnesio- or lithio-derivative,[33] while the chloromagnesio-derivative (VII) could be very readily obtained from the corresponding chlorothioether, which made it possible to obtain the hydroxythioether (VIII), whose conversion with the aid of *m*-chloroperbenzoic acid (MCPBA) into the sulphoxide and the subsequent thermolysis of the latter yielded compound (VI) in an overall yield of 17%.[34] The single-stage synthesis of compound (VI), consisting in the Reformatskii condensation of compounds (I) and (IV) in the presence of zinc,[35] is extremely effective (yield 52%) and apparently the most appropriate method. The corresponding organozinc reagent could be conveniently generated *in situ* from tribromoisoprene.[36] The synthesis of compound (VI) with the aid of the ene reaction of compound (I) with isoprene (III), catalysed by Me_2AlCl, is also attractive by virtue of its simplicity and the ready availability of the starting materials.[37] However, the process is complicated by the concominant formation of the corresponding heterodiene condensation products. A single-stage synthesis of compound (VI) has also been achieved[38] using stannane (V). The use of the related silane (IX) gives an extremely low yield of compound (VI), but this limitation has been obviated by replacing the aldehyde (I) by the acid chloride (X).[39]†



In one of the instances examined above, the 1,3-diene system is introduced into the molecules of compound (VI) in a "masked" form.[34] The same principle, but in a different version, underlies many syntheses of compounds (VI) based on cyclobutane derivatives (Scheme 2). Thus the ambident anion (XI), obtained by the deprotonation of methylenecyclobutane (XV), is converted in 80% yield into a mixture of the regioisomers (XIII) and (XIV) (~1:2) on treatment with the aldehyde (I); the thermolysis of cyclobutene (XIII) gives a quantitative yield of compound (VI):[40]

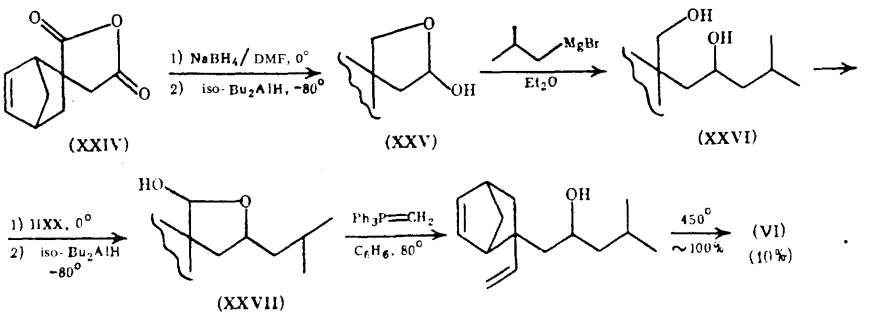
Scheme 2



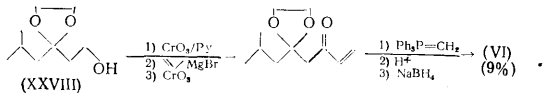
The isomer (XIV) remains a ballast compound under these conditions and its chromatographic separation is fairly difficult. A more effective procedure consists in the initial silylation of compound (XI) to give compound (XII), which subsequently reacts with compound (I) with total allyl rearrangement and gives rise to compound (XIII).[41] The third method of synthesis of this cyclobutene consists in the employment of the readily available *gem*-diselenide (XVI) as the C_4-synthone. Its metallation and treatment with the epoxide (XVII) (the C_6-synthone) lead to the hydroxyselenide (XVIII). The conversion of the latter into the dimethylselenonium derivative and its treatment with KH in dimethyl sulphoxide (DMSO) result in an exceptionally regiospecific formation of compound (XIII).[42] Overall, this method, being extremely laborious, is nevertheless characterised by a fairly high overall yield of compound (VI) (>50%).

The scheme involving the construction of the molecule of compound (VI) by coupling the epoxide (XVII) and buta-2-dienylmagnesium chloride (XX) as the C_6- and C_4-synthones respectively appears very simple and logical.[43] An extremely convenient method of synthesis of compound (XVII) proved to be the condensation of epichlorohydrin with isopropylmagnesium bromide in the presence of one equivalent of CuCl via the stage involving the formation of the intermediate chlorohydrin (XIX); the use of CuCl also makes it possible to increase significantly the yield of compound (VI) in the next stage:[44]

The same principle of the two-synthone approach is illustrated by Scheme 3. Here the key operation is the formation of the dienal (XXII) by the Claisen rearrangement of the vinylallenic ethers (XXI)[45] or (XXIII).[46] In both cases the overall yield of compound (VI) reaches 35%.



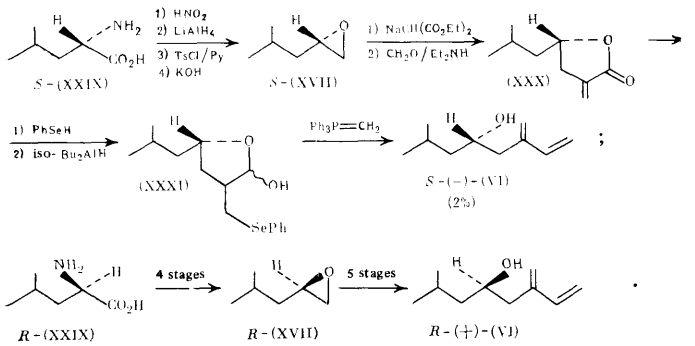
Scheme 3



The synthesis of compound (VI) from itaconic anhydride in the form of its adduct (XXIV) with cyclopentadiene (Scheme 4) is somewhat less effective.[47] The main strategy reduces in this instance to the selective transformation of compound (XXIV) into the hemiacetal (XXV) and subsequently to the just as selective oxidation of the 1,4-glycol (XXVI) with the aid of pyridinium chlorochromate (PCC) to the lactol (XXVII). The methylenation of the latter and the retrodiene removal of the protection of the initial *exo*-methylene bond lead ultimately to compound (VI) in a very moderate yield:

†Here and henceforth the overall yields are indicated in brackets.

Scheme 4

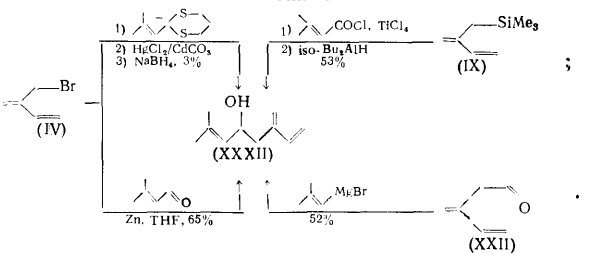


The overall yield in the six-stage synthesis of compound (VI) from the hydroxyacetal (XXVIII) with the aid of traditional methods for the increase in the length of the isoprenoid chain proved to be just as low: [48]

The synthesis of optically active compound (VI), which has been achieved in a low yield but which has made it possible to establish the absolute configuration of the pheromone, was undertaken from *S*-(+)-leucine (XXIX) (Scheme 5). Here the key product was the chiral epoxide *S*-(XVII) obtained in four stages. Its condensation with diethyl malonate and subsequent methylenation give rise to the lactone (XXX), which is transformed into the lactol (XXXI) after the protection of the *exo*-methylene double bond. Its Wittig methylenation, which takes place with the simultaneous removal of the phenyl selenide protecting group, leads to the natural product *S*-(-)-(VI). [49,50] The enantiomer *R*-(+)-(VI) has been obtained analogously from *R*-leucine (XXIX) via *R*-(XVII). [50]

Scheme 5

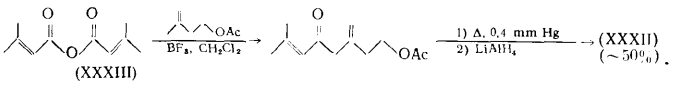
Subsequently both enantiomers (VI) were synthesised via a shorter pathway, using the method described above, [43] from the same chiral epoxides (XVII) and butadienylmagnesium chloride (XX) in an overall yield of ~50%. [51]



It is of interest to note that the biological action of the natural product *S*-(-)-(VI) is not inhibited by the presence of its optical isomer *R*-(+)-(VI), [28,31] at least for the bark beetle *Ips grandicollis* and the scolytid beetle *Pityokteines curvidens*. This fact permits one to hope for a possible practical application of compound (±)-(VI), which will thus remove the necessity for its enantioselective synthesis.

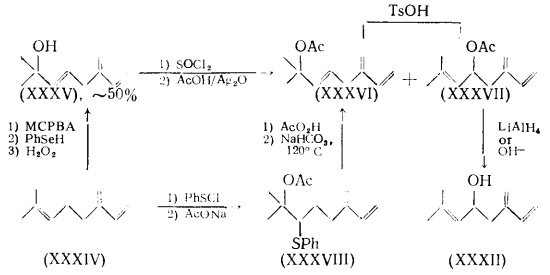
2. Ipsdienol

Like its dihydro-derivative (VI), ipsdienol (XXXII) is an aggregation-sex pheromone in many *Ips* [24-27,29,52-57] and *Pityokteines* [30,31] species and, in contrast to compound (VI), these functions can be fulfilled by both enantiomers of compound (XXXII) (see, for example, Vité et al. [32]).



In conformity with the evident structural characteristics of this compound, the strategy used in many of its total syntheses proved to be analogous to that already considered for ipsenol (VI). Thus the two-synthone approaches ($C_5 + C_5$ or $C_4 + C_6$), represented in Scheme 6, are widely used:

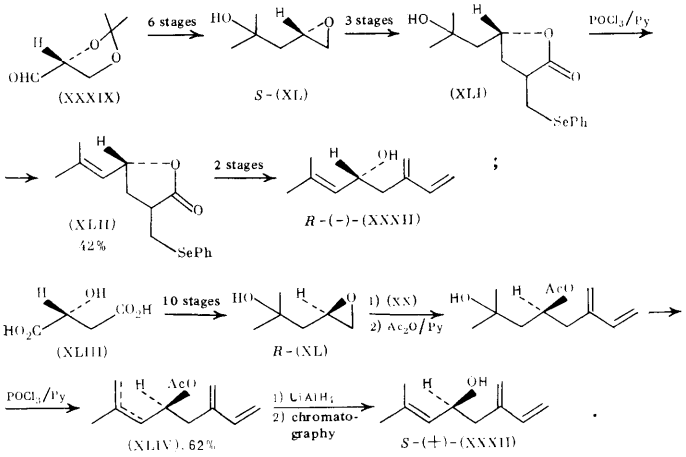
Scheme 6



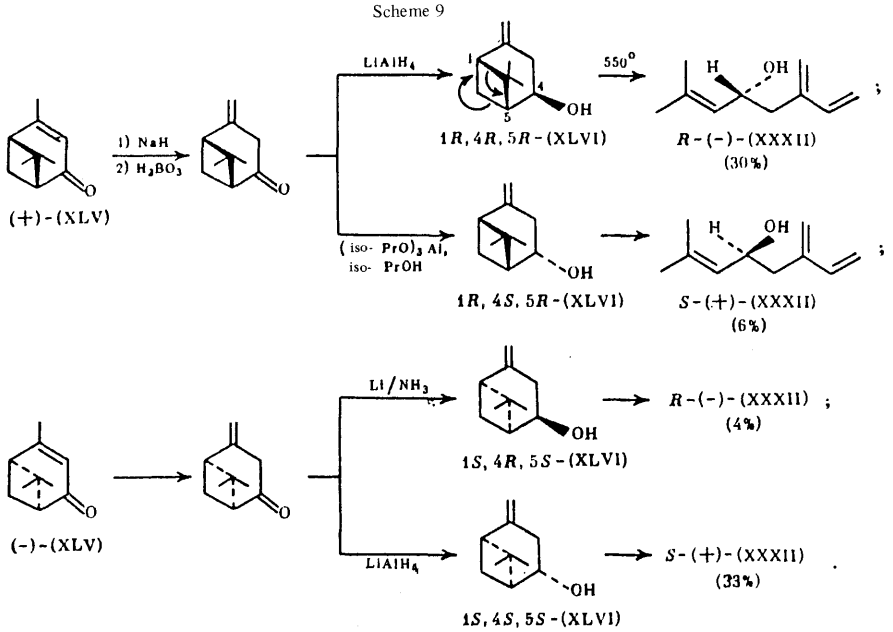
The extremely low overall yield of compound (XXXIII), initially obtained in three stages from the bromo-derivative (IV), can apparently be accounted for by the authors' [24,33] endeavour to confirm in the first place the structure of this pheromone. On the other hand, the simplicity and effectiveness of the synthesis of compound (XXXII) by the Reformatskii method [36,58] as well as the syntheses from the silane (IX) [39] and the aldehyde (XXII) [45,46] are evident.

The method based on the condensation of the anhydride (XXXIII) with isopentenyl acetate [59] proved to be fairly apt, despite the formation of up to 30% of regio-isomers as side products in the first stage:

A fundamentally different approach, directed in essence to the selective hydroxylation of myrcene (XXXIV), which possesses the fundamental structural features of the molecule of compound (XXXII), is illustrated in Scheme 7:



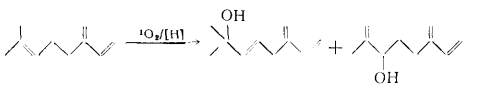
Scheme 7



Thus the selective epoxidation of compound (XXXIV) with subsequent opening of the epoxide ring with the aid of PheH and treatment of the intermediate hydroxyselenide with H_2O_2 gives rise ultimately to amitinol (XXXV), which has proved to be the component of the aggregation pheromones (AP) of the bark beetles (see below). In view of its lack of resistance to the action of acids, the direct rearrangement of the tertiary alcohol (XXXV) proved difficult. An indirect procedure was therefore undertaken: the tertiary alcohol (XXXV) was converted into a mixture of the acetates (XXXVI) and (XXXVII); the latter was isolated from the mixture by the reductive cleavage with lithium tetrahydroaluminate to give the alcohols (XXXV) and (XXXII); and by the selective acetylation of the secondary alcohol (XXXII) with acetic anhydrides and the subsequent chromatography of the mixture of compounds (XXXV) and (XXXVII); the racemic secondary alcohol (XXXII) was obtained from the acetate (XXXVII) in an overall yield of ~10%. [60] A related approach consists in the selective conversion of compound (XXXIV) into the acetoxysulphide (XXXVIII) and the conversion of the latter into the acetate (XXXVII) via the sulphoxide and the tertiary acetate (XXXVI), which smoothly rearranges to compound (XXXVII). [The use of the rearrangement (XXXVI) → (XXXVII) would have probably halved the number of stages in the preceding synthesis.] The hydrolysis of compound (XXXVII) affords the required compound (XXXII) in an overall yield of ~25%. [61]

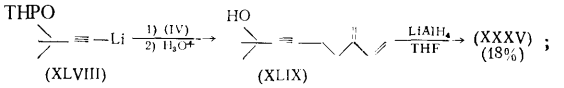
By analogy with the syntheses of the enantiomeric compounds (VI), the optically active isomers of compound (XXXII) have been obtained via the chiral hydroxyepoxides (XL) (Scheme 8). [51,62] Here compound *S*-(XL) was synthesised from a derivative of *R*-glyceraldehyde (XXXIX), which can be obtained in its turn from D-mannitol. The enantiomer *R*-(XL) was prepared from *R*-malic acid (XLIII). The conversion of the epoxide *S*-(XL) into the alcohol *R*-(XXXII) involves the formation of the selenide (XLI) at an intermediate stage (see Scheme 5). Its dehydration leads to the olefin (XLII), whose further transformation into the required compound *R*-(XXXII) was achieved analogously to the synthesis of compound (VI) via Scheme 5 in an overall yield of 0.2% with respect to compound (IX). The enantiomer *S*-(XXXII) was synthesised from the epoxide *R*-(XL), which was condensed by the method described above [43] with butadienylmagnesium chloride (XX). Successive acetylation of the secondary hydroxyl and dehydration lead to a ~1 : 1 mixture of the allyl isomers (XLIV). The absence of regioselectivity at the given stage is undoubtedly a significant disadvantage of the approach considered, because it requires the chromatographic isolation of compound *S*-(XXXII), formed after the reduction of the acetate in an overall yield of 0.03%.

Scheme 8



Scheme 9

An elegant method of synthesis of both enantiomers of compound (XXXII) is based on the four-stage transformation of the optically active verbenones (XLV) (Scheme 9). The β-verbenols (XLVI), obtained by the reduction of the corresponding non-conjugated ketones, were subjected to flash pyrolysis. As a result of the opening of the four-membered ring, the 1,5-diastereoisomers are then converted in pairs into the required compound (XXXII) in approximately identical yields, retaining the absolute configuration of the chiral centre C(4) in the molecule of compound (XLVI).[63] A disadvantage of this scheme is the comparative difficulty of obtaining the optically active verbenones (XLV).



3. Amitinol

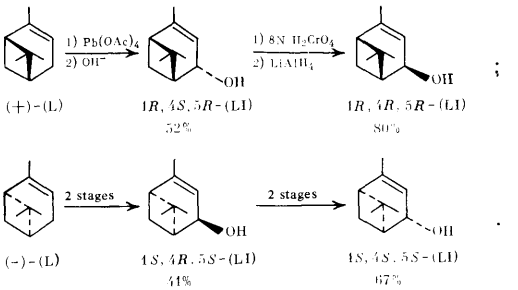
Yet another representative of the linear monoterpenols entering into the composition of the AP of the bark beetle of the genus *Ips* is amitinol (XXXV).[29,64] Apart from the synthesis described above (Scheme 7),[60,61,65] there exists yet another method of obtaining compound (XXXV) from myrcene, which consists in its reductive photochemical oxidation in the presence of $(H_2N)_2CS$ [66] or $n\text{-}Bu_4NBH_4$.[67] The regioisomer (XLVII) formed simultaneously can be separated chromatographically with comparative ease. The preparatively more convenient method employing $n\text{-}Bu_4NBH_4$ [67] is characterised by a somewhat lower yield of compound (XXXV):

(XXXIV) (XXXV) (XLVII)
40—50% 30—40%

A two-synthone ($C_5 + C_5$) scheme has also been described for the construction of amitinol from the bromo-derivative (IV) and the acetylide (XLVIII) with subsequent hydride reduction of the intermediate carbinol (XLIX).[45] However, one should note the moderate overall yield of compound (XXXV) in this instance:

(XLVIII) (XLIX)

THP = tetrahydropyranyl.



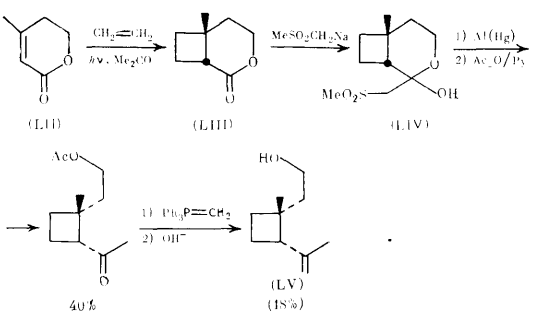
Finally, the pheromone (XXXV) has been recently identified[29] in one of the bark beetle species and has been obtained by the allyl isomerisation of ipsdienol on treatment with 3% HBF_4; the authors unjustifiably assumed that compound (XXXV) had not been synthesised previously.

4. Verbenols

The *cis*- and *trans*-verbenols (LI) have been found in the AP of many species of the *Ips* bark beetle and the timber beetles *Dendroctonus* [24—26,56,68—70] and in many instances the biological action of compounds (LI) can depend significantly on their enantiomeric purity;[26,32,71—73] mainly the 4*S*-(-)-*cis*- and 4*R*-(+)-*trans*-verbenols are active.

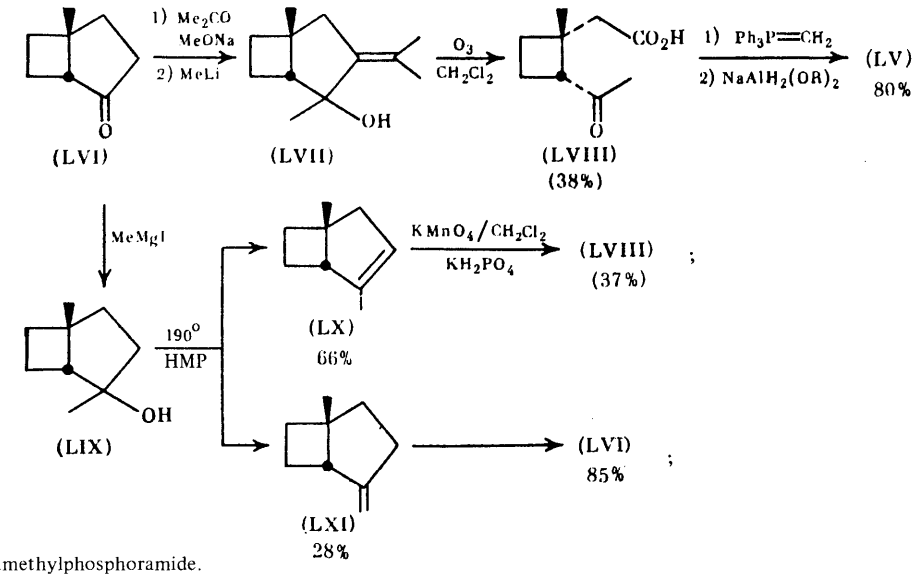
The syntheses of the racemic and chiral compounds (LI) are fairly isotypical and are based on standard and thoroughly investigated transformations of the α- and β-pinene derivatives.[24,33,63,74,75] In particular, the chiral compounds *trans*-(LI) have been obtained by the allyl oxidation of the corresponding α-pinene (L) enantiomers and *cis*-(LI) have been synthesised by the Jones oxidation of *trans*-(LI) to the verbenols (XLV) with a subsequent hydride reduction[74,75] (Scheme 10).

Scheme 10



The partial racemisation occurring during the synthesis of the verbenols can be compensated by their conversion into the D-3β-acetoxyetienic esters and by the improvement of the optical purity of the latter as a result of crystallisation and the regeneration of the required alcohols with the aid of hydride reduction.[74,75]

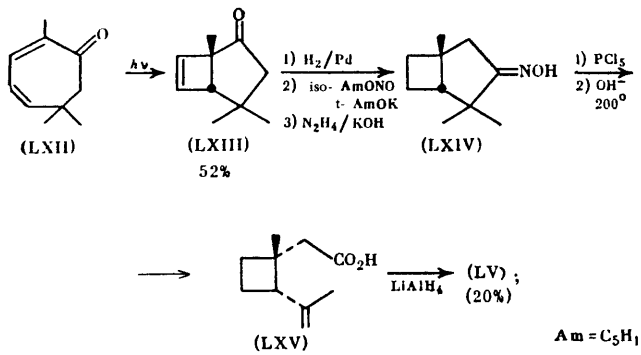
5. Grandisol



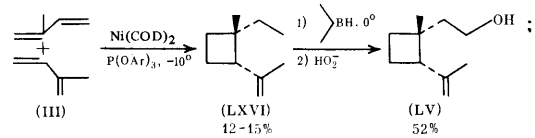
The snout beetle *Anthonomus grandis* is one of the most dangerous pests on the cotton plant, "eating up", for example, 300 million dollars annually on American farms.[76] The aggregation-sexual pheromone "grandlure", produced by the males of this insect, consists of four components, the principal component being (+)-grandisol (LV).[77] Its enantiomer also exhibits a high biological activity,[78] which apparently eliminates the necessity for the chiral synthesis of compound (LV) for practical purposes.

Numerous studies have been devoted to the synthesis of the racemate of compound (LV), evidently owing to the unusual nature of its cyclobutane structure and the growing need for this pheromone. Many methods for the construction of the molecule of compound (LV), developed prior to 1975, have been described in a review,[20] which effectively illustrates the evolution of the overall strategy in the synthesis of substances of this type. We shall therefore consider below only recently published and the most promising of the proposed schemes.

The key stage in the majority of the methods is the formation of the cyclobutane fragment of the molecule of compound (LV) and this is usually achieved by the photochemical [2 + 2]-cycloaddition. Thus the photoadduct (LIII) has been obtained from the lactone (LII) and ethylene; its treatment with the sodium derivative of dimethyl sulphone gives rise to the sulphone (LIV), which has been converted into grandisol by means of four simple operations:[79]



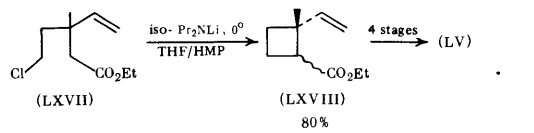
Scheme 11



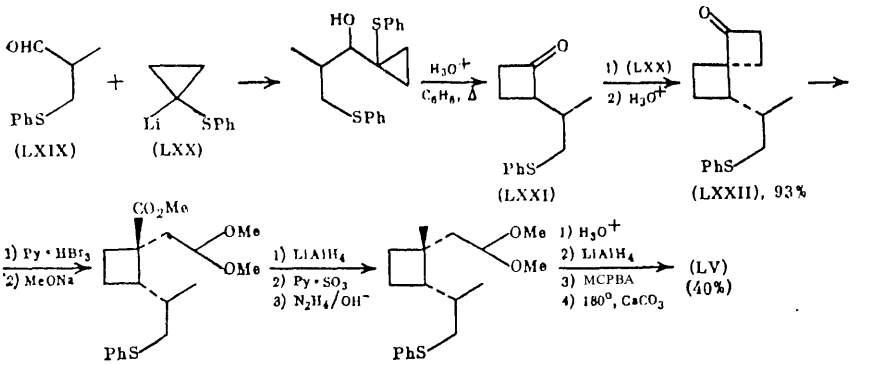
HMP = hexamethylphosphoramide.

The syntheses of compound (LV) based on the use of 3-methylcyclopentenone instead of the lactone (LII) (Scheme 11) can be regarded as just as successful. Here the main task is the specific transformation of the cyclopentane fragment of the photoadduct (LVI). In one instance this has been achieved by its conversion into the isopropylidene-carbinol (LVII) and subsequent ozonolysis to the ketoacid (LVIII) [80] and in another instance by the dehydration of the alcohol (LIX) to the olefins (LX) and (LXI). The oxidative cleavage of the first of these leads to the same ketoacid (LVIII) as above, while the cleavage of the second results in the formation of the initial ketone (LVI). [81]

A novel and extremely effective synthesis of compound (LV) is based on the intramolecular photocyclisation of the readily available eucarvone (LXII). The main difficulty in this approach consists in the shift of the carbonyl functional group in the intermediate (LXIII) to the neighbouring secondary carbon atom, which is achieved by hydrogenation and nitrosation. The subsequent reduction leads to the saturated oxime (LXIV). The Beckmann rearrangement of this kind and hydrolysis of the intermediate nitrile afford the acid (LXV), which is reduced to (±)-grandisol: [82]

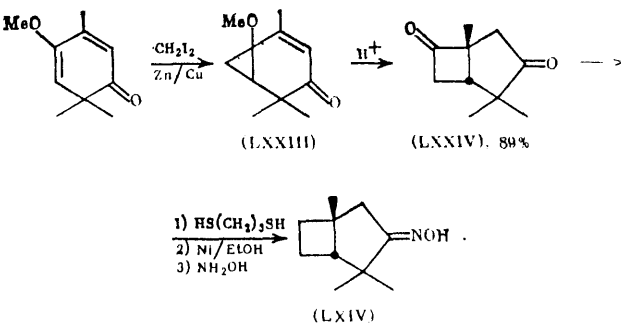


Apart from the photochemical methods, a whole series of fundamentally new approaches to the synthesis of compound (LV) have been described. The zerovalent nickel-catalysed cyclodimerisation of isoprene to the diene (LXVI) with subsequent selective "anti-Markovnikov" hydration of one of the C=C bonds must be regarded as the shortest of these, although its effectiveness is comparatively low: [83]

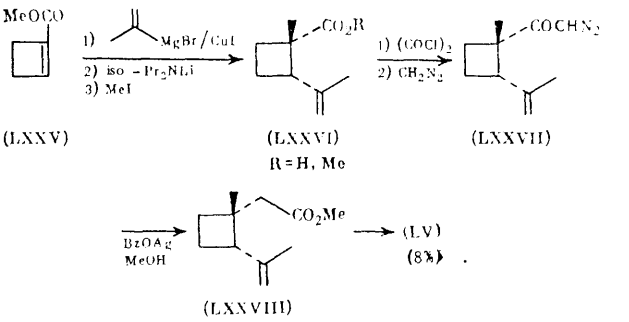


COD = cyclo-octadiene.

The construction of the cyclobutane skeleton of compound (LV) by the intramolecular cyclisation of suitable precursors with functional groups is usually associated with a low stereoselectivity of this key stage. Thus the smooth cyclisation of the δ-chloroether (LXVII) gives rise to a mixture of stereoisomers of compound (LXVIII) (*Z*/*E* ≅ 2:1); the subsequent conversion into compound (LV) entails a laborious operation involving their chromatographic separation. [84] The overall yield of compound (LV) was not indicated in the above study:

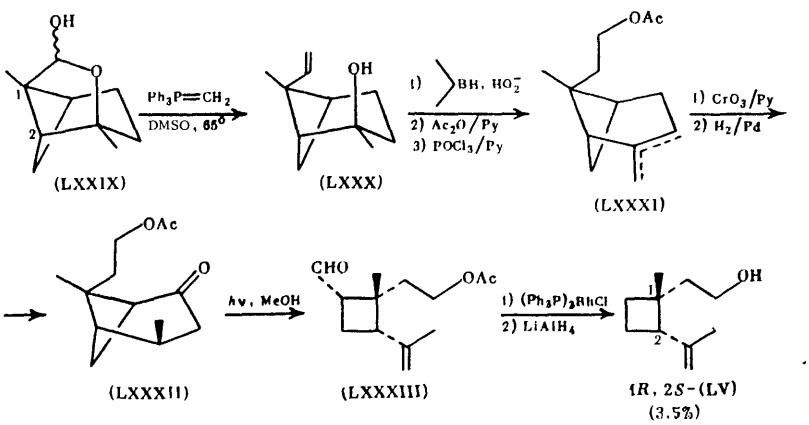


The cyclopropylcarbinyl rearrangement (CPCR) has served as an extremely effective procedure for the formation of the four-membered ring in the molecule of grandisol. The latter has been obtained (Scheme 12) in a very high yield and with a small admixture of the *E*-isomer (20%) from the thioaldehyde (LXIX) and the lithio-derivative (LXX) by the double application of the CPCR, which leads to the cyclobutanones (LXXI) and (LXXII). The required carbon skeleton was then obtained by the haloform cleavage of the spiro-heptanone (LXXII). The required product (LV) is then obtained by the reduction of the ester group to the methyl group and of the acetal group to the alcohol group, followed by the elimination of the elements of PhSH: [85,86]



Scheme 12

An analogous principle underlies another approach leading to the geometrically pure compound (LV) in an overall yield of ~7%.[87] In this case the methoxybicycloketone (LXXIII) is subjected to the CPCR rearrangement and is transformed into the dione (LXXIV), which is then converted into the oxime (LXIV). The formation of compound (IV) from the oxime[82] was examined above:



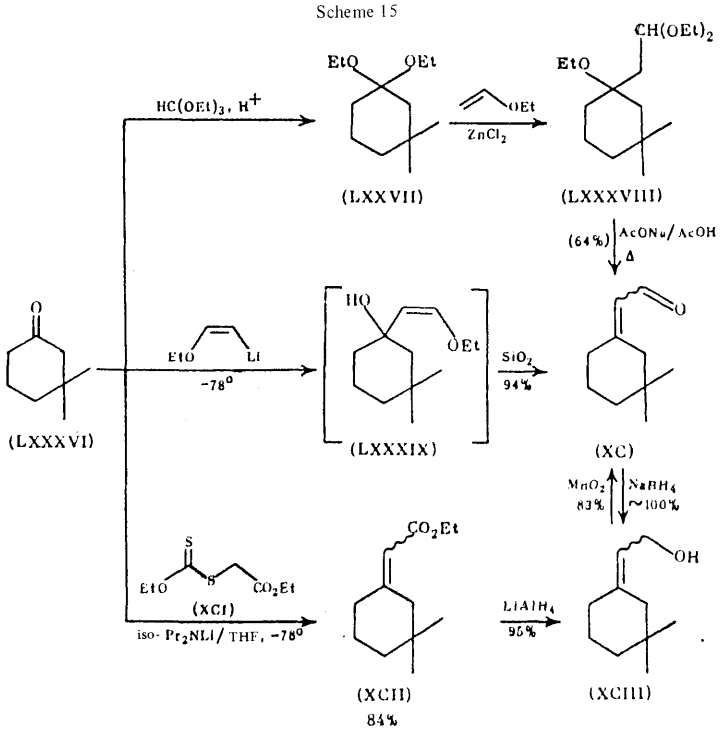
Among the syntheses of compound (LV) based on the use of cyclobutane precursors, mention should be made of the three-stage stereoselective transformation of the conjugated olefin (LXXV) into the ester (LXXVI). Its conversion into the diazoketone (LXXVII) and further into the ester (LXXVIII) makes it possible to obtain compound (LV) smoothly albeit in a low overall yield:[88]

The synthesis of (+)-grandisol (LV) is represented in Scheme 13. Its absolute 1*R*, 2*S*-configuration follows from the known configuration of the remote precursor (LXXIX), in the course of the transformation of which into the required compound the centres indicated are not involved.[89] The lactol (LXXIX), obtained in four stages from (-)-β-pinene, was converted by the Wittig reaction into the olefin (LXXX) and then by three simple operations into a mixture of the olefins (LXXXI). The allyl oxidation of this mixture with subsequent hydrogenation led to a satisfactory yield of the ketone (LXXXII). The Norrish photochemical cleavage of the latter, the deformylation of the aldehyde (LXXXIII) by means of Wilkinson's complex, and the removal of the acetate protecting group yield ultimately the optically pure 1*R*, 2*S*-(+)-grandisol, the biological and physicochemical properties of which correspond to those of the natural product.

Scheme 13

In another procedure (Scheme 14) both optical isomers of compound (LV) have been obtained from the racemic acid (LXXXIV), which can be readily synthesised from the cyclic photoadduct of ethylene with 3-ethoxycarbonylcyclopent-2-enone.[90] Quinine, cinchonine, or brucine salts of this acid have been separated and then converted in pairs into the isopropylidene derivatives (LVII) via stages involving the esters (LXXXV) and ketones (LVI). The conversion of compound (LVII) into the enantiomers of compound (LV) does not differ fundamentally from that considered in Scheme 11.

Naturally, neither of the enantioselective syntheses of compound (LV) is suitable for preparative purposes because of the large number of stages and the low overall yield, but the absolute configuration of this pheromone has been established with their aid.

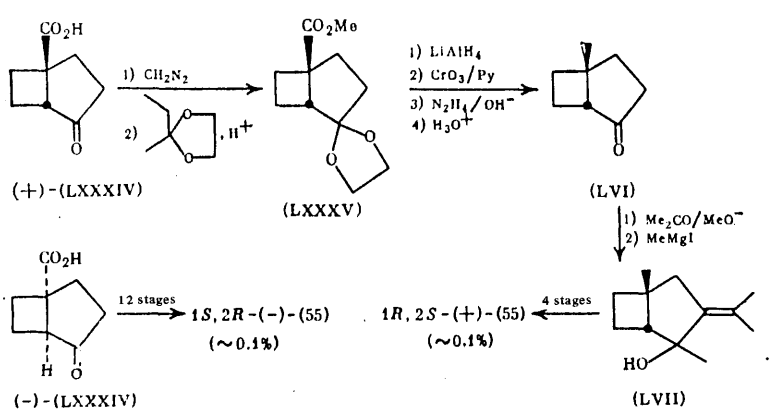


In conclusion one should mention the synthesis of 1*S*, 2*R*-(-)-(LV), carried out in order to investigate the biological properties of this enantiomer; this synthesis involves the separation of the quinine salts of the enantiomeric acids (LXV) obtained by the oxidation of compound (±)-(LV).[78]

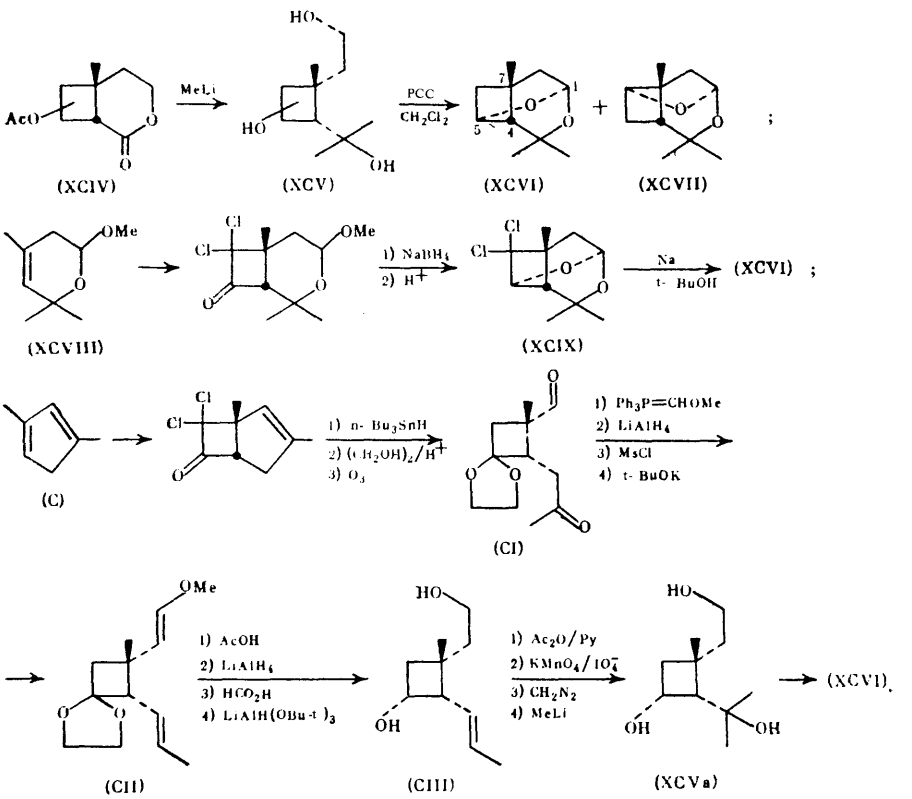
From the wide variety of syntheses of compound (LV), one can apparently isolate the most promising syntheses based on the cyclodimerisation of isoprene[83] and the intramolecular photocyclisation of eucarvone.[82]

6. Cyclohexane Components of "Grandlure"

Apart from compound (LV), the cyclohexane monoterpenes *Z*,*E*-(XC) and *Z*-(XCIII) also enter into the composition of the AP of the cotton snout beetle. The methods of synthesis of these components of "grandlure" are fairly simple and have been largely considered in another review.[13] The majority of the procedures, including those published recently[91-93] (Scheme 15), are based on the employment of the readily available dimethylcyclohexanone (LXXXVI). The condensation of the acetal (LXXXVII) with ethyl vinyl ether gives a quantitative yield of the ethoxyacetal (LXXXVIII), which is subsequently converted into a mixture of the aldehydes (XC). The latter can be separated chromatographically and reduced to the corresponding isomers of the alcohols (XCIII).[91] The synthesis based on the condensation of the ketone (LXXXVI) with ethoxyvinyllithium must be included among the most effective methods. The resulting intermediate (LXXXIX) is smoothly converted into a 1:1 mixture of the isomers of compound (XC) in the course of chromatography of SiO_2.[92] A novel method of synthesis of αβ-unsaturated esters is characterised by high yields; the interaction of the carbanion derived from the dithiocarbonate (XCI) with the ketone (LXXXVI) leads to a ~1:1 mixture of the isomeric esters (XCII).[93] The latter can be reduced to the alcohols (XCIII), whose oxidation gives rise to the aldehydes (XC).[91]



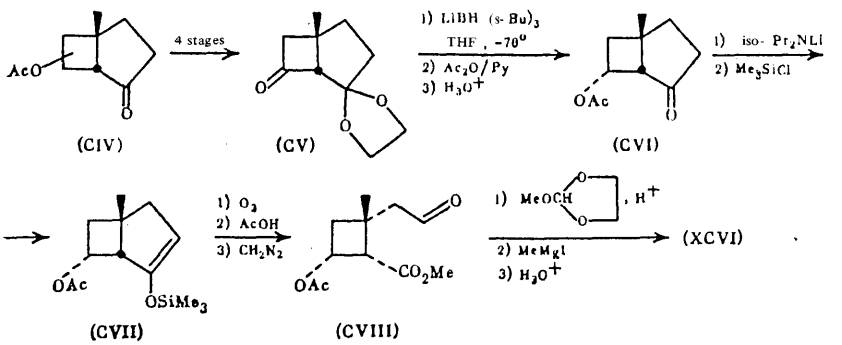
Scheme 15



7. Lineatin

In contrast to the bark beetles of the genus *Ips*, in other representatives of this family (*Scolytidae*), namely the beetles *Trypodendron lineatum*, the AP, called lineatin, is produced by the females. It has been shown recently that the AP has the unusual dioxatricyclononane structure (XCVI).[94,95] It has also been established that the biological action of the natural (+)-isomer is not inhibited by its inactive optical isomer (-)-(XCVI).[96]

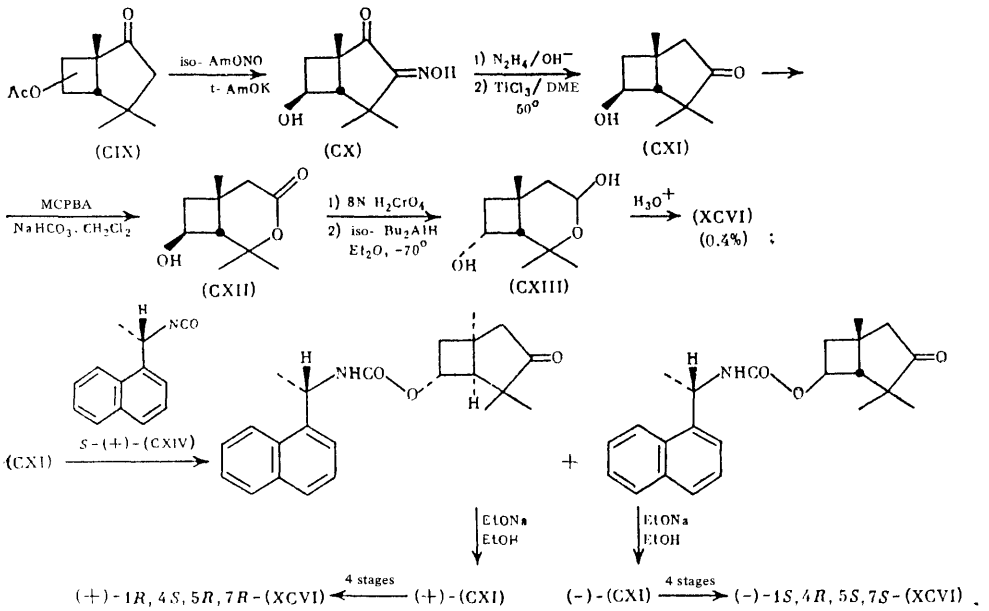
Scheme 14



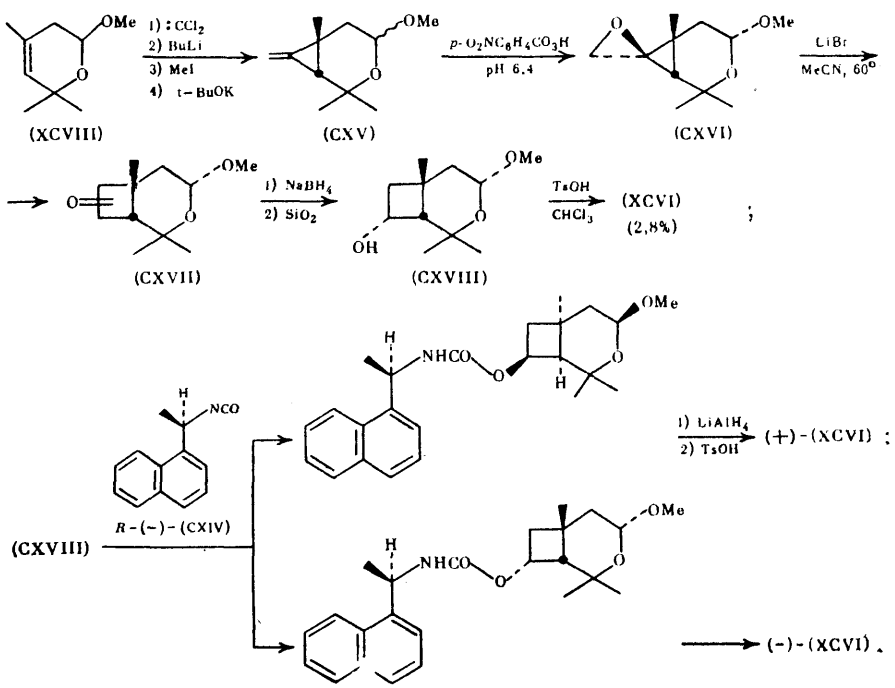
Scheme 16

In the first brief publication on the synthesis of compound (+)-(XCVI) three approaches, which must be regarded as extremely ineffective, are discussed at once. Nevertheless, they make it possible to establish unambiguously the structure of this pheromone[95] (Scheme 16). The cyclobutane fragment of the molecule of compound (XCVI) is then formed, as for compound (LV), by photocycloaddition. In one of the variants of the synthesis, when a mixture of the photoadducts (XCIV) of vinyl acetate and the lactone (LII) was employed, a mixture of the required compound (XCVI) and its regioisomer (XCVII), which can be separated chromatographically, was obtained via a stage involving the triols (XCV). In two other variants the transformation of the photoadducts of dichloroketen and the olefin (XCVIII) or the diene (C) led respectively to the acetals (XCIX) and (CI). The former was subsequently converted into compound (XCVI) by the reductive cleavage of the C–Cl bond, while the latter was converted by a multistage procedure, including the conversion into the vinyl ether (CII) and then into the diol (CIII). The latter was transformed in four stages into the required regioisomer of the triol (XCVa), whose oxidative cyclisation yielded the required compound (XCVI).

The approach involving the transformation of a 7:2 mixture of the photoadducts (CIV) of vinyl acetate and 3-methylcyclopent-2-enone [97] (Scheme 17) proved just as ineffective. Since it was found that the dominant regioisomer behaves as a ballast compound, the first four stages, including the chromatographic stage, reduced to the isolation of the required regioisomer in the form of the ketoacetal (CV). The latter is converted with the aid of a bulky reductant initially into the alcohol with the required *endo*-configuration and then into the ketoacetate (CVI) and the silyl ether (CVII). Its ozonolysis and treatment with acetic acid and then with diazomethane lead to the aldehyde (CVIII), which is transformed by three simple operations into the required compound (+)-(XCVI) in an overall yield of ~0.15%.

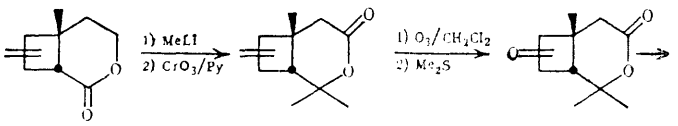


Scheme 17



The synthesis of compound (±)-(XCVI) from the photoadducts of vinyl acetate and 2,4,4-trimethylcyclopent-2-enone, which is a mixture of the ketoacetates (CIX) in proportions of 3:2 with the required regioisomer predominating (Scheme 18), is significantly more successful. [98] In the first stage involving the "displacement" of the C=O group, the ballast isomer (CIX) is eliminated as a result of the retroaldol cleavage of the intermediate β-ketol and the oxime (CX) is converted in two stages into the ketoalcohol (CXI). The latter is transformed by the Baeyer–Villiger reaction into the lactone (CXII), whose conversion into the individual *endo*-isomer of the hydroxylactol (CXIII) is achieved by oxidation with subsequent reduction of the intermediate ketolactone with a bulky reagent. The acid-catalysed cyclisation of compound (CXIII) completes the sequence of reactions.

The synthesis of compound (±)-(XCVI) presented in Scheme 19 is even more effective. [99] The starting compound is the olefin (CXV), obtained in four stages from the dihydropyran (XCVIII). The conversion of this olefin into the epoxide (CXVI) and its subsequent rearrangement lead stereospecifically to the *endo*-isomers of the ketones (CXVII), the ratio amounting to 4:1 with the required isomer predominating. The latter is isolated chromatographically in the form of the alcohol (CXVIII) after the reduction of the mixture and is then cyclised to the required compound (XCVI).



Scheme 18

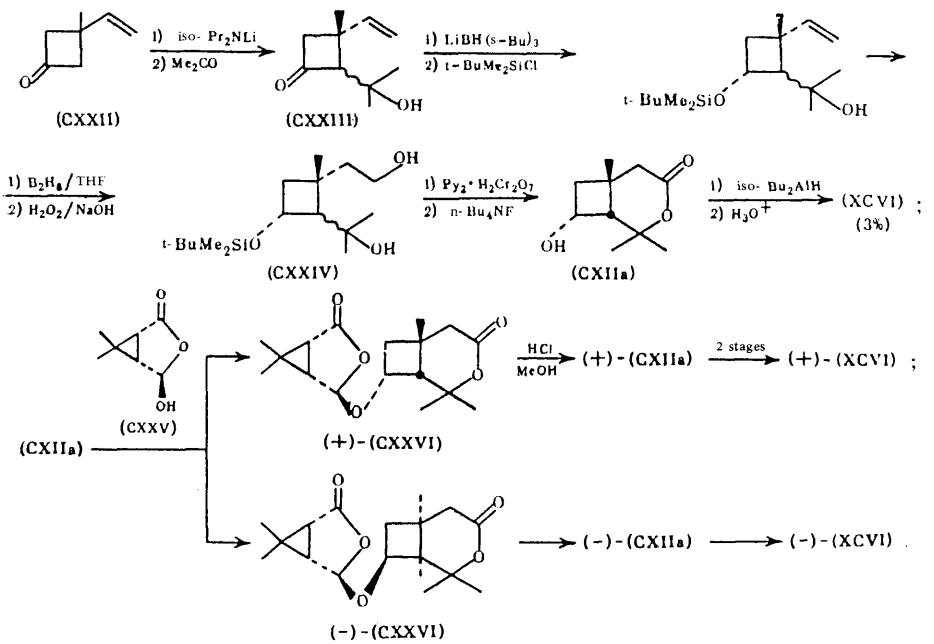
Scheme 19

The synthesis of the racemic compound (XCVI), based on the five-stage transformation of the photoadducts (CXIX) of an allene and the lactone (LII) (the mixture composition is 3:2 with the required isomer predominating) must be regarded as the most effective and shortest of the existing syntheses.[100] The conversion of the mixture of compounds (CXIX) into the olefins (CXX) and their subsequent ozonolysis afford the ketones (CXXI), which are converted, after reduction and cyclisation, into a ~2:1 mixture of the regioisomers (XCVI) and (XCVII). The required isomer (XCVI) is then isolated chromatographically in an overall yield of ~9%:

(CXIX) (CXX) 70% (CXXI) 69%

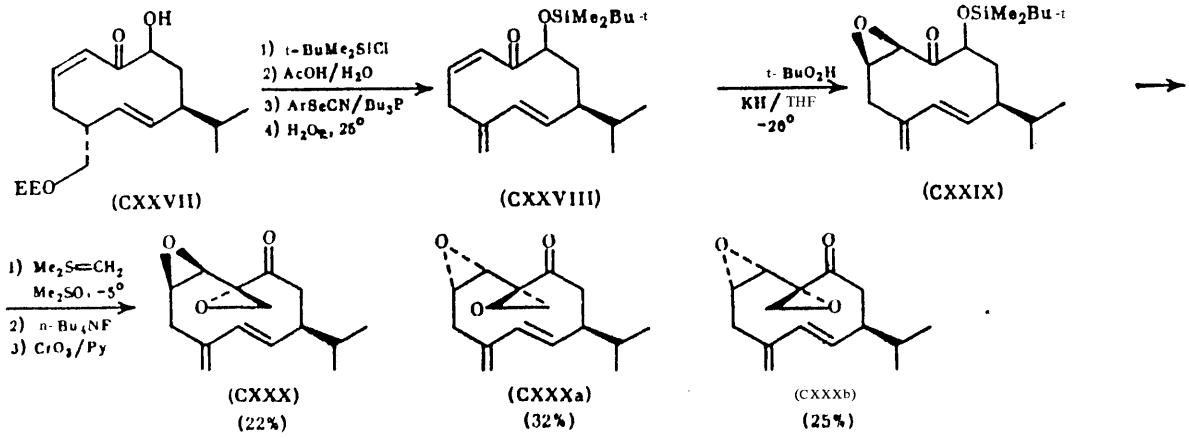
The method of synthesis of compounds (+)-(XCVI) via Scheme 20 [101] from the cyclic adducts of dichloroketen and isoprene, which are readily converted into the cyclobutanone (CXXII) in an overall yield of 39%, can also serve as a fairly effective preparative procedure. Condensation with acetone leads to the ketols (CXXIII), which are subjected to hydroboration, after reduction by a bulky reagent and protection of the secondary hydroxyl, with subsequent oxidation to the diols (CXXIV). The latter are transformed in two stages into the hydroxylactone (CXIIa), whose conversion into the required compound (XCVI) is analogous to that examined in Scheme 18.

The enantiomers of compound (XCVI) have been obtained by means of the chromatographic separation of the diastereoisomeric derivatives synthesised from the alcohol (CXI) and the *S*-(+)-isocyanate (CXIV) [98] (Scheme 18), from the alcohol (CXVIII) and compound *R*-(-)-(CXIV) [99] (Scheme 19), or from the alcohol (CXIIa) and the chiral hydroxylactone (CXXV), which can be obtained from *cis*-chrysanthemic acid[101] (Scheme 20). The subsequent regeneration of the optically active compounds (CXI), (CXVIII), or (CXIIa) and their transformation in the way described above lead to the enantiomers of compound (XCVI), among which the dextrorotary compound proved to be the natural product. X-Ray diffraction analysis of the diastereoisomers (CXXVI) made it possible to establish finally the absolute configurations of the pheromone and its optical isomer as 1*R*, 4*S*, 5*R*, 7*R* for (+)-(XCVI) and 1*S*, 4*R*, 5*S*, 7*S* for (-)-(XCVI).[101]



8. Periplanone B

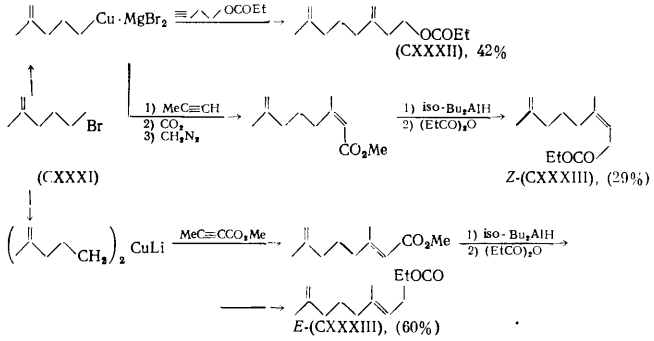
The identification of the SP of the female of the American cockroach *Periplaneta americana* is an extremely complex chemical problem which has been recently solved successfully. As early as 1963, a structure was proposed for this pheromone[102] but it was subsequently disproved[103] and it was not until 13 years later that the structure of periplanone B (CXXX), one of the two main components of the pheromone mixture, was finally elucidated. It is a sesquiterpenoid of the germacrane series.[104-106]



A very elegant, effective, and hitherto unique synthesis of this pheromone led to three of its four possible isomers and in addition made it possible to establish the relative configuration of periplanone B [107] (Scheme 21).

The norgermacrane ketodiol (CXXVII), containing the ethoxyethyl (EE) protecting group for one of its hydroxyls, was used as the starting compound. The silyl protection of the second hydroxyl and the liberation of the first with subsequent two-stage formation of the exo-methylene group

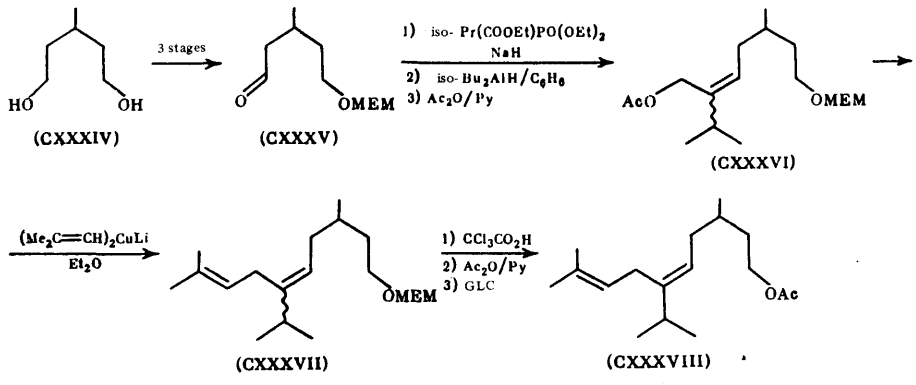
Scheme 20



Scheme 21

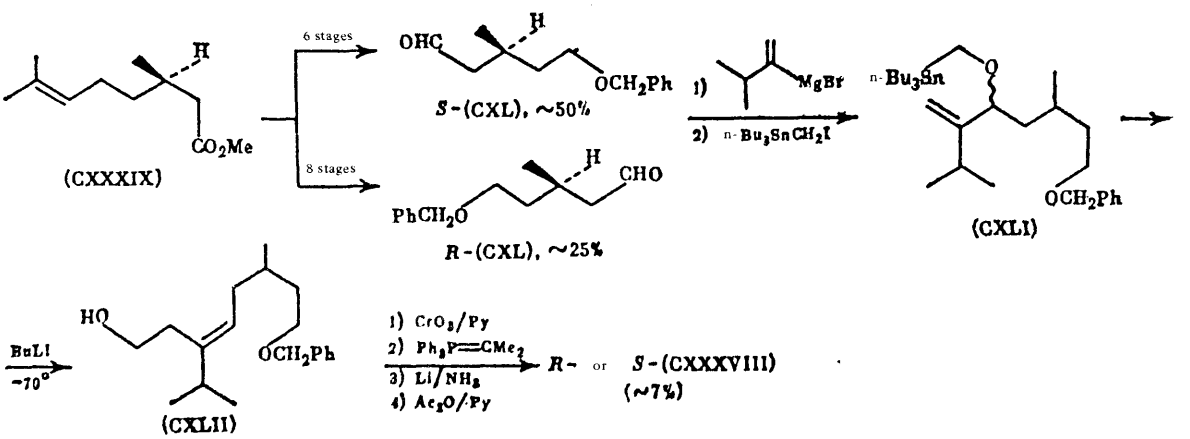
led smoothly to the triene (CXXVIII). Its selective epoxidation at the activated C=C bond yielded the epoxyketone (CXXIX). A second epoxide ring was introduced into this molecule by Corey's method. The subsequent removal of the silyl protecting group and oxidation of the resulting alcohol led to the required compound (CXXX), which exhibited a high biological activity and whose physicochemical properties were found to be identical with those of the natural specimen. The use of various methods for the introduction of the epoxide ring and a change in the sequence of the operations indicated made it possible to obtain in addition two products, (CXXXa) and (CXXXb), isomeric with periplanone B, which differ in the configurations of the two epoxide units.

Scheme 22



The SP of scale insects causing enormous damage, namely the yellow citrus scale insect *Aonidiella citrina* and the white plum scale insect *Pseudaulacaspic pentagona*, possess a more complex irregular sesquiterpene structure. The SP from the first of these insects, namely compound (CXXXVIII), has been obtained in an overall yield of 8% from the glycol (CXXXIV) in accordance with Scheme 23. This glycol was initially converted into the methoxyethoxymethyl (MEM) derivative of the aldehydoether (CXXXV). The conversion of the latter into the ethers (CXXXVI) and (CXXXVII) includes the Wittig–Horner addition of an olefin, which gives a mixture of isomers ($E/Z \cong 4:1$), and substitution of type $S_{N}2$ using lithium diisobutenyl cuprate. The required compound *E*-(CXXXVIII) was isolated in the last stage by means of preparative gas–liquid chromatography (GLC).[112]

9. The Pheromones of Scale Insects

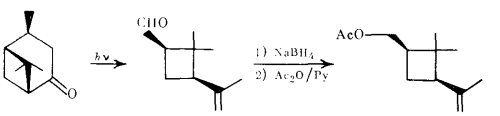


Much attention has been devoted recently to the study of the pheromones of certain scale insects. Thus, a widely distributed pest on various trees, including fruit trees, namely the San Jose scale insect *Quadraspidiotus perniciosus* produces a SP whose components are the propionates of α-myrcenol (CXXXII), α-nerol *Z*-(CXXXIII), and α-geraniol *E*-(CXXXIII).[108–110]

The key stage in the synthesis of each of the three components of this mixture is the addition of organocuprate derivatives of isohexenyl bromide (CXXXI) to substituted acetylenes (Scheme 22):[110,111]

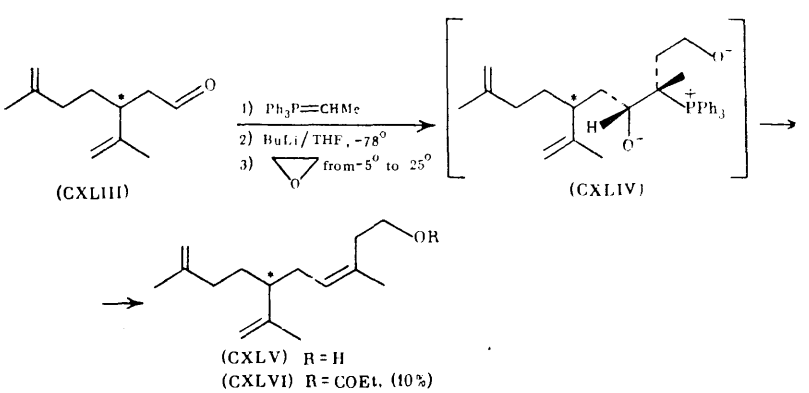
Scheme 23

Scheme 24

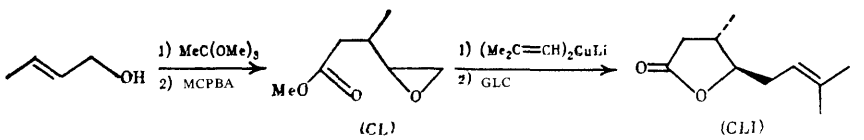


The chiral compounds (CXXXVIII), among which only the *S*-isomer proved to be biologically active, were synthesised (Scheme 24) from methyl *R*-(+)-citronellate (CXXIX) via the aldehydes *S*-(CXL) and *R*-(CXL). The conversion into the final compound (CXXXVIII) was achieved with the aid of the highly stereospecific 2,3-sigmatropic rearrangement of the stannanes (CXLI), leading to the *E*-isomers of compound (CXLII). The latter were converted into the (+)- and (-)-isomers of compound (CXXXVIII) in four fairly simple operations.[113]

Both enantiomers of the SP of the plum scale insect (CXLVI) were synthesised from the chiral aldehydes (CXLIII), which are readily available from the corresponding limonenes (Scheme 25).[114,115] The Corey–Yamamoto addition of an olefin to compound (CXLIII)[116] was first carried out using epoxyethane as the electrophile. The reaction apparently proceeds via the intermediate (CXLIV), giving rise to the trisubstituted homoallyl alcohols (CXLV) in a satisfactory yield and with exceptional stereospecificity (98% of the *Z*-isomer), the alcohol being subsequently converted into the required propionate (CXLVI). Comparison of the spectroscopic and biological properties of the synthetic and natural specimens showed that the latter has the 3*Z*, 6*R*-configuration.

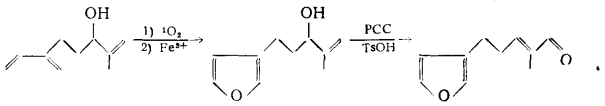


10. Other Sex Pheromones



The citrus mealybug *Planococcus citri* is a citrus pest. Both enantiomers of its SP (CXLIX) have been recently synthesised by the photochemical cleavage of the corresponding *cis*-verbanones (CXLVII) (the yield was not indicated); the aldehydes formed in this process, for example, compound (CXLVIII), were then converted in two stages into the required acetates, among which the (+)-isomer (CXLIX) proved to be biologically active:[117]

The monoterpene lactone (CLI) has been identified as the SP of the pyralid Eldana saccharina—a sugar cane and maize pest. The synthesis of this compound, described without experimental details,[118] was achieved starting with crotyl alcohol via the epoxyester (CL); the required *trans*-isomer (CLI) was obtained by the addition of lithium di-isobutenyl cuprate:



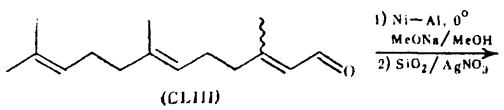
Scheme 25

(CL) (CLI)

Perillenal (CLII) is the SP of the pine sawfly *Neodiprion sertifer*, which causes significant damage to coniferous trees.[119] The pheromone (CLII) has been synthesised from the alcohol (XLVII), which can be obtained from myrcene (see above), by converting the 1,3-diene component of the molecule into a furan component and by oxidation with simultaneous allyl isomerisation of the alcoholic fragment:[67]

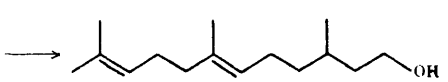
(XLVII) (CLII), 61% (CLII), 35%

It is noteworthy that compound (CLII) had been used earlier as an intermediate in the synthesis of perillene and dendrolasin (see Section IV, Scheme 32).



III. TRACK PHEROMONES AND TERRITORIAL MARKERS

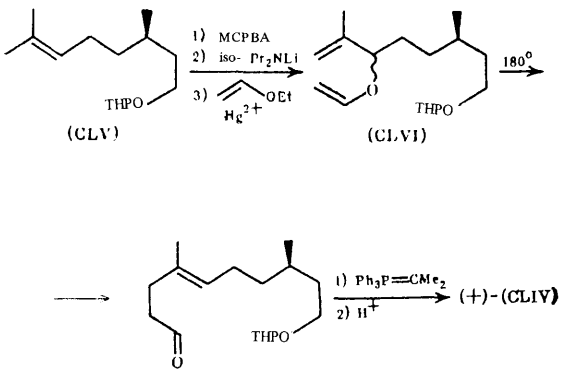
Social insects widely employ chemical signals which determine the direction of the movement of separate individuals to the living quarters, a source of food, etc. Among substances controlling such behavioural responses, various linear and cyclic derivatives of the sesquiterpene and diterpene series have been discovered.



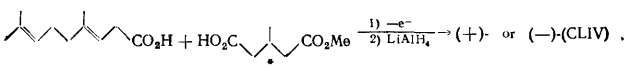
1. Terrestrol

S-(-)-2,3-Dihydrofarnesol (terrestrol) (CLIV) is produced by the males of the bumble bee *Bombus terrestris* and a number of other species of this family of insects[120–123] and is used by them as a marker on the route covered by their movements.

The simplest synthesis of compound (±)-(CLIV) consists in the reduction of *Z*/*E*-farnesal (CLIII) (readily available from dehydronerolidol) in the presence of the Ni–Al alloy and methanolic alkali:[124]



(CLIII)

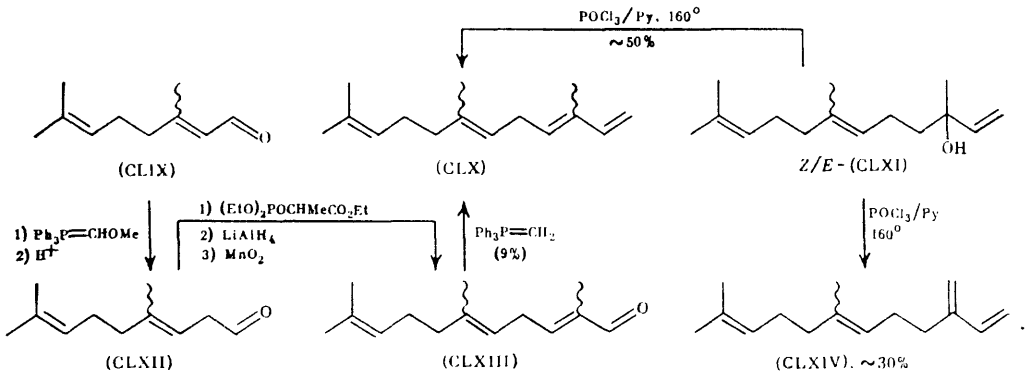


(CLIV), 61%

The synthesis of the optical isomers of compound (CLIV) has also been described. One of the syntheses is based on the ether (CLV) of *R*-(+)-citronellol, which is converted in the first three stages into a mixture of the diastereoisomers of the allyl vinyl ether (CLVI). Their subsequent Claisen rearrangement and combination with an olefin lead ultimately to *R*-(+)-(CLIV) in an overall yield of ~6%:[125]

(CLV) (CLVI)

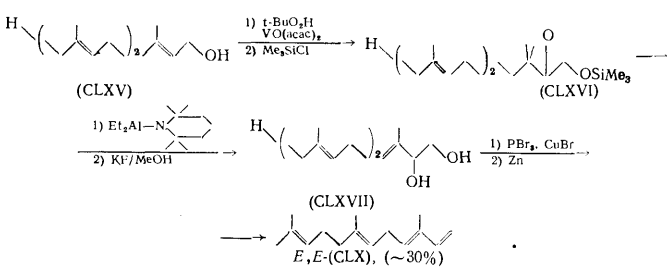
In the second case both optical isomers have been obtained using homogeranic acid (CLVII) with the half-ester of D- or L-3-methylglutaric acid (CLVIII) in the key stage involving the Kolbe coelectrolysis:[126]



(CLVII) (CLVIII) ~(8%)

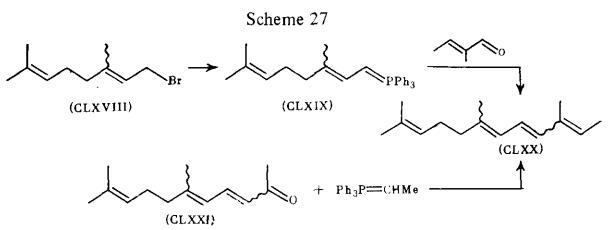
2. α-Farnesenes and Allofarnesenes

It has been shown recently that certain species of ants use various farnesene isomers, produced by the Dufur gland located in the rear part of the abdomen, as track pheromones and territorial markers. Thus *Z*,*E*-α-farnesene (CLX) has been detected in individual *Myrmica* species,[127] while the *E*,*E*-isomer of compound (CLX) [128] as well as *Z*,*Z*,*Z*-allofarnesene (CLXX) have been found in addition in the red ant *Solenopsis invicta*.[129,130]



Some of these sesquiterpenes had been isolated still earlier from other natural sources and their synthesis, also giving rise to a series of possible regioisomers and stereoisomers, including β-farnesenes (CLXIV), has been achieved on the basis of citral (CLIX) and nerolidols (CLXI) (Scheme 26). The conversion of compound (CLIX) into the *Z*,*E*- and *E*,*E*-tetraenes (CLX) under consideration involves threefold combination with an olefin and the intermediate formation of the aldehydes (CLXII) and (CLXIII),[131] while vigorous dehydration of compound (CLXI) yields immediately all the isomers of the farnesenes (CLX) and (CLXIV) mentioned above.[128]

Scheme 26

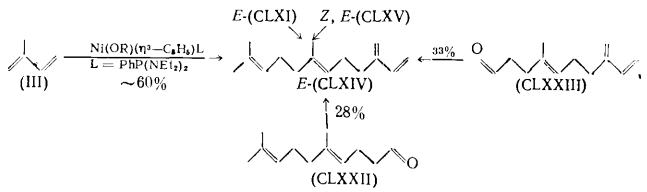


The low yields and the evident non-selectivity of the reactions considered above make it unlikely that the syntheses of α-farnesenes on the basis of the approaches described will be of much use.

The elegant synthesis of compound *E,E*-(CLX) from farnesol (CLXV), involving its selective epoxidation and rearrangement of the epoxide (CLXVI), is free from the above disadvantages. The diol (CLXVII) obtained in a high yield as a result was smoothly converted into the geometrically pure *E,E*-(CLX):[132]

Two approaches have been used (Scheme 27) in the syntheses of all the possible isomers of allofarnesene (CLXX), which made it possible to establish the configuration of the pheromone, which has the *Z,Z,Z*-geometry, as already mentioned.[130] The first synthesis involves the conversion of geranyl and neryl bromides (CLXVIII) into the corresponding phosphoranes (CLXIX) with subsequent addition of an olefinic group by these compounds to tiglic aldehyde, while the second synthesis involves an increase in the length of the isomeric pseudoionones (CLXXI) by a two-carbon fragment with the aid of ethylidenetriphenylphosphorane. It is difficult to estimate their effectiveness (the analysis has been carried out by GLC), but the simplicity of the chosen scheme is evident.

Scheme 27



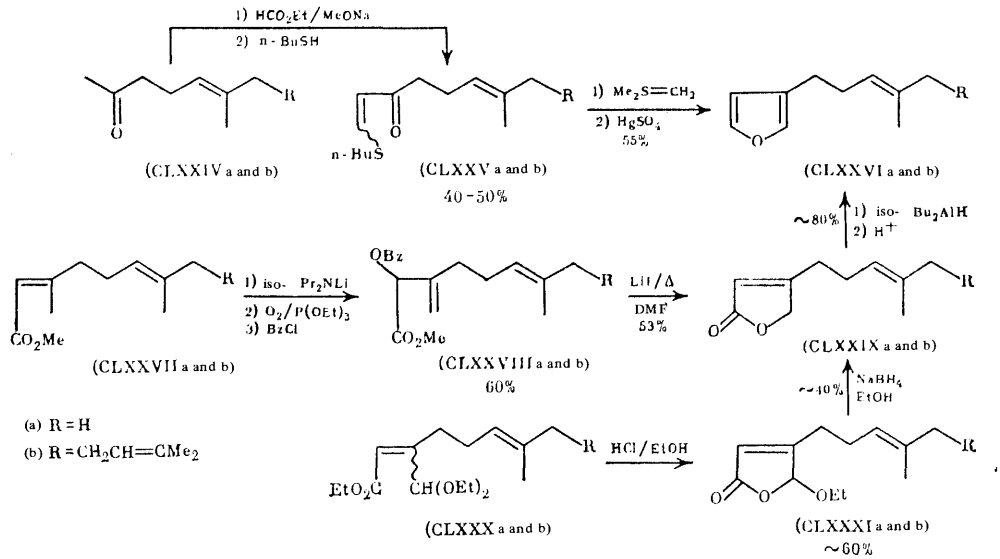
IV. FEAR PHEROMONES

Social insects widely employ chemical signals whose role reduces to warning of danger threatening members of the colony, which ultimately assists in the preservation of the species.

1. *E*-β-Farnesene

When attacked by a predator, many moth species instantly generate a mixture of substances with a protecting action and exhibiting simultaneously a repellant activity in relation to neighbouring members of the colony. The main component of this mixture is in many instances *E*-β-farnesene (CLXIV), which functions as a fear pheromone.[133–139] Special studies have shown that the *E*-geometry of the molecule of the given compound plays a decisive role in its function.[140,141]

The simplest pathway to compound *E*-(CLXIV) consists in the Ni(0)-catalysed trimerisation of isoprene.[142,143] Among other methods, mention should be made of the dehydration of nerolidol *E*-(CLXI)[128] and the six-stage transformation of farnesol *Z,E*-(CLXV),[132] which has been carried out in full conformity with the schemes for the synthesis of α-farnesenes discussed above. Finally, the synthesis of *E*-(CLXIV) from the relatively readily available C_{12}-aldehydes (CLXXII)[48,144] and (CLXXIII)[145] by standard procedures, involving the lengthening of the isoprenoid chain by a three-carbon fragment, has been described:

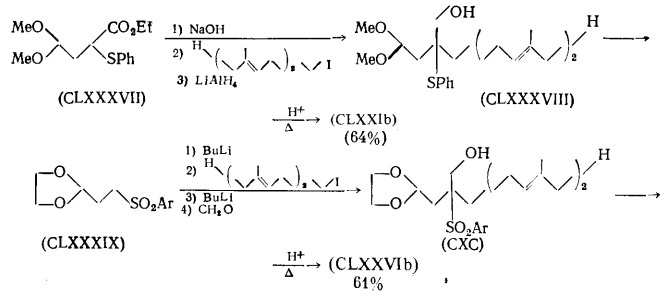


2. Perillene and Dendrolasin

Certain ant species produce perillene (CLXXVIa) and dendrolasin (CLXXVIb) as fear pheromones; these furanoterpenes can in addition fulfil protecting functions.[146,147]

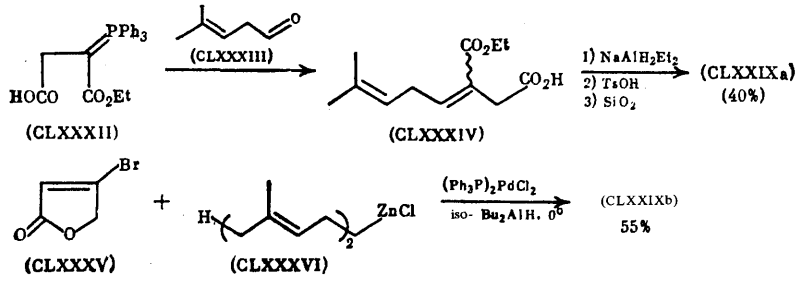
A whole series of syntheses of both pheromones have now been described. One group of syntheses is based on the construction of a 3-substituted furan ring, while those in another begin with furan derivatives already synthesised

Scheme 28



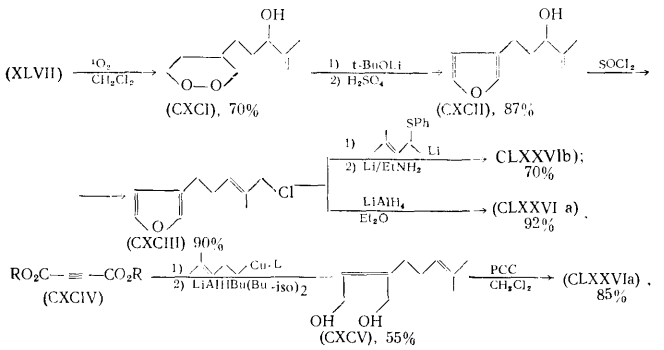
having a functional group at C(3). Thus formylation of methylheptanone (CLXXIVa) or geranylacetone (CLXXIVb) in accordance with Scheme 28 and the interaction of the corresponding thiovinyl ketones (CLXXV, a and b) with dimethylsulphonium methylide yield, after intramolecular cyclisation of the intermediate epoxides and the cleavage of the C–S bond, the required furanoterpenes (CLXXVI, a and b) in an overall yield of ~25%.[148] The conversion of the monoterpene esters (CLXXVIIa) and (CLXXXa) and the sesquiterpene esters (CLXXVIIb) and (CLXXXb) into the same products reduces to the formation of the corresponding furanones (CLXXIX, a and b) and includes the formation of the intermediate allyl benzoates (CLXXVIII, a and b) [149] or the hemiacetals (CLXXXI, a and b).[150] The conversion into the furans (CLXXVI) is carried out almost quantitatively by the acid treatment of the lactols arising on mild hydride reduction of the furanones (CLXXIX).

Other methods of synthesis of compound (CLXXVI) are presented in Scheme 29. According to one of them,[151] the aldehyde (CLXXXIII) is made to combine with an olefinic fragment by means of the phosphorane (CLXXXII), which is readily obtainable from maleic anhydride, to form the half-ester (CLXXXIV), which is transformed as a result of three simple operations into compound (CLXXIXa). In another method the condensation of the chlorozinc derivative (CLXXXVI) with the bromofuranone (CLXXXV), catalysed by a palladium complex, yields the required product (CLXXIXb) in a single stage.[152] Despite the evident effectiveness of both methods, the limited availability of the initial aldehyde (CLXXXIII) and the bromo-derivative (CLXXXV) must be emphasised.



An approach to the synthesis of dendrolasin (CLXXVIb) based on the sulphur-containing acetals (CLXXXVII) and (CLXXXIX) (Scheme 30) is of definite interest. Their deprotonation and subsequent alkylation by homogeranyl iodide followed by the reduction of the ester group or condensation with formaldehyde lead to the corresponding primary alcohols (CLXXXVIII) and (CXC) in high yields. These alcohols are readily converted into the required product (CLXXVIb) by refluxing with toluene-*p*-sulphonic acid in benzene.[153]

Scheme 30

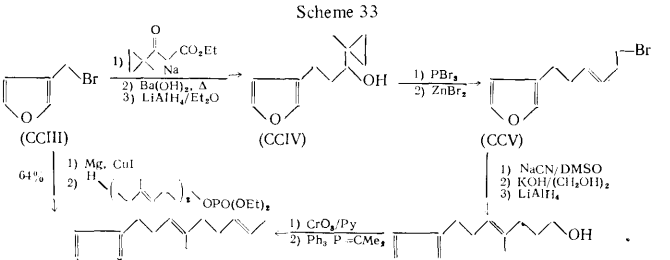


Among other methods for the formation of the hetero-aromatic ring of the pheromones (CLXXVI) based on linear precursors, mention must be made of those based on the photochemical oxidation of the 1,3-diene component of the alcohol (XLVII), which leads to the peroxide (CXCI),[66] and

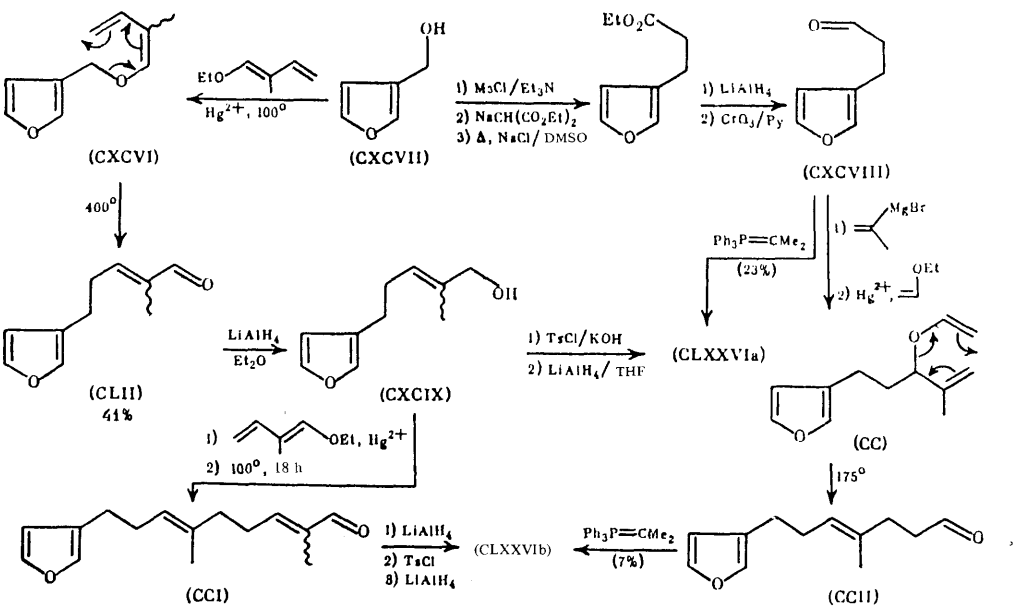
Scheme 29

on the synthesis of the glycol (CXCV) from acetylenedicarboxylic ester (CXCIV) [154] (Scheme 31). The isomerisation of compound (CXCI) on treatment with a strong base and dehydration of the intermediate lactol afford the furan carbinol (CXCII) which is then converted into the allyl chloride (CXCIII). Its hydrogenolysis or the addition of a C_5 unit to it lead ultimately to compound (CLXXVIa) or (CLXXVIb) respectively. Perillene (CLXXVIa) has been obtained almost quantitatively in a single stage by oxidising the glycol (CXCV) with PCC.

Scheme 31

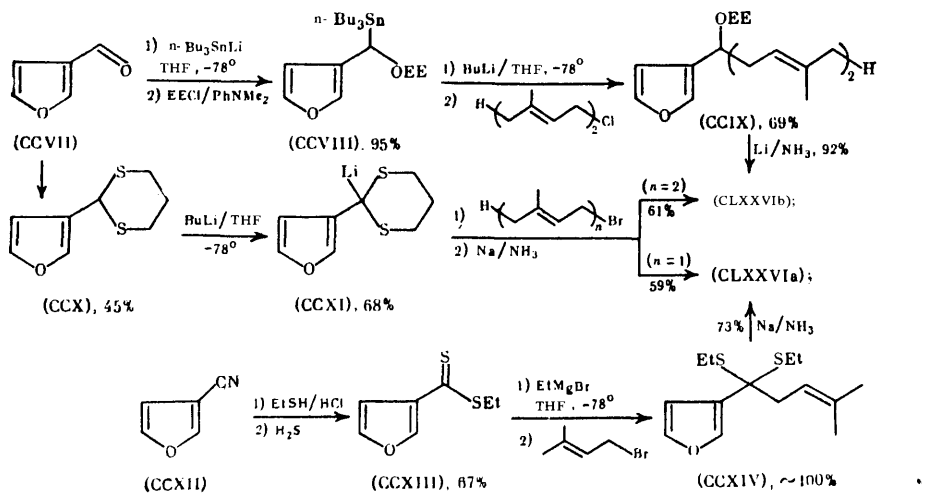


As already mentioned, the syntheses of compound (CLXXVI) in the second group begin with the furan C_5-synthones and reduce to the formation of the isoprenoid side chain. Scheme 32 illustrates one of the approaches using β-furylmethanol (CXCVII) with a Claisen type rearrangement as the key stage. Thus thermolysis of the vinyl ester (CXVI) gave a moderate yield of perillenal in the form of a mixture with $E/Z \cong 5:1$. Repetition of the above operations using the allyl alcohols (CXCIX) ($E/Z \cong 2:1$) led to the aldehyde (CCI) and both products, (CLII) and (CCI), were converted in accordance with the same scheme into the corresponding furanoterpenes (CLXXVI),[155] whose overall yields cannot be estimated. In another version[156] the alcohol (CXCVII) was converted into the aldehyde (CXCVIII) by increasing the length of the chain by a two-carbon fragment in a five-stage process. The aldehyde gave rise to the vinyl ether (CC) in two stages and thermolysis of the ether resulted in the formation of the aldehyde (CCII). The addition of an olefinic fragment to compounds (CXCVIII) and (CCII) by the Wittig method yields the required products (CLXXVIa) and (CLXXVIb) respectively.



One of the first syntheses of dendrolasin (Scheme 33) is based on the conversion of the bromo-derivative (CCIII) into the cyclopropylcarbinol (CCIV). Its homoallyl rearrangement proceeds stereospecifically, giving rise to the bromo-derivative (CCV). The increase of the side chain of the latter by one carbon atom with formation of the alcohol (CCVI) as well as the conversion of the latter into compound (CLXXVIb) were achieved by standard methods, but the yields of the products in the overall scheme were not indicated in the study under discussion.[157]

The single-stage pathway to compound (CLXXVIb), starting with the same bromo-derivative (CCIII) and consisting in the CuI-catalysed condensation of the latter in the form of a Grignard reagent with geranyl diethyl phosphate, appears to be more effective.[158] The allyl regioisomer is formed simultaneously in 17% yield and is separated chromatographically from compound (CLXXVIb).



Scheme 33

Scheme 32

Scheme 34

A large group of syntheses of the pheromones (CLXXVI) begin with β-formylfuran (CCVII) and β-cyanofuran (CCXII) (Scheme 34). Thus stannylation of compound (CCVII) gives rise to a carbinol, which has been isolated in the form of the ethoxyethyl ether (CCVIII). Its metallation and alkylation lead to the derivative (CCIX), whose hydrogenolysis gives rise to dendrolasin in an overall yield of 60%.[159] The syntheses of compounds (CLXXVI) by the alkylation of the lithio-derivative (CCXI), the dithioacetal (CCX),[160] and the related magnesio-derivative, formed *in situ* on interaction of the thioether (CCXIII) with an excess of ethylmagnesium bromide,[161] proved to be just as effective. The reductive cleavage of the intermediate dithioacetals of the type (CCXIV) has been achieved in both cases without complications on treatment with sodium in liquid ammonia.

In conclusion, it must be emphasised that the present review covers data on the synthesis of only monoterpene and sesquiterpene pheromones. The methods of synthesis of certain linear and macrocyclic diterpenoids, identified as pheromones in various insect species, have not been included.

The data examined thus illustrate the abundance of the synthetic procedures, both traditional and most modern, which are used to construct the molecules of a wide variety of isoprenoid pheromones. In the immediate future one may expect a further improvement of such procedures as a result of the elucidation of the structures of new compounds and also in view of the constantly growing need for the synthesis of low-molecular-weight bioregulators belonging to this important class.

---oOo---

During the preparation of the manuscript for the press, a number of publications concerning its individual sections have appeared. Thus the racemic ipsenol and ipsdienol have been obtained recently in high yields by the condensation of two C_5 fragments—of the silane (IX) with isovaleraldehyde and dimethylacrylic aldehyde respectively in the presence of Bu_4NF [162] or with the chlorides of isovaleric and dimethacrylic acids in the presence of $TiCl_4$.[163] The synthesis of the above pheromones as a result of the reaction of the bromo-derivative (IV), catalysed by the Zn/Ag couple, with the nitriles of the above acids is also effective.[164] The Kondakov acylation of isoprene by the chloride of dimethylacrylic acid using $EtAlCl_2$ as the catalyst affords, after the reduction of the intermediate ketone, ipsdienol in 12% yield.[165] Two extremely effective syntheses of compound (XXXII) from myrcene have also been published. In one case myrcene is epoxidised at the trisubstituted C=C bond with subsequent isomerisation of the epoxide on treatment with MeMgI,[166] while in the other case it is converted by a standard method[67] into amitinol, whose acetate isomerises on treatment with $HClO_4$.[167] Both enantiomers of compound (XXXII) were obtained in this process by the chiral reduction of ipsdienone, albeit in a low optical yield.[167]

The key stage in the six-stage syntheses of racemic derivatives of grandisol and lineatin has been the intramolecular cyclisation of 4-bromo-1-trimethylsilylbutyne[168] and 2,5,5-trimethylocta-1,6,7-trien-4-ol [169] respectively. The details of the synthesis of the racemic compound (XCVI) considered in Scheme 20 [101] and of both its enantiomers have been published recently.[170]

The pheromone (CXCIX) of the citrus mealybug has been synthesised non-stereospecifically by adding organocuprates to sulphonylbicyclobutanes.[171] On the other hand, two procedures for the preparation of eldanolide (CLI) from *S*-(+)-glutamic acid and the methyl ester of *R*-(+)-citronellic acid[173] respectively, which have made it possible to establish the 3*S*, 4*R*-configuration of the natural product, are characterised by a high enantioselectivity. Perillenal has been obtained by the allyl oxidation of perillene by SeO_2 in 42% yield.[174]

Farnesene *E*-(CLXIV) has been synthesised recently by the photolysis of 6*E*-farnesyl iodide in 80% yield;[175] the synthesis of this tetraene by the $ZnCl_2$-catalysed condensation of geranyl bromide *E*-(CLXVIII) with isoprenylstannane has been somewhat less successful.[176]

The key stage in the synthesis of perillene (yield not indicated) has been the radical cyclisation of a derivative of γ-dimethylallylpropargyl alcohol.[177] A further three approaches to β-prenylfurans (CLXXVI) from β-substituted furan C_5-synthones have also been published. Thus the reaction of the tosylate obtained from the alcohol (CXCVII) with lithium diprenyl cuprate[178] or of the bromo-derivative (CCIII) with a C_5 π-allylnickel complex[174] gives rise to perillene in 15% yield. On the other hand, a high yield of this compound as well as dendrolasin has been achieved by the Grignard reaction of the same bromo-derivative

(CCIII) with prenyl and geranyl diethyl phosphates respectively.[179]

Affinity Adsorbents Based on Carriers Activated by Epoxy-compounds

B.A.Klyashchitskii and P.V.Kuznetsov

The review is devoted to the synthesis and applications of affinity adsorbents based on carriers activated by epoxy-compounds. The methods for the introduction of epoxy-groups into carriers of different chemical types are discussed and conditions for the immobilisation of three-dimensional spacers and low-molecular-weight and polymeric ligands on carriers containing epoxy-groups are considered. Data are presented on the properties and applications of adsorbents of this type in affinity chromatography.
The bibliography includes 144 references.

I. INTRODUCTION

Extensive data have now accumulated on the synthesis and practical applications in affinity chromatography (AFC) of various types of adsorbents, which have been described systematically in a series of monographs[1-4] and reviews.[5-11] Reviews devoted to specific problems arising in the biospecific purification of individual classes and groups of biopolymers have appeared recently.[12-14]

The development of AFC would have been impossible without continual improvement of the chemical basis of this method, which includes the methods of synthesis and activation of solid carriers, the immobilisation of ligands, the analysis of affinity adsorbents, the study of their properties, etc. The chemical aspects of the AFC method have been the subject of discussion in the above monographs, individual reviews,[15,16] and conferences devoted to AFC.[17] A review of the synthesis and properties of adsorbents for covalent chromatography has been published.[18] It has apparently now become necessary to give a systematic account of specific chemical data on the methods of synthesis of affinity adsorbents of different types. The present review is devoted to the synthesis, properties, and applications of biospecific adsorbents of one of the most promising types, namely adsorbents based on epoxy-activated carriers (EAC).

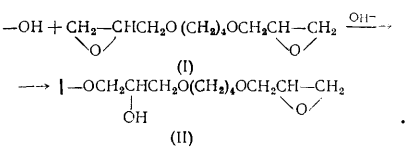
Data on the affinity adsorbents based on EAC have been described in the literature extremely sketchily and in a fragmentary fashion. Nevertheless the application of adsorbents of this kind is organically linked to an urgent problem in AFC—the synthesis of stable materials resistant to hydrolysis, exhibiting a high biospecificity, and capable of functioning for a long time under various conditions. The employment of the classical method of the bromocyanogen activation of polysaccharide carriers[19] does not allow the preparation of adsorbents with a bond between the matrix and the spacer† (ligand) which is highly resistant to hydrolysis.[10-20] Despite a number of successful studies[21-24] using the polymeric spacers in accordance with the principle of multipoint addition, the attention of investigators has been attracted with increasing frequency by adsorbents based on EAC, including Sepharoses.

Apart from a high resistance to hydrolysis, the EAC possess a number of other important advantages—they are fairly hydrophilic and virtually lack charged groups, which reduces to a minimum the non-specific interactions between the biopolymer isolated and the adsorbent. These adsorbents make it possible to immobilise not only ligands with a primary amino-group but also (without additional modification) ligands with other functional groups, for example hydroxy-, carboxy-, and thiol groups. When EAC are used, it is frequently not necessary to introduce additional spacers. It is also quite important that, in the epoxy-activation of agarose carriers, a cross-link is formed between the agarose chains themselves, which imparts additional rigidity to adsorbents of the type of Sepharose and increases the mechanical and chemical stability of the carrier.

The present review gives a systematic account of the principal literature data on the synthesis and applications of adsorbents based on EAC for the purpose of AFC and also for the immobilisation of enzymes.

II. METHODS FOR THE ACTIVATION OF SOLID CARRIERS BY EPOXY-COMPOUNDS

The activation of solid carriers by epoxy-compounds was first proposed in the laboratory of Porath,[25-28] who has made a major contribution to the development of the methods for the separation of biopolymers in general and of AFC in particular.[29]



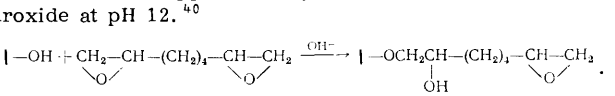
Sepharoses of various brands (2B, 4B, 6B, and CL), satisfying the majority of the requirements which must be met by carriers for the preparation of affinity adsorbents, are used most frequently in activation by epoxides and their derivatives. Celluloses, ultragel, Sephadexes, and other polysaccharide carriers are used more rarely. The employment of methacrylate, methacrylamide, and hydroxylalkyl methacrylate polymeric carriers,[30-33] as well as silica carriers[33,34] has been described.

†The term "spacer" used in the present review [the term "vstavka" or "insert" [10] was employed in the original Russian text (Ed.of Translation)] denotes a compound (or group of atoms) separating the ligand from the surface of the solid carrier. The terms "arms" and "leash" can also be encountered. Apart from "vstavka" mentioned above, the terms "prostranstvennaya gruppa" ("space group"), "speiser" (spacer), and "nozhka" (foot) are also used in the Russian scientific literature.

1. Activation of Polysaccharide Carriers

The methods for the activation of polysaccharide carriers by epoxy-compounds can be divided arbitrarily into two main groups: methods leading to the appearance of highly reactive terminal epoxy-groups on the surface of the carrier [the Sundberg–Porath method (1974) [27] and the method of Axen and co-workers (1975) [35]] and also methods making it possible to modify the surface of the carrier by various functional groups [Hjerten's method (1974) [36,37]].

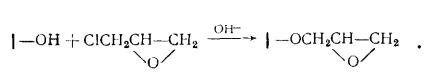
(a) *The Sundberg–Porath method.* The method is based on the reaction of bisoxirans of the type of diglycidyl ether of butane-1,4-diol (I) with Sepharose in a highly alkaline medium (0.4–0.6 M sodium hydroxide)#:



(I) (II)

The reaction time is 6–10 h and the temperature is 20 to 30 °C. The optimum concentration of the bisorixan (I) in the reaction mixture is approximately 30%.[27] The concentration of the epoxy-groups on adsorbent (II) was approximately 800 μmole per gram of the dry gel. According to the data of Sundberg and Porath, the stability of epoxy-activated gels is a maximum when they are stored in dimethyl sulphoxide at 4 °C or in 1 M sodium chloride at pH 6.8 and 4 °C. The epoxidation of CL-Sepharose by this method made it possible to employ the activated matrix for syntheses in non-aqueous media.[38]

The use of the bisoxiran (I) for the activation of cellulose has been recently reported.[39] The activation takes place in 0.6 M sodium hydroxide with added sodium tetrahydroborate (4 mg ml^{-1}) at approximately 20 °C for 18 h. The activity of epoxy-cellulose was fully retained for two weeks when it was stored in 0.1 M sodium hydroxide at 4 °C.

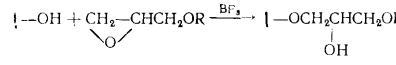


1,2:7,8-Diepoxyoctane (III) has also been used as the reagent for the activation of alginic acid. The epoxidation was carried out at approximately 20 °C for 3 h in 5 M sodium hydroxide at pH 12.[40]

(III)

The Sundberg–Porath method constitutes the basis of the synthesis of the commercial preparation "epoxy-activated Sepharose 6B" (EAS-6B) manufactured by Pharmacia Fine Chemicals (Sweden).

(b) *The Axen method.* This method of activation was first proposed to synthesise (via epoxy-derivatives) highly substituted thiol-containing gels for covalent chromatography.[35] The epoxidation of Sepharose by epichlorohydrin (1-chloro-2,3-epoxypropane) (IV) takes place fairly readily at 60 °C in the course of several hours in 1 M sodium hydroxide:



(IV) (V)

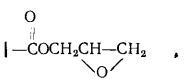
When 0.45 ml of compound (IV) was used for 3 g of the gel, the degree of substitution of approximately 600–700 μmoles of epoxy-groups per gram of dry gel (V) was attained. The optimisation of the epoxidation reaction conditions was subsequently investigated[41] and the following activation conditions were proposed: 30% of Sepharose, 5% of epichlorohydrin, and 0.4 M sodium hydroxide (2 h, 40 °C). It is of interest to note that the attempt to employ added organic solvents in the epoxidation reaction (25% solution of dimethyl sulphoxide or dioxan) did not increase appreciably the amount of epoxy-groups introduced. However, it was shown that in 25% dimethyl sulphoxide a degree of substitution of approximately 700 μmoles of epoxy-group per gram of the dry gel is attained after approximately 1 h, although the highest degree of substitution (800 μmole g^{-1}) is observed when the reaction is carried out in an aqueous medium for 2 h at 40 °C.

Other modifications of the method of Axen and co-workers have also been described. Thus Sepharose (IV) has been epoxidised with 0.48 M epichlorohydrin in 0.5 M sodium hydroxide at 30 °C in the course of 4 h.[42] According to other data,[43] the use of a solution of cetyltrimethylammonium bromide in the epoxidation reaction increased the quality of the gel and made it possible to reduce the activation time to 45 min at 45–50 °C. A method has been described recently[44] for the activation of Sepharose in 2 M sodium hydroxide with the gradual addition of epichlorohydrin to the reaction mixture over a period of 8–10 h at approximately 20 °C. The authors do not quote data for the degree of substitution of the gel by epoxy-groups, although the subsequent immobilisation of a number of enzymes (malate dehydrogenase, lactate dehydrogenase, and alkaline phosphatase) on the metal chelate carriers obtained was successful.

At the present time the method of Axen and co-workers is used to epoxidise Sepharose in order to obtain the commercial preparation "Thiopropylsepharose 6B" (Pharmacia Fine Chemicals). In addition activation of ultragel of type A4R with the aid of compound (IV) constitutes the basis of the preparation of commerical affinity adsorbents produced by the LKB Company (Sweden)—"acriflavin–A4R ultragel" and "heparin–A4R ultragel".

(c) *The Hjerten method.* This method was first developed by the authors in 1974 for the synthesis of neutral gels widely used in hydrophobic chromatography.[36,37] It is based on the reaction of Sepharose with a wide variety of epoxy-compounds in the presence of a catalyst—boron trifluoride:

A large number of hydrophobic adsorbents containing in their structure terminal alkyl and aryl groups, including those with alcoholic, carboxy-, methoxy-, cyano-, and other substituents, have been synthesised by this method.[45,46] The Sepharose gel:dioxan volume ratio in the reaction is 1:1; 1 ml of boron trifluoride etherate is used for 100 ml of the gel suspension. When 5 min have elapsed after mixing the reactants, the corresponding glycidyl ether is added and the reaction mixture is stirred for 40 min at 25 °C. The concentration of the ligands on adsorbents of this type was determined by NMR after acid hydrolysis. The capacity of the adsorbents with respect to the ligand reached 200 μmoles per gram of the dry gel.

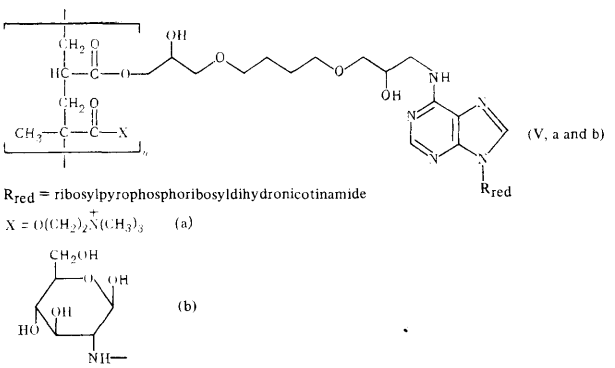


The method of Hjerten and co-workers is the basis of the preparation of the widely used stable hydrophobic commercial adsorbents "octyl-Sepharose CL-4B" and "phenyl-Sepharose CL-4B" (Pharmacia Fine Chemicals) whose capacity in relation

#Here and henceforth the bold line in the reaction schemes denotes the surface of the solid carrier.

to the binding of protein (serum albumin) reaches 15–20 mg per ml of the gel.

2. Synthetic Polymeric Carriers containing Epoxy-Groups

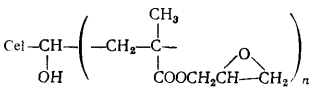


In the group of insoluble matrices obtained synthetically, glycidyl methacrylate gels (GMG), first synthesised by Czechoslovak investigators for the radical copolymerisation of ethylene methacrylate and glycidyl methacrylate, are of considerable interest.[32,33,47] The capacity of the carriers obtained with respect to the epoxy-groups was about 3.5 mmol g^{-1} and the epoxy-group was located on the surface of the carrier on a three-atom spacer:[47]

Turkova et al.[48] recently obtained hydroxyalkyl methacrylate gels (Separons H 300 and H 1000), activated by the epichlorohydrin, and, depending on the degree of activation, the content of the epoxy-groups was 140–1770 μmoles per gram of dry weight. It is of interest to note that the removal of the unreacted epoxy-group after the addition of the ligand, usually achieved by condensation with ethanolamine, was carried out by hydrolysis with 0.1 M perchloric acid.

Another example of EAC based on glycidyl methacrylate is provided by the "oxiran-acrylic carriers" manufactured by Pöhm Pharm (Federal Republic of Germany).[31] It is known that the second component in the copolymerisation reaction is allyl glycidyl ether, methacrylamide, or methylenebisacrylamide. The carriers obtained have a macroporous structure, contain a large number of epoxy-groups (800 to 1000 μmoles per gram of the dry carrier), their swellability does not vary over a wide pH range (from 1 to 10), they have a high mechanical and hydrolytic stability, and they are resistant to microbes. The successful application of the oxiran-acrylic carriers to the immobilisation of proteins and enzymes has been demonstrated.[31] For example, the amount of bound albumin reached 140 mg and that of trypsin was equivalent to 600 activity units per gram of dry carrier. This type of carrier is apparently promising for employment in AFC.

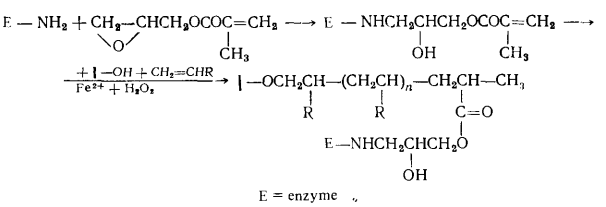
The synthesis of two water-soluble polymers on which NADH was subsequently immobilised, has been described.[30] The first was a copolymer of methacryloylcholine and 3-[4-(2,3-epoxypropoxy)butoxy]-2-hydroxypropyl acrylate. The immobilisation of NADH on this copolymer was achieved in three stages: alkylation of NAD at the N(1) atom, reduction of the nicotinamide component with dithionite, and Dimroth rearrangement involving the transfer of the alkyl bond from the N(1) atom to the exocyclic amino-group of the adenine component. The second polymer was a copolymer of the same epoxy-monomer and *N*-methacryloyl-2-glucosamine. NADH was added to this copolymer via the amino-group at the C(6) atom in a single stage. This resulted in the formation of the conjugates (V, a and b):



R_{red} = ribosylpyrophosphoribosyldihydronicotinamide

X = $O(CH_2)_2\overset{+}{N}(CH_3)_3$ (a)

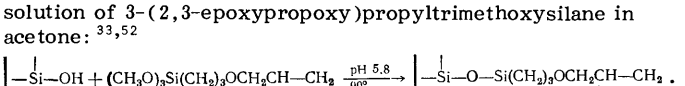
(b)



(V, a and b)

The copolymers of cellulose and poly(glycidyl methacrylate) having the following structure have also been obtained:

Cel = cellulose



They have also been used to prepare immunosorbents[49] and for the immobilisation of certain enzymes.[50] A new type of polymeric material, consisting of a hydrophilic polysaccharide component and a synthetic hydrophobic polymer, has been obtained by graft polymerisation.[51] Sepharose 4B and the Sephadexes G-10 and G-200 were used as the polysaccharide matrices. The copolymerisation process with immobilisation of enzymes (α-amylase, chymotrypsin, and others) can be represented schematically as follows:

E = enzyme

3. Activation of Silica Carriers by Epoxy-Compounds

The activation of carriers of this type has been inadequately investigated, although macroporous silica carriers are in fact important for the introduction of the AFC method into technological schemes for the purification of biopolymers. Porous glasses have been activated by treatment with a 5% solution of 3-(2,3-epoxypropoxy)propyltrimethoxysilane in acetone:[33,52]

A number of enzymes have been successfully immobilised on the carrier obtained and the capacity with respect to the protein was in the range 10–80 mg of the protein per gram of the carrier.[33] The same reagent in the form of a solution in toluene has been used to introduce the epoxy-groups into the silica carrier silochrome.[34] The activation of the "Fractosil-1000" (Merck) silica has been carried out analogously. The capacity of the resulting carrier with

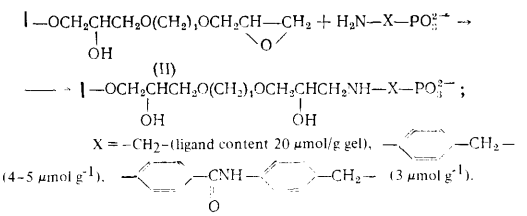
respect to the protein was 20–30 mg per gram of the carrier.[33]

III. IMMOBILISATION OF LIGANDS ON CARRIERS CONTAINING EPOXY-GROUPS

One of the significant advantages of the EAC based on Sepharose (EAS-6B) is the absence of a special stage involving the introduction of a spacer in the synthesis of the affinity adsorbent. Indeed EAS-6B, obtained by the Sundberg–Porath method, has a fairly long hydrophilic spacer which permits the immediate immobilisation of the ligand. This simplifies the syntheses of adsorbents with low-molecular-weight ligands to the maximum extent and in a number of instances results in a process consisting of only one stage.

On the other hand, the application of activated Sepharose, obtained by the method of Axen and co-workers (1,2-EPS), as a rule requires the introduction of an additional spacer. The ligand immobilisation reactions will be considered below in relation to the above types of epoxy-Sepharose.

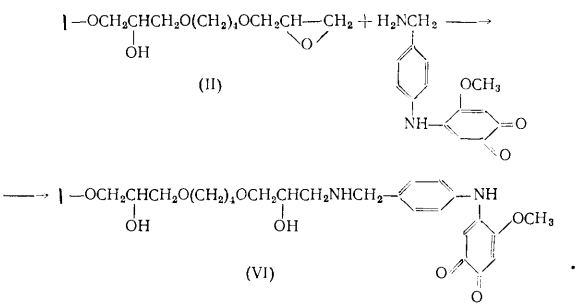
1. Adsorption of Low-Molecular-Weight Ligands or Spacers



(a) *Adsorbents based on EAS-6B.* As a rule the immobilisation of ligands containing amino-, hydroxy-, or mercapto-groups takes place readily at pH from 7 to 13 at a temperature of 20–45 °C in the course of 10–65 h. These general conclusions are illustrated by specific examples in Table 1.

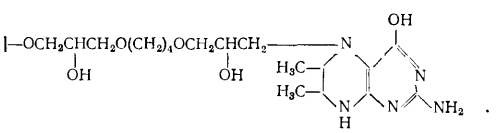
Table 1. Conditions for the immobilisation of low-molecular-weight ligands with amino-, hydroxy-, and mercapto-groups on EAS-6B.

Ligand	pH	Temperature, °C	Time, h	Refs.
		NH_2		
Trimethoprim analogue	9–10	—	16	[53]
Folic acid	10	30	16	[54]
8-Aminoxanthene	10–11	37	20	[55]
Acriflavin	11.5	20	8–10	[56]
S-Hexylglutathione	12	30	16	[57]
Galactosamine	13	30	20	[58]
		OH		
Ribose-5-phosphate	8.5	33	65	[59]
N-Acetylgalactosamine	11	40	16	[60]
Adenosine	11.2	37	24	[61]
Glycerylphosphorylcholine	13	45	20	[62]
		SH		
Reduced glutathione	7*	37	24	[63]



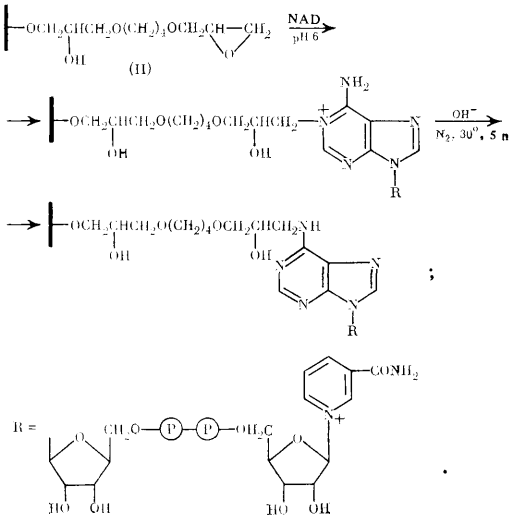
*The immobilisation was carried out in an atmosphere of nitrogen.

Under analogous conditions (0.1 M sodium hydroxide at pH 13), aminomethylphosphonic acid and derivatives of *p*-aminobenzylphosphonic acid were coupled to EAS-6B and the capacity of the adsorbent with the ligand containing the aliphatic amino-group proved to be approximately 4–5 times higher:[64]



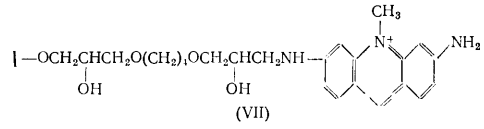
It is of interest that only adsorbents with an aromatic structure were capable of weak binding of alkaline phosphatase.

The use of amino-derivatives of 1,2-benzoquinone as ligands has been described.[65] The reaction was carried out at pH 10 in 0.07 M carbonate buffer solutions in a stream of nitrogen in the course of 5 h; the resulting capacity with respect to the ligand was entirely satisfactory—5.5 μmoles per ml of the packed volume of the gel:



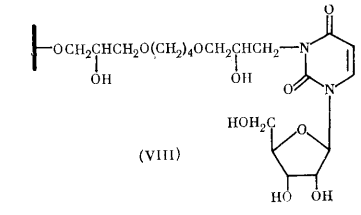
The adsorbent (VI) synthesised proved to be highly stable and was used for about a year for the isolation of menadione reductase.

A high capacity with respect to the ligand—approximately 280 μmoles per gram of gel—has been obtained following the immobilisation via the 5-position of the dimethyl derivative of 2-amino-4-hydroxytetrahydropteridine.[66] The reaction was carried out in deaerated 0.5 M sodium carbonate solution at pH 11.4:

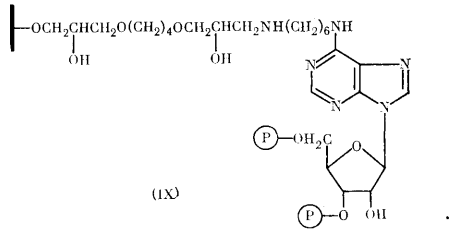


When the ligand contains carboxy-groups, it can be immobilised on the adsorbent as a result of the formation of ester linkages.[33,67] Ligand containing a phenolic hydroxyl also add effectively to EAS-6B in an acid medium. However, when the ligand contains both functional groups, the exact binding sites cannot be always established. Thus the exact structure of the adsorbents obtained from derivatives of auxin (5-hydroxyindolylacetic acid, 2-, 3-, and 4-hydroxyphenylacetic acids, etc.) and antiauxin (2-hydroxy-3,5-diiodobenzoic acid).[68] According to the authors, the adsorbents with indolylacetic acid as the ligand proved to be stable for only two weeks.

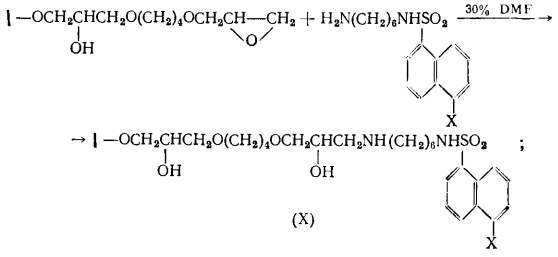
An NAD-containing adsorbent has been synthesised using the Dimroth rearrangement in one of the stages—transfer from the N(1) position in the purine ring to the exocyclic amino-group—for the AFC of dehydrogenases:[69]



Thus the fairly ready alkylation of purines at the N(1) position in interaction with EAS-6B in weakly acid media (pH 5–6) can be regarded as an established fact; the subsequent Dimroth rearrangement leads to the immobilisation of the ligand at the exocyclic amino-group of the adenine ring.

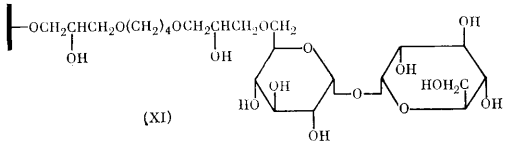


However, in a number of instances, particularly when the reaction is carried out in a strongly alkaline medium, the exact position in the polyfunctional ligand molecule at which the latter adds to EAS-6B is fairly difficult to determine. Thus, the adsorbent with adenosine immobilised on EAS-6B proved to be highly effective in the purification of deaminase.[61] The ligand was bound at pH 11.2 in 0.1 M sodium bicarbonate at 37 °C for 24 h and the authors believe that the ligand is most probably immobilised via the hydroxy-groups of ribose and not via the relatively unreactive amino-groups of adenine. Nevertheless, immobilisation via the exocyclic amino-group of the ligand is also apparently entirely feasible under these conditions—under similar conditions (Table 1) it has been possible to obtain the adsorbent with immobilised acriflavin (VII):[56]

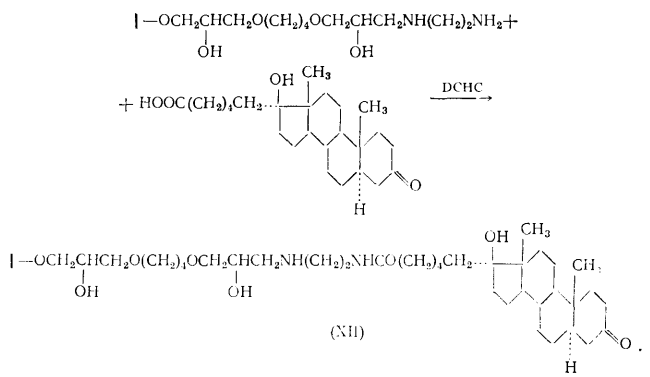


In similar cases, in the presence of several types of reactive groups in the ligand molecule, the proposed structures of the adsorbents probably cannot be regarded as finally established. Thus, Mitina et al.,[70,71] having established the covalent binding of uridine to EAS-6B at 37 °C in 0.1 M sodium hydroxide in the course of 16 h, describe only the postulated structure of the adsorbent (VIII) obtained:

More definite results were obtained after specific preliminary modification of the ligand molecule before immobilisation. For example, cAMP was initially converted into the C(8)-hydroxyethylthio-derivative, which was then readily coupled to EAS-6B at pH 11.[72] N(6)-ε-Amino-hexyl-3,5-ADP was analogously immobilised at pH 10 and 28 °C in the course of 20 h [73] and adsorbent (IX) was obtained:



Derivatives of 1-sulphonaphthalene, which are calmodulin antagonists, have been immobilised at pH 9.8 in 30% dimethylformamide in the course of approximately 16 h at 40 °C via the amino-group of the hexamethylenediamine spacer, which had been previously introduced into the ligand molecule.[74] The adsorbent (X) synthesised contained approximately 20 μmoles of the ligand per ml of the gel.

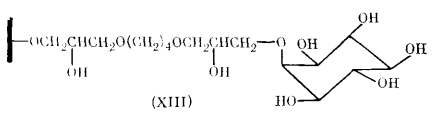


where X = H or Cl.

In connection with this synthesis, mention should be made of the organic solvent (dimethylformamide), which made it possible to obtain an adsorbent with a high capacity with respect to the ligand.

As stated above, carbohydrate ligands can be immobilised on EAS-6B without preliminary modification.[75,76] A detailed chemical study has been made[77] of the immobilisation of carbohydrates on EAS-6B. It was shown that the reaction proceeds mainly via the primary hydroxy-group and in the case of aminosugars it was found that the amino-group is six times more reactive in the reaction with the epoxy-group than the primary hydroxy-group. The preparation of a stable and effective adsorbent (XI) for the biospecific purification of proteins with a high affinity for non-reducing glucopyranosyl residues, by adding unprotected α,α'-trehalose to EAS-6B, has been described:[78]

The use of the short ethylenediamine spacer immobilised on EAS-6B for the subsequent coupling of the carrier to a carboxyl-containing steroid ligand by the carbodi-imide method has been described.[38] The adsorbent (XII) obtained was used for the isolation of steroid-binding serum proteins:



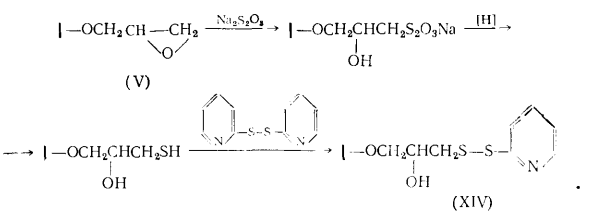
(XII)

An important feature of this synthesis was the use of CL-Sepharose, stable in non-aqueous media, because the ligand was immobilised in a 1 : 1 dioxan–dimethyl–formamide mixture with the aid of dicyclohexylcarbodi-imide (DCHC).

The use of EAS-6B for the synthesis of metal chelate adsorbents has been described.[79,80] The addition of the disodium salt of iminodiacetic acid has been achieved in 2 M sodium carbonate at 65 °C in the course of 24 h. The adsorbent obtained was used to purify nucleoside diphosphatase.[80]

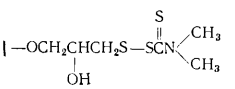
S-Hexylglutathione–epoxy-Sepharose, in which the ligand was immobilised via its amino-group (pH 12, 30 °C), proved to be an interesting adsorbent based on EAS-6B. The unreactive epoxy-groups were blocked by 1 M ethanolamine in the course of 16 h. Several enzymes (glutathione-*S*-aryl transferase[81] and glyoxalase[57]) were purified on this adsorbent and in the latter case the yield of the enzyme was higher than on the adsorbent obtained by activating Sepharose with bromocyanogen.

According to Fazideen and Breitenbach,[82] it was possible to use EAS-6B in the immobilisation of the ligand in an organic solvent (dimethyl sulphoxide), although only in the course of a limited period (1 h at approximately 20 °C). The adsorbent (XIII) obtained was used for the purification of myoinositol oxygenase.



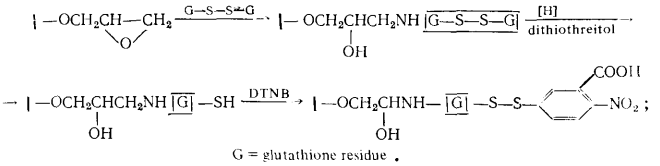
(XIII)

EAS-6B proved to be a convenient carrier for the immobilisation of *m*-aminophenylboronic acid.[83] The adsorbent synthesised bound effectively nucleotides, probably via the formation of a complex with the α-glycol group of ribose, and was investigated in this form by the authors with the aim of purifying several dehydrogenases.



The covalent coupling to EAS-6B of other low-molecular-weight ligands, such as carbohydrate derivatives (*N*-acetyl-*D*-glactosamine,[60] *N*-acetyl-β-*D*-glucosamine,[41] tri-*N*-acetylchitotrioses,[41] cyclohepta-amyloses,[84] and β-*L*-fucosylamine[85]), an aminoalcohol (choline),[86] etc.

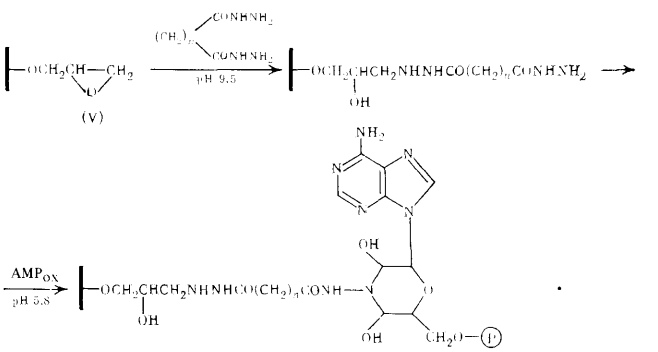
(b) *Adsorbents based on 1,2-EPS.* This type of epoxy-Sepharose[35] generally requires the introduction of an additional spacer in the immobilisation of the ligand. 1,2-EPS was first used to synthesise an adsorbent for covalent chromatography—"thiopropyl-Sepharose" (XIV),[35] which was obtained in accordance with the following scheme:



(XIV)

It is of interest to note that derivatives of di(2-pyridyl) disulphide with nitro- and carboxy-groups have also been investigated as ligands.[87] As expected, these derivatives of thiopropyl-Sepharose proved to be somewhat more active in thiol–disulphide exchange reactions and can be used in covalent chromatography together with the commerical adsorbent. The adsorbent (XV) with the dimethyldithiocarbamate residue as the ligand was obtained in the same study:

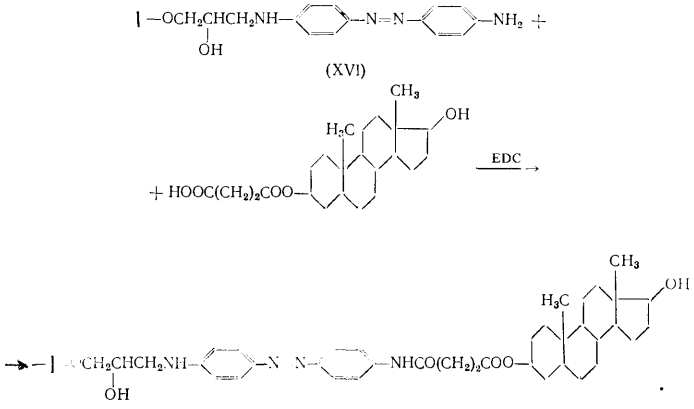
(XV)



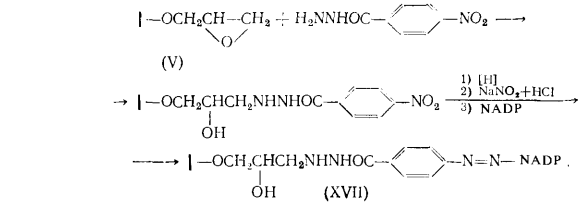
Epoxy-analogues of "activated thiol-Sepharose", the second commercially available adsorbent for covalent chromatography, have also been synthesised. Cystamine, cysteine, and glutathione residues were used as spacers and the ligand was the residue of 5,5′-dithiobis(2-nitrobenzoic) acid (DTNB).[43] The synthesis of the above adsorbents is indicated schematically below:

G = glutathione residue.

The use of adsorbents for the isolation and purification of SH-containing peptides and proteins has been examined in detail in a review.[18]



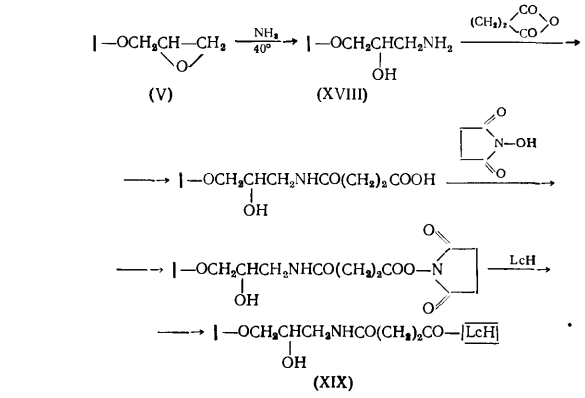
Using dicarboxylic acid hydrazides as spacers, a series of derivatives of hydrazidohydroxypropyl-Sepharose were obtained to which periodate-oxidised[88] nucleotides, for example, adenine and guanine nucleotides,[89] and NADP[43,90,91] were smoothly coupled. The dihydrazides are immobilised on 1,2-EPS at pH 9.5 at approximately 20 °C in the course of 10–16 h.[89] The subsequent addition of the oxidised nucleotides takes place via the ribose ring:



The hexamethylenediamine spacer was used for the immobilisation on 1,2-EPS of certain aminoacids[92] in the form of their *N*-hydroxysuccinimide esters. According to

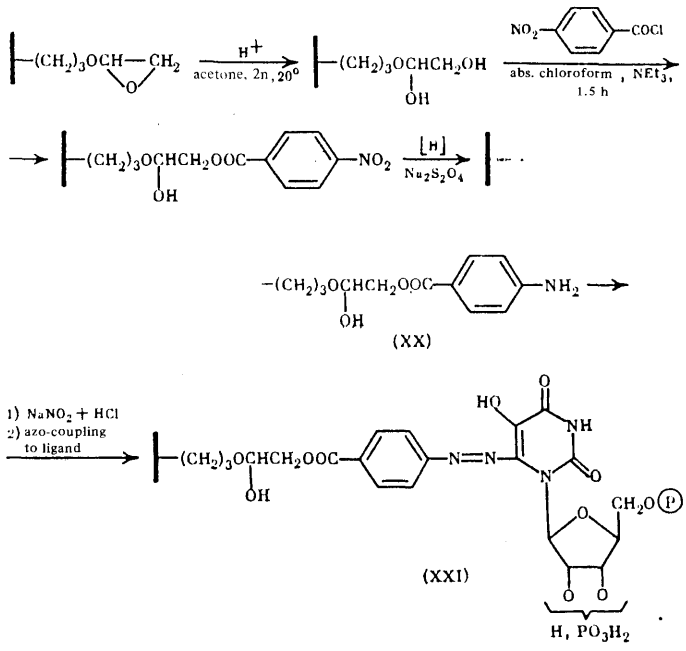
Streikuviene et al.,[93] nonyloxypropyl-Sepharose proved to be most effective for the purification of phospholipase *D*.

The use of 4,4'-azodianiline as a spacer,[94] which was coupled to 1,2-EPS in 50% dimethylformamide in the course of 2 h, is of interest. The resulting coloured product (XVI) was coupled to the succinylated derivative of androstanediol in the presence of 1-ethyl-3-(3-dimethylaminopropyl)-carbodiimide (EDC):



The syntheses of a series of adsorbents with an azo-linkage based on 1,2-EPS have been described. One of the examples of this kind is the preparation of NADP-azobenzo-hydrazidohydroxypropyl-Sepharose (XVII) in accordance with the following scheme:[95]

The spacer (*p*-nitrobenzohydrazide) immobilisation reaction on 1,2-EPS was carried out in aqueous dimethyl sulphoxide.



The amination of 1,2-EPS and EAS-6B has been achieved recently[96] in concentrated ammonia at 40 °C in the course of 2 h and amino-Sepharose (XVIII) and some of its derivatives were obtained for the first time. Thus, after the succinylation stage,[97] it was possible to obtain a highly stable affinity adsorbent (XIX) with hemagglutinin (LcH) as the ligand:

The amide and ester linkages in the adsorbent (XIX) proved stable at pH 9.8 (borate buffer solution). Nor are they ruptured when detergent solutions are used as eluents. Glucosamine-succinyloxypropyl-Sepharose has been obtained via an analogous scheme.[98]

The use of 3-amino-2-hydroxypropyl-Sepharose, obtained by the epoxidation of an agarose carrier with epichlorohydrin by means of a modified method[42] (25 °C, 4 h) followed by treatment with a 2 M ammonia solution for 16 h, for the immobilisation of a steroid ligand, namely 17β-hydroxy-3-oxo-5α-androstane-17α-(6-hexanoic acid) has been described.[99] The ligand was coupled to the amino-Sepharose in 70% aqueous dioxan in the presence of EDC.

(c) *Adsorbents based on silica carriers.* There have been no systematic studies of this group of EAC for the immobilisation of low-molecular-weight ligands. An investigation[34] of the immobilisation of 5-hydroxyuridine 2'(3'),5'-diphosphate on alusil in order to obtain an affinity adsorbent for the isolation of endonuclease A5 is of considerable interest. The azo-adsorbent based on epoxidised alusil was synthesised in accordance with the following scheme:

The content of amino-groups on the aminoaryl derivative (XX) was 133 μmol g^{-1} and the capacity of the azo-adsorbent (XXI) with respect to the nucleotide was 36.5 μmol g^{-1}. According to the authors' data, the adsorbent synthesised exhibited virtually no non-specific sorption and was extremely stable: after six isolation cycles, up to approximately 98.3% of the initial amount of ligand immobilised on the carrier remained. The possibility of employing in the syntheses of azo-adsorbents based on silicas of other spacers described [the *p*-nitrobenzohydrazide spacer[95] and spacers obtained on the basis of the hydrazides of *N*-(*p*-nitrobenzoyl)-ε-aminocaproic acid and *N*-(*p*-nitrobenzoyl)-glycylglycine] must be emphasised.[100]

2. Immobilisation of Polymeric Ligands

The immobilisation of polymers and biopolymers of different classes on EAC has not been studied in detail, although the necessity for such investigations is evident. The available literature data on this question are extremely scanty and scattered. EAS-6B has been usually employed for this purpose because of the presence in a carrier of this type of a long spacer, which ensures a fairly high reactivity of the carrier in reactions with biopolymers and the necessary steric accessibility of the immobilised ligand.

Lipopolysaccharides,[101,102] antibodies to human leukocytic interferon,[103] glycoproteins,[96] cellular material,[104] inhibitors of trypsin and trypsin-like enzymes,[27] polysaccharides,[76] and polynucleotides[105,106] have been covalently coupled to EAC as ligands. After the preliminary modification of its active centre with citraconic anhydride, ovomucoid was coupled to EAS-6B at pH 10 in the course of 16 h at 40 °C.[107] The percentage binding of the trypsin-like enzymes by this epoxy-adsorbent proved to be 92% compared with 30% for Sepharose activated with cyanogen bromide.

According to the data of Ustav et al.,[105] the periodate-oxidised t-RNA has been successfully immobilised on hydrazidoadipoyl-EAS-6B.

A simple and effective method of attaching DNA to epoxycellulose has been proposed.[39] The biopolymer was immobilised in 0.1 M sodium hydroxide at 20 °C in the course of 2 h. The DNA content in the resulting adsorbent was approximately 40 mg per ml of the gel. The adsorbent was distinguished by high stability with respect to organic solvents—ethanol, dimethylformamide, dioxan, toluene, etc., and also 2 M sodium chloride or 0.1 M sodium hydroxide in the course of 24 h at approximately 20 °C. The efficiency of the binding of polynucleotides varied in the sequence poly(dT) > poly(dC) = poly(dA) > poly(dG).

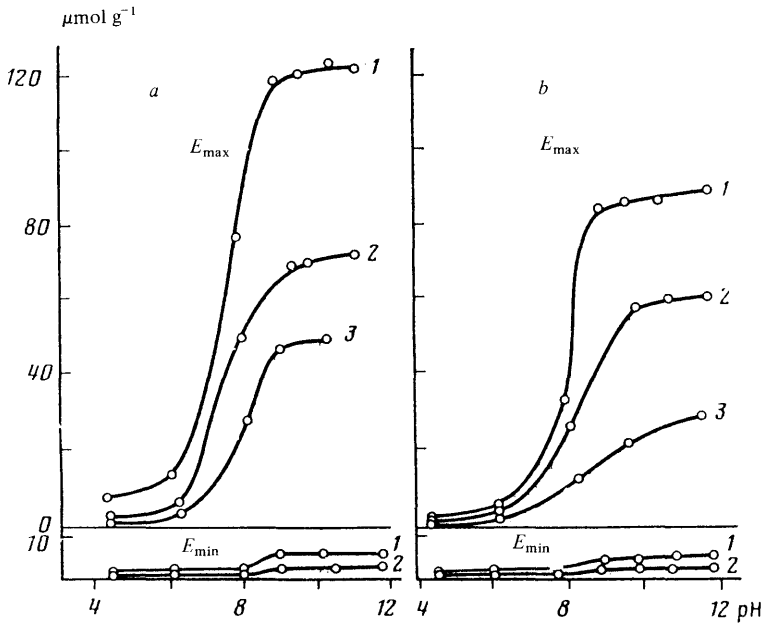
Studies of the conditions governing the immobilisation of peptides and proteins on EAC are of definite interest. Thus the optimum conditions for the attachment of glycyl-leucine to EAS-6B (pH 11, 50 °C in the course of 15 h) have been investigated.[27] The optimum binding conditions for the inhibitor of soya bean trypsin involve treatment in 0.5 M carbonate buffer solution at pH 9.5 and 25 °C for 24 h. The cell membrane proteins were immobilised on EAS-6B under similar conditions in the preparation of immunoadsorbents:[104] 0.05 M borate buffer solution at pH 9 in the course of 16 h at approximately 20 °C.

The data presented above suggest that biopolymers are immobilised on EAC under approximately the same conditions (alkaline medium, temperature 20–30 °C) as the coupling of low-molecular-weight ligands. The adsorbents obtained are as a rule highly stable.

A more detailed study of the processes involving the coupling of peptides and proteins to EAC, in particular GMG§, has been undertaken.[33,47] The author showed that a peptide of the type of glycyl-leucine is bound preferentially to GMG via the α-amino-group and the maximum degree of binding is observed after 72–96 h at 25–37 °C. The process proved to depend greatly on the pH with an optimum at pH 9.7. The capacity with respect to the ligand was approximately 20 μmol g^{-1}. The bond between the matrix and the ligand proved to be extremely strong: even acid hydrolysis under severe conditions led to the appearance of only trace amounts of glycine. On the other hand, the binding of the epoxy-groups of the carrier to the carboxy-groups of the ligand was independent of the pH. The ester linkage formed was hydrolysed in the usual way.

§Glycidyl methacrylate gel (Ed.of Translation).

In the immobilisation of serum albumin and trypsin on GMG, the maximum degree of binding of these proteins was found in an acid medium at pH 3, which suggested the important role of carboxy-groups in the coupling processes. The involvement of the lysine ε-amino-groups in the proteins investigated in the binding processes is manifested in the pH range 7–11. According to the authors, the immobilisation via the ε-amino-group is independent of the pH. The capacity with respect to the ligand of the adsorbents obtained at pH 8–11 was 3–4 times lower than for the adsorbents synthesised at acid pH. Apart from trypsin and albumin, it proved possible to immobilise also amino-glucosidase on GMG in an acid medium.[106] Subsequently it was shown that polymers with indole and phenol groups were effectively bound in an acid medium.[67] The optimum binding of indole-containing derivatives was observed at pH 3.85, the binding efficiency diminishing with increase of pH. Imidazole-containing derivatives had a binding optimum at pH 8.15.[33] For derivatives containing a primary amino-group, the binding optimum was detected at pH 9.55.

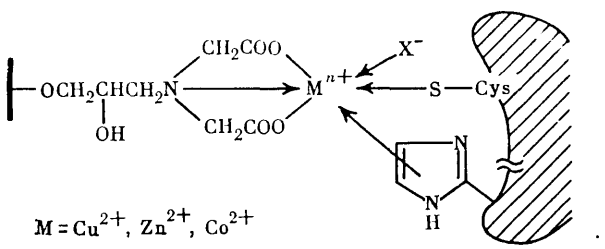


Data obtained in the study[33] of the influence of the nature of proteins on their immobilisation on EAC are of great interest. It was found that not only the binding conditions and the nature of the protein ligand but also the type of the polymer matrix are important in immobilisation. The results of these studies are presented in Table 2.

Table 2. Optimum pH for the immobilisation of certain proteins on various types of EAC.[33]

Immobilised protein*	Type of EAC**				
	porous glass	silica carrier	EAS-6B	GMG	Oxiranacrylic carrier
Serum albumin (4.9)	4 (45), 8.5 (20)	5 (50)	8 (300)	5 (20), 8 (10)	4—10 (50)
Papain (8.7)	8.5 (60)	8 (40)	9 (300)	7 (25)	—
Antilysin (10)	10 (80)	10 (20)	10 (300)	10 (15)	9.5 (100)
Trypsin (10.1)	8.5 (10)	3 (20)	11 (20)	3 (5)	10 (20)
Chymotrypsin	7—8 (50)	7—8 (20)	11 (40)	3 (10), 10 (5)	—

*The isoelectric point is indicated in brackets.
**The amount of immobilised protein in mg per gram of carrier is indicated in brackets.



It follows from Table 2 that EAS-6B shows the maximum capacity with respect to the ligand and that only for this matrix was the immobilisation pH always in an alkaline region (pH 8–11). Such non-selectivity with respect to the nature of the immobilised protein should apparently be attributed to the effect of the spacer, which has the maximum length for the given type of EAC—12 carbon and oxygen atoms. Similar results have been obtained also for the oxiran-acrylic carrier. On the other hand, GMG and the adsorbent based on silica are the most sensitive to the nature of the immobilised protein and their capacity with respect to the ligand is low—for GMG it is lowest among all the EAC investigated. For certain proteins a clear-cut relation is observed between the isoelectric point and the optimum pH for immobilisation (for example, in the case of antilysin and to a lesser extent papain and albumin). According to the authors, the results for antilysin can be explained by the absence from this protein of tryptophan which tends to bind in an acid medium.

Dependence of the attachment of glycyl-D-phenylalanine to Separon H 300 (*a*) and Separon H 1000 (*b*), activated with epichlorohydrin, on the pH and reaction time; E_{max} = carriers activated to the maximum extent (1550 μmol g^{-1} for Separon H 300; 1700 μmol g^{-1} for Separon H 1000); E_{min} = carriers activated to the minimum extent (240 μmol g^{-1} for Separon H 300; 140 μmol g^{-1} for Separon H 1000); *1*) 48 h; *2*) 24 h; *3*) 12 h.

An analogous investigation has been carried out on epichlorohydrin-activated hydroxyalkyl methacrylate gels.[48] A study was made of the coupling of various amino-derivatives as a function of the pH, the reaction time, the ligand concentration, the degree of epoxidation of the carrier, and the chemical structure of the ligand. The Figure illustrates the dependence of the coupling of glycyl-D-phenylalanine on various types of epoxy-activated Separons on the pH of the medium and the reaction time.[48]

The covalent immobilisation of albumin and NAD-pyrophoshorylase on EAS-6B took place at 4 °C in the course of 28 h.[109] A number of enzymes (peroxidase, α-amylase, α-chymotrypsin, and glucose isomerase) have been recently immobilised using graft-polymerisation.[51] The method of non-covalent immobilisation for certain enzymes containing imidazole and thio-groups on an epoxy-activated metal chelate carrier is of definite interest.[44] The authors proposed the following structure of the carrier–enzyme complex:

Alkaline phosphatase and malate and lactate dehydrogenases have been immobilised in this way.

IV. THE APPLICATION OF ADSORBENTS BASED ON CARRIERS ACTIVATED BY EPOXY-COMPOUNDS IN AFFINITY CHROMATOGRAPHY

One of the main advantages of EAC is the simplicity of the preparation of affinity of adsorbents on their basis, the process involving only one stage in many instances. The biospecific adsorbents synthesised are exceptionally stable and are hardly hydrolysed in an alkaline medium. Thus the adsorbent with cAMP, immobilised on EAS-6B via the alcoholic hydroxyl, lost only approximately 0.04% of the ligand after storage in borate buffer solution for six months at 4 °C.[72] Immunoadsorbents based on EAS-6B lost the radioactive ligand to the extent of only 0.04–0.02%, while the percentage loss of radioactivity for the analogue based on Sepharose activated with bromocyanogen was 0.6–1.1% under the same conditions.[103] The complete absence of the scission of the coenzyme during the storage of NAD-containing epoxy-adsorbents compared with the bromocyano- and azo-derivatives has been demonstrated.[69]

A second important advantage of the adsorbents based on EAC is their high biospecificity owing to the hydrophilic nature of the spacer and the absence of additional ionogenic groups. As a consequence of this there is a possibility of employing adsorbents of this kind at earlier stages in the isolation and purification of biopolymers. For example, the direct use of thyroxine-epoxy-Sepharose[110] for the AFC of the serum in the early stages of the purification proved successful in the isolation of thyroxin-binding globulin. A 1000-fold purification of the test protein with a yield of about 70% was achieved. A fairly high degree of purification in the AFC stage (by a factor of 600) was retained also after the preliminary chromatography of the serum on hydroxyapatite.

Epoxy-activated Separon 1000 with the methyl ester of L-phenylalanyl-D-phenylalanine attached as the ligand has been used for the AFC of pepsin and proteinases from *Aspergillus oryzae*.[48] The high mechanical stability of the adsorbent made it possible to carry out the analytical AFC of pepsin under high pressure.

8-Aminoxanthine-epoxy-Sepharose showed a high selectivity in the single-stage isolation of the enzyme urate oxidase.[55] The degree of purification was by a factor of 88, the yield of the enzyme reached 93%, and the eluent was a 5 mM solution of uric acid.

The maximum degree of purification of cholinephosphate cytidylyltransferase on an EAS-6B-based adsorbent was by a factor of approximately 250 in the AFC stage with an overall yield of 59%.[62] A similar degree of purification (by a factor of 200) has been observed in the isolation of glutathione reductase on NADP-hydrazidoadipoylhydroxypropyl-Sepharose.[111] It is important to note that the adsorbent employed in the above study proved to be highly selective with respect to glutathione reductase (the arsenic-resistant fraction) and hardly bound the thiol-disulphide enzymes of the arsenic-sensitive fraction. An effective express method has been developed with the aid of this adsorbent for the preparation of almost homogeneous glutathione reductase.[111] It is remarkable that in both cases the AFC was carried out directly with the supernatant isolated after fractionation with ammonium sulphate. A simple and rapid three-stage method for the purification of α-amylase from triticale included in the last stage AFC on cyclohepta-amylose-epoxy-Sepharose.[84] It resulted in a final purification of the enzyme by a factor of 143 with an overall yield of about 33%.

In a number of studies the AFC on epoxy-sorbents was used in the concluding stages of the purification. Thus the application of pteridine-epoxy-Sepharose in the last (fifth) stage of the isolation of phenylalanine hydroxylase from rat liver permitted a degree of purification of the enzyme in the AFC stage by a factor of about 30.[66] The overall degree of purification was by a factor of 510 and the yield was 98%. The final phenylalanine hydroxylase preparation contained an admixture with catalase activity. AFC on *S*-hexylglutathione-epoxy-Sepharose was used in one of the stages of the purification of glyoxalase[57] and chromatography on this adsorbent led to an enzyme with a higher specific activity than purification on the adsorbent based on the bromocyanogen-activated Sepharose.

The use of metal chelate adsorbents based on epoxy-Sepharose has been described.[80,112-114] The purification of nucleoside diphosphatase by a factor of 194 and with a yield of about 16% has been achieved on these adsorbents.[80] The eluent was a 15 mM solution of L-histidine in 10 mM maleate buffer solution.

It is known that adsorbents based on EAC are widely used also in hydrophobic chromatography. Studies of the relation between the chemical structure of the adsorbents and the characteristics of the adsorption of various proteins are of definite interest. Studies[45,46] of blood proteins established the following general features. Adsorbents with lengths of the alkyl chain ranging from C_1 to C_5 gave rise to a relatively low degree of adsorption of blood proteins, while an increase in the hydrophilicity and polarity of the ligand by the introduction of hydroxy-, methoxy-, or cyano-groups greatly reduced the degree of adsorption. The maximum decrease was observed after the introduction of the cyano-group. On the other hand, the presence of a positive charge in the ligand molecule (a quaternary ammonium group) increased the degrees of adsorption of all the proteins investigated. It must be emphasised that the optimum lengths of the hydrocarbon chain in the ligand are different for different proteins. Fibrinogen, thrombin, and globulin have a binding optimum on the ligand with a C_7 chain, while for albumin and immunoglobulin G the adsorption optimum is on the ligand with a C_8 chain. The presence of branches in the ligand decreases the degree of adsorption.

The isolation of prephenate dehydratase has been achieved using adsorbents with a hexamethylenediamine spacer and certain aminoacids as ligands.[92] *N*-Acetylated derivatives of these adsorbents lost their capacity to bind the enzyme. At the same time the enzyme could be desorbed only from the aminohexyl and glycylaminohexyl analogues of 1,2-EPS (in 0.5 M sodium chloride or 140 mM hexamethylenediamine).

A study[115] undertaken to screen the affinity adsorbents for the isolation of inorganic pyrophosphatase[115] showed that hexylepoxy-Sepharose with a high ligand concentration (40 μmol ml^{-1}) strongly bound the enzyme with a complete retention of its pyrophosphatase activity. The protein could not be eluted (1 M sodium chloride, substrate). On the other hand, the bromocyanogen analogues of the adsorbent (admittedly with a ligand concentration lower by a factor of 4–7) bound the enzyme much less strongly. It was readily eluted from these adsorbents with 0.05–0.1 M sodium chloride solution.

A number of studies have been published recently concerning the use of commerical Octyl-Sepharose and phenyl-Sepharose for the hydrophobic chromatography of many biopolymers, for example, choline acetyltransferase,[116] specific endonucleases,[117] alkaline phosphatase, and 5'-AMP nucleosidase,[118] and restriction endonuclease REcoCK,[119] and also for the separation of the phospholipid and protein components of complex III of the respiratory chain of mitochondria,[120] for the immobilisation of trypsin with preliminary modification of the enzyme,[121] for the isolation of microsomal cytochrome P-450,[122] for the investigation of cobalamin-binding proteins,[123] for the purification of calmodulin,[124] etc.

It has been noted that in certain cases where adsorbents based on Sepharose activated with cyanogen bromide are used the ligand undergoes appreciable bioinactivation, while the analogous epoxy-adsorbent retains a satisfactory affinity for the biopolymer isolated.[107] Thus in the AFC of a trypsin-like enzyme the highest percentage binding was achieved for the adsorbent based on EAS-6B (92%).

Thiopropyl-Sepharose is one of the adsorbents widely used in covalent chromatography.[35] The spectrum of its applications is fairly wide, encompassing the isolation of thiol-containing proteins,[125,126] thiol-containing peptides,[127] and mercurated polynucleotides.[128] The possibility of separating two similar thiol-disulphide oxidoreductases, protein disulphide isomerase, and glutathione-insulin transhydrogenase by covalent chromatography on thiopropyl-Sepharose has been demonstrated.[129] The supernatant was subjected to preliminary purification by fractionation with ammonium sulphate, gel-filtration on Sephadex G-200, and ion-exchange chromatography. The eluents for covalent chromatography were thiols with an increasing reducing capacity—20 mM L-cysteine, 50 mM reduced glutathione, and 20 mM dithiothreitol. The employment of thiopropyl-Sepharose made it possible[130] to separate highly reactive thiols, for example, cysteine proteinase from *Actinidia chinensis*, from the remaining thiol-containing components. The application of reduced thiopropyl-Sepharose in the purification of cytoplasmic aldehyde dehydrogenase involving the removal of an admixture of mitochondrial proteins has been described.[131] The same adsorbent modified with 2-hydroxy-5-nitrobenzyl bromide was used for the immobilisation of α-chymotrypsin

and β-amylase.[132] The problems of the application of covalent adsorbents are specifically considered in a review.[18]

The principal studies dealing with the applications of adsorbents based on EAC in AFC are listed in Table 3.

Table 3. The application of adsorbents based on EAC for the isolation and purification of biopolymers.

Ligand (spacer)	Biopolymer isolated source)	Refs.
	EAS-6B	
Inhibitor of osya bean trypsin	Trypsin (commercial preparation)	[27]
Ovomucoid	Trypsin-like enzyme (from *Streptomyces erethreus*)	[107]
Myoinositol	Myoinositol oxygenase (from rat kidneys) myoinositol kinase (from *Lemna gibba*)	[82]
Adenosine 3′,5′-diphosphate (hexamethylenediamine)	Succinate thiokinase (from pig heart)	[73]
Choline	Choline and enthanolamine kinases (from rat liver)	[86]
8-Hydroxyethyl-cAMP	Regulatory subunit of protein kinase	[72]
S-Hexylglutathione	Glutathione S-transferase (from human placenta)	[81]
Reduced glutathione	Glutathione S-transferase (from human liver)	[63]
Glycerylphosphoryl choline	Cholinephosphate cytidylyltransferase (from rat liver)	[62]
Ribose-5-phosphate, neopyrithiamine, thiamine pyrophosphate, hydroxythiamine	Transketolase (from *Candida utilis* and baker's yeast)	[59]
Adenosine	Adenosine deaminase (from human erythrocytes)	[61]
S-Hexylglutathione	Glyoxalase I (from rabbit liver)	[57]
2-Amino-4-hydroxy-6,7-dimethyl-5,6,7,8-tetrahydropteridine	Phenylalanine hydroxylase (from rat liver)	[66]
Trimethoprim and its analogues	Dihydrofolate reductase (from *E.coli*)	[53]
Aminomethyl-4-anilino-5-methoxy-1,2-benzoquinone	Menadione reductase (from rat liver)	[65]
8-Aminoxanthene	Urate oxidases (from ox liver, rat liver, and yeast)	[55]
Folic acid	Ribonuclease A (from ox pancreas)	[54]
Ditto	Endonucleases EcoRI (from *E.coli*) and BglII (from *Bacillus globiggii*)	[117]
NAD^+ or NADH	Alcohol and lactate dehydrogenases	[69]
3-Aminophenylboronic acid + nucleotides and coenzymes	Dehydrogenases	[83]
Cyclohepta-amylose	α-Amylase (from a hybrid of wheat and full flax)	[84]
Aminomethyl-, 4-aminobenzyl-, and *N*-(4-aminobenzyl)-4-aminobenzyl-phosphonic acids	Alkaline phosphatase (from ox small intestine)	[64]
Arabinan	α-L-arabinofuranosidase (from *Aspergillus niger*)	[76]
Iminodiacetic acid + Cu^{2+}	Nucleoside diphosphatase (from rat liver)	[80]
Ditto	Lactoferrin (from human milk)	[112]
Iminodiacetic acid + Zn^{2+}	Alpha$_2$-SH-glycoprotein (from human plasma)	[113]
D-Galactosamine	β-Galactosyl-binding lectin (tridacnin) from *Tridacna maxima*)	[58]
Trehalose	Concanavalin A (from *Canavalia ensiformis*)	[78]
N-Acetyl-D-galactosamine, *N*-acetyl-D-glucosamine	Lectins (from soya beans and wheat seedlings)	[60]
Tri-N-acetylchitotriose, methyl *N*-acetyl-β-D-glucosaminide	Agglutinin (from *Solanum tuberosum*)	[41]
17β-Hydroxy-3-oxo-5α-androstane-17β-(6-hexanoic acid) (diaminoethyl)	Steroid-binding protein (from human serum)	[38]
Auxin analogues	Auxin-receptor proteins	[68]
Thyroxin	Thyroxin-binding protein (from human serum)	[110]
N-(6-Aminohexyl)-5-chloronaphthalene-1-sulphonamide	Calmodulin and calcium-binding protein S-100 (from ox brain)	[74]
Agglutinin from *Ricinus communis*	Tyroglobulin	[41]
t-RNA (hydrazidoadipoyl)	Ribosomal proteins	[105]
Iminodiacetic acid + Zn^{2+}	Interferon (from human fibroblasts)	[114]
Interferon from human leukocytes	Corresponding antibodies	[103]
β-Ecdysone	Proteins of the corresponding antiserum	[133]
Lipopolysaccharides from *Shigella sonnei*	Homologous antiserum, bacteriophage SKVI	[101]
Membrane material from human lymphoblastoid cells	Corresponding antibodies	[104]
	EAS-6B and 1,2-EPS	
Haemagglutinin (succinyl)	Glycoproteins	[96]
	1,2-EPS	
2-Thio-4-(nitro, carboxy)pyridine; tetramethylthiuram disulphide residue	Cysteine peptides, mercaptalbumin, papain, urease, ox serum albumin, pancreatic ribonucleases	[87, 127]

Ditto or NADPH (hydrazidosuccinyl, hydrazido-adipoyl)	"	[90, 91, 111]
Aminoacids (hexamethylenediamine, succinyl)	Prefenate dehydratase	[92]
3-Hemisuccinate of 5α-androstane-3β, 17β-diol(4,4′-azodianiline)	Testosterone-oestradiol-binding globulin (from human plasma	[94]
Cortisol, 5α-dihydrotestosterone	Steroid-binding proteins	[134]
Adenine and guanine nucleotides (hydrazidoadipoly)	Elongation factor Tu (from *E.coli* MRE 600)	[89]
Alkyls, hydroxy(alkoxy)alkyls, and their cyano- and carboxy-derivatives	Albumin, globulin, fibrinogen, prothrombin	[45, 46]
Thiopropyl	Protein disulphide-isomerase (from ox liver), glutathione-insulin transhydrogenase (from ox liver)	[126, 129]
Ditto	Actinidin (from *Actinidia chinensis*)	[130]
"	Copper-binding proteins from human liver	[125]
	Amino-1,2-EPS	
Lactose, melibiose, maltose, *N*-acetylchitotetraose; glucosamine, galactosamine(succinyl)	Agglutinins (from soya, *Arachis hypogaea*, wheat seedlings, etc.)	[98]
17β-Hydroxy-3-oxo-5α-androstane-17α-(6-hexanoic acid)	Androgen-binding protein (from rat epididymis)	[99]
	Epoxycellulose	
Deoxyribonucleic acid	Polynucleotides, complementary m-RNA (from bird liver)	[39]
	GMG	
Trypsin	Trypsin inhibitors	[47]
	Epoxy-separon H 1000	
Methyl ester of L-phenylalanyl-D-phenylalanine (ε-aminocaproyl)	Pepsin and proteinases (from *Aspergillus oryzae*)	[48]
	Silica(alusil)	
5-Hydroxyuridine 2′(3′), 5′-diphosphate (*p*-azobenzoyl)	Endonuclease A5 (from actinomycetes)	[34]

---o0o---

The data described above show that biospecific adsorbents based on EAC constitute one of the commonest types of adsorbents currently used in AFC and related methods. One sometimes encounters the view that AFC in a pure form does not exist at all and that the biospecific interaction of the biopolymer to be isolated with the sorbent in AFC is inevitably accompanied by a complicated set of interactions including non-specific electrostatic, hydrophobic, and other effects. Both AFC and associated methods, such as hydrophobic, covalent, and metal chelate chromatography are therefore incorporated in a single group of methods. This tendency carries the risk, both formal and purely theoretical, of an erroneous interpretation of the chromatographic results, particularly when the AFC method is used for the investigation of the mechanisms of biochemical reactions, for the determination of the constants for the association of biopolymers with low-molecular-weight ligands, etc. An arbitrary mixing of the methods, indicated above, for the isolation and purification of biopolymers can be caused, and this is not the least important cause, by the application in AFC, particularly for preparative purposes, of carriers such as porous glass, silochromes, and a number of others, which by their very nature can introduce into the purification process non-specific interactions which do not, however, prevent in many cases the attainment of a fairly high degree of purification of the biopolymer.

The efforts of investigators concerned with the further development of the AFC method will undoubtedly be directed to the elimination or reduction to a minimum of non-specific

effects in the chromatographic process, because this will make it possible to demonstrate fully the unique possibilities of the AFC method. For a clear-cut formal separation of the AFC method from other purification procedures, the term "bioaffinity chromatography" has been proposed.[10,135,136] The new methods for the activation of polysaccharide matrices which have appeared recently have been chosen to obviate the disadvantages of the method of bromocyanogen activation, which is still most widely used. These include the modification (based on the study of the reaction mechanism) of the bromocyanogen method itself,[137,138] the employment of reactive sulphonyl chlorides[139,140] and carbonylating reagents,[141,142] *O*-succinylation,[143] the application of activated chloroformates,[144] and a number of others. Activation by epoxy-compounds occupies an honourable place among these methods. Its evident advantages, namely simplicity, chemical strength of the bond formed, hydrophilicity of the adsorbents obtained, and elimination or reduction to a minimum of the charged groups of the adsorbent, promote the maximum approach of the interaction between the biopolymer to be isolated and the immobilised ligand to processes occurring under physiological conditions, i.e. the achievement of the idea of the AFC method in a pure form. One may also expect further extensive application of adsorbents based on EAC for the effective purification of biopolymers and as a refined instrument for biochemical research.

Structural Disorder and Mechanochemical Reactions in Solids

P.Yu. Butyagin

The present review is devoted to an analysis of the relationship between the changes in the structure and reactivity of solids, brought about by the development of a deformation. It has been shown that the principal regular features of mechanochemical transformations are determined by the extent of the structural disorder, the processes involved in its relaxation with the liberation of stored energy, and the mobility of the atoms. The part played by each of these factors has been examined for mechanically activated chemisorption, the ionisation of structural defects, the production of various non-equilibrium states on relaxation, the excitation of the mobility of the structure with the intensification of diffusion-controlled reactions, etc. The bibliography contains 87 references.

I. INTRODUCTION

Deformation is the first response of a solid to the action of external mechanical forces. The external changes in the shape and dimensions of the solid reflect the changes in the order of the arrangement of the atoms, that is the structure of the substance with the development of the deformation. The nature of the internal changes depends on the type of solid and on the conditions of mechanical loading. They may be restricted to an increase or decrease in the interatomic distances, new defects (point, line, plane) may be produced, the type of crystal lattice may change, and in the limit the crystal may be transformed to an amorphous mass or, on the contrary, an amorphous substance may crystallise on deformation. Structural changes inevitably influence the structure-sensitive properties of a substance—its reactivity and transport phenomena (diffusion, thermal conductivity, electrical conductivity, etc.).

From the mechanochemical viewpoint, three aspects of these changes are important.

1. The structural disorder in the substance. The appearance of vacancies, interstitial atoms, and dislocations, which act as centres for the development of topochemical transformations, the production of broken bonds, which initiate various reactions, including chain processes, and the creation of chemically active freshly formed surfaces represent the most familiar examples illustrating the role of structural defects in the mechanical activation of solid reagents.

2. The second factor is structural relaxation, involving the most varied processes, which often have unexpected consequences. The wide variety of relaxation phenomena was revealed after the processes of deformation and breakdown in solids began to be studied by modern electrophysical and optical methods. The emission of fast electrons (with energy up to several keV, the Deryagin effect) and slow

electrons, mechanoluminescence, radiation in the radio and X-ray ranges, acoustic emission, the decomposition of a substance with the ejection of atoms and molecular fragments, and other phenomena have been discovered. It cannot yet be stated that all these phenomena are direct consequences of relaxation processes, but for each of them there exists at least one hypothesis relating the observed effect to the production, movement, and disappearance of structural defects. It should be noted that the energy liberated when defects disappear may reach several eV, that is it is quite sufficient for electronic excitation, ionisation, or bond rupture.

3. No less important is the third factor, which can be called the mobility or dynamics of the structure. In the development of a deformation, the new structure not only is formed, but also "lives". The internal stresses are weakened, and the forces of interatomic, intermolecular, or interionic interaction in the crystal are modified. Point defects are produced and displaced, dislocations multiply and move, grain boundaries are displaced, cracks appear and grow, etc. The mobility of the structure in the development of a deformation creates extremely favourable conditions for solid-phase chemical reactions.

Under real conditions, all three factors involved in the effect of deformation on the reactivity of a substance operate simultaneously. When the deformation of a substance and a chemical reaction are separated by an appreciable time interval, sufficient for the completion of relaxation processes, only the first factor—the existence of a changed structure in the substance—operates. The increase in reactivity due to stable changes in the structure of a substance is usually called mechanical activation.

There are also processes in which the principal rôle is played by the last factor, that is the mobility of the structure; these are associated with the intensification of chemical transformations in substances, where a reaction is possible, but the thermal motion, including translational diffusion, is completely "frozen", and the mobility of the particles, required for the reaction to take place, is brought about only by plastic deformation. The basic literature can be found in monographs, collected papers, and reviews.[1–20] The part played by structural disorder, its relaxation, and mobility in mechanochemistry is examined below for specific examples.

To compare the efficiencies of the action of the above factors, it is necessary to know the energy yield of the corresponding processes, since it is only in energy units that it is possible to compare the emission of electrons, the production of dislocations, luminescence, and chemical transformations. The measurement and calculation of these energy yields, which represent the quantitative basis of mechanochemistry, have not yet been sufficiently recognised; an exception is provided by ultrasonic chemistry.[21]

II. STRUCTURAL DISORDER

The treatment of various materials in mechanochemical reactors (apparatus for fine subdivision, the application of shock waves or pressure, shear combined with deformation, etc.) is accompanied by the production of structural disorder, which is preserved partly or completely for a fairly long time interval after the mechanical treatment has stopped. A clear and distinct indication of the extent of structural breakdown is provided by the change in the density of a substance after mechanical treatment. In quartz, the density decreases from 2.4 g cm^{-3} to 2.2 g cm^{-3},[13,22] corresponding to an increase in free volume by 8–9%. (For comparison it may be noted that the natural free volume of polymeric glasses is close to 2.5%.) These data reflect the state of quartz some time after mechanical treatment, when the structure has partly relaxed. During the development of the deformation, the extent of the decrease in the density of the substance is even greater, and the layer next to the surface is permeable to gases. The mechanically activated solubility of argon in quartz at 80 K and a pressure of 20 hPa is 10^{-2} mole kg^{-1}.[23] Similar effects are characteristic of metals, whose crystal lattices are much denser.[24]

In two-dimensional and one-dimensional systems such as highly anisotropic layer crystals and linear polymers, the degree of deformational disorder is even greater, and the state of limiting decrease in density may be frozen and preserved for study.[23,25] Since the excess free volume is so large that it is accessible to a gas, the extent of the disorder can be characterised by the sorptive capacity or the specific surface S, calculated using the BET equation from the isotherms for the reversible adsorption of argon or other gases at 80 K. The internal surface area generally corresponds to tens of hundreds of m^2 g^{-1}. In molybdenum disulphide (see Fig. 1*a*), thermal mobility of the atoms sufficient for healing appears at 150–200 K.

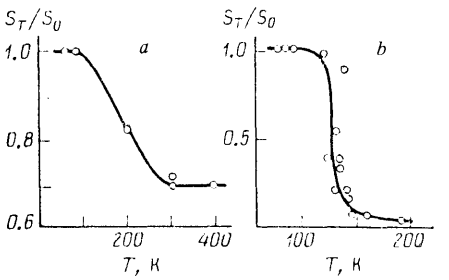

Figure 1. Thermal sintering of mechanically disordered powders of molybdenum disulphide (*a*) and polymethyl methacrylate (*b*);[23,25] S_0 and S_T are the specific surfaces at temperatures of 80 K and T.

The effect of structural disorder in polymers is even greater. For example, in polymethyl methacrylate after mechanical treatment at 80 K, the sorption of argon at a pressure of only 10 hPa is close to 10 mole kg^{-1}; the gas can be removed by evacuation, and adsorbed again. The internal surface area, calculated formally from the sorption isotherms, reaches 600–800 m^2 g^{-1}. The structure loosened to the maximum extent by deformation can be preserved for an unlimited time only at a temperature below 120 K (Fig. 1*b*). Above this temperature, spontaneous sintering begins, with a decrease in the internal surface area accessible to a gas by a factor of several hundred.[25] This extensive decrease in density is the clearest example of the effect of deformation on the structure of a solid.

The relationship between the changes in the structure and reactivity of a solid is important for mechanochemistry. Comparatively detailed information on the nature of mechanical defects, their concentration and reactivity, the direction of elementary reactions involving them, and the kinetic and thermochemical parameters has been obtained for the surface

of solids, where these defects are accessible to molecules from the gas phase. The friction and fracture surfaces of quartz,[15,26,27] silicon,[28] graphite,[29] and other crystals[30,32] have been studied.

Mechanically stimulated chemisorption on the surface of quartz has been described most systematically. The external manifestation of the phenomenon is that the initially inert surface of the solid, as a result of mechanical treatment, becomes chemically active in reactions with gases. Thus SiO_2, which is the highest oxide of silicon, does not react with oxygen under ordinary conditions; the product of the mechanochemical reaction is a previously unknown surface peroxide, assumed to have the structure $\equiv Si-O-O-O-Si\equiv$.[26] The formation of this peroxide can be represented as follows:

$$\equiv Si\cdot \quad \equiv SiOO\cdot \quad Si{=}O$$
$$+\ O_2 \rightarrow \quad +$$
$$\equiv SiO\cdot \quad \equiv SiO\cdot \quad Si{=}O$$

Oxygen is attached to the free radical $\equiv Si^{\bullet}$, produced at the point of mechanical rupture of the siloxane bond, after which the peroxide radical $\equiv SiOO^{\bullet}$ recombines with the $\equiv SiO^{\bullet}$ radical. The final result is that an oxygen molecule is "built into" the broken bond.

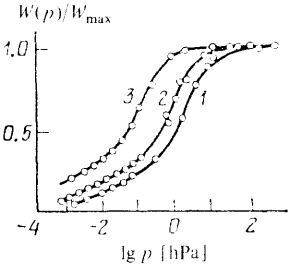

Figure 2. The mechanically activated chemisorption of hydrogen on the surface of quartz at different temperatures, K: *1*) 370; *2*) 300; *3*) 80.[26]

The regular features of mechanical chemisorption are illustrated by the graphs in Fig. 2. For a specific surface of quartz greater than 2–5 $m^2\ g^{-1}$, the reaction is initiated by friction, that is by deformations in the layer next to the surface of the powder particles.[26] The graph giving the dependence of the reaction yield on the gas pressure $W(P)$ has a characteristic inflection.[33] At a high pressure, when the frequency of the collisions of the gas molecules with the surface is high, the reaction yield $W(P)$ has its highest value and is independent of pressure. Under these conditions, all the structural defects produced are involved in the reaction, and the consumption of the gas characterises the number of active centres formed by the friction of the particles of the powder against one another. The energy yield of the formation of the short-lived active centres is 10^{-1}–10^{-2} mole MJ^{-1}. At a low pressure, when the collisions of the molecules with the surface are infrequent, some of the short-lived centres are able to disappear before reacting with the gas, so that the yield of the reaction decreases.

In the absence of a gas, that is on mechanical treatment of the powder in a vacuum, up to 6×10^{16} m^{-2} free radicals $\equiv Si^{\bullet}$ and $\equiv SiO^{\bullet}$ are stabilised on the quartz surface.[15,34] The structure and chemical properties of the free radicals on a quartz surface have been studied in detail by EPR, chemisorption and thermal desorption, microcalorimetry, and luminescence. Detailed information on the reactivity of mechanical radicals, including a description of the stepwise mechanism, the kinetic law, the rate constants, and the heats of the reactions with CO, O_2, H_2, CO_2, and various organic molecules, have been published.[15]

The free radicals $\equiv Si^{\bullet}$ and $\equiv SiO^{\bullet}$ are not the only defects produced mechanically on the disordered surface of quartz. A smaller number of silicon atoms with two broken bonds, that is silylene centres =Si:, are stabilised.[15] It has been suggested that =C: atoms exist on the fracture surface of graphite,[29] =Ge: atoms on the surface of germanium oxide,[30] and Sn^{2+} ions on the surface of tin oxide.[16,31,32]

An important contribution to chemical activity is made by deformed bonds, which act as carriers of residual internal stresses. They were first detected in the elongation of polymers.[18] Deformed siloxane bonds are observed from the displacement of the stretching band in the infrared spectra.[35] The chemical properties of the deformed bonds on a quartz surface are similar to those of the radical pairs $\equiv Si...OSi\equiv$. Thus hydrogen reacts with them practically instantaneously at 80 K; the activation energy of the reaction

$$\equiv SiO... Si\equiv + H_2 \rightarrow \equiv SiOH + HSi\equiv$$

does not exceed 2–3 kcal $mole^{-1}$;[26] such a low activation energy is characteristic of free-radical, and not molecular reactions. The deformed bonds readily undergo not only hydrogenation but also hydrolysis[36,37] and carbonation. The energy of deformation is liberated in all these reactions.

To determine the surface concentration of deformed bonds, they are titrated with H_2 and CO_2. For the same exposure in the gas, the quantity of bonds reacting with CO_2 is several times greater than the quantity reacting with H_2; the difference is due to the non-uniformity of the distribution of the stresses in the bonds and the corresponding distribution with respect to reactivities. Judging from the consumption of hydrogen,[26] the concentration of deformed bonds on the surface of mechanically activated quartz at 80 K is approximately ten times the concentration of radicals, and reaches $(4–6) \times 10^{17}$ m^{-2}.

The curves in Figs. 3*a* and 3*b* illustrate the thermal stability of the active centres on the surfaces of quartz and magnesium oxide.[15,26,38] The concentration of radicals is independent of temperature; their stability is determined primarily by the purity of the reaction system; the more thoroughly traces of moisture are removed, the more stable the radicals. As expected, the concentration of deformed bonds, reflecting the magnitude of the residual stresses, decreases with increase in temperature.

Thus the nature of mechanical chemisorption on the surface of covalent crystals can be represented as follows. The friction and fracture of the particles of the substance leads to the production of disorder in the surface and to the deformation and rupture of chemical bonds. At room temperature, the deformed bonds undergo a spontaneous decrease in length, and some of the radicals disappear under the influence of friction; thus the complete utilisation of the work done in producing the disorder requires the creation of conditions in which the rate of the reaction of gases with the surface is greater than the rate of disappearance of the short-lived active centres.[39]

The disordered surface of magnesium oxide, which is a stable ionic crystal with melting point ~2900 K, has a high concentration of chemically active centres [up to 1×10^{14} cm^{-2} in the reaction with H_2, and $(3–5) \times 10^{14}$ cm^{-2} in the reaction with CO [38]]; the active centres are stable in a vacuum at

room temperature (see Fig. 3*b*). Hydrogen on this surface dissociates to give atoms with the formation of Mg–H and Mg–OH groups.

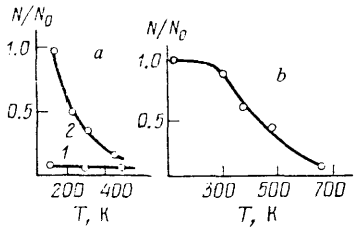

Figure 3. The thermal stability of the active centres on the surface of the oxides of silicon (*a*) (*1*—free radicals, *2*—deformed siloxane bonds) and of magnesium (*b*); N_0 and N_T are the initial and current concentrations of centres.[26,38]

For crystals made up of close-packed ions, the concepts of deformed and broken bonds become indefinite. Taking the extreme limiting case of a purely ionic structure (see Ref. 40, and also a criticism of this approach for alkaline earth metal oxides[41]), the high chemical activity of the disordered surface of MgO can be explained qualitatively as follows.[38] The MgO crystal consists of the chemically inert ions Mg^{2+} and O^{2-} with noble-gas electronic structures; these ions are energetically unfavourable in the free state. To obtain Mg^{2+} and O^{2-} ions in the gas phase from metallic magnesium and molecular oxygen, an energy of ~35 eV is required. When the small doubly-charged ions are close packed, however, there is a gain of electrostatic interaction energy, which more than compensates the loss. Thus the anions and cations are stable in the regular lattice, and the MgO crystal is inert and stable. After the mechanical production of disorder in the crystal, the packing of the ions becomes loose. The average number of neighbours of each ion becomes smaller, and the interatomic distances greater, compared with the regular lattice. Thus in the disordered regions there is a decrease in the strength of the electrostatic interaction responsible for the stability of the ions. Total loss of stability leads to the loss of an electron, that is to the conversion of the O^{2-} ion into the chemically active radical-ion O^-.

The stability of ions can be characterised by the energy required to transfer an electron from the anion to the cation:

$$Mg^{2+}O^{2-} \longrightarrow Mg^{+}O^{-} .$$

In a regular crystal, this energy, which is equal to the width of the band gap, is close to 8 eV. On a surface disordered by friction, the energy of electronic excitation should be smaller. In principle, it can be estimated from the position of the long-wave edge of the absorption band in the spectrum of the surface.

Fig. 4 gives the diffuse reflectance spectrum for a disordered MgO surface (curve *1*). The edge of the band corresponds to an energy of ~4–5 eV, compared with 8 eV for the regular crystal.[38] A similar effect was recently detected in other disordered oxides.[32] The displacement of the boundary of the absorption band by 3–4 eV can be regarded as a measure of the energy of disorder of the surface. After the chemisorption of hydrogen, as a result of which the most active parts of the surface are "worked out", the boundary of the spectrum is displaced to the left by ~1 eV (curve *2* in Fig. 4).

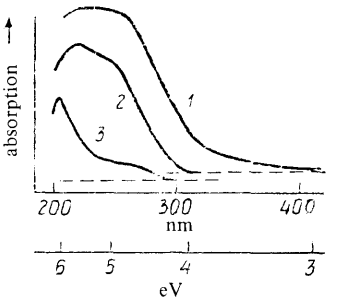

Figure 4. Diffuse reflectance spectra of magnesium oxide powders: *1*) after mechanical treatment; *2*) after reaction with hydrogen; *3*) after heating in a vacuum.[38]

The initial energy yield of the mechanically stimulated chemisorption of hydrogen for MgO is greater than that for quartz, and is equal to ~0.2 mole MJ^{-1}.[38] The excess energy of the disordered surface, calculated from the displacement of the long-wave boundary of the spectrum (by 3–4 eV) and the concentration of active centres (~5 × 10^{18} m^{-2}), is on the average 2–3 J m^{-2} or 100 kJ $mole^{-1}$ for all the ions of the surface.[38]

For the chemical behaviour of a substance, it is important that the mechanical work is used up in increasing the strength of the electron-donor properties of the anions. In the approximation being considered, the energy of chemical reactions on the disordered surface of an ionic crystal is explained by the following thermochemical cycle:

$$\begin{array}{l} Mg^{2+}O^{2-} \longrightarrow Mg^{+}O^{-} \\ O^{-} + XY \longrightarrow OX^{-} + Y \\ Mg^{+} + Y \longrightarrow Mg^{+}Y \\ \hline Mg^{2+}O^{2-} + XY \longrightarrow YMg^{+}OX^{-} \end{array}$$

where XY is a chemisorbed molecule, for example H_2, H_2O, etc. When the energy required for electron transfer (first stage) is lowered to the value of the thermal effect of the two subsequent exothermal chemical reactions, the overall reaction becomes energetically favourable.

Thus whereas in photochemistry the transfer of an electron takes place as a result of the absorption of a quantum of light, and the lifetime of the active excited state $\{Mg^{+}O^{-}\}$ is short, in mechanochemistry the ionisation is facilitated by the production of structural disorder, and the active state is metastable at room temperature.

In magnesium oxide (see Fig. 5), the ionisation energy is lowered to 4 eV. In crystals with a narrower band gap (GeO_2, SnO_2[32]), the absorption spectrum of the surface states after the production of disorder extends to the long-wave boundary of the visible range; in this case the first stage of the thermochemical cycle examined above takes place spontaneously. Similar processes are possible in organic compounds. Calculations[42] have shown that a local increase in the C–C bond in polyethylene should be

accompanied by a decrease in the ionisation potential to half its value; the transfer of an electron from the deformed bond into a structural trap then becomes possible.[43]

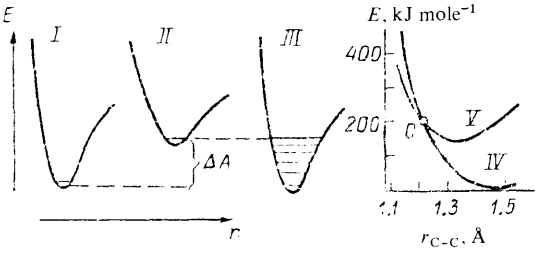

Figure 5. The relaxation of elastically deformed bonds (for explanation see text).

These examples are given here to emphasise that in the band gap of deformed ionic and covalent crystals, donor and acceptor electron levels localised on structural defects are created. These levels may be ionised thermally, and may capture biographic electrons or holes, that is electrons or holes previously existing in the crystal, including those from impurity atoms with variable valence.

The existence of easily ionisable defects is confirmed by their partial ionisation during the mechanical treatment of solids, and also by the anomalously high radiation yield for the formation of paramagnetic centres under the influence of ionising radiation on mechanically disordered crystals.[20,44] Thus after mechanical treatment and irradiation with a dose of less than 1 Mrad, 10^{17} g^{-1} F-centres are produced in radiation-stable magnesium oxide.[44] Their concentration does not increase with increase in the dose, since the vacancies are created during mechanical treatment, and irradiation leads only to their occupation by electrons.

The production of structural disorder in inorganic salts containing complex polyatomic anions should apparently increase their tendency to decompose. In fact, complex anions such as N_3^-, $C_2O_4^{2-}$, NO_3^-, etc., after the loss of an electron, are converted into a singly-charged form or a neutral species; this state is generally unstable, and the loss of the electron initiates the subsequent breakdown of the anion into individual fragments. The probability of breakdown is naturally much greater on the surface or close to defects, where there are no geometric restrictions on the formation of products.

Thus the increase in the donor properties of anions in the production of disorder must be regarded as one of the most important factors in the processes involved in the mechanical decomposition of inorganic compounds. This approach to the nature of the decomposition is confirmed by the influence of metal oxides on the extent of the mechanical degradation of nitrates.[45] This work was begun about 20 years ago, but was subsequently neglected.

III. STRUCTURAL RELAXATION

The chemical and physical effects accompanying the restoration of a mechanically disordered structure are extremely varied, and this variety is the most interesting feature of the processes involved in the deformation and breakdown of solids. The variety is due to the partial ionisation of structural defects and the existence in the deformed solid of both neutral and electrically charged centres. It is usual[2-5] to divide conditionally the entire range of phenomena into mechanochemical and mechano-emission phenomena, the former being produced by the relaxation of neutral disordered parts of the structure with the liberation of elastic energy, and the latter involving the recombination of charges and the decay of electric fields. There is obviously no distinct boundary between these overlapping groups of phenomena.

1. Excited States

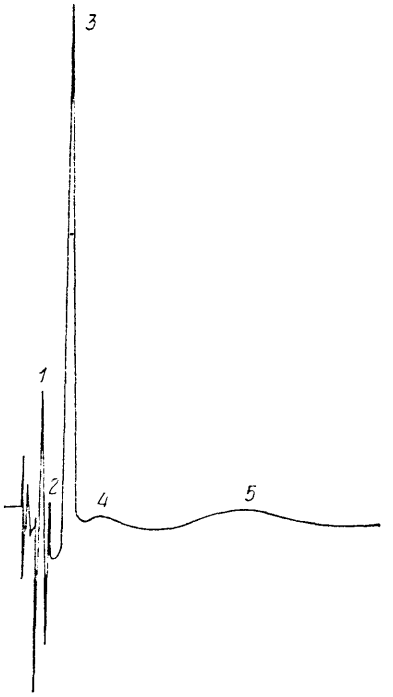
In the restoration of a mechanically disordered structure, vibrational and electronic excited states are produced.[46,47] Vibrational excitation is possible as a result of the transformation of elastic energy into vibrational energy on free contraction of a previously elongated chemical bond.[46] This process is explained by Fig. 5, where *I* is the potential curve for the interaction of the atoms, *II* is the same for the elastically deformed bond, and ΔA is the work of deformation. The change *II* → *III* illustrates the relaxation of an elongated bond under conditions when no work is done against external forces. When the deformational energy liberated on bond relaxation is comparable with even half of the bond strength, the level of vibrational excitation will correspond to an effective temperature of tens of thousands of degrees. The excited bond can either undergo thermalisation (Joule heat) or take part in a chemical reaction.

The simplest example of the almost free contraction of bonds is provided by the relaxation of an elongated chain of atoms after its rupture. The model of a contracting chain has recently been the subject of computer experiments. The chain consisted of 20–100 spheres with the mass and dimensions of carbon atoms,[48] and the potential of the interaction between them was given by a Morse function. The preliminary deformation reached 0.5–1.5 Å per bond. After elongation, one end of the chain was "released" and the coordinates of all the atoms were followed. At a definite level of the excess energy, the contraction was accompanied by bond rupture. The calculated mass spectra of the fragments (for preliminary elongation of all the bonds of the chain by 1 Å) are given in Table 1.

Since the lifetime is short, the participation of vibrationally excited states in bimolecular reactions with species of the surrounding medium is less probable than monomolecular transformations such as, for example, decomposition of the substance. Decomposition is studied (see Fig. 6) by deforming or rupturing the specimens before their introduction into the mass spectrometer or chromatograph, which records the ejection of atoms of molecular fragments. The elongation and rupture of polymers gives a whole series of low-molecular compounds,[18,49,50] from hydrogen atoms to compounds containing 2–6 carbon atoms. The fracture of alkali metal halide crystals is accompanied by the ejection of neutral metal and halogen atoms,[51,52] whereas the carbonates under the same conditions decompose with the liberation of carbon dioxide,[14] the nitrates with the liberation of oxygen and oxides of nitrogen,[53] etc.[55] Not all of these effects can be fully explained by the decay of vibrationally excited states.[54]

In early studies,[51] most attention was directed to proving the existence of mechanical decomposition of the substance, and the quantity of fragments formed was not always measured. In polymers, the yield of low-molecular compounds is much lower than the number of ruptures of the

macromolecules. In the fracture of different crystals, the yield of fragments (calculated for 1 m^2 of surface formed) apparently varies from 10^{15}–10^{17} molecule m^{-2} in alkali metal halide crystals[51,52] to 10^{18}–10^{19} molecule m^{-2} in alkaline earth metal carbonates.[14] In a number of cases, the yield is possibly too high, because not all authors have taken account of the intensive sputtering of the substance in the initial period of growth of the crack; the part played by this phenomenon has been analysed.[52]



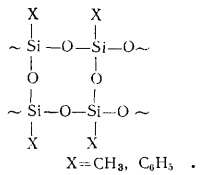


Figure 6. Chromatogram of the low-molecular products of the mechanical degradation of polypropylene: *1*) methane, *2*) ethane, *3*) propane, *4*) propylene, *5*) butane fraction.[49]

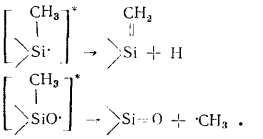
Table 1. The calculated number of fragments[48] in the free contraction of a chain of carbon atoms.



Number of C atoms in the chain	Number of C atoms in the fragment						
	1	2	3	4	5	6	7
30	4	5	1	—	1	—	1
50	6	12	1	4	—	—	—
100	14	13	7	6	4	—	1

A quantitative study of low-temperature (80 K) mechanical decomposition has been carried out for polysiloxanes with a ladder structure, namely polymethyl- and polyphenylsilasesquioxanes:[50]

Contrary to widespread opinion, the rupture of the siloxane bonds takes place by a free-radical mechanism.[56] At 80 K, the degradation is accompanied by the ejection of hydrogen atoms and methyl radicals (for X = C_6H_5, benzene is ejected) with a probability of ~0.8, calculated for each bond rupture. As a result of secondary reactions, the H atoms and $CH_3^{\cdot}$ radicals are converted into H_2, CH_4, and C_2H_6.[50]

The primary radicals formed at the moment of rupture of the elongated polymer chain are apparently excited, and have an excess of vibrational energy; thus in spite of extensive cooling, they decompose at the β-bond with a probability close to unity:

This decomposition route is facilitated by the fact that the expenditure of energy in the rupture of the C–H and Si–C bonds is partly compensated by the gain on the formation of unsaturated groups.

The excitation of vibrations with a high amplitude changes the nature of the interaction between the atoms at the points of maximum separation from and closest approach to one another. The removal of atoms may be completed by bond rupture, and when there is appreciable approach of the carbon atoms at the end of a ruptured polymer chain, when the distance decreases to the value characteristic of a double bond, rearrangement of the atoms may take place. This situation was first analysed for the removal of a hydrogen atom from a vibrationally excited terminal radical of the type ~CHX–$\dot{C}H_2$:[57]

The potential curves (see Fig. 5) corresponding to the initial (IV) and final (V) states intersect at the point *C*. For reaction to take place, that is the transformation (IV) → (V), it is necessary that the level of excitation reach the crossing point of the potential curves.

A characteristic feature of ionic compounds is that the mechanical rupture of the bonds is preceded by the transfer of an electron from the anion to the cation.[7] This characteristic feature of ionic compounds has been used to explain the emission of neutral atoms during the fracture of alkali metal halide crystals;[58] it was assumed that in the mouth of the growing crack there is excitation of the vibrations of ions, whose amplitude is such that electron transfer from a halide ion to a metal ion takes place at the point of maximum separation from one another. Neutral atoms, which are not held by forces of electrostatic interaction, leave the surface. The results of calculations[58] showing that the emission of the atoms amounts to 10^{19} m^{-2} are too high, since for this yield, the energy used up in the sputtering of the substance is greater than the energy of breakdown; this mechanism may however make a contribution to the overall yield of the emission of atoms (see Ref. 54 for other mechanisms).

The range of mechanochemical relaxation phenomena is not restricted to the vibrational excitation of bonds. When various structural defects disappear, energy is liberated in

quantities of up to several eV, which is sufficient for electronic excitation. Under favourable conditions, the production of electronically excited states can be detected from the characteristic luminescence of the specimen. Comparatively bright mechanoluminescence (or triboluminescence) is characteristic of materials whose structures contain luminescent centres, that is luminophores. Substances in which luminescent defects are formed as a result of mechanical treatment are more interesting; examples of solids of this kind are provided by quartz[59] and copper.[60] In quartz, the luminescent structural defects are atoms with one or two broken bonds, the free radicals $\equiv SiO^{\bullet}$, and the silylene centres =Si:. The excited electronic state of the $\equiv SiO^{\bullet}$ radicals corresponds to an energy of 1.91 eV, and these radicals show luminescence in the red range of the spectrum. The silylene centres correspond to a blue luminescent band with a maximum at 2.65 eV.[59]

When fine quartz powders are subjected to mechanical treatment, the structural defects, including luminescent defects, are localised chiefly on the surface of the particles. Under these conditions, luminescence is observed when the surface is excited by ultraviolet light or friction, or by the heat of chemical reactions with gases.[59] The relaxation of residual stresses is also accompanied by luminescence. In the first studies, the excitation of triboluminescence in quartz was related to the processes involved in the disappearance of short-lived active states, for example the recombination of neighbouring radicals and the relaxation of extensively deformed siloxane bonds. The subsequent determination of the details of the electronic excitation routes encountered considerable difficulties. It was found that the contribution of processes involving the transfer of energy to the luminescence centres is small,[59] and it appears that during friction or on the relaxation of stresses, at least some of the $\equiv SiO^{\bullet}$ and =Si: centres are produced even in the electronically excited state.

Thus one of the elementary acts in the relaxation of stresses may be the reaction of a $\equiv SiO^{\bullet}$ radical with an adjacent highly deformed $\equiv Si...O...Si\equiv$ bond:

$$\equiv SiO^{\bullet} + \equiv Si..O...Si\equiv \rightarrow \equiv Si-O-Si\equiv + [\equiv SiO^{\bullet}]^{*} \ .$$

The reaction gives the electronically excited radical $[\equiv SiO^{\bullet}]^{*}$ and a non-deformed siloxane bond. Reaction (1) describes not only the production of electronically excited states but also the migration of defects with scattering of the energy, that is the development of plastic deformation.

The mechanoluminescence of copper has been observed[60] during strong impact on the end face of a metal bar; the luminescence was produced on its opposite side. Several years after the detection of the luminescence of metals, a theory was proposed, relating this phenomenon to the annihilation of edge dislocations in the volume or on the surface of the metal.[61] The energy required for the excitation of the luminescence (2.15, 1.25, and 0.85 eV) is liberated in the recombination of electrons with holes localised on the copper atoms at the centre of the edge dislocation; at these atoms there are broken bonds similar to those of free radicals at the centres of the dislocations in covalent semiconductors. The characteristic luminescence times correspond to the times taken for the dislocations to reach the surface after impact.

Thus the pictures of the build-up and quenching of the mechanoluminescence in quartz, copper, and other substances reflect the processes involved in the production, migration, and disappearance of structural defects.

2. Mechano-emission Phenomena

The emission of fast and slow electrons, including exo-emission, electrical conductivity pulses, X-rays, static electricity, gaseous discharge, and various forms of luminescence, that is a complete range of electrophysical phenomena accompanying deformation and cohesion and adhesion breakdown, are usually distinguished in the group of mechano-emission effects. Mechano-emission phenomena have been examined in comparative detail in a number of reviews, collected papers, and monographs.[1-5,9,54,55]

As noted above, the factors responsible for mechano-emission phenomena are to be found in the production, interaction, and scattering of electric charges, and one of the principal directions of research in this field still involves the interpretation of the mechanisms of the ionisation of a substance and the creation of electric fields. Several mechanisms have been discussed. The thermo- or auto-ionisation mechanism was examined above; it involves the capture of electrons (or holes) on the local levels of structural defects.

The dislocation mechanism involves charge transfer by mobile dislocations. The dislocations in crystals are electrically charged;[62,63] their charge is compensated by a cloud of charges of opposite sign, localised on point defects. During deformation and breakdown, the dislocations carry their charge on to the surface. When fracture is unsymmetrical, different parts of the crystal are deformed in different ways, and in the mouth of the growing crack there is a component of the movement of the dislocations directed towards the thicker part of the crystal; the excess charge is carried with the dislocations. In alkali metal halide crystals, the excess charge reaches $10^{5}-10^{7}$ CGSE unit m^{-2} or $10^{14}-10^{16}$ centre m^{-2}. In this case the results of calculations[64] agree with the results of measurements of the magnitude of the charge.[65]

The polarisation mechanism is the simplest to explain. The electric fields are produced in this case as a result of the orientation of the polar molecules during the development of the deformation; a similar effect is observed when there is a relative displacement of ions of opposite charge. Thus for identical orientation of all the side groups of polymethyl methacrylate, the charge density would be 9×10^{7} CGSE unit m^{-2}; the experimental value is approximately 10 times smaller, 6×10^{6} CGSE unit m^{-2}. The polarisation mechanism plays the principal role in the production of electrets in polymers;[66] an appreciable polarisation EMF is produced when shock waves pass through a substance.[67]

The mechanism of the separation of the electrical double layer is characteristic of the breakdown of adhesion contact. An electrical double layer is always produced at the boundary of contact between two surfaces of different kinds, and from this viewpoint the breakdown of adhesion contact is identical to the separation of the plates of a capacitor.[9] The charges produced when a polymer film is torn from a support, or when plates of mica are split, represent the most familiar examples of the consequences of electrification by this mechanism.

The production of electric fields during the deformation or breakdown of solids is usually accompanied by scattering of the excess charge. The charged centres preserved after mechanical treatment are responsible for post-effects—a decrease in electrical conductivity, the emission of electrons or ions, and luminescence excited by the recombination of charges.[68] These processes are completed with increase in temperature (exo-emission, thermoluminescence) and by the adsorption of gases and vapours on the surface.[69]

In the deformation and breakdown of solids in air or in another gas atmosphere, the principal route for the scattering of the charges is by electrical breakdown, that is gaseous discharge accompanied by characteristic luminescence, acoustic effects, etc. In a vacuum, the charges may be scattered in several ways. When the electron is firmly bound to a centre, for example to a structural defect, the decisive factor in the scattering of charges is the stability or mobility of the defects themselves. Thus in polymers, electrons may be stabilised in so-called structural traps or vacancies. On deformation or with increase in temperature, the structural traps are destroyed, with the liberation of electrons and the excitation of emission, conductivity, or recombination luminescence.[43] Processes of this type include the capture of *F*-centres by moving dislocations with subsequent recombination of charges. In the other limiting case, when the concentration of charges is high, and the electrons are not so firmly bound to the traps, the principal role in the relaxation of charges is played by the emission of electrons, brought about by their repulsion from one another. The intensity of the emission of electrons in a vacuum is determined by the fluctuations in the surface charge density; for a local charge density of 10^8 CGSE unit m^{-2}, the energy of the emitting electrons may reach 10^1–10^2 keV.[54,68]

A radiation mechanism of charge scattering has been proposed to explain the mechano-emission effects accompanying the splitting of alkali metal halide crystals.[54] The electrically charged walls of the growing crack represent a rapidly separating capacitor, in the field of which the velocity of the electrons and ions leaving the surface is increased. The accelerated particles bombard the opposite wall of the crack, producing excitons; some of the excitons decay with the ejection of a free cation. The cation is accelerated by the field of the capacitor, bombards the opposite wall of the crack, etc. The consequences of the individual stages, that is the emission of accelerated electrons (Deryagin effect), exciton luminescence, the emission of excited cations, and the appearance of radiation defects on the walls of the crack, have been detected by various methods.[51,52,70,71]

IV. DEFORMATIONAL MOBILITY AND THE KINETICS OF DIFFUSION-CONTROLLED REACTIONS

During the deformation of solids, different forms of mobility are excited. These include both the usual forms of thermal motion, but mechanically activated, and also purely mechanical deformational mobility. In the first case, the mobility is clearly activational in character, and the movement of particles requires that an energy barrier be overcome. In the second case, the motion is practically athermal, and the contribution of thermal fluctuations to the mobility is negligible compared with the role of internal stresses. The movement of dislocations and grain boundaries can be classified as deformational mobility.

Familiar examples of the mechanical activation of thermal motion include ascending diffusion, diffusion creep, diffusion along dislocations, etc. The role of super-equilibrium defects in activated diffusion has been less extensively studied. For the vacancy mechanism, the diffusion coefficient is directly proportional to the concentration of vacancies. For many materials at room temperature this is negligible, but it may be increased sharply by mechanical treatment, reaching 10^{16}–10^{17} g^{-1}.[20,44] The diffusion coefficient is also increased by many powers of ten. This effect is apparently important for the mechanical activation of sintering processes.

At a concentration of vacancies of ~10^{17} g^{-1}, a solid is saturated by defects to almost the same extent as on fusion, when there is one vacant site for every 10^3–10^4 atoms in lattice sites. This state differs from fusion in that it is produced at a comparatively low temperature, when jump-over by the atoms is difficult. As the deformation develops, however, this restriction is removed, since the internal stresses lower the barrier to jump-over. Thus the state of a substance at the moment of intensive deformation can be represented as "cold fusion". This terminology is already encountered in the literature.[72]

The mechanical mobility of a structure should also be revealed in the kinetics of chemical reactions. The relationship between reaction rate and molecular mobility is one of the basic characteristic features of chemical reactions in solids. The mobility produced by internal stresses is no exception to this rule.

A convenient system for the study of the mobility of a structure subjected to different mechanical treatments may be provided by diffusion-controlled completely frozen reactions between particles which are distributed in a solid matrix and which do not react with one another only because of the absence of mobility. These processes include so-called static reactions between adjacent particles, for example between radicals in pairs or between a radical and a neighbouring molecule of the matrix, and also reactions between particles situated at an appreciable distance from one another, for example the recombination of radicals or charged centres. It has been established experimentally that reactions of both types are much more intensive in a deformed material.[72–76]

To determine how the rate of a chemical reaction is related to the development of deformation, and to estimate the work done in bringing about a reaction, quasi-monomolecular statistical reactions and bimolecular diffusion-controlled reactions in systems with frozen translational mobility are examined separately below.

1. Statistical Pseudo-monomolecular Reactions

The mechanical intensification of reactions between adjacent particles has been observed in dilute frozen solutions of polymers at 80 K.[73] Mechanical treatment was accompanied by degradation of the macromolecules P with the formation of radicals $R^{\bullet}$ and their secondary reactions with molecules of the matrix: hydrogen atom donors HX or the monomer M:

$$P \rightarrow R^{\bullet} \qquad (2)$$

$$R^{\bullet} + HX \rightarrow RH + X^{\bullet} \qquad (3a)$$

$$R^{\bullet} + M \rightarrow RM^{\bullet} \ . \qquad (3b)$$

The extent of the transformation in replacement (3a) or addition (3b) reactions was followed by EPR. Fig. 7*a* shows the changes in the concentration of the radicals $R^{\bullet}$ (curve *1*) and $RM^{\bullet}$ (curve *2*) and the total concentration $R^{\bullet} + RM^{\bullet}$ (curve *3*). On prolonged mechanical treatment of the specimens, reactions (3a) and (3b) were accompanied by the disappearance of the radicals, and when this process stopped, the reactions stopped. The curves giving the change in the concentrations of the radicals $R^{\bullet}$, $RX^{\bullet}$, or $RM^{\bullet}$ during the mechanical treatment of the powders were used to calculate the rates of the free-radical replacement and addition reactions at 80 K. The rates of most of the addition reactions studied corresponded, to within a factor of 10–100, to the value extrapolated to 80 K using the Arrhenius equation with the parameters k_0 and E characteristic of the liquid phase. The method involving the

mechanical treatment of frozen solutions has been used to compare the reactivities of various radicals and molecules at low temperatures.[73]

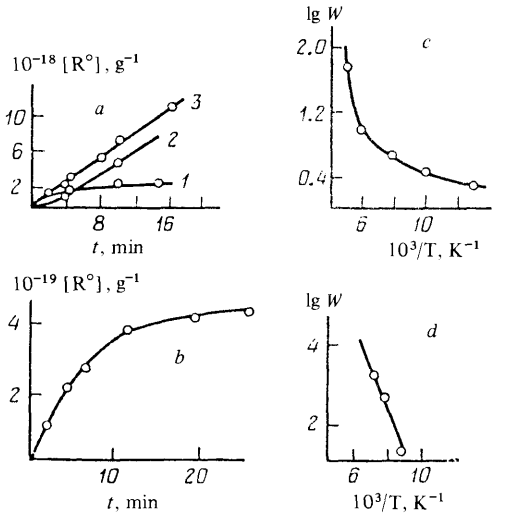


Figure 7. Free-radical reactions during the mechanical treatment of polymers (*b*) and their solid solutions (*a*, *c*, *d*);[73,77,81] rate of supply of mechanical energy in the range 1–10 W g^{-1}; *a*) addition of $\sim CH_2\dot{C}(CH_3)COOCH_3$ radicals to tetrachlorobenzoquinone at 80 K; *b*) formation and disappearance of free radicals in polystyrene at 80 K; *c*) replacement $R^{\bullet} + CH_2(COOH)_2 \rightarrow RH + \dot{C}H(COOH)_2$; *d*) addition $R^{\bullet} + CH_2{=}CH(C_6H_5) \rightarrow R{-}CH_2\dot{C}H(C_6H_5)$.

As an illustration, Fig. 7 compares the results of measurements of the rates (w) of mechanically intensified reactions involving the transfer of a hydrogen atom and addition (Fig. 7*d*) over a wide temperature range.[59] The temperature coefficient of the addition reaction in the frozen solutions is close to the activation energy of this reaction in the liquid phase (Fig. 7*d*). For the replacement reaction (Fig. 7*c*), the Arrhenius law is not observed, since at a low temperature, the transfer of a hydrogen atom takes place by a tunnelling mechanism.

A rigorous description of the kinetics of mechanically intensified random reactions was recently carried out[78] using the concept of the mechanical movement of kinetically non-uniform systems in which there is a wide distribution of reaction centres with respect to reaction rate constants. In solids at a low temperature, when the mobility is frozen, the non-uniformity is due to differences in the nature of the immediate environment of the particles.[79]

Under ordinary conditions, the relative arrangement of the particles remains unchanged during the reaction, and the function $n(k)$ characterising the distribution of the particles with respect to the rate constants remains constant; the reaction leads to gradual "burn-out" of the fractions of the distribution with rate constants close to the maximum value k_{max}. Deformation influences the structure of the immediate environment of the particles and displaces the reaction system, restoring the burnt-out "rapid" fractions. As a result, a varying distribution of the particles with respect to rate constants $n(k, t)$ is established, depending on the frequency of the mechanical displacement ν and the time t.

The number of particles in an arbitrarily selected fraction of the current distribution with respect to rate constants $n(k, t)$ is determined by the ratio of the rates of three processes:[78]

$$\frac{d}{dt}\{n(k, t)\} = -kn(k, t)\,dk - \nu n(k, t)\,dk + \nu N(t)\,\frac{n(k, 0)\,dk}{N(t)} \quad .$$

The first two terms characterise respectively the loss of particles from the fraction as a result of the reaction with rate constant k and mechanical displacement with frequency ν. The third term describes the replenishment of the fraction k as a result of a redistribution of the particles from other fractions on mechanical displacement: of the total flux $\nu N(t)$, where $N(t)$ is the current concentration of particles, only the fraction $n(k)dk/N(t)$ corresponding to the contribution of this fraction to the current concentration $N(t)$ enters the fraction k.

Under conditions of intensive displacement, the current distribution function $n(k, t)$ does not differ greatly from the original function $n(k)$, since for $\nu \ll k_{max}$ the loss of the rapidly burnt-out fractions is immediately made good by replacement; the rate of the process is therefore described by the equation for a first-order reaction

$$-\frac{dN(t)}{dt} \approx k_{max}\frac{N(t)}{\ln(k_{max}/k_{min})}$$

but the effective concentration is lower than the total concentration by a factor of $[\ln(k_{max}/k_{min})]^{-1}$. The factor $[\ln(k_{max}/k_{min})]^{-1}$, determined by the width of the hyperbolic distribution of the particles with respect to rate constants,[80] takes account of the fact that the reaction develops only as a result of the particles in that part of the distribution adjoining k_{max}. In other words, in spite of strong displacement, the reaction rate remains slower than the maximum possible.

Thus intensive mechanical displacement moves a slow reaction, retarded because of the absence of mobility, into conditions close to kinetic. On less intense mechanical treatment, or in a reaction system with high values of k_{max}, when $k_{max} > \nu > k_{min}$, the observed rate constants are determined by the frequency of the displacement:[78]

$$-\frac{dN(t)}{dt} = \nu\frac{\ln(k_{max}/\nu)}{\ln(\nu/k_{min})}N(t) \quad .$$

2. Bimolecular Reactions

The displacements of structural elements, associated with the development of a deformation, through distances which are large compared with the lattice parameters can readily be detected from the intensification of reactions involving the recombination of radicals (by EPR) or charged centres (from the luminescence). Bimolecular reactions of this type have been observed during the mechanical treatment of polymer powders in mills,[73,74,81,82] during the plastic deformation of substances on Bridgman anvils,[6,11,12] during the monoaxial elongation of polymer films,[75,76] in the shear deformation of alkali metal halide crystals,[83] and in other systems.

The limit of the accumulation of active centres during the mechanical treatment of solids is related to deformational recombination. This phenomenon has been detected during the subdivision of polymer and quartz powders, and its essential feature is that the number of free radicals at first increases according to a linear law, but after some time their

accumulation stops, in spite of the fact that the mechanical degradation continues at a constant rate[74] (see Fig. 7*b*). During fine subdivision, work is done chiefly to deform the shape of the particles of the powder and in friction. For polymers, for which the yield stress is low ($\sim 10^7$ N m^{-2}), even under comparatively mild dispersal conditions, for an energy intensity of 0.1–1.0 J g^{-1} s^{-1}, bulk deformation conditions are produced, that is the mechanochemical transformations are due chiefly to plastic deformation of the particles, and not to their splitting or to friction against one another.

For solid quartz powders under the same conditions, friction takes place.[26] The deformation is localised in a thin layer of the particles next to the surface, and all the active centres are concentrated on the surface and accessible to molecules from the gas phase. For solid materials, the change from surface deformation (friction) conditions to bulk deformation conditions is possible when there is a decrease in the particle size[46] or a sharp increase in the energy intensity.[84]

Bulk and surface deformations lead to the rupture of chemical bonds and the migration of radicals, and hence to their encounter and disappearance. Migration may be due either to the direct displacement of the structural elements with localised active centres or to the breakdown of macroradicals with the subsequent diffusion of low-molecular fragments, or to various relay mechanisms, such as the gliding of dislocations or the displacement of free-radical states to the quartz surface according to scheme (1).

Thus the current concentration of defects such as radicals or other active centres during mechanical treatment is determined by the competition between the processes of their formation and disappearance.

The formation of defects is characterised by the magnitude of the energy yield $G_M(R^\bullet)$, which is determined from the slope of the initial section of the accumulation curve (see Fig. 7*b*). On the stationary section, where the concentration of defects is equal to the limiting concentration $[R^\bullet]_\infty$, the energy yields for their formation $G_M(R^\bullet)$ and disappearance $G_M(-R^\bullet)$ are equal to one another.

Table 2. The energy yield and the limiting concentrations of free radicals during the mechanical treatment of powdered polyethylene and quartz (calculated from published data[15,74,81]).

Substance	Degradation conditions	G_M, mole MJ^{-1}	$[R^\bullet]_\infty$	σ, N m^{-2}
Polyethylene	volume deformation	$\sim 10^{-3}$	~ 10 mole m^{-3}	$\sim 10^7$
Quartz	friction	$\sim 10^{-3}$	$\sim 10^{-7}$ mole m^{-3}	10^9–10^{10}

The values of the parameters $G_M(R^\bullet)$ (to within an order of magnitude) and $[R^\bullet]_\infty$, characterising the processes involved in the formation and disappearance of radicals during the mechanical treatment of polyethylene and quartz in a vibration mill (intensity ~1 W g^{-1}), are given in Table 2. Unfortunately, these parameters cannot be estimated for other materials, since the appropriate papers do not give the expenditure of mechanical energy.

Plastic deformation may be homogeneous and cover the entire volume of the substance. The softer the material and the greater the load, apparently, the closer the dynamics of mechanochemical transformations are to this homogeneous model. Much more frequently, however, plastic deformations develop in local zones: in the glide planes of dislocations, in the layers between crystallites, in shear bands, etc. The micro-heterogeneity of the development of deformation is clearly revealed in the processes involved in the disappearance of radiation defects as a result of deformation. Thus when there is appreciable shear deformation of γ-irradiated alkali metal halide crystals, only 5–10% of the defects, situated in the glide planes of the dislocations, disappear.[83] During the monoaxial elongation of polymer films, ~50% of the radiation-induced radicals disappear.[75] In the binary systems hydrocarbon–halogen, etc., γ-irradiated at a low temperature, slight initial deformation initiates a chain reaction covering ~1/4 of the volume of the substance;[85,86] the chain process apparently develops according to the following scheme: deformation–reaction with a change in volume–shrinkage deformation–reaction etc.

Displacement within the entire volume of a substance at the molecular level has been observed during the mechanical treatment of powders in mills, where the particles are subjected to repeated impact. Under these conditions, practically all the radicals produced by γ-irradiation in polymers disappear,[78] but the mechanochemical reaction of metals with halogens, sulphur, selenium, or tellurium takes place explosively.[87]

The nature of the relationship between deformation and the yield of a bimolecular reaction depends on the mechanisms of the development of the deformation and the migration of the reaction centres. The dynamics of the development of a reaction in the glide plane of dislocations can be considered first: a geometric model of the process is shown in Fig. 8*a*. Moving from left to right, the dislocation covers all the reaction centres in the glide plane, and they react with one another in a narrow zone close to its centre.

The change in the concentration of reaction centres on the dislocation line (n_L, m^{-1}) as it moves in the direction x is given by the relationship

$$\frac{dn_L}{dx} = (1 - r_0 n_L) n_s - r_0 n_L n_s$$

where r_0 is the capture cross-section radius, and n_S the concentration of centres in the glide plane of the dislocation, m^{-2}. In all cases, $n_L = bn_S$ and $n_S = bn$, where b is the lattice parameter, and n the volume concentration of reaction centres, m^{-3}. For $L = 1$, the product $r_0 n_L$ characterises the degree of filling of the dislocation line by reaction centres, the first term corresponds to the fraction of centres captured on the free sections of the dislocation line, and the second term corresponds to the number of collisions leading to reaction and the liberation of centres from the dislocation line. The expression for the current concentration of centres on the moving dislocation line has the form:

$$n_L(x) = \frac{1}{2r_0}\{1 - \exp(-2r_0 n_s x)\} + n_0 \exp(-2r_0 n_s x) .$$

The number of centres disappearing on collision with a dislocation is given by

$$-dn_L = 2r_0 n_L(x) n_s dx .$$

Substituting the function $n_L(x)$ and integrating gives

$$\Delta n = n_s x - \frac{1}{2} n_\infty \{1 - \exp(-2r_0 n_s x)\} .$$

This equation describes the development of the bimolecular reaction in the glide plane of a dislocation. Initially, in the acceleration section, the reaction centres accumulate on the

dislocation line; after the limiting concentration of centres $n_{\infty,L}$ (equal to half the number of positions on the dislocation line) has been reached, stationary reaction conditions are established, when all the centres appearing react immediately. The distance x_{cr} at which the change in conditions takes place is $x_{cr} \cong n_{\infty,L}/n_s$. When the critical mean free path is greater than the average distance between dislocations, the most favourable conditions for the reaction, for which $\Delta n \cong n_s x$, cannot be established, since the dislocations will arrive too early at an area free from reaction centres.

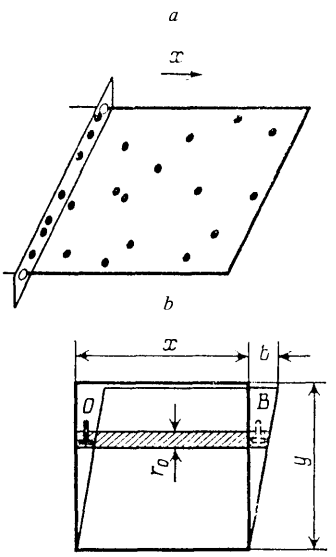

Figure 8. Diagrams explaining the development of a bimolecular reaction in the glide plane of a dislocation (for explanation see text).

To estimate the energy yield of a bimolecular reaction stimulated by the movement of dislocations, Fig. 8*b* can be considered. The volume V corresponding on the average to one dislocation and equal to $V = xy : 1$, is outlined by the continuous line in Fig. 8*b*. Under the influence of the shear stress σ, the dislocation is displaced from the position O to the position B, at the boundary of the volume V, which is equivalent to a displacement of all the substance above the glide plane by an amount equal to the lattice parameter b. The relative deformation ε is then given by $\varepsilon = b/y$. The work A done by the shear force in the path b is equal to $A = \sigma b x . 1$, and the number of particles Δn reacting in the path x in the glide plane of the dislocation is equal to $\Delta n = n r_0 x . 1$. Since the path x is the average distance between the dislocations in the glide plane, paths whose length is greater than x will be "superfluous". Under the most favourable conditions, the energy yield of the reaction G_M is given by the expression:

$$G_M = \frac{\Delta n}{A} = \frac{r_0 n}{b\sigma} \quad \text{or} \quad G_M \simeq \frac{n}{\sigma_y} \ .$$

In the last relationship it is assumed that $r_0 \cong b$, and that the stress σ is close to the yield stress σ_y.

For $\sigma_y \cong 10^7$ N m^{-2} and $n = 10^2$–10^3 mole m^{-3} (which corresponds to a number of centres ~10^{20} cm^{-3}), the energy yield may reach 10–100 mole MJ^{-1}, that is in the example being considered, the work done in carrying out the reaction should be comparable with the heat required to fuse the reaction system.

The energy yield of the reaction when the deformation develops by a slip mechanism can be estimated similarly. When the atom planes slip relative to one another, the particles of one plane encounter particles situated in the other. To a first approximation it can be assumed that for a relative displacement of the planes through a distance Δl, the number of reacting particles in unit area is given by:

$$\Delta n_s = r_0 \Delta l n_s^2 \quad \text{or} \quad \Delta n = r_0 b \Delta l n^2 \ .$$

The work A done in the displacement of the planes relative to one another is equal to $A = \sigma \Delta / b$, and the energy yield of the reaction $GM(-R^{\bullet})$ is given by

$$G_M(-R^{\bullet}) = \frac{\Delta n}{A} = \frac{V_0}{\sigma} n^2 \ .$$

Here, the product $r_0 b^2$ is taken as equal to the reaction volume V_0. In contrast to the dislocation mechanism, in the case of the slip mechanism the energy yield is directly proportional to the square of the concentration of centres. A similar relationship will be observed when there is external friction:

$$G_{fr}(-R^{\bullet}) = \frac{r_0}{\sigma_{fr}} n_s^2 \ .$$

Here, the tangential stress σ_{fr} is equal to $\sigma_{fr} = \mu p$, where μ is the coefficient of friction, and p the normal pressure.

In internal and external friction, the free radicals are formed at the point of rupture of the bonds and disappear. Under stationary conditions, the yields of the formation $G_M(R^{\bullet})$ and disappearance $G_M(-R^{\bullet})$ of radicals are equal to one another, and the concentration is equal to the limiting value $[R^{\bullet}]_{\infty}$. Since for polyethylene and quartz, $G_M(R^{\bullet})$ and $[R^{\bullet}]_{\infty}$ are known (see Table 2), it is possible to estimate the magnitude of the tangential stresses under the conditions of the mechanical treatment of the powders. The results of the estimates are given in the last column of Table 2. In the calculations it was assumed that $r_0 \cong 3 \times 10^{14}$ m mole^{-1}, and $V_0 \cong 1 \times 10^4$ m^3 mole^{-1}. In polyethylene, the stresses are of the same order of magnitude as the yield stress (10^7 N m^{-2}), whereas in quartz they are 10^2–10^3 times greater.

Under real conditions, the energy yield may be influenced by several factors. In the first place, the probability of the reaction when the particles meet may be less than unity. Next, to complete the reaction it is necessary to have plastic deformation of the entire volume of the crystal, and not merely the regions adjoining the glide planes, so that the stresses should be much greater than the yield stress. Finally, under real conditions it is difficult to avoid superfluous displacement of the dislocations, and superfluous deformation. Nevertheless, deformation recombination provides a convenient and informative method for studying the processes involved in the development of deformation; the first studies in this direction have already been carried out.[83]

---o0o---

Mechanical stresses, like ionising radiation and other physical methods of acting on a substance, initiate and accelerate chemical reactions. In photochemistry and in radiation chemistry, the energy quanta interacting with a

substance are comparable to or greater than the strength of the chemical bonds, so that the chemical action of the radiation is natural. In mechanochemistry, on the other hand, the average level of the elastic potential is usually very low, and the possibility of the production of chemical effects is not always obvious; it is therefore necessary to assume that mechanisms for concentrating the energy exist. One of the principal ways in which the elastic energy can be concentrated is by the formation of structural defects.

The production of vacancies and interstitial atoms, dislocations, and internal and external surfaces of separation by various treatments reflect a general tendency shown by crystals to transform energy supplied from outside into the energy of crystal lattice defects. On thermal treatment, Frenkel defects are stabilised in crystals; the energy used in their formation is compensated by the increase in the configurational entropy of the crystal when vacancies and (or) interstitial atoms are produced in its volume.

In exactly the same way, in the elastic deformation of a crystal, the state of the crystal in which the dislocations or other defects at which the excess energy is concentrated are distributed in the volume is theremodynamically more favourable than the state in which there is a uniform distribution of the elastic stresses throughout all the interatomic bonds. The stabilising factor in this case also is the contribution of the configurational entropy S_c to the free energy of the crystal. Since $S_c = k \ln W_D$ (where W_D is the thermodynamic probability of the crystal with defects, equal to the number of ways in which these defects can be arranged in the lattice sites), the increase in free energy on production of the defects is given by:

$$\Delta F = F_D - F_0 = -kT \ln W_D .$$

Here, F_0 is the free energy of the elastically deformed crystal, and F_D the same for a crystal in which all the energy of deformation is concentrated in structural defects.

Thus the tendency for the excess energy to be concentrated in structural defects is a characteristic feature of the crystalline state of a substance. The nature of mechanochemical transformations is to a considerable extent related to this characteristic feature of solids.

It follows from the experience gained in mechanochemistry, and partly reflected in the present review, that the production of defects and the subsequent production of structural disorder are unavoidably accompanied by a perturbation of the electronic sub-system of a substance, ionisation, various relaxation processes, and excitation of the mobility of the structure; this provides the means by which mechanical stresses have an effective action on the reactivity of solids.

Regular Kinetic Features of the Dissolution of Metal Oxides in Acidic Media

I.G.Gorichev and N.A.Kipriyanov

A comparative analysis of experimental data and theories interpreting the regular kinetic features of the dissolution of metal oxides in acids has been carried out. Theories of the conjugated transfer of the cations and anions of the oxide to the electrolyte solution do not explain the results obtained. The regular kinetic features of the dissolution of oxide phases have been interpreted for the first time on the basis of the present-day theory of semiconductors, electrochemical concepts, and models of heterogeneous kinetics. The proposed electron-proton mechanism explains all the available data on the kinetics of the dissolution of oxides in mineral acids and complexones.
The bibliography contains 214 references.

I. INTRODUCTION

The intensification and optimisation of the processes involved in the etching of metals, the extraction and concentration of ores, and the removal of deposits from thermal power engineering equipment represent an important scientific and technical problem, requiring a knowledge of the mechanisms of these processes. In the present review, the complex character of the dissolution processes is demonstrated for the case of the reaction of metal oxides with aqueous solutions of various acids, for which the data on the kinetics and mechanism have not yet been adequately reviewed. A deeper analysis of the regular kinetic relationships obtained has been carried out using present-day electrochemical concepts, the zone theory of oxides, and heterogeneous models of the dissolution of oxide phases in acidic media.

The kinetics of the dissolution of metal oxides in electrolytes is influenced by the physicochemical properties of both the semiconducting oxides (the degree of covalent character of the bond, the presence of defects in the crystal lattice, the concentration of alloying additives, the crystallographic orientation of the active surface of the crystal, the nature of the active centres, the specific features of the surface states, which differ considerably from the states in the volume of the solid phase) and the solutions (concentration, pH, redox potential, presence of complex-forming reagents).

The existing reviews on this topic[1-16] do not cover the sources completely. An exhaustive analysis of data on the influence of ionising radiation on the kinetics of the dissolution of solids has been carried out.[5,17] The present review systematises the theoretical aspects of the kinetics of the dissolution of oxide phases. Electrochemical concepts have been used to explain many kinetic parameters (the order of the reaction with respect to different ions of the electrolyte), and the influence of oxidising agents, reducing agents, complex-forming reagents, and the adsorption of protons. For the quantitative calculation of the kinetic parameters of dissolution, the experimental data have been treated using present-day theories of the kinetics of heterogeneous processes. It has been shown that morphological models not only make it possible to take account of the change with time in the surface area of the dissolving oxide, but also help to explain the comparatively high activation energy of the dissolution of oxide phases in acids.

II. ANALYSIS OF THE KINETIC CURVES FOR THE DISSOLUTION OF METAL OXIDES IN ACIDIC MEDIA

1. Form of the kinetic curves. The typical form of the curves for the dissolution of powdered oxide specimens as the plots of the fraction of the dissolved substance α against the time t is shown in Fig.1. In the general case, the rate of dissolution $\partial\alpha/\partial t$ passes through a maximum (at $\alpha \cong 0.5$ to 0.7).[2,18-20] The section corresponding to the decrease in the rate of dissolution is difficult to analyse, since it depends to a marked extent on the characteristic features of the size distribution of the particles at this stage of the process.

2. Analysis of the curves for the dissolution of metal oxides in acids on the basis of affine transformations. The method of affine transformations[9,21,22] makes it pcssible to determine whether changes in the mechanism (stages) of a process are due to a particular factor influencing the rate of dissolution. If the kinetic curves corresponding to different values of any parameter are reduced to a single scale relative to the time $t/t_{0.5}$ (Fig.2), the sequence of stages in the dissolution process is assumed to be always the same from the start to the end of the reaction; the rate of the process is limited by a single stage, and not by several stages. This makes it possible to represent the rate of dissolution ($\partial\alpha/\partial t$) in the form of a function with separable variables

$$\partial\alpha/\partial t = f(T, a_{H^+}, E) \cdot f(\alpha) \qquad (1)$$

where $f(T, a_{H^+}, E) = (\partial\alpha/\partial t)_{sp}$ is the specific rate of dissolution corresponding to unit surface area of the specimen; and $f(\alpha)$ is a function reflecting the nature of the change in

the surface area of the specimen in this process. Change in the variables, T, E, and a_{H^+} influences the time taken to reach a definite fraction (α) of dissolved oxide, whereas the morphology of the surface of the specimen remains unchanged for different successive values of α.[21]

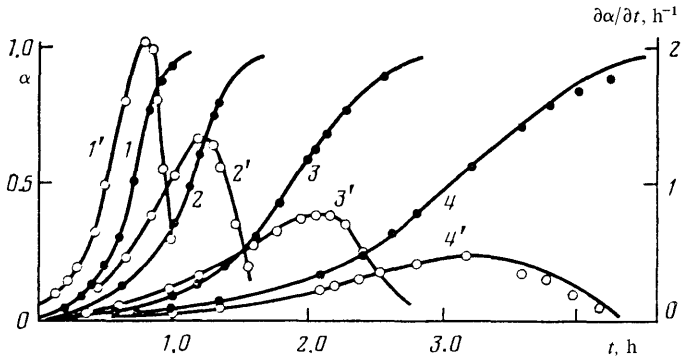

Figure 1. Time dependence of the fraction (α) of dissolved oxide CuO (*1*–*4*) and the specific rate $\partial\alpha/\partial t$ (*1'*–*4'*) of the dissolution of this oxide in aqueous H_2SO_4 solutions with different pH values at an electrolyte temperature of 25 °C; *1*) 0.43 (k_i = 7.37 h^{-1}); *2*) 0.65 (k_i = 3.65 h^{-1}); *3*) 0.85 (k_i = 2.14 h^{-1}); *4*) 1.05 (k_i = 1.34 h^{-1}). Points—experiment; lines—calculation using Eqn.(52), where $A = 0.022$.[166]

3. The theory of the specific rate of dissolution of oxide phases proposed by Nernst. In the literature up to the present, the specific rate of dissolution of crystals (1) has been calculated using the mathematical expression proposed by Nernst and Noyes.[23] The unsatisfactory features of the calculation of the specific rate of dissolution using Nernst's theory can be demonstrated. It follows from Nernst's theory[23] that the diffusion of the ions in the boundary layer of an electrolyte at the surface of separation with an oxide is the limiting stage of the dissolution of the solid

$$(\partial\alpha/\partial t)_{sp} = D(c_{sat} - c)/V \cdot \delta = k_1(1-\alpha) \qquad (2)$$

where D is the diffusion coefficient of the ions, c the concentration of the salt in the volume, c_{sat} the concentration of the salt in the saturated solution, V the volume of solution, and δ the thickness of the electrical double layer. Since Eqn.(2) does not make possible a complete description of all the regular kinetic features of dissolution, use is made of an expression of the form

$$(\partial\alpha/\partial t)_{sp} = k_2(c_{sat} - c)^n \qquad (3)$$

where n and k_2 are independent of the hydrodynamic conditions. According to Eqn.(3), the driving force of the dissolution is the difference between the salt concentrations ($c_{sat} - c$).

The unsatisfactory features of Eqns.(2) and (3) include the fact that they cannot explain the high value of the activation energy (65–85 kJ $mole^{-1}$). For a process taking place in the diffusion range, its value is 15–20 kJ $mole^{-1}$. In practice, Eqns.(2) and (3) are applicable in rare instances, since the values of k_1 and k_2 depend on the dissolution time and on the states of the volume and surface phases. Eqns. (2) and (3) describe the distribution of the concentration of the dissolved substance at a definite distance from the boundary of the solid phase, but they do not reflect the changes in concentration with time.[2] The data in Ref.24 were obtained with vigorous stirring of the electrolyte, when further increase in the rate of movement of the particles had no influence on their rate of dissolution; under these conditions, the equation of diffusion kinetics is not applicable. Kabai[24–27] modified Eqns.(1) and (3) and obtained the expression

$$\alpha = c/c_\infty = 1 - \exp[-(kt)^\gamma] \qquad (4)$$

where γ is a constant which depends on the nature of the system. Detailed verification of Eqn.(4) shows that it is inapplicable even for $\gamma = 1$.

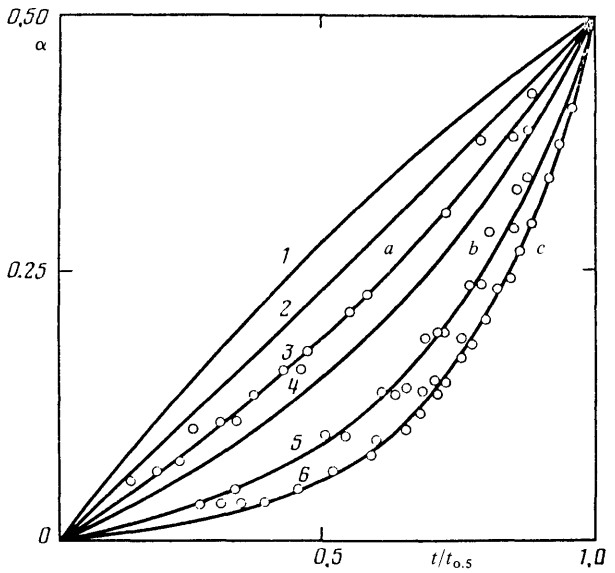

Figure 2. Dependence of the fraction of dissolved magnetite on the reduced time $t/t_{0.5}$ in aqueous solutions of H_3PO_4 (*a*), EDTA (*b*), and HEDP (*c*) under different experimental conditions (concentration, temperature, pH). Lines—calculation using Eqn.(52) for different values of A: *1*) $A = 10$; *2*) $A = 0.45$; *3*) $A = 0.20$; *4*) $A = 0.10$; *5*) $A = 0.025$; *6*) $A = 0.010$. Points—experimental data for different experimental conditions.

In the early nineteen-fifties, experimental data were obtained,[2] showing that these ideas cannot be used to describe the regular kinetic features of the dissolution of metal oxides, since analysis of the dependence of the specific rate of dissolution of oxide phases in acids on various factors established that it is determined by the concentration gradients of the protons and electrons (potential) and the stoichiometric composition of the solid phase, and this is not reflected in Eqns.(2) and (3). An explicit mathematical expression describing the specific rate of dissolution of oxides has not yet been found.

III. THE STRUCTURE OF THE ELECTRICAL DOUBLE LAYER AT THE OXIDE/ELECTROLYTE BOUNDARY AND THE DISTRIBUTION OF CHARGE AND POTENTIAL IN IT

In the dissolution of non-stoichiometric oxides (wustite, magnetite, uraninite, cobalt(II) oxide, pyrolusite, nickel(II) oxide, tenorite, and other oxides), the rate of the process depends on the potentil difference (Fig.3), since this process is determined by the rate of the transfer of ions through the electrical double layer.[2,3,28,29] It is possible to distinguish increases in the rate of dissolution due to the reduction (MnO, Mn_2O_3, MnO_2, Fe_2O_3, Fe_3O_4, FeO) and due to the oxidation (NiO, Cu_2O, UO_2) of the surface layers of the oxides.[2,3,30,31]

1. Nature of the Potential at the Oxide/Solution Boundary

When an oxide is brought into contact with a solution, an electrical double layer is produced at the oxide/electrolyte boundary (Fig.4). The total decrease in the potential (E) relative to the potential of the corresponding reference electrode (E^0) is given by

$$E=E_{sc}+E_H+E_{el}+E^0$$
