The Present State and Prospects for the Development of the Field of Polycondensation

V.V.Korshak

The aim of the review is to survey and examine data obtained in recent years and characterising the progress in the field of the synthesis of polymers by polycondensation methods. The rule of functionality is shown to have limited applicability and a new formulation, taking into account the structure of the monomers and the reaction conditions, is proposed.
It is also shown that the rule of the non-equivalence of the functional groups does not hold solely in equilibrium polycondensation reactions and that the polymers obtained by polycondensation methods are of the heterounit type. The ways in which anomalous units are formed and the influence of the heterounit structure on the set of properties of the polymer synthesised have been established. Data on the kinetics and mechanism of non-equilibrium polycondensation are considered.
The great importance of catalysis in polycondensation reactions as one of the most significant factors governing progress in this field is demonstrated. Methods for the synthesis of conformationally regular polymers have been discovered by studying acceptor-catalytic polycondensation.
A significant influence of solvents on polycondensation processes has been demonstrated. The characteristic features of joint polycondensation involving non-equilibrium reactions, the prospects for the further development of polycondensation processes, and the possible future of polymers obtained in this way are examined.
The bibliography includes 215 references.

I. INTRODUCTION

The field of polycondensation has been developing at a rapid rate at the present time and the manufacture of polymers obtained by polycondensation methods has been expanding. The development of research into processes involving the synthesis of polymers by polycondensation methods has enriched polymer science in polymer formation reactions and numerous new polymers and has made it possible to understand the mechanism of polycondensation processes[1].

The aim of the present review is to indicate the advances made at the present time in the polycondensation methods for the synthesis of polymers. Clearly it is quite impossible to describe the development of this enormous field within the framework of a single article. Recognising this, the author's aim was to attempt the more modest task of demonstrating in relation to individual examples the advances made in this field and of indicating the principal trends in the development of polycondensation synthesis.

Since the time when Berzelius proposed the concept of polymers and Gay-Lussac and Pelouze obtained the first synthetic polyester by the polycondensation of a hydroxy-acid, 150 years have elapsed[2]. This was followed by the publication of communications concerning the syntheses of various polymers by polycondensation processes. Thus Liebig[3] obtained an acetaldehyde resin in 1835, Berzelius[4] synthesised the first branched polyester in 1847, and Butlerov[5] obtained polyformaldehyde in 1859 by the condensation of methylene iodide. In 1872 Bayer[6] achieved for the first time the synthesis of a phenol-formaldehyde polymer, which served as the basis for studies by many investigators. In 1909–1912 Baekeland[7] and Petrov[8] created on this basis the manufacture of phenol-formaldehyde polymers (bakelite and carbolite).

The studies by Carothers[9] on the polycondensation of dicarboxylic acids with diamines and glycols constituted an important stage in the development of polycondensation. The discovery of polysiloxanes by Andrianov in 1937 [10] led to the appearance of a new branch of polycondensation, namely the synthesis of polymers with inorganic main molecular chains[11]. In subsequent years there was a growth of the number of studies in the field of polycondensation[1,12–15].

Table 1 lists the names of individual types of polycondensation and the dates of their discovery.

Table 1. Polycondensation processes.

Name of reaction	Year of discovery	Refs.	Name of reaction	Year of discovery	Refs.
Equilibrium polyesterification	1833	[2]	Polyrecombination	1957	[22]
Polyamidation	1862	[16]	Oxidative polycondensation	1960	[23]
Phenol-aldehyde polycondensation	1872	[6]	Polycyclocondensation	1960	[24]
Polyazination	1889	[17]	Conformationally specific polycondensation	1960	[25]
Interfacial polycondensation	1898	[18]	Condensation polydisproportionation	1972	[26]
Polyheterocyclisation	1908	[19]			
Polycoordination	1953	[20]			
Acceptor-catalytic polycondensation	1956	[21]			

Thus one may note that polycondensation, as a fundamental synthetic process, has now provided science and technology with an enormous number of polymeric structures and has played an important role in the formulation of the fundamental ideas of polymer science[12–15]. It must be emphasised that it is also very important as a method of synthesis of natural polymers, because many of the most important biopolymers such as proteins, nucleic acids, natural rubber, cellulose, starch, glycogen, chitin, pentosans, and many others, as well as enzymes and hormones are evidently formed in living organisms via various polycondensation processes[1].

II. INDUSTRIAL PRODUCTION OF POLYCONDENSATION POLYMERS

The role of polycondensation in industry is now very considerable. It needs to be said that in general the plastics industry arose in its time as an industry based on the employment of polycondensation processes and only subsequently polymerisation processes began to develop to an increasing extent. The first synthetic industrial products were phenol-formaldehyde polymers synthesised in 1909–1912 by Baekeland and Petrov, after which glyptals and in 1920 carbamides were developed. Polymerisation polymers were produced on a large scale as early as the 1930's. At the present time polycondensation polymers also play a considerable role in the plastics and artificial fibres industry. Table 2 illustrates the world production of the most important polycondensation polymers[27–29]. It shows that the production of polycondensation polymers has doubled each 10 years. Data are listed only for the four leading polymers in this field, because the others, whose number is fairly large, make a much smaller contribution to industrial production. They include alkyd polymers, polycarbonates, polyarylates, epoxides, polyorganosiloxanes, poly(phenylene oxides), polyimides, etc. The polymers obtained by polycondensation methods occupy a fairly major place in the overall production of polymers.

Table 2. The world production of the most important polycondensation polymers (in thousands of tonnes).[27–29]

Name	Years		
	1960	1970	1980
Foam plastics	700	1600	2500*
Polycarbamides	600	2050	2560*
Polyamides	406	1897	3125
Polyesters	123	1643	5132
	1829	7190	13317
Total growth of production, %	100	393	728

*Data for 1979.

It needs to be said that, when polymers are subdivided into polymerisation and polycondensation types, one must always bear in mind the fact that such subdivision is to a large extent conventional not only as regards the meaning given to these terms but also because there exists at present an increasing group of polymers, which are obtained as a result of the simultaneous employment of polymerisation and polycondensation reactions. These include, for example, unsaturated polyesters, which are obtained in the first stage via polycondensation reactions, while in the last stage they are hardened by polymerisation processes involving their double bonds. Polyester urethanes are likewise obtained as polycondensation products in the first stage in the form of branched polyesters, which undergo joint polymerisation with di-isocyanates in the subsequent stage.

III. CERTAIN CHARACTERISTIC FEATURES OF POLYCONDENSATION

Polycondensation processes differ significantly from polymerisation processes. In the first place attention should be drawn to the greater universality of polycondensation

processes and the wide variety of the structures which can be obtained with their aid. The structures obtained by polymerisation processes are less varied. Among polycondensation polymers, there is a large group of polymers distinguished by a high thermal stability and strength, electrically conducting polymers, physiologically active polymers, etc.

It can be assumed that approximately 25000, i.e. one half, of the papers published annually and describing the synthesis of new polymers deal with polymers obtained by polycondensation[15]. Finally, yet another of the most important differences consists in the fact that these two processes differ greatly as regards the number of chemical reactions employed. In the case of polymerisation we are dealing virtually with two chemical processes: addition to a multiple bond between two atoms and addition to rings. On the other hand, several tens of chemical reactions are used in polycondensation at the present time and the number of such reactions increases each year. We have in addition a new but very promising field of polymer science involving inorganic polymers, which is almost entirely based on polycondensation, since the majority of heterochain inorganic polymers are obtained by polycondensation[30].

The same remark applies also to biopolymers, which are likewise obtained mainly by polycondensation methods[15].

After this brief description of the characteristics of polycondensation reactions, we shall deal with the present state of this field, attention being concentrated primarily on the characteristic features of polycondensation and the causes of the appearance of a heterounit structure, as well as the formation of a macromolecule, its kinetics and mechanism, and the influence of the process conditions, catalysts, and solvents on this reaction, i.e. the questions which at present determine the progress in the field of polycondensation.

Table 3. The equilibrium constants of certain equilibrium and non-equilibrium polycondensation reactions[12-14].

Reaction investigated	Starting materials	K_p
	Equilibrium polycondensation	
Polyesterification	Pentamethylene glycol + adipic acid	6.00
Polyamidation	ω-Aminoundecanoic acid	8.88
Polycoordination	Beryllium acetylacetonate + 4,4'-di-(acetoacetylphenyl) ether	4.00
	Non-equilibrium polycondensation	
Polyesterification	Dian + 2,2-di(4-hydroxyphenyl)propane diformate	$4.74 \cdot 10^3$
Esterification	Phenol + benzoyl chloride	$4.48 \cdot 10^3$
Polycyclisation	Dihydrazide of di(carboxyphenyl) ether + dichloride of di(carboxyphenyl) ether	$1 \cdot 10^{25}$
Polyamidation	Pyromellitic acid dianhydride + aminophenyl) ether	$1 \cdot 10^5$

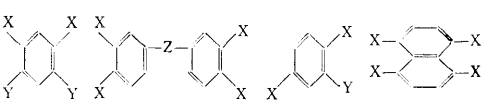
IV. EQUILIBRIUM AND NON-EQUILIBRIUM POLYCONDENSATION

The study of the characteristic features of polycondensation processes led the present author to the conclusion that all the known polycondensation reactions can be combined into two large groups known as (1) equilibrium and (2) non-equilibrium polycondensation[12-15,31,32]. The difference between them is determined mainly by the equilibrium constant of the given process. Equilibrium polycondensation involves reactions whose equilibrium constants are below 10^3 ($K_e < 10^3$), while reactions whose equilibrium constants are above 10^3 ($K_e > 10^3$) belong to non-equilibrium polycondensation[15,33-35]. Table 3 presents examples of reactions of both types.

Equilibrium polycondensation and its features have been studied in greater detail[12,14,15,33]. These two types of polycondensation processes also differ as regards the properties of the polymers formed, the reaction mechanism, the nature and mechanism of the action of the catalysts, kinetics, molecular weight distribution, the mechanism of joint polycondensation, the structure of copolymers, and other characteristic features of these processes, which will be considered below[32-35].

Non-equilibrium polycondensation has been studied in less detail and this factor necessitates a detailed investigation of the laws controlling its course. The importance of this field is due to the fact that non-equilibrium polycondensation actually makes it possible to synthesise polymers at a higher rate and to obtain high-molecular-weight polymers with new structural units and an interesting set of physical and chemical properties[13,14,15,34,36,37].

V. THE FUNCTIONALITY OF THE STARTING MATERIALS



The functionality of the starting materials is one of the fundamental concepts in the field of polycondensation[38-47,143]. Kienle was the first to draw attention to this concept and emphasised its importance in processes involving the formation of three-dimensional network polymers[42].

Carothers[9] formulated the rule of the functionality of the initial monomers, pointing out that linear polymers are formed when the initial monomers are bifunctional. On the other hand, if their functionality is three and more, gel formation takes place and a three-dimensional insoluble and infusible polymer is produced. This is expressed by the relation $P = 2/f$, where P is the degree of reaction and f the functionality, i.e. the number of functional groups in the monomer molecule.

In the case of a bifunctional monomer $P = 1$, which leads to the formation of a linear polymer. For a trifunctional monomer, $P = 2/3$ and for a tetrafunctional one, $P = 1/2$, which implies the formation of three-dimensional polymers, i.e. a gel.

Subsequently many investigators turned their attention to problems of functionality and attempted to find the most effective forms of the expression for functionality and for the application of this concept to polycondensation processes[38-47].

In the course of the development of polymer science, an increasing number of instances have been observed in which the Carothers rule was not confirmed and tri- and tetrafunctional monomers proved capable of forming polymers with linear macromolecules[31,47]. The formation reactions of various polyheteroarylenes, in which tetrafunctional compounds such as tetramines, dihydroxydiamines, tetracarboxylic acids, diaminodicarboxylic acids, and similar compounds having the general formula

are used, may serve as examples. In this case the mutual arrangement of the functional groups is decisive. For an

arrangement of the functional groups which permits the formation of five- or six-membered rings, linear macromolecules of heterocyclochain polymers are obtained. This demonstrates the possibility of the formation of linear polymers made up of tri- and tetra-functional monomers, which had been previously regarded as impossible[38,47]. One must therefore conclude that not only the overall functionality of the initial monomers but also the corresponding favourable mutual arrangement of the functional groups in the unit or the initial monomers is important for the foration of linear polymers. This enabled the author to reformulate the question of the importance of the functionality of the monomers in non-equilibrium polycondensation[15,47] and to put forward a different treatment of the concept of functionality[1,15,38,47]. Functionalities of three types, designated as possible (Φ_p), practical (Φ_{pr}), and relative (Φ_r) functionalities, were proposed[47]. The possible functionality is defined as the total number of functional groups of all types contained in the monomer or oligomer molecule. The practical functionality is defined as the number of functional groups involved in the polycondensation process in the formation of bonds between the constituent units of the polymer, while the relative functionality represents the ratio of the possible and practical functionalities and is given by the equation $\Phi_r = \Phi_p/\Phi_{pr}$. The relative functionality characterises the difference between the reactivities of the reacting monomers and oligomers.

If questions of functionality are considered from the standpoint of its dependence on the structure of the monomers, then the monomers can be divided into two large groups: normal and anomalous monomers. The normal monomers obey the Carothers rule, while the anomalous monomers do not. Accordingly, the possible functionality of the normal monomers is somewhat greater than their practical functionality:

$$\Phi_p > \Phi_{pr},$$

which means that the relative functionality is greater than unity:

$$\Phi_r > 1.$$

The difference between the possible and practical functionalities

$$\Phi_p - \Phi_{pr} = \Phi_{ap}$$

represents the active possible functionality (Φ_{ap}), which determines the possibility of further growth of the molecule. Accordingly, linear polymers are formed when $\Phi_p = 2$. Three-dimensional polymers are produced when the active possible functionality is greater than two:

$$\Phi_{ap} > 2.$$

The questions involving the formation of cyclic groups are then of secondary importance, although cyclic groups of different size are formed in the synthesis of three-dimensional network polymers, which ultimately leads to a three-dimensional network construction, i.e. to a gel point[1,48–52]. It has been noted that the gel point depends on the flexibility of the polymer molecules and on the concentration of the polymer in solution[48]. One must therefore conclude that not only the overall functionality of the initial monomers but also the corresponding favourable mutual *ortho*-arrangement of the functional groups in the unit or in the initial monomers, i.e. the so-called "*ortho*-effect", is important for the formation of linear polymers.

VI. THE RULE OF THE NON-EQUIVALENCE OF FUNCTIONAL GROUPS

The rule of the non-equivalence of the functional groups is known to be valid in all instances of polycondensation where the starting materials are bifunctional[53]. The molecular weight of the polymers produced in the equilibrium polycondensation reaction is regulated on the basis of this principle by adding different amounts of monofunctional substances or an excess of one of the initial monomers. Fig.1 illustrates this relation for equilibrium polycondensation[53]. Its investigation in non-equilibrium polycondensation for starting materials with a higher functionality showed that here too the excess of one of the starting materials has in most cases an analogous influence in the reactions of tetrafunctional monomers, which leads to a decrease of the molecular weight in proportion to the excess of one of the initial monomers. Such a relation has been observed in many instances of non-equilibrium polycondensation. Fig.2 illustrates the dependence of the viscosity of the solution of the polyimide formed on the excess of the starting materials in the reaction of a diamine with pyromellitic acid dianhydride[54]. Fig.3 shows that the reaction of a diamine with the dichloride of *m*-carbaboranedicarboxylic acid is also very sensitive to the excess of the starting materials[55].

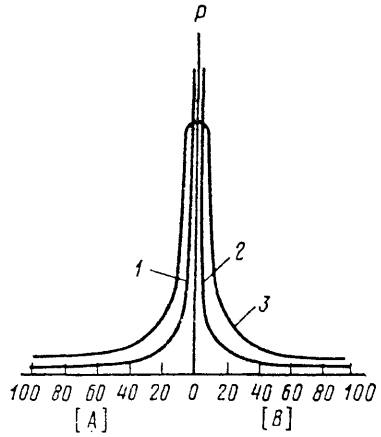


Figure 1. Dependence of the polymerisation coefficient *P* of the polymer obtained by the polycondensation reaction on the excess of the starting materials A and B: *1*) and *2*) calculated; *3*) experimental.

In general, the reactions of different tetrafunctional nucleophiles with tetracarboxylic acids or their derivatives obey the rule of the non-equivalence of the functional groups, as shown in a general form in Fig.4.[56]

Thus the examples presented demonstrate fairly clearly a distinct dependence of the molecular weight (MW) of the polymer synthesised on the excess of one of the initial monomers also in the case of tetrafunctional monomers and hence the "rule of the non-equivalence of the functional groups" remains in force and also in relation to polyfunctional monomers in non-equilibrium polycondensation[53].

The possibility of the acceleration of the concluding stage of the non-equilibrium polycondensation reaction as a result of the introduction of monomers with more reactive functional groups than the terminal groups has been demonstrated and it has been shown that the maximum attainable molecular weight of the polymer depends on the stoichiometric composition of the reaction mass and on the relative reactivities of the functional groups of the monomer[57].

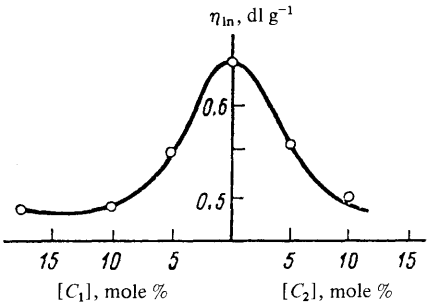

Figure 2. Dependence of η_{ln} for a solution of anilinephthalein polypyromellitimide on the ratio of the starting materials; c_1 = dianhydride concentration; c_2 = diamine concentration.

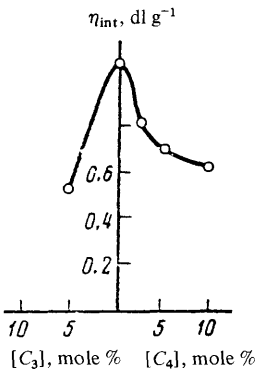

Figure 3. The influence of the ratio of the starting materials on η_{int} for 0.5% solutions of polyamido-*m*-carbaborane in DMF; c_3 = diamine concentration; c_4 = acid chloride concentration.

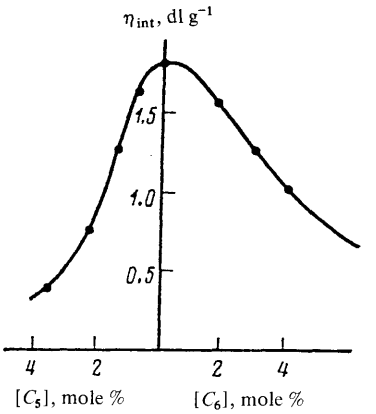
VII. THE HETEROUNIT STRUCTURE OF THE POLYMERS FORMED IN NON-EQUILIBRIUM POLYCONDENSATION PROCESSES

Heterounit polymers are produced in the non-equilibrium polycondensaton reaction as a result of the formation of anomalous units in the set of polycondensation reactions, illustrated in Fig.5.[58-61]

The anomalous units formed under these conditions differ in their structure from the main units of the macromolecule.



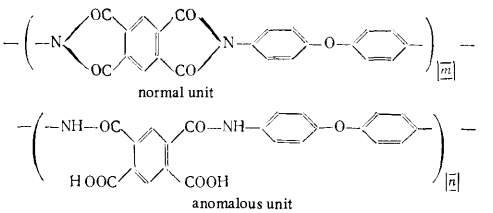


Figure 4. The influence of the excess of the starting materials on the viscosities of solutions of polymers obtained from various tetrafunctional monomers (dicarboxylic acid dihydrazides, bis-o-aminophenols, dianilinodiamines, and bisanthranilic acid diamides) by reaction with polycarboxylic acids; c_5 = nucleophile concentration; c_6 = electrophile concentration.

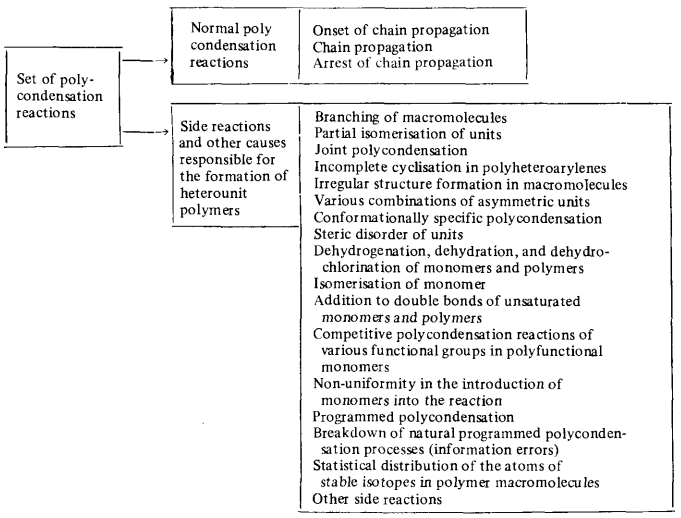
The formation of the anomalous units generates the so-called "heterounit" polymers[14,36,58,62-66]. The present author suggested that the structure of the heterounit polymers be expressed by the general formula

$$-[-(-M-)_{\boxed{m}}-(-A-)_{\boxed{n}}-]_x- \ ,$$

where M is the normal unit, A the anomalous unit, and the coefficients $\boxed{m}$ and $\boxed{n}$ denote the statistical distribution of the M and A units. The real formula of the polymers such as, for example, polyimide is therefore as follows:

In this case the anomalous units are those in which ring closure has not taken place. In other instances there is a possibility of side reactions of different character, as shown in Fig.5. The presence of the anomalous units has a significant influence on the entire set of the chemical and physical properties characteristic of the given polymer[58,63,67-69]. The study of the conditions leading to the formation of the anomalous units and hence to the appearance of heterounit polymers is one of the most important tasks in synthetic polymer chemistry, since without it it is impossible to understand and explain fully the dependence of the properties of the polymers on their structure[14,36,58,62-66]. The presence of anomalous units of different kinds has been demonstrated for many classes of polymers obtained by polycondensation methods[15,62]. These include representatives of polyamides[70], polyesters[71], polycarbonates[81], unsaturated polyesters[72], polyarylates[73,74], polybenzimidazoles[75], pyrrones[76], and polyimides[77,78]. The presence of non-cyclised and anomalous structures in polybenzoxazoles[79], polyquinoxalines[80], polytriazines[81], squaric acid polyamides[82], polysulphones[83], and other polymers[84] has been established recently. To complete

the picture, one should add that anomalous units are present also in polymers obtained by polymerisation methods from monomers and by the modification of polymers[63,64,85].



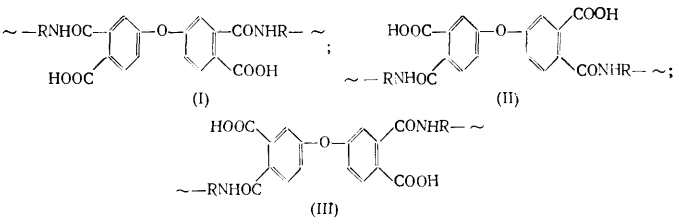


Figure 5. The set of polycondensation reactions.

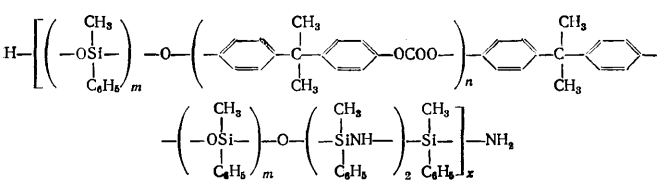
Finally isotopes are a significant factor in the formation of heterounit structures. The point is that all organogenic elements from which the majority of polymers are constructed each have several stable and radioactive isotopes. Stable isotopes forming part of the composition of the polymers are distributed statistically in their macromolecules and each macromolecule therefore has a structure different from that of the others. This naturally affects the properties of the polymers, as shown in relation to deuterated polyethylene[65]. The substitution of hydrogen by deuterium in polyethylene results in an appreciable alteration of physical characteristics such as density, melting point, glass point, yield point, and chemical properties. This led to the conclusion that the presence of isotopes in macromolecules promotes the acquisition of a heterounit structure by polymers[40,41,86,87]. At the same time account must be taken of the possibility of the combination of a series of effects and the simultaneous operation, together with the isotope effect, of factors such as branching, isomerisation, etc. The influences of these effects may coincide and enhance one another.

The heterounit structure should be manifested particularly significantly in the case of biopolymers, where one may expect extremely specific and very marked manifestations of the isotope effect. In fact, we know that extremely small changes in the structures of substances such as proteins, nucleic acids, etc., have a significant influence on biological functions. At the same time it is known that different isotopes are non-equivalent as regards their physiological properties. Thus, among the causes responsible for the heterounit structure of polymers, one should include also the influence of stable isotopes in monomer and polymer molecules. Branching is a very special case in the heterounit structure of polycondensation products. It can arise as a result of various side reactions and owing to the use in the polycondensation reaction of starting materials with a functionality greater than two. For example, the addition of laproxid during the synthesis of poly(ethylene terephthalate) (lavsan) leads to the formation of a branched polyester[88].

The determination of the extent of the heterounit structure in polyamidoacids by ^{13}C NMR demonstrated the presence of three possible structures[89]:

The contents of these isomers vary within the following limits as a function of the nature of the solvent: (I) from a mole fraction of 0.33 to 0.46; (II) from 0.11 to 0.18; (III) from 0.43 to 0.49.



Since the presence of anomalous units in heterounit polymers influences significantly their chemical and physical properties, this factor must be taken into account in considering the relation between the structure and properties of polymers[14,44,50].

VIII. THE SYNTHESIS OF ORGANOELEMENTAL POLYMERS

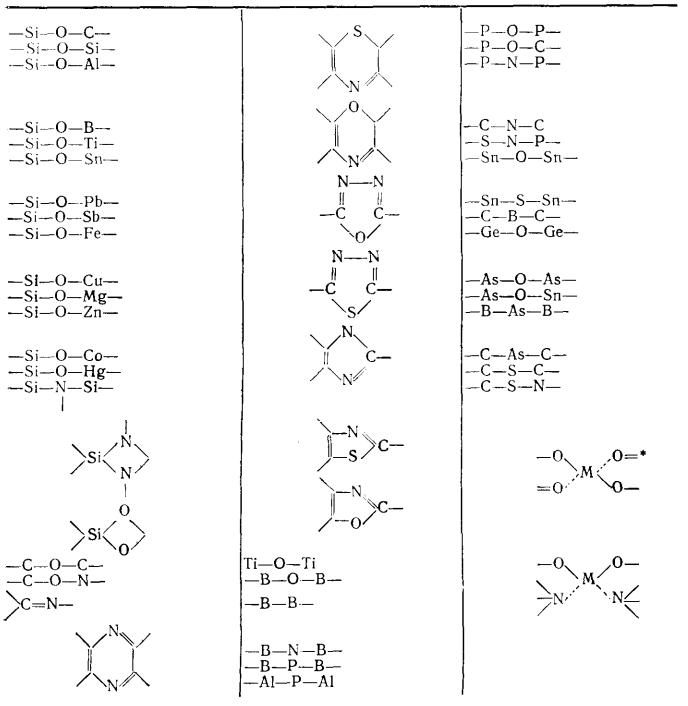
An interesting feature of polycondensation processes is that this is in fact the main procedure whereby polymers containing different elements in the Periodic System are obtained. The usual organic polymers consist of elements such as carbon, hydrogen, oxygen, and nitrogen. The remaining elements are typical for organoelemental polymers. Polymers incorporating such elements, which are listed in Table 4, have now been obtained[37,40,41,86,87,90,91]. The table shows that there is a very great variety of organoelemental polymers obtained by polycondensation methods; 75 elements have already been incorporated in polymers of this kind. Evidently there is every reason to assume that further development of research into organoelemental polymers will enrich science and practical applications by a large number of new and interesting polymers.

New bonds between elements are formed in organoelemental polymers, imparting a new set of properties to the polymeric structures formed. Various heterobonds between the atoms constituting the polymer chain are presented in Table 5.

Among block copolymers, there exists an organoelemental block copolymer containing polycarbonate and polysilazasiloxane blocks having the following structure[92]:

IX. THE KINETICS AND MECHANISM OF THE POLYCONDENSATION REACTION

The kinetics of equilibrium polycondensation processes have been investigated in relation to a large number of examples[1,12,31,34,93]. However, many investigations devoted to



these problems are still being published. The kinetics of the non-equilibrium polycondensation reactions have been studied in less detail.

The successful investigation of the kinetics of the formation reaction of cardo-polymers has been possible by virtue of their solubility, since the starting materials employed are diamines with bulky substituents, such as, for example, anilinephthalein[94]. The introduction of polar groups into the polyimide unit with the aid of monomers of the type of di(3-amino-4-methoxyphenyl)methane has also made it possible to obtain soluble polymers and to investigate the process kinetics[61].

The study of the kinetics of the synthesis of polymers such as polyphenylquinoxalines[95], polyimides[96–98], polybenzoxazoles[97], polyoxadiazoles[99–101], polyarylates[102] and polyphenylenes[103] has likewise been described.

The kinetic curves for the reaction of terephthalic acid chloride with phenolphthalein in the presence of triethylamine are presented in Fig.6.[104] We see that the process is extremely rapid even at low temperatures.

It is of interest that the dependence of the viscosity of the polyarylate obtained on the reaction temperature is unusual and is expressed by a curve with two maxima, as shown in Fig.7.[102,105,106] This can be explained by the complex temperature dependence of the reaction rate constant[104,105].

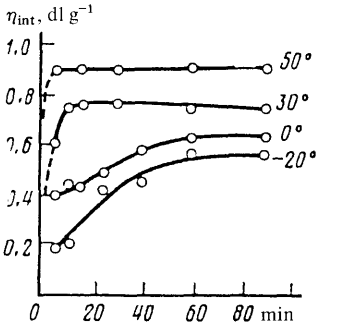

Figure 6. Variation of η_{int} of the polyarylate in the synthetic process.

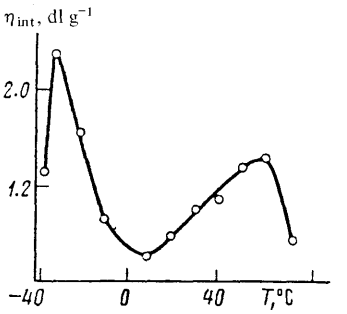

Figure 7. Temperature variation of η_{int} of the polyarylate.

Kuchanov[49] calculated the influence of the method of measuring out the monomers on the molecular weight distribution of the polymers obtained by non-equilibrium polycondensation and concluded that the number-average polycondensation coefficient is inversely proportional to the square root of the rate of introduction of the monomer.

In the single-stage synthesis of polyimide from pyromellitic anhydride and anilinephthalein in solution in nitrobenzene, the reaction should proceed as shown in Fig.8.[54] The yield of the polymer is then almost independent of the

reaction time, since the polymer is formed quantitatively after only 1 h.[107]

In the two-stage formation of polyoxadiazoles the second stage involves the closure of the heterocycle. Fig.9 presents curves describing the variation of the activation energy for the cyclisation of polyhydrazides[108]. The figure shows that an interesting feature of this process is the fact that the activation energy increases with increase of the degree of cyclisation, which is evidently associated with the increasing rigidity of the macromolecular chain and the steric hindrance to the heterocyclisation reaction.

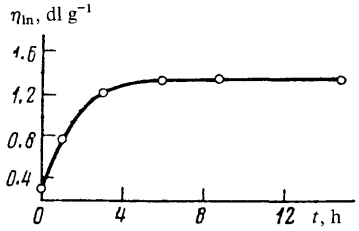

Figure 8. Dependence of η_{ln} of anilinephthalein polypyromellitimide on the reaction time.

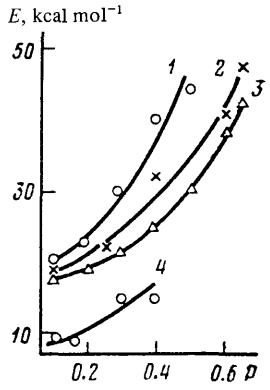

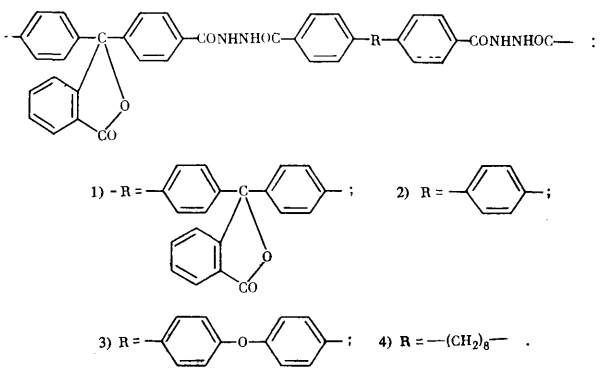

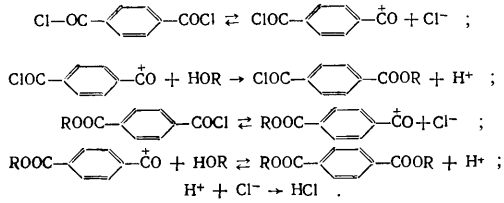

Figure 9. Dependence of the activation energy E for heterocyclisation on the degree of reaction P of the polyhydrazide having the general formula

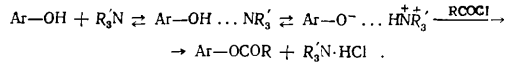
It has been found that the order in which the starting materials are mixed in the non-equilibrium polycondensation reaction has a considerable influence on the structure of the polymer formed when asymmetric monomers are used[109].

It is noteworthy that the mechanisms of various kinds of polycondensation reactions have been elucidated in detail only in a small number of instances. The mechanism of non-equilibrium polycondensation has been studied mainly in relation to polycondensation in solution[13,110].



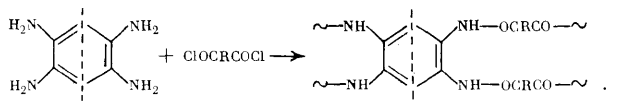
The study of the high-temperature non-equilibrium polycondensation of dicarboxylic acid chlorides with bisphenols in solution led to the conclusion that the reaction proceeds via an ionic mechanism in accordance with the equations[111,112]

The study of non-equilibrium polycondensation in solution in relation to the acceptor-catalytic polyesterification in the presence of tertiary amines led to the conclusion that the reaction can involve both the nucleophilic catalytic mechanism

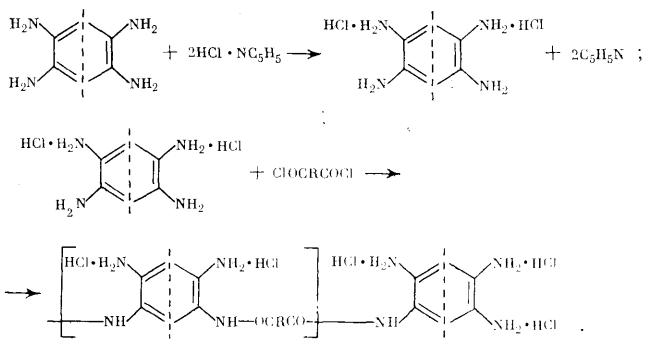
and the general base catalytic mechanism

The particular pathway followed depends on the basicity of the tertiary amine and hence on its ability to form a hydrogen bond with phenol[113–116]. For a more basic amine, general base catalysis predominates[116].

An interesting feature of the polycondensation reaction is the possibility of its occurrence via two pathways, namely via the single-stage substitution



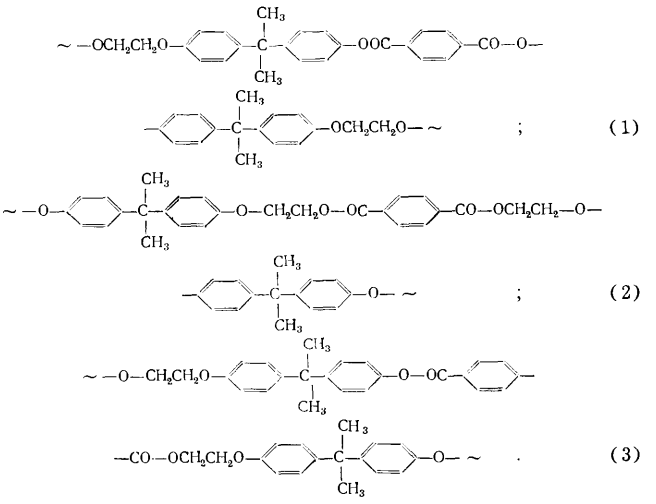
and via repeated dimerisation



Evidently in practice both versions are realised, possibly with one of them predominating depending on the reaction conditions and the nature of the starting materials. It must be emphasised that this constitutes a significant difference between polycondensation processes and polymerisation in which there is no chain growth via repeated dimerisation.

Among the interesting results of the study of the mechanism of non-equilibrium polycondensation, mention must be made of a new procedure for the regulation of the structure of the macromolecule formed. It has been found that the addition of pyridinium chloride in the polycondensation of aromatic tetramines with carbaborane-*m*-dicarboxylic acid chloride makes it possible to obtain a linear polymer, while the reaction in the absence of this additive leads to the formation of a branched and cross-linked polyamide[117,118]. The reaction mechanism which explains the structure-regulating influence of pyridinium chloride is as follows: the reaction of the tetramine with the acid chloride gives

rise to a trimer:

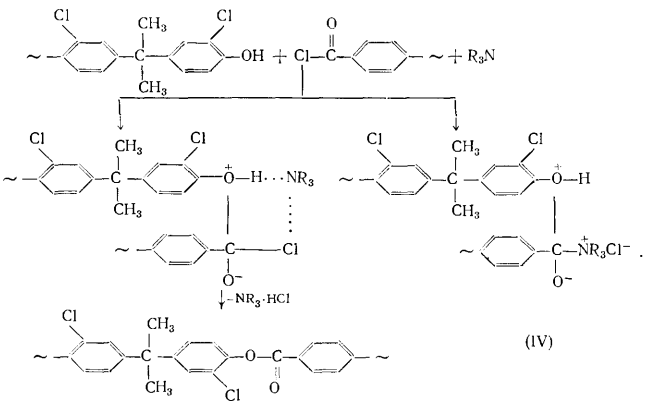


However, if pyridinium chloride is added, then the tetramine becomes bifunctional as a result of salt formation and a soluble linear polymer is therefore produced on treatment with the dicarboxylic acid dichloride:

Thus the amino-groups are neutralised, which prevents branching and terminates the growing chain at a specific reaction stage. An analogous pattern has also been observed in the reaction of bis(o-aminophenols) with acid dichlorides[66].

One of the important characteristics of polymers is the regularity of the structure of the polymer chain, which is particularly important for units with an asymmetric structure and determines the "head to tail", "head to head" and "tail to tail" dispositions.

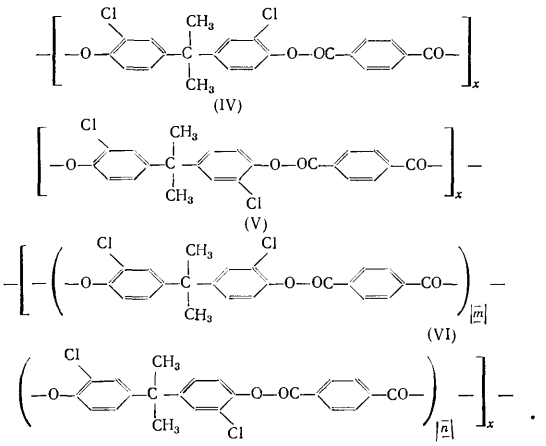
The study of the acceptor-catalytic polycondensation of terephthalic acid chloride with the β-hydroxyethyl ether of 2,2-di(4-hydroxyphenyl)propane showed that, when the reaction is carried out under the usual conditions with the simultaneous introduction of the starting materials, a polymer with a statistical distribution of units is formed[119]. If the terephthalic acid chloride is added gradually to the reaction mixture, a difference in the reactivity of the hydroxyls is manifested and a polymer in which the "head to head" (1) and "tail to tail" (2) units predominate is obtained:



On the other hand, the "head to tail" configuration (3) is encountered more rarely. Thermodynamic methods have been recently applied on an increasing scale to the study of polycondensation processes. Thus a detailed investigation has been made of the thermodynamics of the synthesis of a series of polyheteroarylenes which led to the discovery of the temperature limits of the occurrence of the individual stages of the reaction and the thermodynamic functions of the polymers and the equilibrium constants of the process have been obtained, showing that the reactions are of the non-equilibrium polycondensation type[76,120]. Among the interesting approaches to the investigation of non-equilibrium polycondensation, mention must be made of the use of correlation analysis, whereby one can predict the reactivities of monomers with interdependent and independent reaction centres and calculate the rates of various polycondensation processes from the joint polycondensation constants[121].

A mechanism of the elementary stage in the polycondensation of diamines with pyromellitic anhydride postulating a consecutive electron and proton transfer in the electronically excited state of the complex formed by the reactant and solvent molecules has been proposed on the basis of the study of the phototransfer and thermal transfer of an electron[122].

X. CONFORMATIONALLY REGULAR POLYCONDENSATION



The study of the non-equilibrium polycondensation reaction in relation to the interaction of dicarboxylic acid chlorides with bisphenols in the presence of catalysts such as tertiary amines led to the formation of polyarylates whose properties differed depending on the reaction conditions and the nature of the catalysts.

The mechanism of the acceptor-catalytic polyesterification reaction occurring in this instance can be represented by the following scheme[123]:

In this case one can obtain a polyester containing two conformations of the units differing in the mutual arrangement of the halogen atoms. It has been shown for acceptor-catalytic polyesterification that the nature of the solvent and the catalyst plays a major role[25]. Thus the polycondensation of 2,2-di-(3-chloro-4-hydroxyphenyl)propane with terephthalic acid chloride leads to the formation of polyarylates with different properties, melting points, and solubilities depending on the reaction conditions[25,124]. The study of the polyarylates showed that they are conformationally regular polymers and consist of conformers with

different conformations, arising by virtue of hindered rotation[123,125]. They have the following structures:

(IV)

(V)

(VI)

Formulae (IV) and (V) represent two extreme structures: cisoid and transoid respectively. They can be regarded as analogues of the isotactic and syndiotactic structures of polyolefins. Formula (VI) corresponds to an atactic polymer containing both conformations, distributed in the polyarylate molecule either statistically or in blocks[126,127].

Similar polymers have also been obtained from other dian derivatives containing two methyl or two nitro-groups[128]. All such polymers evidently contain blocks made up of regularly distributed units. The size of the blocks depends on a number of factors and can vary within specific limits depending on the conditions of the synthesis and the nature of the solvent and the catalyst[123,125,127,129].

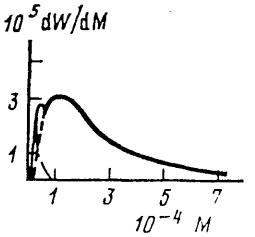
XI. THE MOLECULAR WEIGHT DISTRIBUTION IN THE POLYCONDENSATION PRODUCTS

The question of the molecular weight distribution in the polycondensation products has been studied in detail by a number of investigators[48,130,131]. It has now been established that, depending on the method of polycondensation, polymers with different molecular weight distribution functions are formed[131,132].

An interesting feature of the polycondensation in a solvent–precipitant system is the formation of polymers with a narrow molecular weight distribution (MWD). This is achieved by using solvents in which the polymer with chains having a length greater than the specified value P_C are insoluble[131].

The homogeneity of the reaction mass is also important for the MWD, since inhomogeneity leads to an increase of polydispersity[130]. Polycondensation yields products whose MWD can vary within wide limits. Thus, according to literature data, the polydispersity coefficient varies within wide limits ranging from 1 to 43.[32] Consequently there is no complete consistency with Flory's theory[133], according to which the polycondensation products must have the most probable distribution corresponding to a polydispersity of two. The non-equilibrium polycondensation of pyromellitic anhydride with di(4-aminophenyl) ether yielded polymers whose molecular weight distribution M_w/M_n varied from 1.53 to 3.72.[134,135] The narrower distribution can be explained by the fact that a helical conformation is products under the conditions of the synthesis, the degree of conversion into the helical form increasing when the MWD becomes wider[136,137].

The study of the MWD of the polyarylates obtained from phenolphthalein and terephthalic acid chloride by gel permeation chromatography revealed a bimodal distribution with respect to the molecular weight, as shown in Fig. 10.[138]



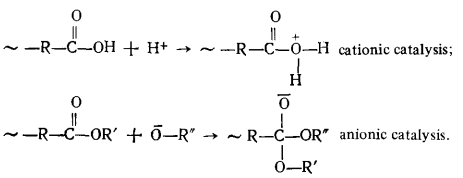


Figure 10. Molecular weight distribution curve for polyarylate.

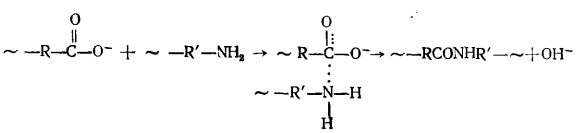
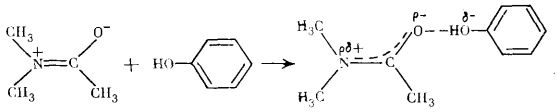
This type of MWD can be explained by the fact that, together with the linear polyarylate, a cyclic polymer (macrorings) is formed[139]. The formation of cyclic polymers in the polycondensation reaction together with linear polymers had been observed earlier in the synthesis of polydimethylsiloxanes, poly(ethylene terephthalate), polyamides, and polyesters[140].



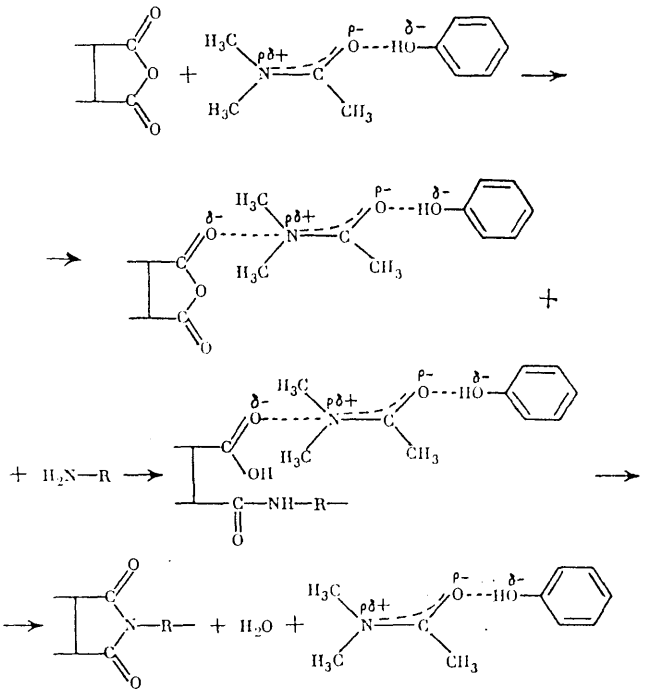
XII. CATALYSIS IN POLYCONDENSATION REACTIONS

Catalysis is known to play a major role in polycondensation processes[15,33,41,141,143]. The application of catalysts in polycondensation processes makes it possible to accelerate the reaction and to obtain polymers with a broad spectrum of properties[47,141,142,146,147].

Catalysis in non-equilibrium polycondensation reactions can proceed as cationic, anionic ionic-coordination, and free-radical process depending on the nature of the starting materials and the catalysts[15,141,142]. The intermediate complexes are illustrated schematically below:

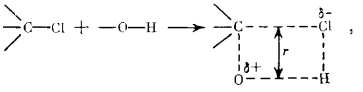


Accordingly, the mechanism of the polycondensation of a diamine with a dicarboxylic acid involving nucleophilic substitution is as follows[144]:

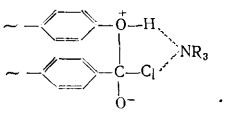


For the amide catalysis of the polyimide formation reaction, the following reaction mechanism, in which an amide–phenol

complex is formed initially, has been proposed[145]:



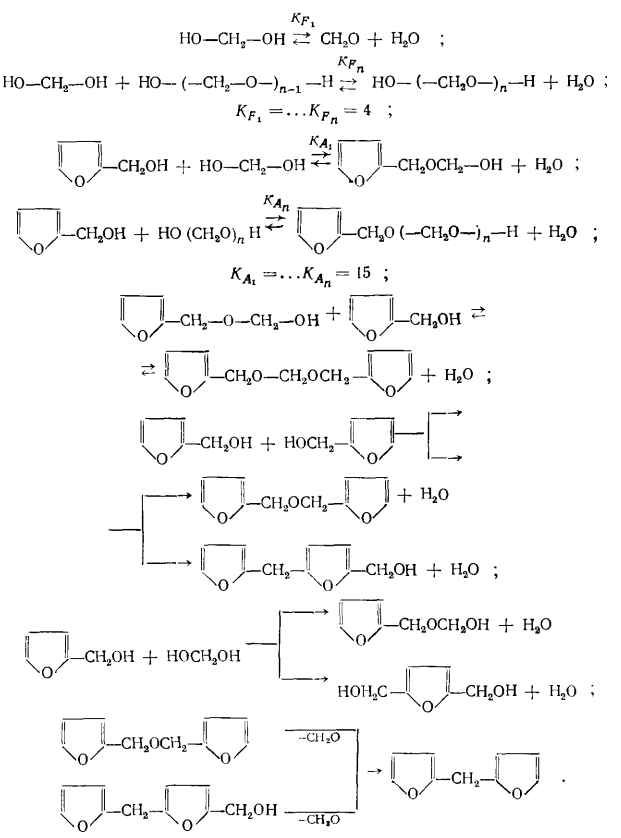
This is followed by the formation of a ternary catalytic complex:



The imide ring is formed in this way and the complex is regenerated[145].

The following transition state has been proposed to account for the mechanism of the poly(ethylene terephthalate) formation reaction:

where r is the diameter of the "active component" of the activated complex[148].

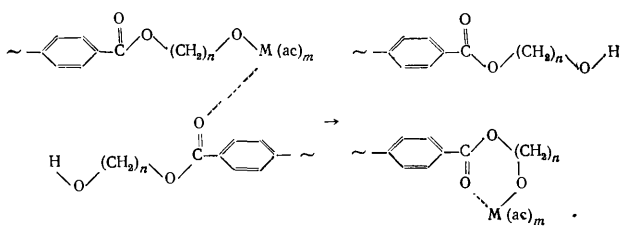


Ionic-coordination catalysis obtains, for example, in the presence of tertiary amines with formation of an intermediate complex, which probably has the following structure:

As will be shown below, the formation of such complexes facilitates the polycondensation process and makes it possible to obtain conformationally regular polymers.

Various compounds of many elements, indicated in Table 6, have now been investigated as polycondensation catalysts[15, 41, 129].

The following reaction scheme has been proposed for the condensation of furfuryl alcohol with formaldehyde in the presence of an acid catalyst (a 10% aqueous solution of 84% H_3PO_3):[149]



At the end of this reaction chain, difurfurylidenemethane becomes the main product.

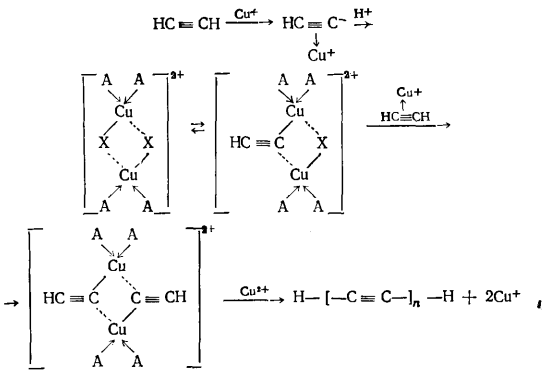


Table 6. Elements whose compounds have been used as polyesterification catalysts[15].

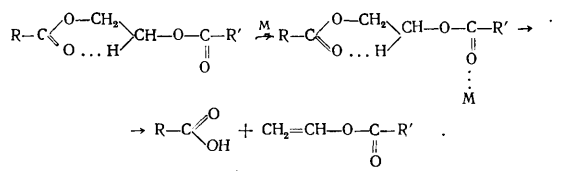
6	—	Hg	—	Pb	Bi	—	—	
7	—	—	—	Th	—	U	—	— — —

The effect of metal acetates as catalysts in the synthesis of poly(ethylene terephthalate) has been explained by the following scheme[147]:



The free-radical catalysis by copper–amine complexes obtains, for example, in the oxidative polycondensation of acetylene, leading to the formation of carbyne—the third linear form of carbon[150]:

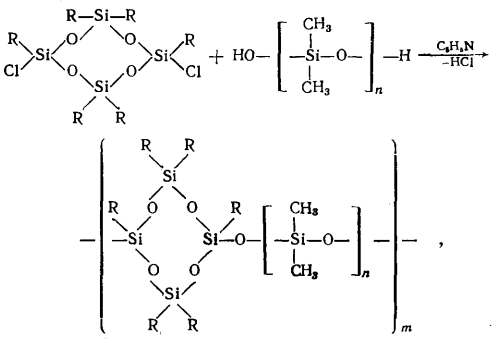
where A is the complexone residue.

The Andrianov reaction, which involves the catalytic polycondensation of organosilazanes, has been investigated on a large number of examples. Its general character has been demonstrated in relation to a series of organosilazanes and the formation of polycyclic polymers containing a trisilyl-substituted nitrogen atom in the chain has been established[151,152].

Together with the acceleration of the polycondensation, catalysts can also induce undesirable reactions involving the decomposition of the polymers, accompanied by the darkening of the products and the degradation of the macromolecules. The following mechanism of the action of metal ions as catalysts of the degradation of a polyester has been proposed[147]:

It is of interest to note that catalysts influence the reaction and the properties of polyheteroarylenes not only in the first but also in the second stage of reaction. This has been observed for polyimides obtained under the catalytic influence of phosphoric acid[153].

XIII. JOINT POLYCONDENSATION



Joint polycondensation has been attracting increasing attention of investigators[103,109,154–160]. It has been established that anion-exchange resins can be used as effective catalysts in the joint polycondensation of dicarboxylic acid chlorides with bisphenols and glycols. The possibility of employing different types of anion exchangers and of obtaining copolymers with different microstructures arises under these conditions[161]. Studies of joint polycondensation have demonstrated the influence of the reactivity of the initial monomers and of the way in which the reaction is carried out on the structure of the polymer formed. Turska and co-workers derived a kinetic equation describing the joint polycondensation reaction of three bifunctional monomers A, B, and C. These monomers are selected in such a way that the monomer A reacts with the monomers B and C, but the latter do not react with one another[162]. The same workers studied the influence of the reactivity of the functional groups of the monomers on the composition of the copolymer and the structure of the macromolecular chain in the non-equilibrium polycondensation reaction[163] and determined the isokinetic temperature T_i for each pair of monomers for which the rate constants for both reactions are identical:

$$T_i = \frac{E_{AB} - E_{AC}}{R\,(B_{AB} - B_{AC})} ,$$

where E_{AB} and E_{AC} are the activation energies for the corresponding polycondensation reactions, B_{AB} and B_{AC} are the pre-exponential factors in the Arrhenius equation, and R is the gas constant.

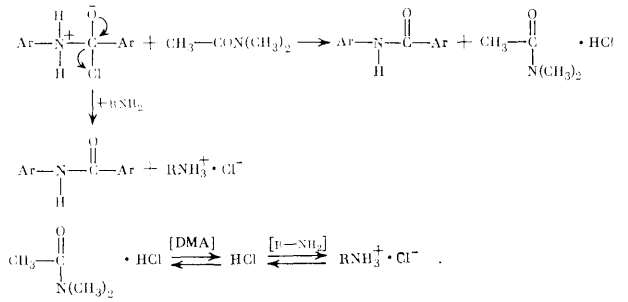
If $K_{AB} > K_{AC}$ at a temperature below T_i, then at a temperature above T_i the relative reactivities of the monomers B and C are reversed and the latter becomes more reactive than the monomer B. Consequently the distribution of the B and C units along the macromolecular chain varies with temperature. On the other hand, at a reaction temperature equal to T_i a product of constant composition, independent of the degree of reaction and with a statistical distribution of the B and C units, is formed. Hence arises the possibility of regulating the joint polycondensation process by selecting an appropriate reaction temperature[156,163]. The joint polycondensation reaction can be directed, if so desired by the investigator, towards the formation of a statistical copolymer or a block copolymer. If, as usual, the two monomers are mixed with the intermonomer, then a statistical copolymer is always formed. On the other hand, if the intermonomer is gradually introduced into the mixture of the comonomers then a block copolymer is produced[154]. The slower the addition of the intermonomer, the more pronounced the block structure of the copolymer formed under these conditions[157].

An extremely interesting feature of polycondensation is the possibility of obtaining with its aid block copolymers having a polyblock structure, in contrast to polymerisation where block copolymers with only di- and tri-block structures are possible[110]. As an example, we quote Andrianov's synthesis[158] of block copolymers containing linear and cyclic groups, achieved by carrying out the reaction in pyridine:

where n = 2, 4, 12, 25, and 70.

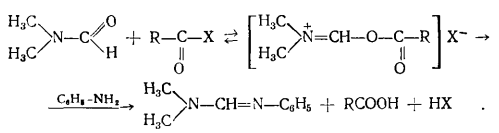
The nature of the solvent in which the polyarylate is synthesised influences the structure of the copolymer obtained. The distribution of the units in the copolymer obtained by the reaction of isophthaloyl chloride with a mixture of di(4-aminophenyl) ether and di(4-aminophenyl) sulphone has been investigated as a function of the polycondensation conditions[159]. It was found that in sulpholan there is a distinct tendency towards the formation of blocks. However, in the presence of epoxypropane, which is a weaker acid acceptor, it is possible to obtain copolymers with a high content of alternating structures[159].

The order of mixing of the reactants is also extremely important. Thus, if a mixture of one diol and triethylamine is taken for the reaction after which the dicarboxylic acid chloride is added and only then the second diol is introduced, a block copolymer is obtained[109,160]. On the other hand, if triethylamine is added to a solution of the acid chloride and one diol and the second diol is only then introduced, a statistical copolymer is obtained[109].



XIV. THE INFLUENCE OF SOLVENTS

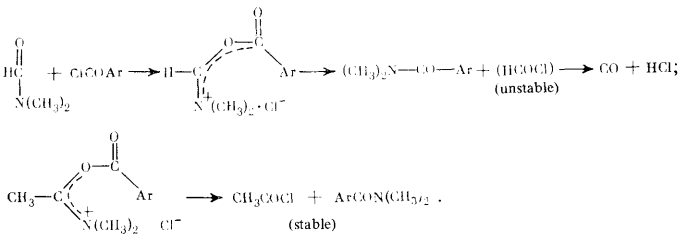
The study of the mechanisms of the reactions used in non-equilibrium polycondensation has led to the discovery of the major role of solvents. This led in its turn to the discovery of conformationally specific polycondensation[25], of a method for the synthesis of block copolymers[154], etc.



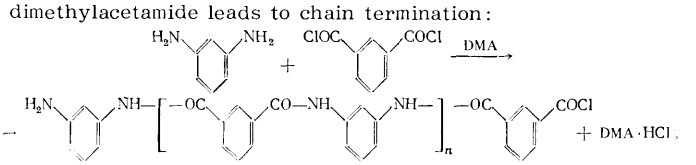
It has been shown that the nature of the solvent has a significant influence on the molecular weight and yield of the polymers formed in the non-equilibrium polycondensation of acid anhydrides and chlorides with aromatic diamines[164] and also in the reaction of phenol with formaldehyde and in other instances of polycondensation[165,166].

Sokolov found that the addition of water makes it possible to alter very appreciably the conditions in the synthesis of polyamides from dicarboxylic acid difluorides and dichlorides and diamines[156,167].

Herlinger et al.[168] showed that non-equilibrium polycondensation in solution in amide solvents proceeds via a stage involving the formation of a reaction complex of the acid chloride and the amine, which is followed by the formation of an amide linkage and the hydrochloride of dimethylacetamide:



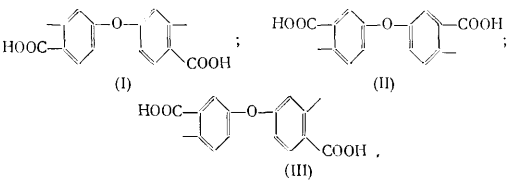
The study of the polycondensation of dicarboxylic acid halides with diamines in solution in dimethylformamide (DMF) showed that this too results in the formation of reactive adducts of the acid halides with DMF.[169] The later react with amines (for example, aniline) to form *N*,*N*-dimethyl-*N'*-phenylformamidine:



Under these conditions, the acid acceptor can also be the unreacted amine, which influences the course of the process, altering the ratio of the starting materials so that the course of the polycondensation reaction depends on the equilibrium $RNH_2.HCl \rightleftharpoons DMA.HCl$.[168]

In addition there is also the possibility of a transamidation reaction via the mechanism

This reaction, which has been studied using ^{14}C-labelled dimethylacetamide leads to chain termination:



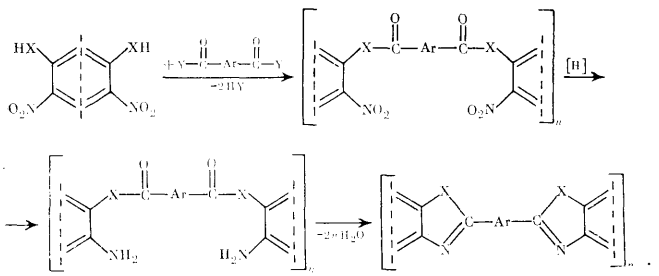
H_2N-polymer-$COCl + CH_3^{14}CON(CH_3)_2 \rightleftarrows H_2N$-polymer-$CO\text{-}N(CH_3)_2 + CH_3^{14}COCl$;

H_2N-polymer-$CON(CH_3)_2 + CH_3^{14}COCl \rightleftarrows CH_3\text{-}CO\text{-}NH$-polymer-$CO\text{-}N(CH_3)_2$.

The use of the tracer atom technique (^{14}C) showed that the rates of propagation and termination of the polymer chain are in the ratio 280 : 1. Kinetic studies demonstrated that 70 to 80 °C is the upper temperature limit beyond which a polymer with a high molecular weight can not be obtained owing to the high rate of the transamidation reaction and hence of chain termination[168].

An interesting case illustrating the role of the solvent is provided by the reaction of bis-α-diketones with tetramines, which is used for the synthesis of polyphenylquinoxalines[170]. It has been found that the rate of reaction of the amino- and keto-groups in chloroform is higher by a factor of 10^5–10^6 than in tetrahydrofuran.

The nature of the solvent in which the reaction takes place has a significant influence on the process. Thus all three isomeric structures are formed in the reaction of the anhydride of bis(3,4-dicarboxyphenyl) ether with 9,9-di(4-aminophenyl)fluorene[89]:

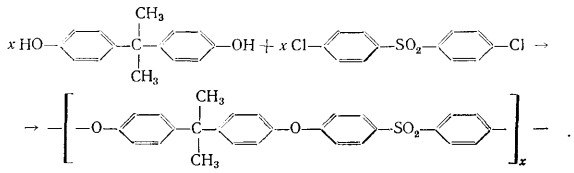


Their ratios vary somewhat depending on the nature of the solvent. Thus they are (I) : (II) : (III) = 0.33 : 0.18 : 0.49 in hexamethylphosphoramide and (I) : (II) : (III) = 0.46 : 0.11 : 0.43 in *N*-methylpyrrolidone. Steric factors and not the basicity of the amine play a significant role in this instance. It is of interest to note that the isomeric composition of the polyamidoacid in solution in *N*-methylpyrrolidone does not vary with time whereas in dimethyl sulphoxide there is a gradual enrichment in structure (I).

XV. NEW POLYMERS AND METHODS OF SYNTHESIS

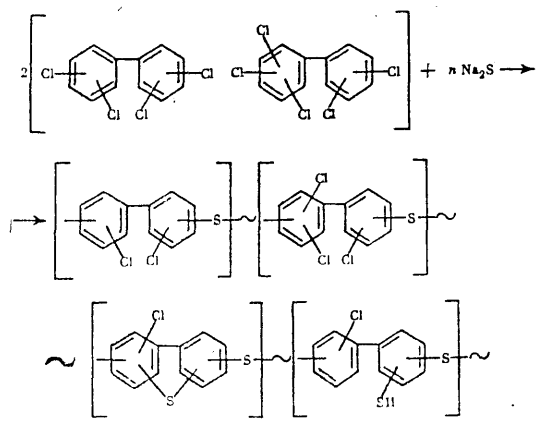
We shall consider briefly certain examples characterising the advances in the creation of new polymers and the development of new methods of synthesis[171]. Great improvements

in the processes involving the synthesis of industrial polycondensation polymers (polycarbonates and carbamide and phenol-formaldehyde polymers) have been achieved recently[146,147]. Among the new synthetic processes, the reductive polyheterocyclisation reaction, constituting a new method of synthesis of polyheteroarylenes, has been described[172]. The synthetic reaction of polybenzazoles proceeds in accordance with the equation



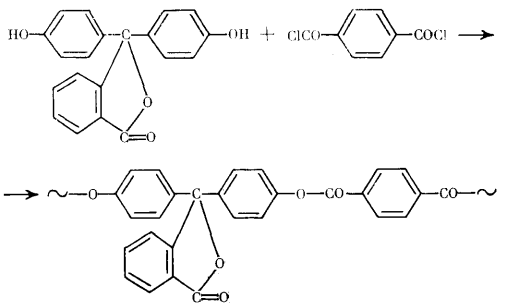
It is noteworthy that studies have been carried out recently whose aim was to seek new polycondensation methods. These include the work of Sokolov, who proposed two new methods for carrying out such reactions. These are the gas-phase polycondensation and emulsion polycondensation[173-176].

Emulsion polycondensation resembles closely interfacial polycondensation, since in both cases the reaction systems employed are heterogeneous. In emulsion polycondensation the reaction zone consists of the total volume of one of the phases and the rate-limiting stage is the chemical interaction[175,177]. The method of thin-layer interfacial polycondensation using monomeric aerosols has also been proposed[134,177].



The solid-phase polycondensation used in the form of an improved modification as a method of synthesis of polyheteroarylenes should also be mentioned[178,179].

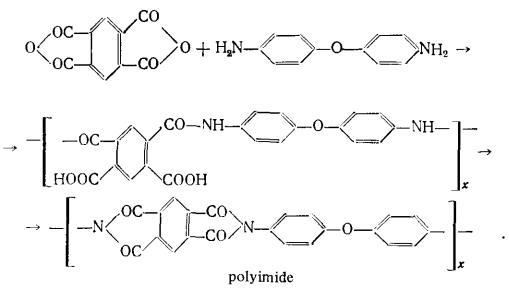
The dehydrochlorination of bisphenols and di(chlorophenyl) sulphone leads to the formation of polysulphonylethers[180,181]:



These polymers have a set of valuable properties and, in particular, they are imcombustible. The block copolymers based on oligosulphonylethers are especially interesting[182,183].

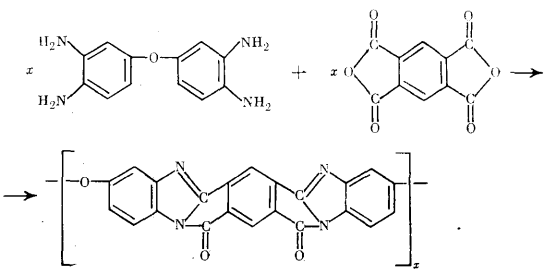
The polycondensation of polychlorobiphenyls with sodium sulphide leads to the formation of poly(biphenylene sulphides):

It is of interest that, although the functionality of the initial monomers is fairly high, soluble polymers are formed[184].



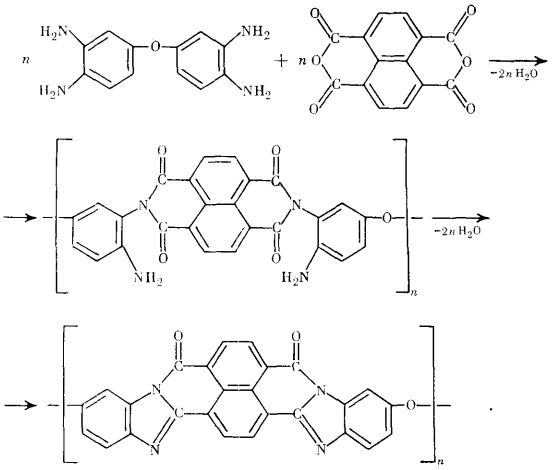
By carrying out the reaction of bisphenols with acid chlorides in the presence of tertiary amines, it is thus possible to obtain cardo-polymers[185]. The polyarylate formed in the reaction of terephthalic acid dichloride with phenolphthalein is an example of a cardo-polymer[185]:

A characteristic feature of cardo-polymers is that their chains contain carbon atoms incorporated simultaneously in cyclic groups making up the polymer chain (they are designated by circles below). Accordingly, the structure of the cardo-polymer can be represented schematically as follows:



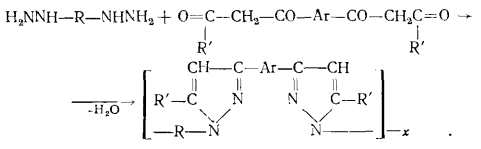
Polycyclisation comprises a large group of polycondensation reactions based on the interaction of dicarboxylic acid esters and fluorides as well as their other derivatives and tetracarboxylic acid anhydrides with diamines, hydroxyamines, mercaptoamines, and tetramines, leading to the formation of various polyheteroarylenes[37,59,63,64]. Thus polyamides, which are some of the most thermostable polymers, have been obtained by the reaction of diamines with acid dianhydrides[89,186-189]:

polyimide



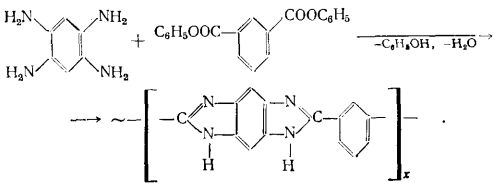
Ladder polymers, an example of which is provided by pyrrones, constitute an interesting group of thermostable polymers. The pyrrone formation reaction proceeds in accordance with the equation[37,60,190,191]

The synthesis of polyamidoacids, the corresponding polycarboximides, and pyrrones by the reaction of di(4-amino-3-carboxyphenyl)methane with the dianhydrides of pyromellitic

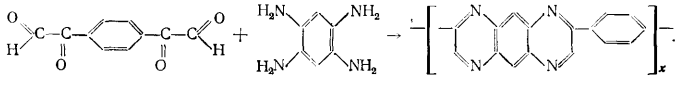


and benzophenone-3,3',4,4'-tetracarboxylic acids has been described[192].

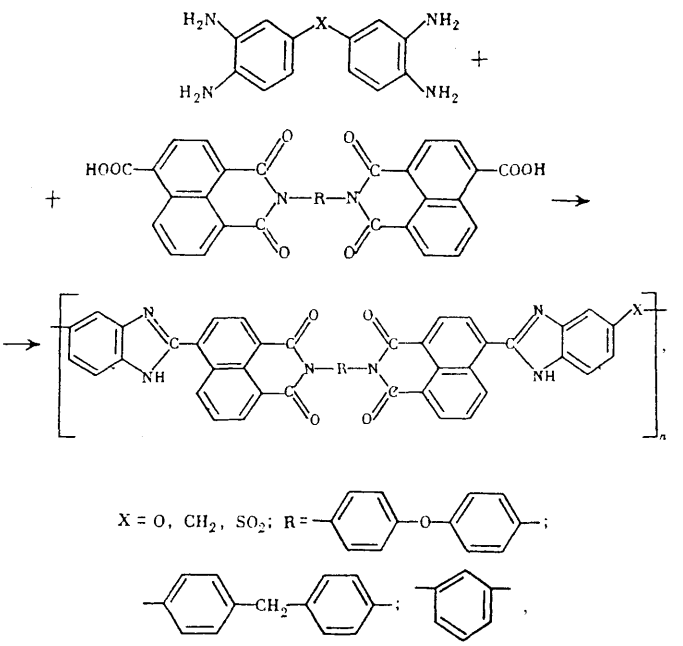
The study of the reaction of di(3,4-diaminophenyl) ether with the dianhydride of naphthalene-1,4,5,8-tetracarboxylic acid showed that the heterocyclisation reaction proceeds via a stage involving the formation of aminoimide rings[193]:



These are examples of a polycyclisation reaction which results in the formation of polymers containing various heterocycles. The great interest throughout the world in polymers of this kind can be explained by the fact that most of them are substances with high thermal stability and this feature has attracted much attention to them and has led to a very great increase in the efforts devoted to research in this field. During the last 10–15 years, when thermostable polymers have also attracted extensive interest, many hundreds if not thousands of polymers of this type have been obtained and it would be impracticable to describe the characteristics of all of them. One must quote several formation reactions of the most widely known polymers of this type in order to demonstrate their characteristic features.

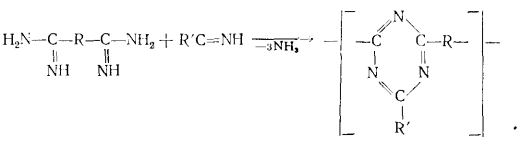


The formation reaction of polypyrazoles, where the starting materials are bis(β-diketones) and dihydrazides, proceeds in accordance with the equation[194]



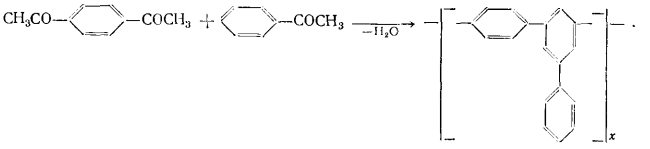
The formation reaction of polybenzimidazoles is[75,195]

Finally we may also mention the formation reaction of polyquinoxalines which involves the interaction of tetramines with dialdehydediketones or tetraketones[80,196]:



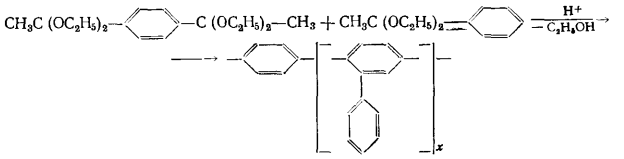
Polybenzimidazolimides, synthesised via the reaction[197]

constitute a new class of polymers. Many more reactions of this type could be quoted but those described above are sufficient to illustrate their general characteristics.



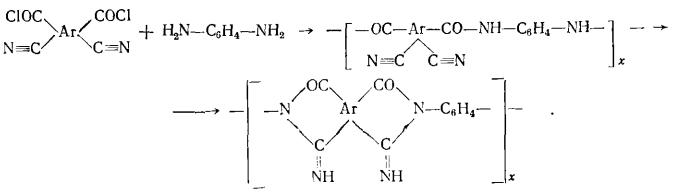
A few words should be devoted to a variety of the polycondensation reaction, namely the polycyclocondensation reaction. In contrast to the polycyclisation discussed above, where a polymer is formed initially and then a heterocycle, i.e. there is a two-stage process, the polycyclocondensation reaction proceeds in such a way that cyclisation is the first stage of the polymerisation process.

As an example, we may quote the formation reaction of triazine polymers involving the polycondensation of mono- and di-amidines[198]:



This reaction has attracted attention because the polymer obtained has rubber-like properties and a high thermal stability.

Another example is the recently discovered polycondensation reaction of ketones leading to the synthesis of polyphenylenes[199,200]:



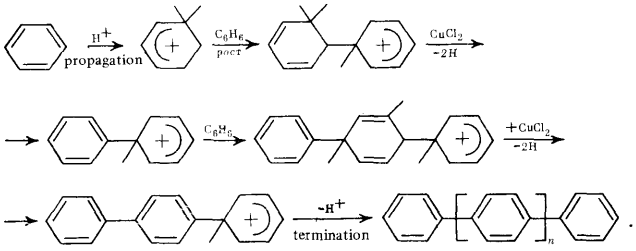
The polycondensation of acetyl groups involves the formation of a new benzene ring joined to the phenyl groups present in the initial monomer. This results in the formation of a soluble and fusible polymer. The reaction constitutes a new method of synthesis of thermostable polyphenylenes.

The reaction has been simplified by replacing the ketones by their ketals[201]. The polyphenylene formation reaction then proceeds in accordance with the equation

A novel instance of polycyclisation is isomerisation polycyclisation distinguished by the fact that the molecule of the initial monomer contains cyano-groups. As a result of this, low-molecular-weight products are not produced in the first stage of the reaction and instead there is addition to the triple bond with formation of a polyiminoimide[186]:

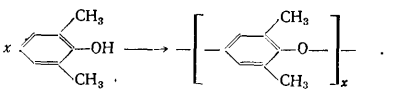
A series of polyheteroarylenes containing several heterocycles and carbocycles in the ring, for example, the imide and oxadiazole rings, the imide and benzimidazole rings, the imide and pyridine as well as pyrimidine rings in various combinations, etc. have been obtained[188,197,202].

An interesting group of dehydropolycondensation reactions is based on dehydrogenation with evolution of hydrogen[203]:



$$R_2BH + HBR_2 \rightarrow RB{-}BR + H_2 .$$

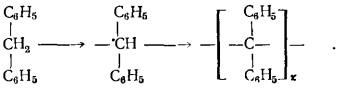
Oxidative dehydropolycondensation is a dehydrogenation reaction under the influence of oxidants and is widely used for the synthesis of various polymers.



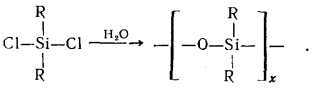
The oxidative dehydropolycondensation of acetylenic compounds is widely employed for the synthesis of polymeric structures containing triple bonds in the chain. A linear carbon polymer, namely carbyne, has been obtained by this reaction[204]:

$$n\,H{-}C{\equiv}C{-}H \rightarrow -(-C{\equiv}C-)_n- .$$

The benzene oxidation reaction, discovered by Kowacic and widely used by other investigators to synthesise polymeric structures, belongs to this class. In this case the oxidant is copper(I) chloride and the reaction thus involves the combination of residues with formation of a polyphenylene structure[205]:

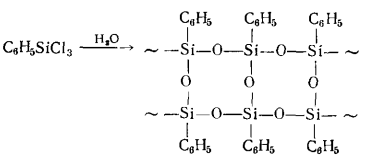


An interesting instance of the oxidative dehydropolycondensation reaction is the oxidation of 2,6-dimethylphenol, leading to the formation of poly(phenylene oxide), which is nowadays manufactured on an industrial scale[206]:

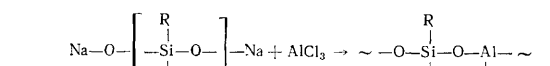


Finally we may mention the amine oxidation reaction used to obtain structures containing double bonds between nitrogen atoms as well as aromatic rings. The polymeric systems obtained in this way are of interest from various points of view[207]:

$$n\,(Ar)_2NH \rightarrow -[-Ar{-}N{=}N-]_n- .$$



The polyrecombination reaction involves the synthesis of polymers in which the free radicals formed in the first stage from the peroxide abstract a hydrogen atom from the molecules of the initial monomer and thus give rise to free radicals which subsequently recombine to form a polymeric structure. In the case of diphenylmethane the reaction proceeds in accordance with the equation[22,208]



The syntheses of organoelemental polymers involving an increasing number of elements have developed very extensively. This field was initiated by the synthesis of polysiloxanes:

This reaction is used widely in industry to manufacture a wide variety of siloxane polymers and oligomers[11,209]. The use of trichlorophenylsilane as the starting material makes it possible to obtain ladder polymers of the type of polyphenylsiloxane[210,211]:

The reaction of organosiloxane blocks with metal salts leads to the formation of polyorganoaluminosiloxanes[212,213]:

The use of salts of other metals leads to the formation of polyorganometallosiloxanes[90,214].

A large number of organoelemental polymers have been obtained by the polycondensation reaction.

XVI. PROSPECTS FOR THE DEVELOPMENT OF POLYCONDENSATION

The present state of the study of polycondensation processes and their utilisation for the synthesis of polymers with a set of properties specified beforehand is characterised, as shown by the examples presented, by a series of significant achievements. There is no doubt that the further development of polycondensation synthesis will enrich polymer science in a large number of new polymers with a set of valuable properties[215]. The development of syntheses of various copolymers, among which mention may be made of

block copolymers of various types, which are of interest as starting materials for the preparation of separating membranes, is extremely promising. The synthesis of various kinds of polymers modelling natural polymers and biopolymers, particularly for use in medicine, is of great interest.

The problem of the study of the characteristic features of polycondensation is of great theoretical importance as regards control of the reactions involving the growth of the macromolecule in order to regulate the size and structure of the polymer chain. Control of the formation reaction of anomalous units, leading to the formation of heterounit polymers, is very important in this sense. This permits a more detailed regulation of the properties of the polymers obtained. The search for new reactions leading to the synthesis of polymers via polycondensation is one of the most important problems in this field. The expansion of the range of monomers and the wide variety of the structures produced are important in this instance.

It is now apparent that the development of new ways of carrying out the polycondensation reaction constitutes an important step towards advances in this field.

New possibilities for the regulation of the macromolecular structure are then created and one can synthesise the required polymers, in particular those with the required supermolecular structure, crystalline or amorphous, as well as conformationally regular polymers. Naturally problems associated with the synthesis of new polymers satisfying the needs of the modern technology and various branches of industry as regards new materials superior to those already known remain important. Among the important problems of this kind, one may point to those involving the formation of thermostable polymers, polymers with a high mechanical strength, effective adhesive properties, hardness, and elasticity, incombustible polymers, polymers with a set of specific properties of the kind possessed by semi-conductors, photosensitive polymers, etc.

In the field of polycondensation processes themselves, there is every reason to expect new advances in the immediate future involving the achievement of controlled polycondensation synthetic methods. Among problems of this kind, one may point to those involving the regulation of the molecular weight in order to obtain high-molecular-weight polymers and also the search for new polycondensation processes. A most important task is to achieve control of synthetic processes of a kind which would permit the regulation of the geometrical and heterounit structures of polymers and hence the synthesis of polymers with the required optimum set of properties. One of the most important ways of solving problems of this kind involves the wide-scale development of research into catalytic processes in polycondensation, the discovery of new ways of regulating the processes involving the synthesis of polymers in polycondensation reactions, and the expansion of the assortment of such reactions.

In conclusion one should note that, as can be seen from the examples presented, there has been considerable progress in the field of polycondensation. New synthetic reactions of polymers are being discovered and synthetic reactions already known are being investigated and improved. As a result, science is being enriched in a large number of new polymers and many of the polymers already known, now obtained by improved methods, have acquired a set of more valuable properties. Our time is characterised by a deepening of the knowledge of increasingly complex chemical reactions and the formation of new extremely complicated polymeric structures, which reflects the growing sophistication of the chemical art in the synthesis of polymers. Methods for the formation of anomalous units, leading to a heterounit structure of polymers, which is an important factor in the determination of the relation between the structure and properties of polymers, have been devised. Finally, an especially characteristic feature of the polycondensation synthesis is the synthesis of polymers not only for constructional purposes but also to an increasing extent of compounds with specific properties such as thermostable, semiconducting, electrically conducting, photoelectrically active, and biologically active polymers, biopolymers, catalysts, ion-exchange resins, and similar polymers with specific properties.

Organometallic Catalysis in Diene and Cyclo-olefin Polymerisation Processes. I. The Polymerisation and Copolymerisation of Dienes Under the Influence of Organometallic Transition Metal Compounds. The Stereoregulation Mechanism

B.A.Dolgoplosk and E.I.Tinyakova

The results of experimental studies on the synthesis of individual organometallic transition metal compounds and of studies on their catalytic activity in stereospecific diene polymerisation and copolymerisation processes are surveyed. The kinetics of the polymerisation under the influence of various nickel-, chromium-, titanium-, and molybdenum-containing systems are examined. The stereoregulation mechanism and the principal characteristics of coordination copolymerisation are discussed on the basis of the experimental data.
The bibliography includes 125 references.

I. INTRODUCTION

The question of the nature of the active centres affecting various types of stereoregulation and of the mechanism of their action has been at the centre of the attention of investigators from the instant of the establishment of the field of synthesis of rubbers by the polymerisation of dienes. This is mainly due to the fact that the properties of the polymers are directly related to the structure of the units in the polymer chain. Thus polybutadiene containing only 1,2-units has a glass point $t_g = -10$ °C, while the rubbers made from it are brittle already at 0 °C. *cis*-Polybutadiene is a highly elastic rubber with $t_g = -108$ °C, while *trans*-polybutadiene is a crystalline fibre with a melting point of ~+140 °C. In the polymerisation of isoprene the number of different variants of the microstructures of the units increases and new structures associated with the inhomogeneity of the distribution of 1,4-units in terms of the "head to tail" and "head to head" arrangements (1,4–1,4; 1,4–4,1; 4,1–1,4) appear. This also applies to other dienes.

Highly stereoregular butadiene and isoprene polymers of different structures were first obtained in the presence of Ziegler type catalysts consisting of transition metal compounds and organoaluminium compounds. Other components ensuring a higher selectivity of the action of the catalytic system and reproducibility of the results are added to them in in many instances.

Table 1 presents the compositions of systems characterised by the highest stereospecificity; some of them are of industrial importance. It is seen from the results presented that only lanthanide-containing systems are equally stereospecific for the formation of *cis*-units in the polymerisation of both butadiene and isoprene. The cobalt and nickel systems are stereospecific for butadiene and lead to the formation of a polyisoprene with a mixed structure. The $TiCl_4$–AlR_3 system is a stereospecific catalyst of the *cis*-polymerisation of isoprene, while in the polymerisation of butadiene many *trans*-units are formed. Vanadium systems based on $VCl_3(VOCl_3, VCl_4)$ are stereospecific in the formation of *trans*-units in the polymerisation of butadiene, while systems without a halogen cause the formation of 1,2(3,4)-units.

Table 1. Catalytic systems with stereospecific activity in the polymerisation of dienes.

Catalytic system*	Contents of units, %				Refs.
	cis-	*trans*-	1,2-	3,4-

An enormous number of studies have been made on the kinetics of the polymerisation of dienes and olefins under the influence of Ziegler systems. The experimental data, particularly the effective activation energies and the reaction orders with respect to the catalyst and the monomer, cannot be used to characterise the active centres, since the probability of the formation of new active centres based on more reduced compounds of the metal increases with increase of temperature or with increase of the concentration of the system components.

The authors of the early investigations assumed that the organoaluminium compound plays the main role in chain propagation steps. However, as research into this field developed, it became clear that the main role in the chain propagation steps is played by the transition metal compound. The concept of the two-centre (multicentre) stereoregulation mechanism in which the atoms of both the transition metal and aluminium are involved has become most widely adopted. The complexity of the composition of Ziegler-Natta catalytic systems and the wide variety of the reactions between their components precluded the finding of direct experimental approaches to the elucidation of the nature of the active centres and the stereoregulation mechanism. New possibilities for the solution of this problem have arisen as a result of the employment of individual organometallic compounds for the initiation of polymerisation.

II. THE SYNTHESIS OF ORGANOMETALLIC COMPOUNDS OF TRANSITION METALS AND THE STUDY OF THE STEREOSPECIFICITY OF THEIR ACTION IN THE POLYMERISATION OF DIENES

The organic derivatives of transition metals with carbon–transition metal π-allyl and σ-bonds which have been synthesised and used in the polymerisation of dienes are listed in Table 2. Compounds having the general formula $\pi\text{-}R_nM$, where R = allyl, crotyl, or pentenyl and M = Ni^{2+}, Co^{3+}, Cr^{3+}, Cr^{2+}, V^{3+}, Nb^{3+}, or Rh^{3+}, were obtained from the corresponding alkenylmagnesium halides and metal chlorides in diethyl ether. Their stability increases in the sequence allyl < crotyl < pentenyl. We have shown[29,39,41] that the pentenyl complexes of many transition metals are stable at 0–20 °C, while the corresponding π-allyl complexes are stable below −20 °C.[24]

π-Alkenylnickel halides have been largely obtained by the Fischer method from nickel carbonyl and the corresponding alkenyl halide.

π-Oligodienylnickel chloride has been obtained by a new method of synthesis based on the interaction of nickel chloride and AlR_3 in the presence of small amounts of a diene (molar ratios Ni : Al : diene = 1 : 3–5 : 10–30),[26] for example:

$$NiCl_2 + R_3Al \rightarrow R_2AlCl + RNiCl \xrightarrow{C_4H_6} R(C_4H_6)_nNiCl.$$

At the end of the reaction the hydrocarbon solution was washed with an aqueous solution of acid to remove completely the organoaluminium compound. The π-alkenylnickel chloride remained entirely in the hydrocarbon solution, the yield amounting to ~90% of theoretical. The oligodienylnickel chloride is more stable than $\pi\text{-}C_3H_5NiCl$ and $\pi\text{-}C_4H_7\text{.NiCl}$. The π-allyl compounds π-RNiOY have been obtained from $\pi\text{-}R_2Ni$ and the corresponding acid (CCl_3COOH, $CH_3C_6H_4OSO_2H$, and o,o-dinitrophenol).[27]

Tribenzyltitanium and tris(trimethylsilylmethyl)titanium can be obtained from $TiCl_3$ and the corresponding organolithium compounds at temperatures in the range −30° to −40 °C in 50–60% yield[37]. However, TiR_3 and other transition metal compounds can be synthesised more conveniently in a more reduced state by a method which we proposed[36] on the basis of the reaction

$$MR_{n+1} + LiC_2H_5 \rightarrow LiR + MR_nC_2H_5 \rightarrow MR_n + 0.5C_2H_4 + 0.5C_2H_6 \quad ,$$

where R = benzyl, trimethylsilylmethyl, or allyl. The reaction is carried out in a hydrocarbon solvent and the yield of MR_n is nearly quantitative. Trimethylbenzyltitanium is fairly stable at 20 °C in solution in aromatic and aliphatic hydrocarbons; the presence of even small amounts of an electron donor [tetrahydrofuran (THF), ether] reduces sharply the stability of the compound. In hydrocarbon solutions tribenzyltitanium is associated and the concentration of paramagnetic species is only 2–3% of the total content of Ti^{3+}, in contrast to tri-π-allyltitanium, which is monomeric in solution and the concentration of the paramagnetic species corresponds to that of Ti^{3+}.[52] Benzyltitanium halides are stable only below −30 °C, disproportionating quantitatively on raising the temperature with formation of equivalent amounts of titanium(II) and titanium(IV) compounds[37]. The occurrence of this reaction precludes the synthesis of TiR_3 from $TiCl_3$ + RMgCl(RLi) above −20 °C.[53] The disproportionation reaction is fully suppressed in the presence of small amounts of diene[51]. It has been shown that butadiene is inserted in the Ti–benzyl bond with formation of trioligodienyltitanium. A similar compound has also been obtained by the reaction of $TiCl_3$ with oligodienyl-lithium in solution in toluene[52]. Tri-π-oligodienyltitanium is monomeric in solution and the concentration of paramagnetic species corresponds to that of Ti^{3+} determined by reaction with Fe^{3+}; the compound is stable for a long time at room temperature[52].

Table 2. The organometallic compounds synthesised and used as catalysts of the polymerisation of dienes.

Organometallic compound	Methods and conditions of synthesis	Refs
$\pi\text{-}R_2Ni$(R = allyl or crotyl)	$NiCl_2$ + RMgCl; ether; −30–−40°	[24]
π-RNiX (R = allyl, crotyl, pentenyl, or cyclohexadienyl; X = Cl, Br, or I	$Ni(CO)_4$ + RCl; benzene; 60–65°	[25]
$\pi\text{-RNiCl}$ [$R = R'(diene)_n$]	$NiCl_2 + AlR_3' + C_4H_6(C_5H_8)$ (1 : 2÷5 : : 10÷30); 0°	[26]
π-RNiOY (R = allyl or crotyl)	$\pi\text{-}R_2Ni$ + HOY; toluene; −30°; OY = CCl_3COO, CF_3COO, o,o-dinitrophenoxy, or $CH_3C_6H_4OSO_2$	[27]
$\pi\text{-}R_3Cr$ (R = allyl, pentenyl, or crotyl)	$CrCl_3$ + RMgX; ether; −20°	[28, 29]
$\pi\text{-}R_2Cr$ (R = allyl or pentenyl)	$CrCl_2$ + RMgX; ether; 0-20°	[29]
$\pi\text{-}R_2CrOSi\vert SiO_2$	$\pi\text{-}R_3Cr + HOSi\vert SiO_2$	[30]
$\pi\text{-}RCr(OSi)_2\vert SiO_2$	$\pi\text{-}R_3Cr + HOSi\vert SiO_2$	
$\pi\text{-}RCr(OAl\vert)_2\vert Al_2O_3$	$\pi\text{-}R_3Cr + HOAl\vert Al_2O_3$	[30]
$\pi\text{-}R_2CrCl$	$\pi\text{-}R_3Cr$ + HCl; toluene; −30°	[31]
$(C_6H_5CH_2)_4Ti$	$TiCl_4$ + RMgCl; ether + heptane; −25°	[32, 33]
$(C_6H_5CH_2)_3TiI$	$TiR_4 + I_2$; toluene + benzene; −20°	[33]
$(C_6H_5CH_2)_3TiBr$	$TiR_4 + Br_2$; toluene + benzene; −20°	[33]
$(C_6H_5CH_2)_3TiCl$	TiR_4 + HCl; toluene; −16°	[33]
$[(CH_3)_3SiCH_2]_nTiCl_{4-n}$	$TiR_4 + TiCl_4$	[34, 35]
$(C_6H_5CH_2)_3Ti$	$(C_6H_5CH_2)_4Ti + LiC_2H_5 \rightarrow [(C_6H_5CH_2)_3TiC_2H_5] \rightarrow TiR_3$	[36]
$(C_6H_5CH_2)_2TiI$	$TiR_3 + 0.5I_2$; toluene + benzene; −35°	[37]
$(C_6H_5CH_2)_2TiCl$	TiR_3 + HCl; toluene + benzene; −35°	[37]
$C_6H_5CH_2TiCl_2$	TiR_3 + 2HCl; toluene + benzene; −20–−35°	[37]
$C_6H_5CH_2TiI_2$	$TiR_3 + I_2$; toluene + benzene; −35°	[37]
$[(CH_3)_3SiCH_2]_3Ti$	$TiCl_3 + LiCH_2Si(CH_3)_3$; ether; −50°	[37]
$(C_3H_5)_3Ti$, $(C_4H_7)_3Ti$	$TiCl_3$ + RMgX; ether; −30°	[1, 38]
$(C_5H_9)_3Ti$	$TiCl_3$ ($TiCl_4$) + RMgX; ether	[39]
$[C_3H_5(C_4H_6)_n]_3Ti$ ($n = 2 \div 10$)	$TiR_3 + (2-10)C_4H_6$; toluene; −20°	[40]
$(C_5H_9)_3V$	$VCl_4 + C_5H_9MgX$; ether; −30°	[41]
$[(CH_3)_3SiCH_2]_3V$	$VCl_3 + (CH_3)_3SiCH_2Li$; ether + heptane	[42]
$(\pi\text{-}C_3H_5)_4Mo$(W, Zr)	$MCl_4 + C_3H_5MgX$	[43,45]
$(C_3H_5)_nMo$(W, Zr)X_{4-n}	$M(C_3H_5)_4 + HX$	[46]
$(C_3H_5)_3Nb$	$NbCl_3 + C_3H_5MgX$; ether	[47]
$(C_3H_5)_2NbCl$	$NbR_3 + HCl$	[47]
$(C_3H_5)_3Rh$	$RhCl_3 + C_3H_5MgCl$	[47]
$(C_6H_5CH_2)_3Nd$	$NdCl_3 + LiCH_2C_6H_5$; ether; −25°	[48]
$RLnCl_2$(R = $C_6H_5CH_2$, $(C_6H_5)_3C$)	Ln + RCl; THF; 20–40°	[49, 50]

Tribenzylneodymium is stable only below −20 °C, but in the presence of dienes it is stabilised and induces their polymerisation at 50 °C. All three Nd–benzyl bonds are involved in the polymerisation process and the active centre is a trioligodienyl derivative of neodymium, which proved to be fairly stable[48].

Thus it has been established in relation to Ti^{3+}, Nd^{3+}, and other ions that the oligodienyl derivatives of transition metals are much more stable than the corresponding π-allyl, benzyl, etc. derivatives. This finding has been explained[52] on the basis of the idea of the stabilising action of the π-complexes of the transition metal with the double bonds of the oligodienyl chain.

Arylalkyl-lanthanide dichlorides have been obtained by the oxidative addition of arylalkyl halides to the metallic lanthanide (Nd, Pr, Ho, or Gd) in THF.[49,50] A distinctive feature of the compounds formed is their ability to metallate THF.

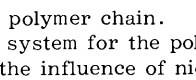
The reaction involving the addition of dienes and olefins to the M–H bond is a source of the formation of organometallic compounds. Thus the interaction of dienes with nickel, cobalt, and chromium hydrides leads to the formation of the corresponding π-allyl complexes, which can participate in polymerisation like the compounds described above[54]. In essence, this type of reaction obtains in systems of the Ziegler type when hydrogen is used to regulate the molecular weight:

$$pMX_n + H_2 \rightarrow pH + HMX_n \xrightarrow{C_4H_6} \pi\text{-}C_4H_7MX_n \xrightarrow{C_4H_6} \text{chain propagation},$$

where p is the polymer chain.

An effective system for the polymerisation of dienes is formed under the influence of nickel and other metal subhalides obtained by heating *in vacuo*.[55] In this case a very small amount of paramagnetic NiCl species, incorporated in the mass of nickel chloride, is produced. These species become organometallic active centres initiating the polymerisation of butadiene, particularly after the extinction of the paramagnetic signal by hydrogen (the formation of $HNiCl|NiCl_2$). In a number of instances metal hydrides can serve as a convenient source in which active centres are formed. In view of the lower stability of σ bonds compared with π-allyl bonds in olefins (styrene and ethylene), the reaction of the latter usually terminates with formation of oligomers and the active centre propagating the chain in HNiX:[56]

$$HNiX + H_2C{=}CHC_6H_5 \rightarrow H_3C{-}CH(C_6H_5)NiX \xrightarrow{H_2C=CHC_6H_5}$$
$$\rightarrow H_3C{-}CH(C_6H_5)CH_2{-}CH(C_6H_5)NiX \rightarrow H_3C{-}CH(C_6H_5)CH{=}CHC_6H_5 + HNiX\ .$$



Studies have established that organometallic compounds of transition metals are the true active centres for the polymerisation of dienes and the stereospecificity of their action is determined by the nature of the metal and the ligands surrounding it.

Table 3 presents experimental data characterising the stereospecificity of the action of various organometallic compounds in the polymerisation of butadiene and isoprene. Polymerisation proceeds in all cases throughout the addition of the monomer to the carbon–transition metal bond. The active centre of the growing chain is an organometallic compound of the alkenyl type with a π-allyl or σ bond depending on the nature of the transition metal. π-Allylnickel halides are *trans*-regulating catalysts leading to the formation of crystalline *trans*-polybutadiene and *trans*-polyisoprene[57–59,65]. π-Allylnickel iodide is the most active in the π-allylnickel halides. One should note that the π-alkenylnickel halides are as a rule dimeric and the order of the polymerisation reaction with respect to the catalyst is 0.5.[57] It follows from this that only small numbers of monomeric forms, which exist in equilibrium with the associated species, participate in the polymerisation reaction.

It is seen in relation to $\pi\text{-RNiOCOCCl}_3$ as an example that the substitution of the halogen by a more electronegative group reverses the stereospecificity of the action of the catalyst (from *trans*- to *cis*-). The most effective and stereospecific, in relation to *cis*-stereoregulation in the polymerisation of butadiene, are the products of the interaction of π-RNiX with electron acceptors (A_1 and A_2); charge-transfer complexes (CTC) and complexes with the transfer of an anion (ATC):

$$\underset{\vdots\ A_1^-}{\pi\text{-}R\overset{+}{N}iCl} \qquad \underset{ATC}{\pi\text{-}R\overset{+}{N}i\,[ClA_2]^-}$$
CTC

Table 3. The stereospecificity of the action of organometallic compounds of transition metals in the polymerisation reactions of butadiene and isoprene.

*A = acceptor—chloranil, chloral, CCl_3COOH, CCl_3COCl, $M(OCOCCl_3)_2$ (M = Zn, Ni, or Mg), $TiCl_4$, AlX_3, $NiCl_2$, $CoCl_2$, etc.

Chloranil, fluoranil, chloral, trichloroacetic acid, etc. have been investigated as the acceptors A_1 and various metal salts playing the role of Lewis acids ($AlCl_3$, zinc trichloroacetate,

$ZnCl_2$, $NiCl_2$, and other salts) have been studied as the acceptors A_2.[60,61,68–70] In both cases (CTC and ATC) the increase of the efficiency of the action of the system is associated with the increase of the positive charge on the nickel atom. Some of the catalytic systems investigated proved to be extremely effective even at −15 °C. Investigations have established that, when π-RNiX interacts with acceptors, side reactions take place and lead to the decomposition of a considerable proportion of the organonickel compound, as a result of which the amount of the effective active centres propagating the polymerisation reaction is 10–15% of the π-RNiX introduced[71–73]. In all cases the reaction is of first order with respect to the catalyst.

Organochromium compounds (π-R_3Cr and π-R_2Cr) lead preferentially to the formation of 1,2(3,4)-units in the polymerisation of dienes[29,31]. In all cases low-molecular-weight polymers are formed (the average degree of polymerisation is 25–30) containing a conjugated system of double bonds at one end of the chain. The molecular weight of the polymer is independent of the monomer concentration although the propagation reactions have been shown to be of first order with respect to the monomer[31]. Hence it follows that not only the propagation reaction but also the chain transfer reaction proceeds with participation of the monomer:

The quantitative Diels–Alder reaction of polymer chains with maleic anhydride indicates the *trans*-conformation of the diene end of the chain (analogue of *trans*-piperylene). The use of π-allyl compounds of chromium thus leads to the possibility of obtaining oligomeric unsaturated products with the functional group at one end of the chain.

In contrast to the comparatively unstable π-alkenyl derivatives of chromium, the organometallic compounds of chromium(II) and chromium(III), bound chemically to the SiO_2 or aluminosilicate surface, are fairly stable, propagating the polymerisation process via the "live" chain mechanism even at ~70 °C. These systems are extremely stereospecific for the formation of *trans*-units in the polymerisation of various dienes[30,62]. The *trans*-conformation of the units is fully retained in the copolymerisation of dienes. The above systems can be used to obtain the corresponding crystalline homopolymers (butadiene and isoprene) as well as amorphous *trans*-copolymers. All the groups bound to the chromium atom participate in the polymerisation reaction and the molecular weight of the polymer increases continuously with the degree of polymerisation. The similarity of the copolymerisation constants (r_1 and r_2) for butadiene, isoprene, and piperylene must be noted. The identity of the microstructures of the polymers and the identify of the constants of the copolymerisation of butadiene with isoprene permitted the conclusion that the chromium oxide catalyst known previously (CrO_3 on a carrier) acts via analogous stages involving organochromium compounds[30].

π-Alkenylchromium compounds, bound chemically in Al_2O_3, are *cis*-stereoregulating catalysts in the polymerisation of butadiene and isoprene, in contrast to the compounds described above. However, they rapidly lose their activity at a comparatively low degree of polymerisation[62]. The most important distinctive feature of this system is the formation of a polymer with a very high molecular weight even at a low degree of conversion, which indicates a very high rate of chain propagation. When the allyl groups in π-R_3Cr are substituted by electronegative groups, the system becomes *cis*-stereoregulating[31].

Like polyallylchromium compounds, tetrabenzyltitanium induces the formation of mainly 1,2(3,4)-units. The substitution of one benzyl group by a chlorine, bromine, or iodine atom increases the content of *cis*-units (in the sequence indicated). Tribenzyltitanium iodide is a highly stereospecific catalyst for the synthesis of *cis*-polybutadiene. The somewhat smaller content of *cis*-units in the polyisoprene formed can be due to the contamination of the system by a very small amount of oxygen-containing impurities. It has been established that the addition of small amounts of THF or diethyl ether to $(C_6H_5CH_2)_3TiI$ reverses the stereospecificity of the action of the system from 1,4-*cis*-specificity to 1,2-stereoregulation, as in the case of organolithium compounds. Only one benzyl group participates in polymerisation steps under the influence of $(C_6H_5CH_2)_4Ti$ and $(C_6H_5CH_2)_3TiI$; this is illustrated by the data in Fig. 1, which presents the yields of toluene in the decomposition of the polymerisation mixture by an aqueous solution of acid at the end of the polymerisation reaction[33],

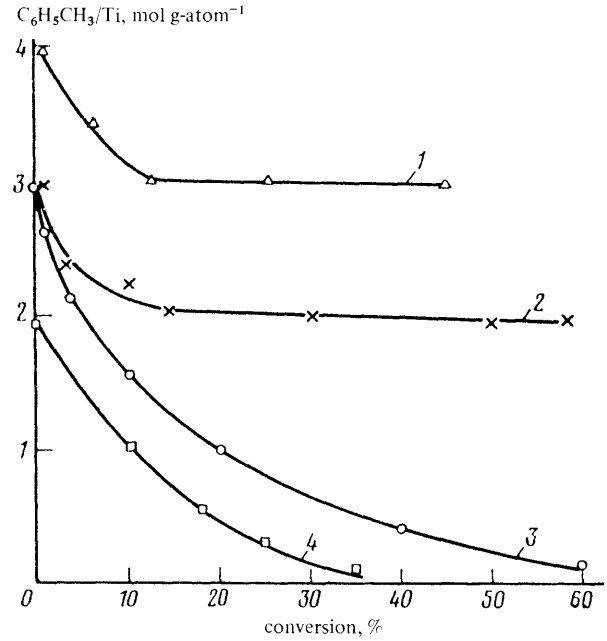

Figure 1. The consumption of benzyl groups in the polymerisation of butadiene {$[C_4H_6]$ = 5 M} under the influence of benzyl derivatives of titanium(IV) and titanium(III):[33,37,40]
1) $(C_6H_5CH_2)_4Ti$, [Ti] = 5 × 10^{-3} M, 50 °C, *o*-xylene;
2) $(C_6H_5CH_2)_3TiI$, [Ti] = 1.5 × 10^{-3} M, 25 °C, *o*-xylene;
3) $(C_6H_5CH_2)_3Ti$, [Ti] = 10 × 10^{-3} M, 50 °C, toluene;
4) $(C_6H_5CH_2)_2TiI$, [Ti] = 3 × 10^{-3} M, 25 °C, toluene.

It is important to note that tetrabenzyltitanium remains in the quadrivalent state throughout the polymerisation process. Titanium(III) compounds have so far been investigated only

in the polymerisation of butadiene. Tribenzyltitanium leads to the preferential formation of 1,2-units and, in contrast to tetrabenzyltitanium, all the benzyl groups are involved in the polymerisation reaction (Fig. 1). Among all the halogeno-derivatives of tervalent titanium, only $(C_6H_5CH_2)_3TiI$ is a highly effective catalyst of the synthesis of *cis*-polybutadiene. The polymerisation proceeds with an appreciable induction period due to the slow initiation stage—the insertion of butadiene in the titanium–benzyl bond. The induction period disappears completely following the addition of organoaluminium compounds (R_3Al and R_2AlCl; Al/Ti = 1 mol mol^{-1}) to R_2TiI. It has been shown for the $(C_6H_5CH_2)_2$. .TiI + R_2AlCl system[74] that the exchange reaction results in the immediate substitution of the benzyl groups by isobutyl groups, to which butadiene adds in a broad front:

$$(C_6H_5CH_2)_2TiI + (iso\text{-}C_4H_9)_2AlCl \rightarrow (iso\text{-}C_4H_9)_2TiI + (C_6H_5CH_2)_2AlCl .$$

At the end of the polymerisation process, after the decomposition of reaction mixture with an aqueous solution of acid, all the benzyl groups of the initial dibenzyltitanium iodide can be detected quantitatively in the form of toluene (Fig. 1).[74] It follows from the results that the true active centre in the Ziegler "titanium" system used under industrial conditions to synthesise *cis*-polybutadiene is apparently the compound R_2TiI.

Tri-π-allylniobium leads to the formation of amorphous 1,2-polybutadiene and the substitution of even only one of its allyl groups by chlorine leads to *cis*-stereoregulation. Among all the polyallyl derivatives of transition metals, only the rhodium compounds lead to *trans*- and not 1,2(3,4)-units.[47]

Tetra-allyl derivatives of molybdenum and tungsten do not themselves induce the polymerisation of dienes; polymerisation catalysts based on them are formed after the substitution of one allyl group by a halogen atom or other anionic species[43,45,46]. Two allyl groups in the resulting active centres are linked to the Mo(W) atom by a π-allyl bond and are not involved in polymerisation; one allyl group is linked to the metal by a σ bond and polymerisation proceeds via the latter. The organometallic active centres indicated are extremely stereospecific for the formation of amorphous and crystalline 1,2-polybutadiene. The syndiotactic arrangement of units predominates in the chain[44].

Like $(\pi\text{-}C_3H_5)_3Rh$, tribenzylneodymium leads to *trans*-structures in the polymerisation of butadiene and isoprene[48].

Triphenylmethylneodymium dichloride, containing 3–4 THF molecules in the coordination sphere, becomes an effective *cis*-regulating catalyst of the dimerisation of isoprene and butadiene after the introduction of tri-isobutylaluminium (Al/Nd = 3–5 mol mol^{-}).[49] The role of AlR_3 is still obscure—it is not clear whether it is involved only in complex formation with THF or whether it plays the role of an electron acceptor, forming complexes with $R'NdCl_2$. One cannot rule out the possibility that, as in the $(C_6H_5CH_2)_2TiI$ + R_2AlCl system examined above, the rate-limiting stage in this instance is the addition of the first diene molecule to the Nd–C bond, while the organoaluminium compound eliminates the induction period by replacing the triphenylmethyl group by the isobutyl group in the $(C_6H_5)_3CNdCl_2$ molecule.

The *trans*-isomer and not the *cis*-isomer is involved in the polymerisation of piperylene under the influence of transition metal compounds and RLi in hydrocarbon media in the vast majority of cases. This is correlated with the fact that *trans*-piperylene is capable of bidentate coordination to the metal. For the same reason, only the *trans*-isomer enters into the Diels–Alder reaction with maleic anhydride.

The polymerisation of cyclohexadiene can lead to two types of structure with the *cis*-conformation of units:

1,4-unit 1,2-unit

An amorphous polymer with approximately equal contents of the 1,4- and 1,2-units is formed under the influence of RLi in hydrocarbon and solvating media and systems of the Ziegler type (R_3Al + $TiCl_4$, R_3Al + VCl_3, etc.). The equal contents of the 1,4- and 1,2-units are apparently correlated with the equal probabilities of the formation of the active centres  -M and . Blocks of 1,2-units cannot arise in the chain owing to steric hindrance. A crystalline polymer with a melting point of the crystalline phase of ~270 °C is formed under the influence of complexes of π-allylnickel halides with electron acceptors (chloral etc.). The polymer contains more than 90% of 1,4-units and its glass point is ~120 °C.[75]

Table 4. Kinetics of the polymerisation of dienes under the influence of organometallic compounds of transition metals.

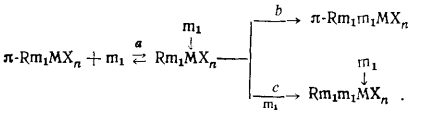
*At low monomer concentrations the rate of polymerisation increases with increasing concentration, while at higher concentrations (2–4 M and above) the rate is independent of the monomer concentration. The lower the catalyst concentration[29,65] and temperature[81], the lower the monomer concentration at which the zero order of the reaction with respect to the monomer is observed.

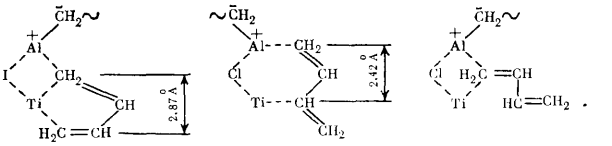


III. KINETICS OF THE POLYMERISATION OF DIENES UNDER THE INFLUENCE OF ORGANOMETALLIC COMPOUNDS OF TRANSITION METALS

The kinetics of the polymerisation of butadiene and isoprene, in particular the reaction orders with respect to the monomer and the catalyst and the effective activation energy have been studied for a series of systems characterised by different stereospecificities of their action. In certain cases the concentration of the effective active centres for the

chain transfer reaction were determined experimentally. The results of these investigations are summarised in Table 4.

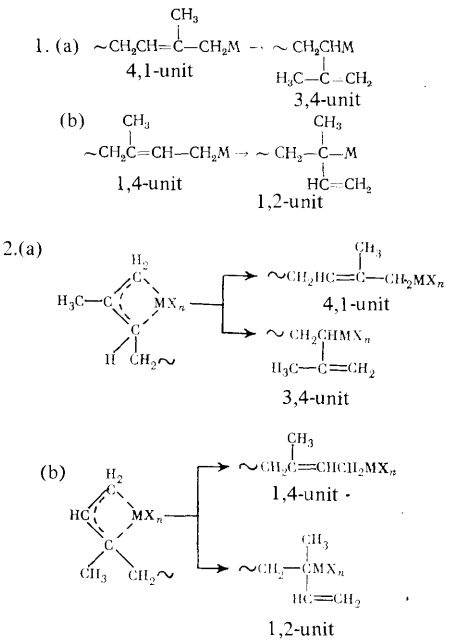
The effective activation energies E_a^{eff} for various systems vary from 6 to 19 kcal mol^{-1}. The π-RNiCl.chloranil, π-RNiCl.Ni$(OCOCCl_3)_2$, and tribenzyltitanium iodide systems are characterised by very low activation energies (6 to 8 kcal mol^{-1}). In most cases the rate of polymerisation of dienes is proportional to the concentration of the organometallic compound. In polymerisation under the influence of di-π-allylnickel iodide the order of the reaction at the catalyst concentration normally employed, i.e. $[Ni] > 10^{-3}$ M, is 0.5–0.6. Hence it follows that, like the initial π-allylnickel iodide, oligodienylnickel iodides exist in a dimeric form and the polymerisation reaction involves the monomeric form π-RNiI. The reaction order of 0.6 for the polymerisation of isoprene indicates a somewhat greater tendency of oligoisoprenylnickel iodide towards dissociation. At very low π-RNiI concentrations (10^{-5}–10^{-6} M) the reaction is first order with respect to the catalyst in the polymerisation of butadiene[76], which suggests that at such concentrations the monomeric form π-RNiI predominates.



The order of reaction with respect to the monomer varies from 1 to 2, which reflects the influence of the stage in which the monomer is coordinated to the active centre. The mechanism of the incorporation of the monomer into the polymer chain presupposes an equilibrium stage involving the coordination of the monomer to the active centre and the stage in which it is inserted in the chain via a unimolecular or bimolecular mechanism:

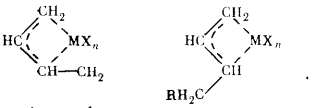
Pathway *b* presupposes a unimolecular mechanism of the insertion of the coordinated monomer in the polymer chain via the C–M bond, while pathway *c* presupposes a bimolecular mechanism involving the displacement of a coordinated monomer by another monomer molecule (from the solution). There is a possibility that both reaction pathways operate simultaneously and the order with respect to the monomer can vary from 1 to 2 depending on which of the above stages limits the overall rate of the process.

IV. THE MECHANISM OF STEREOREGULATION IN THE COORDINATION POLYMERISATION OF DIENES



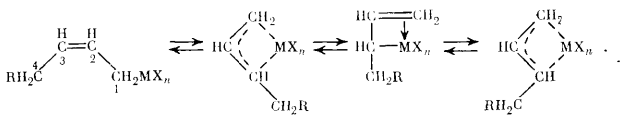
In the majority of studies on the polymerisation of dienes under the influence of Ziegler systems published previously the nature of the active centres and the polymerisation mechanisms were regarded from the same standpoint as in the consideration of the polymerisation of olefins. The structure of a bimetallic complex with bridge bonds was attributed to the active centre. In the first investigations it was assumed that chain propagation proceeds via the C–Al bond of the organoaluminium compound bound in a complex with a transition metal salt. Later schemes presuppose that the transition metal plays a decisive role in this complex and that the monomer is inserted not only in the Al–C bond but also in the carbon–transition metal bond. Furukawa[83] assumed that the structure of the units formed is determined by the length of the C–M bond which is correlated with the electronegativity of the metal. With decrease of the distance between two neighbouring sites, the structure becomes more favourable for coordination in the sequence *cis*-addition, *trans*-addition, and 1,2-addition, in which suitable distances are 2.87, 2.42, and less than 2.42 Å respectively:

In Ziegler catalysis stereoregulation is achieved by a complex catalyst having two coordination centres. The idea that a second, non-transition metal (aluminium) etc. must be present in the complex proved invalid after the possibility of the stereospecific catalysis under the influence of individual organometallic compounds of transition metals had been established. The first stage of the polymerisation reaction is coordination of the monomer to the transition metal.



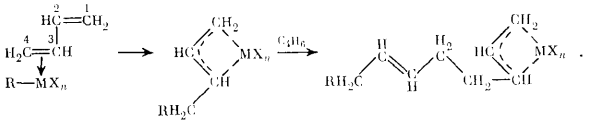
1. The Mechanism of the Formation of 1,4-*cis*- and *trans*-Units

In considering the question of the stereoregulation mechanism, we begin with the assumption that the structure of the units formed on polymerisation is determined by the structure of the terminal unit in the active centre and not the configuration of the monomer in solution[84–86]. This means that the *cis*- and *trans*-units are not genetically linked to the cisoid or transoid state of the monomer. The microstructure of the polymer chain already yields some information about the nature of the active centres. Thus in the organometallic σ-compounds of transition metals and lithium and in the π-allyl complexes the contents of 1,2- and 3,4-units also reflect a definite conformation of the active centre, for example:

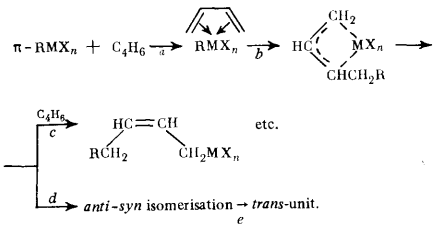


The formation of 1,2- and 3,4-units is genetically linked to a specific concentration of the terminal σ- or π-allyl active centre. The simultaneous presence of 1,2- and 3,4-units in polyisoprene therefore indicates the inhomogeneity of the chain structure in terms of the "head to tail" arrangement (the 1,4–1,4, 1,4–4,1, and 4,1–1,4 structures).

Examples of organometallic σ-compounds of transition metals initiating polymerisation are provided by titanium(IV) compounds as well as the organomolybdenum compounds R
|
π-R_2MoX, in which only the allyl group linked to molybdenum by a σ bond participates in chain propagation. The organometallic derivatives of alkali and alkaline earth metals and apparently the majority of organolanthanide compounds belong to a similar type. The alkenyl derivatives of transition metals, particularly those containing the metal in a reduced state, are formed as the stable compounds of the π-allyl type with two possible configurations (*anti*- and *syn*-), for example, for the crotyl derivatives, we have

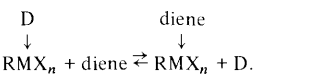


anti-complex *syn*-complex



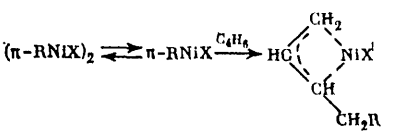
The *anti*-complex can be regarded as a seed giving rise to a *cis*-unit, while the *syn*-complex is a similar seed for a *trans*-unit. Tolman established for the first time that, when butadiene adds to HNi^+L_4 (L = phosphate ligand), an *anti*-complex is formed initially and isomerises subsequently to the *syn*-complex[87]. The *anti–syn* isomerisation can be represented only as a process proceeding via an intermediate σ-state, in which the metal is bound to a third carbon atom, because direct *cis–trans* transitions are energetically difficult:

The isomerisation takes place as a result of the migration of the "counterion" in the allyl conjugation system. The equilibrium amount of the σ-forms in the π-allyl complexes depends on the nature of the metal and the surrounding ligand. Naturally the electron-donating compounds forming complexes with the transition metal, which include also the monomer undergoing polymerisation, displace the equilibrium towards the σ-forms. If there is one vacancy (for coordination) at the transition metal, the diene can be coordinated via only one double bond, assuming a transoid conformation in the coordination sphere of the metal. The primary insertion of the monomer in the chain can then lead to a *trans*-unit:[85]

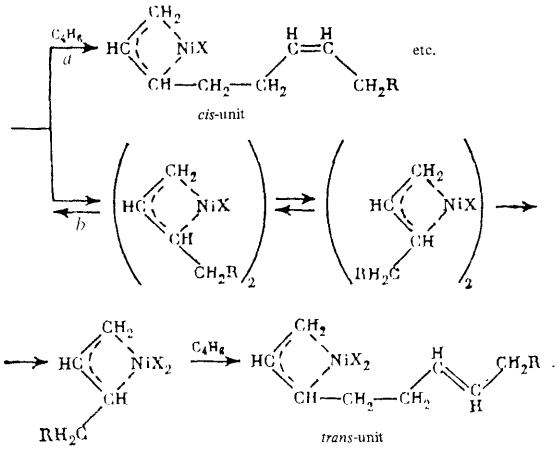


However, in the vast majority of cases the conjugated diene plays the role of a bidentate ligand, which assumes a cisoid conformation on the metal. This entails the transition from the π-allyl structure of the active centre to the σ-state:

The bidentate coordination of the conjugated diene is most likely for the monomeric form of the organometallic compound, characterised by the greatest number of vacancies for coordination.



The polymerisation reaction consists of a sequence of stages involving the formation of a π-complex with the diene and its conversion into a π-alkenyl complex after the insertion of the diene in the chain with subsequent transition to the σ-state on coordination with the next monomer molecule (reactions *a–c*). Pathway *d* leads to the *anti–syn* isomerisation of the complex and the formation of *trans*-units. Thus, in polymerisation under the influence of monomeric forms of the organometallic compound, the chain microstructure is determined by the ratio of the rates of growth and isomerisation of the active centre. For systems in which the reaction is of first order with respect to the monomer, one may expect that, at very low monomer concentrations where the "lifetime" of the terminal unit increases, the number of *trans*-units should increase at the expense of the *cis*-units. This has been confirmed experimentally in the case where individual organonickel and Ziegler systems with participation of titanium and cobalt compounds were used[88] (Fig. 2). The results of studies presented in Fig. 2 show that in all cases indicated an appreciable decrease of the content of the *cis*-units and the corresponding increase of the content of *trans*-units are observed at low monomer concentrations (up to 0.4 M). Any factors favouring the "sticking" of the terminal unit in the active centre increase the role of the isomerisation in reaction. Electron-donating compounds (D) (ethers, sulphides, and amines) have a similar effect, being coordinated to the transition metal and displacing the diene:

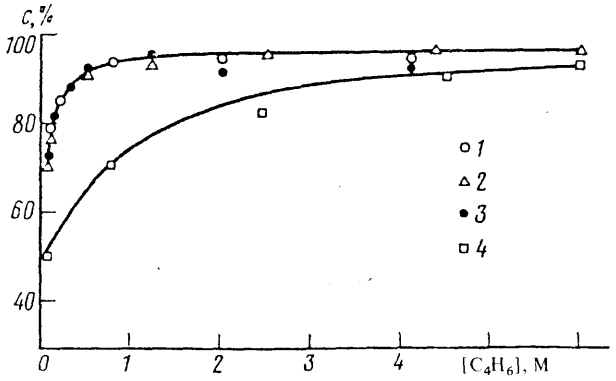


As will be shown below, the second monomer (m_2) has an analogous effect in copolymerisation if the rate of its insertion in the chain is less than the rate of insertion of the first monomer (m_1).

The question of the stereoregulation mechanism in cases where the organometallic active centre is in an associated state and the main true active centre in the chain propagation stage is the monomeric form is of great interest. This applies, for example, to the *trans*-regulating π-alkenylnickel halides, which exist in solution in the form of dimers and for which the reaction order with respect to the catalyst is 0.5,[57] and also to the butadienyl and isoprenyl derivatives of lithium. The latter exist in a hydrocarbon solution in the form of the associated species $(RLi)_4$ and the reaction order with respect to the catalyst is 0.25.[91,93] It follows from the data presented that, in the instances indicated, generally a small number of the monomeric active centres, in equilibrium with the associated species, participate in the polymerisation.

The mechanism of the chain propagation reaction involving π-alkenylnickel halides is[86,89]

In the primary product of the addition of the diene to the monomeric form π-RNiX the unit has the *cis*-conformation. In the associated species formed subsequently the π-alkenyl unit undergoes the *anti–syn* (*cis–trans*) isomerisation, which leads to *trans*-units on subsequent dissociation[89]. Since the fraction of the monomeric forms is very small, the associated species, not involved in the chain propagation steps, play a decisive role in the formation of microstructures. It is essential to note that only *trans*-β-butene is formed in the hydrogenolysis of π-crotylnickel chloride with complete absence of *cis*-butene[90]. This shows that the equilibrium concentration of the *syn*-form of π-crotylnickel halides is close to 100%.



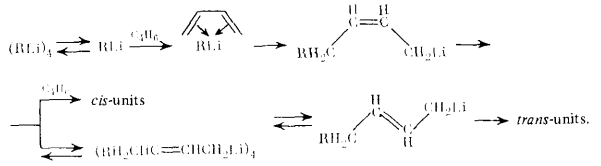


Figure 2. The influence of the monomer concentration on the microstructure of polybutadiene[88] (*c* = content of *cis*-units): *1*) π-C_5H_9NiCl–$Ni(OCOCCl_3)_2$; *2*) π-$C_3H_5NiOCOCF_3$; 3) $CoCl_2$–R_2AlCl; 4) TiI_2Cl_2–R_3Al; *1*), 3), and 4) 20 °C; 2) 40 °C; *1*), 3), and 4) solvent–toluene; *2*) solvent–heptane.

In the case of organolithium compounds the chain microstructure depends greatly on the RLi concentration in solution, which is illustrated by the data in Table 5. With decrease of the RLi concentration, the content of the *cis*-units in polyisoprene and polybutadiene increases. Presumably at vanishingly low concentrations of organolithium compounds only the *cis*-units are formed. The higher content of the *cis*-units in polyisoprene compared with polybutadiene for the same RLi concentration is consistent with the higher rate of chain propagation. It has been shown[93] that the rate of homopolymerisation of isoprene is significantly higher than that of butadiene. The mechanism of stereoregulation in the polymerisation of dienes under the influence of organolithium compounds must be represented by the same general scheme as for π-allylnickel halides:

The *cis–trans* isomerisation in the associated species apparently proceeds as a result of the transfer of the counterion (Li^+) to neighbouring molecules in the associated species and not via a unimolecular mechanism, because direct *cis–trans* transitions require a high activation energy.

Table 5. The influence of the catalyst concentration on the microstructure of the polymers obtained under the influence of organolithium compounds (20 °C, solvent—heptane).

0.00001	86	10	4	—	[92]						

Polyakov et al.[94] showed for the first time that polymerisation on crystalline ethyl-lithium with supply of the diene from the gas phase takes place very slowly and leads to the preferential formation of 1,2(3,4)- and *trans*-units. Such a structure is characteristic of polymerisation involving the more polarised C–Li bond in the associated species.

The structure of such associated species depends greatly on their composition, which is indicated by the different compositions of the butenes formed on decomposition of the homoassociated crotyl-lithium species or mixed associated species incorporating crotyl-lithium and lithium alkyl by water or acid. In the former case β-butenes are formed preferentially, while in the latter α-butene is the preferred product[95].

The differences between the microstructures of polyisoprene and polybutadiene at the same RLi concentration can also be explained by the different rates of the *cis–trans* isomerisation in the associated species.

It was shown above that, depending on the nature of the ligands, either *trans*- or *cis*-units are formed in the presence of the same transition metal. It might have been expected that the rate of propagation in a *cis*-regulating system (v_a) would be significantly higher than in a *trans*-regulating system (v_b). Table 6 presents data illustrating the decrease of the rate of chain propagation (v_a/v_b) in the

presence of the same metal (Ni, Cr, and Ti) when the stereospecificity of the catalytic action is reversed from *cis*-stereoregulating to *trans*-stereoregulating.

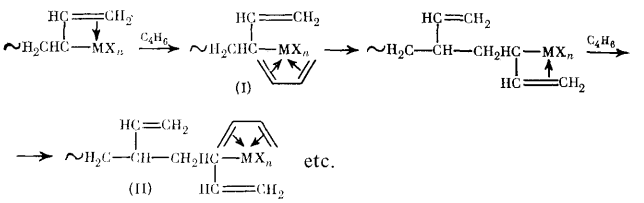
Table 6. Comparison of the rates of chain propagation in the *cis*- and *trans*-stereoregulating systems[96].

No.	Catalytic system	Contents of units, %				v_a/v_b
		cis-	*trans*-	1,2-	3,4-	
	Isoprene					
1a	π-RCr(OAl)(OAl) | Al_2O_3	95	0	0	5	10^3
1b	R(R)Cr—O—Si | SiO_2	0	95	0	5	
	Butadiene					
2a	π-RNiCl·Ni(OCOCCl$_3$)$_2$	97	0	3		$7.8\cdot10^2$
2b	(π-RNiI)$_2$	0	95	5		
3a	$(C_6H_5CH_2)_3TiI$	95	2	3		$7.4\cdot10^3$
3b	$(C_6H_5CH_2)_4Ti$	20	20	60		

The positive role of electron-accepting components forming complexes with the organometallic active centre consists in a decrease of the probability of the formation of the associated species and in an increase of the rate of chain propagation. It is noteworthy that mainly *trans*-structures (95–98% of *trans*-units) are produced in systems involving vanadium compounds characterised by very high rates of chain propagation (indicated by the formation of isoprene and butadiene polymers with very high molecular weights). When account is taken of the considerations described above concerning the stereoregulation mechanism, this can be due by the very high rate of the *cis*–*trans* isomerisation or monodentate coordination of the diene.

2. The Mechanism of the Formation of 1,2(3,4)-Structures

The preferential formation of 1,2(3,4)-units in the polymerisation of dienes under the influence of RLi in solvating media or under the influence of RK(RNa) is always associated with an increase of the polarity of the C–M bond. As in all the anionic systems, leading to the preferential formation of 1,2(3,4)-structures, in the copolymerisation of butadiene (m_1) with styrene (m_2) in systems of this kind, styrene is much more reactive than butadiene ($r_2 \gg r_1$). On the other hand, in coordination systems dienes are appreciably more reactive than styrene regardless of the nature of the stereoregulation, which is illustrated by the data in Table 7.



The results presented show that the formation of 1,2(3,4)-units in the systems considered is associated with the coordination mechanism of the catalytic action and not with the polarisation of the C–M bond. As mentioned above, the preferential formation of 1,2(3,4)-units is characteristic of organometallic compounds of the type MR_n ($M = Ti^{3+}$, Ti^{4+}, Cr^{3+}, or Cr^{2+}), R_3MoX, R_3WX, etc. and the formation of a crystalline or amorphous polymer with a syndiotactic arrangement of units (for R_3MoX and R_3WX) is characteristic of the polymerisation of butadiene. Many of the systems indicated in Table 7 are also active in olefin polymerisation processes, which indicates the stability of the organometallic σ-compounds. The stability of the C–M σ-bond increases in the polymerisation of dienes as a result of its conjugation with the double bond.

Table 7. The relative reactivities of butadiene (m_1) and styrene (m_2) in coordination copolymerisation (solvent—toluene).

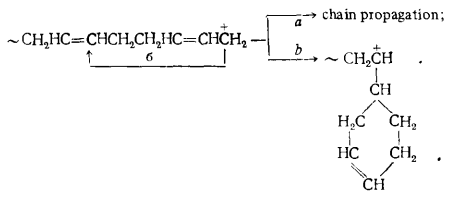
*Solvent—THF.
**Solvent—benzene.

Although the mechanism of the formation of 1,2-units in coordination systems has not so far been studied experimentally, one may put forward certain considerations concerning the most probable pathway leading to the formation of syndiotactic structures under the influence of organomolybdenum, organotungsten, and organocobalt compounds, as well as organic derivatives of certain other metals[101]:



Complexes (I) and (II), formed alternatively in the course of chain propagation, differ sterically by the positions of the π-coordinating double bonds in the terminal unit of the polymer chain and the monomer. This chain propagation mechanism leads to a syndiotactic arrangement of units.

V. THE COPOLYMERISATION OF DIENES IN COORDINATION SYSTEMS

There is an antiparallel variation of the relative activities of dienes in cationic and anionic systems: chloroprene, butadiene, isoprene, *trans*-piperylene, cyclohexadiene, and 2,3-dimethylbutadiene. The reactivities increase in the above sequence when the active centres are cationic and decrease in polymerisation under the influence of anionic systems[97]. The above diene reactivity series in cationic systems is well illustrated by the increase of r_2 in the copolymerisation of isobutene (m_1) with dienes (m_2). The similarity of the copolymerisation constants r_1 and r_2 in the cationic copolymerisation of dienes with the corresponding olefins, for example, in the copolymerisation of butadiene with β-butene,[102] favours the development of cyclisation processes in the polymerisation and copolymerisation of

dienes:

In view of its high steric probability, reaction *b* takes place very vigorously even for low degrees of polymerisation and leads to cyclisation and loss of unsaturation.

In anionic copolymerisation, for example, under the influence of organometallic derivatives of alkali metals, the values of r_1 and r_2, reflecting the reactivity of the monomers, are consistent with the above sequence.

Table 8. The relative reactivities of the monomers (m) in coordination copolymerisation.

*A = acceptor.

The most important characteristic feature of the copolymerisation in coordination systems, particularly under the influence of organometallic compounds of transition metals, is the role of the coordination stage in the reactivity of the monomers. The probability of the incorporation of the monomer in the chain is determined both by the equilibrium in the coordination stage

$$RMX_n \overset{m_1}{\rightleftarrows} RMX_n + m_1; \quad RMX_n \overset{m_2}{\rightleftarrows} RMX_n + m_2$$

and by the rate of incorporation of the coordinated monomer in the chain. Since the "lifetime" of the terminal chain in the active centre depends on the rate of incorporation of the coordinated monomer (m_1 and m_2) in the chain, the rate of the *cis–trans* isomerisation of this unit should also vary in the copolymerisation process. The structure of the copolymers can therefore differ extremely significantly from that of homopolymers. Table 8 presents data for the relative reactivities of dienes in copolymerisation under the influence of various Ziegler systems and organonickel and organolithium compounds. It is seen from these results that the values of r_1 and r_2 depend greatly on the nature of the organometallic active centre. The copolymerisation in hydrocarbon media under the influence of RLi, where characteristics most typical for anionic systems are manifested, can serve as a comparison standard. Whereas the reactivity of butadiene (r_1) is much higher than those of isoprene, piperylene, and 2,3-dimethylbutadiene (r_2) in anionic systems, in systems of the Ziegler type the reactivities of the same pairs of monomers greatly approach one another, in some cases become identical, and in a few instances, for example in the copolymerisation of butadiene with isoprene or cyclohexadiene under the influence of π-RNiI, r_2 is much higher than r_1.

Table 9. The relative reactivities of the monomers (m) and the microstructure of the copolymers (m_1-butadiene, degree of conversion ~10%).

*Content of m_2 in the copolymer.

A second distinctive feature of the copolymerisation under the influence of coordination systems with participation of transition metals is the mutual influence of the monomers on the chain microstructure. The structure of the copolymers differs in most cases from that of the homopolymers obtained in the presence of the same catalysts. Under the influence of the second monomer (isoprene, piperylene, 2,3-dimethylbutadiene), participating in the copolymerisation, the *cis*-butadiene units in the copolymer are converted into the *trans*-units whose number is approximately equal to the content of the second monomer in the chain. This indicates a direct genetic relation between the conversion of the *cis*-butadiene unit into the *trans*-unit and the incorporation of

Table 10. The relative reactivities of the monomers (m) and the microstructure of the copolymers (m_1—butadiene).

the second monomer in the chain. Table 9 presents data for the copolymerisation of butadiene with other monomers under the influence of the *cis*-regulating TiI_4–R_3Al and π-RNiCl.A systems. Together with the increase of the content of the *trans*-butadiene units, a change in the microstructure of the isoprene and 2,3-dimethylbutadiene units incorporated in the chain towards an increase of the content of the *cis*-units is observed. In all the instances discussed, electron-donating additives (ethers, sulphides, and amines) exert the same influence on the butadiene homopolymer structure as the second comonomer in copolymerisation.

It is noteworthy that the rate of chain propagation decreases on passing from homopolymerisation to copolymerisation and, in the homopolymerisation of butadiene, also under the influence of added electron-donating compounds. In the copolymerisation of butadiene (m_1) with cyclohexadiene (m_2) under the influence of the complexes π-RNiX.A we have $r_2 > r_1$ and the *cis*-configuration of the butadiene units is fully retained in the copolymer[113]. The *trans*-configuration of the units is fully retained in the copolymers in the copolymerisation of butadiene with isoprene and of butadiene with piperylene under the influence of *trans*-regulating systems (π-RNiI, π-$R_2CrOSi|SiO_2$).[111] These postulates are illustrated by the data in Table 10.

In the copolymerisation of butadiene with other dienes in the presence of Ziegler systems containing active centres involving cobalt compounds, an inversion of stereoregulation is also observed under the influence of the second monomer, but it involves a change to 1,2-units and not *trans*-units, the number of the former corresponding approximately to the molar content of the second monomer in the chain. This is illustrated by the data in Table 11. Evidently, for approximately equal values of r_1 and r_2, isoprene and 2,3-dimethylbutadiene induce a sharp increase in the content of buta-1,2-diene units in the copolymer chain. Bearing in mind that the system based on cobalt compounds is used under certain conditions to synthesise crystalline 1,2-polybutadiene, presumably, on coordination of the second, more electron-donating monomer, the terminal butadiene unit passes to the σ-state, as in the mechanism proposed above for molybdenum and tungsten compounds. Electron-donating additives (ethers, sulphides, and amides), leading to an increase of the number of 1,2-units, exert a completely analogous influence on the microstructure of the butadiene homopolymer.

Table 11. The relative reactivities of the monomers (m) and the chain microstructure in copolymerisation under the influence of the $CoCl_2.C_2H_5OH$ + $(iso\text{-}C_4H_9)_2AlCl$ (m_1—butadiene) catalytic system[104,107,108].

m_2	$[m_2]$, mole fraction	Contents of units in butadiene component, %			r_1; r_2
		cis-	*trans*-	1,2-	
Isoprene	0 0.32 0.53	94 75 58	3 7 3	3 18 39	r_1=1.0±0.1; r_2=0.9±0.1
2,3-Dimethylbutadiene	0.27 0.41	44 26	7 6	49 68	r_1=0.74±0.02; r_2=0.67±0.05

*Content of m_2 in the copolymer.
**Overall content of the *cis*- and *trans*-units.

It is noteworthy that in butadiene–isoprene copolymers the 3,4-units, whose content in the copolymer obtained in the presence of the "cobalt" system reaches 31%, have disappeared from the isoprene component of the copolymer chain. This means that only 1,4-isoprene units adjoin the butadiene units in the chain. In the butadiene–2,3-dimethylbutadiene copolymers the conversion of the *trans*-units of 2,3-dimethylbutadiene, adjoining the butadiene units, into the *cis*-units is observed. In the joint presence of the second monomer and an electron donor, a still more marked increase of the content of buta-1,2-diene units in the copolymer is observed. The rate of the process decreases

significantly in the presence of the second monomer or an electron-donating additive[104,107,108].

Studies in individual fields have been surveyed and published in other reviews[60,86,101,123–125].

VI. CONCLUSION

The investigations carried out have shown that the true active centres for the stereospecific polymerisation of dienes are individual organometallic compounds of transition metals. Chain propagation takes place as a result of the insertion of the monomer in the carbon–transition metal bond. The stereospecificity of the catalytic action is determined by the nature of the metal and the ligands surrounding it.

Experimentally supported hypotheses concerning the stereoregulation mechanism, according to which the structure of the polymer chain units is determined by that of the terminal unit in the active centre in the chain propagation stage, have been put forward. The specific features of coordination copolymerisation, distinguishing it from ionic and radical copolymerisation, have been determined.

Organometallic Catalysis in Diene and Cyclo-olefin Polymerisation Processes. II. The Metathesis Reaction in Polymer Chemistry

B.A.Dolgoplosk and Yu.V.Korshak

The development of ideas concerning the mechanism of the metathesis reaction and its employment in polymer chemistry are examined. The possible applications of the metathesis reaction in the synthesis of polymers by the polymerisation of cyclo-olefins and cyclodienes with ring opening and via the degradation of high-molecular-weight rubbers and their modification are discussed.
The bibliography includes 160 references.

I. THE MECHANISMS OF REACTIONS INVOLVING RING OPENING IN CYCLO-OLEFINS AND METATHESIS REACTIONS OF OLEFINS

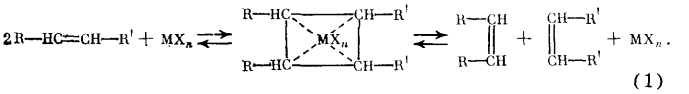
The polymerisation of norbornene under the influence of the $TiCl_4$–$Al(C_7H_{13})_4$ catalytic system with formation of a polymer in which the double bonds of the initial monomer are fully retained was first carried out in 1955–1956.[1-3] Subsequently Natta and other investigators[4-8] demonstrated the possibility of synthesising analogous linear polymers from cyclopentene, cyclo-octadiene, and other cyclo-olefins with the aid of catalytic systems containing tungsten or molybdenum compounds and organoaluminium compounds. The compositions of the above systems resemble those of the Ziegler catalysts for the polymerisation of olefins and dienes.

Truett and co-workers[2,3], who investigated this reaction with respect to norbornene, concluded that the ring opening in the polymerisation of norbornene takes place at the C–C bond adjoining the double bond:

Natta and co-workers, who studied the polymerisation of a series of cyclo-olefins with ring opening, initially adopted an analogous view as to the reaction mechanism[9].

Studies on the redistribution of double bonds in olefins under the influence of catalysts containing molybdenum and tungsten compounds in combination with alkylating agents developed independently and simultaneously. In 1964 Banks and Bailey[10] demonstrated for the first time that, when propene is maintained over MoO_3 or WO_3 on Al_2O_3 at 120 °C and a pressure of 35 atm, small amounts of ethylene and butene are formed. Subsequently many other catalytic homogeneous and heterogeneous catalytic systems, incorporating tungsten, molybdenum, rhenium, or tantalum compounds in combination with alkylating agents (particularly with organoaluminium or organotin compounds) were put forward[11-22]. In homogeneous systems the reaction involving the redistribution of double bonds in many olefins takes place at very high rates without heat changes at normal temperatures[23,24].

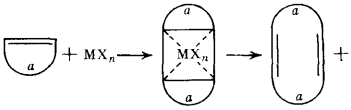
In a number of studies[24-26] using ^{14}C-labelled and deuteriated olefins it was shown experimentally that the olefin disproportionation reaction proceeds via the direct rupture of the double bonds. For example, this has been demonstrated[24] for the cometathetical reaction of but-2-ene and perdeuterobut-2-ene:



$$CH_3HC{=}CHCH_3 + CD_3DC{=}CDCD_3 \rightleftarrows 2CH_3HC{=}CDCD_3 \quad .$$

On the basis of a study of the composition of the decomposition products of ozonised copolymers of ^{14}C-labelled cyclopentene with cyclo-octene, Dall'Asta and Montroni[27] showed that the polymerisation of cyclo-olefins with ring opening also proceeds with the rupture of the double bonds and that its character is analogous to that of the reaction of olefins under the influence of the same catalytic systems. Subsequently the term "metathesis reactions" was proposed for the reactions of the given type proceeding via a stage involving the dissociation of multiple carbon–carbon bonds.

Reviews have been devoted to various aspects of the metathesis reactions[28-37]. Table 1 presents the compositions of the catalytic system used for the polymerisation of cyclo-olefins.



1. Development of Ideas about the Process Mechanism

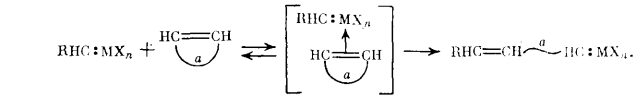
In order to account for the mechanism of the metathesis reactions of olefins, Bradshaw et al.[38] introduced the concept of an intermediate consisting of a quasi-cyclobutane ring made up of two olefin molecules in which all the carbon atoms are linked by equivalent bonds to the transition metal:

(1)

Scott[39] applied these ideas to ring opening in cyclo-olefins:

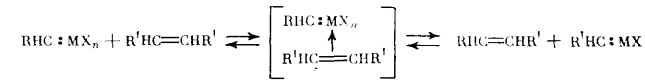
(2)

Eqns.(1) and (2) presuppose a stepwise process with formation of oligomeric cyclo-olefin polymerisation products in the initial stages in the latter case. It has been noted[40] that these ideas conflict with the formation of high-molecular-weight products in polymerisation processes, which enabled the authors[40] to put forward certain considerations concerning the chain nature of the process involving carbene complexes.



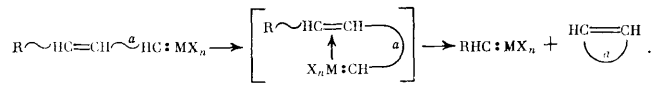
Systematic investigations[41–44] have shown that, even for a low degree of conversion of cyclo-olefins (cyclopentene, norbornene, cyclo-octene, and cyclo-octadiene), high-molecular-weight products are formed. In certain systems the intrinsic viscosity of the polymers formed in the initial stages of the process reached 7–9. These results yielded the unambiguous conclusion that the process has a chain mechanism[40–42,45,100]. As will be shown below, the formation of a small amount of oligomers in certain cases is due to the development of the reverse cyclodegradation process.

Table 1. Catalytic metathesis systems active in the cyclo-olefin ring opening reaction.



Transition metal compound (A)	Alkylating agent (B)	[A]/[B], mol mol^{-1}	Cyclo-olefin	Refs.
		Heterogeneous systems		
$MoO_3\|Al_2O_3$	$LiAlH_4$	—	Cyclopentene	[11]
$CoO—MoO_3\|Al_2O_3$	—	—	Cyclo-octene	[12, 13]
$Re_2O_7\|Al_2O_3$	—	—	Cyclo-octene, cyclopentene	[14]
		Homogeneous systems		
$TiCl_4$	C_2H_5MgBr	2/1	Norbornene	[1]
$TiCl_4$	$LiAl(C_3H_7)_4$	3/1÷5/1	Norbornene	[3]
$(NH_4)_2IrCl_6$; $RuCl_3$	$SnCl_2$; Zn+CH_3COOH	—	Norbornene derivatives	[17]
$MoCl_5$	$Al(C_2H_5)_3$	2 5/1	Cyclobutene, cyclopentene	[4, 5]
WCl_6	$Al(C_2H_5)_3$	2.5/1	Cyclopentene	[5]
WCl_6	$Al(C_2H_5)Cl_2$	5/1	Cycloheptene,	[6]
WF_6	$Al_2(C_2H_5)_3Cl_3$	7/1÷1/2	Cyclo-octene	[18]
$MoCl_2\cdot 2P(C_6H_5)_3(NO)_2$	$Al(CH_3)Cl_2$	10/1	Cyclopentene	
$WCl_2\cdot 2P(C_6H_5)_3(NO)_2$	$Al_2(CH_3)_3Cl_3$	10/1	Cyclopentene	[19, 20]
$(CO)_5W=C(C_6H_5)_2$	—	—	Cyclo-octene	[21]
$TaCl_5$	$LiCH_2Si(CH_3)_3$	1/1	Cyclo-octene	[16]

The possibility of the initiation of the cyclo-olefin polymerisation reaction by the decomposition products of diazo-compounds arising when the latter interacts with WCl_6 and $MoCl_5$ constitutes direct experimental proof of the carbene nature of the active centres[46,47]. Phenyldiazomethane, diazoacetate, and trimethylsilyldiazomethane, which are decomposed catalytically under the influence of tungsten and molybdenum halides with the liberation of nitrogen and the formation of carbene complexes, were used as the initial diazo-compounds.

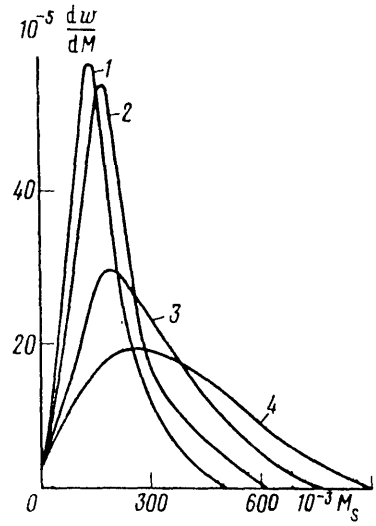


The results obtained served as a basis for the consideration of the reaction mechanism[40,45]. The scheme presented below presupposes the coordination of the monomer to the transition metal attached to a carbene species and its incorporation into the chain with regeneration of the carbene complex:

An analogous mechanism has been proposed for the metathesis of olefins:

Since the polymer chain formed in the polymerisation of cyclo-olefins retains the double bonds, the latter can participate in metathesis reactions. When the growing carbene active centre interacts with a double bond in its own chain, a cyclodegradation reaction, which leads to the formation of cyclic oligomeric molecules, takes place:

The contribution of these reactions in the polymerisation of cyclo-olefins increases as the monomer concentration diminishes, which leads to the formation of oligomers and to the broadening of the molecular weight distribution (MWD) of the polymer. Fig. 1 presents data illustrating the variation of the MWD with the degree of reaction[48].



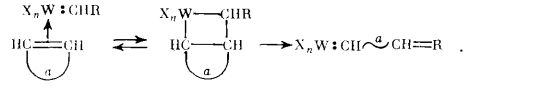


Figure 1. The molecular weight distribution of cyclo-octa-1,5-diene (COD) polymers obtained for different degrees of conversion; [COD] = 0.9 M; [Al]/[W] = 5/1; [COD]/[W] = 800/1; 20 °C in toluene. Degree of conversion (%): 1) 19; 2) 25; 3) 31; 4) 44.[48]

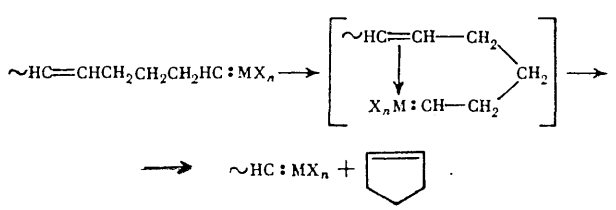
If there is no monomer in the system, then, as will be shown below, the same catalysts induce the cyclodegradation of unsaturated polymers in solution. The idea that the process has a chain mechanism (via stages involving the formation of carbene complexes) was subsequently confirmed by a number of other investigators[49–51] and is at present generally accepted.

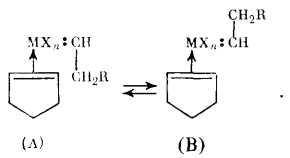
On the grounds that metallocyclobutane compounds of the type

initiate the ring opening in cyclo-olefins, the authors of a number of studies suggested that the chain propagation stage can proceed via similar intermediates[49,51,53–56]:



This hypothesis appears to us unlikely, since the rate of chain propagation exceeds by several orders of magnitude the rate of initiation by such organometallic compounds. Furthermore, one should note that the decomposition of compounds of this kind at low temperatures proceeds via carbene formation stages[57].

In a number of studies devoted to the reactions of stable carbene complexes of tantalum and niobium incorporating olefins, the formation of intermediate unstable metallocyclobutane species has been postulated[58,59]. However, the decomposition of these intermediate compounds proceeds via the usual β-elimination pathway and leads to various isomers of linear olefins containing the initial carbene fragment. An extremely striking feature is that the products of the metathetical reaction were not detected in the instances considered[22,58], but in a number of reactions it was possible to isolate a metallocyclopentane complex formed as a result of the cycloaddition of two molecules of the initial olefin to the transition metal compound[60]. Similar metallocyclopentane complexes had been considered earlier as intermediates in the metathesis reaction[61], but in subsequent studies by Grubbs and co-workers[62] and Schrock and co-workers[63,64] it was shown that the cyclopentane derivatives of tantalum and niobium are effective catalysts of the selective dimerisation of various olefins and show no activity in the metathesis reaction.



The polymerisation of cyclo-olefins under the influence of metathesis catalysts is a reverisble process which in the case of cyclopentene leads to a polymer–monomer equilibrium, while in the case of other cyclo-olefins a polymer–oligomers equilibrium obtains. The position of equilibrium in a polymerisation reaction for *trans*- and *cis*-polypentenamers is characterised by the data in Fig. 2.[65,66]

For the *cis*-conformation of the units of the polypentenamer, the equilibrium content of the monomer in solution is significantly higher than for the *trans*-polypentenamer, which is apparently due to the greater steric mobility of the coordination of the active centre to the double bond of the neighbouring unit:

The ratio of the *cis*- and *trans*-units in the cyclo-olefin polymers depends significantly on the nature of the catalytic system and the polymerisation temperature. Table 2 presents data characterising the microstructure of the chain in polypentenamers obtained in the presence of various catalytic systems and at various temperatures.

The initial cyclo-olefins are characterised in most cases by the *cis*-conformation of the units (cyclobutene, cyclopentene, norbornene, cyclo-octadiene, and cyclo-octene); the formation of *trans*-units in the polymer must therefore be associated with isomerisation steps. It has been suggested[69] that the isomerisation may be due to the rotation of the carbene active centre. The energy of rotation about the C : M bond for various carbenes bound in complexes with tantalum compounds is 12–22 kcal mole^{-1}.[70] For systems active in metathesis reactions, these values may be significantly lower. It is most likely that the rotations about the C : M carbene bond are executed at the instant of the coordination of the monomer to the transition metal:

The state (A) leads to the *cis*-unit and the state (B) to the *trans*-unit. The very marked temperature dependence of the ratio of the *cis*- and *trans*-units in the polypentenamer (Table 2) indicates a low activation energy for the *cis*–*trans* rotations of the carbene active centre. A similar temperature dependence, albeit less marked, has been observed also for other cyclo-olefins.

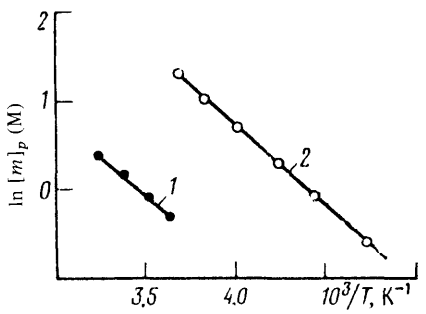


Figure 2. Temperature variation of the equilibrium monomer concentration $[m]_p$ in the cyclopentene–polypentenamer system: 1) *trans*-polypentenamer[65]; 2) *cis*-polypentenamer[66].

Table 2. The influence of temperature and catalyst on the structure of cyclopentene polymers.

Al/W = 7/1	+30	10	90	[18]

In the catalysis of metathesis by systems incorporating tungsten compounds, tungsten atoms in a valence state ranging from zero to 4–5 are apparently involved. An example of the participation of zero-valent tungsten is the initiation of polymerisation under the influence of $(CO)_5W : C(C_6H_5)_2$.[21]

In the usual systems containing $RAlCl_2$ and WCl_6 tungsten is in the (4–5)-valence state[71]. An example of the initiation of metathesis under the influence of Mo^{2+} is provided by the

$MoCl_2.2NO.(C_6H_5)_3P-RAlCl_2$ system[20]. Catalytic systems containing Mo^{4+} are also effective[72]. In the stable Fischer carbenes the valence of the metal is always zero or 1, and the carbene species contain as a rule one or two heteroatoms (O, N, or S) at the carbene carbon atom. These factors and also the presence of stabilising ligands (CO, phosphine groups, etc.) at the metal atoms are responsible for the stability of the carbene complexes. It has been shown[73] in relation to chromium complexes that some of them can be used in metathesis reactions.

Since the rate of chain propagation depends greatly on the nature of the metal and the ligands surrounding it, this is reflected correspondingly also in the chain microstructure; the higher the rate of propagation the smaller the contribution of the *cis–trans* isomerisation of the active centre. The *cis–trans* isomerisation can occur also in the polymer chain under the influence of the components of catalytic systems. Thus it has been shown for cyclododecane containing a non-equilibrium proportion of molecules in the *cis*- and *trans*-conformations that it isomerises under the influence of metathesis catalysts, cationic systems, and C_6H_5S radicals[74]:

Reaction *a*, leading to a state of equilibrium of cyclododecene, is much faster than reaction *b*. The equilibrium content of the *cis*- and *trans*-units, characteristic of linear olefins, is therefore found in the polymer chain obtained at room temperature.

As in all other chain polymerisation processes, in the reactions considered very small amounts of compounds leading to the formation of carbene species more stable than the growing chain species partially or completely inhibit the polymerisation. Thus, in the polymerisation of cyclopentene in the presence of metathesis catalysts, very small amounts of alkyl vinyl ethers, alkyl vinyl sulphides, and trimethylvinylsilane fully inhibit the polymerisation reaction[75–77]:

$$\sim HC{=}CH(CH_2)_3HC{:}MX_n + H_2C{=}CHXR \rightarrow RXHC{:}MX_n + \sim HC{=}CH(CH_2)_3HC{=}CH_2;$$
$$X = O, S, Si .$$

The presence of a heteroatom at the carbene active centre is known to entail the stabilisation of the carbene, which renders energetically unfavourable its participation in the opening of the cyclopentene ring, since it leads to the formation of a more active carbene species. The above considerations are correlated with the finding that the efficiency of the initiation by diazo-compounds decreases in the sequence

$$C_6H_5CHN_2 > RO{-}CO{-}CHN_2 > (CH_3)_3SiCHN_2 .$$

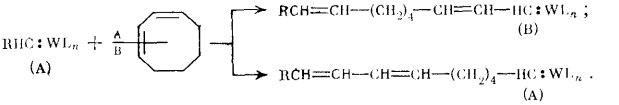
The compound $(C_6H_5)(C_6H_5CO)CN_2$, leading to the formation of the stable carbene $(C_6H_5)(C_6H_5CO)C:MX_n$, does not initiate polymerisation[78].

The chain character of the process and the decisive role of the reactivity of the carbene species in its kinetics can be illustrated also in relation to the metathesis of olefins. It has been shown[79–81] that a degenerate metathesis reaction of α-olefins [reaction (3)] is 10^2–10^3 faster than reaction (4):

$$RHC{=}CH_2 + R'HC{=}CD_2 \begin{cases} \rightarrow RHC{=}CD_2 + R'HC{=}CH_2 , & (3) \\ \rightarrow RHC{=}CHR' + H_2C{=}CD_2 . & (4) \end{cases}$$

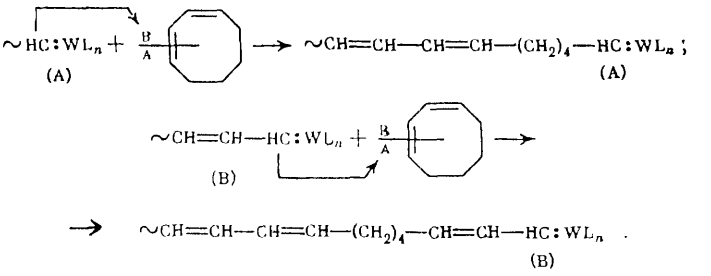
The cause of this phenomenon has been explained[58,82]. Pathway (3) occurs as a result of the alternate exchange of the secondary carbene complexes with similar reactivities:

$$R'HC{:}MX_n \rightarrow RHC{:}MX_n \rightarrow R'HC{:}MX_n \text{ etc.}$$



Reaction (4) can proceed only via consecutive stages involving the formation of secondary and primary carbene complexes:

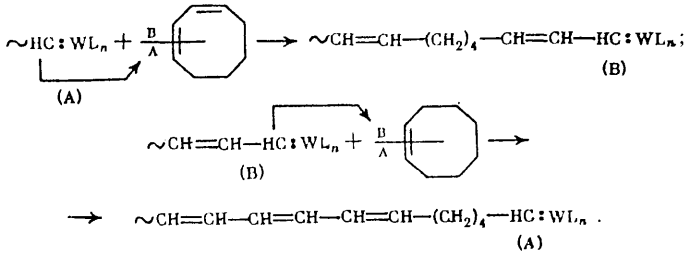
$$R'HC{:}MX_n \underset{\downarrow}{\uparrow} H_2C{:}MX_n \underset{\downarrow}{\uparrow} RHC{:}MX_n \underset{\downarrow}{\uparrow} D_2C{:}MX_n \underset{\downarrow}{\uparrow} R'HC{:}MX_n \text{ etc.}$$



Under the conditions of the chain process, in which the length of the kinetic chain reaches 10^5–10^7, even small differences between the reactivities of the primary and secondary carbene complexes lead to a marked retardation of the reaction. These features are fully analogous to those of the free radical reactions of olefins.

An interesting case of the involvement of conjugated dienes in a metathesis reaction has been investigated[83]. It was shown that cyclo-octa-1,3-diene polymerises in the presence of the $Cl_4W[OCH(CH_2Cl)_2]_2-Al(C_2H_5)_2Cl$–dibutyl ether systems; up to a degree of conversion of the monomer of 30%, the process occurred with formation of a high-molecular-weight soluble polymer. The fairly high effectiveness of cyclo-octa-1,3-diene in the polymerisation reaction is apparently due to the displacement of the double bonds in its molecule from coplanarity[84]. The polymer obtained contained conjugated diene groups, which, in contrast to the initial monomer, readily underwent the Diels–Alder reaction, forming reactive adducts.

In contrast to cyclo-olefins and non-conjugated cyclodienes, in the polymerisation of cyclo-octa-1,3-diene there is a possibility of the formation of two different types of carbene centres differing in their reactivities[83]:



The "head-to-tail" chain propagation should involve the formation of a polymer containing regularly alternating diene sequences. In this case, after each addition of an alternate cyclo-octa-1,3-diene molecule, an active centre of the same type is regenerated (A or B):

However, the presence of triene and isolated –C=C– bonds in the cyclo-octa-1,3-diene polymers together with diene bonds indicates the occurrence of interconversions of the non-conjugated carbene centre (A) and the carbene centre

(B) conjugated with a double bond:

The conversion of the non-conjugated carbene centre into the more stable conjugated centre, (A) → (B), is energetically more favourable, which leads to the preferential formation of diene sequences in the polymer.

The molecular weight characteristics and the MWD of cyclo-octa-1,3-diene polymers have been investigated[48] and it has been shown that, up to a degree of polymerisation of 35%, the molecular weight of the polyoctadienamer increases linearly with the degree of conversion, which is consistent with the mechanism of the propagation of "live" chains. Fig.1 shows that the polymers obtained initially have a narrow molecular weight distribution with a polydispersity coefficient of 1.25 to 1.30. The equality of the polydispersity coefficients found ($\bar{M}_W/\bar{M}_n \cong \bar{M}_Z/\bar{M}_W$) as well as the form of the MWD curves confirm the fact that the cyclo-octa-1,5-diene polymers investigated (polyoctadienamers) have a molecular weight distribution close to the Poisson distribution.

Analogous results have been obtained for polypentenamer specimens obtained in the presence of the $Cl_3Mo(stearate)_2$–$Al(C_2H_5)_2Cl$ system, as shown by Pakuro et al.[86] This demonstrates the occurrence of a polymerisation process without termination in the presence of the systems indicated. It is noteworthy that a very small number of the active centres, in which the carbene species are stabilised by coordination to the transition metal atom, participate in the polymerisation reaction. For a number of other catalytic systems, a broad MWD is observed in the initial stage of the process, which may be associated both with the low rate of the initiation stage[87,88] and with chain termination.

As in the case of typical Ziegler catalysts, chain termination in the metathesis reaction can occur as a consequence of the presence of various admixtures (water, alcohols, etc.) in the reaction systems. However, complete termination of the chain metathesis process is also possible as a result of side reactions leading to the destruction of the carbene species. This applies particularly to reactions involving insertion into the C–H, C–C, and C=C (the formation of cyclopropane groups) bonds, as well as other reactions characteristic of free carbenes.

The unstable carbene complex $(CO)_5W:C\begin{smallmatrix}H\\C_6H_5\end{smallmatrix}$ has been obtained[89]; by reacting at the instant of formation with various α- and β-olefins, it gave rise to cyclopropane derivatives in a yield up to 98%. An analogous reaction involving conversion into cyclopropane derivatives has been described for the stable carbene complexes of chromium and iron[90,91]. This reaction is undoubtedly one of the possible variants of chain termination in metathesis, which was first noted by Dolgoplosk et al.[40] On the basis of quantum-chemical calculations for various intermediate states of the carbene complexes of tungsten, molybdenum and chromium, Rappe and Goddard[92] concluded that in the case of chromium this termination pathway is dominant and that this explains the low activity of chromium in metathesis reactions.

2. Generation of Carbene Active Centres in the Decomposition of Organometallic Compounds of Transition Metals

The question of the pathways leading to the formation of carbene active centres initiating the metathesis reaction remained least clear. Since the primary step in metathesis systems always leads to the formation of an organometallic compound, only the decomposition of such a compound can serve as a source of carbenes. Schrock and co-workers[93–95] showed that stable carbene species are formed on decomposition of pentabenzyltantalum and pentaneopentyltantalum:

$$(C_6H_5CH_2)_5Ta \rightarrow (C_6H_5CH_2)_3Ta:CHC_6H_5 ,$$
$$[(CH_3)_3CH_2]_5Ta \rightarrow [(CH_3)_3CH_2]_3Ta:CHC(CH_3)_3 .$$

The ways in which carbene species arise on decomposition at the instant of the formation of various organometallic compounds of transition metals have been investigated in greatest detail by Dolgoplosk and co-workers[97–99,101]. The $(CH_3)_3.SiCH_3Li$–WCl_6 system proved to be effective for the polymerisation of cyclopentene at temperatures down to −78 °C. The reaction of $(CH_3)_3SiCH_2Li$ with tungsten and other transitional metal halides in the absence of a monomer can proceed via the following main pathways:

$$(CH_3)_3SiCH_2MCl_n \rightarrow (CH_3)_3SiCl + H_2C:MCl_{n-1} ; \quad (5)$$

$$[(CH_3)_3SiCH_2]_2MCl_{n-1} \rightarrow (CH_3)_4Si + (CH_3)_3SiHC:MCl_{n-1} ; \quad (6)$$

$$[(CH_3)_3SiCH_2]_2MCl_{n-1} \rightarrow (CH_3)_3Si{-}CH_2CH_2Si{-}(CH_3)_3 + MCl_{n-1} . \quad (7)$$

Reaction (5) leads to the formation of methylene carbene; its contribution can be estimated from the yield of $(CH_3)_3SiCl$. The contribution of reaction (6) can be estimated from the yield of $(CH_3)_4Si$, since it has been shown that the formation of $(CH_3)_3SiCH_2D$ is not observed in the products of the reaction when the latter is carried out in a perdeuteriated solvent. The experimental data are listed in Table 3. These questions have been examined in greatest detail by Dolgoplosk[15].

Table 3. Composition of the products of the interaction of $(CH_3)_3SiCH_2Li$ with MCl_n.

$ReCl_5$	1.0	20	5	55	100	[102]

*Recombination product.

When metal (W, Mo, Ta, Re, or Nb) halides are used, a considerable number of methylene species, which are the most active in the initiation of metathesis reactions, are formed. The formation of a considerable amount of tetramethylsilane in all cases proves that carbenes of the type $(CH_3)_3SiCH$: play a role; as shown in the decomposition of $(CH_3)_3SiCHN_2$, these carbenes are also involved in the initiation of the metathesis reaction but with a lower efficiency. Twice the amount of the $(CH_3)_4Si$ found, $(CH_3)_3SiCl$, and the groups forming part of the composition of the R–R products enter into the overall group balance.

In the case of the $(CH_3)_3GeCH_2Li$–WCl_6 system, the reaction involving the formation of methylene carbene predominates (up to 50% of the total amount of the groups which have reacted[98]). The decomposition of trideuteromethyl derivatives of tungsten and molybdenum in dibutyl ether proceeds analogously[101]. The main decomposition products are CD_3CD_3, $CD_2{=}CD_2$, and CD_4. The yield of CD_4 is 60 to 70% mole in the case of $MoCl_5$, which shows that the reaction leads to the formation of carbynes:

$$(CD_3)_2\,MoCl_3 \rightarrow CD_4 + D_2C{:}\,MoCl_3\ ;$$
$$(CD_3)_3\,MoCl_2 \rightarrow 2CD_4 + DC{\vdots}\,MoCl_2\ .$$

Carbene, carbyne, and carbide species bound to the metal have been found in the reaction products. For all the metal halides quoted above, the reaction with benzylmagnesium chloride takes place analogously in diethyl ether at 20 °C.[104] The fraction of carbene species can be estimated from the yield of toluene, because, when the reaction was carried out in perdeuterodiethyl ether, the formation of appreciable amounts of $C_6H_5CH_2D$ was not observed:

$$(C_6H_5CH_2)_2\,MX_n \rightarrow C_6H_5CH_3 + C_6H_5HC{:}\,MX_n\ ;$$
$$(C_6H_5CH_2)_3\,MX_{n-1} \rightarrow 2C_6H_5CH_3 + C_6H_5C{\vdots}\,MX_{n-1}\ .$$

Table 4 presents the compositions of the reaction products.

Table 4. Composition of the products of the interaction of benzylmagnesium chloride with metal halides in ethyl ether at 20 °C.

MCl_n	$RMgCl/MCl_n$, mol mole^{-1}	Yield, % of theoretical				Refs.
		toluene	stilbene	tolane	bibenzyl	
$MoCl_5$	3	14—16	0.8—1.5	0.3—0.7	25—27	[104]
WCl_6	4	17.7	0.5	0	19.1	[103]
$ReCl_5$	3	22—27	1.7—2.0	0	18—20	[103]

Thus the carbene pathway to the decomposition is characteristic not only if the compounds of the metals used in metathesis reactions but also of many other transition metals widely employed in heterogeneous and homogeneous catalysis. In the tetra-allylsilane–WCl_6 system[105,106], recommended for the synthesis of *cis*-polypentenamer by the polymerisation of cyclopentene at −30 °C, the reaction leads to the generation of considerable amounts of propene:

$$(H_2C{=}CHCH_2)_2\,WCl_4 \rightarrow CH_3HC{=}CH_2 + H_2C{=}CHHC{:}\,WCl_4\ .$$

The polymerisation of cyclopentene is apparently initiated by the vinylcarbene complex. The catalytic systems usually consist of alkyl derivatives of aluminium or tin and tungsten and molybdenum halides. It is well known that the alkyl derivatives of transition metals decompose via the β-elimination pathway:

$$(CH_3CH_2)_2\,MX_n \rightarrow H_2C{=}CH_2 + H_3C{-}CH_3\ .$$

So far there are no direct ways of investigating the contribution of α-decomposition in the systems indicated, which leads to a formation of carbene active centres. However, experimental studies have shown that α-decomposition also takes place in the systems considered:

$$(CH_3CH_2)_2\,MX_n \rightarrow H_3C{-}CH_3 + CH_3HC{:}\,MX_n\ .$$

When the reaction was carried out with WCl_6 and $MoCl_5$ in the presence of trimethylvinylsilane, the formation of appreciable amounts of propene was observed[107,108]. Since the presence of the silicon atom at the carbene active centre greatly stabilises the latter, the chain transfer reaction

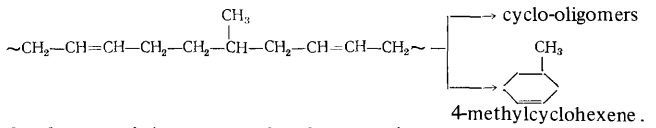
$$CH_3HC{:}\,MX_n + H_2C{=}CHSi(CH_3)_3 \rightarrow (CH_3)_3SiHC{:}\,MX_n + CH_3HC{=}CH_2$$

becomes energetically favourable.

The data obtained illustrate only qualitatively the α-decomposition reactions, since the carbenes formed in this process largely disappear as a result of side reactions with the solvent and only a small fraction of the carbenes, stabilised as a result of coordination to the transition metal, are involved in polymerisation.

In the analysis of the nature of the transition metal–carbene bond, Rappe and Goddard[92] concluded that it depends significantly on the valence state of the metal. Quantum-chemical calculation has shown that this bond is covalent for transition metal complexes in higher oxidation states and is mainly of the coordinate type (with a low barrier to rotation) for the more reduced forms of the metal, for example in the complex $(C_5H_5)_2TaCH_2(CH)_3$.[22,70]

II. THE DEGRADATION OF POLYMERS UNDER THE INFLUENCE OF METATHESIS CATALYSTS



1. Cyclodegradation of Polyalkenamers

It has been shown for the first time in a number of studies[109–111] that *cis*-polybutadiene undergoes rapid degradation in solution under the influence of metathesis catalysts at room temperature. The chain character of this process has been demonstrated[112] by carrying out the reaction in dilute (1%) solution of *cis*-polybutadiene in the presence of minimal amounts of the catalyst. In this case the carbene active centres arise only on individual polymeric molecules and intramolecular chain transfer reactions mainly develop as a consequence of the low polymer concentration. The study of the reaction products demonstrated the constancy of the MWD of the high-molecular-weight polybutadiene in the simultaneous presence in the system of oligomeric products formed on decomposition of the individual polybutadiene molecules. Thus this process, which occurs at room temperature, is of the same chain character as the radical depolymerisation reactions of polystyrene and poly(methylacrylates) at high temperature. In the last two processes the initial monomer is formed preferentially, while the products of metathesis reactions are cyclic oligomers arising as a result of chain transfer with rupture.

In certain cases the degradative cyclisation reaction of polyalkenamers leads to the formation of cyclo-olefins, which has been demonstated for polypentamer[65] and an alternating propene–butadiene copolymer[113]. The degradative cyclisation of polypentamer and the character of the variation of the MWD under the influence of the WCl_6–tetramethyldisilacyclobutane system, active in the metathesis reactions in linear olefins, have been investigated[87,88]. The degradation of polypentamer (72–83% of *trans*-units) was carried out at 20 °C at a polymer concentration below the equilibrium monomer concentration at the given temperature (equal to 0.88 M for the formation of *trans*-polypentamer). Under these conditions, the degradation proceeds with 100% conversion of polypentenamer into cyclopentene:

$$-[-CH_2-CH{=}CH-CH_2-CH_2-]_n- \rightarrow n\,\square\ .$$

The degradation of the alternating butadiene–propene copolymer under the influence of the $Cl_4W[OCH(CH_2Cl)_2]_2$–$AlC_2H_5Cl_2$ system takes place with formation of cyclo-oligomers, which are subsequently converted into 4-methylcyclohexene (yield above 90%):[113,160]

4-methylcyclohexene.

In the remaining cases the degradation of unsaturated polymers leads to cyclic oligomeric products. The degradative cyclisation of linear *cis*-polybutadiene and *cis*-polyoctadienamer in the presence of tungsten-containing catalysts is accompanied by an appreciable *cis-trans* isomerisation of the double bonds (Table 5).

Notation: *c* is the polymer concentration, α^P and α^O are the contents of *cis*-units in the polymer and oligomer respectively, and Δ is a fresh portion of the catalyst.

*For the polyisoprene degradation processes, the time is given in hours.

The use of the $MoCl_3(stearate)_2$–$(C_2H_5)_2AlCl$ molybdenum-containing systems makes it possible to achieve a far-reaching degradation of *cis*-polybutadiene with retention of the *cis*-configuration of the double bonds in the cyclo-oligomers. After 15–20 min have elapsed from the start of the reaction, the molecular weight of polybutadiene diminishes by a factor of approximately 100 and the system rapidly attains a state close to equilibrium, as shown by the constant molecular weight, i.e. the intrinsic viscosity $[\eta]$, after the addition of a fresh portion of the catalyst. The study of the polydispersity of the cyclo-oligomers obtained indicates a broad MWD of the final product ($\bar{M}_w/\bar{M}_n > 4$).

The degradation of *cis*-polyisoprene in dilute solutions in hydrocarbons proceeds at a considerably lower rate[115]. In view of the high sensitivity of the polymer to cationic reactions, due to the presence of tungsten and alkylaluminium halides, the process is carried out in the presence of an electron donor (anisole, etc.). The $W[OCH(CH_2Cl)_2]_2Cl_4$–$Al(C_2H_5)_2Cl$–anisole metathesis system (with the ratios Al : W : AH=5 : 1 : 5) is extremely stable and remains active for several days. The degradative cyclisation of polyisoprene makes it possible to obtain oligomers with more than 97% of *cis*-units and the theoretical degree of bond unsaturation; $[\eta] = 0.3$, while the initial intrinsic viscosity is $[\eta] = 5.9$ ($\bar{M}_v = 1.07 \times 10^6$).

As already mentioned previously, the degradative cyclisation of polyalkenamers takes place in the polymerisation of cyclo-olefins simultaneously with the chain propagation reaction. It has been shown[113,114] that the decrease of the molecular weight of the polymer during the polymerisation of cyclo-octa-1,5-diene at an initial monomer concentration of 8 wt.% is particularly rapid after the consumption of the monomer. The cyclo-oligomers formed, with $[\eta] = 0.22$, are characterised by a broad MWD ($\bar{M}_w/\bar{M}_n = 4$–5).

It has been established that the concentration of cyclo-oligomers increases with time[116] and that the state of equilibrium depends on the initial concentration of double bonds in the system[114]. The equilibrium concentrations of the cyclo-oligomers of cyclo-octa-1,5-diene and cyclo-octene have been found and their entropies of formation have been determined[117].

Thus the application of metathesis catalysts made it possible to achieve intramolecular cyclisation reactions, which had been previously believed to be characteristic solely of polycondensation processes. Jacobson and Stockmayer[118] were the first to examine theoretically the ring–linear chain equilibrium and pointed out the possibility of obtaining macrocyclic polymers under conditions close to the critical concentration of the solution. Studies of the hydrodynamic properties of solutions of polyoctadienamer relative to linear 1,4-polybutadiene permitted the conclusion that macrorings are present in cyclo-octa-1,5-diene polymers[48]. Scott[154] arrived at an analogous conclusion on the basis of the gel-chromatographic analysis of high-molecular-weight polypentenamer specimens.

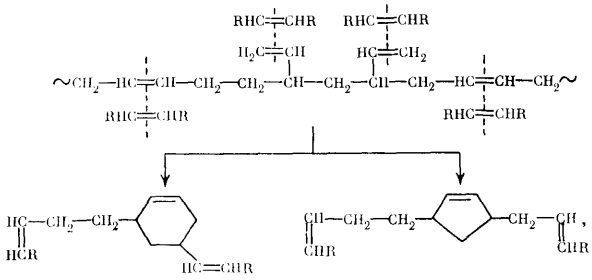
2. Degradation of Polyalkenamers in the Presence of Linear Olefins

The cometathesis of polyalkenamers with linear olefins made it possible to achieve a more far reaching degradation process in order to obtain low-molecular-weight linear oligomers.

Low-molecular-weight *cis*-oligomers of isoprene[115] were first obtained by the degradation of high-molecular-weight *cis*-polyisoprene in the presence of the $Cl_4W[OCH(CH_2Cl)_2]_2$–$Al(C_2H_5)_2Cl$–anisole system and linear olefins (Table 6). The formation of oligomers with the most probable molecular weight distribution and a slight loss of unsaturation, due to the presence in the oligomers of residues of C_9–C_{19} olefins in the form of end groups, are characteristic features in this instance.

The products of the degradation of 1,4-polybutadiene in the presence of oct-4-ene and dodec-6-ene under the influence of the WCl_6–$Al(C_2H_5)Cl_2$ catalyst have been investigated chromatographically in a series of studies[119–121] and oligomers having the general formula $R=[=CH-(CH_2)_2-CH=]_n=R$, where R is the residue of a symmetrical olefin and $n = 1$–4, were obtained. A function for the final molecular weight distribution of the linear products of the cometathesis of

polyalkenamers with olefins was obtained[122] and is one of the variants of the statistical Schultz–Flory distribution.



The degradation of modified rubbers[126–128] does not proceed quite so smoothly and the yield of oligomeric products is as a rule low. The cometathesis of partially hydrogenated 1,4-*cis*-polybutadiene (which is a successful model of the ethylene–butadiene copolymer) with oct-4-ene has been carried out in the presence of the WCl_6–$Sn(CH_3)_4$ system[123,124]. Analysis of the composition of the low-molecular-weight products permitted the conclusion that the homogeneous hydrogenation is statistical in character, while in heterogeneous catalytic hydrogenation the formation of block structures was observed.

Table 6. Certain properties of the oligomers obtained by the cometathesis of *cis*-polyisoprene with C_9–C_{12} α-olefins in the presence of the $Cl_4W(OR)_2$–$Al(C_2H_5)_2Cl$–anisole system (Al : W : AH = 5 : 1 : 5, 20 °C).

$[\eta]$*, dl g^{-1}	$\bar{M}_w$	$\bar{M}_n$	$\bar{M}_w/\bar{M}_n$	Loss of unsaturation a, %	Content of units, %		
					cis-	3,4-	*trans*-
0.15	8390	4160	2.01	6	95	3	2
0.16	11 150	5000	2.23	8	96	3	1
0.12	6 200	3100	2.00	7	94	3	3

*Initial viscosity $[\eta]$ = 5.9.

The degradation of cross-linked rubbers in order to elucidate their structure was investigated by Ast and co-workers[123,125] and Hümmel and co-workers[129,130]. Studies of the degradation of a weakly cross-linked 1,4-*cis*-polybutadiene in the prsence of hex-3-ene have been carried out[130] over a wide range of temperatures and component ratios of the WCl_6–$Al(C_2H_5)Cl_2$ catalytic system in order to discover the optimum process conditions. An interesting result has been obtained in a study[131] where the possibility of obtaining mono- and di-substituted cyclopentenes and cyclohexenes by the cometathesis of polybutadienes having a high content of 1,2-units with various olefins has been demonstrated. The reaction takes place in the presence of the catalytic system WCl_6–$Sn(C_2H_5)_4$–$(C_2H_5)_2O$ via the mechanism

and when hex-3-ene is used, but-1-ene, which is a product of the cometathesis of the vinyl groups with the initial olefin, is also formed[132].

III. THE SYNTHESIS OF POLYMERS AND OLIGOMERS BY THE METATHESIS OF CYCLO-OLEFINS

1. Thermodynamics of Ring Opening in Cyclo-olefins

A characteristic features of the polymerisation reactions of the majority of cyclo-olefins under the influence of metathesis catalysts is low enthalpy changes, which makes it possible to carry out the reaction in solutions at high concentrations and in bulk in the monomer. The heat of reaction depends on the strain energy of the initial cyclo-olefin, which is determined by the distortion of the main valence angles of the carbon–carbon bonds and the deformation resulting from the interaction of the atoms non-bonded by valence forces.

Data allowing inferences about the strain energies of the rings in cyclo-olefins have not yet been obtained for all cyclo-olefins. To a certain extent, the heats of hydrogenation of cyclo-olefins reflect the ring strain. It has been shown, for example, that the heats of hydrogenation of *trans*- and *cis*-cyclo-octenes are 134.8 and 98.1 kJ mol^{-1} respectively[133], which indicates a greater ring strain in the *trans*-isomer. The heat of hydrogenation of bicyclo-[2.2.1]hept-2-ene (norbornene) is extremely high and amounts to 138.4 kJ mol^{-1}.[133]

The ring strain energy of C_5 and C_6 cyclo-olefins should be minimal. As a consequence of the low enthalpies of ring opening, the equilibrium for these monomers is markedly displaced towards the monomer. The ΔH_n, ΔS_n^0, and G_n^0 for the polymerisation processes cyclopentene (liq.) → *trans*-polypentenamer (h.e.†) [134] and cyclopentene (liq.) → *cis*-polypentenamer (h.e.) [135] have been determined in a number of studies and the limiting temperatures of these transitions have been estimated (305 and 350 K respectively[135]).

Table 7. Thermodynamic parameters of the polymerisation of cyclo-olefins in bulk (298.15 K; 101.325 kPa).

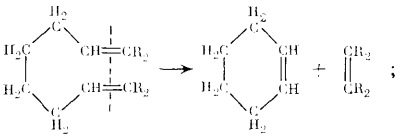
***The value for the cyclopentene → *cis*-polypentenamer transition in polymerisation in solution is quoted.



Kulagina[136] and Lebedev[137] determined the thermodynamic parameters of the cyclo-olefin → polyalkenamer transitions for certain other cyclo-olefins: cyclohexene, cyclo-octene,

† Highly elastic (Ed of Translation).

and cyclo-octa-1,5-diene. The enthalpy of polymerisation of the latter monomer has also been determined by Kozina and Cherednichenko[138].

Table 7 presents published standard enthalpies, entropies, and Gibbs free energies for the polymerisation reactions of certain cyclo-olefins. It is seen that the cyclohexene (liq.) → polyhexenamer (h.e.) transition is thermodynamically impossible at room temperature; however, the positive Gibbs free energy $\Delta G_n^0 = +6.2$ kJ mol^{-1} is low and does not rule out in principle the possibility of the opening of the cyclohexene ring by metathesis with formation of a crystalline polymer. The available reports in the literature concerning the attempt at the polymerisation of cyclohexene in the presence of metathesis catalysts show that a polyhexenamer has not yet been obtained.

Treatment of non-conjugated octa-1,7-dienes with metathesis catalysts induces the intramolecular ring closure reaction and leads to the formation of cyclohexene[139-141]:

R = H, D.

It has been shown[142] that this reaction proceeds quantitatively and with a selectivity close to 100%. A non-conjugated cyclic diene, namely cyclohexa-1,4-diene, has been obtained analogously by the metathesis of linoleic and linolenic esters isolated from natural oils[143].

The thermodynamic parameters of the polymerisation of 4-methylcyclohexene with ring opening have been determined[136] and it has been shown that the polymerisation is thermodynamically prohibited in all phase states down to 0 K. Indeed it has been established[160] that the alternating butadiene–propene copolymer is fully degraded to 4-methylcyclohexene under the influence of metathesis catalysts.

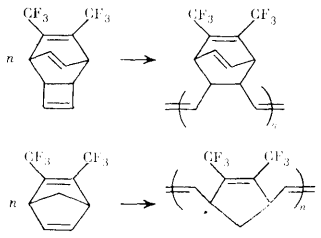
The ring strain in cyclo-olefins such as *cis*-cyclo-octene and *cis,cis*-cyclo-octa-1,5-diene (Table 7) is fairly high and the equilibrium monomer concentration is low at the usual temperatures.

2. Synthesis of Cyclo-olefin Polymers and Oligomers

The metathesis reactions of cyclo-olefins make it possible to obtain polymers which could not be synthesised by the methods of polymer chemistry known previously. Among all the cyclo-olefin polymers known at the present time, those of cyclopentene, norbornene, and cyclo-octene have acquired the greatest technical importance.

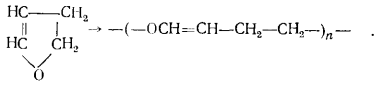
Polypentenamer, in which the double bonds have predominantly the *trans*-configuration, is obtained by the polymerisation of cyclopentene under the influence of metathesis catalysts based on tungsten compounds, for example WCl_6–$Al(C_2H_5)_3$ [5] and WCl_6–C_2H_5OH–$Al(C_2H_5)Cl_2$ [65] at room temperature. A polymer with a high content of *trans*-units has also been obtained using tungsten hexafluoride in combination with $Al(C_2H_5)Cl_2$.[18] In the polymerisation of cyclopentene in the presence of the WCl_6–$Al(C_2H_5)_3$ system modified by the introduction of benzoyl peroxide, the content of *trans*-units reaches 90%.[144] The melting point of *trans*-polypentenamer (80% of *trans*-units) is close to room temperature; this polymer is capable of undergoing forced crystallisation on extension, which leads to the spontaneous strengthening of rubbers[145,146].

The *cis*-polypentenamer described by Natta et al.[5] was obtained in the presence of the $MoCl_5$–$AlEt_3$ molybdenum-containing catalyst. Later Haas et al.[18] reported the synthesis of a polypentenamer containing up to 85% of *cis*-units, for which tungsten hexafluoride and a polymerisation temperature of −30 °C were employed. An effective system for the catalysis of the *cis*-polymerisation of cyclopentene, proposed by Makovetskii and Red'kina[66], consists of a combination of WCl_6 with tetra-allylsilane and ensures the formation at −30 °C of a polypentenamer containing 98% of *cis*-units. The *cis*-polypentenamer obtained has the lowest glass point $T_g = -114$ °C among polyhydrocarbons and exhibits an extremely low rate of crystallisation at low temperatures (−78 °C).[35,144] This elastomer is one of the most frost-resistant rubbers.



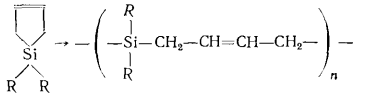
Polynorbornene, the polymer of norbornene, which is the first representative of the group of bicyclo-olefin polymers, has also found a practical application. Oil-filled rubbers (up to 400 wt.%) based on it are manufactured and are used as vibration eliminating materials[85,96]. The polymerisation of this most reactive cyclo-olefin with ring opening can be achieved in the presence of virtually any metathesis catalyst[17,147], including titanium-containing catalytic systems[3]. The polymers obtained, having a mixed *cis/trans* configuration (43/57), have an amorphous structure and $T_g = 54$ °C.[148] A *trans*-polyoctenamer, a crystalline polymer with a melting point of 62 °C and containing 90% of *trans*-units[6], has been obtained by the polymerisation of cyclo-octene in the presence of the WCl_6–$Al(C_2H_5)Cl_2$ system. A polyoctenamer with a melting point of 58 °C and containing 65% of *trans*-units has been obtained in the presence of the WCl_6–$Al(iso\text{-}Bu)_2Cl$ system[150]. This polymer can be of interest for the preparation of biodegradable films. Its *cis*-isomer is also promising as regards practical applications[151]. As a consequence of the relatively low content of α-methylene groups at the double bonds, this elastomer is much more resistant to oxidation than rubbers based on butadiene and isoprene. A disadvantage of *cis*-polyoctenamer is a high rate of crystallisation. However, its capacity for crystallisation can be appreciably reduced by the introduction of *trans*-units. Thus polyoctenamers containing approximately 30% of *trans*-units do not crystallise down to −100 °C.[152]

The polymerisation of cyclo-octa-1,5-diene leads to the possibility of obtaining polymers (analogues of 1,4-polybutadiene) without vinyl side groups; however, the formation of oligomeric products in the course of polymerisation[100,149] renders this process unpromising from the practical standpoint.

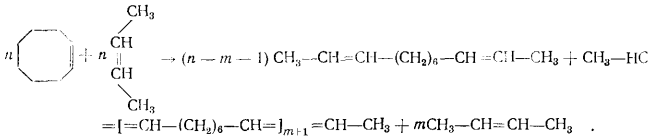


Various rubbers, including non-crystallisable rubbers, can be obtained from cyclo-octa-1,5-diene–cyclo-octene copolymers. These have not undergone a technical development because the above cyclo-olefins are not manufactured in sufficient amounts. The copolymerisation reactions of various cyclo-olefins have been investigated in detail[148,150,153].

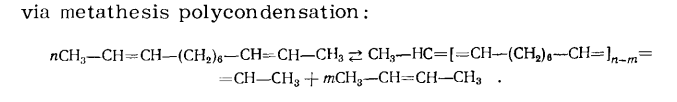
The modification of finished rubbers can be achieved by their cometathesis with cyclo-olefins containing functional groups or by the copolymerisation of the usual cyclo-olefins and cyclo-olefins with functional group substituents. Thus the copolymerisation of the *exo*-adduct of cyclopentadiene and maleic anhydride with cyclopentene has been achieved[155] and a polymer containing anhydride groups has been obtained. It is of interest that the *endo*-adduct does not exhibit a catalytic activity in the metathesis reaction.



Polymers of fluorine-containing cyclo-olefins have been obtained[156,157]:



It has been shown[73] that 2,3-dihydrofuran can be polymerised with ring opening in the presence of the stable Fischer carbenechromium complexes $(CO)_5Cr{=}CPh_2$ and $(CO)_5Cr{=}C(OCH_3)Ph$:



The polymerisation of dialkylsilacyclopentene with ring opening in the presence of metathesis catalysts had been reported even earlier[158]:

The cometathesis of cyclic and linear olefins as well as the degradation reactions of saturated polymers in the presence of linear olefins are reactions of the same type and can be used to synthesise linear unsaturated oligomers. In this case linear olefins are effective chain transferring agents comparable in their reactivity with cyclo-olefins. The cometathesis of cyclopentene and cyclo-octene with *cis*- and *trans*-but-2-enes and *trans*-oct-4-ene under the influence of the WCl_6–tetramethyldisilacyclobutane system in stoichiometric proportions of the olefins has been studied[159]. The cometathesis reaction was completed by the formation of linear oligomers in a quantitative yield. The ratios of the rate constants for reactions involving chain transfer to a linear olefin and the propagation rate constants were 0.16 (cyclo-octene–*trans*-octene), 0.48 (cyclo-octene–*trans*-but-2-ene), and 0.82 (cyclo-octene–*cis*-but-2-ene), which indicates virtually identical reactivities for *cis*-but-2-ene and cyclo-octene. In the latter case mainly the linear dodeca-2,10-diene and a small amount of oligomers are formed for equimolar amounts of cyclo-octene and *cis*-but-2-ene:[115]

The removal of the equilibrium amount of but-2-ene leads to an increase of the molecular weight of linear oligomers via metathesis polycondensation:

This reaction proceeds via stages with a chain mechanism and at the same time has the main features of equilibrium polycondensation. The determination of the equilibrium constant yielded a very low value (1.3×10^{-3}), which indicates an almost complete shift of the equilibrium to the left. Nevertheless, if the low-molecular product (but-2-ene) is carefully removed from the reaction mass, it is possible to obtain oligomers with $\bar{M}_n = 20\,000$.

The synthesis of oligomers of cyclo-octa-1,5-diene and cyclo-octene by their cometathesis with oct-1-ene, propene, pent-1-ene, hex-1-ene, and hept-1-ene has been described[152]. The use of higher C_9–C_{12} α-olefins makes it possible to regulate simultaneously the degree of unsaturation of the oligomers obtained. Thus products whose degree of unsaturation was close to that of plant oils have been obtained in this way from cyclopentene[160].

The cometathesis reactions of polybutadiene and polyisoprene with olefins are undoubtedly of interest as a new method for the synthesis of oligomeric products. The process takes place at room temperature and leads to the formation of low-molecular-weight isoprene *cis*-oligomers and butadiene oligomers with a mixed structure. In contrast to the degradative cyclisation process, in the latter case oligomeric products are characterised by an exponential equilibrium distribution ($\bar{M}_w/\bar{M}_n \cong 2$).[115] The use of metathesis catalysts also leads to the possibility of carrying out the degradation of polybutadiene and polyisoprene gels with transfer of the degradation products to the solution.

---o0o---

Thus it was shown above that the metathesis reaction proceeds via a chain mechanism under the influence of carbene complexes of transition metals. The carbene species are formed on decomposition of organometallic compounds of transition metals at the instant of their generation. In the presence of metathesis catalysts degradative chain cyclisation of unsaturated polymers takes place at room temperature with formation of a set of cyclic oligomeric molecules having a broad molecular weight distribution. In the presence of olefins the same reactions lead to linear oligomers with the most probable molecular weight distribution. The metathesis reaction is promising from the standpoint of the synthesis of polymeric materials.

Polyfluoroalkoxyphosphazenes—a Promising Class of Organoelemental Polymers

S.V.Vinogradova, D.R.Tur, and I.I.Minosyants

The results of the synthesis of polyfluoroalkoxyphosphazenes and also polyorganophosphazenes containing various non-fluorinated organic groups as substituents at the phosphorus atoms together with fluoroalkoxy-groups are surveyed. The characteristics of the formation of these polymers by the chemical modification of polydichlorophosphazene are examined. A systematic account is given of the literature data on the properties of polyfluoroalkoxyphosphazenes and their practical applications. The ways in which varieties of the macromolecules of these polymers arise and the influence of the nature and number of anomalous units on their properties are considered. Attention is drawn to a fundamentally important characteristic feature of polyfluoroalkoxyphosphazenes, namely the high sensitivity of their properties to anomalous units when the content of the latter is less than 1 mole %.
The bibliography includes 179 references.

I. INTRODUCTION

Among high-molecular-weight polyorganophosphazenes having the general structure

most attention has been attracted at the present time by polyfluoroalkoxyphosphazenes, where R = $OAlk_F$, which have properties of interest from the practical point of view. The chemical structure of their macromolecules has the following features. The main chain is made up of alternating phosphorus and nitrogen atoms and each second chain atom (nitrogen) has no substituents. Furthermore, the presence of fluoroalkoxy-groups as substituents at the phosphorus atom is responsible for a comparatively high fluorine content in these polymers (more than 40%). This ensures the following properties of polyfluoroalkoxyphosphazenes: flexibility and elasticity at low temperatures, effective resistance to oil and petrol, improved fire resistance, water- and dirt-repelling properties, etc.

During the last ten years, a comparatively large number of studies have been published on polyfluoroalkoxyphosphazenes, demonstrating the undoubted interest of investigators in these polymers. At the same time a series of the existing reviews[1-26] and monographs[27-34] deal with polyfluoroalkoxyphosphazenes either together with other polyphosphazenes, merely as one of the possible types of such polymers, or in terms of a specific aspect of their properties, so that the treatment is incomplete and insufficiently comprehensive.

This review surveys the main literature data on the synthesis, properties, and the most promising applications of polyfluoroalkoxyphosphazenes.

II. THE SYNTHESIS OF POLYFLUOROALKOXYPHOSPHAZENES

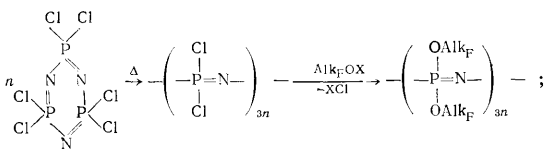
Polyfluoroalkoxyphosphazenes are comparatively new polymers. The first data concerning their successful synthesis were published almost simultaneously in the Soviet Union[35] and in the USA [36,37] as late as 1965–1966, when comparatively high degrees of nucleophilic substitution of the chlorine atoms in a high-molecular-weight fully soluble polydichlorophosphazene by fluoroalkoxy-groups were achieved and polyorganophosphazenes with an improved hydrolytic stability were obtained.

Later, attempts were made to synthesise polyfluoroalkoxyphosphazenes also by other procedures. Thus, Prons et al.[38] tried to carry out the thermal polymerisation of hexakis(3,3,3,2,2-pentafluoropropoxy)cyclotriphosphazene and Allcock et al.[39] attempted the synthesis of hexakis(trifluoroethoxy)cyclotriphosphazene in the melt at temperatures in the range 200–300 °C by analogy with the polymerisation of hexachlorotriphosphazene[36,37] However, it was found that fully substituted fluoroalkoxycyclotriphosphazene cannot be subjected to thermal polymerisation. On the other hand, it has been shown that rings with different degrees of substitution of the chlorine atoms nevertheless enter into both polymerisation and copolymerisation reactions[38] but with formation of a polymer having a lower molecular weight {the intrinsic viscosity $[\eta] = 0.5 - 0.6$ dl g^{-1} in organofluorine solvents} than in the polymerisation of hexachlorocyclotriphosphazene. The copolymerisation of partly substituted cyclic compounds with hexachlorocyclotriphosphazene[39] followed by the substitution of the residual chlorine by trifluoroethoxy-groups yielded polyorganophosphazenes with a much higher molecular weight (100000–400000). A polyphosphazene with a molecular weight of 110000 and $[\eta] = 0.71$ dl g^{-1} has been obtained in solution in tetrahydrofuran by Allcock et al.[39] and in the copolymerisation of hexakis(trifluoroethoxy)cyclotriphosphazene and hexachlorotriphosphazene.

Despite the fact that the above studies led to the discovery of the possibility, in principle, of the polymerisation of partly substituted cyclic compounds, this method of synthesis of polyfluoroalkoxyphosphazenes is of theoretical rather than practical interest owing to its more laborious nature and lower molecular weights of the resulting polymers than in the case where polydichlorophosphazene is used as the starting material.

Together with the attempt at the thermal polymerisation of fluoroalkoxycyclotriphosphazenes, studies have also been made of the possibility of their catalytic polymerisation[39,40].

However, the formation of a high-molecular-weight poly-[bis(trifluoroethoxy)phosphazene] from hexakis(trifluoroethoxy)cyclotriphosphazene in the presence of CsCl as the catalyst at 275 °C was not observed[39].



Kolkmann[40] studied the possibility of the polymerisation of hexakis(trifluoroethoxy)cyclotriphosphazene in the presence of acid catalysts such as BCl_3 (at 150 °C), BF_3, BBr_3, $TiCl_4$ (at 120–200 °C), CF_3SO_3H, $CF_3Se(O)OH$, and HCl, as well as basic catalysts such as K_2CO_3, Li_2O, MgO, CaO, BaO, CoO, and $N(C_2H_5)_3$, and also water (at 150 °C). The formation of a polyphosphazene with a molecular weight of 23000–33000, in which approximately half of the initial fluoroalkoxy-groups have been exchanged for chlorine, was observed only in the presence of an equimolar amount of BCl_3. Hexakis(hexafluoroisopropoxy)cyclotriphosphazene does not polymerise and does not react with BCl_3 at 225 °C according to Kolkmann's data[40].

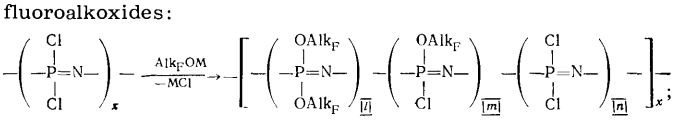
Thus investigators have still not been able to find a realistic method for the polymerisation of fully substituted cyclic compounds—hexa(fluoroalkoxy)cyclotriphosphazenes.

Flindt and Rose[41] showed that poly[bis(trifluoroethoxy)-phosphazene] with a molecular weight of 10000 and soluble in acetone, isobutyl methyl ketone, tetrahydrofuran (THF), and ethyl acetate is formed from tris(1,1,1-trifluoroethoxy)-*N*-trimethylsilylphosphine imine at 200 °C.

Yet another procedure for the synthesis of linear oligomeric fluoroalkoxyphosphazenes from hexachlorocyclotriphosphazene and organosilanes having the formula $ROSiMe_3$, where R = $HCF_2CF_2CH_2$ or $HCF_2(CF_2)_3CH_2$, in the presence of a mixture of H_3PO_4 and pyridine and also polyphosphoric acid as catalysts, has been proposed[42–44].

Among the methods of synthesis of high-molecular-weight polyfluoroalkoxyphosphazenes known at the present time, the most promising is a two-stage procedure consisting of the thermal polymerisation of hexachlorocyclotriphosphazene with formation of polydichlorophosphazene and subsequent substitution of the chlorine atoms in the latter by fluoroalkoxy-groups in accordance with the mechanism

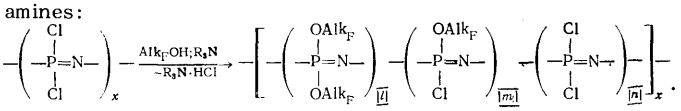
X = H, metal.



Before proceeding to a deeper analysis of the literature data on the synthesis of polyfluoroalkoxyphosphazenes by this method, it is useful to consider briefly the intermediate product—polydichlorophosphazene. In the early studies devoted to the polymerisation of hexachlorocyclotriphosphazene and considered in fair detail in a number of reviews[45–48], a cross-linked insoluble polydichlorophosphazene, virtually unsuitable for further reactions involving the substitution of chlorine by fluoro-alkoxy-groups, was mainly obtained. It was not until 1965–1966 that a fully soluble polydichlorophosphazene was obtained for the first time[35–37] and it was shown that the cross-linked polymer is not a direct polymerisation product but is formed from a non-cross-linked polymer[36]. It was also shown that a fully soluble polydichlorophosphazene can be obtained at a rigorously controlled temperature (250° ± 1 °C) by stopping the heating of the system when the polymerisation mixture loses its fluidity[28].

There is still no unanimous view among investigators concerning the chemical structure of the soluble polydichlorophosphazene. For example, Singler et al.[80] attribute a linear structure to the polymer, while Allcock[28] believes that the soluble polydichlorophosphazene obtained by the polymerisation of hexachlorocyclotriphosphazene by limiting the degree of conversion has almost certainly a branched structure. However, in both cases these are merely assumptions by the investigators, because polydichlorophosphazene was in no way characterised from this standpoint in their studies.

The influence of the heterounit structure of the initial polydichlorophosphazene, due to the branching of its macromolecules, on the synthesis and properties of polyorganophosphazenes was studied for the first time by Korshak et al.[49] It was shown experimentally in relation to the polymer-analogue substitution of chlorine atoms in the linear[50,51] and branched[52] polydichlorophosphazenes by trifluoroethoxy-groups that the presence of branches hinders the attainment of high degrees of substitution and has a significant influence on the solubility and thermomechanical properties of the polyorganophosphazene formed[49].



These data permit the conclusion that, in order to obtain reliable, satisfactorily reproducible results in the synthesis of polyfluoroalkoxyphosphazenes, it is necessary in the first place to characterise rigorously the initial polydichlorophosphazene not only in terms of the molecular weight but also in terms of the degree of branching.

The substitution of chlorine atoms in polydichlorophosphazene by fluoroalkoxy-groups in a series of organic solvents has been achieved in two ways—by condensation with fluoroalkoxides:

M=Na, Li, K; $l \gg m + n$

and with fluorinated alcohols in the presence of tertiary amines:

The characteristics of these reactions have still been little studied and most of the literature data on the synthesis of polyfluoroalkoxyphosphazenes reduce mainly to the description of methods for the preparation of specific specimens of such polymers.

Thus the synthesis of these polymers using sodium fluoroalkoxides as the nucleophiles has been described in a number of studies[36,37,53–67]. Some investigators used lithium[34,60,64,65] and potassium[65,70] fluoroalkoxides together with sodium fluoroalkoxides for the same purpose.

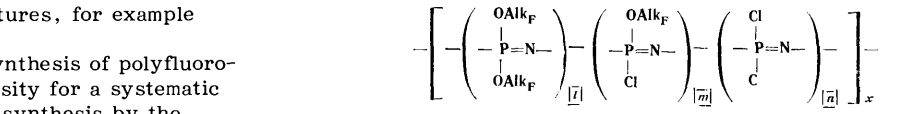
Unfortunately, analysis of the literature data does not permit a conclusion about the advantages of a particular alkali metal in the given polymer–analogue substitution reactions and systematic studies on these lines have not been carried out. At the same time, sodium fluoroalkoxides are used most often apparently mainly because sodium is most readily available and is easiest to handle.

According to Sharov and co-workers[60,65], the nature of the alkali metal can, however, influence the stage of aggregation of the fluoroalkoxyphosphazene polymers. In particular, under comparatively mild conditions of synthesis, when the polarity of the reaction medium (diethyl ether–toluene or dibutyl ether–toluene) is low and at reaction temperatures not exceeding 60 °C, amorphous polymers are formed when lithium fluoroalkoxide are used. The polymers obtained under the same conditions but using sodium and potassium fluoroalkoxides have a crystalline structure.

In the synthesis of polyfluoroalkoxyphosphazenes based on the macromolecular reaction of polydichlorophosphazene with sodium fluoroalkoxides, benzene[37,53–59,65,67], toluene[55–67],

chlorobenzene[55,57], and THF [57,61,62,67] were used as solvents for polydichlorophosphazene. Sodium fluoroalkoxides were obtained in solution in THF,[37,53-67] dioxane[55,67], diethyl ether[65], dibutyl ether[65], and diethylene glycol dimethyl ether[55]. In the course of the substitution of the chlorine atoms in polydichlorophosphazene by fluoroalkoxy-groups using sodium fluoroalkoxides, the polyorganophosphazenes formed are as a rule precipitated[37,53-60,65-67]. It has been suggested in the patent literature[61,62] that, in order to improve the rate of reaction and the degree of substitution of chlorine atoms by fluoroalkoxy-groups, the substitution reactions be carried out under homogeneous conditions in THF, in which certain polyfluoroalkoxyphosphazenes are readily soluble. The amount of unsubstituted chlorine in these compounds amounts to 0.06 wt.% under these conditions according to patent data[61,62]. Allcock and Cook[57] also obtained poly[bis(2,2,3,3-tetrafluoropropoxy)phosphazene] in solution in tetrahydrofuran but with a much higher content of unsubstituted chlorine (0.42 wt.%). At the same time, despite the precipitation of the polymer, a series of polyfluoroalkoxyphosphazenes whose chlorine content did not exceed 0.05 wt.% were successfully synthesised in mixtures of solvents such as benzene and THF.[56,59] Hence it is evident that the "homogeneity" or "heterogeneity" of the reaction mass is not always a decisive factor for the attainment of high degrees of the substitution reaction.

Among investigators there is no unanimous view concerning the optimum temperature for the successful polymer-analogue substitution of chlorine by fluoroalkoxy-groups. This reaction has been carried out most frequently by prolonged refluxing of the reaction mixtures[36,37,53,55,57,58,61,62] but in certain studies lower temperatures, for example 40 °C, have also been indicated[56,59].



This state of the problem of the synthesis of polyfluoroalkoxyphosphazenes led to the necessity for a systematic study of the characteristics of their synthesis by the chemical modification of polydichlorophosphazene with fluoroalkoxides. In relation to the synthesis of poly[bis(trifluoroethoxy)phosphazene], we investigated the influence of various factors on the degree of the polymer-analogue substitution of chlorine atoms in polydichlorophosphazene by fluoroalkoxy-groups[67,69] and on the effectiveness of the hydrolytic side reactions during synthesis[66-68].

The investigation established that the main polymer-analogue reaction involving the substitution of chlorine by trifluoroethoxy-groups with the aid of sodium trifluoroethoxide is as a rule characterised by high degrees of conversion even in those cases where the polyfluoroalkoxyphosphazene does not dissolve in the reaction medium and precipitates after only a few minutes from the start of the reaction. On the other hand, the absolute amounts of the residual chlorine then depend on the temperature, the nature of the solvents, and the concentrations and ratios of the initial component. The highest degrees of the substitution reaction (up to 99.95 mole %) are obtained in solvent mixtures such as benzene–THF, toluene–THF or in solution in THF at room temperature for a reaction time of ~3 h, a concentration of the initial polydichlorophosphazene of ~20 g l^{-1}, and in the presence of a threefold excess of sodium trifluoroethoxide calculated per P–Cl group. The effectiveness of hydrolytic side reactions is determined by the nature of the solvent, the temperature, and the duration of the substitution reaction and depends significantly on the amount of water in the reaction system (even at the level of 10^{-2}–10^{-3} vol.%). Hydrolytic side reactions take place to the least extent at room temperature when the main reaction time is not more than 3 h and polyfluoroalkoxyphosphazene precipitates during the reaction, particularly from a toluene–THF mixture.

Since the unsubstituted P–Cl groups in polyphosphazenes are hydrolytically extremely unstable[28], the attainment of high degrees of the substitution reaction is naturally urgently required in the synthesis of polyfluoroalkoxyphosphazenes. Because of this, the degree of substitution is one of the most important characteristics of polymers of this kind. It can be inferred quantitatively from the content of unsubstituted chlorine.

Table 1 lists the contents of unsubstituted chlorine in polyfluoroalkoxyphosphazenes obtained by substituting the chlorine in polydichlorophosphazene by sodium, lithium, and potassium fluoroalkoxides under different substitution reaction conditions. It is seen that the authors of the relevant investigations did not always indicate the amount of unsubstituted chlorine in the polymer. Furthermore, in a number of instances, it was estimated extremely approximately and some workers[36,53,71] actually quote a zero chlorine content, which is unlikely, since polymer-analogue reactions do not as a rule take place to the extent of 100%. Overall, the polyfluoroalkoxyphosphazenes synthesised are usually characterised by a low content of residual chlorine by weight, which indicates a high degree of the given polymer-analogue substitution reaction.

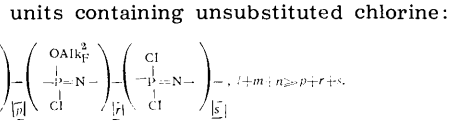
A large number of polyfluoroalkoxyphosphazenes containing various fluoroalkoxy-groups as substituents at the phosphorus atoms have now been obtained. These are, firstly, polyfluoroalkoxyphosphazenes in the synthesis of which mixtures of two different fluoroalkoxides were used for the reaction with polydichlorophosphazene[56,59,76-87] (Table 2). At the same time, the synthesis of polyfluoroalkoxyphosphazenes by the substituent exchange reaction

on heating in solution, in accordance with the following scheme, has been described[88,89]:



Using dihydric fluorinated alcohols, for example, 2,2,3,3,4,4-hexafluoropentanediol, the vulcanisation of polyfluoroalkoxyphosphazenes can be achieved by this reaction[89,90].

*In reality the chemical structure of the copolymers is much more complex owing to the presence of a certain amount of anomalous units containing unsubstituted chlorine:

However, in most cases, the vulcanisable fluoroalkoxyphosphazene polymers contain a small amount of a third substituent at the phosphorus atoms with a reactive group which cross-links the polymer in subsequent chemical reactions, for example, double bonds, active HO and NH groups, silicon-containing groups, and other groups[91—98]. Secondly, polyphosphazenes containing comparable amounts of fluoroalkoxy- and non-fluorinated alkoxy or aryloxy-groups as a framework for the phosphorus atoms can be assigned to the same type.

Among polymers of this kind, a polyorganophosphazene with two different alkoxy-groups at the phosphorus atom, containing 1.6 moles of trifluoroethoxy-groups and 0.4 of a mole of ethoxy-groups[73,74], as well as polyphosphazenes with three different substituents, where the content of alkoxy-groups having less than 16 carbon atoms is up to 35 mole %,[99] have been described. Polyphosphazenes of the type indicated, with reactive hydroxy-groups in the alkoxy-substituents, which are capable of being hardened by reaction with di-isocyanates and tetracarboxylic acid dianhydrides, have been synthesised[100].

In the synthesis of polyphosphazenes with fluoroalkoxy- and aryloxy-groups, various investigators used sodium[101,102] or lithium[103—109] fluoroalkoxides and phenoxides. On the other hand, when polydichlorophosphazene was treated with 4-cyanophenol, Na_2CO_3 was used as the HCl acceptor, after which the partially substituted polyphosphazene was condensed with sodium trifluoroethoxide[110].

In a number of instances, where it was not possible to achieve high degrees of substitution of polydichlorophosphazene with the aid of various nucleophiles, further substitution was carried out very successfully with the aid of sodium trifluoroethoxide[111—119] and lithium 2,2,3,3-tetrafluoropropoxide[109,120,121]. Polymers containing ~50% of fluoroalkoxy-groups as substituents at the phosphorus atom were as a rule obtained under these conditions.

Allcock and co-workers[122—124] obtained coloured polyfluoroalkoxyphosphazenes by substituting some of the chlorine atoms in polydichlorophosphazene by chromophoric groups and the remaining chlorine atoms by trifluoroethoxy-groups. They used the sodium derivatives of 2-hydroxy-1-azonaphthalene, 4-phenylazoaniline, 2-amino-1-phenylnaphthalene, 1-phenylazo-4-*p*-hydroxyphenylazonaphthalene, etc. as the chromophoric reagents, the molar ratio of the usual and chromophoric substituents ranging from 1:1 to 15000:1.

Together with polydichlorophosphazene, Allcock and co-workers[125—127] also used polydifluorophosphazene as the starting material in the synthesis of polymers containing fluorinated and non-fluorinated groups at the phosphorus atom. In particular, the high reactivity of polydifluorophosphazene compared with polydichlorophosphazene made it possible to achieve a degree of substitution of 50—90% of fluorine atoms by alkyl and phenyl groups, while in polydichlorophosphazene phenyl-lithium substitutes only 10% of the chlorine[114]. The residual chlorine atoms were substituted in both cases by sodium trifluoroethoxide. However, studies with polydifluorophosphazene involve considerable experimental difficulties, because of its high sensitivity to hydrolytic side reactions.

As already mentioned above, several attempts to achieve the substitution of chlorine atoms in polydichlorophosphazene by fluoroalkoxy-groups by condensation with fluoroalcohols in the presence of tertiary amines have been described. Thus, as early as 1964, Lenton et al.[128] reported the synthesis of a cross-linked partly substituted polymer by treating dichlorophosphazene swollen in benzene with a mixture of trifluoroethanol and pyridine. According to patent data[53], a soluble polyfluoroalkoxyphosphazene containing ~2% of unsubstituted chlorine can be obtained from the insoluble polydichlorophosphazene by treating it with a mixture of trifluoroethanol and triethylamine.

It is noteworthy that despite the much smaller number of publications on the synthesis of polyfluoroalkoxyphosphazenes in the presence of tertiary amines, a series of important features of this process have already been discovered. In particular, a study has been made of the macromolecular reaction of polydichlorophosphazene with trifluoroethanol in the presence of triethylamine in tetrahydrofuran in the temperature range between −5° and 60 °C.[129,130] It was shown that, together with the substitution of chlorine atoms by trifluoroethoxy-groups, there is a side reaction in this instance between polydichlorophosphazene and triethylamine, leading to the formation of a heterounit polymer containing at best ~3% of unsubstituted chlorine.

Tate et al.[131] synthesised polyorganophosphazenes by substituting the chlorine in polydichlorophosphazene by trifluoroethanol and other non-fluorinated nucleophiles in the presence of triethylamine in THF at 80—120 °C. They

reported that fully substituted non-cross-linked polymers were obtained under these conditions. On the basis of these results, the authors concluded that in the early syntheses the side reactions accompanied by the cross-linking of the polyorganophosphazene were due to the presence of traces of moisture in the reaction medium and the incomplete substitution of chlorine atoms was caused by the short reaction time and mild reaction conditions.

This method of synthesis of polyorganophosphazenes was also used to obtain a large number of polyphosphazenes containing trifluoroethoxy- and various non-fluorinated groups at the phosphorus atom[132-147]. However, according to patent data, such polymers contain 2 wt.%[133] and more[138-140,146] of unsubstituted chlorine, which conflicts to a large extent with the report that the chlorine is fully substituted in the presence of triethylamine[131].

In the presence of triethylamine, other workers[148] obtained in addition phosphazene polymers containing substituents based on thienyl alcohols and trifluoroethoxy-groups at the phosphorus atoms.

Overall, the available literature data on the synthesis of polyfluoroalkoxyphosphazenes in the presence of tertiary amines show that the degree of this reaction is much lower than in the condensation of polydichlorophosphazene with fluoroalkoxides; on the other hand, it greatly exceeds 50% and the attainment of its limiting degree at the level of 90–95% cannot be explained either by a decrease of the reactivity of the second chlorine atom after the substitution of the first or by the increase of steric hindrance. We believe[130] that one can postulate that the effect is due to the properties of the macromolecules in solution, in particular the formation of associated species comprising partly substituted polyphosphazene macromolecules owing to the lower rate of substitution reactions in the presence of tertiary amines compared with alkoxides.

In order to elucidate the possibilities for the synthesis of graft copolymers on the basis of polyphosphazenes, polydichlorophosphazene was condensed with a high-molecular-weight poly(arylene sulphoxide), containing a reactive terminal hydroxy-group, in solution in THF in the presence of triethylamine with subsequent substitution of the chlorine atoms in the polyphosphazene fragments by fluoroalkoxy-groups with the aid of sodium fluoroalkoxides[149] or trifluoroethanol in the presence of triethylamine[150]. The graft copolymers thus obtained contain a comparatively large number of unsubstituted chlorine (2–3 wt.%) like the homofluoroalkoxyphosphazenes synthesised in the presence of tertiary amines.

The above survey of literature data on the synthesis of polyfluoroalkoxyphosphazenes shows that a comparatively large number of polyfluoroalkoxyphosphazenes and polyphosphazenes with various substituents, including fluoroalkoxy-groups, at the phosphorus atoms have already been synthesised. However, the majority of the data are presented in patents and the aim of the relevant studies was to obtain new polyphosphazene structures. The characteristics of the formation of these polymers have been studied mainly only for poly[bis(trifluoroethoxy)phosphazene]. This makes it difficult to survey the literature data in order to discover the general principles of the synthesis of polyfluoroalkoxyphosphazenes.

Nevertheless, detailed examination of specific experimental data obtained by various investigators permits the conclusion that the chlorine atoms in the fully soluble polydichlorophosphazene undergo most successful polymer-analogue substitution by fluoroalkoxides, in the first place sodium fluoroalkoxides. This method of synthesis actually ensures the formation of polyfluoroalkoxyphosphazenes having the highest molecular weights and with a comparatively high degree of substitution.

III. THE PROPERTIES AND APPLICATIONS OF POLYFLUOROALKOXYPHOSPHAZENES

Despite the fact that there are many obscure questions concerning the synthesis of polyfluoroalkoxyphosphazenes, requiring further study, a number of specific and extremely valuable, from the practical point of view, properties of these polymers have already been discovered. The available literature data on the properties of polyfluoroalkoxyphosphazenes mainly refer to polymers with identical or two different fluoroalkoxy-groups at the phosphorus atoms. The properties of polymers with fluorinated and non-fluorinated substituents have so far been very little studied. The literature data only for the properties of polyphosphazenes with fluoroalkoxy-groups will therefore be considered below.

According to the literature, polyfluoroalkoxyphosphazenes can have a partly crystalline or amorphous structure. Thus the polyfluoroalkoxyphosphazenes synthesised by the substitution of the chlorine atoms in polydichlorophosphazene with the aid of sodium fluoroalkoxides have as a rule a partly crystalline structure. This is indicated in particular by X-ray diffraction data for five fluoroalkoxy-substituted polyphosphazenes: $[NP(OCH_2CF_3)_2]_n$, $[NP(OCH_2C_2F_4H)_2]_n$, $[NP(OCH_2C_2F_5)_2]_n$, $[NP(OCH_2C_3F_7)_2]_n$, and $[NP(OCHC_2F_6)_2]_n$.[28,30] At the same time it has been stated in the literature that fully amorphous polymers are formed under comparatively mild conditions of synthesis when lithium fluoroalkoxides are used[65]. Amorphous poly-[bis(trifluoroethoxy)phosphazene] has been obtained also in the polymer-analogue conversion of polydichlorophosphazene in the presence of triethylamine and LiCl.[49]

***Freon E-2 = $F(CFCF_3CF_2O)_2CHFCF_3$.

The amorphous or partly crystalline structures of the polymers obtained using a mixture of sodium fluoroalkoxides depend on the chemical structure and proportions of the latter[77]. Depending on their chemical and geometrical structures, these fluoroalkoxyphosphazene polymers are soft plastics or elastomers[28,65,77,81].

Table 3 shows that certain fluoroalkoxyphosphazenes are easily soluble in readily available organic solvents such as acetone, THF, ethyl methyl ketone, etc. However, with increase of the number of CF_2 groups in the side substituents, the solubility of the polymers is significantly impaired. The replacement of the terminal CF_3 group by CF_2H in such substituents again ensures a high solubility of the polymers.

At the same time polyfluoroalkoxyphosphazenes are exceptionally resistant to liquid hydrocarbons[87]. They do not dissolve in hexane and benzene and are fairly resistant to the action of rocket fuel[151], which makes these polymers extremely promising for use as oil- and petrol-resistant rubbers.

The ready solubility of poly[bis(trifluoroethoxy)phosphazene] and also certain polymers with two different fluoroalkoxy-groups at the phosphorus atoms leads to the possibility of the study in greater depth of the hydrodynamic and rheological properties of the solutions and molecular weight characteristics of these polymers. A series of investigations devoted to these questions have already been published[31,78,80,85,152–155]. Table 4 presents the literature data for the molecular weight characteristics of polyfluoroalkoxy-phosphazenes. It is seen that all the test specimens are characterised by a very high molecular weight and a broad molecular weight distribution.

Table 4. Molecular weight characteristics of certain polyfluoroalkoxyphosphazenes.

According to Hagnauer and Schneider[80], the molecules of the polyfluoroalkoxyphosphazenes investigated are relatively linear and their broad molecular weight distribution must be attributed to the mechanism of the polymerisation of hexachlorocyclotriphosphazene and not to branching. However, this conclusion does not explain the appreciable discrepancies between the molecular weight distributions of specimens Nos.4–6 (Table 4) obtained from polydichlorophosphazene synthesised by the polymerisation of the same amount of the trimer (4 g) under identical conditions.

Carlson et al.[85] also failed to observe an appreciable branching of the macromolecules. They suggest that the broad molecular weight distribution indicates the presence in the polymer of a supermolecular structure of the type of associated species. Thus there is no unanimity among investigators concerning the causes of the broad molecular weight distribution in polyfluoroalkoxyphosphazenes.

In certain cases in the study of the concentration dependence of the intrinsic viscosities of solutions of polyfluoroalkoxyphosphazenes in Freon E-2 an anomalous character of such viscosity was observed, namely an increase of η_{int} with dilution[80]. Furthermore, many specimens had anomalously high Huggins constants (usually more than 1.0) in Freon E-2. The authors attribute these phenomena to the aggregation of the macromolecules owing to the presence in the polymer of groups such as P–OH, >NH, P–O–P, and P=O.

At the same time Aharoni[155] reported recently the discovery of a region of mesomorphous behaviour of solutions of poly[bis(trifluoroethoxy)phosphazene].

Estimates of the glass points of polyfluoroalkoxyphosphazenes yielded extremely interesting results. The data in Table 5 show that low glass points are characteristic of these polymers. This applies also to fluoroalkoxyphosphazene elastomers whose glass points are in the range between −64° and −77 °C.[31]

*Methods: DTA = differential thermoanalysis; TA = torsional analysis; TM = thermomechanical tests on A.I.Marei's apparatus[65].

Within the framework of the model of atom–atom potential functions, Allen and Allcock[156] studied the energy surface of polyorganophosphazenes and showed that the potential energy surfaces of polyalkoxyphosphazene molecules, including poly[bis(trifluoroethoxy)phosphazene], contain a large number of minima separated by low barriers. This explains the high flexibility of these polymers and their low glass points T_g. The results of the theoretical calculation are in satisfactory agreement with X-ray diffraction data available for poly[bis(trifluoroethoxy)phosphazene].

At the same time it is striking that the glass points determined by different investigators for the same phosphazene structures show large discrepancies in a number of instances (Table 5, polymer Nos.1, 2, 3, and 8). The causes of these discrepancies are so far obscure but one cannot rule out the possibility that they are associated to a large extent with the non-reproducibility of the results obtained in the synthesis of polyfluoroalkoxyphosphazenes, which has been frequently mentioned in the literature[8,30].

Another interesting feature was observed in the study of the physical transformations in polyorganophosphazenes by scanning calorimetry, the thermoanalytical method, nuclear magnetic resonance, and X-ray diffraction[30,32,59,65,72,157–162], namely the occurrence of two first-order transition temperatures. Table 6 presents the available data concerning this question as regards polyfluoroalkoxyphosphazenes. It is

seen that this aspect of poly[bis(trifluoroethoxy)phosphazene] has been mainly investigated among polyfluoroalkoxyphosphazenes. At the lower transition temperature $T(1)$ the crystalline phase is seen to melt with retention of a definite degree of order, i.e. at $T(1)$ the polymer passes to a mesomorphous state. The upper temperature, at which there is a transition to an isotropic liquid, is the true melting point T_m. In poly[bis(trifluoroethoxy)phosphazene], these two transitions are separated by an unusually wide temperature range amounting to 150 K.[30,32] According to data published recently[65], the width of this range can actually exceed 200 K for certain polyfluoroalkoxyphosphazenes.

Table 6. Thermal transitions in polyfluoroalkoxyphosphazenes.

Polymer	$T(1)$, °C	T_m, °C	Method*	Refs.
$[NP(OCH_2CF_3)_2]_n$	92	240	DSC	[30, 32, 157]

$\{NP[OCH_2(CF_2)_5CF_2H]_2\}_n$	1	240	DSC	[65]

*DSC = differential scanning calorimetry.

From the practical standpoint, the temperature $T(1)$ is the upper limit of the temperature range in which the polymeric materials can be used. Above $T(1)$, the polymer can be moulded as a thermoplastic, but this entails the displacement of a semirigid structure and not viscous flow.

A more detailed consideration of this phenomenon in polyfluoroalkoxyphosphazenes is not necessary in the present review, since several extremely detailed reviews have been devoted to this question[30,32].

In certain reviews published recently[29,30,32], in the discussion of the question of physical transitions in polyorganophosphazenes under the influence of heat, 360 °C is stated to be the temperature of the onset of the thermal degradation of poly[bis(trifluoroethoxy)phosphazene], determined by thermogravimetric analysis. In reality, the question of the temperature of the onset of the decrease of mass on heating of this polymer is more complex and not quite so unambiguous. This can be illustrated by the data obtained by Connelly and Gilhan[59] and also by Zeldin et al.[75] in a dynamic thermogravimetric analysis of poly[bis(trifluoroethoxy)phosphazene] in an atmosphere of nitrogen. The temperature of the onset of the decrease of mass obtained by the first set of investigators (at a heating rate of 2 K min^{-1}) is ~250 °C, while in the second study (at a heating rate of 5 K min^{-1}) it was close to 350 °C. Such a significant discrepancy between the results cannot naturally be explained solely by the difference between the rates of heating. This is most likely to be associated with definite differences between the chemical structures of the polymer specimens investigated in the two studies.

At the same time, the results of thermogravimetric analysis (TGA) reflect the decrease of mass and yield only preliminary information about the thermal stability of polyfluoroalkoxyphosphazenes. For a deeper investigation of the thermal stability of these polymers, a number of isothermal experiments have been performed with subsequent estimation of the molecular weight characteristics of the test polymers[57,71,82,86]. It was found that, in the temperature range 150–200 °C, polyfluoroalkoxyphosphazenes already undergo a comparatively rapid decrease of viscosity and molecular weight. The dissociation of the polyfluoroalkoxyphosphazene macromolecules in this temperature range takes place at random and is accompanied by a very slight depolymerisation[82].

Such behaviour of polyfluoroalkoxyphosphazenes at comparatively low temperatures is apparently associated with the presence of defective units in their molecules, in particular with the content of unsubstituted P–Cl bonds, branches, etc.

In order to increase the thermal stability of polyfluoroalkoxyphosphazene, zinc and magnesium di(8-hydroxyquinolates)[97,163], zinc and lead dimethyldithiocarbamates[164], and also the zinc derivative of 2-mercaptobenzothiazole[165] have been proposed as stabilisers. Their action involves the deactivation of the defective groups in the polyfluoroalkoxyphosphazene macromolecules by complex formation with units containing the P–Cl, P–OH, and P=O bonds[163].

The data obtained in the study of the photolysis of poly[bis(trifluoroethoxy)phosphazene][72,73] show that this polymer exhibits a high resistance to light. However, the residual unsubstituted P–Cl groups promote the degradation of the polymer, since they increase the amount of light absorbed by the specimen.

Fluoroalkoxyphosphazene polymers are extremely resistant to action of boiling water[55,151]. For example, there are data showing that certain vulcanisates retain ~85% of their initial strength characteristics after 900 h at 100 °C and in 100% relative humidity[151]. In the cold they do not change even after coming into contact with concentrated NaOH and KOH solutions for many months[28,55,151]. The data concerning the action of various acids on polyfluoroalkoxyphosphazenes are extremely contradictory. Thus Rose and Reynard[55] reported that these polymers do not react with concentrated H_2SO_4 at a low temperature. Allcock[28] noted their resistance to glacial acetic acid. However, in a later publication Vicic and Reynard[151] drew attention to the fact that strong inorganic acids and glacial acetic acid impair the mechanical parameters of these polymers. According to these investigators, even dilute acid solutions cause slight hydrolysis of polyfluoroalkoxyphosphazenes. It is noteworthy that all the considerations described above refer to polyfluoroalkoxyphosphazenes tested in the solid state.

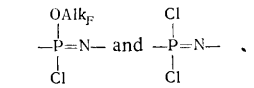
Polyfluoroalkoxyphosphazenes do not burn in air. The oxygen index of the flammability of these polymers and materials based on them is 47–65,[83,166] reaching as much as 80 in certain cases[65].

According to Allcock's data[28], poly[bis(trifluoroethoxy)phosphazene] films have effective water repellent properties with a wetting angle of 100 °C and a critical surface tension of 19.7 dyn cm^{-1}. In terms of the latter characteristic, they approach Teflon (22 dyn cm^{-1}) and polydimethylsiloxane (18 dyn cm^{-1}).[28] Allcock[28] notes that poly[bistrifluoroethoxy)phosphazene] and poly[bis(pentafluoropropoxy)phosphazene] films are very flexible and can be readily oriented on extension, giving rise to material with a high tensile strength. At the same time, Singler et al.[8] characterised poly[bis(trifluoroethoxy)phosphazene] as an elastic but weak material. Materials having a tensile strength of 175 kg cm^{-1} with 200% elongation on rupture have been obtained on the basis of fluoroalkoxyphosphazene elastomers, but, overall, a tensile strength of ~100 kg cm^{-2} accompanied by 100–200% elongation is more characteristic of such vulcanisates[31].

As regards the possible applications of polyfloroalkoxyphosphazenes, one should note in the first place their likely usefulness as oil- and petrol-resistant elastomeric materials with an improved fire resistance over a wide range of working temperatures combined with an effective frost resistance. In particular, compositions based on vulcanised elastomers are being developed at the present time for sealing devices in oil seals, sleeves, washers, fuel hose, etc. in the working temperature range from −60 to +200 °C.[8, 31,83,151]. The application of polyfluoroalkoxyphosphazenes in the textile industry has been proposed. It involves the impregnation of textiles with these polymers in order to impart to them water- and dirt-repellent properties[167]. At the same time, there exist patent data according to which polyfluoroalkoxyphosphazenes can be used as binders in compositions for water-impermeable galvanic cells[168–171] and for electrodes in chemical cells[172].

Studies of the possible applications of poly[bis(trifluoroethoxy)phosphazene] in the solution of the problem of resistance to thrombosis and biocompatibility are of undoubted interest[33,34,172,173]. Preliminary selective tests *in vitro*[33] and also *in vivo*[34] enabled the authors to conclude that further studies of polyfluoroalkoxyphosphazenes from the standpoint of their possible use in medicine are desirable. At the same time it has been shown that the high resistance to thrombogenesis in contact with native blood and the contancy of the physicochemical and mechanical properties after prolonged contact with a medium close in composition to blood make these polymers extremely promising for vascular surgery[173].

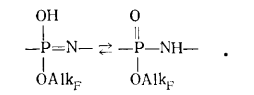
Such a wide variety of properties, which are promising from the practical point of view, makes it possible to classify polyfluoroalkoxyphosphazenes as polymers with a wide range of purposes, which is apparently the reason for the increased interest in these polymers during the last 15 years.



Overall, analysis of the literature data on the properties of polyfluoroalkoxyphosphazenes permits the following conclusions. On the one hand, polyfluoroalkoxyphosphazenes are undoubtedly interesting polymers with a wide variety of valuable properties. On the other hand, in the analysis of these properties attention is drawn in many instances to their very significant non-reproducibility. Therefore, some of the results achieved at the present time undoubtedly cannot as yet be regarded as optimal. The non-reproducibility of many properties of these polymers can be caused in the first place by the formation of anomalous units during synthesis which can influence their properties. This resembles the situation demonstrated by Korshak[174], for many heterounit organic polymers. Bearing this in mind, we thought it useful to consider this problem specially.

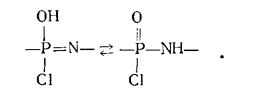
IV. THE INFLUENCE OF THE HETEROUNIT STRUCTURE OF POLYFLUOROALKOXYPHOSPHAZENES ON THEIR PROPERTIES

The heterounit structure of polyfluoroalkoxyphosphazenes can arise during their synthesis for several reasons and its chemical nature can be diverse. In the first place it is due to the branching inherited from the initial polydichlorophosphazene. This type of heterounit structure can, however, be virtually eliminated by employing as the starting material the linear polydichlorophosphazene obtained in accordance with the method developed recently for the polymerisation of hexachlorocyclotriphosphazene in a preheated polymerisation system[50,51].



Another type of heterounit structure arises owing to the incomplete substitution of chlorine in the initial dichlorophosphazene, which, like, incidently, the majority of other macromolecular reactions[175], does not go to 100% completion. On this basis, one can assume that polyfluoroalkoxyphosphazene contain, together with units of the dominant type

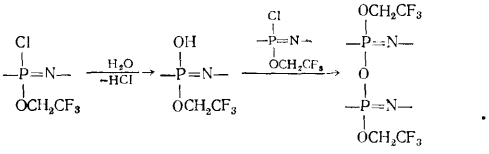
also various amounts of intermediate and initial units:



Since very high degrees of substitution (>99%) are nevertheless as a rule comparatively readily attained in the synthesis of polyfluoroalkoxyphosphazenes, it is natural to expect that their molecules contain mainly anomalous intermediate units with one unsubstituted chlorine atom at the phosphorus atom. However, in a study of the photolysis of poly[bis(trifluoroethoxy)phosphazene], Ferrar et al.[73] detected *gem*-1,1-$N_3P_3Cl_2(OCH_2CF_3)_4$ in the degradation products together with a cyclic trimer fully substituted by trifluoroethoxy-groups. This constitutes direct evidence for the presence in the polymer also of anomalous initial units with two unsubstituted chlorine atoms at the phosphorus atom. The amount of residual chlorine in polyfluoroalkoxyphosphazenes is a measure of the overall content of anomalous units with unsubstituted P–Cl groups.

We have shown[66–68] that yet another very significant type of heterounit structure can arise owing to the occurrence of hydrolytic side reactions in the synthesis of polyfluoroalkoxyphosphazenes. The anomalous units formed in this process can be present in the polymer in two tautomeric forms:

In addition, there is also a possibility of the combination of heterounit structures of different chemical types involving a single anomalous unit:



Such wide variety of anomalous units makes it significantly difficult to obtain stable readily reproducible results in the synthesis of polyfluoroalkoxyphosphazenes. This has led to the necessity for the investigation of the influence of the number and nature of the anomalous units on the set of properties of polyfluoroalkoxyphosphazenes. The study of hydrodynamic, conductimetric, and dielectric properties of dilute solutions of poly[bis(trifluoroethoxy)phosphazene] with different heterounit structures[176–178] by three independent methods led to the discovery of previously unknown polyelectrolyte properties of polyfluoroalkoxyphosphazenes in solution in organic solvents and showed that the presence of the specific amount of anomalous units with P–Cl and P–OH groups leads to the appearance of ionogenic groups in these polymers. An important feature of the polymers is the high sensitivity of their properties to small amounts of anomalous units (<1 mole %).

An electron microscope study of dilute solutions of poly[bis(trifluoroethoxy)phosphazene][179] made it possible to obtain more complete information about the character of the acquisition of polyelectrolyte properties by a polyfluoroalkoxyphosphazene, showing that, in dilute solutions in

polar and moderately polar solvents of the type of acetone and THF, poly[bis(trifluoroethoxy)phosphazene] exists in the form of individual macromolecules and that the formation of ionised groups in it is predominantly intramolecular.

The presence of anomalous units with residual P–Cl groups as well as very small amounts of P–OH and P(O)–NH groups, arising as a result of hydrolytic side reactions, reduces significantly the hydrolytic stability of poly[bis(trifluoroethoxy)phosphazene][66,67]. For example, the polymer containing ≥0.2 wt.% of unsubstituted chlorine is hydrolytically so unstable that it loses its solubility in organic solvents even at room temperature. The loss of solubility is associated in this instance with the formation of cross-links between the macromolecules of poly[bis(trifluoroethoxy)-phosphazene] in accordance with the following scheme:

When the chlorine content is <0.2 wt.%, the polymer is hydrolytically more stable. However, when the chlorine content is in the range 0.06–0.20 wt.%, an appreciable decrease of [η] is nevertheless observed after boiling the polymer in aqueous acetone (at 56 °C), i.e. at a comparatively low temperature. Only in those cases where the amount of unsubstituted chlorine in poly[bis(trifluoroethoxy)phosphazene] does not exceed 0.06 wt.%, which corresponds (without taking into account other anomalous units) to a chlorine content of 0.21 mole %, is the polymer hydrolytically stable also on boiling in aqueous acetone.

All the factors described above are valid only when the polymer contains virtually no partly hydrolysed fragments. Their presence has the same unfavourable influence on the hydrolytic stability of polyfluoroalkoxyphosphazenes as the presence of unsubstituted P–Cl groups. Consequently, the hydrolytic stability of polyfluoroalkoxyphosphazenes at moderately high temperatures depends on the overall content of all the anomalous units with P–Cl, P–OH, and P(O)–OH groups. This conclusion has a direct bearing on the stability and reproducibility of the results, which had not been taken into account previously in the synthesis of polyfluoroalkoxyphosphazenes. To ensure the stability and high reproducibility of the results in the synthesis of such polymers, the overall content of the anomalous units should not exceed 0.2 mole %. Therefore, the valuable properties of polyfluoroalkoxyphosphazenes, characteristic of units of the dominant type, can be achieved only when a very far-reaching polymer-analogue substitution reaction is carried out under conditions ensuring a virtually total absence of hydrolytic side reactions and a minimal hetero-unit structure of these polymers.

Latest Advances in the Field of Carbaborane-containing Polymers

N.I.Bekasova

The results of studies of carbaborane-containing polymers with different structures, carried out in the last six years, are surveyed. The methods of synthesis of carbaborane-containing polymers, their physicochemical properties, and their practical applications are considered.
The bibliography includes 128 references.

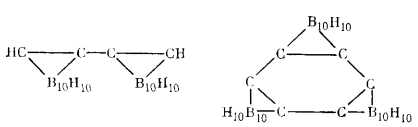
VI. Heterochain polymers 65

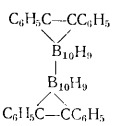
I. INTRODUCTION



Carbaborane-containing polymers have already been known for approximately twenty years. Many of these unusual and very interesting polymers are capable of withstanding extremely severe conditions under which the organic polymers decompose almost completely.

The latest review on the synthesis and properties of carbaborane-containing polymers, included in the book "Advances in the Synthesis of Organoelemental Polymers"[1], contains data published between 1966 and 1976 inclusive. The chemistry of carbaborane-containing polymers is nowadays continuing to develop vigorously. The aim of the present review is to survey data which have been published from 1977 to 1982; the review also includes articles published in 1977 but not included in the earlier review[1]. In order to make it easier to become acquainted with the new advances in the study of carbaborane-containing polymers of different structure, the data surveyed are arranged in the same sequence as in Korshak's book[1]. Three isomeric forms of carbaborane have come to be represented in the following manner[1]:

II. POLYCARBABORANYLENES



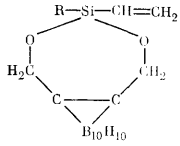
There are no examples in the literature of the specific synthesis of polycarbaboranylenes (i.e. polymers in which the carbaborane fragments are connected directly to one another via a C—C, B—C, or B—B bond). However, the condensation of carbaboranes with evolution of H_2 and the formation of oligomers has been described in some studies. Thus, when *o*-carbaborane was exposed to γ-radiation at 31 °C, the formation of dimers and trimers with a C—C bond and having the following structure was observed[2]:

A cyclic *o*-carbaborane trimer has also been detected in the γ-radiolysis of 1-phenyl-*o*-carbaborane (at 31 °C), which is accompanied by the evolution of benzene[3]. Under analogous conditions, partial isomerisation of *o*-carbaborane to *m*-carbaborane and of *m*-carborane to *o*-carbaborane, accompanied by the formation of dimeric and polymeric products (yield ~ 24%), was observed[4]. The authors believe that the polymers have a complex composition: both the polymers obtained on exposure of *o*-carbaborane to γ-radiation and the polymers derived from *m*-carbaborane contain isomeric *o*- and *m*-carbaborane fragments.

The formation of polycarbaboranylenes with an assumed B—B bond was also noted on heating *o*-, *m*-, or *p*-carbaborane *in vacuo* at temperatures above 600 °C.[5]

It is known that, when carbaboranes are heated in air at ~250 °C, they are oxidised with formation of B—OH and B—O—B bonds[6]. The formation of a dimer with a B—B bond, observed[7] on heating diphenyl-*o*-carbaborane in air in the temperature range 260–330 °C, is therefore extremely unusual. The structure of the dimer

was confirmed by gas–liquid chromatographic, mass-spectrometric, and ebullioscopic data.



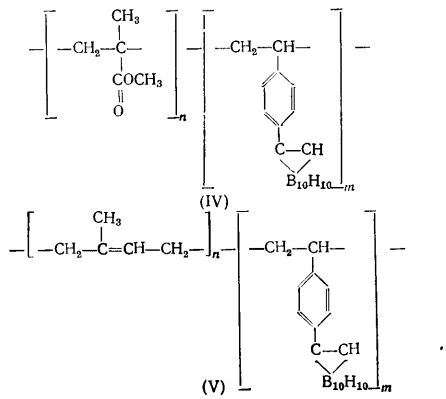
III. CARBOCHAIN POLYMERS

The synthesis and study of carbochain polymers and copolymers containing carbaborane groups in the side chain continues to attract the attention of investigators. Few studies devoted to the homopolymerisation of alkenylcarbaboranes have been published. Steric hindrance due to the bulky carbaborane groups is manifested[1] in the homopolymerisation of 1-alkenyl-*o*-carbaboranes. In addition, the electron density in the double bond diminishes due to the highly electron-accepting *o*-carbaborane fragments. For this reason, 1-alkenyl-*o*-carbaboranes polymerise less effectively the closer is the double bond to the carbaborane group. The hypothesis that the free-radical oligomerisation of 1-alkenyl-*o*-carbaboranes can lead to the formation of two different oligomers has been confirmed with the aid of a

quantum-chemical calculation of the charge distribution in 1-alkenyl-*o*-carbaboranes[8]. One of the oligomers consists of a polyethylene chain with the *o*-carbaboranyl group in the side chain, while the second oligomer contains the *o*-carbaborane fragment in the main chain.

The capacity of 4-(1-*o*-carbaboranyl)styrene for homopolymerisation under various conditions has been investigated[9]. Polymers with the highest molecular weight [$M \cong 60\,000$, softening temperature (soft.temp.) 280–340 °C] have been synthesised by the thermopolymerisation of 4-(1-*o*-carbaboranyl)styrene at 160–200 °C. In the presence of radical initiators (for example, t-butyl peroxide) polymers with $M \cong 12\,000$ and a softening temperature of 320–340 °C are formed. The homopolymerisation of 4-(1-*o*-carbaboranyl)-styrene via an anionic mechanism in the presence of C_4H_9Li takes place slowly, while the polymerisation via a cationic mechanism in the presence of $BF_3.O(C_2H_5)_2$ does not occur at all. From the infrared spectra of the polymers obtained, one can assume that the homopolymerisation of 4-(1-*o*-carbaboranyl)styrene proceeds in all cases mainly via the vinyl group. Thermogravimetric analysis of these polymers has shown that the weight loss by their specimens is ~20% at 400–430 °C.

The study of the homopolymerisation of *o*-carbaborane-containing exocyclic vinylsilanes with various substituents R at the silicon atom has been described[10]:



R = CH_3 (I); OCH_3 (II); Cl (III).

It has been established that the homopolymerisation of compound (I) in bulk (a mixture of benzoyl and t-butyl peroxides was used as the initiator) proceeds via the vinyl group with formation of a dimer. The homopolymerisation of compounds (II) and (III) via the vinyl group is accompanied by the partial substitution of the $SiOCH_3$ and SiCl groups by SiOH and the partial dissociation of one of the SiO bonds; this results in the formation of a mixture of dimers, trimers, and cross-linked oligomers. The latter are obtained on interaction of the SiOH groups with $SiOCH_3$ and SiCl. The formation of oligomers alone, and not polymers, has been explained[10] by the steric hindrance generated by the seven-membered exocyclic groups. All the homopolymers are colourless viscous liquids.

The copolymerisation of compounds (I), (II), and (III) with methyl acrylate takes place more readily. It has been carried out under the same conditions as the homopolymerisation[10]. The content of the initial vinylsilanes in the reaction mixture varies from 1 to 20 mole %. Solid glass-like substances with *M* ranging from 400 000 to 800 000 were obtained in all cases. Compound (II) proved to be the most reactive of the monomers; after the introduction of compounds (I), (II), and (III) into the reaction mixture in an amount of 20 mole %, the contents of their unit in the copolymers were 9, 12, and 3 mole % respectively.

The copolymerisation of 1-vinyl-*o*-carbaborane with styrene (in proportions of 1 : 3) under the influence of γ-rays has been investigated[11]. It was established that the copolymer consists of 11 or 12 units and that there are approximately 9 styrene units for each two 1-vinyl-*o*-carbaborane units. The copolymer softens at 85 °C and melts fully at 105 °C. Its structure was investigated with the aid of NMR and flash pyrolysis methods. However, the authors[11] were unable to determine the location of the *o*-carbaborane fragment (in the main or side chain).

New copolymers having the following structure have been synthesised on the basis of 4-(1-*o*-carbaboranyl)styrene and methyl acrylate[12]:

(IV)

(V)

The copolymers were obtained in 80–90% yield in bulk on heating the monomers to 80 °C in the presence of radical type initiators (t-butyl peroxide and azobisisobutyronitrile). The molecular weight of the copolymers (IV) increases from 3460 to 7130 as the ratio of 4-(1-*o*-carbaboranyl)styrene and methyl methacrylate is altered from 1 : 1 to 1 : 4, while the molecular weight of the copolymers (V) increases from 3550 to 278 000 as the ratio of 4-(1-*o*-carbaboranyl)styrene and isoprene is altered from 1 : 1 to 1 : 10. The influence of the heterounit structure (i.e. the ratio of the numbers of units *n* and *m*) on the glass point and on the onset of intense loss of weight has been analysed[12]. It has been shown that the thermal characteristics of the copolymers (IV) vary additively with the extent of their heterounit structure, while for the copolymers (V) the relation is non-additive.

Copolymers containing hydroxy- or carboxy-groups have been synthesiseed by the copolymerisation of 1-vinyl-*o*-carbaborane, 1-isopropenyl-*o*-carbaborane, or 1-acryloyloxymethyl-*o*-carbaborane with isoprene, butadiene, or chloroprene in solution in dioxane at 65 °C for 72 h in the presence of 4,4'-azobis(4-cyano-1-pentanol).[13] The authors note that the large difference between the polarities of the selected co-monomers ensures ease of copolymerisation. In all cases an increase of the content of unsaturated *o*-carbaborane derivatives in the reaction mixture from 5 to 50 wt.% entails a decrease of the yield and molecular weight of the copolymers. For example, the yield of the copolymer of acryloyloxymethyl-*o*-carbaborane with chloroprene decreases from 85 to 70% and its molecular weight decreases from 7400 to 4300.

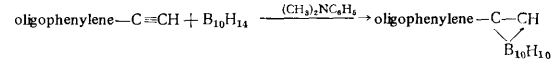
The copolymers, which can be used as plasticisers and catalysts of the combustion of solid rocket fuels, have been obtained by the aqueous emulsion copolymerisation of methacryloyloxymethyl-*o*-carbaborane with butadiene in the presence of azobisisobutyronitrile, dodecanethiol, and benzylacetyldimethylammonium chloride at 50 °C with vigorous stirring[14]. Depending on the ratio of the comonomers, the copolymers contain 10–80 mole % of butadiene units and 90–20 mole % of methacryloyloxymethyl-*o*-carbaborane.

In order to modify low-density polyethylene, a study has been made of the radical copolymerisation of ethylene with 1-isopropenyl-*o*-carbaborane in an autoclave at a pressure of 1400 kg cm^{-2} and a temperature of 160 °C.[15] It has been established by infrared spectroscopy that the copolymerisation involves mainly the double bonds and that its rate and the molecular weight of the copolymers decrease rapidly with increase of the content of the *o*-carbaborane derivatives in the reaction mixture from 1 to 40 mole %. All the copolymers

obtained in this way are solid plastics soluble in aromatic hydrocarbons and capable of being pressed at 130–170 °C to form transparent elastic films. The specimens containing 2–3 mole % of 1-isopropenyl-*o*-carbaborane had a tensile strength and a relative elongation on extension of not less then 100 kg cm^{-2} and 300% respectively. With increase of the content of 1-isopropenyl-*o*-carbaborane in the copolymer, the density of the latter also increases (to 1 g cm^{-3}) and its thermo-oxidative stability improves. The effect of γ-radiation on copolymers containing 0.28–0.30 mole % of 1-isopropenyl-*o*-carbaborane has been investigated[16]. Measurements of the properties related to the strength of the copolymers have shown that their radiation stability is close to that of polyethylene. The resistance of the copolymers to oxidation diminishes after γ-irradiation.

The interaction of a chloromethylated polystyrene–divinylbenzene copolymer with lithio-*o*-carbaborane has been described[17]; on the basis of the results of elemental analysis for boron, the authors assume that the chlorine atoms in at least three-quarters of the chloromethyl groups have been substituted by the *o*-carbaboranyl groups.

Data on the use of polymers and copolymers based on various alkenylcarbaboranes in adhesives for the improvement of their thermal stability[18,19] and for the preparation of anion-exchange resins[20] are presented in the patent literature.



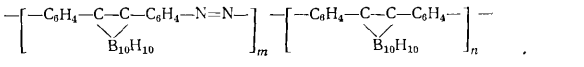
The copolymers of the diallyl esters of *m*- or *p*-carbaboranedicarboxylic acids and methyl methacrylate have been recommended as materials suitable for use in an atmosphere of oxygen at elevated temperatures[21].

IV. POLYMERS OF THE POLYPHENYLENE TYPE

A large number of publications devoted to the synthesis and investigation of polymers of the polyphenylene type, containing carbaborane fragments in both side and main chains, have appeared in recent years. Thus, after radiolysis, 1-phenyl-*o*-carbaborane was found to undergo oligomerisation as a result of the abstraction of hydrogen from the benzene ring with formation of dimers, trimers, and tetramers[3].

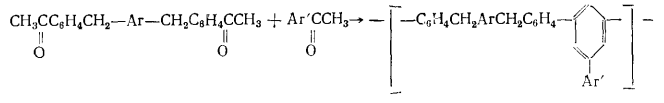
The polycondensation of 1,2-diphenyl-*o*-carbaborane in the presence of Lewis acids and oxidising agents yielded an oligomer with $M = 1300$, soluble in benzene and chloroform and not melting up to 350 °C.[22] According to thermogravimetric data, the mass of the specimen of the oligophenylene obtained does not change up to 500 °C; at 900 °C the weight loss is 11.6%.

Oligophenyl-*o*-carbaboranes, which are amorphous pale-brown powders readily soluble in the usual organic solvents, have been synthesised by the reaction of oligophenylene containing terminal triple bonds with decaborane in accordance with the following scheme[23]:



Infrared spectroscopic data and the results of elemental analysis have shown that the replacement of the ethynyl linkages in the oligophenylene by *o*-carbaborane fragments takes place almost quantitatively. The absence of residual ethynyl groups from the oligophenyl-*o*-carbaborane is responsible for its complete inability (in contrast to the usual oligophenylene) to pass to an infusible and insoluble state on heating to 300 °C. The oligophenylene-*o*-carbaboranes are characterised by a higher thermal stability (both in an inert atmosphere and in air) than the initial oligophenylenes. The yield of the carbon residue is 84.5% for oligophenylene-*o*-carbaborane at 900 °C according to thermogravimetric data, while the yield for the usual oligophenylene under analogous conditions is 68%.

The recombination of the phenyl and azophenylene decomposition products of 1,2-bis(*N*-nitrosoacetamidophenyl)-*o*-carbaborane



resulted in a quantitative yield of a *o*-carbaborane-containing polyazophenylene having the following structure[24–26]:

This polymer is a pale-brown powder soluble in chloroform, benzene, dimethylformamide, and tetrahydrofuran. Its structure has been confirmed by elemental analysis and infrared and ultraviolet spectroscopy. On isothermal heating at 400 °C in an atmosphere of helium, the mass of the polymer specimen initially decreases rapidly by ~10% and then remains almost unchanged for 3 h. According to the results of dynamic thermogravimetric analysis in air, polyazophenylene with *o*-carbaborane fragments is stable up to 350 °C and above this temperature there is an appreciable increase in the mass of the polymer specimens (up to 30% at 600 °C) owing to the oxidation of B–H groups and the formation of the B–O–B groups.

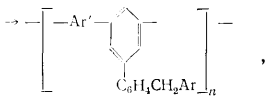
The ability of the *o*-carbaborane fragments of polyazophenylene to combine vigorously with O_2 at high temperatures with formation of inactive products can be used, according to the authors[25,26], for the inhibition of the thermo-oxidative degradation of thermostable polymers. Indeed, the copolymers of styrene with the decomposition products of 1,2-bis(*N*-nitrosoacetamidophenyl)-*o*-carbaborane, containing between 4 and 38 wt.% of polyazophenylene fragments, exhibit a high thermo-oxidative stability at 400–450 °C.[24]

Polyphenylenes, the first stage of the synthesis of which can be represented schematically by the reaction

(where Ar = *o*-, *m*-, or *p*-carbaboranylene and Ar′ = phenyl or benzyl-*o*-, -*m*-, and -*p*-carbaboranyl) have been obtained by Korshak and co-workers[27–29] by the joint polycyclocondensation of 4,4′-diacetyldibenzyl-*o*-, -*m*-, and -*p*-carbaboranes and various aromatic monoacetyl derivatives (in benzene at 20 °C in the presence of gaseous HCl as the catalyst) with subsequent heat treatment. Instead of acetyl derivatives, their ethylketals can be used in the reaction.

Korshak and co-workers[27–29] noted that the polycyclocondensation of the above compounds does not proceed unambiguously and is accompanied by the formation of dypnone as well as linear and cyclic polyvinylene fragments. The oligophenylenes obtained in this way, containing *o*-, *m*-, or *p*-carbaborane groups in the main molecular chain and in certain cases also in the side chain, are readily soluble in many organic solvents and in chloroform the oligomer concentration can be more than 20%.

All the carbaborane-containing oligophenylenes have low molecular weights ($\bar{M}_n = 1100–4600$), but their fractionation yielded a fraction with $\bar{M}_w = 115\,000$.[27,28] According to the results of thermomechanical studies, the softening temperature of the oligophenylenes synthesised is in the range 150 to

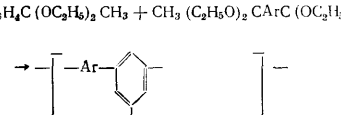


220 °C; at 400–500 °C in an inert atmosphere in the course of 4 h or during pressing with heating up to 400–450 °C at a pressure of 1000 kg cm^{-2}, they are converted into infusible and insoluble three-dimensional polymers as a result of the interaction via the terminal acetyl and ketal groups. According to infrared spectroscopic data, there are no ketal, acetyl, or dypnone groups in the hardened polymers.

The results of thermogravimetric analysis showed that the mass of the heat-treated polymer specimens increases by up to 18% at 400 °C in air as a consequence of the oxidation of the carbaborane groups at the B–H bond. On further increase of temperature to 1000 °C, an appreciable change in the mass of the specimen is not observed. The high thermal stability of the polymers, which are not deformed up to 450 °C, has been noted[27,28]. Detailed study of the properties of the oligophenylenes obtained from derivatives of isomeric carbaboranes enabled the authors[27,28] to conclude that the solubility and thermal stability of the oligomers synthesised are almost independent of the carbaborane isomer from which they have been obtained.

Polyphenylenes with *o*-, *m*-, or *p*-carbaborane fragments in the main chain exhibit an improved adhesion to glass fibre, amounting to 250–350 kg cm^{-2}, and have been recommended for use as thermostable binders for glass plastics[29].

Korshak and co-workers[27,30] also obtained oligophenylenes containing carbaborane fragments in the side chain by the polycondensation of the ethylketals of 4-acetylbenzyl-*o*-, -*m*-, or -*p*-carbaboranes with various ethylketals of aromatic diacetyl derivatives in accordance with the scheme



$$ArCH_2C_6H_4C(OC_2H_5)_2CH_3 + CH_3C(OC_2H_5)_2Ar'C(OC_2H_5)_2CH_3 \rightarrow$$

where Ar = *o*-, *m*-, or *p*-carbaboranyl and Ar′ = C_6H_4, $C_6H_4C_6H_4$, or $C_6H_4CH_2C_6H_4$. All the oligophenylenes synthesised in this way have low molecular weights (M = 1400–3200) and are readily soluble in organic solvents such as benzene, toluene, or dioxane and harden at 400–450 °C with formation of three-dimensional polymers. According to thermogravimetric data obtained in air, the mass of the specimens of the hardened polymers begins to decrease in the temperature range 550–600 °C.

The authors[27,30] noted that the introduction of carbaborane fragments into the polyphenylene side chain increases their thermal stability but this effect is smaller than in polyphenylenes containing carbaborane groups in the main macromolecular chain. In order to simplify the synthesis of polyphenylenes with *o*-carbaborane fragments, 4-acetylbenzoyl-*o*-carbaborane, whose synthesis is also technologically complex, has been replaced recently by the more readily available ethylketal of acetylbiphenylyl-*o*-carbaborane:[31,32]

$$HC(B_{10}H_{10})C{-}C_6H_4C_6H_4C(OC_2H_5)_2CH_3 + CH_3(C_2H_5O)_2CArC(OC_2H_5)_2CH_3 \rightarrow$$

;

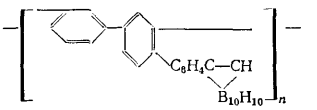
Ar = C_6H_4, $C_6H_4C_6H_4$, $C_6H_4OC_6H_4$, $C_6H_4SC_6H_4$, $C_6H_4CH_2C_6H_4$.

It has also been suggested that the replacement of the methylene bridge by a phenylene bridge on passing from 4-acetylbenzyl-*o*-carbaborane to acetylbiphenylyl-*o*-carbaborane increases the thermal stability of the final polymers.

The polycondensation of acetylbiphenylyl-*o*-carbaborane with the ethylketals of various aromatic acetyl derivatives has been carried out at temperatures between −20° and 150 °C in benzene or dichlorobenzene, toluene-*p*-sulphonic acid being used as the catalyst instead of gaseous HCl at 100 °C and above[31,32]. Infrared spectroscopic data for the oligophenylenes obtained showed that the macromolecules contain the dypnone fragments

and in an amount greater than in oligophenylenes without *o*-carbaborane fragments.

The oligophenylenes synthesised from acetylbiphenylyl-*o*-carbaborane were less soluble than oligphenylenes based on 4-acetylbenzyl-*o*-carbaborane: they dissolved fully only in chloroform and *o*-dichlorobenzene and were insoluble in benzene, toluene, and dioxane. However, their thermal stability did indeed prove to be higher than those of oligophenylenes based on 4-acetylbenzyl-*o*-carbaborane.

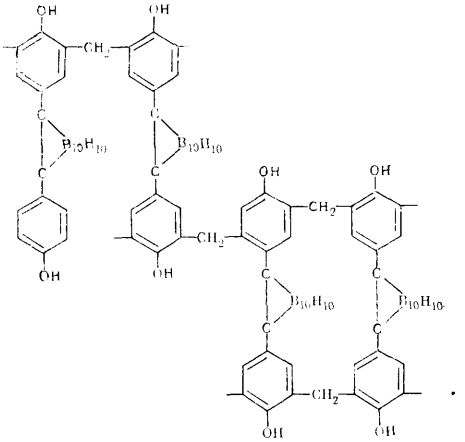


In order to optimise the structure formation process in polyphenylenes with terminal acetyl groups, a study has been made[33] of their interaction with the following di(hydroxymethyl)-*o*-carbaborane derivative:

It was established that at 200–300 °C the acetyl groups of polyphenylene interact with the above compound to form cross-linked monomers whose thermal stability is analogous to that of polyphenylene heat-treated at 450 °C without additives.

The use of *o*-carbaborane-containing polyphenylenes as binders for thermostable glass plastics[33] and for the manufacture of constructional materials[34] has been described.

In addition, *o*-carbaborane-containing oligophenylenes having the structure



have been considered[35] as the ligands for the synthesis of π-arenechromium carbonyl complexes.

V. PHENOL-FORMALDEHYDE POLYMERS

Studies on the synthesis and properties of carbaborane-containing phenolformaldehyde polymers have continued in recent years. Mixed phenol-formaldehyde polymers of the resol type, based on 1,2-di(4-hydroxyphenyl)-*o*-carbaborane and phenol, whose molar ratio was varied from 1 : 3 to 1 : 21, have been synthesised and thoroughly investigated[36–39]. In contrast to resol, which is based solely on 1,2-di(4-hydroxyphenol)-*o*-carbaborane and hardens at 200–220 °C, mixed *o*-carbaborane-containing resols exhibit an enhanced fluidity (the softening temperatures are in the range 60–110 °C) and harden under the conditions usual for phenol-formaldehyde resols. With decrease of the content of the *o*-carbaborane fragments in the resol, its softening temperature diminishes from 110° to 60 °C, the mass of the coke residue falls from 61% to 18% on heating in air to 900 °C, and the molecular weight increases from 650 to 800.

From data obtained by NMR and infrared spectroscopy, the following structure has been proposed[39] for the resol based on 1,2-di(4-hydroxyphenol)-*o*-carborane hardened at 250 °C for 1 h:

The chemical reactions occurring in resols and resites based on 1,2-di(4-hydroxyphenyl)-*o*-carbaborane on heating in the range 50–450 °C in air and *in vacuo* have been investigated[37]. It was established that at 50–200 °C structure formation in the *o*-carbaborane-containing resol proceeds via the mechanism usual for resols and the *o*-carbaborane groups do not undergo significant transformations, the degree of reaction depending on the heating conditions (in air or *in vacuo*).

From the results of elemental analysis and infrared spectroscopic data as well as studies of the thermo-oxidative degradation of a number of model compounds, it has been suggested[37] that the large carbon residue from the *o*-carbaborane-containing resites is caused either by the oxidation of the B–H group in the *o*-carbaborane nuclei or by the interaction of the *o*-carbaborane fragments with atmospheric moisture and the phenolic hydroxyls and the inhibition of the thermo-oxidation of the organic fragments of the resites in the presence of *o*-carbaborane groups or the products of their thermal or thermo-oxidative reactions.

In order to elucidate the nature of the high thermal stability of the *o*-carbaborane-containing resites, their EPR spectra were investigated[38,40] and a study was made of their structural transformations by X-ray diffraction after heat treatment in the temperature range 200–1200 °C.[41] The results confirmed that both the oxidation of the B–H group of the *o*-carbaborane fragment and other processes associated with the consumption of these groups are most characteristic of *o*-carbaborane-containing resites at temperatures above 400 °C. An appreciable amount of hydrogen is evolved and the three-dimensional polymer network is compacted as a result of the formation of strong B–B, B–O–B and possibly B–C linkages. By virtue of the presence of the thermally stable macronetwork system, the resulting radicals are therefore unable to emerge from the "cage" and undergo secondary recombination processes. It has been suggested[40] that the hydrogen split off from the B–H bond can interact with the radicals, inhibiting further polymer decomposition processes.

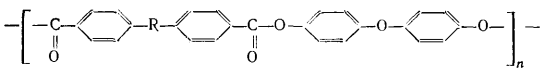
Adhesives whose main strength characteristics are not reduced after prolonged (500 h) ageing at 500 °C have been prepared on the basis of *o*-carbaborane-containing resol resins[42]. There are tentative data concerning the synthesis of phenol-formaldehyde resins based on phenolphthalein *N*-[4-(*o*-carbaboranyl)phenyl]imide, which have been recommended as thermostable binders[43], and concerning the use of di[*N*,*N*'-di(hydroxymethyl)aminophenyl]-*o*-carbaborane for the hardening of phenol-formaldehyde oligomers[44].

VI. HETEROCHAIN POLYMERS

1. Polyesters

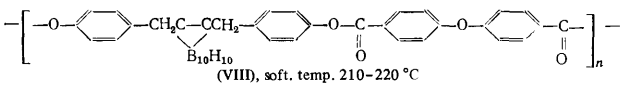
The number of studies on the synthesis of carbaborane-containing polyesters has diminished while the number of publications devoted to the investigation of the properties of the previously synthesised polyesters with carbaborane fragments remains comparatively large.

Korshak and co-workers described the synthesis of unsaturated carbaborane-containing polyesters[45]. Polyesters having different structures were synthesised, their boron content varying from 1 to 33 wt.%, which corresponds to the variation of the ratio of the number of carbaborane fragments to the number of unsaturation centres from 1 : 36 to 1 : 1. The starting compounds were *m*- and *p*-carbaboranedicarboxylic acids or their dichlorides, maleic anhydride, and various saturated and unsaturated aliphatic glycols such as ethylene glycol, hexamethylene glycol, but-2-enediol, but-2-ynediol, triethylene glycol, and tetraethylene glycol. All the carbaborane-containing unsaturated substances obtained proved to be oligomers having molecular weights ranging from 1400 to 6300 and readily soluble in organic solvents. Most of them readily copolymerise with styrene and form cross-linked polymers whose decomposition temperatures were in the range 275–400 °C. It has been established[45] that the thermal stability of the polymers synthesised depends mainly on the structure of the initial glycol and that the variation of the amount of boron in the polymer from 1 to 19 wt.% does not have a significant influence.



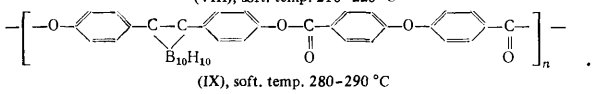
Thermostable adhesive compositions with a shear strength of 330 kg cm^{-2} at 25 °C and 50–60 kg cm^{-2} at 250 °C have been obtained from unsaturated polyester-*m*-carbaboranes containing 2–3 wt.% of boron[45]. In addition, the same polyesters containing 5–11 wt.% of boron were used to obtain an optical adhesive thermally stable up to 250 °C and ensuring the formation of a transparent adhesive seam with a transmittance coefficient up to 92% in the wavelength range 0.4–1 μm.[46]

The reaction of 1,2- or 1,7-di(hydroxymethyl)carbaborane with 1,3-di(10-carboxydecanyltetramethyldisiloxane yielded *o*- and *m*-carbaboranesiloxane polyesters[47]:



$$\mathrm{HOCH_2RCH_2OH} + \mathrm{HOC(CH_2)_{10}Si(CH_3)_2OSi(CH_3)_2(CH_2)_{10}COOH} \rightarrow \text{polyester.}$$

where R = *o*-carbaboranylene or *m*-carbaboranylene. The study of the kinetics of this polycondensation reaction showed that the introduction of the carbaborane fragments into the macromolecular chain greatly reduces the rate of formation of the polymers and the rate of reaction of the dibasic acid with 1,7-di(hydroxymethyl)-*m*-carbaborane is higher than that of the reaction with 1,2-di(hydroxymethyl)-*o*-carbaborane. It has been suggested[47] that the thermal stability of the carbaboranesiloxane polyesters is not inferior to that of the carbaborane-containing polyarylates, but, in contrast to the latter, they have lower softening temperatures. They are soluble in many solvents.

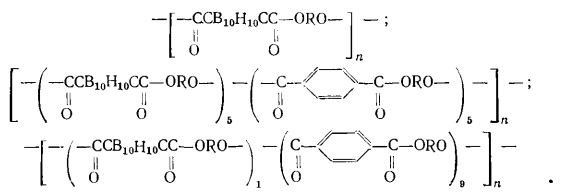


A number of studies[48–56] have been devoted to the carbaborane-containing polyesters with the following structure described previously:

R = *o*-carbaboranylene [compound (VI), soft. temp. 260–280 °C] or *m*-carbaboranylene [compound (VII), soft. temp. 240–260 °C]

(VIII), soft. temp. 210–220 °C

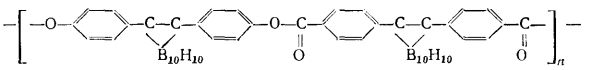
(IX), soft. temp. 280–290 °C



The kinetics of sorption and structural transformations in the tetrahydrofuran-polymers (VI)–(IX) systems have been investigated and it has been shown that the sorption of tetrahydrofuran vapour entails an improvement of the amorphous structure of the polymer, while in the case of polymers tending to crystallise there is a transition from the amorphous to a partly crystalline state[49]. The authors note that during the sorption of tetrahydrofuran vapour only the polymer (IX) crystallises. The latter phenomenon agrees well with the result of a study (by the dipole moment method) of the structures of low-molecular-weight compounds which serve as models of the polymers investigated[50]. It was established that the polymer (IX) can be represented by only one conformer, while a set of conformers is characteristic of other polymers.

In addition it has been shown that the vibrations of the *o*-carbaborane nucleus are hindered compared with the *m*-isomer both owing to the much more effective conjugation of the *o*-carbaborane fragment with the aromatic rings and due to steric effects. This feature is reflected in the relaxation processes in the carbaborane-containing polymers, the results of the study of which by various methods indicate an increase of the rigidity of the macrochain and an increase of the softening temperature on passing from *m*- to *o*-carbaborane-containing polyesters[51,52].

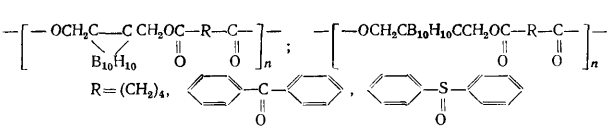
Ionic electrical conduction is mainly characteristic of carbaborane-containing polyesters, the conductivity of *o*-carbaborane-containing polyesters being higher by 1–2 orders of magnitude than the corresponding values for polyesters with *m*-carbaborane fragments[53].



The structural-chemical transformations of *o*- and *m*-carbaborane-containing polyarylates on isothermal heating (225 to 325 °C) *in vacuo* in the presence of oxygen have been investigated[55]. It has been established that at a temperature as low as 225 °C processes involving the rupture of the ester linkage take place in the polymers with simultaneous changes in the carbaborane fragments (decrease of the number of B–H bonds and the appearance of the B–O–B linkages) and the formation of cross-linked structures. It has been shown that in the presence of oxygen the latter are formed owing to the interaction of the carbaborane fragments with oxygen, while *in vacuo* they result from the interaction with the oxygen-containing groups in the macromolecules.

In order to elucidate the influence of the quantitative content of *m*-carbaborane fragments on the thermal stability of polyarylates, a comparative study has been made of the thermal stabilities of polymers having the following structures[57]:

It has been established that the temperature of the onset of the decomposition of the test polymers (evolution of gaseous degradation products) *in vacuo* decreases from 375° to 320 °C as their content of *m*-carbaborane fragments increases. The different transformations of the *m*-carbaborane groups with evolution of hydrogen begin in all the polyesters at a temperature lower by 20–25 °C than the degradation of the main chain with formation of CO and CO_2. It is noteworthy that the weight loss by the polyester specimens at 700 °C diminishes from 34.7 to 19.5 wt.% with increase of their content of *m*-carbaborane fragments.

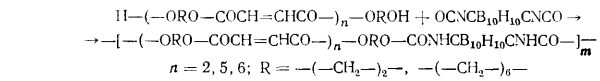


The structure of the involatile residues from the polyarylate having the structure

after its vacuum heat treatment in the temperature range 300–1200 °C has been studied by X-ray diffraction[56]. It was found that heating to 300 °C hardly induces any changes in the crystalline polymer specimen; under analogous conditions, an amorphous specimen becomes crystalline. An increase of the temperature to 400 °C leads to the complete disruption of the crystalline structure of the polyarylate and its conversion into the amorphous form. After heating at 500 °C, considerable chemical transformation occur in the polymer and an appreciable amount of H_3BO_3 is formed, indicating the interaction of the *o*-carbaborane groups and the products of their thermal transformations with the oxygen bound chemically in the polymer. At 600 °C the structure of the polyarylate with *o*-carbaborane fragments is fully disrupted and a dense network structure with strong B–B and B–O bonds is produced. Treatment at 700 °C leads to the appearance of a small number of graphite blocks; subsequent heat treatment of the polymer up to 1000 °C is hardly reflected in the structure and the mass of the specimens changes by only 5–8% under these conditions.

From their investigation, the authors[56] concluded that the main difference between the *o*-carbaborane-containing polyarylates and their normal analogues consists in the displacement of the temperature of the extensive decomposition and the rearrangement of the initial structure into the region of high temperatures and also in a specific interaction of the *o*-carbaborane fragments or the products of their thermal transformations with the chemically bound oxygen.

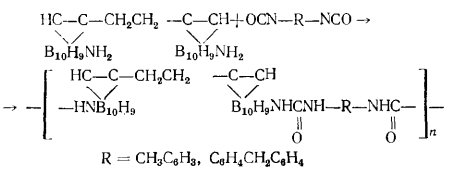
However, in the case of thermally less stable structures, for example, polyesters with aliphatic fragments having the structure



the presence of carbaborane groups does not affect the mechanism of the degradation of the polymers in the temperature range 300–420 °C.[58] The polyesters of aromatic dicarboxylic acids are stable on heating to 350 °C and those of

adipic acid are stable up to 250 °C. The thermal degradation of these polymers in the above temperature range proceeds without change in the carbaborane fragments via the mechanism usual for organic polymers.

There exist data concerning the use of *o*-carbaborane-containing polyarylates as binders for the formation of thermoplastic and thermostable self-lubricating materials[59] and for the preparation of negative photoresistors[60]. Furthermore, the VK-28 epoxide adhesive, which hardens at 150–200 °C and forms adhesive junctions between steel specimens having a shear resistance of 100–140 kg cm^{-2} at 20 °C and 80–90 kg cm^{-2} at 250 °C, has been devised on the basis of carbaborane polyethers[42,61].



2. Polyurethanes and Polyureas

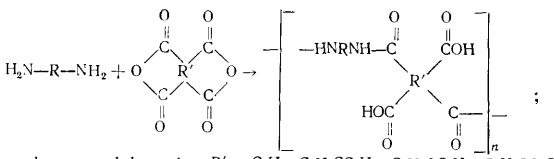
The synthesis of *m*-carbaborane-containing unsaturated polyurethanes, formed by the interaction of unsaturated oligoesters with *m*-carbaboranylene di-isocyanate in accordance with the scheme[62]

has been described. The reaction is almost quantitative and does not involve the formation of volatile products. The polymers obtained are colourless rubber-like substances which are readily soluble in chloroform, tetrahydrofuran, acetone, benzene, and styrene and are insoluble in alcohol, ether, and hexane. They exhibit an effective adhesion to metallic surfaces and are capable of being hardened by styrene at 80 °C. According to thermogravimetric data obtained in air, the weight loss by the hardened polyurethane specimens is 5% at 340–350 °C (for a heating rate of 4.5 K min^{-1}). An adhesive composition, which hardens at room temperature after 6 h or at 85 °C after 2 h is effective at temperatures ranging from −60° to +150 °C, and can be used to join articles made of metals, plastics, ceramics, and glass, has been obtained on the basis of the *m*-carbaborane-containing polyurethanes synthesised[63]. In addition, the VK-20 hot-hardening adhesive, which is a polyurethane composition modified by a carbaborane-containing compound, has been described[42,64]. The adhesive junctions based on it are effective for 500 h at 350–400 °C and briefly at 800 °C. The VK-20 M adhesive, whose composition is analogous to that of the VK-20 adhesive, contains a catalyst which makes it possible to harden it at room temperature[42].

o-Carbaborane-containing polyureas have been obtained by the interaction of 1,2-di(*B*-amino-*o*-carbaboranyl)ethane with di-isocyanate in tetrahydrofuran at 18–25 °C in accordance with the scheme[65]

These polymers soften at 195–200 °C, begin to decompose at 240–250 °C, and their coke residues after heat treatment in air at 800 °C amount to 90–92%.

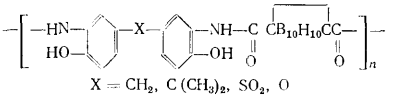
3. Polyamides



In the publications of the last decade comparatively little attention has been devoted to the synthesis of new carbaborane-containing polyamides[66–68], but a whole series of studies have been undertaken to investigate various properties of polyamides described previously[69–83].

A diamine in which the amino-groups were attached to a boron atom of the carbaborane nucleus and not to a carbon atom was first used for the synthesis of carbaborane-containing polyamides[66]:

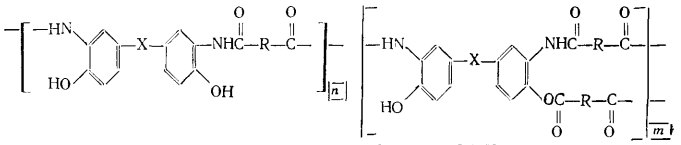
Polyamides stable on heating in air to 320–330 °C were obtained by the polycondensation of this diamine with aromatic dicarboxylic acid dichlorides.



The synthesis and properties of polyamidoacids, obtained by the reaction of *m*- or *p*-carbaboranylenediamines with tetracarboxylic acid dianhydrides, has been reported[67]:

R = *m*-carbaboranylene or *p*-carbaboranylene; R′ — C_6H_2, $C_6H_3CC_6H_3$, $C_6H_3OC_6H_3$, $C_6H_3SO_2C_6H_3$.

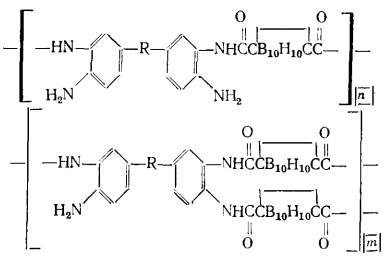
All the *m*- and *p*-carbaborane-containing polyamidoacids are light coloured powders with η_{int} = 0.1–0.5 dl g^{-1}, which are readily soluble in the majority of organic solvents. *p*-Carbaborane-containing polyamidoacids hardly undergo a change in their viscosity characteristics on storage in the dry stage and in solution (in *N*-methylpyrrolidinone). Polyamidoacids with *m*-carbaborane fragments gradually decompose; their viscosity characteristics (the value of η_{int}) decrease from 0.35 to 0.20 dl g^{-1} after storage for a month.



A study has been published[68] in which *p*-carbaborane-containing polyhydroxyamides having the structure

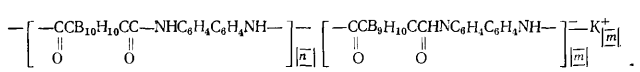
were obtained by analogy with the *m*-carbaborane-containing polyhydroxyamides described previously[1]. The structure of the *p*-carbaborane-containing polymers has been confirmed by elemental analysis and by comparing their infrared spectra with those of a model compound—the 1,12-di(*o*-hydroxyphenylamide) of *p*-carbaboranedicarboxylic acid. In contrast to the infusible *m*-carbaborane-containing polyhydroxyamides, the *p*-carbaborane-containing polyhydroxyamides soften in the range 220–270 °C and their molecular weights are 9000 to 10 000. As regards chemical stability, polyhydroxyamides with *p*-carbaborane fragments are analogous to the corresponding *m*-derivatives.

It has been noted[69] that, depending on the conditions in the formation of *m*- and *p*-carbaborane-containing polyhydroxyamides (depending on the ratio of the starting materials, the nature of the solvent, and other factors determining the course of the polycondensation process), their



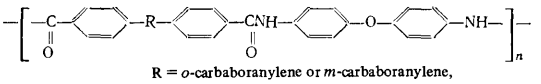
macromolecules can incorporate both linear and branches units:

R = *m*-carbaboranylene or *p*-carbaboranylene; X = CH_2, $C(CH_3)_2$, SO_2, O .



Their ratio $n : m$ varies from 1 : 0 to 0 : 1. The degree of heterounit structure in these polymers has been estimated quantitatively with the aid of infrared spectroscopy[69].

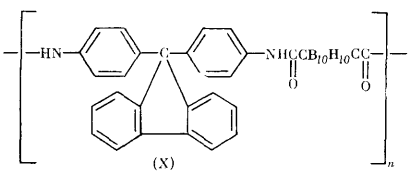
The relation between certain properties of *p*-carbaborane containing polyaminoamides and the structure of their macromolecules has been investigated[70]:



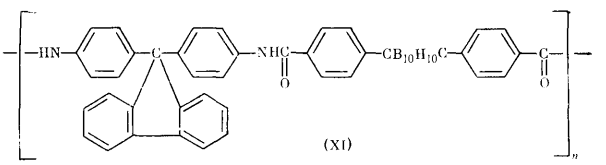
It was established that, as the degree of heterounit structure of the polyamides ($n : m$) varies from 0.9 : 1 to 1 : 9, the degree of their 'swellability' in tetrahydrofuran increases from 55% to infinity (i.e. the polymers become soluble) and the interchain distance in the polymer diminishes from 5.8 to 5.4 Å.

In the study of the chemical stabilities of the *m*-carbaborane-containing polyamides obtained previously it was observed that the *m*-carbaborane fragments are cleaved to the dicarbaundecaborate anion by dimethylformamide on heating to 100 °C or by alcoholic alkali in solution in tetrahydrofuran to form polyamides having the following structure[71]:

The dicarbaundecaborate fragments in these polyamides were determined quantitatively by ^{1}H NMR [72] and it was shown that the heterounit polyamide in which the numbers of the *m*-carbaborane and dicarbaundecaborate fragments are approximately equal ($n \cong m$) differs in a number of features from the polyamide containing only *m*-carbaborane groups ($m = 0$). Thus, in contrast to the latter, the heterounit polyamide does not dissolve in tetrahydrofuran, but is readily soluble in dimethyl sulphoxide and methanol, and transparent films of the polymer can be obtained from these solutions. The presence of dicarbaundecaborate fragments in the macromolecule greatly reduces the chemical and thermal stabilities of the polymer. Thus the viscosity of the heterounit polyamide decreases from 1.20 to 0.7 dl g^{-1} in boiling water after 3 h, while under the influence of dry HCl it diminishes from 1.20 to 0.3 dl g^{-1} in 1 h. The initial *m*-carbaborane-containing polyamide remains unchanged in both cases. The temperature of the onset of evolution of hydrogen from the heterounit polyamide is 80 °C, while that for the *m*-carbaborane-containing polymer is 200 °C.[71]

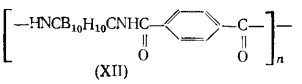


The electrophysical properties of *o*- and *m*-carbaborane-containing polyamides having the structure



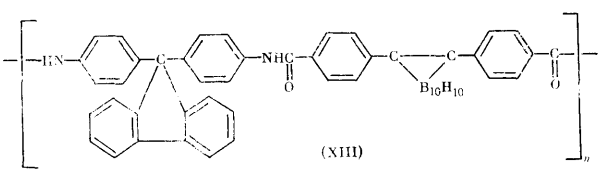
R = *o*-carbaboranylene or *m*-carbaboranylene,

have been investigated. It was shown that the replacement of the *o*-carbaborane fragment in the polyamides, as in the carbaborane-containing polyarylates, by the *m*-carbaborane fragment diminishes the rigidity of the macrochains[73].

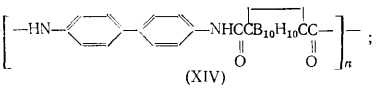


The study of the structural transformations of polyamides having the structures

(X)

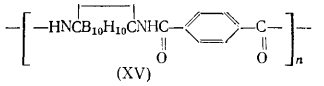


(XI)



(XII)

at 100–350 °C *in vacuo* in an atmosphere of oxygen and water vapour established that in the above temperature range their macromolecules undergo simultaneously cross-linking and cleavage[74]. The branching and cross-linking processes predominate in the polyamide (XI), while chain dissociation as a consequence of the cleavage of the *m*-carbaborane fragments predominates in the polyamides (X) and (XII).



Questions concerning the degradation of the *m*-carbaborane-containing polyamides (X)–(XII) as well as polyamides with *o*- and *p*-carbaborane fragments having the structure

(XIII)

(XIV)

(XV)

in vacuo and in an atmosphere of oxygen and water vapour at 200–800 °C have been considered in detail in a review by Korshak et al.[6] The study of carbaborane-containing polyamides of this kind revealed the influence on the thermal stability of the polymers not only of the isomerism of the carbaborane group but also of the chemical nature of their substituents, in particular the influence on the stability of the carbaborane nucleus by nucleophilic and electrophilic groups such as the carbonyl, phenyl, and amide groups.

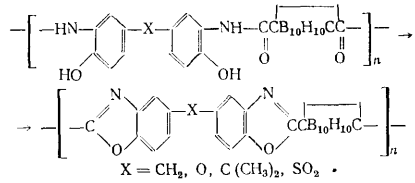
Korshak et al.[6] established that the isomerism of carbaborane influences significantly the stability of polyamides *in vacuo*. Whereas the breakdown of the *o*- and *m*-carbaborane fragments is the main degradation reaction in the polyamides (X)–(XIII), the amide groups becoming resistant to homolytic and heterolytic decomposition reactions, in the *p*-carbaborane-containing polyamides the NH–CO linkages are broken.

The isomeric *m*- and *p*-carbaborane-containing polyhydroxyamides have also significantly different thermal stabilities[68].

The antifriction properties of the *p*-carbaborane-containing polyamide (XIV) and its *m*-isomeric analogue have been investigated in the temperature range 250–450 °C.[75] On the basis of the results, the authors concluded that the hydrogen formed in large amounts on decomposition of *m*-carbaborane-containing polyamides creates a reducing medium between the surfaces involved in friction, which leads to the inhibition of the oxidative processes occurring at high temperatures. This is to a large extent responsible for the improvement of the lubricating properties of the antifriction plastics based on *m*-carbaborane-containing polyamides compared with the *p*-carbaborane-containing polyamides (a smaller amount of hydrogen is evolved from the latter in the experimental temperature range) and compared with polyamides without carbaborane fragments (these hardly evolve hydrogen at the above temperatures).

A series of studies in which the polyamides of *m*-carbaboranedicarboxylic acid were used as stabilisers against the thermal and thermo-oxidative degradation of aromatic cardo-polyamides[76–80] and polyphenylquinoxalines[81] have been published. It was established that, both *in vacuo* and in oxygen, the polyamides of *m*-carbaboranedicarboxylic acid are effective stabilisers of cardo-polyamides, which is reflected both in a considerable decrease of the rate of evolution of carbon oxides and in a decrease of the weight loss by the polymer specimens at 300–450 °C.[76,79] The authors suggest that the high thermal stability of specimens of aromatic cardo-polyamides to which 0.5 wt.% of the polyamide of *m*-carbaborane-dicarboxylic acid has been added is due to the appreciable weakening of the degradative processes and the formation during heat treatment of cross-linked structures containing the thermally stable B–N, B–C, and B–O bonds[82,83].

4. Poly-Schiff Bases

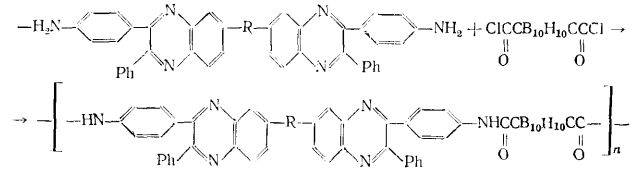


Only tentative data have been published about *m*- and *p*-carbaborane-containing poly-Schiff bases[84,85]. These polymers were first obtained by French investigators by the interaction of *m*- or *p*-carbaboranedialdehydes with various aromatic diamines in halogenated hydrocarbons, phenols, dioxan, and tetrahydrofuran in the presence of acceptors of the water involved, namely sodium and magnesium sulphates, calcium chloride, or molecular sieves. Polymers having the structure

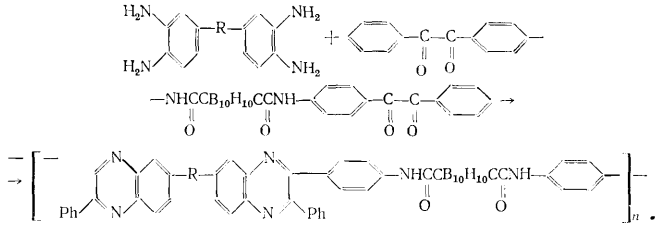
$$H_2—[—NArN=CH—R—CH=]_n=O$$

(R = *m*-carbaboranylene or *p*-carbaboranylene; n = 5–1000), which are readily soluble and thermally stable, were obtained. They have been recommended for the manufacture of films, adhesives, and surface coatings.

5. Polyheterocycles



Recently Korshak and co-workers synthesised carbaborane-containing polybenzoxazoles and polyphenylquinoxalines which had not been described previously[86–88]. *p*-Carbaborane-containing polybenzoxazoles were obtained by the thermal or chemical (in polyphosphoric acid) cyclocondensation of the corresponding poly-*o*-hydroxyamides in accordance with the scheme[86,87]

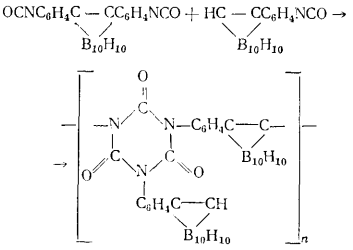


X = CH_2, O, $C(CH_3)_2$, SO_2 .

The structure of the polybenzoxazoles obtained was confirmed by elemental analysis and by comparing the infrared spectra of the polymers and model compounds. All the *p*-carbaborane-containing polybenzoxazoles are yellowish or pale-brown powders, which are amorphous (according to X-ray diffraction data) and soluble in amide solvents and in a tetrachlorethane–phenol mixture. The intrinsic viscosities of these polymers are 0.4–1.1 dl g^{-1}, their softening temperatures are in the range 290–360 °C, their decomposition temperatures are 400–550 °C, and their coke residue in air at 900 °C amounts to 80–98%. Polybenzoxazoles with *p*-carbaborane fragments are hydrolysed by hot water (η_{int}^{25} diminishes from 1.1 to 0.4 dl g^{-1} after boiling the polymer in water for 24 h).

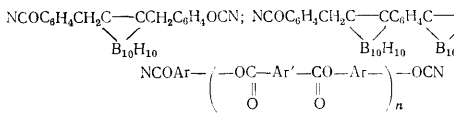
m-Carbaborane-containing polyphenylquinoxalines have been synthesised in two ways[88]: 1) by the polycondensation of bis(aminophenylquinoxalines) with *m*-carbaboranedicarboxylic acid chloride in tetrahydrofuran at room temperature using triethylamine as the acceptor of the hydrogen chloride evolved:

2) by the interaction of aromatic tetramines with *m*-carbaborane-containing bis(α-diketone) at room temperature in *m*-cresol or in chlorinated hydrocarbons with added proton donors:



The use of mixtures of *m*-carbaboranedicarboxylic acid chloride with the chlorides of other dicarboxylic acids in various proportions in the first method of synthesis or of mixtures of bis(α-diketones) in the second method makes it possible to vary the content of the *m*-carbaborane fragments in the polymers and the properties of the latter in the required way. The *m*-carbaborane-containing polyphenylquinoxalines synthesised are fibrous or powdered products

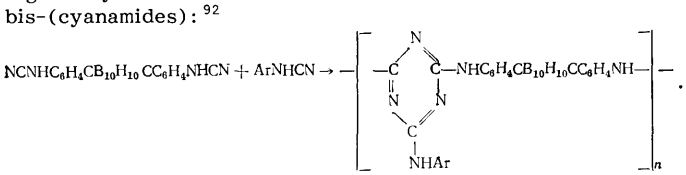
with intrinsic viscosities in the range 0.8–2.2 dl g^{-1}. Depending on the quantitative content of the *m*-carbaborane groups in their macromolecules, the polymers soften in the temperature range 280–310 °C or begin to decompose, without softening, at ~400 °C. The carbon residue from the polymers after heat treatment in air at 800 °C amounts to 32–57%, while in an inert atmosphere it amounts to 70–80%. The solubilities of certain *m*-carbaborane-containing polyphenylquinoxalines in chloroform and tetrahydrofuran make it possible to obtain films with effective physicomechanical parameters from their 10% solutions.



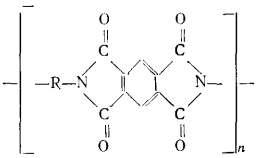
It is believed[88] that *m*-carbaborane-containing polyphenylquinoxalines are of undoubted interest for practical applications as heat-resistant and thermostable film materials, coatings, binders, fibres, etc.

There are reports in the patent literature concerning the synthesis of *o*- and *m*-carbaborane-containing polyisocyanurates, polycyanurate, and polymelamines[89–92]. *o*-Carbaborane-containing polyisocyanurates have been obtained by the polycyclotrimerisation of 1,2-di(isocyanatophenyl)-*o*-carbaborane with 1-isocyanatophenyl-*o*-carbaborane in a polar organic solvent (butyl acetate or dimethylformamide) or without solvent at 150–170 °C:[89]

Mixtures of various mono- and di-isocyanates have also been used instead of the *o*-carbaborane-containing monoisocyanates. Depending on the ratio of the starting materials, fusible soluble or infusible and insoluble polymers with enhanced thermal and thermal-oxidative stabilities were obtained.



Polycyanurates with *o*- and *m*-carbaborane fragments have been obtained either by the polycyclotrimerisation of the *o*- and *m*-carbaborane derivatives[90,91]

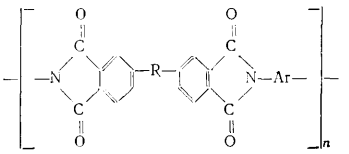


Ar = *o*-carbaboranylene, Ar′ = *o*- or *m*-carbaboranylene, and *n* = 1–20,

or by their copolymerisation with the monocyanate C_6H_5OCN. The temperature of the onset of decomposition of these polymers is 310–380 °C in air and 380–390 °C in an inert atmosphere, their specific impact strength reaches 30 kg cm^{-2}, their Brinell hardness is 1600 kg cm^{-2}, and their bending strength is 1500 kg cm^{-2}. The authors[90,91] suggested that the degradation of polycyanurates begins with the hydrolytic cleavage of the ester linkage and is accompanied by the subsequent decomposition of the triazine ring via both heterolytic and homolytic mechanisms.

The corresponding polymelamines have been synthesised by the polycyclotrimerisation of the *m*-carbaborane-containing bis(cyanamides) or their mixture with aromatic mono- and bis-(cyanamides):[92]

The thermal and chemical cyclodegradation of *m*- and *p*-carbaborane-containing polyamidoacids, which results in the formation of the polyimides having the following structure have been described[67]:



R = *m*-carbaboranylene or *p*-carbaboranylene.

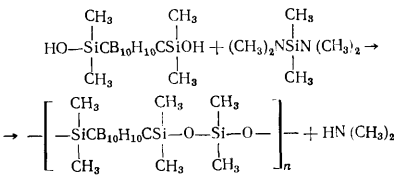
It has been established that the formation of *m*-carbaborane-containing polyimides is accompanied by the conversion of the *m*-carbaborane fragments into dicarbaundecaborate fragments, while the conversion of polyamidoacids with *p*-carbaborane groups into a polyimide takes place without the cleavage of the *p*-carbaborane nucleus.

All the polyimides obtained in this way are soluble in amide solvents and the intrinsic viscosities η_{int} = 0.15–0.40 dl g^{-1} have been obtained for them. The polyimides with *m*-carbaborane fragments do not soften and begin to be oxidised in air at 250 °C, while those with *p*-carbaborane fragments soften at 400–450 °C with decomposition. The carbon residues from these polymers after heating in air up to 800 °C amount to 79–100%.

The study of the thermal degradation of these polymers in the temperature range 100–600 °C established that the introduction of *m*-carbaborane fragments into the polyimide macromolecule reduces the rate of the homolytic and heterolytic decompositions of the rings to a greater extent than the introduction of *p*-carbaborane groups[93].

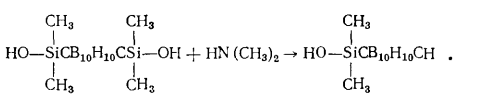
The electrophysical properties and molecular mobilities of *o*- and *m*-carbaborane-containing polyimides having the following structure have been studied in detail[94,95]:

R = *m*-carbaboranylene or *o*-carbaboranylene.



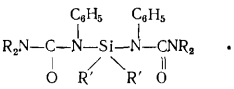
The study of the pyrolysis of these polyimides at 1000 °C in an inert medium and in air established that the diphenyl-*o*-carbaborane or diphenyl-*m*-carbaborane fragments with the adjoining imide rings are subjected to homolytic decompositions to the greatest extent and their primary decomposition products can be H_2 (from carbaborane fragments), carbon monoxide (from the imide ring), benzene, and mono- and di-phenyl-*o*- or -*m*-carbaboranes[96]. The yield of carbon from the *o*- and *m*-carbaborane-containing polyimides in an inert atmosphere is 93–95% on heating to 900 °C.

6. Polysiloxanes and Polysilazanes



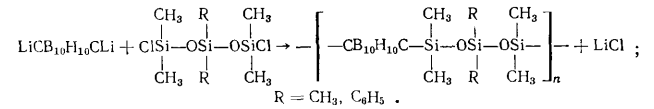
The studies in the field of new methods of synthesis of *m*-carbaborane-containing polysiloxanes of the type of Dexsil and the studies of their properties continue to develop vigorously. The difficulties in the synthesis and vulcanisation of these polymers, in which improved thermal stability is combined with elasticity, hinder their practical application[97].

In the methods of synthesis of Dexsils used previously[1] the difficulties were associated with the employment of iron(II) chloride as the catalyst of the condensation of *m*-carbaborane-containing chlorosilane and alkoxysilane, which induced premature structure formation and prevented the formation of

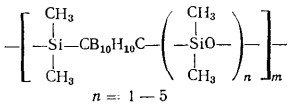


linear polymers. A new method of synthesis of linear Dexsils with a molecular weight of ~18 000, based on the condensation of an *m*-carbaborane-conaining disilanol with a reactive silane, for example bis(*N*,*N*-dimethylamino)dimethylsilane or bis(*N*,*N*-dimethylcarbamato)dimethylsilane, under mild conditions has been described[97]:

The formation of Dexsils with higher molecular weights by both procedures is prevented by the occurrence of the side reaction



Dexsils with molecular weights > 25 000 have been synthesised using stable bisureidosilanes as the reactive silanes[97–99]:



With increase of the molecular weight of Dexsils to 283 000, there is a sharp improvement of their elastomeric properties. Thus polymers with molecular weights of 50 000, 150 000, and 283 000 have tensile strengths of 7.0, 7.2, and 23 kg cm^{-2} and relative elongations of 5, 60, and 700% respectively.

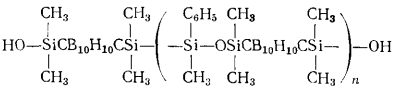
A new method of synthesis of Dexsils[97–99] facilitates its modification. For example, by employing a certain amount of bis(ureido)diphenylsilane or bis(ureido)methylphenylsilane in the bis(ureido)silane mixture during the synthesis, one can introduce phenyl groups into Dexsils in order to improve their thermo-oxidative stability[98]. Trifluoropropyl groups are introduced similary into Dexsils in order to improve their resistance to the action of solvents[100].

American investigators proposed another very convenient method of synthesis of Dexsils directly from *m*-carbaborane[101]:

However, the molecular weights of the polymers thus obtained are low. Studies on the influence of the length of the siloxane fragment on the thermal characteristics of poly-*m*-carbaboranylenesiloxanes having the structure

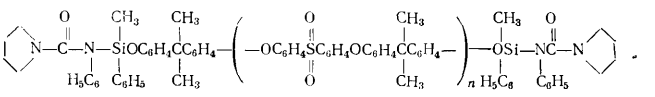
are being continued[102,103]. Their results confirm the earlier conclusion that, with increase of the length of *n* of the siloxane fragment from 1 to 5, the glass points of the polymer gradually diminish from 25° to −88° and the weight losses by the polymer specimens after heat treatment at 800 °C in argon increase greatly.

The thermal, thermo-oxidative, and hydrolytic stabilities of high-molecular-weight poly-*m*-carbaboranylenesiloxanes have been studied in detail[103–105]. It was established[104] that the main transformations are undergone by the polymers in the temperature ranges 240–310 °C and 450–550 °C. A virtually complete loss of solubility of the polymer without change in the mass of its specimens is characteristic of the first temperature range, while only a change in the mass of the specimens, amounting to 3–6% in argon and 1–3% in air, is characteristic of the second range.



It has been shown that the thermal degradation of poly-*m*-carbaboranylenesiloxanes involves two competing processes: the degradation of the main chain, which results in the formation of oligomeric products, and the dissociation of the Si–C and C–H bonds accompanied by the evolution of CH_4 and H_2 and leading to structure formation[103]. The replacement of one or several methyl groups by phenyl groups activates the structure formation processes and diminishes the weight losses by the polymer specimens. The thermo-oxidative stability of poly-*m*-carbaboranylenesiloxanes greatly increases in the presence of Fe_2O_3.[106]

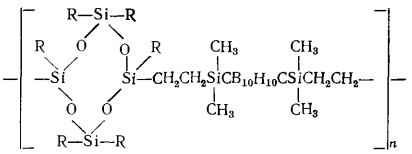
A characteristic feature of the thermal degradation of poly-*m*-carbaboranylenesiloxanes is an insignificant content of cyclic oligosiloxanes in the decomposition products[105]. It has been suggested[105] that the large bulk of the *m*-carbaborane groups prevents the formation of a helical form of the macromolecule and hinders thereby the decyclopolymerisation of the *m*-carbaborane-containing polysiloxanes. It has also been noted that the introduction of *m*-carbaborane fragments into the main chain of siloxane polymers reduces their hydrolytic stability as a result of of the appearance of the hydrolytically weak Si–$C_{carbaborane}$ linkage in these substances[104].



A method for the quantitative determination of the degree of branching of poly-*m*-carbaboranylenemethylphenylsiloxane, obtained in the presence of catalytic amounts of $FeCl_2$, has been proposed[107].

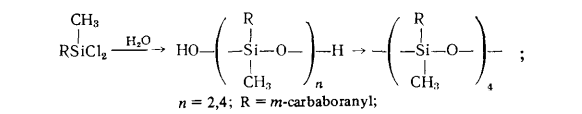
Poly-*m*-carbaboranylenesiloxanes tend to crystallise, which greatly impairs their elastomeric properties[108]. In order to diminish the crystallinity of these polymers, it has been suggested[108] that some of the *m*-carbaborane fragments be replaced by *p*-carbaborane fragments or that dimethylsiloxane units be replaced by diphenylsiloxane units. It was established that the introduction of 30 mole % of *p*-carbaborane or 33 mole % of diphenylsiloxane fragments into poly-*m*-carbaboranylenesiloxanes is sufficient for the formation of a fully amorphous polymer.

A new thermoplastic elastomeric block copolymer with $M \cong 10^6$ has been obtained by the reaction of poly-*m*-carbaboranylenesiloxane having terminal OH groups (molecular weights 45 560), i.e.

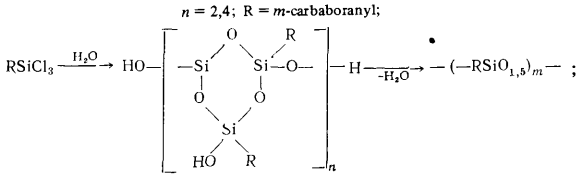


with the polysulphone (molecular weight 6020) [109]

It was shown that this block copolymer has two glass points (−27° and 165 °C), which correspond to the elastic (poly-*m*-carbaboranylenesiloxane) and rigid (polysulphone) blocks. According to thermogravimetric data, the block copolymer is stable up to 400 °C and is usable in the range from −40 °C to >300 °C. Polyimides, polyesters, poly(phenylene sulphides), and polybenzimidazoles can also be used for the preparation of the block copolymers instead of the polysulphone[110].



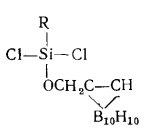
There exist patent data concerning the synthesis of linear *m*-carbaboranylenesiloxane oligomers having the following structure[111]:



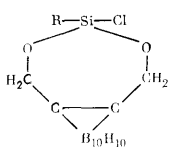
R = alkyl or aryl and n = 3-5.

These are formed when equimolar amounts of divinylorganocyclosiloxane and di(hydroxymethyl)-*m*-carbaborane interact at 50–200 °C in the presence of a hydrosilylation catalyst. When trivinylorganocyclosiloxane is used, branched oligomers are obtained[112]. All the oligomers synthesised in this way are transparent viscous liquids with $M \cong 2000$, which are readily soluble in aromatic hydrocarbons, ethers, and esters. The authors[112] recommend their use as thermostable rubbers and hermetic seals. The temperature of the onset of the thermo-oxidative degradation of the oligomers in air is ~400 °C. Infrared spectroscopic data have shown that the oligomers are synthesised solely as a result of the hydride addition reaction with retention of the structures of the initial compounds in the oligomers.

Oligomers with silanol groups have been obtained by the hydrolytic polycondensation of *m*-carbaboranylmethylorganochlorosilanes. Compounds with cyclic or cyclic-three-dimensional structures are formed from these substances at 250 °C:[113]



n = 2,4; R = *m*-carbaboranyl;



n = 2,3; m = 18, 24 .

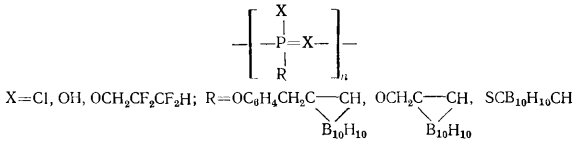
The hardening of phenol-organosilicon oligomers by *N*,*N*-di(hydroxymethyl)aminophenol-*o*-carbaborane has been studied[114] and it has been found that the polymers hardened in this way exhibit a high thermal stability and heat resistance, while materials based on them possess improved dielectric properties.

Oligomeric organosilazanes containing *o*-carbaborane-fragments in the main or side chains in their molecules were synthesised for the first time by the ammonolysis of *o*-carbaboranylmethoxy(organo)dichlorosilanes

or *o*-carbaboranylenedimethoxy(organo)chlorosilanes

R = CH_3, C_6H_5, $CH{=}CH_2$

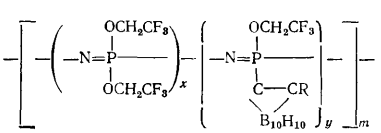
or by the co-ammonolysis of their mixture with organochlorosilanes having the formula R_mSiCl_{3-m}.[115,116] The *o*-carbaborane-containing oligo-organosiloxanes obtained have been recommended as hardening and modifying agents for polyphenylenes[117].



The practical value of poly-*m*-carbaboranylenesiloxanes, in which a high thermal stability (up to 500 °C) is combined with effective fire resistance (oxygen index 62), has been noted in a review[118]. These polymers have found extensive applications as the liquid phases in gas chromatography for the separation of organosilicon and organic substances[119] and for the analysis of polycyclic aromatic hydrocarbons at 20–450 °C.[120]

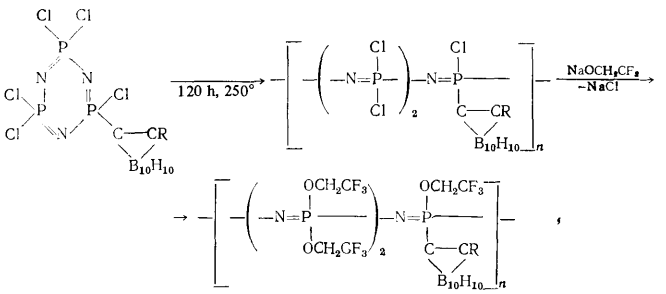
Adhesive compositions, capable of being used for a long time (up to 2000 h) at 600 °C and of withstanding brief exposures to a temperature of 1200 °C, have been created on the basis of *m*-carbaborane-containing polysiloxanes[42,121]. These adhesives are designed for the glueing of semiconducting materials to metals and silicate glasses in electrovacuum devices.

Poly-*m*-carbaboranylenesiloxanes are used as coatings for conducting wires and other articles capable of withstanding a temperature of ~300 °C [118,122] and also as lubricating materials in constructions subjected to irradiation at high temperatures[123].



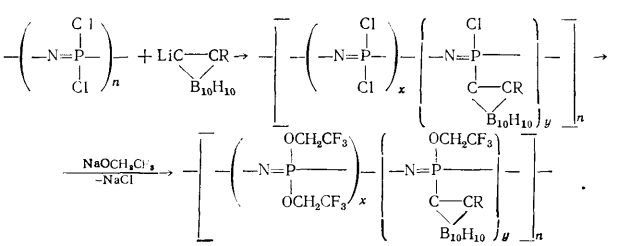
7. Polyphosphazenes

In order to improve the thermal stability of polyphosphazenes, Korshak and co-workers attempted to introduce *o*- and *m*-carbaboranyl groups into these polymers; as a result, *o*- and *m*-carbaborane-containing polyphosphazenes



were obtained for the first time and characterised[124,125]. It was shown that, when polydichlorophosphazenes react with monolithio-derivatives of the corresponding *o*-carbaboranes or with monomercapto-*m*-carbaborane in solution in tetrahydrofuran, the maximum degree of substitution of chlorine by *o*- or *m*-carbaboranyl groups does not exceed 50%. The polymers obtained are white or pale-yellow powders with intrinsic viscosities ranging from 0.15 to 3.00 dl g^{-1}. Their chemical and thermal stabilities are determined by the character of the groups surrounding the main polymer chain. The softening temperatures of these polymers are therefore in the range 90–270 °C and the carbon residue after heat treatment in helium at 900 °C is 26–100%.

Somewhat later Allcock and co-workers[126–128] described *o*-carbaborane-containing polyphosphazenes having the structure



R = CH_3, C_6H_5 .

These polymers were obtained by two methods: either by the polymerisation of the corresponding mono-*o*-carbaboranyl-pentachlorocyclotriphosphazene in sealed tubes with subsequent substitution of chlorine atoms by CF_3CH_2O groups:

or by the interaction of polydichlorophosphazene (molecular weight 10^4–10^6) with monolithio-*o*-carbaborane:

The molecular weights of some of the *o*-carbaborane-containing polyphosphazenes obtained in this way reached 10^5 and the carbon residue in an inert atmosphere at 1000 °C was 56.5%. The authors[128] recommend *o*-carbaborane-containing polyphosphazenes for use as thermostable thermally insulating materials.

---o0o---

Thus the literature data published in recent years permit the conclusion that carbaborane-containing polymers continue to attract the attention of investigators. The study of the properties of polymers with carbaborane fragments, their modification, and the search for new, simpler methods of synthesis of polymers showing the greatest promise in practical applications are of special interest.

As regards the prospects for the further development of the chemistry of carbaborane-containing polymers, one can suppose that, in view of the high cost of the starting materials, the amount of these polymers manufactured will not be great; nevertheless, in view of their unique properties, they will probably become in future some of the most important of polymeric materials.

The Mechanism and Kinetics of the Polymerisation of Conjugated Diacetylenes. The Physical Properties of Polydiacetylenes

G.A.Vinogradov

The mechanisms of the polymerisation of disubstituted conjugated diacetylenes initiated in different ways are examined as are the factors influencing the polymerisation kinetics, the yield of the polymer, and the molecular weight distribution and the structure of the final product. Various physical properties of the most highly investigated polydiacetylenes are discussed: optical (including thermo- and solvato-chromism), non-linear optical, paramagnetic, electro-physicalm mechanical, etc. properties. The possible practical applications of polydiacetylenes are indicated.
The bibliography includes 289 references.

I. INTRODUCTION

In polymer chemistry, the preparation of polymeric single crystals of macroscopic size has been of interest for a long time. It has been shown[1] that at the present time this problem can be solved for polymers with conjugated bonds only in the case of polydiacetylenes—polymers based on disubstituted diacetylenes (DA) with conjugated triple bonds having the structure $R-C\equiv C-C\equiv C-R'$ (in the present review DA will be understood only as diacetylenes having this structure).

During the comparatively short time that has elapsed since the publication by Wegner in 1969 of the first communication on this topic, it has been possible to synthesise several hundreds of DA with substituents of various types, and in many cases polymerise them with the formation of crystals and multilayers having different kinds of morphology. The materials obtained have many interesting properties which determine their possible practical applications (for example, non-linear optical properties, thermo- and solvato-chromism, high mobility of current carriers, high mechanical strength, thermal stability, etc.). Furthermore, the study of DA, of the mechanism and kinetics of their polymerisation, and of the relation between the electronic and molecular structures and the properties of the polymer help in the solution of many general problems of the chemistry and physics of polyconjugated systems whose investigation has been in most cases complicated by their structural and molecular inhomogeneity. In this sense polydiacetylenes (PDA) provide a unique opportunity, as model objects, for the investigation of the general characteristics of polyconjugated systems, since the specimen always represents a set of fairly long macromolecules having the same conformation. Certain PDA are soluble which makes it possible to study their equilibrium properties under conditions independent of external molecular stresses.

Only those DA which in the monomeric phase give rise to single crystals or mono- or multi-layers and polymerise subsequently with retention of the topological correspondence between the molecular structures of the monomeric and polymeric phases will be considered in the present review. The review is devoted mainly to questions of the kinetics and mechanism of the polymerisation of DA, the relation between the structure of PDA and their physical properties (optical, mechanical, and electrophysical) and their practical applications; the methods of synthesis of the initial DA will not be considered. In the foreign literature there are a number of reviews devoted to various questions of the synthesis and physical properties of DA and PDA[2-12]†. This review reflects the latest advances in the study of the physical properties of PDA. In those cases where there is no unanimous view concerning some problems, the alternative approaches are described.

II. PRINCIPLES OF TOPOCHEMICAL POLYMERISATION

The solid-phase polymerisation of DA belongs to the class of topochemical reactions. According to Wegner's definition[2,11], topochemical polymerisation is understood as a non-diffusional conversion of a monomer single crystal into the corresponding polymer single crystal in which the mass centres of the monomeric units retain their initial crystallographic positions and the symmetry of the monomeric units in the monomer and polymer single crystals remains the same. The polymerisation reaction of DA, which is in essence a 1,4-*trans*-addition reaction, is achieved as a result of specific rotations of the monomeric units relative to the positions of their centres of mass, is determined by

† In addition, during the preparation of this article for the press, the following reviews were published: D.Bloor, Mol. Cryst.Liq.Cryst., 1983, **93**, 183; D.Bloor, in "Developments in Crystalline Polymers - 1", (Edited by D.C.Bassett), Applied Sci.Publ., London, 1982, p.151.

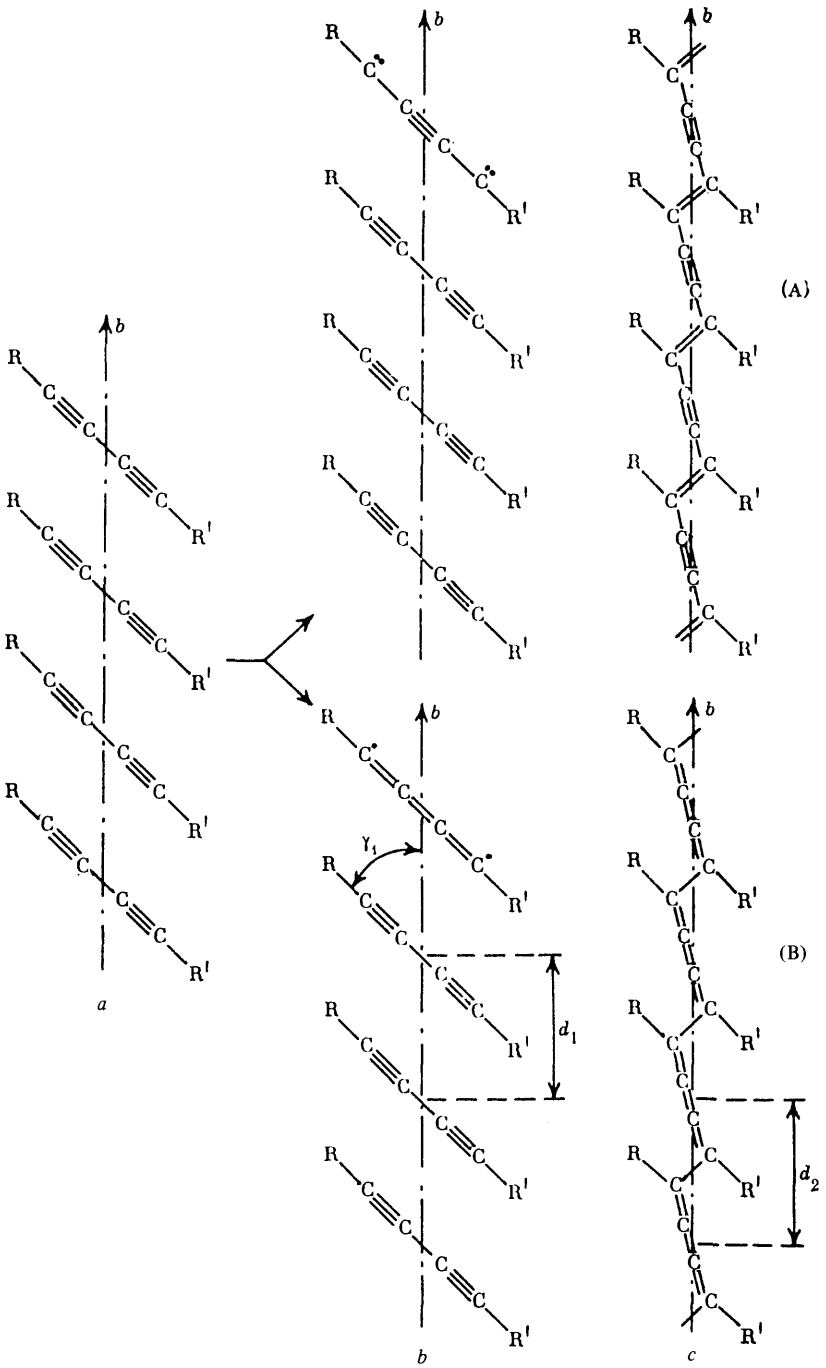

Figure 1. Schematic illustration of the topochemical polymerisation of DA: [2] *a*) arrangement of DA monomers in the single crystal; *b*) the structure of the initiating species in the carbene (above) and radical (below) initiation; *c*) PDA can exist as a function of type of initiation and structure factors in the enyne (A) or butatriene (B) mesomeric forms; *d*) axis of polymer chain.

the packing of the monomer in the crystal lattice, and proceeds without the formation of side products (Fig.1). Such stereospecific polymerisation results in the formation of a stereoregular polymer with a linear disposition of the macromolecules and with a small number of defects; in a number of instances the length of the polymer chain is comparable to the dimensions of the single crystal.

It has been shown by the topographic method using synchrotron radiation# that the solid phase polymerisation of diacetylenes is a true topochemical polymerisation, which takes place in the undeformed lattice of the monomer single

crystal in the absence of defects, in contrast to the other known solid-phase reactions, which can occur only in the vicinity of defects, dislocations, and admixtures.

The specific requirements which must be met for the occurrence of a topochemical reaction have been formulated by Baughman[10,13,14], who proposed several criteria whose fulfilment is necessary for the occurrence of such polymerisation reactions.

1. The criterion of minimum displacements states that the actual reaction pathway must be one in which the smallest mean square displacements of atoms take place. If this criterion for the four carbon atoms of the monomeric DA unit involved in the transition from the monomer to the polymeric phase is defined by the expression

$$R = \left\{\sum_{i=1}^{4} [(x_i, y_i) - (x_i', y_i')]^2\right\}^{1/2},$$

where x_i, y_i, x_i', and y_i' are the coordinates of the atoms in the monomeric and polymeric phases, then, according to Baughman, only those DA for which R is less than ~ 1.08 Å on passing from the monomer to the polymer are reactive.

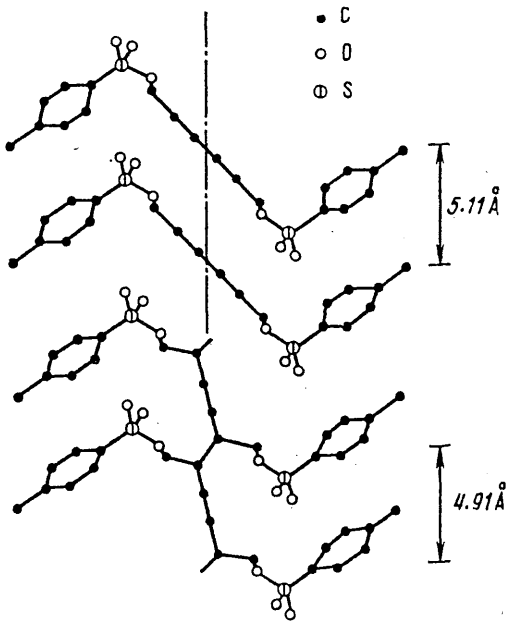

Figure 2. Projection of the crystal structure of TS (above) and poly-TS (below) onto the plane coinciding with the polymer skeleton[2].

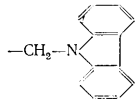
As a rule the angle $\gamma_1 \cong 45°$ for the reactive DA and the relative lattice contraction $(d_1 - d_2)/d_2$ in the polymerisation reaction should not exceed approximately 0.1 (Fig.1), although there are exceptions to this empirical rule[2]. Fig.2 illustrates the changes in the geometrical disposition of the atoms of the monomeric TS unit (see Table 1 below) on passing from the monomer to the polymer. Evidently these changes are indeed small and reflect the rotation of the diacetylene group and the slight displacement and rotation of the benzene rings[2]. According to the minimum displacements criterion, the contribution of the lattice to the activation energy for the polymerisation reaction increases monotonically with increase of the mean square displacement of the atoms necessary for the occurrence of the reaction.

2. The group-theoretical criterion according to which the following conditions must be fulfilled for the reaction pathway to be unique: (a) the symmetry point group of the monomer must be a possible symmetry point group of the monomeric unit in the polymer and (b) the symmetry space group linking the reacting monomers must be a possible symmetry element between the corresponding monomeric units in the polymer chain. In other words, on passing from the monomer to the polymer, the degree of symmetry (point and space symmetry) must not decrease, i.e. during the reaction time all the crystallographic symmetry elements of the monomeric phase must be retained.

3. The criterion of the uniqueness of the phase transformation, which states that the polymer formed must be incorporated in the monomer matrix in the form of a solid solution for all degrees of conversion of the monomer. According to the last requirement, the monomeric and polymeric phases must be in equilibrium whatever the degree of conversion of the monomer[15].

The available literature data concerning unsuccessful attempts to polymerise a particular DA or the reported impossibility to attain 100% conversion of the monomer in the polymerisation reaction indicate the failure of at least one of the above criteria. Evidently the requirements enumerated impose very severe limitations on the size and interaction of the substituents. The role of the latter in topochemical polymerisation is great and reduces to the following[16]: the substituents control the packing of the monomer; they exert a steric influence on the reactivity, determining the unique reaction pathway; the interaction of the substituents controls the changes in the geometrical dimensions of the crystal lattice during polymerisation; they "soften" the mechanical stresses arising in the course of polymerisation owing to the incompatibility of the crystal lattice parameters of the monomer and the polymer. The specific requirements imposed on the substituents in the DA molecule are that as a rule they must have either a high dipole moment or the capacity to form intramolecular or intermolecular hydrogen bonds[17]. An obligatory condition is the presence in the substituent of one or several methylene groups, which separate the triple bonds and the functional groups of the substituents and whose purpose is to ensure the necessary flexibility in the rotation of the diacetylene groups during polymerisation with retention at the same time of the necessary interaction of the substituents.

Of the several hundred DA synthesised at the present time, only several tens proved capable of topochemical polymerisation. However, a polymer single crystal of large size and with a high degree of perfection cannot be obtained from all these monomers either. In certain cases the reaction does not lead to 100% conversion whatever the conditions. Furthermore, DA are known which are capable of existing in various crystalline modifications of which some are reactive, while others cannot be polymerised under any conditions[1,18-21]. Sometimes the monomer gives rise to up to 5 crystalline modifications on crystallisation[15,22]. All this shows that the geometrical packing of the molecules in the monomer single crystal, which specifies the distances between the reacting centres, and also the direction and the extent of the migrations of the atoms required for the reaction to occur are some of the decisive factors determining the reactivity.



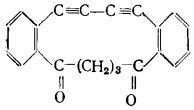


Table 1 presents the structural formulae and the abbreviations for the diacetylenes which polymerise quantitatively to give rise to polymers for which the greatest number of kinetic and physical investigations have been carried out.

III. THE MECHANISM AND KINETICS OF THE POLYMERISATION OF DIACETYLENES

The following features are characteristic of the polymerisation of the majority of DA:

(1) The polymerisation is initiated thermally, with the aid of ultraviolet light or X-rays, as a result of the application of hydrostatic pressure, and also under the influence of active gases, for example, halogens, nitrogen dioxide, ozone, etc.

** Cyclic monomer.

(2) On the basis of the kinetic curves, it is possible to distinguish autocatalytic (TS) and asymptotic (MBS) polymerisations§ (Fig.3). A fairly long induction period (up to 60 days at room temperature for TS) is observed in autocatalytic polymerisation during which an approximately 10% degree of conversion is attained, after which an autocatalytic stage is observed during which the latest polymerisation increases by a factor of several hundreds[24–27]; this stage is usually completed after the attainment of 100% conversion of the monomer.

(3) The range of variation of the activation energy in thermal polymerisation is fairly narrow, amounting to 80–105 kJ $mole^{-1}$.[25] For example, an activation energy of 94.3 kJ $mole^{-1}$ describes superbly the kinetics of the thermal polymerisation of TS in the temperature range 291–364 K, where the rates of polymerisation differ by a factor of 2400.[28]

§ The terms "autocatalytic" and "asymptotic" polymerisation are used for brevity in defining two different types of kinetics on the basis of the form of their kinetic curves. In fact the nature of the polymerisation is not autocatalytic[23].

(4) The polymerisation initiated by X-rays or ultraviolet light proceeds with an activation energy of approximately 10 kJ $mole^{-1}$.

(5) The activation energy for thermal polymerisation is constant over a wide range of conversions (up to 95%)[29].

(6) In the same range of degrees of conversion, the reaction is of first order with respect to the monomer.

(7) The pre-exponential factor in the expression for the first-order rate constant for thermal polymerisation in the autocatalytic stage is 10^{-8}–10^{-7} s^{-1}.[27,28]

(8) The capacity of the monomer crystal for polymerisation is determined by its previous history, in particular its crystallisation conditions[1,30] and purity[25].

(9) The polymerisation reaction is not initiated by radical initiators. Thus dicumenyl peroxide inhibits rather than initiates polymerisation[131].

(10) In many instances DA have two and more crystalline modifications differing sharply in their reactivity[15,22].

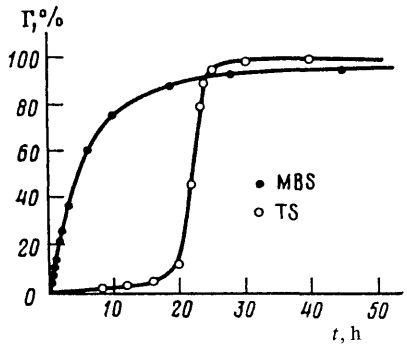

Figure 3. Kinetic curves for the polymerisation of TS and MBS at 333 K.[19] The degree of conversion of the monomer and the polymerisation time are plotted along the ordinate and abscissa axes respectively.

It is noteworthy that in the polymerisation of certain DA there may be deviations from the above rules. For example, the reaction sometimes ceases at a degree of conversion of 50–70%[16,32–34].

A kinetic mechanism of the solid-phase polymerisation of DA has been proposed by Baughman[35]. For autocatalytic polymerisation, the mechanism can be described qualitatively as follows. In the induction period stage of the polymerisation, oligomeric molecules with chain lengths corresponding to several tens of monomeric units are formed[28,36–38]. Since the transition from the monomer to the polymer crystal usually entails a decrease of the distance between the monomer units by 5–8%, the oligomeric molecules formed and the monomeric matrix are in a strained state: the bonds in the oligomeric molecules are extended relative to their equilibrium dimensions, while those in the monomer matrix are actually compressed. The elimination of these strains is accompanied by rapid polymerisation. At this instant the entire crystal decreases fairly rapidly in size in the direction of the growing chains (the *b* axis of the crystal lattice) and favourable energetic conditions are created for the occurrence of polymerisation.

The theory of topochemical polymerisation of DA was developed further in a study[39] where account was taken of a series of published comments and amendments. The observed

relation between the contraction along the *b* axis and the degree of conversion of the monomer (Fig.4) can serve as confirmation of this theory[40]. Analogous results have been obtained in dilatometric studies of the thermal TS polymerisation[41]. It has been established by dilatometric[40,41] and X-ray diffraction[38] methods that the lattice parameter along the *b* direction varies continuously with increasing degree of conversion. On the other hand, it has been found by the neutron scattering method[42] that this parameter changes abruptly. In contrast to γ-rays, a stream of neutrons does not initiate polymerisation and in this sense the neutron scattering method is more reliable; however, the experimental errors associated with this method are greater than in the case of the previous methods. At any rate, a correlation is always observed between the crystal lattice parameter along the *b* direction and the degree of conversion of the monomer. The interaction of the monomeric molecules during polymerisation is not accompanied by a change of the conditions along the *a* and *c* crystallographic directions. These results are fully consistent with the theory[35]. Generally speaking, the small change in the crystal lattice parameters on passing from the monomer to the polymer does not influence the feasibility of the polymerisation reaction and determines merely its kinetics and the quality of the final polymeric products.

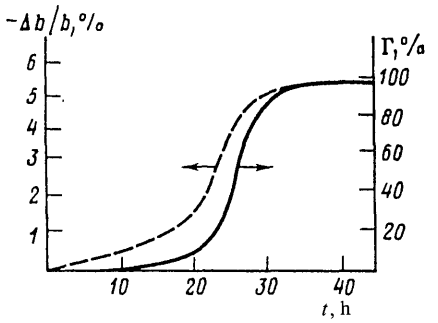

Figure 4. Kinetic polymerisation curve and the relative linear contraction of a TS single crystal along the *b* axis during thermal polymerisation at 323.2 K.[40]

The following postulates were made in the analysis of the kinetic polymerisation mechanism[35]: (1) the active centres are formed at a rate (calculated in terms of the concentration of the monomer which has not reacted) which is independent of the degree of conversion of the monomer; (2) the rate of deactivation of the active centres is independent of the degree of conversion of the monomer and is much greater than the rate of the competing chain initiation reaction; (3) the lifetime of the active centre propagating polymerisation is independent of the degree of conversion. In this mechanism the quantities which depend on the degree of conversion are the enthalpy components of the free energy for the initiation and chain propagation. This influence is due to the energetic strains in the reaction mixture matrix which is in the solid state.

Apart from the activation energy, the heat of polymerisation of various diacetylenes has also been determined. Over a wide temperature range, this quantity is −(120–150) kJ mole^{-1} for the majority of DA[24,43]. Furthermore, the heat of polymerisation has been calculated[25] with the aid of Dewar's "bond length–bond strength" relation and $\Delta H_p = -132$ kJ mole^{-1} for structure (B) of the polymer chain and $\Delta H_p = -123$ kJ mole^{-1} for structure (A) were obtained (Fig.1). The exothermic heat change is attributed to the addition of the monomer to the reactive end of the polymer chain.

It was later established in relation to 4BCMU¶ that the heat of polymerisation of the DA which polymerise predominantly only under the influence of illumination and γ-irradiation is much smaller than the usual values and amounts to approximately 100 kJ mole^{-1} (approximately 0.95 eV). Owing to the low heat of polymerisation, 4BCMU hardly undergoes thermal polymerisation. The low heat of polymerisation is attributed to the energetically unfavourable interaction of the side groups in the polymer compared with the monomer.

In discussing the mechanism of the thermal polymerisation, two structures are generally considered as the possible initiating species; the bicarbene structure $R\ddot{C}-C\equiv C-CR=RC-C\equiv C-C\ddot{R}$, first proposed by Wegner[22], and the biradical structure $R\dot{C}=C=C=CR-RC=C=C-\dot{C}R$. From the energetic standpoint, the formation of biradicals is more favourable than that of bicarbenes and there is a greater number of data showing that the biradical dimer is responsible for the initiation step[24,25,44,45]. Thus estimates of the energies of formation of bicarbenes and biradicals from the Dewar relations yielded 235 and 85 kJ mole^{-1} respectively[25]. However, EPR signals due to the bicarbene structure have been observed in the autocatalytic stage of thermal polymerisation[46–48]. It may be that a biradical is formed initially and then isomerises to a bicarbene[49].

The comparatively low ΔH_p constitutes indirect confirmation of the biradical mechanism of initiation[29]. Generally speaking, the initiation process and the structure of the final product are not related, since during polymerisation there are apparently transitions between the intermediate oligomeric molecules involving a decrease of multiplicity. The type of structure is then determined mainly by energetic factors, the electron energy, and the crystal strain energy. Virtually only the substituents determine the sequence of the bonds in the polymer chain.

Theoretical study of the unimolecular polymerisation initiation reaction using the Woodward–Hoffman rules[50] established that the formation of the monomeric bicarbene initiating species is photochemically allowed but thermally prohibited and, conversely, that the formation of a biradical is thermally allowed but photochemically prohibited. If there were no changes in multiplicity in the subsequent transformation, then thermal initiation would lead exclusively to form (B) of the polymers, while photochemical initiation would lead exclusively to form (A). In the study of initiation via the dimer, the conclusions concerning the formation of a biradical or a bicarbene being allowed in different types of initiation would apparently be the opposite to those established for the monomer.

Studies have been recently published whose authors note that the polymerisation model proposed[35] does not always make it possible to describe certain experimental results. For example, in the study of the thermal TS polymerisation under pressures[40,51], it was established that the reduction of the induction period of the reaction with increasing pressure is greater than predicted by the theory. Furthermore, in the investigation of the thermal polymerisation of the same monomer deuteriated in various positions[52], unusually large isotope effects were observed in the induction period stage of the polymerisation, which is difficult to explain in

¶ See H.Eckhardt, T.Prusik, and R.R.Chance, Macromolecules, 1983, **16**, 732.

terms of the theory[35]. A normal isotope effect is observed in the autocatalytic state.

An alternative model of the thermal polymerisation has been proposed[52], according to which excited states are constantly created in the monomer matrix. It has been suggested that the migration of the excitation energy in the lattice is a random process with considerable scattering[53]. In their diffusion pathway the excited states encounter randomly distributed but localised defects and are captured by them. If the lifetime of the excited state in such a trap is fairly long, then the state can serve as an initiator of chain polymerisation. Here there is a possibility of the following variants: (a) in the pure monomer matrix the concentration of defects is low and the rate of initiation is therefore also low; (b) for the average degree of conversion, the concentration of defects is large and many chain initiators are therefore formed, which leads to an increase of the overall rate of polymerisation. This approach explains the isotope effect and is consistent with the observed form of the kinetic polymerisation curve and with the earlier hypothesis that thermal polymerisation is initiated by the crystal defects[49,54]. The correctness of the choice of this type of polymerisation mechanism is confirmed by data concerning the influence of the previous history of the specimen, in particular its purity, on the duration of the induction period and the polymerisation rate constants[29]. Attempts have also been made to incorporate the influence of the anharmonicity of the bond vibrations and of the electron–phonon interaction in the explanation of the mechanism and kinetics of the polymerisation reaction[55].

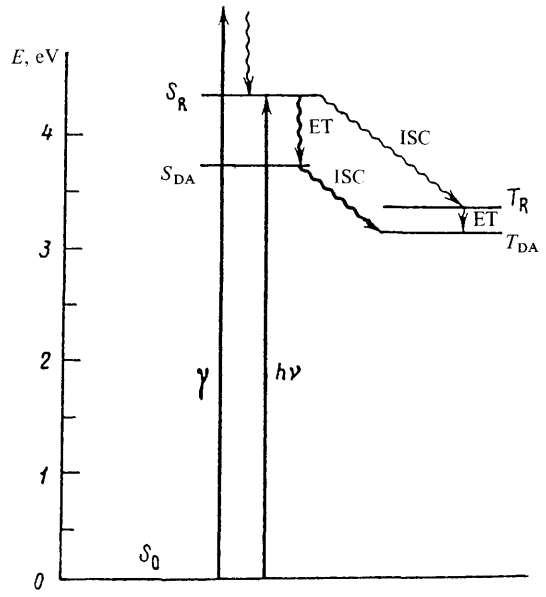

Figure 5. Diagram of the electronic levels of DA and the substituent R.[49] The possible pathways followed in the energy transfer are designated by thin wavy lines; the most probable pathway is shown by a bold wavy line.

Despite certain advances in the understanding of the mechanism and kinetics of thermal polymerisation, many problems remain unsolved. In particular it is not clear how energy is transferred to the reaction centre and is captured by it and the detailed mechanism of the initiation and the nature of the molecular excitation in thermal polymerisation are not understood. Indeed, the activation energy for thermal polymerisation $\Delta E_a \simeq 1.0$ eV,[49] while the energy of the lowest known triplet state in DA is approximately 3.1 eV[56]. The situation was actually made somewhat more complicated when it was established that certain DA are photopolymerised on sensitisation by phenazine[57,58] and by cyanine dyes[59,60]. Compared with DA, phenazine has a lower energy of the excited state[58] and therefore should inhibit rather than initiate the photopolymerisation of DA.

The influence of strain in the crystal on the polymerisation kinetics has not been ultimately elucidated either. In the study of the polymerisation of two monomers, MBS and TS, which have very similar molecular structures, it was established that MBS polymerises asymptotically[19,61], while a distinct autocatalytic stage is characteristic of the polymerisation of TS (Fig.3). Optical and Raman spectroscopic data have shown that during polymerisation the changes in the MBS and TS crystal lattices are the same[62], but the strain in the MBS crystal was greater than in the TS crystal[61,63]. Consequently the autocatalytic stage in the polymerisation of MBS should be more pronounced than for TS. Mixed crystals of the same monomers have been polymerised in different proportions[64]. With increase of the MBS content, the inductive period shortens. Since the crystal structures of these monomers are virtually identical, the differences between the polymerisation kinetics are hardly likely to be associated with the differences in the molecular packing and between the strains of these crystals. Analogous results have been obtained in the study of the polymerisation of mixed crystals of TS and diacetylenes with $R = R' = CH_2OSO_2C_6H_4X$, where X = Cl or Br[20,65]. This apparent contradiction can be obviated if it is supposed that the differences between the kinetics of the polymerisation of TS and MBS are associated with the longer lifetime of the active centre in MBS and hence with the larger pre-exponential factor[63]. Generally speaking, the two factors—the crystal strain and the lifetime of the active centre—are inter-related. Thus in the TS polymerisation it was observed by differential scanning calorimetry that the kinetics of the polymerisation reaction in the inductive period stage are virtually indistinguishable for single crystals of different qualities, whereas the rates of polymerisation in the autocatalytic stage can differ almost by an order of magnitude while the activation energy remains constant (93.4 ± 3.8 kJ mole^{-1}), which has been attributed to the difference between the pre-exponential factors due to the different strains in the single crystals[66].

The model of the polymerisation process involving the rotation of rigid diacetylene bonds in the plane of the polymer skeleton does not apparently fully correspond to reality and can describe the polymerisation process only in broad outline. It may be that the details of the topochemical polymerisation of diacetylenes can be understood when account is taken of the influence of low-energy phonons and also when one considers a reaction involving the rotation of non-rigid diacetylenic linkages with displacement of the carbon atoms from the plane of the skeleton†.

It is also incomprehensible why the kinetics obey the first-order law with respect to the monomer up to such high degrees of conversion.

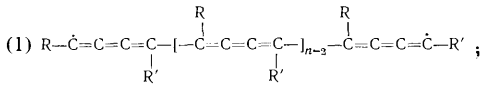
A characteristic feature of the polymerisation induced by ultraviolet light and radiation is that it occurs regardless of whether an electronic state of the DA molecule is excited or whether the electronic excitation is initially localised at a

† See D.Bloor, Mol.Cryst.Liq.Cryst., 1983, **93**, 183.

substituent[22,67]. An electronic level scheme has been published[49] for substituted DA (Fig.5). The authors suggest the following scheme for the formation of active centres

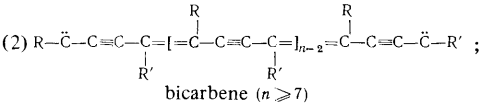
$$S_0 + h\nu \rightarrow S_R \xrightarrow{ET} S_{DA} \xrightarrow{ISC} T_{DA} \rightarrow \text{polymer},$$

where S and T are the corresponding spin states of the DA and the substituent R, ET is the energy transfer, and ISC is intersystem crossing. All the energies of the electronic states of DA and the substituent, with the exception of the energy of the triplet state of DA, have been determined[49]. The only assumption made on the basis of the scheme is that T_{DA} lies below T_R. Later this hypothesis was confirmed and it was established that $T_{DA} = 3.1-3.2$ eV[56]. In this connection it is of interest to note that the polymerisation of the DCHD monomer is not initiated by ultraviolet light[68,69]. This can apparently be explained by the fact that the lowest excited energy state of the DCHD monomer is the triplet state of the carbazole group, i.e. the sequence in which the T_R and T_{DA} levels alternate changes (Fig.5) and the final stage of the energy degradation process is the triplet state of carbazole, which is incapable of initiating polymerisation. It can be assumed that the DA for which $T_R > 3.1$ eV will undergo photopolymerisation (provided, of course, that topological correspondence is observed).



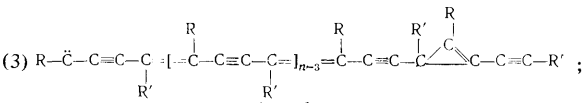
The kinetics of the polymerisation induced by ultraviolet light and radiation have been examined[49]. Both polymerisation stages are as a rule observed for these types of initiation: the induction period and the autocatalytic stage[49,70]. The study of the low-temperature photopolymerisation of DA led to a detailed determination of the initiation and chain propagation mechanisms, the chemical structure of the intermediate oligomeric chains, and also the multiplicity and the interconversions of various radical states of the growing ends of the oligomeric chains.

Biradicals[45,71] and symmetrical and asymmetric carbenes[45,46,71-76] have been detected by the EPR and optical absorption spectroscopic methods at 4.2 and 77 K in photoinitiated polymerisation. These states were identified as intermediate triplet states. For dimers and short oligomers, the interacting carbenes at the ends of the chains give rise to quintet[72,74,77,78] and singlet[74] states. Various types of intermediate species as well as the kinetics of their formation and destruction have been examined[67].

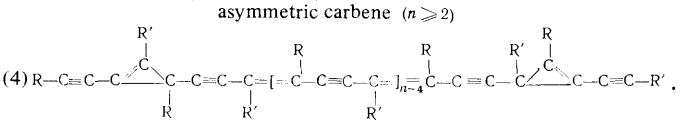


The polymerisation initiation process and the initial stage of the polymerisation have been thoroughly investigated at low temperatures, where the lifetimes of the excited initiating species and active polymerisation centres are sufficiently long to be determined experimentally. At low temperatures ($T < 200$ K) the initiation process is a two-quantum process[67,78], which follows from the experimentally observed quadratic dependence of the rate of formation of the active centres on the intensity of the irradiating light. The first absorbed quantum ($\lambda \lesssim 310$ nm) results in a transition of the monomer to an electronically excited state, which is converted into a monomeric biradical as a result of intersystem crossing[78]. The absorption of the second quantum results in the transition of the adjoining monomer molecule to a vibrationally excited state as a result of internal conversion. The combination of these molecules into a biradical dimer, capable of further chain propagation, actually constitutes the polymerisation initiation step. The subsequent photoreactions, consisting in the growth of the polymer chain by one monomer unit following the absorption of each quantum, is possible on irradiation with light at longer wavelengths, for example, 446 or 498 nm.[67]

At high temperatures ($T > 200$ K) there is a linear dependence of the rate of formation of dimers on the light intensity#, so that monomer molecules in vibrationally excited states are produced thermally.



It has been possible to identify by the EPR method numerous intermediate triplet states of the oligomers in a low-temperature photoinitiated topochemical polymerisation[74]. It was found that there are only four types of products with different chain lengths§



(1) biradical ($2 \leqslant n \leqslant 6$)

(2) bicarbene ($n \geqslant 7$)

(3) asymmetric carbene ($n \geqslant 2$)

(4) stable oligomer ($n \geqslant 3$)

Among all the details of the structures represented, only the existence of the pseudocyclopropene ring is hypothetical and is based on the assumption of the intramolecular deactivation of the active centres. It has been postulated that the pseudocyclopropene structures are stabilised by the molecular field of the crystal.

Analogous studies designed to discover the intermediate photopolymerisation products and to determine their nature have been carried out in connection with the photopolymerisation of TS at high temperatures[79]. A specially devised method was used to record the optical absorption spectra of short-lived (< 50 μs) intermediate species. The essential feature of the method was that it involved the recording of differential absorption spectra representing the difference between the absorption spectra after irradiation with a laser pulse ($\tau = 15$ ns, $\lambda = 308$ nm) and before irradiation. Several similar spectra have been recorded over a period of approximately 10^{-5} s. This method makes it possible, firstly, to isolate the spectra of the newly formed photoproducts and their measurement is not interfered with by traces of the polymer present in the specimen and, secondly, one can detect extremely short-lived species and investigate the kinetics of their formation, their interconversions, and destruction.

At least five intermediate species were detected, of which only one, having the maximum at the shortest wavelength in the absorption spectra, is a direct consequence of irradiation with light and was identified as a dimer. The remaining four products arise from the consecutive addition of monomer molecules, which takes place as thermal processes. The activation energy for the addition of the monomer is 0.25–0.30 eV and the pre-exponential factor is approximately 10^{11} s^{-1}. At low temperatures the quantum yield in

See H.Gross, W.Neumann, and H.Sixl, Chem.Phys. Letters, 1983, **95**, 584.

§ H.Gross and H.Sixl, Chem.Phys.Letters, 1982, **91**, 262.

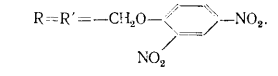
the formation of dimers $\Phi \cong 10^{-2}$, diminishing to 10^{-3}–10^{-4} s with increase of temperature. The quantum yield Φ is highest for the defect-free monomer single crystal, but there are no channels for the transfer of energy to defects and the growing polymer chain.

The overall quantum yield (the number of polymerised monomeric units per absorbed light quantum) varies within wide limits: from 0.06 for TS (Bhattacharjee and Patel[80]) to 50 (Bhattacharjee and Patel[80]) and 90 (Shand and Chance[81]) for 4BCMU. Here one can trace a kind of compensation effect: the DA which have a high ($\gg 1$) polymerisation quantum yield do not undergo effective thermal polymerisation, while the DA which do undergo effective thermal polymerisation have a low ($\ll 1$) photopolymerisation quantum yield. Chemical actinometry[80] and photoacoustic spectroscopy[81,82] were used to determine the quantum yield. It was found that the rate of the photoinitiated polymerisation of DA greatly diminishes with increasing degree of conversion[83], which can be explained by energy transfer from the excited state of the monomer to the polymer chain. Such transfer is an important rate-limiting factor in photopolymerisation and must be taken into account in the determination of the quantum yield.

The kinetic polymerisation chain length depends on the stress applied to the monomer lattice[53]. The chain character of the photopolymerisation process has been demonstrated by photoacoustic spectroscopy[82]. Estimation of the lifetimes of the excited states yielded values differing by several orders of magnitude, from 10^{-3} s in the studies of Wegner and co-workers[52,53] to approximately 10^{-6} s in the study of Chance and Shand[82].

The photoinitiated polymerisation has been studied with irradiation of TS crystals by light through a dense grid under normal conditions[84] and with application of hydrostatic pressure[85]. Subsequently the reaction front profile in the shadow zone was investigated by scanning electron microscopy. The spatially isotropic growth of the polymer chains in the shadow zone and not only along the directions of the chain indicates the initiation in the primary step. Indeed, when one monomer molecule adds on, the energy liberated is 1.6 eV,[24] which exceeds the activation energy for the reaction ($\Delta E_a \cong 1.0$ eV). The excess energy liberated spreads isotropically from the reaction zone and gives rise to the vibrational excitation of the adjoining DA molecule, initiating thereby secondary polymerisation.

The photosensitised polymerisation of diynoic acid mixed with phenazine[57,58] and the autosensitised photopolymerisation of multilayers[86] can be explained analogously. The application of an electric field does not alter the rate of reaction or the profile of the reaction front; consequently the hypothesis[86] of the secondary initiation with the aid of the free carriers generated on deactivation of the electronically excited state is unfounded. A number of features of the photopolymerisation sensitised by cyanine dyes[59], in particular the independence of the maximum degree of conversion and the dye concentration and the high (approximately 90 Å) sensitisation radius[60] can be explained within the framework of the model postulating thermal initiation by the excess thermal energy liberated in the course of the u.v.-initiated polymerisation.



Similar results were obtained on sensitisation of the photopolymerisation by acridine and anthraquinone dyes¶, which are electron donors, in contrast to cyanine dyes. The authors of the above study nevertheless hold the view that charge transfer plays a decisive role in the photoinitiated polymerisation sensitised by electron-donating and electron-accepting dyes. The quantum yield of the photopolymerisation sensitised by cyanine dyes is in the range $0.7 \times 10^{-3} < \Phi < 17 \times 10^{-3}$: the corresponding values for the acridine and anthraquinone dyes are 2×10^{-3} and 7×10^{-3} respectively.

The radiation-initiated polymerisation of the various DA is characterised by a greater difference in the number of polymerised monomeric units per 100 eV of the irradiation energy [$G(-m)$]. Thus $G(-m) \cong 2 \times 10^5$ for 4BMCU[87] and $G(-m) = 66$ for TS[37,87]. When the substituents are altered, the sensitivity of the DA to ionising radiation on polymerisation can change by 6–7 orders of magnitude[87]. It has been suggested that the initiating species in the γ-initiated polymerisation is a biradical dimer[44,71]. The difference between the types of initiating species in photopolymerisation and γ-polymerisation is apparently associated with different selection rules for electronic transitions in various types of initiation.

In the study of polymerisation under the conditions of hydrostatic pressure, it was established[40,51] that, as in polymerisation under normal conditions, the reaction is first order with respect to the monomer up to 90% conversion and that pressure does not alter the activation energy for initiation and chain propagation. However, with increase of pressure, there is a decrease in the induction period, which disappears at $p > 3$ kbar; the polymerisation rate constant increases exponentially with increase of pressure. The increased rate constant for the reaction is attributed mainly to the component of the hydrostatic pressure acting at right angles to the direction of the growing chains and inducing the mutual approach of the hydrocarbon atoms of neighbouring monomeric units, which promotes the reaction. The decrease and even the disappearance of the induction period with increase of pressure is apparently associated with the fact that, under these conditions, the crystal lattice parameters in the monomeric and polymeric phases are equalised.

In the initial stage of polymerisation fairly long oligomeric chains are formed rapidly for all types of initiation[88]. The degree of polymerisation changes from $n \cong 20$ at the beginning of the induction period to $n \cong 40$ at the end of this period and reaches $n \cong 140$ in the autocatalytic stage[28]. At the instant of the completion of the polymerisation, n increases still further.

The molecular weight distribution in the initial stage of the polymerisation has been investigated† by an independent method—with the aid of X-ray diffraction for DA and TS with substituents:

The latter monomer polymerises fairly slowly under the influence of γ-rays and the molecular weight distribution curves and the average degrees of polymerisation could be determined for this monomer during the polymerisation reaction. Their values, which are close to those determined previously, are following values for different degrees of conversion Γ: $n = 22$ ($\Gamma = 0.65\%$), $n = 38$ ($\Gamma = 4.5\%$), and $n = 47$ ($\Gamma = 16\%$). Analogous results were obtained for the polymerisation of TS.

The molecular weight distributions for soluble PDA [poly-(3)4BCMU] have been determined by gel permeation chromatography[89,90] and $M_n = 49 \times 10^5$ g mol^{-1} (poly-3BCMU, $n \cong$

¶ See C.Bubeck, K.Weiss, and B.Tieke, Thin Solid Films, 1983, **99**, 103.

† See P.A.Albony, J.N.Patillon, and J.P.Pouget, Mol. Cryst.Liq.Cryst., 1983, **93**, 239.

10^3)[90] and $M_n = 1.2 \times 10^6$ g mol^{-1} (poly-4BCMU, $n \cong 2.4 \times 10^3$)[89] were obtained; the polydispersity index is $M_w/M_n \cong 5$.

Later more detailed studies were made[91] of the molecular weight distribution (MWD) for poly-3BCMU in γ-initiated polymerisation with various irradiation doses in the range from 0.09 to 45 Mrad and fairly high molecular weights and narrow MWD were obtained for small doses ($M_n = 1.33 \times 10^6$ g mol^{-1}, $M_w = 3.9 \times 10^6$ g mol^{-1}, $M_w/M_n = 2.93$, dose = 0.09 Mrad). The values of M_n and M_w diminish significantly with increase dose of radiation and the polydispersity index increases very strongly; for example, $M_n = 1.79 \times 10^5$ g mol^{-1}, $M_w = 2.31 \times 10^6$ g mol^{-1}, and $M_w/M_n = 12.8$ have been obtained for a dose of 15 Mrad. As the irradiation dose is increased from 0.09 to 45 Mrad, the degree of conversion of the monomer rises from 21% to 49%. The decrease of the molecular weight of the polymer is attributed to degradation during irradiation. High molecular weights have been obtained for PDA with R = R' = $(CH_2)_5OC(O)X$ in a study by Plachetta and Schulz[92]: $M_n = 2.4 \times 10^5$, 3.4×10^5, and 3.2×10^5 g mol^{-1} and $M_w/M_n = 3.33$, 3.94, 3.75 for X = $CH(CH_3)_2$, $CH_2C_6H_5$, and CH_2-α-naphthyl respectively.

Analogous studies have been carried out for poly-TS at conversions from 0 to 12%, at which the polymer is still soluble[37]. In this range of degrees of conversion the MWD is fairly broad and does not change with the degree of conversion and $n \cong 20$. It may be that this low value of n is due to the degradation of the polymer in the strong solvent (dimethylformamide, chloroform) used in the determination of the MWD[93], since $\bar{M}_n$ determined by other methods is much greater[24,38].

IV. THE ELECTRONIC STRUCTURE OF POLYDIACETYLENES

Polydiacetylenes constitute a convenient and unique object for the theoretical description and investigation of the electronic structures of polyconjugated systems. There are exhaustive data on the structures, bond lengths, and valence angles of certain PDA. There are also extensive experimental data for the optical properties of these polymers[4,5]. The energies and polarisations of the electronic transitions have been determined on the basis of these results and the vibrational energies of the excitation of various bonds have been found from infrared and Raman spectroscopic data[6]. The polymers considered are of interest also because they constitute in essence a model one-dimensional system of virtually infinite length made up of rigorously repeating monomeric units without defects in the structure and conformation of the chains. This simplicity of the structure is, however, only apparent. Calculation of the electronic structure and ultimately the understanding of the physical properties are complicated by the interaction of the side groups of a single chain and also by the intermolecular interaction between chains.

The studies which have been made on the electronic structure of PDA were devoted mainly to the elucidation of the nature of the long-wavelength optical absorption with an energy of approximately 2 eV, the influence of the substituents and external conditions on the electronic structure of PDA, and also certain electrophysical properties.

In the study of the electronic structure of PDA many unsolved problems are common to all types of conjugated systems, for example, the question of the nature of the forbidden energy gap in the spectrum for one-electron excitations. So far there is no unanimous view concerning the origin of this gap even for polyene systems. The extreme views are that the gap can be attributed either to the alternation of the bond lengths (the Peierls instability of the one-dimensional metal relative to the doubling of the crystal lattice period) or that its nature is of the correlation type (the Mott–Hubbard electronic phase transition due to the electron interaction). For conjugated systems, this problem has been investigated in detail[94] and the hypothesis that the nature of the energy gap is of the correlation type appears to be supported by the soundest arguments.

The question of the nature of the energy gap in PDA is masked by the fact that the alternation of bond lengths is a permanent property of these systems, which can be readily adopted as the cause of the appearance of the energy gap. In describing the electronic structure of PDA, one must bear in mind all the theoretical data which have accumulated on conjugated systems and studies must be made taking into account the electron interaction. The question of the nature of the gap in PDA was specially studied[95] with the aid of a modified Hubbard Hamiltonian; it has been shown that the contribution of the Coulombic correlations to the energy gap is approximately 1.9 eV and that the exciton band is split off from the conductivity band only when account is taken of the electron interaction at the neighbouring atoms.

Table 2. Results of the calculations of the width of the forbidden gap ΔE for PDA.

Method of calculation	Free electron[a]	Hückel	Extended Hückel[b]	X_α^c	PPP + CI[d]	LCAO-MO SCF[e]	LCAO-MO + CI[f]	CNDO/S + CI	STO-3G basis	7s/3p basis	Effective Hamiltonian	ΔE_{exp}, eV

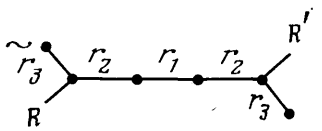
Refs.	[96]	[97]	[98, 99]	[100, 101]	[102]	[103]	[104, 105]	[106]	[107–109]	[110]	[111, 112]	

Remarks: [a] A modified method of free electrons with sinusoidal modulation of the potential was used; [b] the numerical values quoted in accordance with Parry's data[98]; [c] the calculation was performed for the model compound 1,5,9-tridehydro(12)annulene; [d] Ono's parametrisation; [e] the gap width for seven substituents was calculated by Parry[103]; here the minimum and maximum values are quoted; [f] Yarkony[104] used the experimental geometry corresponding to poly-TS and poly-TCDU; [g] the scatter of the values is associated with the different geometries chosen for the molecule for which the calculations were made; [h] the gap widths determined from the positions of the optical absorption maxima are quoted; the width of the forbidden gap is greater by several tens of electron-volts; [i] the literature data are quoted in Section V of this review.



The range of suitable methods for the study of the electronic structure of PDA is fairly broad: from the simple free electron in a potential box and Hückel methods to non-empirical calculations. Attention has been concentrated in the calculations on the correct description of the energy of the longest-wavelength optical transition. A satisfactory description of this quantity is usually regarded as one of the principal criteria of the applicability of a particular computational method. The results of the calculations of the width of the forbidden gap are presented in Table 2. Evidently

satisfactory optical excitation energies are obtained, as was to be expected, only in calculations which include the configurational interaction, which takes into account partly the electron interaction. Much attention has also been devoted to questions of the relative stabilities of structures (A) and (B) and a correct description of the behaviour of the energy gap in the excitation spectrum in the transition (A) → (B). The ground state of the PDA chain is structure (A). A non-empirical calculation[110] with the optimisation of bond lengths and angles in terms of the 7s/3p basis set showed that structure (A) is more stable by approximately 50 kJ mol^{-1} per C_4H_2 unit than structure (B). In order to understand the nature of this transition, it is necessary to go beyond the limits of the Hartree–Fock approximation.

As an illustration of the relative nature of the concepts concerning structures (A) and (B) of the PDA chain which have been introduced, Table 3 presents the experimental and calculated bond lengths in real and model PDA. It is evident that, although poly-PTS, poly-DCHD, and poly-HDU have been arbitrarily assigned to the (A) type while poly-TCDU and poly-BPG have been assigned to the (B) type, nevertheless the bond lengths in polymers of both types are fairly remote from the theoretical values calculated for the model compounds.

Theoretical studies have led to certain general conclusions. The long-wavelength optical absorption has an exciton character. The difficulties associated with the correct description of the behaviour of the energy gap in the (A) → (B) transition indicate a number of factors which have not been taken into account, such as the influence of the intramolecular and intermolecular forces in the interaction between chains and also the influence of substituents. If the overall energy of the crystal is divided arbitrarily into two components—the electronic energy and the crystal field energy, then the above effects can in fact be attributed to the crystal field energy.

Table 3. The carbon–carbon bond lengths in the main chains of various PDA determined by X-ray diffraction (in accordance with Karpfen's data[110]) and calculated by the *ab initio* method in terms of the STO-3G basis set for the "ideal" structures (A) and (B)[108]

Polymer	r_1, Å	r_2, Å	r_3, Å
Poly-PTS	1.19	1.43	1.36
Poly-DCHD	1.21	1.44	1.33
Poly-HDU	1.21	1.41	1.36
Poly-TCDU	1.24	1.37	1.44
Poly-BPG	1.29	1.38	1.42
Structure (A)	1.20	1.45	1.34
Structure (B)	1.26	1.35	1.48

At the present time there are no theoretical methods whereby one could calculate simultaneously and with self-consistency both energy components. It is therefore necessary to justify model concepts which makes it possible to take into account in the first place the intermolecular interactions and their influence on the electronic structure of PDA. Numerous experimental results have shown that the forces governing these interactions are fairly large.

V. THE OPTICAL PROPERTIES OF POLYDIACETYLENES

The intense optical absorption of photons with an energy of approximately 2 eV ($\lambda_{max} \cong 620$ nm) is due to the presence of the conjugation system in PDA and in this sense the latter resemble polyenes[96]. However, in contrast to the optical spectra of the known polymers with conjugated bonds, having a broad structureless maximum and a long-wavelength absorption "tail",[113] the PDA spectra have characteristic features whose broad outline can be seen from Fig. 6.[114] The anisotropy of the crystal structure of PDA is responsible for the anisotropy of virtually all the physical properties including optical properties. The optical absorption therefore depends on the polarisation of light relative to the crystallographic axes. For light polarised parallel to the plane of the conjugation chain, a sharp absorption edge is observed in the region of approximately 2 eV, where a fairly narrow maximum is observed in reflection spectra. The smallest energy of the optical transition in solid PDA (approximately 1.89 eV) has been obtained for poly-DCHD.[115] The degree of dichroism of PDA single crystals is fairly large; thus in the case of poly-TS, for light polarised approximately parallel to each of the three principal crystallographic axes, the absorption coefficients at $h\nu \cong 2$ eV are respectively 9×10^5, 2×10^3, and 5 cm^{-1}.[5] Analogous results have been obtained for other PDA[89,115,118]. For partly polymerised specimens, the edge of the absorption band and the reflection maximum are more diffuse[114], but their positions are related to the kinetic polymerisation curve: at the instant when the autocatalytic stage begins, there is also a sharp bathochromic shift of the absorption edge and reflection maximum frequencies[119].

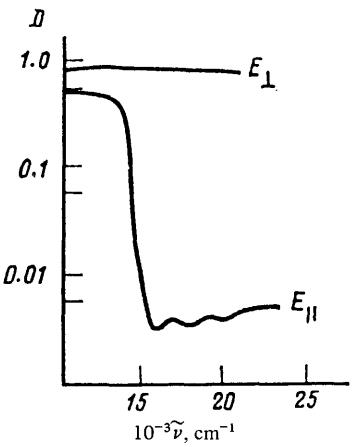


Figure 6. Optical transmission spectrum of a single crystal of poly-TS for light polarised parallel ($E_\parallel$) and at right angles ($E_\perp$) to the *b* axis.[114]

The initial DA are usually colourless or only slightly coloured. Changes in the colour of the partially polymerised DA are already observed for a monomer conversion of approximately 0.01%, since the molar absorption coefficient of

PDA is very high ($\varepsilon \geq 1.7 \times 10^4$ dm^3 mol^{-1} cm^{-1}).[120,121] As polymerisation proceeds, the colour deepens and at the end of the polymerisation reaction the PDA usually has a metallic lustre with various colour tints. In terms of colour and other optical characteristics, PDA can be divided into two categories. The first includes PDA coloured reddish-gold and the second PDA coloured green and blue. PDA with sulphonate substituents (poly-TS, poly-MBS) belong to the first category and those with urethane substituents (poly-TCDU, poly-ETCD, etc.) belong to the second[122]. The number of methylene groups in the diacetylene $X-(CH_2)_n-C\equiv C-C\equiv C-(CH_2)_n-X$, separating the functional groups X (urethane, sulphonate etc.) and the triple bond, is apparently more important for the colour of PDA than the type of substituent[8]. Thus the majority of partly polymerised DA with $n = 1$ and 2 are red and those with $n = 3$ and 4 are blue.

In order to extend the range of the colour changes, DA with the chromophoric azobenzene groups $-C_6H_4N{=}NC_6H_5$ in the side chains have been synthesised[43]. At a low degree of conversion, the colour of the DA is determined by the chromophores. The partly polymerised DA has a colour which is determined both by the chromophores and by the absorption due to the conjugation chain. At a degree of conversion $\gtrsim 10\%$, the colour is determined mainly by the absorption due to the conjugation chain in the macromolecule formed.

Various optical methods, mainly transmission or reflection spectroscopy, have been used to investigate PDA. For a fully polymerised specimen, the depth of penetration of light in the most interesting spectral region is approximately only 100 Å,[16] which imposes definite limitations on the applicability of the technique of transmission spectroscopy. With the aid of this method, the greatest reliability of the results is achieved in the study of specimens with low (approximately 1%) degrees of conversion. Parameters such as the absorption band shape, the absorption coefficient, and others are then measured directly.

On the other hand, the possibilities of reflection spectroscopy are manifested most effectively in the study of specimens with a high degree of conversion. The determination of the spectroscopic parameters involves in this instance the application of the Kramers–Kronig dispersion relation between the real and imaginary components of the complex dielectric constant. The procedure whereby the absorption spectrum is deduced from the reflection spectrum with the aid of the dispersion relation is not unambiguous, since there is an uncertainty associated with the necessity for extrapolations. However, the results obtained with the aid of transmission and reflection spectroscopy agree[116].

The long-wavelength optical absorption was initially attributed to the direct interband electron transition from the valence to the conductivity band, which was seemingly confirmed by the analysis of the optical absorption line forms of certain PDA.[114,123–126] This analysis indicated the existence of a one-dimensional Van Hove singularity, which arises in a vertical interband transition when there is a plateau on the dispersion curve relating the energy to the wave vector.

On the other hand, there exists much evidence supporting the view that the long-wavelength edge of the optical absorption band is associated with exciton absorption. One of the most important indirect arguments in support of this view is the absence of photoconductivity at the optical absorption edge of PDA[127,128] and the hypsochromic shift of the maximum in the photoconductivity spectra relative to the maximum in the absorption spectrum. The magnitude of this shift is 3000 cm^{-1} for poly-TS[127] and is anomalously large (approximately 15000 cm^{-1}) for poly-CDU.[117] Consequently the long-wavelength optical absorption gives rise to an excited state. This excited state is most probably an exciton. The evidence in support of the exciton nature of the absorption is also provided by the lateral phonon bands in the optical absorption spectra and by the resonance Raman scattering[114]. Apart from indirect data, there exists also direct experimental evidence that the long-wavelength optical absorption in PDA has an exciton character. Surface exciton states have been observed for poly-TS[129,130] and the method of electric field-modulated reflection spectroscopy yielded analogous results: the width of the forbidden gap is $\Delta E = 2.44$ eV for poly-TS[131,132] and $\Delta E = 2.335$ eV for poly-DCHD[133]. The reflection spectra of both polymers showed a signal due to the exciton absorption for an energy smaller by 0.48 eV than the width of the forbidden gap[134]. Identical results have been obtained in the study of poly-TS in polarised thermo-reflection#. In this method the temperature of the specimen is modulated (frequency ~ 1 Hz, amplitude ~ 1 K) and derivatives of the absorption spectrum in polarised light are recorded. This method is extremely sensitive, particularly in relation to the temperature-dependent regions of the TS spectrum. The following data have been obtained with its aid: the exciton absorption begins with an energy of 2.00 eV and the width of the forbidden gap is 2.44 eV. The results of the analysis of the optical absorption line form near its absorption edge have also been revised recently. It has been found that the asymmetric Lorentz form, corresponding to the exciton model, provides the best description of the experimental line[5,116,135]. A similar ambiguity in the treatment of the line form also arose in connection with the narrow energy range in which linearisation was carried out and with the errors associated with this factor.

An interesting feature of the TS monomer and of its partly and fully polymerised specimens is that at low temperatures all the lines observed in the optical absorption and reflection spectra[123,126,136–138], the piezomodulated absorption spectra[136], the Raman spectra[138], and the EPR spectra[76] are divided into doublets. The splitting is observed down to the very lowest degrees of conversion (1%)[138] and even for the pure monomer[38]. The splitting in the optical spectra at 300 K is almost zero, but increases monotonically with decrease of temperature, amounting to 30 meV at the helium temperatures. Line splittings are not observed in the optical spectra of other PDA[115,117,124,125]. In order to explain this phenomenon, it is necessary to answer two fundamental questions: firstly what is the nature of the splitting of the bands and secondly why is it observed only for TS and its polymer.

The first attempts to account for the band splitting were made on the basis of X-ray diffraction data. It was established that the size of the unit cells of TS and its polymer is doubled in the low-temperature phase along the *a* crystallographic direction[135,140,141]; the number of monomeric units in the unit cell of the crystal is also doubled, which can be explained by the changes in the distances between the monomeric units in pairs owing to the reorientation of the substituents[141,142]. As a result, each of two types of molecules has a different environment and in such a situation it is logical to expect the splitting of all the observed lines to give doublets.

It has been suggested that the observed transition is a second-order phase transition[142,144]. In the study of this phase transition by spectroscopic methods[142,143], the critical

See S.Stizza, I.Davoli, V.Prantera, A.Bianconi, J.Glinski, and J.Kalinowski, J.Phys.C., Solid State Phys., 1983, **16**, 2165.

parameters were determined and an attempt was made to determine the order parameters. Comparison with the available exact results based on the theory of critical phenomena established that the two-dimensional phase transition apparently takes place at low temperatures, acquiring a three-dimensional character in the vicinity of the critical temperature. The broad temperature range of the transition indicates the important role of fluctuations. Regions with an altered orientation of the groups arise at random throughout the bulk of the specimen and are of the fluctuation type, so that reorientation is hardly likely to occur simultaneously. The character of the temperature dependence of the line splitting of the spectra (the logarithm of the splitting energy varies linearly with the lattice parameter along the *c* crystallographic direction) shows that the splitting is two- or three-dimensional[145].

In order to identify the nature of the band splitting in the spectrum of poly-TS, the PFBS monomer, isomorphous with TS, in which the intermolecular interaction is stronger owing to the presence of the fluorine atom which also has a van der Waals radius close to that of the methyl group, was synthesised[146]. However, it was found that, although the optical and Raman spectra of poly-TS and poly-PFBS are virtually identical at 300 K, there is no band splitting in the spectrum of poly-PFBS even at low temperatures[139]. Clearly the band splitting is not associated with the intermolecular interaction of the polymer chains[147,148] and is due to the existence of two types of polymer chains having different environments.

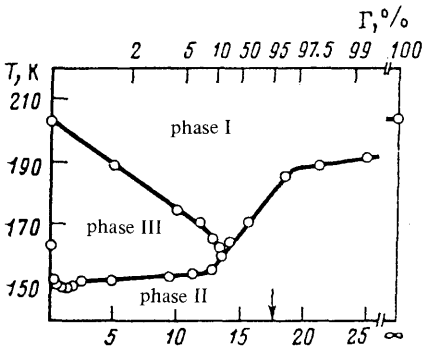

Figure 7, Phase diagram of partly polymerised TS.[154] The arrow denotes the instant of the maximum rate of polymerisation (at 60 °C) during the autocatalytic stage; phase I—single crystal with two monomeric units ($z = 2$) in the unit cell; phase II—$z = 4$; phase III—incommensurable phase.

The situation became more complex and more difficult to explain when yet another, third stable phase, corresponding to an incommensurable modulated structure, was observed in the spectrum of TS for a degree of conversion < 50%[150-152] (Fig.7). The temperature range corresponding to the existence of this phase is a maximum for a low degree of conversion (~ 1%) and is between 163 and 206 K, becoming gradually narrower with increase of the degree of conversion and disappearing in the autocatalytic stage. According to X-ray diffraction data, the incommensurable phase is modulated with a wave vector $\mathbf{q} = \frac{1}{2}\mathbf{a}^* + (T)\mathbf{b}^*$,[153,154] where the lattice period along the *b* direction depends on temperature. The intensities of the corresponding satellite lines in X-ray diffraction vary in accordance with the law $(T_c - T)^{2\beta}$, where $\beta = 0.43$ and $T_c = 199.2$ K. The critical exponent for the specific heat is approximately 0.7, which is too large for any simple model[150].

Two features of the incommensurable phase were observed by low-frequency polarised Raman scattering: (1) at temperatures approximately 15 K below the critical temperature, the existence of a soft mode (amplitone) was observed, the mode becoming softer as T_c is approached from the low-temperature side; (2) the line observed at 13 cm^{-1} is characteristic only of the incommensurable phase[153]. The first feature shows that for $T < T_c$, there is a mutual displacement of the monomeric units or parts from the latter relative to one another. When static shifts of this kind become commensurable with the average phonon vibration amplitude, the multiphonon scattering process is transformed into first-order Raman scattering, which is the reason for the appearance of the line at 13 cm^{-1}.[153]

In the study of the pyroelectric effect for TS along the *b* direction over a wide range of degrees of conversion, it was found that, when the temperature is altered, the pyroelectric coefficient has maximum values near the phase transition temperatures[155]. The phase transition temperatures agree well with those obtained previously[154]. The existence of the pyroelectric effect shows that the crystal loses its centre of symmetry and that the extent to which central symmetry is lost is a maximum near the critical temperatures, possibly owing to the occurrence of macroscopic fluctuations.

Anomalies have also been observed in the rate of propagation of sound§, showing that the phase transitions in the monomeric TS single crystal occur at 159 and 192 K and those in the polymer occur at 196 K.

Sharp phase transitions were detected with the aid of the methods enumerated above as the temperature was varied; however, the optical splitting varies smoothly with temperature. The causes of such behaviour are still obscure. Nor is the detailed nature of the formation of the incommensurable structure itself in TS and its partly polymerised crystal clear. It may be that the identity of the modulation wavelength of the incommensurable structure (b^*/δ) with the chain length of the polymer during the inductive period is not fortuitous[28].

(a) Thermochromism and Solvatochromism

The phenomenon of thermochromism, i.e. the change in colour with temperature, is normally confined to the bisurethane polymeric derivatives of diacetylene; poly-TCDU[117,156,157], poly-ETCD[158,159], and others. For example, the crystal of poly-ETCD is green in reflected light at a temperature below that of the colour transition, while above the transition temperature it acquires reversibly a red colour[158]. Changes in the reflection spectrum appear at 115 °C and cease at 130 °C. Subsequently on heating to 180 °C, no changes take place in the spectra. The shift of the maximum in the reflection spectra of poly-ETCD is hypsochromic and amounts to approximately 2750 cm^{-1}. With decrease of temperature the reverse colour change occurs at a temperature (approximately 70 °C) differing greatly from that of the forward transition. Such marked hysteresis is typical for thermochromism in PDA and is evidence for the occurrence of a first-order phase transition. The observed thermochromic transition is multiply reversible. Thermochromism is observed not only for single crystals[33,160] but also for amorphous film and solutions[89,161-163].

§ See W.Rehwald, A.Vonlanthen, and W.Meyer, Phys. Stat.Solidi, 1983, **B.A75**, 219.

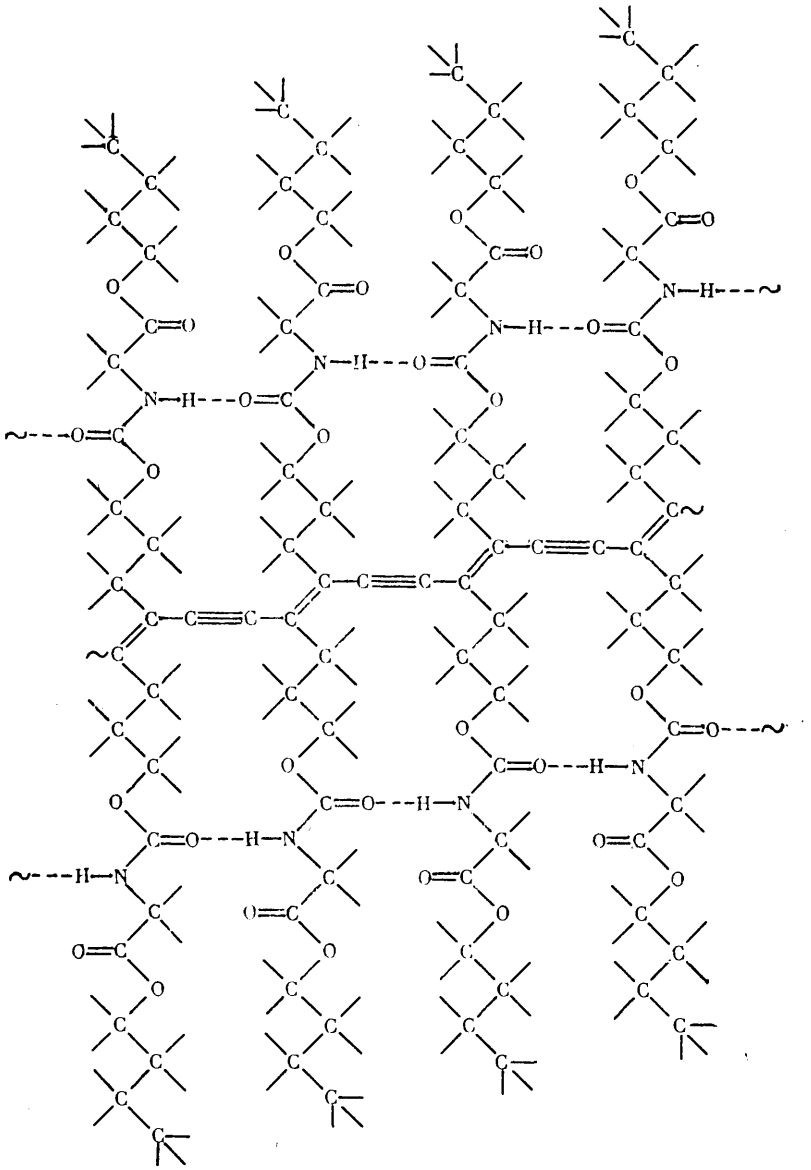

Figure 8. A fragment of the chain of poly-3BCMU in the planar conformation; the intramolecular hydrogen bonds are shown dashed[121].

For partially polymerised *n*ACMU (n = 3,4; A = E,B) and a degree of conversion of approximately 5%, the changes in colour from dark-blue to red with increase of temperature to the melting point take place smoothly. For fully polymerised specimens, the colour changes take place abruptly, over a range of approximately 5 K, and only two colour transitions are observed (Table 4). Two endothermic peaks at the temperatures corresponding to the colour change have also been observed by differential scanning calorimetry[164]. The first endothermic peak is associated with the fusion of the polymer, which remains oriented due to hydrogen bonding. The second endothermic peak is associated with the rupture of the hydrogen bonds and the complete fusion of PDA[165]. Fig. 8 presents as an example a fragment of the chain of poly-3BCMU with intramolecular hydrogen bonds. The shift of the maxima in the reflection spectra of substituted bisurethane PDA in thermochromic transitions is approximately 3000 cm^{-1} and with increase of temperature the position of the maximum changes from 15500 to 18500 cm^{-1}.[89,117,158] Sometimes the shift of the maximum can approach 5000 cm^{-1}.[121]

The temperature range in which thermochromic transitions are observed for PDA is fairly broad and is not limited to positive temperatures. Changes in colour are observed for a series of PDA down to approximately −200 °C.[8] For example, the majority of the red PDA gradually change colour to blue on cooling to the temperature of liquid nitrogen. However, these transitions are not phase transitions, in contrast to those in the high-temperature range.

It is noteworthy that there is one exception here. The DCHD single crystal undergoes a first-order phase transition

at atmospheric pressure and a temperature of 142 K with a sharp colour change[167]. At this temperature the crystal contracts along the *b* axis by approximately 8% and its density increases by approximately 5%¶. Owing to the large change in density at the phase transition point, the transition is very sensitive to pressure: its temperature increases by approximately 300 K at a pressure of 300 MPa.

Table 4. The thermochromism of poly-*n*ACMU with the substituents R = R′ = $(CH_2)_nOCONHCOO(CH_2)_mH$.[33]

Polymer	*m*	*n*	Temperature of colour transition, °C	
			gold-green → red	red → yellow
Poly-4BCMU	4	4	112	136
Poly-3BCMU	4	3	160	183
Poly-4ECMU	2	4	118	137
Poly-3ECMU	2	3	192	—

[11] См. *Rehwald W., Vonlanthen A., Meyer W.* Phys. Stat. Solidi 1983, B. A75, S. 219.

Soluble PDA have been obtained from DA with urethane substituents. Depending on the changes in the external conditions (temperature, solvent, pH of the medium), numerous phase transitions, called a "transition tree", have been obtained for solutions of these polymers[166]. The total number of transitions involving a colour change is approximately 15. In the series of soluble PDA, the colour transitions have been most thoroughly investigated for poly-*n*ACMU[33,120,167].

The solvatochromism of solutions of these polymers has been investigated under the conditions of changes in the solvent/non-solvent volume ratio, for example, the chloroform/hexane ratio[33,89,120,121,162,167]. The colour of a solution of poly-3BCMU in pure chloroform is yellow. When hexane is added in an amount sufficient to give a composition with 75 vol.% of chloroform, the colour remains unaltered. On further decrease of the relative content of chloroform to below 75 vol.%, there is a sharp colour change to blue and a blue precipitate is deposited (the colour changes are sharp, so that the titration method can be used). The maximum in the absorption spectrum of poly-3BCMU shifts from 21300 cm^{-1} (yellow solution) to 15900 cm^{-1} (blue solution)[167]. The absorption maximum of the blue solution (15900 cm^{-1}) constitutes the absorption limit for a polyene and PDA of infinite length[96]. Analogous colour changes have been observed for a solution of poly-TCDU[168]. Detailed studies of the solvatochromic transitions of poly-3BCMU in a chloroform/hexane mixture showed[91] that the solvent/non-solvent ratios at which colour changes occur differ in the forward and reverse titrations.

Another possible way of influencing the colour of the solutions is by altering the pH of the medium for water-soluble PDA with the substituents $(CH_2)_nOCONHCH_2COO^-K^+$ (n = 3,4) and $(CH_2)_nCOO^-K^+$ (n = 1,2).[169,170] When the pH changes from 9 to 3, the colour of the solution changes from yellow to red or purple.

¶ See D.Bloor, I.F.Chalmers, R.J.Kennedy, and M.Motevalli, Mol.Cryst.Liq.Cryst., 1983, **93**, 215.

An isosbestic point is frequently observed for the thermochromic and solvatochromic transitions, indicating the absence of intermediate products in transitions between two forms of different colour[161,162,169].

It has been suggested that the solvatochromic transitions in PDA solutions have the following cause. In a "poor" solvent or a weak electrolyte, the macromolecules have a planar arrangement of their skeleton, which is additionally stabilised by intramolecular hydrogen bonds (see Fig.8). When a "good" solvent is added or with increase of the concentration of ions in solution, these bonds are ruptured and the planar conformation breaks down, which leads to an alteration of the optical properties[120,121,161,167]. The hypothesis of the existence of planar PDA chain conformations has been confirmed experimentally by viscometric[91] and light scattering[92] methods. The conformational changes lead to statistically distributed breaks in the conjugation chain when the polymer skeleton rotates relative to single bonds and a distribution with respect to effective conjugation lengths l_{eff} arises[121]. Comparison with the spectra of model conjugated molecules has led to the estimate $l_{eff} \gtrsim 30$ repeat units for blue PDA (600 nm < λ_{max} < 700 nm), 20 < l_{eff} < 30 for red PDA (500 nm $\lesssim \lambda_{max} \lesssim$ 600 nm), and l_{eff} < 6 for yellow PDA (400 nm $\lesssim \lambda_{max} \lesssim$ 500 nm)[8].

The method of photoselection with the aid of Raman scattering was used to justify this hypothesis experimentally[171,172]. It is assumed that one conformationally disordered polymer chain consists of a set of chromophores differing in l_{eff} and having as a result different vibrational spectra. The observed absorption band consists of an inhomogeneously broadened line with contributions due to different chromophores. Analysis of the line shape in different solvents where PDA has different colours made it possible to determine the distribution of l_{eff} for the same polymer having, however, different conformations.

Evidently the thermochromic transitions in the crystallised state of PDA cannot be explained by changes in the conformations of the macromolecules. The initial explanation of the thermochromism was based on the hypothesis that this phenomenon is associated with transitions between the mesomeric structures (A) and (B) in the polymer chain[117,118,158]. Indeed the optical absorption spectrum of poly-ETCD at a temperature below the transition point resembles the spectrum of poly-TS for which the structure (A) of the polymer chain has been established. Above the transition point, the spectrum of poly-ETCD resembles that of the poly-DCHD, which has a structure of type (B).

Another view on the cause of the changes in the optical properties of PDA involves the hypothesis that they are determined by the strain in the macromolecular chain and hence by its deformation[173]. Similar deviations from equilibrium bond lengths in a conjugated polymer chain arise owing to interactions of the substituents. The absorption energy of "free" PDA in solution in the equilibrium conformation is approximately 2.4 eV. The smaller value observed in films and crystals is due to the stress applied to the polymer chain as a result of intramolecular and (or) intermolecular interactions of the side groups[4]. The most important causes responsible for the position and form of the optical absorption band are, firstly, the statistical (time-average) deformation of the polymer skeleton and, secondly, dynamic deformation. Whereas the first cause determines the position of the band and its inhomogeneous broadening, the second determines the homogeneous (temperature-dependent) band width. A large inhomogeneous band width can be observed in highly strained or disordered systems[173] and the change in optical absorption takes place owing to the homogeneous band broadening[93]. In other words, it is assumed that the

conjugated PDA chain is rigid and does not undergo conformational changes, while alteration in external conditions leads to the appearance of only a gradual deformation of the bond lengths in the chain. It may be that the thermochromic transitions in the solid PDA are associated with the trans-orientation or a change in the packing of the substituents, which leads to the deformation of the conjugation chain and changes in the electronic structure and colour.

Apart from the thermochromic and solvatochromic phenomena described above, there are a series of physical and chemical transformations of DA and their polymers accompanied by a change in colour[8]. These include the fusion of PDA, the extraction of the monomer from partly polymerised DA, and others. A correlation is almost always observed between the number of methylene groups N_{CH_2} joining the DA triple bond to the functional group and the observed colour transition. For example, in the extraction of the monomer from partly polymerised DA, red specimens with $N_{CH_2} = 1$ and 2 remain red, while blue specimens with $N_{CH_2} = 1,2,4$ become red ($\lambda_{max} = 530 \pm 10$ nm). Thus, regardless of the initial colour, the extraction of the monomer leads to the appearance of a red colour. On the other hand, the extraction of the solvent from partly polymerised DA with $N_{CH_2} = 3$ does not affect the colour. Apart from the colour changes, a correlation has been observed between the number of methylene groups and the solubility and fusibility of PDA[8]. Almost all PDA with $N_{CH_2} = 1$ are infusible and decompose on heating without melting; they are also insoluble in the usual organic solvents. An increase in the number of methylene groups leads to an improvement of fusibility and solubility. Almost all PDA with $N_{CH_2} = 4$ melt and the majority of them are soluble.

(b) Fluorescence

Like the model long polyenes, fully polymerised PDA specimens do not fluoresce. The exceptions are the radiation-polymerised BPG[125], PDA with defects[125,174,175], certain soluble PDA[169,170], and also PDA with chiral substituents in only one of the reactive phases[121].

The causes of the absence of fluorescence of the fully polymerised specimens are obscure, but they can be as follows[168]: (1) the high efficiency of the absorption of the emitted light quanta (reabsorption of light) owing to the small depth of penetration by light which is only 10–100 nm; (2) non-radiative processes in the deactivation of excitation; (3) the transmission of excitation to low-lying energy states from which emission takes place but which have not so far been detected experimentally; rapid intersystem crossing to a triplet level, whose energy is less than half the width of the forbidden gap, and subsequent non-radiative decomposition with emission of phonons may constitute this process.

Some of the monomeric DA are phosphorescent. For example, DCHD phosphoresces with a well-resolved spectrum corresponding to emission from four traps, whose depths are 2.8, 8.7, 27.8, and 45.7 meV.[68] It has been assumed[68] that these traps are populated and liberated via a triplet exciton band. Direct emission from this band cannot be detected for some reason. The arrangement and concentration of the traps are not random, since the ratio of the phosphorescence band intensities is the same for different specimens. The time of emission from the traps is less than 7 s. It has been suggested that the traps have a triplet spin polarisation.

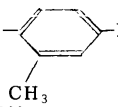
Almost nothing is known about the nature of the broad fluorescence bands of the DCHD monomer. From the instant of the beginning of polymerisation, both the phosphorescence and fluorescence are fully absorbed by the conjugated polymer skeleton[176]. Certain partly polymerised PDA do fluoresce. Thus the partly polymerised TS specimen gives rise to a fairly satisfactory fluorescence spectrum[175]. On excitation with light (at 4.2 K), two emission bands were observed at 20486 and 20802 cm^{-1} accompanied by vibrational side bands. The emission band frequencies are displaced by approximately 4000 cm^{-1} towards shorter wavelengths relative to the optical absorption edge of the polymer. Furthermore, four additional emission bands are observed whose wavenumbers $\tilde{\nu}_{fl}$ are related to the wavenumber of the exciting light $\tilde{\nu}_{exc}$ by the simple expression $\tilde{\nu}_{fl} = \tilde{\nu}_{exc} - \tilde{\nu}_i$, where $\tilde{\nu}_1 = 988.7$, $\tilde{\nu}_2 = 1227$, $\tilde{\nu}_3 = 1513$, and $\tilde{\nu}_4 = 2085$ cm^{-1}. The ν_i were assigned to the vibrational energies of the excited state of the fluorescent centre. It is surprising that these quantities, which refer to an excited state, agree well with the vibrational energies of the ground state of the chain observed with the aid of Raman spectroscopy: 955, 1205, 1487, and 2088 cm^{-1}.[177]

The spectroscopic characteristics of the fluorescence of the partly polymerised poly-TS are independent of the type of specimen (single crystal, polycrystalline material, or powder). The observed fluorescence is attributed to the geometrically and energetically localised states. The concept of geometrical localisation arose owing to the dependence of the fluorescence intensity on the position of the laser spot of the exciting light on the surface of the crystal. On passing from one irradiated site to another, the fluorescence intensity can then change by a factor of 100 and the maximum intensity is observed when the boundaries between the crystals are irradiated. The energetic localisation is understood as the absence of an energy linkage between the fluorescence centres and the polymer chain[174].

In order to elucidate the role of defects in fluorescence, a study has been made[174] of a specially prepared poly-TS specimen with a large number of defects[174]. The absorption spectra recorded at 4.2 K showed new (relative to the defect-free specimen) bands; two narrow bands (at 20665 and 21050 cm^{-1}) and two broad bands (at 20500 and 20830 cm^{-1}). The positions of the last two bands coincide with those of the fluorescence bands. It is not clear why fluorescence is observed for only one of the pairs of bands observed in absorption.

As regards the nature of the fluorescent centres, it has been suggested that they may consist of triplets at the end of the polymer chain which have become frozen in the ground state. In this case the absorption and fluorescence are associated with the allowed $T-T$ transition[175]. The fluorescence of solutions is determined by sections of the polymer with disrupted chain conjugation[169].

(c) Non-linear Optical Properties



The tensor molecular polarisability $\mathbf{P}$ and the applied electric field $\mathbf{E}$ are linked by the relation $\mathbf{P} = \chi^{(1)}\mathbf{E} + \chi^{(2)}\mathbf{E}^2 + \chi^{(3)}\mathbf{E}^3$, where $\chi^{(1)}$ is the coefficient of the linear optical susceptibility and $\chi^{(2)}$ and $\chi^{(3)}$ are the coefficients of the non-linear second- and third-order optical susceptibilities respectively. For centrally symmetrical molecules, to which the vast majority of PDA belong, $\chi^{(2)} = 0$. In calculations based on the perturbation theory using the free electron model, $\chi^{(3)} \propto L^5$, where L is the length of the conjugation chain in the linear molecule[178], while in calculations based on the π-electron approximation $\chi^{(3)} \propto N_d^6$, where N_d is the electron localisation parameter[179]. It has been shown experimentally that $\chi^{(3)}$ does not increase with increasing conjugation chain length as rapidly as predicted by the theory. The

explanation is that the real electron potential is periodic, for example, owing to the alternation of the bond lengths, the degree of delocalisation of electrons is therefore smaller than in the free electron model[178].

The non-linear optical susceptibility coefficient is fairly high for PDA single crystals. Thus $\chi^{(3)} = 7 \times 10^{-11}$ CGS units for poly-TCDU and $\chi^{(3)} = 8.3 \times 10^{-10}$ CGS units ($\lambda = 1.89$ μm) for poly-TS.[178,180] The electrical breakdown parameter for PDA is very high. For poly-TCDU it is 50 GW cm^{-2} in the picosecond range, which is higher by a factor of 20 than for germanium. If one considers the quality parameter defined as $\chi^{(3)}/n^2$ (n is the refractive index), the latter is found to be 1.1×10^{-11} for poly-TCDU and 4.5×10^{-10} for poly-TS, compared with, for example, 2.5×10^{-11} for germanium and 0.45×10^{-11} for gallium arsenide (all the values are expressed in CGS units). Multilayers based on DA also possess non-linear optical susceptibility†. $\chi^{(3)} = (0.67 \pm 0.20) \times 10^{-12}$ CGS units for the ammonium salt $CH_3-(CH_2)_{17}-C\equiv C-C\equiv C-COO^-NH_4^+$, which yields $\chi^{(3)} \cong 1.34 \times 10^{-11}$ CGS units when account is taken of the degree of conversion.

The non-linear optical properties of solutions of poly-3(4)BCMU have been investigated by the method of three-wave mixing, in which two light beams from laser sources with frequencies ω_1 and ω_2 were directed onto the specimen and the generation of light with the frequency $\omega_3 = 2\omega_1 - \omega_2$ was observed[181-184]. It was found that there is a large contribution by the direct two-photon absorption with a cross-section β to the third-order non-linear optical susceptibility coefficient. The value obtained for a solution of poly-4-BCMU is $5 \times 10^{48} \lesssim \beta \lesssim 10^{-46}$ cm^4 s photon^{-1} (chain unit)$^{-1}$, which is the highest known value, much greater than, for example, that for CS_2, where $\beta \cong 5 \times 10^{-49}$ cm^4 s photon^{-1} molecule^{-1}.

The occurrence of the two-photon absorption and its large cross-section can limit the application of PDA as active elements in non-linear optics. On the other hand, studies of poly-TS and poly-TCDU single crystals have led to the hypothesis that the observed absorption is not a two-photon process and is more likely to be a two-stage process: the absorption of the first photon creates a defect in the conjugation chain, for example, by transition of an electron to a localised orbital; the absorption of the second photon is associated with a transition whose initial or final state is a newly formed defect[185]. Subsequent experiments should provide an answer to the question of the role of the two-photon absorption and its nature and hence of the practical value of PDA from the standpoint of their application in non-linear optics.

In order to expand studies on the non-linear optical properties of PDA and of their possible applications, asymmetric DA[186,188] and DA with chiral substituents[21,189] have been synthesised. The generation of a second harmonic has been observed for DA with R = CH_2NH–  –NO_2 and R′ = $(CH_2)_8CONHC_2H_5$ and its polymer[188]. The possibility of using multilayers based on PDA in integrated non-linear optics and also in light guides has also been considered[190].

VI. ELECTRON PARAMAGNETIC RESONANCE IN POLYDIACETYLENES

During the polymerisation of diacetylenes, considerable changes take place in the EPR spectrum. In the initial polymerisation stage several lines are observed, many of which are characterised by the anisotropy of properties as a function of changes in the mutual orientations of the external magnetic field and the crystal[46]. As polymerisation reaches completion, the number of lines and the overall paramagnetic susceptibility diminish until a single weak signal, characteristic of all polyconjugated systems, remains when almost 100% conversion of the monomer is reached[48]. Such a change in the EPR spectrum on polymerisation is explained by the fact that in the initial polymerisation stage the main contribution to absorption comes from the active species at the end of the growing chains, while after the completion of polymerisation the EPR signal is determined by the paramagnetic species bound to the polymer chain. In conformity with such subdivision, the study of the EPR parameters in the initial polymerisation stage can yield information about the polymerisation kinetics and about the structure of the active centre propagating the chain, while the conformational structure of the polymer chain can be investigated by studying the EPR spectrum after the end of polymerisation.

The observed EPR spectrum in the initial polymerisation stage can be described by the spin Hamiltonian $H = \mu_B \mathbf{BgS} + D\hat{S}_z^2 + E(\hat{S}_x^2 - \hat{S}_y^2)$.[46] The g-tensor is almost isotropic and its principal values hardly differ from the g-factor of the free electron. The splitting parameters at zero field on polymerisation of TS and BPG are very similar and amount to $D/hc \cong 0.26-0.27$ cm^{-1} and $E/hc \cong -0.05- -0.08$ cm^{-1}, which indicates the identical mechanism of initiation and the identity of the paramagnetic centres active in polymerisation. The smallness of the parameter E shows that the distributions of the spin density of the carbon atom in the sp-hybridised state along the x and y axes are approximately equally probable.

In the ultraviolet-initiated polymerisation a number of lines in the EPR spectra and the range of variation of the zero field splitting parameters increase. For example, lines due to nine non-equivalent triplet centres have been observed for TS and the following values have been obtained for them: 0.275 $cm^{-1} \leq D/hc \leq 0.367$ cm^{-1} and -0.008 $cm^{-1} \leq E/hc \leq -0.006$ cm^{-1}.[76] The study of the dependence of the line intensities in the EPR spectrum and of the zero field splitting parameters on the degree of polymerisation together with a parallel investigation of the optical properties made it possible to reach well-founded conclusions concerning the nature of the initiating species in the structure of the active polymerisation centres. During the ultraviolet polymerisation of BPG, optical spin polarisation is observed[191]. The proposed mechanism of this phenomenon consists in the absorption of light (280 nm $\leq \lambda \leq$ 370 nm) by the benzene ring of the substituent and the subsequent triplet energy transfer to the conjugated chain via intersystem crossing $S_1 \rightsquigarrow D_0$, where S_1 is the excited singlet state of the benzene ring of the substituent and D_0 the triplet state of the DA molecule. As a result, two new emission lines are observed in the EPR spectra. Optical electronic spin polarisation ($\lambda < 590$ nm) is observed also for the ground triplet state of the poly-TCDU chain having the structure ~CR–RC=C–C≡CR.[88] The authors explain this phenomenon with the aid of a Jablonski diagram.

As polymerisation proceeds, the intensity of the high field lines, characteristic of the triplet state, diminishes until the ultimate disappearance of the lines at the end of the rapid stage of the reaction. After the completion of polymerisation, a single line remains with a g-factor close to that of the free electron. As in the discussion of the mechanism of the formation of paramagnetic centres in polyconjugated systems, it has been suggested that the paramagnetic properties of PDA are determined mainly by the delocalised structural

† See F.Kajzar and J.Messier, Thin Solid Films, 1983, **99**, 109.

defects of the polymer chain[114] which can have, for example, the following structure:

$$\sim\!=\!RC\!-\!C\!\equiv\!C\!-\!\dot{C}R\!-\!RC\!=\!C\!=\!C\!=\!CR\!-\!RC\!=\!C\!=\!C\!=\!CR\!-\!R\dot{C}\!-\!C\!\equiv\!C\!-\!CR\!=\!\sim\ .$$

It is easy to represent different mesomeric forms of this biradical which correspond to the migration of the free spin along the chain. It is less likely that the paramagnetism is due to inactive radicals at the ends of the growing polymer chains[47].

The parameters of the EPR signal in the fully polymerised PDA specimens are very similar to the known characteristics of the EPR signals for other polyconjugated systems. In particular the g-factor is $g = 2.0023 \pm 0.0002$,[46] the line form at the centre is Lorentzian, the wings have the Gaussian shape[16,46], and the line width, measured between the points of maximum slope, varies from 5 G for poly-TS[46] to approximately 10 G for poly-HD.[16] The concentration of the paramagnetic species depends on the nature of the monomer and amounts to 1.6×10^{17} spins g^{-1} for poly-HD[36] and 8×10^{15} spins g^{-1} for poly-TS.[48] As for other polyconjugated systems, the EPR signal of PDA is readily saturated for low UHF field powers and a relation is observed between the intensity of the EPR signal and the degree of crystallinity (the degree of packing in the case of polyconjugated systems): the greater the degree of crystallinity, the lower the concentration of paramagnetic centres[192].

As for polyconjugated systems, in the case of PDA the previous history of the specimen is found to influence the behaviour of the EPR parameters. This is apparently associated with the slow relaxation of the internal stresses in the crystal and the consequent change in the number of paramagnetic defects in the chain due to this process. A narrow EPR signal ($\Delta B = 0.9$–1.2 G) has been observed for poly-TS in addition to the usual EPR signal[192]. Irradiation of a PDA specimen having $R = CH_2OH$ and $R' = CH_3$ by light at a wavelength $\lambda \cong 700$ nm results in the observation of a narrow signal (< 3 G) in the "tail" of the optical absorption. This signal is of unknown origin, appearing and disappearing reversibly at all temperatures from liquid helium temperature to room temperature. Its lifetime amounts to hours at 4.2 K and seconds at 30 K.[5]

The study of the temperature variation of the EPR signal intensity in poly-TS led to the following results[193]. In the range 90–220 K the paramagnetic susceptibility obeys the Curie law, which indicates a constant density of defects in this temperature range, provided that the PDA paramagnetism is attributed to structural defects. Activated processes, leading to an increase of the number of paramagnetic species, begin above 220 K. In the temperature range 233–353 K the EPR signal intensity is given by the expression $\chi'' = \chi_0''[\exp(-\Delta E/kT)]h\omega/2kT$, where $\Delta E = 75 \pm 25$ meV; this quantity is thought to be related to the activation energy for the formation of mobile paramagnetic defects[46]. The product of the spin–spin and spin–lattice relaxation times T_1T_2 was measured in the same temperature range and it was established that at 250 K there is a fairly sharp change in the law governing the temperature variation of the product of the reciprocals of the relaxation times: $1/T_1T_2 \propto T^{1.8}$ at temperatures below 250 K and $1/T_1T_2 \propto T^{9.3}$ above 250 K, i.e. there is apparently a change in the relaxation mechanism from the direct mechanism at low temperatures (the theoretical power exponent of the temperature is $n = 2$) to a two-phonon Raman mechanism ($n = 9$). Below the transition temperature, the molecular movements of the chains are "frozen", whereupon their densest packing is attained and the number of chain defects is constant. Above this temperature the mobility is "unfrozen" and the number of defects is determined by the temperature. It is apparently not fortuitous that a phase transition associated with the reorientation of the substituents is in fact observed in this temperature range[126,135,138,140,141].

The overall experimental results indicate the dependence of the EPR signal parameters on the nature of the initial monomer, the method used to isolate the polymer, and the previous thermal and morphological history of the specimen[194]. Thus the EPR signal intensity during polymerisation at conversions > 10% can either decrease (TS)[114] or increase (HD)[16]. Such behaviour is attributed to the different degrees of strain in the polymer chains formed, which is greater in the case of HD[16]. This is also indicated by the greater width of the absorption line for HD. It has likewise been suggested that only a small proportion of all the chain defects are paramagnetic while the majority are non-paramagnetic and the chain defects are attributed to the transition from the non-paramagnetic strained state of the polymer chain to a state having a lower energy with breakdown of the conformation and the formation of paramagnetic defects[192]. Different defects, allowed by the topology and symmetry, have been considered theoretically[195].

VII. ELECTROPHYSICAL PROPERTIES OF POLYDIACETYLENES

In terms of their absolute dark conductivity, the PDA are dielectrics. The dark conductivities of polymers obtained from different initial monomers vary from 10^{-16} to 10^{-10} Ω^{-1} cm^{-1}.[69,127,128,196] According to the kinetic analysis of the carriers, the dark conductivity of PDA is due to the ionisation of impurities.[197] Indeed, the dark current is determined by the quality of the crystal and the time for which it is maintained *in vacuo* before the measurements and varies from specimen to specimen. For example, the decrease of the dark conductivity on passing from measurements in air to measurements *in vacuo* amounts to several orders of magnitude[10].

It was later established that the dark conductivity, which obeys Ohm's law like the dark current limited by the space charge, is determined by the localised levels at distances of 0.80 ± 0.02 eV from the edge of the band and their concentration, which corresponds to $\lesssim 1$ centre per meter of the length of the polymer chain[198]. The level with an energy of 0.80 eV functions as the donor for the Ohmic dark conductivity and as a trap for the injected carriers. For all the orientations of the polymer single crystal relative to the external electric field and under all conditions of study, the dark current obeys the law $i \propto \exp(-\Delta E/kT)$, where $\Delta E = 0.80$ eV. The sign of the carrier could not be determined.

By analogy with the familiar results obtained for the doping of polyacetylene, the PDA specimens were also treated with halogen vapours[199]. Thus polyhexa-2,4-diyn-1-ol absorbed iodine vapour in an amount up to 1.2 atoms per unit, forming a lustrous black material. The dark conductivity increased by 6–7 orders of magnitude and in terms of its increment the effect proved almost the same as for $(CH)_x$. The colour of polyocta-3,5-diyne-1,8-diol did not change and its weight did not increase on treatment with iodine vapour or solution, which can be explained by the dense molecular packing of the hydrogen-bonded macromolecules. The diffusion of the large iodine molecules between such macromolecules is greatly hindered. The doping with iodine was carried out for two-layer poly(diacetylenecarboxylic acid) films. In this case the increase of the dark conductivity is not so great and σ increases from 10^{-10} to 10^{-7} Ω^{-1} cm^{-1}. The increase of the conductivity is reversible: after the removal of iodine, the conductivity returns to its initial value[200]. Somewhat better

results were obtained when the doping was carried out before polymerisation. For example, the specific conductance $\sigma = 10^{-4}\ \Omega^{-1}\ cm^{-1}$ was obtained for the TS crystal doped with iodine and polymerised at room temperature[201]. Analogous investigations have been carried out for other DA and the influence of various factors on the specific conductances of the doped polymers was studied.

Numerous studies have been devoted to the photoconductivity of PDA. It was established as a general rule that the maximum on the spectral photoconductivity curve is always displaced towards higher energies relative to the maximum in the optical absorption spectrum. The absolute photocurrent in PDA depends greatly on the nature of the monomer and can vary by several orders of magnitude[2,10,117]. The yields of the photocurrent carriers of both signs are the same, which indicates their dipolar generation[202]. An approximately linear dependence of the photocurrent on the exciting light intensity has been observed[127]. Like other physical properties, the photoconductivity is found to be anisotropic: for light polarised parallel to the chain, the photocurrent is approximately 10 times[158] and the quantum yield in the formation of the carrier is approximately 100 times[203] greater than for the light polarised at right angles to the chain. The ratio of the photocurrent to the dark current at 300 K is approximately 300; it increases with decrease of temperature to approximately 600 at 120 K for an electric field strength of 1300 V cm^{-1}.[127]

The mobility of the carriers, one of the most important characteristics of photoconductors, is unusually high for organic materials and, according to data obtained by different methods for different specimens, varies within wide limits: from 1–5 $cm^2\ V^{-1}\ s^{-1}$ [202–206] to 10^2,[207] 2.8×10^3,[133] 6×10^3,[208] and even $2 \times 10^5\ cm^2\ V^{-1}\ s^{-1}$.[209] The mobilities calculated by quantum-chemical methods are $10^3\ cm^2\ V^{-1}\ s^{-1}$ [97] and $1.7 \times 10^3\ cm^2\ V^{-1}\ s^{-1}$.[107] Other workers[206–210] continue to adopt for the mobilities values in the range 1–10 $cm^2\ V^{-1}\ s^{-1}$. More careful experiments and the theoretical consideration of the mechanism of the formation of the current carriers and the associated kinetics should indicate the true mobility and the causes of such large discrepancies between the experimental values.

Like other physical properties, the mobility is anisotropic $\mu_\parallel / \mu_\perp = 10^2–10^3$.[128,198,203,204] An even greater anisotropy ($> 10^4$) has been found for the microscopic mobility#. The rate of drift of the carriers is in the range from 240 m s^{-1} [204] to 900 m s^{-1},[202] while another study[209] yielded an unexpected result, namely that the rate is constant at 2×10^3 m s^{-1} and is independent of the electric field strength down to the lowest values ($E < 1$ V cm^{-1}) and is comparable to the estimated velocity of sound (5×10^3 m s^{-1}).[42]

According to various estimates, the lifetime of the carriers ranges from $10^{-6}–10^{-8}$ s[128,202,205] to 10^{-13} s.[133] Owing to the differences between the estimated mobilities and lifetimes of the carriers, the estimated length of the free path varies within a wide range: from approximately 10 nm for monolayers and multilayers of cadmium polydiacetylenecarboxylate salts[211] to 1 mm in a single crystal of poly-TS.[207,209] The latter value is in surprisingly good agreement with the average length of the unaffected sections of the polymer conjugation chain (0.1–1 mm) obtained from the measured density of dislocations ($\sim 10^{13}$) m^{-2})[212] and, provided that this agreement is not fortuitous, the length of the free path is limited solely by the dislocations in the single crystal which serve as traps for the carriers. The average length of the carrier path between interactions with acoustic phonons has been estimated as 8 μm.[209] The effective mass of the carrier is surprisingly small ($m^* = 0.05m_0$) for organic crystals[133].

In the study of photoconductivity over a wide range of energies of the light quanta (from 0.62 to 3.1 eV), the principal qualitative characteristics of the behaviour of the spectral curve were elucidated.[207,213] One of the main features proved to be a rapid decrease of photoconductivity at $\hbar\omega < 0.8$ eV, which is consistent with data[198] indicating the existence in PDA of localised impurity levels with the same energy. The spectral photoconductivity curve can be divided into three regions: (1) in the region where $\hbar\omega < 2.0$ eV, photoconduction takes place as a result of the ionisation of impurities; (2) in the region where $2.0 < \hbar\omega < 2.4$ eV, it arises as a consequence of the exciton absorption with subsequent autoionisation of excitons; (3) in the region where $\hbar\omega > 2.4$ eV, direct generation of current carriers in an interband transition is observed. The quantum efficiency of the irradiation is high in the first and third regions and is small in the second region. The photoconductivity maximum in the first region at 1.64 eV[197] is fairly difficult to account for. Nor is it clear whether or not it is fortuitous that the energy of this maximum is approximately equal to twice the energy of the traps.

The one-dimensional conductivity model is valid for the current flowing along the polymer chain[213–217]. According to its electronic properties, PDA belong to the class of semiconductors with broad bands. The existence of bands with a width amounting to several electron-volts has been established for these substances with the aid of calculations and electronic spectroscopy for chemical analysis (ESCA) and electron injection[208] and photoemission[218] methods. However, it is not clear how these results can be reconciled with the high mobility of current carriers observed for PDA which is characteristic only of semiconductors with narrow bands.

Compared with many polymers having conjugated bonds, the PDA have fairly weak electrophysical characteristics. There are several reasons for this. Firstly, the structure of the chain in these polymers is significantly one-dimensional, which leads to the effective recombination of the carriers located on one chain and their consequent low concentration. Indeed not more than two carriers per polymer chain have been observed[209]. Secondly, a pure PDA single crystal contains a very small number of impurities and defects, so that the impurity conductivity is low. Thirdly, a characteristic feature of the optical absorption of PDA is that the probability of the transition to the exciton levels is much higher than that of the direct interband transition. The exciton states lie approximately 0.5 eV below the bottom of the conductivity band and their lifetime is very short. The probability of the thermal ionisation of excitons with formation of free carriers is therefore negligible. These factors create serious difficulties for the practical employment of PDA as photoconductors.

On the other hand, the mobility of the carriers in PDA is very high. Therefore, if it were possible to create a high concentration of carriers (one of the obstacles to this is the one-dimensional character of the polymer chain), one might hope to obtain high electrophysical characteristics of PDA. Another way of increasing the photoconductivity involves the sensitisation of the photoconduction either by means of chromophores constituting a component of the side substituents in the PDA chain or by introducing chromophores capable of cocrystallisation with the DA monomers and the subsequent formation of PDA. In both cases it is possible to achieve a location of the chromophores which is the closest possible to the polymer chain in order to ensure the

---

most effective charge transfer. Furthermore, the introduction of chromophores must not hinder the solid-phase polymerisation and the electronic structure must promote most effectively the sensitisation of the photoconduction in PDA. The first attempt of this kind was undertaken in a study of the photoconductivity of poly-DCHD containing carbazole side groups[219].

It may be that an improvement of the electrophysical properties can be attained by employing isostructural doping (i.e. doping which does not alter the structure of the PDA crystal or multilayers).

VIII. RAMAN SPECTROSCOPY OF POLYDIACETYLENES

The application of the Raman spectroscopic method to the study of PDA is one of the examples illustrating the extensive possibilities of this method[6]. In contrast to other procedures, Raman spectroscopy can yield direct information about the bond sequence in the polymer, about the degree of their strain, and about the influence of the surrounding monomer matrix on the growing polymer chain[4,5]. Despite the fact that, according to the results of analysis, the total number of vibrations active in the Raman spectrum of PDA is fairly large, only a small proportion of such vibrations are enhanced by resonance, which results in a considerable simplification of the Raman spectra. This can be explained by the fact that the intense optical absorption observed in the visible region owing to the excitation of the π-electron conjugation system in the polymer chain leads to the resonance enhancement of only those vibrations which induce the modulation of electron density along the chain. The resonance enhancement effect is so large that Raman spectra without noise can be recorded for only 20 DA monolayers[220] or for a degree of conversion of the monomer much less than 1%.[221] The normal vibrations of the main chain, which do not induce the modulation of the electron density along the chain, and the vibrations of the side groups are almost inactive in the Raman spectra.

Between four and nine bands in the range 600–2200 cm^{-1} have been observed in the Raman spectra of DA and PDA specimens[177]. The emission is highly polarised for all the bands and the electric field vector is parallel to the direction of the polymer chain[138]. The position and form of the bands depend on the nature of the substituents, the temperature, the mechanical stress applied to the specimen, and the wavelength of the exciting light.

The largest number of studies have been performed for TS and its partly and wholly polymerised specimens. For the fully polymerised poly-TS crystals, only four intense bands are observed in the Raman spectra: $\tilde{\nu}_1 = 2086$, $\tilde{\nu}_2 = 1485$, $\tilde{\nu}_3 = 1203$, and $\tilde{\nu}_4 = 952$ cm^{-1}. The changes in the positions of these lines during polymerisation have been investigated[221]. During the induction period of the polymerisation reaction (degree of conversion of the monomer < 10%), the frequencies in the Raman spectra are independent of the degree of polymerisation. During subsequent polymerisation, the frequencies increase: the shifts of $\tilde{\nu}_1$ and $\tilde{\nu}_2$ are much greater than those of $\tilde{\nu}_3$ and $\tilde{\nu}_4$ and amount, for example, to approximately 60 cm^{-1} for $\tilde{\nu}_1$. In addition it has been established that the polymerisation is spatially inhomogeneous. This is manifested particularly by the broadening of the line, the appearance of additional lines, and by the fact that the intensities and frequencies of the lines are sensitive to the position of the laser beam relative to the surface of the irradiated specimen[221].

The dependence of the frequency shift on the application of external mechanical stresses to poly-TS has been investigated[222,223]. The Raman bands are then displaced towards higher frequencies, while the optical absorption maximum at 2 eV is actually displaced towards lower energies "at a rate" of approximately 8 meV $kbar^{-1}$. Both these results are in satisfactory agreement with predictions based on the molecular orbital method. It has been suggested that the changes in the Raman frequencies during polymerisation and the frequency shift when external mechanical stresses are applied to the specimen have a common basis—namely they are due to the appearance of strain in the polymer chain and the change in the force constants of the bonds.

The thermal polymerisation of MBS, a monomer isomorphous with TS, has been investigated by the Raman method[19,63]. The positions of the lines in the Raman spectra of MBS virtually coincide with their positions in the spectrum of TS, although the initial molecular strain in the polymer chain of MBS is greater. This excess strain is, however, eliminated in the very early stages of the polymerisation of MBS because of the easier, compared with TS, reorientation of the side substituents, which leads to a longer lifetime of the active centre and to a higher pre-exponential factor, which determines the significant difference between the kinetic curves for the polymerisation of TS and MBS.

Other DA have also been investigated by the Raman method. The spectra of the partly and fully polymerised BPG have a greater number of bands than that of TS[125], which can be explained by the presence of structures without a centre of symmetry, by the Fermi resonance interactions, or, finally, by vibrations in the substituents linked to the polymer skeleton. The frequency shifts in the Raman spectra of BPG on passing from the monomer to the polymer are greater than for TS.[224]

In contrast to poly-TS, the frequencies of the Raman lines of poly-HDU subjected to stretching stresses decrease linearly with increase in the length of the specimen[225]. It has been demonstrated by Raman spectroscopy that the phase transition in DCHD is due to a rearrangement of the side groups, which leads to an alteration of the strain in the crystal[160]. The frequency shift following the introduction of phenazine into the cocrystallising composition with diacetylenemonocarboxylic acid is small, indicating an effective cocrystallisation which does not give rise to additional strains[34].

A very intense narrow line has been observed in the Raman spectrum following the absorption of O_2 molecules on the surface of the single crystals of certain PDA[226]. The resonance enhancement occurs in this instance owing to the considerable energy transfer from the conjugated skeleton to the O_2 molecule in the electronic transition in PDA with an energy of 2.39 eV. The Raman frequency $\tilde{\nu} = 1521$ cm^{-1} has been obtained for a poly-TS single crystal.

Because of the large number of observed bands due to the functional side groups in the infrared spectra of diacetylenes and their polymers and the difficulty of interpreting these lines, studies have been performed only in the near infrared ($\tilde{\nu} = 3500–12000$ cm^{-1})[227] and the far infrared ($\tilde{\nu} = 5–120$ cm^{-1})[143].

IX. OTHER EXPERIMENTAL METHODS FOR THE INVESTIGATION OF POLYDIACETYLENES

Polydiacetylenes have fairly good mechanical properties. For example, the tensile strength of poly-HDU is approximately 1.7×10^7 Pa, while the dynamic modulus is approximately 4.7×10^6 Pa.[228] If the modulus is calculated per PDA

molecule, its value is almost the same as for diamond. The maximum disruptive stress depends on the size of the specimen: it is greater, the smaller the crystal, which indicates the decisive role of dislocations or other defects in the breakdown of the specimen. The anisotropy of the mechanical properties of PDA is very pronounced[229]. The mechanical properties have been examined in greater detail by Young and Zachmann[230].

The temperature coefficient of the linear expansion α for the PDA investigated is negative over a wide temperature range 231–233, which have been attributed mainly to the increase of the amplitude of the torsional vibrations as the temperature increases and with decrease of the length of the polymer chain due to this effect. The typical values of α are -10^{-5}– -10^{-6} K^{-1}.

The specific heats of a poly-TS single crystal and their temperature variation have been determined in the temperature range from 3 to 300 K.[144] The experimental results are described satisfactorily by the long chain model involving the presence of acoustic and optical phonons.

A pyroelectric effect has been observed for poly-TS[155,234], which is extremely strange, since theory predicts its existence only for molecular crystals without central symmetry. The measurements are performed along the *b* axis, the pyroelectric constant changes sign several times as the temperature is varied, and its maximum value is approximately 10^{-10} CGS units. Pyroelectric properties have also been observed for other PDA.[235]

The ^{13}C NMR method has been used to study solutions of poly-3(4)BCMU[93,236] and it has been established that these polymers have the (A) structure of the chain and that in the gel state the chain has a rigid planar conformation.

The ESCA method has been used to determine the positions and widths of the valence and conductivity bands[237–240]. The ionisation potentials of several of the PDA investigated proved to be similar, amounting to 7 ± 1 eV. Unfortunately the application of the ESCA method is complicated by the considerable contribution of the photoelectrons emitted by the substituents, which precludes the determination of other parameters of the electronic structure of the polymer chain.

In contrast to the ESCA method, the electron photoemission method[218] does not suffer from problems associated with the movement of the charge within the material and the results obtained with its aid may be more reliable. Thus it has been found that the ionisation potential is 7 ± 1 eV, the electron affinity is 5 ± 1 eV, and the width of the forbidden gap is 2.1 ± 0.1 eV. According to the diamagnetic susceptibility measurements, the conjugation in PDA is significantly one-dimensional with a large electron delocalisation region[241].

X. THE POSSIBLE APPLICATIONS OF DIACETYLENES AND POLYDIACETYLENES

The specific features of the reactivity of DA, the characteristics of its structure, and the changes in its physical properties on passing from the monomer to the polymer as well as a number of the physical properties of DA-based polymers determine the possible applications of these compounds.

For example, DA with $R = R' = CH_2OCONH(CH_2)_3CH_3$. .(HDDBU) and $R = R' = CH_2OCONHC_2H_5$ accelerate the radiation-induced cross-linking of polyethylene (PE).[242] The dose in the irradiation of the PE + HDDBU mixture necessary to attain the gel point is smaller by a factor of 15 than for pure PE. The reason why the radiation-induced cross-linking of PE is accelerated only by the DA indicated above consists in the fact that these monomers cocrystallise homogeneously with PE, while others form their intrinsic phase on mixing.

It has been suggested that the numerous colour changes in PDA during its polymerisation be used for the direct visual indication of the previous radiation and thermal history of the specimens[87,243,244]. Both the individual DA and the numerous cocrystallising compositions are very sensitive and visually observable indicators of γ-irradiation doses in the range from 50 rad to 50 Mrad.

The reversible thermochromic transitions in various PDA at temperatures from −180° to 220 °C can be used as temperature indicators and also in indexing devices[245].

Diacetylenes and polymers based on them can be used as indicators of ozone[246], since even small amounts of this gas decolorise the materials by breaking the conjugation chain.

The solubilities of certain PDA as well as their ability to change colour when external conditions are altered made it possible to create on their basis one-component inks and dyes[247].

Cocrystallising compositions made up of HDU and a symmetrical DA with $R = R' = CH_2OCONHC_6H_4Cl$ have been suggested for the recording of fingerprints[248]: polymerisation does not take place on a surface containing traces of fat, while on a clean surface thermal polymerisation occurs with a change in colour from red to violet over a period of approximately 10 min at room temperature or approximately 1 min at 120 °C.

The ability of DA to change colour on polymerisation under the influence of external sources (irradiation with ultraviolet light, γ-rays, and electrons) has led to numerous suggestions for their employment as carriers of information. One can achieve thereby a high density of the recording of information. For example, the resolution attained for a TS single crystal (> 1000 line mm^{-1}) is better than for highly resolving photographic films based on AgBr and photoresistors[249]. Amplitude and phase holograms[249,250], also with a high resolution, have apparently been obtained for the first time for organic crystals on the same TS single crystal. A disadvantage of the TS single crystal is its brittleness. The technology of the employment of DA for the recording of information can be improved by using multilayers[251]. An important advantage of the application of DA for this purpose is the fact that there is no need for a development process in order to obtain an image or information.

The use of DA, particularly of their multilayers, as photoresistors and electronic resistors in lithography is extremely promising. The general requirements which must be met by the materials used for this purpose are a high resolution, high contrast, a high sensitivity, uniformity of the coating, etc.[252] The first results obtained (resolution ~ 50 nm, sensitivity ~ 10^{-6} C cm^{-2}) showed that the employment of multilayer coatings in electronic lithography and photolithography is promising[252–254].

Yet another possibility for the recording and storage of information is provided by the suggestion that multilayers each of which carries an electric charge be used[255]; the charge is photoinjected into a film in a time sequence corresponding to the information introduced, after which it is distributed in space and arranged in order with the aid of a controlling electric field.

The prospects for the application of DA and their polymers in non-linear optics are no less promising. Apart from the high non-linear third-order optical susceptibility coefficient examined above, which is itself important for practical applications, it has been reported[188,256] that a second harmonic of the emission can be generated on the basis of DA and their polymers and that the characteristics are greatly improved compared with those known for inorganic materials,

such as, for example, lithium niobate. It has been suggested that DA and their polymers be used as planar waveguides and other non-linear optical elements[190]; the losses in such waveguides are very small, amounting to 0.01–0.1 dB km^{-1}.[256]

However, one should note that despite the promising predictions as regards the application of DA and their polymers for practical purposes, there exist a number of obstacles to their extensive use. The point is that monomeric diacetylenes can frequently be obtained only as a result of fairly complex multistage syntheses; they must be stored under special conditions (in solution or at low temperatures in the dark); the single crystals must be grown by special methods; it is also difficult to obtain their multilayers. However, the prospects for the employment of DA and PDA are so great and promise so much that these temporary difficulties will undoubtedly be overcome.

XI. MONOLAYERS AND MULTILAYERS BASED ON DIACETYLENES

Problems of the kinetics and mechanisms of the polymerisation and the physical properties and applications of diacetylenes and polyacetylenes were examined above mainly in relation to their single crystals, because the ability to form single crystals is their characteristic feature and determines many of their experimentally observed parameters and properties. In practice, with the exception of several illustrative examples, diacetylenes capable of forming monolayers and multilayers have not been considered. This class of acetylenes has recently attracted special attention in view of the prospects for their practical applications (see Section IX of this review).

The class of diacetylenes capable of forming monolayers and multilayers includes asymmetrically substituted DA, one of the substituents of which is markedly hydrophobic while the other is hydrophilic, and which usually have the structure $H(CH_2)_m-C{=}C-C{\equiv}C-(CH_2)_nCOOX$, where $m,n \geq 0$ and X = H or alkali metal cation. These diynoic acids, transferred from a solvent onto the surface of water, are oriented on the latter in a strictly defined manner. If a support whose surface has been specially treated to increase the extent of its interaction with the hydrophobic end of the DA molecule begins to be immersed in the liquid phase, then the monomolecular DA layer can be "removed" from the surface of water and transferred onto the support with retention of the orientation of the substituents; the diacetylenic bonds are themselves oriented in a specific manner under these conditions. Thus the monolayer on the support has been specially prepared for subsequent topochemical polymerisation. This procedure, involving the transfer of the monolayer from the surface of water onto the support, can be repeated many times; the number of deposited layers is determined by the number of immersions of the support in water. This method for the preparation of monolayers and multilayers has been called the Langmuir–Blodgett method§.

Without considering in detail all the problems associated with DA monolayers and multilayers in view of the limited size of this review, we shall nevertheless mention a number of the most important studies. The synthesis and polymerisation of diynoic acids[257–266], the structure and morphology of the monolayers and multilayers formed[267–275], and their properties[276–280] have been described and their practical applications have been considered[190,252,253,281,282]. Naturally related problems have also been dealt with in some investigations.

Monolayers and multilayers which serve as models of biological membranes and are distinguished from other similar objects by improved properties have been created on the basis of diacetylenes. The syntheses and properties of compounds of this kind have been described[283–289].

The field of polymer and physical chemistry associated with the study of DA and polymers based on them is at present in a period of growth: the classes of newly synthesised DA are being expanded, the spectrum of their physical properties is increasing, new and interesting qualities of these materials have been discovered, and their practical applications have been extended. The studies which have been carried out are of interest also because the results obtained and the conclusions reached have a general bearing on all polymers with a conjugation system. The fact that many diacetylenes are obtained in the form of single crystals provides a unique possibility for their investigation by the latest experimental methods, many of which can be used also in the study of other polymers with conjugated bonds.

The investigations carried out have explained many hitherto obscure problems, for example, the influence of the system of conjugated bonds on the physical properties, the characteristics of the optical absorption and the role of excitons, the character and mechanism of the dark conductivity and photoconductivity, the problems of the initiation, mechanism and kinetics of polymerisation, and many others. Naturally there are also many unsolved problems in these fields. The study of the phase transitions in polydiacetylenes, which are accompanied by an alteration of many physical properties, is also of great interest. In this connection one must determine the order parameters and the critical parameters and compare the observed transitions with some kind of known model based on the theory of critical phenomena. Possibly one should also create an intrinsic theory.

The purely scientific interest and especially the prospects for the practical application of polydiacetylenes constitute an effective stimulus for their investigation and for general progress in this field.

Some Problems of the Kinetics and Thermodynamics of Polymer Formation Reactions

V.V.Ivanov, M.A.Markevich, and V.I.Irzhak

The characteristic features of the thermodynamics, kinetics, and mechanism of the ionic polymerisation of oxygen- and nitrogen-containing heterocycles as well as aldehydes are considered. The interchain exchange and polymerisation reactions under non-standard physical conditions are discussed.
The bibliography includes 155 references.

I. INTRODUCTION

Compared with anionic[1] and cationic[2] polymerisation of vinyl monomers, ionic processes involving the formation of heterochain polymers exhibit considerable specific features. Many fundamental characteristics of these processes have been observed in the study of the kinetics of the polymerisation of cyclic acetals and ethers, nitrogen-containing heterocycles, and aldehydes, which are largely examined below. In order to understand the complex kinetics of the ionic polymerisation of heterocycles, it is necessary to take into account the active role of the macromolecules formed, which influence all the steps in the polymerisation process—the initiation of the growing active centres and the propagation, transfer, and termination of the reaction chains[3].

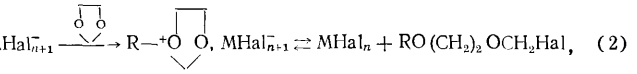
One of the distinctive features of ionic polymerisation is the multiplicity of types of active centres (free ions, contact ion pairs linked to different extents, covalent centres, solvate-separated ion pairs, ion triplets, etc.), which exist in equilibrium, different active centres exhibiting different reactivities[1,4]. When the counterions are in addition linked to one another via the bond system of the polymer chain, a special type of ionic polymerisation arises—zwitterionic polymerisation characterised by specific kinetic and thermodynamic features.

The thermodynamic parameters of polymerisation have been used traditionally to analyse the possibility of the conversion of a given monomer into a polymer. An important step towards the understanding of the general characteristics of polymerisation has been the determination of a relation between the kinetics and thermodynamics of heterophase polymerisation. The development of ideas concerning the dependence of the reactivity of the active centres on their phase state made it possible to explain the kinetics of the polymerisation reaction in which the polymer constitutes a separate phase.

This review deals with problems of the influence on the polymerisation kinetics of factors such as pressure, electric field, and other physical process conditions. The studies by N.S.Enikolopov included in the present review were completed mainly towards the 1970s, but they yielded many fundamental results which have exerted and continue to exert a significant influence on the development of the field under consideration.

II. CATIONIC POLYMERISATION OF HETEROCYCLES

Among the heterocyclic monomers polymerised via a cationic mechanism, cyclic acetals proved to be an extremely unusual class of monomers. The majority of the reactions in which acetals can participate are characteristic also of ethers, but the reactivity of the former is so much greater that the difference between them assumes a qualitative character. In particular, owing to the different reactivities of the acetal and ether linkages, the opening of the acetal ring in polymerisation takes place exclusively at the acetal linkage.



Accordingly, cyclic acetals should be much more reactive in polymerisation than, for example, tetrahydrofuran. In practice, the behaviour of cyclic acetals is much more complex: depending on the type of cationic catalyst, the rate of their polymerisation can be much greater than, similar to, or even lower than that of cyclic ethers. Tetrahydrofuran polymerises in the presence of different catalysts with similar process rate constants, while the effective rate constants for the polymerisation of 1,3-dioxolan in the presence of the same catalysts vary almost by four orders of magnitude[5]. The cause of this anomaly is associated with the influence of the nature of the counterion on the overall concentration of active centres: the following equilibrium plays the most important role in the establishment of the concentration of the active centres[5-12]:

(1)

where M is the metal (Sb, Sn, etc.) and Hal is the halogen. Other possible causes, namely the influence of the counterion on the state of the ions $\rightleftharpoons$ ion pairs equilibrium or the direct influence of the counterion on the reactivity of the active centres in the form of ion pairs, do not contribute significantly to the rate of reaction.

In many instances, an additional decrease in the concentration of the active centres associated with slow initiation is observed:

(2)

where R^+ is the cation of the initial salt.

Reactions (1) and (2) naturally do not exhaust all the different versions of the formation of active centres with reversible decomposition of the counterion; in the general case there is a possibility of a set of compounds of the type $MHal_{n-k}(^{\sim}OCH_2)_k$, where $k \leq n$, with the corresponding counterions $[MHal_{n-k+1}(^{\sim}OCH_2)_k]^-$. A spectroscopic confirmation of this fact has been described[13].

An important consequence of the decisive role of equilibria of type (1) is effective cocatalysis when substances which are ineffective as catalysts but can displace equilibrium (1) towards the active centres are introduced into the system (Table 1).

Table 1. The influence of the concentration of the added α-chloromethyl ether (c) on the rate (w) of the dissociation reactions of the acetal linkages*.[5,6,12]

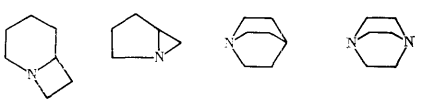
Catalyst	$10^{-4}c$**, mole %	w/w_0***
Polymerisation of 1,3-dioxolan		
$(C_2H_5)_3O^+SbCl_6^-$	1.6	300
$SbCl_5$	0.7	190
$Ph_3C^+SbCl_6^-$	2.2	90
Methylal + ethylal model system		
$(C_2H_5)_3O^+SbCl_6^-$	7	25
$SnCl_4$	2	25

*Solvent—CH_2Cl_2; 20 °C.

**The concentration of the additive relative to the amount of the catalyst.

***Here w_0 is the rate of reaction in the absence of additives.

Thus in the case of cyclic acetals a type of "living" polymerisation obtains where only a small proportion of macromolecules grow in each instant but the dynamic equilibrium (1) ensures the possibility of the growth of all the chains throughout the process. In contrast to the usual polymerisation via the "living" chain mechanism, in the case of acetals, the concentration of the growing macromolecules is determined by the constant of equilibrium (1) and by the equilibrium constants of the analogous interactions of the initial and substituted Lewis acids with the polymer chain. On the basis of these ideas, it has been possible to explain the linear growth of the molecular weight of the polyacetals as a function of the degree of conversion, observed in many instances, i.e. a constant number of chains, which, however, is not identical to the number of catalyst molecules and depends on the temperature and other process parameters[14].



Later studies yielded convincing evidence showing that the equilibrium mechanism of the formation of ionic active centres plays an important role not only in the polymerisation of cyclic acetals but also in the cationic polymerisation of other heterocycles, particularly tetrahydrofuran[1,15-21].

The study of the polymerisation reactions of cyclic acetals permitted a significant step forward in the development of ideas concerning the relative reactivities of the free ions and ion pairs. The results of experiments designed to investigate the influence of the ionic strength of solutions and of the dielectric constant of the medium on the polymerisation process led to the conclusion that intense solvation of the cations by the monomers and delocalisation of the positive charge should equalise the reactivities of the free ions and ion pairs[22]. In contrast to the anionic polymerisation of vinyl monomers, the rate constants for the propagation of ions and ion pairs proved to be similar.

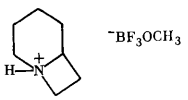
The initiation methods in the polymerisation of cyclic acetals are distinguished by a wide variety[4,5,23-33] in both the chemical and the kinetic sense. Depending on the reactivity of the active centres in relation to the acetal linkages and on the stability of the counterions, there is a possibility of the equilibrium[5,9,29,32], stationary[5], or mixed[5,10] initiation mechanisms. The case of the stationary mechanism, which obtains in the initiation of polymerisation by salts with fairly stable counterions, is extremely interesting; the initiation of the polymerisation of 1,3-dioxolan by the oxonium salt $(C_2H_5)_3O^+SbF_5^-$ can serve as an example of this kind[5].

The polymerisation of cyclic acetals is instructive also because many types of interactions characteristic of the cationic polymerisation of other heterocyclic monomers, for example, esters and ethers, are effectively realised in this process. The systems considered are characterised by a high sensitivity to the presence of microamounts of nucleophilic impurities (water, alcohols, etc.), the involvement in various stages of the reaction of not only the initial monomer but also of other heterocycles formed from the polymer chain via a depolymerisation mechanism, and the effective formation of complexes between different system components[34-46]. The proof of the fact that the polymer molecules are capable of participating, together with the monomer, in the formation of complexes with the catalyst and also in initiation, in reactions with the impurities, etc. was extremely important for the understanding of the experimental kinetics in the systems considered[34-36].

The cationic polymerisation of oxygen-containing heterocycles has much in common with the analogous processes involving many cyclic amines: 1-azabicyclo[4.2.0]octane (conidine), 1-azabicyclo[3.1.0]hexane (ABH), 1-azabicyclo[2.2.2]octane (quinuclidine), and 1,4-diazabicyclo.[2.2.2]octane (triethylenediamine):[47-49]

conidine ABH quinuclidine triethylenediamine

Table 2. The chain propagation rate constant (k_p) in the cationic polymerisation of conidine and the influence of catalysts of different types*.[47,48]



Catalyst	Concentration, M	k_p, litre mol^{-1} min^{-1}
BF_3-conidine	$5\cdot10^{-3}$	0.29
Ditto	$1\cdot10^{-2}$	0.48
Conidine hydrobromide	$5\cdot10^{-3}$	0.23

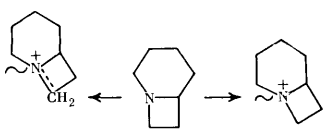
N-Ethylconidinium iodide	$1\cdot10^{-2}$	0.21
Ditto	$6\cdot10^{-2}$	0.59

*Solvent—methanol; 60 °C.

The nature of the active centres for the polymerisation of cyclic amines is the same and is independent of the type of initiator: the active centres are quaternary ammonium salts. This is indicated, in particular, by the finding that the

chain propagation rate constant is independent of the nature of the initiator at the concentration of the active centres corresponding to their virtually complete dissociation into the free ions (see Table 2).



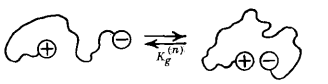
The structure of the initiating species in the conidine–CH_3OH–BF_3 system has been unambiguously established by ^1H, ^{11}B, and ^{19}F NMR.[49]

In virtually all cases the polymerisation of nitrogen-containing heterocycles is a process without termination, which proceeds via a mechanism of the "living" polymer type. In initiation by alkyl halides or quaternary ammonium salts, the rate of initiation is fairly high and the reaction takes place without an induction period and without self-acceleration. The molecular weight of the polymer increases in proportion to the initial monomer concentration and the degree of conversion and is independent of temperature, the monomer concentration, and the nature of the counterion. In the polymerisation of nitrogen-containing rings under the influence of acids, tertiary ammonium salts, and BF_3–monomer complexes, all the kinetic features fully agree with the mechanism involving a slow initiation stage. In conformity with this mechanism, the number-average degree of polymerisation $\bar{P}_n$ increases in proportion to the square root of the degree of conversion[5].

It is of interest to note the similarity between the nitrogen- and oxygen-containing rings in the sense that the tertiary ammonium ions used as catalysts react much more slowly with their monomers than R_4N^+, completely analogously to the mechanism of the inhibiting action of water in the polymerisation of oxygen-containing rings, where tertiary oxonium ions R_3O^+ are converted into the relatively inactive secondary ions R_2OH^+.

The available data show that the chain propagation in the polymerisation of cyclic amine proceeds via the nucleophilic attack on the active centre by the monomer; for example, in the case of conidine (the counterion is omitted) we have

The structure of the initial ring is retained in this process, while the reactivity is determined mainly by the ring strain[49].



Conductimetric studies of ammonium salts in polymerising systems, experiments with added neutral salts, and the study of the influence of the nature of the counterion on the reaction kinetics suggest that the active centres in the polymerisation of nitrogen-containing rings are free ions and ion pairs[48]. The decisive argument in support of this conclusion is the change in the rate of polymerisation and the influence of neutral salts which suppress the dissociation of ion pairs and shift the equilibrium ions $\rightleftharpoons$ ion pairs towards the latter. In contrast to the majority of the data available at present, the rate of polymerisation increases in this instance, since ion pairs are more active than the free ions in the polymerisation of the cyclic amines investigated and the greater the size of the counterion the higher the rate constant for the propagation of the macroion pair. The size of the cation has an analogous influence on the process kinetics: the ratio of the rate constants for the propagation reactions involving the ion pair and the free ion is greater for a four-membered ring than for a three-membered ring in the presence of the same counterion.

The conclusion that the reactivities of the free ions and ion pairs in the polymerisation of cyclic amines are similar was confirmed later in studies by other workers[50]. A similar situation is typical for the cationic polymerisation of many other heterocycles, for example, tetrahydrofuran, oxepan, and sulphur-containing monomers[4,5].

III. ZWITTER-IONIC POLYMERISATION

In the ionic polymerisation of vinyl monomers and heterocycles, the mechanism by which the active centres formed by the ions are linked to one another solely by electrostatic interaction forces is most frequently encountered. However, there is a possibility of ways of initiating polymerisation in which dipolar active species (zwitter-ions) are formed and the subsequent growth of the polymer molecule takes place via the addition of the monomer molecules to the cation (cationic mechanism) or the anion (anionic mechanism); the anion and cation are then on the opposite ends of the polymer chain. The addition of monomer molecules does not alter the zwitter-ionic nature of the active centres and is accompanied by an increase of the number of covalent bonds between the oppositely charged groups.

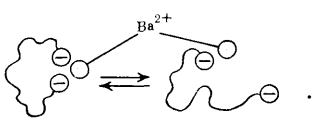
A statistical description of the behaviour of the macromolecule in solution is based on the idea of a Gaussian coil, the average distance between the ends of which increases with increase of the chain length. In the case of a polymer zwitter-ion, the electrostatic interaction between the charges at the ends of the chain should lead to their mutual approach and the formation of an ion pair:

However, such a change in the coil conformation is accompanied by a decrease of the entropy of the macromolecule.

Allowance for the configurational statistics of the polymer chain and the law of electrostatic interaction between the charges of the polymer zwitter-ion made it possible to obtain an expression for the equilibrium constant of the dissociation of an isolated polymeric zwitter-ion as a function of the degree of polymerisation n:[52,53]

$$K_g^{(n)} = K_g^{(1)} n^{3/2},$$

where $K_g^{(1)}$ is a constant which depends solely on the thermodynamic flexibility of the chain. In contrast to the usual dissociation of electrolytes, including polymeric electrolytes, the dissociation constant of the growing zwitter-ion depends on its length and the probability of finding an active centre in the form of a free ion increases with increasing degree of polymerisation of the zwitter-ion. If the reactivities of the free ions and ion pairs are different and the former are more reactive, then the rate of growth of the polymeric zwitter-ion should increase with increase of its length. This fact, which is fundamentally new in polymer chemistry, seemingly contradicts Flory's fundamental postulate that the reactivity of the active centres is independent of the length of the macromolecule; however, in reality there is no contradiction here: the reactivities of the ion pairs and the free ions are independent of the length of the macromolecule and there is only a change in the probability of the existence of the active centres in these states.



The anionic zwitter-ionic mechanism obtains in the polymerisation of acrylonitrile and its derivatives, β-propiolactone, and formaldehyde under the influence of triethylphosphine as the initiator and of ε-caprolactone and cyclic sultones under the influence of tertiary amines[54–67]; one of the examples of the cationic zwitter-ionic polymerisation is that of epoxides under the influence of BF_3.[68,69]

Another characteristic feature of the zwitter-ionic polymerisation initiated by triethylphosphine is the slow accumulation of ions in the system during the reaction which is due to the slow initiation. The increase of the overall concentration of ions owing to the initiator which has reacted leads to the suppression of the dissociation of the polymeric zwitter-ions via mechanism (3).† The decrease of the concentration of the free anions active in polymerisation also takes place owing to their interaction with the cations of the chains which have been destroyed. Since the ion pairs in the test systems are less reactive than the free ions, the suppression of polymerisation and even its complete arrest, unrelated to the exhaustion of the reactants, are observed during the process. The introduction of a fresh portion of the initiator does not then renew the polymerisation process.

The influence of these factors on the process kinetics has been analysed in relation to the anionic zwitter-ionic polymerisation of methacrylonitrile under the influence of $(C_2H_5)_3P$: the rate of polymerisation and the molecular weight of the polymer decrease during the process faster than would be expected solely from the decrease of the concentrations of the reactants[57,58].

An important kinetic consequence of the zwitter-ionic mechanism of polymerisation is the broadening of the molecular weight distribution (MWD) within the polymers with increase of the concentration of the monomer as a result of a sharp increase of the contribution of the free ions to the polymerisation with increase of the molecular weight of the growing polymer chain.

The ideas developed above concerning the specificity of the growth of the active centres in the form of zwitter-ions were extended subsequently to the anionic polymerisation of styrene under the influence of dianions combined with Ba^{2+} as the counterion: in this case the active centre dissociates only once in tetrahydrofuran:

Chain propagation takes place mainly with participation of singly dissociated barium salts of polystyrene which are in fact zwitter-ions: it has been established that the effective propagation rate constant increases with increased degree of polymerisation, in full agreement with one of the fundamental features of the kinetics of the zwitter-ionic polymerisation[53,70-73].

IV. THERMODYNAMICS OF POLYMERISATION

The relation between the rate of the process w_p and the equilibrium monomer concentration [A] is well known for homogeneous polymerisation:

$$w_p = -\frac{d[A]}{dt} = k_p c^* ([A] - [A]_{lim}) , \qquad (4)$$

where $[A]_{lim}$ is the limiting, equilibrium concentration of the monomer, c* the concentration of the active centres, and k_p the propagation rate constant. This law obtains in the polymerisation of many unsaturated and cyclic monomers for which the enthalpy and entropy contributions to the free energy of polymerisation are comparable in magnitude. However, another form of the relation between the process kinetics and thermodynamics, which obtains in those cases where the polymerisation is reversible but the polymer forms a separate phase, as, for example, in the heterophase polymerisation of trioxane, escaped the attention of investigators[74-85].

In a polymerisation system of this type the growing macromolecule can be either fully crystallised, so that the active centre is located on the surface of the polymer crystal, or is partly dissolved in the reaction medium, whereupon the active centre is located at the end of the dissolved section of the polymer chain. The equilibrium monomer concentrations in relation to the polymer in the dissolved and crystalline states are different. The addition of the monomer to the surface active centre with formation of a solid polymer is thermodynamically more favourable, so that the equilibrium monomer concentration is in this case lower than in relation to the polymeric centre in solution.

Thus processes involving the addition of the monomer to the active centre at the dissolved end fragment of the macromolecule, the reverse reaction involving the depolymerisation of this section of the chain, chain propagation, the depolymerisation of the active centres on the surface of the crystal, as well as the crystallisation and dissolution of the growing chain takes place in the polymerisation system. The character of the dependence of the rate of reaction on the monomer concentration is determined by the ratios of all these processes. If, for example, the rate of crystallisation is lower than the rate of growth of the dissolved part of the macromolecule, then chain propagation takes place mainly at the active centres in solution and the process is described by the equation for reversible polymerisation [Eqn.(4)] with $[A]_{lim}$ corresponding to the monomer $\rightleftharpoons$ dissolved polymer equilibrium.

With decrease of the monomer concentration, the rate of growth of the dissolved part of the macromolecule becomes less than the rate of crystallisation and the kinetics are described by the same equation (4) but with another limiting monomer concentration, that in equilibrium with the crystalline polymer.

Accordingly, a number of anomalous features are observed in the polymerisation of trioxane: apparently high reaction orders with respect to the monomer and their dependence on the nature of the solvent, temperature, etc. These features cannot be explained by any ideas concerning the ionic liquid-phase processes other than those described above.

The situation where not only the initial monomer but also other "secondary" comonomers, formed via a depolymerisation mechanism, are in equilibrium with the polymer chain is fairly common. The study of a system of such equilibrium yields valuable additional information about the process. In the polymerisation of trioxane not only the initial monomer (Tr) but also formaldehyde (F) and an eight-membered cyclic acetal–tetraoxane (TTR) (larger rings are present in smaller amounts) are present in the system in equilibrium with the polymer, so that the process can be described by the following scheme:

$$\begin{array}{c} F \\ \downarrow\uparrow \\ T_r \rightleftarrows P_d^{(\nu)} \rightleftarrows P_s , \\ \uparrow\downarrow \\ TTR \end{array}$$

where P_s and $P_d^{(\nu)}$ are the solid polymer and the dissolved ends of the polymer chain with a degree of polymerisation ν respectively. This scheme makes it possible to explain the dependence of the stationary formaldehyde and tetraoxane concentrations on that of trioxane and also the anomalous dependence of the rate of polymerisation and of the induction period on the initial monomer concentration[81].

†Mechanism (3) is not shown in the original Russian text (Ed.of Translation).

Another important aspect of the kinetic-thermodynamic approach to polymerisation processes is the possibility of regulating the polymer structure by carrying out the reaction in the vicinity of the thermodynamic monomer–polymer equilibrium. The essential feature of such regulation consists in the following. The differences between the chemical potentials of the states of the polymers having different structures at high monomer concentrations, i.e. under conditions remote from equilibrium, are usually significantly smaller than the change in the chemical potential in the monomer–polymer transition. Therefore, all possible structures of the polymer are thermodynamically almost equally probable and the preferential selection of structures takes place only for kinetic reasons as a function of the type of catalyst, temperature, and solvent. However, if the polymerisation is carried out under conditions close to the monomer–polymer equilibrium, then certain structures are thermodynamically prohibited, so that at low monomer concentrations small differences between the chemical potentials of the initial and final states of the polymer can be both positive and negative. In the limiting case, the polymer formed must have only the thermodynamically most favourable structure.

If one considers the supermolecular structure of the polymer, it is found that the latter varies with the ratios of the rates of three processes: the chemical formation reaction of the polymer, the segregation of the polymer as a separate phase, and structural transformations within the polymer phase. Different supermolecular structures have indeed been observed in the polymerisation of a series of monomers in different solvents with variation of the thermodynamic polymerisation conditions by varying the monomer concentration. For example, in the polymerisation of trioxane and triethylenediamine, small globular structures are formed at a high monomer concentration, while at low concentrations the products are large well-organised lamellar crystals[86–88].

V. SOLID-PHASE POLYMERISATION

The kinetics of reactions in the solid phase are significantly specific. The differences between them and those of reactions in the gas and liquid phases are related, on the one hand, to the difference between the energies of individual molecules and the appearance of collective energy levels and, on the other, to the geometrical fixation of the molecules in space relative to one another and the appearance of different types of defects in the structure of the substance.

The study of solid phase polymerisation developed extensively in the 1960s and has at present become an independent branch of polymer chemistry. The polymers formed in the solid phase differ in their chemical structure, stereoregularity, crystallinity, and orientation from the polymers synthesised by the usual methods in solutions[89]. Studies of the polymerisation of various monomers (trioxane, tetraoxane, hexamethylcyclotrisiloxane, etc.) in the solid phase under the influence of ionising radiation or ionic catalysts established[90] that the polymerisation kinetics are in many respects identical regardless of the method of initiation. This made it possible to devise a general kinetic scheme for solid phase polymerisation taking into account the characteristic features of the structure of the solid. This concept is based on the following ideas[90].

1. As a result of the virtually complete absence of the translational diffusion of polymer molecules, monomer molecules, or various impurities, the migration of the active centre in space and its collisions with the monomer or impurities take place mainly as a result of chain propagation steps.

2. The inhomogeneities in the crystal lattice (dislocations, tracks, vacancies, etc.) are the sites where the growing polymer chains are terminated.

3. The anisotropy of the reactivity of the macromolecules growing in the crystal lattice determines their preferential growth along one of the crystallographic axes.

Thus the active centres having the same chemical structure but located in different environments exhibit different reactivities. The transfer of the active centre from one environment to another takes place as a result of the chain propagation step or some kind of physical process involving a change in the structure or in the perfection of the crystal lattice[90–94].

VI. POLYMERISATION UNDER EXTREME CONDITIONS

Together with the traditional chemical methods for influencing ionic polymerisation processes, considerable possibilities are associated with physical methods. Only the influence of the temperature and medium are widely used in practice; the influence of a high pressure and an electric field have been much less investigated but are extremely promising.

1. Polymerisation Under Pressure

Although the form of the dependence of the rate constant for an elementary reaction k on the pressure p is general and is described by the formula

$$\frac{d \lg k}{dp} = -\frac{\Delta V^{\neq}}{RT},$$

where $\Delta V^{\neq}$ is the change in volume on activation, the influence of pressure on polymerisation can be extremely complex because different values of $\Delta V^{\neq}$ occur for different elementary polymerisation steps. This has been established in a comparative study of the influence of pressure on the radical polymerisation of propene and methyl methacrylate, the cationic polymerisation of styrene and tetrahydrofuran, and the solid-phase polymerisation of trioxane[95,96].

In the radical polymerisation of α-olefins the possibility of obtaining a high-molecular-weight polymer is limited by the appearance in the chain propagation reactions of the relatively inactive allyl radicals, formed as a result of chain transfer to the monomer. It has been shown[95] that the application of pressure (>3000 atm) in the polymerisation of propene imparts "life" to the allyl radicals with a significant increase of the reinitiation rate constant. The influence of pressure on the molecular weight obeys a complex relation; however the growth of $\bar{P}_n$ with pressure is highly pronounced. In the radical polymerisation of methyl methacrylate, an increase of pressure leads to an increase of both the rate of polymerisation and of the molecular weight, which is related to the increase of k_p and the decrease of the rate constant for the destruction reaction.

In the cationic polymerisation of styrene under the influence of $HClO_4$ in chlorobenzene, a significantly more appreciable accelerating influence of pressure is observed than in radical polymerisation; this difference has found a natural explanation as a result of the decrease of the dielectric constant under the influence of pressure[96].

The solid phase polymerisation of trioxane (in the presence of I_2 as the initiator at 50–70 °C) is sharply retarded with increase of pressure, which is accompanied by the anomalously high value $\Delta V^{\neq} = 120$ cm^3 mol^{-1}. In this process the polymer chain is known to grow while disrupting the crystal lattice of the monomer[90]; pressure prevents such breakdown and leads to an effective decrease of the rate of polymerisation.

Unexpected effects were obtained when a system undergoing polymerisation was subjected to the simultaneous influence of pressure and shear deformations (see Zharov's review in the present issue).

2. The Influence of the Electric Field

Ionic polymerisation systems are in essence aqueous solutions of electrolytes in which some of the ions are active centres in the growing polymer chains, i.e. are fixed on macromolecules. By applying an electric field, it is possible to displace the ion pairs $\rightleftharpoons$ free ions equilibrium towards the latter in a manner very familiar for many of the usual systems in high electric fields whose strength exceeds 50 kV cm^{-1}.

In contrast to low-molecular-weight electrolytes, the mobility of the macroion is significantly lower than that of the counterion. As a consequence of this, the application of an electric field entails the formation of a space charge in fields whose strength is ~1 kV cm^{-1} together with an increase of the degree of dissociation of the polymeric ion pairs (as a result of the preferential removal of the counterion to the electrode). A detailed theory of the transient processes occurring in polymerisation systems following the application of an external field has been developed[97–99] and a relation has been established between the parameters of the electric field and the reaction kinetics.

When both macrocations and macroion pairs with propagation rate constants k_+ and $k_\pm$ are involved in the process simultaneously, the corresponding ratio of the rate of polymerisation in the electric field (w_E) to that in its absence (w_0) is

$$\frac{w_E}{w_0} = \frac{1 + (k_\pm/k_+ - 1)\,\bar{P}_E/c_0}{1 + (k_\pm/k_+)\,\alpha} ,$$

where c_0 is the concentration of the active centres, α the degree of their dissociation, and $\bar{P}_E$ the average stationary concentration of active centres, which depends on the mobilities of the macroion and counterion, the electric field strength, and the rate constant for the discharge of the ions at the electrode. The conditions under which the rate of polymerisation should increase or the latter should be inhibited following the application of a field have been determined[97,98,100]. Together with the change in the rate of polymerisation under the influence of the electric field, the molecular weight of the polymer increases. For a specific ratio of the constants $k_\pm$ and k_+, the degree of polymerisation increases throughout the reaction volume or in separate sections of the latter[101,102]. For example, the rate of polymerisation of trioxane under the influence of $SnCl_4$ in nitrobenzene increases by a factor of 2–7 when a field is applied, while the molecular weight of the polymer doubles[102].

3. Polymerisation Near the Consolute Point

One of the first studies of polymerisation near the consolute point for a binary liquid mixture was that of the radical polymerisation of acrylonitrile in heptane in the region of the phase diagram which includes the consolute point and corresponds to the separation of the system into two phases[103]. The interest in these investigations is due to the fact that, in the vicinity of the consolute point, there is an anomalous decrease of the macroscopic diffusion coefficient, an enhancement of the concentration fluctuations, an increase of the viscosity of the system, etc. It is to be expected that the anomaly in the physical properties of the medium has an unusual effect on the polymerisation reaction. Indeed, in the polymerisation of acrylontrile in the vicinity of the consolute point, distinct minima are observed in both the rate of polymerisation and in the molecular weight of the polymer. Kinetic studies combined with the investigation of the state of the system near the consolute point by the paramagnetic label method suggest that the polymeric radicals can give rise to stable clusters[103–105]. Similar phenomena apparently play a significant role in certain multiphase systems.

VII. INTERCHAIN EXCHANGE IN POLYMERS

In 1962 Enikolopov[106] pointed out the possibility of interchain exchange in polymerisation reactions and proposed a mechanism for this reaction, which was subsequently called the reaction involving chain transfer via the polymer with the dissociation of the macromolecule (CTD).[107–110]

The interchain exchange reactions in polycondensation processes had been well known long before the studies of Flory and Korshak were undertaken[111–114]. However, it was believed that interchain exchange is possible only in polycondensation processes and it was regarded as one of the fundamental differences between polycondensation and polymerisation processes. It is nowadays generally recognised that the capacity for interchain exchange is determined solely by the structure of the macromolecule and the type of the active centre and is characteristic of all heterochain polymers regardless of the method of their synthesis.

The essential feature of the CTD reaction is the exchange interaction of two chains, one of which constitutes the active centre and the other an inactive macromolecule, which proceed via a heterolytic or homolytic substitution mechanism. In a general form, the mechanism of the CTD reaction can be represented schematically as follows:

$$\sim(R^1)^{\bullet} + \underset{\displaystyle R^3}{\overset{\displaystyle R^2}{X}} \rightleftarrows \sim R^1\!-\!\underset{\displaystyle R^3}{\overset{\displaystyle R^2}{X^{\bullet}}}\!- \begin{cases} \rightleftarrows \sim(R^2)^{\bullet} + \sim R^1XR^3\sim \\ \rightleftarrows \sim(R^3)^{\bullet} + \sim R^1XR^2\sim \end{cases} \qquad (5)$$

where X is a heteroatom (O, N, S, P, Si, etc.) and $\sim(R^i)^*$ an active macrospecies (cation, anion, or radical).

The above mechanism is fairly universal and makes it possible to understand the fundamental kinetic features of the ionic polymerisation reactions of heterocycles and also the form of the variation of the molecular weight distribution of the macromolecules in these processes.

The CTD reaction is in essence yet another stage (together with chain initiation, propagation, and transfer reactions) in the formation reactions of macromolecules.

1. The CTD Reaction as a Factor Governing the Attainment of the Equilibrium Distribution of Macromolecules

It is seen from Scheme (5) that a process occurring via the mechanism indicated is reversible and should lead to a redistribution of the macromolecules with respect to size and composition, i.e. should influence important properties of the

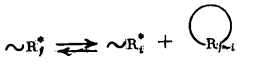
polymers formed, such as the MWD and the distribution of units in the copolymers, which determine in their turn the fundamental physicomechanical and rheological characteristics of the polymers. Evidently[74,115,116] an equilibrium characterised by the most probable distribution of macromolecules with respect to size must be ultimately established in the system where the CTD reaction takes place; here one must note particularly that this distribution is established regardless of the details of the mechanism and the rates of any other reactions occurring in the system. For linear molecules, the equilibrium MWD function is

$$\frac{[R_j]}{\sum_{i=1} [R_i]} = \frac{1}{P_n} \exp(-j/P_n), \qquad (6)$$

where $[R_j]$ is the concentration of macromolecules with a length j and P_n is the number-average degree of polymerisation.

It is noteworthy that the above MWD function is used only for the description of macromolecules with flexible chains; for macromolecules with rigid chains, the MWD function becomes narrower and, for example, for rigid rods, assumes the form[107,117]

$$[R_j] \propto j^2 \exp(-3j/P_n).$$



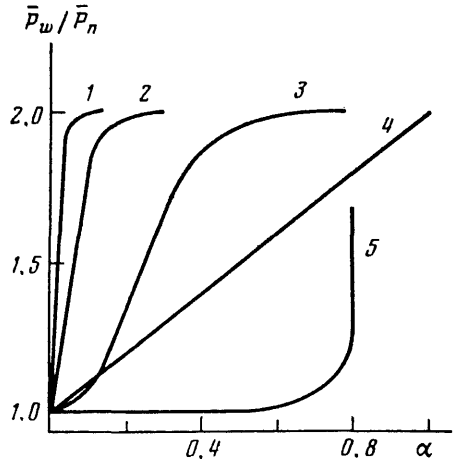
The form of the equilibrium distribution function is also determined by the interaction of the macromolecules with the medium: in a θ-solvent, in moderately concentrated solutions, and in bulk, Eqn.(6) is valid, while in the case of a dilute solution in a good solvent the exponential distribution assumes a different form[110,116]:

$$[R_j] \propto \exp\left(\frac{5}{2}\alpha^2 + \ln \alpha^3 - \gamma j\right),$$

where γ is a constant coefficient and α the degree of swelling of the macromolecule in solution, which depends on its length (i.e. on j).

If the polycondensation or polymerisation reaction takes place in a poor solvent, from which the polymer is precipitated to form a separate phase, then the equilibrium MWD is also exponential. A detailed thermodynamic analysis of such systems has been carried out[116].

It follows from Scheme (5) that the object of attack by the active centre of the macromolecule can also be its own chain. Evidently, under these conditions cyclic macromolecules with different molecular weights are formed together with linear macromolecules. This situation is fairly characteristic and in many polycondensation (the formation of polysiloxanes, polyesters, polyamides, etc.) and polymerisation (the synthesis of polyacetals, polyesters, polyethers, polyamides, etc.) processes the formation of both low- and high-molecular-weight cyclic products is observed[107,110-113]. In this case the CTD reaction can be represented schematically as follows:



Apart from monocyclic species, in concentrated solutions of polymers with flexible chains there is a possibility of the formation of catenanes and in the case of polyfunctional polymers rings with a very complex topology can be produced[118] (pp.133–139).

The equilibrium distribution of rings with respect to size has been obtained on the freely jointed chain model[119]:

$$[R_j] \sim j^{-5/2} \exp(-j/P_n). \qquad (7)$$

This equation is valid only for the description of MWD of fairly large rings; on the other hand, in the case of small and moderately large rings (up to 10–12 members) their energy strain plays an important role and Eqn.(7) therefore becomes unsuitable.

We considered above the MWD functions at equilibrium, which can be established in a macromolecular system not only via the mechanism of a CTD reaction but also as a result of polycondensation or reversible polymerisation. The fundamental difference between these mechanisms of the formation of a polymer with an equilibrium MWD consists in the kinetics of its attainment[107,120-123], which is illustrated in the Figure. In polycondensation, the parameter $\bar{P}_w/\bar{P}_n$, characterising the width of the distribution, increases linearly with the degree of conversion (see Figure, curve 4). In reversible polymerisation a narrow MWD ($\bar{P}_w/\bar{P}_n = 1$) is maintained virtually until the attainment of the equilibrium degree of conversion and $\bar{P}_w/\bar{P}_n \to 2$ only within a very short range of degrees of conversion following the attainment of equilibrium (curve 5). In contrast to the previous instances, the rate of establishment of the equilibrium MWD in a CTD reaction depends on the chain length and increases sharply with increase of the latter (curves 1–3) owing to the increase of the number of reaction centres.

The character of the variation of the width of the distribution ($\bar{P}_w/\bar{P}_n$) in polymerisation and polycondensation processes[107]: 1)–3) polymerisation without chain termination and with instantaneous initiation in the presence of CTD [$k_{CTD}/k_p = 1$; monomer/catalyst concentration ratio: 1) 10^4; 2) 10^3; 3) 10^2]; 4) linear polycondensation in the absence of CTD; 5) reversible polymerisation without chain termination and chain transfer; α = degree of conversion.

The results of the analysis of the kinetics of the attainment of the equilibrium MWD, presented in a general form in the Figure, show that the CTD reaction is a much more vigorous process, leading to the attainment of the equilibrium MWD, than polycondensation or reversible polymerisation. The character of the $\bar{P}_w/\bar{P}_n$–α kinetic curves is a criterion of the occurrence of the CTD reaction in the reaction system and is used for a quantitative assessment of the relative rate of this reaction ($\varepsilon = k_{CTD}/k_p$, where k_{CTD} is the rate constant for the CTD reaction and k_p the chain propagation rate constant). In particular, such estimates have been carried out for polyacetals[122] and polyethers[123].

When copolymer formation reactions are considered, the question of the kinetics of the attainment not only of the equilibrium MWD but also of the equilibrium distribution of the macromolecules with respect to composition and of the distribution of units in the chain arises.

It has been shown theoretically that the distribution of the sequences of units of each type with respect to length in the copolymer obeys an exponential law[107] and the average number of blocks in the chain (l) is described by the expression[124]

$$l^2 = K(m_a - l)(m_b - l) ,$$

where K is a combination of the rate constants for the cross-exchange reactions between the chains, l the number of blocks of units of a given type in the chain, and m_a and m_b are the total numbers of monomeric units of types A and B respectively.

The relations obtained have been confirmed experimentally for a series of objects in a number of investigations[11,36,40,46,125–131]. It is noteworthy that in the general case the quantitative study of the formation of polymers in the interaction of two homopolymers or the study of the polymerisation of one of the monomers in the presence of another homopolymer is extremely difficult and this problem has been solved successfully only in the study of thermostable formaldehyde copolymers[127,129]. However, the problem simplifies considerably if one employs model low-molecular-weight compounds. In this case it is possible not only to estimate the combinations of the constants for the cross-exchange between the chains but also to determine separately all the rate constants for the elementary reactions[11,126,128,131].

2. The Role of CTD in Individual Stages of the Polymerisation Process

A second important aspect arising when the formation reactions of heterochain polymers are considered is the need to allow for the active role played by the resulting macromolecules themselves. Indeed, it is seen from Scheme 5 that the CTD reaction proceeds via an intermediate stage involving the formation of an unstrained 'onium ion whose reactivity differs in the general case from that of the growing active centre. As a consequence of this, the nature and concentration of the active centres change. The kinetic effects are then in essence caused by the competition between the chain propagation reactions at the free active centres (R_j^*) and the active centres bound in a complex with a macromolecule (R_jp)*. These reactions can be represented by the following kinetic scheme:

$$R_j^* + m \xrightarrow{k_1} R_{j+1}^* ,$$

$$R_j^* + p \rightleftarrows (R_jp)^* ,$$

$$(R_jp)^* + m \xrightarrow{k_2} R_{j+1}^* + p .$$

Evidently, the case where $k_2 < k_1$ corresponds to the progressive retardation of the chain propagation reaction. If $k_2 = 0$ and the equilibrium in the complex formation reaction between the growing active centre and the macromolecule is strongly displaced to the right, the implication is that the growing active centres are deactivated in the given system and that the rate of polymerisation decreases until the complete arrest of the reaction. It has been shown in a series of experimental studies that both these cases are characteristic of the ionic polymerisation of heterocycles[14,22,35,132,133]. Thus in the cases considered, the influence of the macromolecules formed reduces mainly to the inhibition of the polymerisation process.

The macromolecules are actively involved also in the initiation stage[107], because the growing active centres can be formed in the interaction of the catalyst (Ct) with both the monomer and the polymer:

$$Ct + m \xrightarrow{k_1} R_1^* ,$$

$$Ct + p_j \xrightarrow{k_2} R_i^* + p_{j-i} .$$

Under the influence of the catalyst, the macromolecules decompose under these conditions to yield growing active centres, which do not differ in their chemical nature from those arising on direct interaction of the catalyst with the monomer. When $k_2 > k_1$, the rate of accumulation of the active centres in the polymerisation system increases progressively, so that the polymerisation should be clearly autocatalytic. A whole series of similar instances have been observed experimentally in the cationic polymerisation of cyclic acetals under the influence of protic and aprotic acids[29,36,134].

The second possible version of the involvement of macromolecules in the initiation step corresponds to the scheme

$$Ct + m \xrightarrow{k_1} R_1^* ,$$

$$Ct + p_j \rightleftarrows Ct p_j .$$

In this case, the macromolecule reacts with the catalyst molecules to form complexes which are inactive in polymerisation, playing the role of a kind of inhibitor. The fraction of the catalyst bound in a complex with the polymer is determined by the relative basicities of the heteroatom in the monomer and polymer molecules. Such a situation frequently arises in the polymerisation of many cyclic ethers under the influence of Lewis acids[135,136].

If a low-molecular-weight substance is present in the polymerisation system and is involved in the reaction as a chain transfer agent, then the reaction

$$R_j^* + XY \xrightarrow{k_n} R_jY + X^*$$

results in the formation of an active fragment X* whose reactivity towards the monomer is in general different from that of the growing active centre. The reinitiation reaction can occur when the active fragment X* interacts with the monomer or polymer molecule:

$$X^* + m \xrightarrow{k_1} R_1^* ,$$

$$X^* + p_j \xrightarrow{k_2} R_i^* + p_{j-i} .$$

If the case where $k_1 \ll k_p$ and $k_2 \gg k_1$ obtains, then analysis shows[107] that a completely unusual autocatalytic character of the polymerisation process itself and the consumption of the chain transfer agent should be observed. Such a case has in fact been noted in the polymerisation of dioxolan in the presence of chain transfer agents generating a proton as the active fragment[137].

The different versions examined demonstrate convincingly that one cannot understand the extremely complex kinetics of the ionic polymerisation of heterocycles without taking into account the active role which the macromolecules formed themselves play in such polymerisation. The macromolecules influence all the stages of the polymerisation process—the initiation of the growing centres and the propagation, transfer, and termination of the reaction chains. This influence is exerted because each active species in the system is capable of reacting with any unit of the polymer chain to form an active centre bound in a complex, whose decomposition results in the formation of new active centres with a modified reactivity.

This is manifested particularly strikingly in the copolymerisation of heterocycles when the interchain exchange processes occurring in the system supplement the cross-exchange reactions, which leads to an alteration of the concentrations of all types of growing active centres. In consequence of this, the dependence of the composition of the copolymer formed on that of the monomer mixture is not described by the classical Mayo-Lewis equation. This problem has been analysed in detail and methods have been developed for the determination of the copolymerisation constants in the presence of the CTD reaction[107,126]. The use of the classical version of the Mayo–Lewis equation leads to effective copolymerisation constants which must be approached with much caution.

It remains to note yet another important feature of systems in which the CTD reaction occurs, namely the appearance of a special kind of "living" state of the polymerisation system[107, 109,114,138]. It is characterised by the fact that, in contrast to the classical "living" polymerisation[1], in the CTD reaction each "dead" macromolecule can be "revived" regardless of the nature of the terminal groups. This ultimately results in the involvement of all the macromolecules, both "living" and "dead", in the propagation process.

One of the important aspects of the relevant studies is investigation of the detailed mechanism of the elementary step in the CTD reaction. In a general form, it can be represented by Scheme (5), but in each specific instance, when the chemical nature of the polymer chain is varied, the actual reaction mechanism becomes more complex. Nevertheless, in all the instances investigated, it has been shown that the reaction must proceed via the intermediate formation of an active growing centre bound in a complex with a macromolecule[40,107,120,132]. For example, it has been shown[132] that the interaction of the macrocation with the chain leads to a large increase of viscosity owing to the effective increase of the molecular weight.

The exchange reactions can be simply and conveniently modelled with the aid of low-molecular-weight compounds, which simulate particular functional groups involved in the CTD. The low-molecular-weight compounds model either the reagent (the growing active centre) and the substrate (the macromolecule attacked by the active centre) or only the substrate. In the latter case only the chain transfer to the low-molecular-weight compound is in essence investigated. Such studies have been carried out for a whole series of compounds: ethers[120], esters[40,46,125,139–142], and acetals[4,11, 36,106,143]. The available information about the mechanisms of many interchain exchange reactions in various derivatives of carboxylic acids, sulphur-, phosphorus-, silicon-, and metal-containing compounds, and certain other systems has been surveyed and described systematically in a monograph[107].

3. CTD As a Method of Synthesis

The possibility of the practical employment of interchain exchange reactions for the synthesis and chemical modification of polymeric materials is very important. Their use for the synthesis of statistical block and graft copolymers as well as polymers with specified terminal functional groups is most promising. In principle, there is a possibility of two methods of synthesis of copolymers using interchain exchange reactions: the polymerisation of the monomer in the presence of another homopolymer and the interaction of two homopolymers.

In the former case, i.e. in the polymerisation of the monomer in the presence of another homopolymer, the polymerisation is accompanied by CTD to the "foreign" homopolymer present in the system. At the beginning of the process, a block copolymer is formed and then transformed into a statistical copolymer as the vigorous interchain exchange reaction proceeds. This method has been applied to a number of systems, in particular to the cationic polymerisation of cyclic ethers, esters, and acetals in the presence of heterochain polymers of different kinds[130,133,144].

If the comonomers differ sharply in their reactivities, then their copolymerisation leads initially to the homopolymerisation of the more reactive monomer and then the less reactive monomer polymerises in the presence of the second homopolymer. In the absence of interchain exchange such a reaction would have led to the formation of a mixture of homopolymers but in systems where a sufficiently intense interchain exchange takes place a statistical copolymer is produced. The copolymerisation of trioxane with dioxolan, where the latter is consumed during the induction period of the polymerisation of trioxane, proceeds in this particular way[145]. A similar situation obtains also in a number of other systems[107].

In such cases one should speak of polymerisation in the presence of another homopolymer rather than copolymerisation, although externally the process appears to be the usual copolymerisation. On this basis, a method has been developed for the synthesis of mixed carboheterochain block copolymers[146], which is the most general of those known at the present time[107]. It consists in the cationic or anionic polymerisation of vinyl monomers in the presence of heterochain polymers, whose bonds may be ruptured under the influence of the growing ions. This method is entirely universal; any heterochain polymers obtained by both polymerisation and polycondensation can be used in the reactions and the reaction itself can be carried out both homogeneously and heterogeneously. It is important that the polymerisation process can also be carried out directly on the finished articles (fibres, films) made of heterochain polymers, which makes it possible to modify the properties of only a thin surface layer.

When two homopolymers interact in the presence of a catalyst, block or statistical copolymers are also produced[107].

If the heterochain homopolymer is made to react with low-molecular-weight compounds, which behave as agents transferring the reaction chain, then the polymer is degraded and the chains formed contain the corresponding terminal groups. This principle has been used to obtain polymers and oligomers with specified end groups and it can be applied also in the usual version of the polymerisation of a monomer in the presence of a chain-transfer agent[107]. When the interchain exchange reactions take place in such systems, the relative rates of consumption of the reactants (of the monomer and the chain-transfer agent) are unimportant for the final result, since a continuous redistribution of the end groups in the macromolecule takes place under these conditions.

The above methods for the modification of heterochain polymers have been used successfully for the solution of various practical problems and in the first place for the thermal stabilisation of polymers based on formaldehyde. Above the limiting temperature, such polymers decompose fully to the monomer as a result of depolymerisation. This virtually precludes their conversion into finished articles, since the temperature at which this is done usually exceeds the limiting temperature. This contradiction can be resolved by creating conditions under which the induction period of the given chain process is significantly longer than the time necessary for the working of the polymer. Depending on the degradation mechanism[110], this can be achieved in two ways. If the initiation reaction of the thermal degradation of the polymers begins from the end of the chain, then end groups whose thermal decomposition takes place above the limiting temperature for the given polymer must be introduced

into the latter. On the other hand, if the initiation is random, as, for example, in the thermo-oxidative degradation of polyformaldehyde, then the introduction of stable units by the formation of a copolymer makes the kinetic chain length in the degradation process significantly smaller than the average chain length of the copolymer.

Both these procedures have been applied successfully using the interchain exchange reaction for the solution of the problem of the thermal stabilisation of polymers based on formaldehyde. The following methods have been developed for the synthesis of formaldehyde homopolymers and block copolymers via a cationic mechanism (using catalysts of the type of Lewis acids and their complexes): (a) polymerisation with stabilisation of the end groups via chain transfer to low-molecular-weight linear acetals[147,148]; (b) copolymerisation of formaldehyde with cyclic acetals[149, 150]; (c) polymerisation of formaldehyde accompanied by chain transfer with dissociation of macromolecules into polymeric acetals or ethers[127,151,152]; (d) exchange reactions between polyformaldehyde and linear polyethers and polyacetals[153].

The study of copolymerisation by the second of the methods listed above in the gas phase in a flow system showed that a special type of copolymerisation takes place in which a true copolymer is obtained despite the fact that the monomers are polymerised on active centres of different types[149].

Oligomeric products of different types with two functional reactive groups, obtained using the interchain exchange reaction, found extensive applications as starting materials for the synthesis of polymers, plasticisers, intermediates in organic synthesis, surfactants, etc.[107,120,154]

One of the exceptionally important problems in practice is the employment as a secondary starting material of used articles made of polymeric materials or of industrial waste. In the case of polymers having heterocarbon linkages in the main or side chains, the application of the interchain exchange reactions to the solution of this problem is of interest. A series of successful examples of this kind already exist[107,155], but the extensive possibilities inherent in the interchain exchange reaction for such purposes have still been inadequately employed in theoretical research and in practice.

This review has dealt with the results of kinetic and structural studies of cationic polymerisation reactions of heterocycles. The set of data obtained for the mechanisms of the reactions investigated demonstrate convincingly the fruitfulness of the kinetic approach. Further development of this field will be directed towards the determination of quantitative kinetic data; this will make it possible to develop and supplement the existing ideas concerning the nature of the active centre in the cationic polymerisation of heterocycles and to establish a relation between its reactivity and structure.

An important kinetic method involves the study of low-molecular-weight models. In this case it is frequently possible to obtain the most clear-cut correlations between the kinetic constants and thermodynamic parameters, i.e. the structure of the reacting substances. However, the complete transfer of the results obtained to polymeric objects is not always possible, since the polymeric nature and the specific features of the physical state of the polymer chain are in many instances largely manifested in the chemical reactions of the polymers; an example of this is provided by zwitter-ions. Allowance for the physical state of the system in the study of the kinetics of the formation reactions and transformations of macromolecules becomes more important the finer the details of the mechanism in which the investigator is interested.

The Synthesis and Properties of Polymerisation-filled Polyalkenes

F.S.D'yachkovskii and L.A.Novokshonova

The general principles of the polymerisation filling of polyalkenes and various other polymers have been examined. Physical and chemical methods for activating mineral and organic fillers, which lead to the production on their surface of active centres initiating polymerisation processes, have been discussed. The kinetic characteristics of the polymerisation of various monomers on a surface have been examined. The results of studies of the properties and various characteristic features of the structure of polymerisation-filled compositions have been described.
The bibliography contains 65 references.

I. INTRODUCTION

The importance of filled polymers has increased sharply in recent years. This is due to two factors: firstly, the introduction of mineral and organic fillers into polymers gives materials with a new set of properties, and secondly, the presence of fillers leads to a decrease in the relative proportion of polymer in the final product, giving a saving in organic raw material or an increase in the production of the final product for the same amount of polymer. The rate of increase in the production of fillers for polymers in the developed capitalist countries is several times the rate of development of the production of polymeric materials[1-3]. Among the plastics produced at present, the greatest tonnage corresponds to polyalkenes (polyethylene, polypropylene), polyvinyl chloride, and polystyrene plastics. Thus the development of effective methods for introducing fillers into these polymers to obtain constructional materials for various purposes based on them is a task of practical importance.

The traditional method of obtaining filled thermoplastics involves the mechanical mixing of the polymer and the filler in powdered form or the combination of the components in a polymer melt. At the present time, practically all forms of filler in other countries are treated with special substances, or finishes, such as silanes and titanates[2], which give the surface of the filler improved adhesive properties with respect to the polymer. The aim of the finishing is to increase the degree of filling, and to improve the physicomechanical properties of the composites and their workability. The finishing of fillers is a multi-stage energy-consuming process. The expenditure on the preparation of the mixture compositions is 20-30% of the cost of the composite[3].

In spite of all the difficulty of introducing a filler into a polymer, considerable progress has been made in this field, and the world production of filled compositions is increasing steadily[1-3]. In 1975, a fundamentally new way of obtaining filled polymers was proposed, namely polymerisation filling, in which the polymer-filler composition is obtained by polymerising the corresponding monomer on the surface of an organic or inorganic filler, that is directly in the course of the synthesis of the polymers[5]. The polymerisation processes in this case can be initiated by complex catalysts, organometallic compounds, free radicals, or ions, fixed on the surface. As a result of the polymerisation of the monomer on the surface of the filler, the latter is covered by a layer of polymer, that is a polymeric capsule is in fact formed[4-6].

The method of polymerisation filling opens up extensive possibilities for the synthesis on filler surfaces of various polymers (homo- and copolymers, block copolymers, two different polymers, etc.).

Control of the kinetics of the process makes it possible to obtain polymer coverings of different thickness, that is compositions with practically any degree of filling (up to 95% of filler by volume). Thus control of the nature of the polymer matrix and the polymer-filler ratio makes it possible to create completely new composition materials which cannot be obtained by ordinary mixing methods.

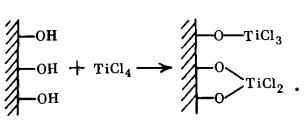
Work on the synthesis and study of new types of polymer compositions, norplasts, is now being actively developed under the direction of N.S.Enikolopov in the Institute of Chemical Physics of the Academy of Sciences of the USSR and other research establishments in the Soviet Union. These studies are combined in a complex directed scientific and technical programme. A review of work on polymerisation filling using radical polymerisation was published recently[7]. The polymerisation of styrene on the surface of various materials has been studied[8-10].

In recent years, work on the development of a method for introducing fillers into polymers at the synthesis stage has also begun in other countries. Thus the firm of Dupont (USA) has published a series of studies on the polymerisation filling of super-high-molecular polyethylene by inorganic fillers[11].

The overall process of the production of a polymerisation-filled composite consists of three main stages: 1) the preparation of the filler, 2) the production of active centres on its surface, and 3) the polymerisation of the monomer on the surface. The present review examines methods for activating the surface of fillers, mainly using metal-complex and organometallic catalysts. The characteristic features of the kinetics of the polymerisation of monomers, mainly alkenes, on activated fillers, the structure of the materials formed, and their physicomechanical properties have been discussed.

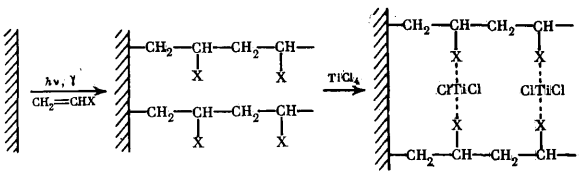
II. PRINCIPLES OF THE POLYMERISATION FILLING OF THERMOPLASTICS

1. Methods for Activating the Surface of Fillers



The activation of a filler involves the creation on its surface of active polymerisation centres; this can take place by an ion-coordination, radical, or ionic mechanism.

The preparation of a filler for polymerisation filling by ion-coordination polymerisation involves the removal, from its surface or from the bulk of the filler, of compounds which inhibit the polymerisation process. These compounds include H_2O, O_2, CO_2, CO, SO_2, NH_3, etc. A large number of hydroxide groups or a high acidity of the surface may also lead to retardation of the polymerisation process. In chemical technology, various methods have been developed for the thermal treatment and for the removal of oxygen from dispersed materials. For example, it is possible to use vacuum treatment, azeotropic drying, and sweeping with inert gases under different temperature conditions. From the viewpoint of the technology of removing inhibiting impurities, it is appropriate to use dispersed materials such as perlite, porous glass, Keramzit (light-weight aggregate), cement dust, etc., whose production involves high-temperature treatment. These fillers contain a minimum amount of moisture and hydroxide groups. Their subsequent treatment involves chiefly the removal of oxygen.

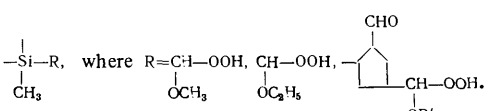


To carry out polymerisation filling by ion-coordination polymerisation, it is necessary to fix metal-complexes or organometallic catalysts on the surface of the filler. Methods have been developed[12,13] for fixing these catalysts, and the methods can be divided into two groups: physical and chemical. In the first case, precipitation (by different methods) of transition metal compounds leads to the formation of a solid phase of transition metal derivatives on the surface or in the pores of the filler. These processes may be accompanied by reduction or oxidation of the transition metal, and they do not require the presence of functional groups on the filler surface. A strong bond is formed between the solid phase of the transition metal compound ($TiCl_3$, VCl_3) and the filler, and this bond is not broken during polymerisation filling. The presence of the solid phase is particularly important for the production of stereoregular polymers such as polypropylene.

The physicomechanical properties of compositions based on polypropylene are determined to a large extent by the ratio of the isotactic and atactic fractions in the polymer. It is therefore necessary to obtain catalysts, fixed on the surface of the filler, which have not only a sufficiently high activity but also a high stereospecificity in the polymerisation of propylene. Of various methods for fixing titanium chlorides on the surface of fillers to act as highly stereospecific catalysts in the polymerisation of propylene, the most promising was found to be the reduction of $TiCl_4$ by organoaluminium compounds on the filler surface[14]. When this method is used, the $TiCl_3$ phase is formed on the surface of the fillers, including those which do not contain functional groups. It is possible to vary both the quantity of titanium fixed and the type of crystallographic modification[14]

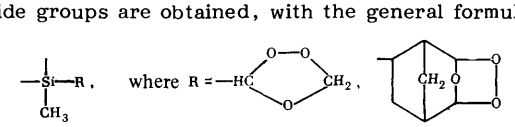
Chemical methods of fixing are based on the reaction of transition metal compounds or organometallic compounds with reactive groups on the surface. The surface of an inorganic filler may carry hydroxide groups, whose surface density is easily controlled by thermal and chemical treatment[15-17]. The magnitude of the surface concentration of OH groups is reflected in the nature of the fixing of the catalytic systems. By appropriate reactions, OH groups can be converted into active polymerisation centres, for example:

Analogous processes take place in the case of compounds of other transition metals. If the surface has no reactive groups, it can be made functional by seeding the surface with small quanities (0.1–2%) of monomers with functional groups, using the published method[18]. These methods are convenient in the production of polymer–polymer compositions by the synthesis of one polymer on the surface of another.



The use of mineral fillers containing catalytically active impurities is of interest. For example, heated kaolin is catalytically active in the polymerisation of ethylene, because of the presence of TiO_2.[11]

The subsequent reaction of transition metal compounds, fixed to the surface, with organometallic compounds (AlR_2Cl, LiR, AlR_3) leads to the formation of active centres, which bring about polymerisation on the surface in the gas phase or in liquid media.



Organometallic compounds of the transition metals can be used for the polymerisation filling of polyethylene[19]. These catalysts have a high activity, and do not require additional activation in the polymerisation medium by an organoaluminium cocatalyst. The formation of the active component in these catalysts takes place by the reaction of the organometallic compound with the surface hydroxide groups of the filler. Compounds of the type $(E{-}O{-})_x{-}MR_y$, where E = Si or Al, M is a transition metal, and R = C_3H_5, $CH_2C_6H_5$, BH_4, etc., are formed on the surface. Filled polyethylene can be obtained using one-component catalysts (for example $TiBz_4$) deposited on natural oxide fillers: asbestos, perlite, alumina, belite sludge, etc.[19]. A high catalytic activity is observed when organic and hydride compounds of zirconium are used.

The dependence of the quantity of catalyst fixed on the conditions under which the process is carried out has been studied[19,20,22]. In the chemical fixing of transition metal derivatives, the limiting quantity of fixed metal is restricted by the number of reactive functional groups on the surface, and for swollen perlite, for example, it amounts to 0.04–0.05% of the mass of perlite. With physical methods for the deposition and formation of the transition metal compound phase on the surface, the quantity of catalyst may be appreciably higher[20,21].

In polymerisation filling processes taking place by a radical mechanism, use is made of fillers which are peroxide group carriers (dialkyl, hydroperoxide) or fillers with groups on their surface capable of polymerisation[23-26]. Comparatively simple methods have been proposed for obtaining peroxide-containing mineral fillers with the general formula:

A mineral filler containing vinylmethylsilyl or norbornenylsilyl groups has been ozonised in alcohol or an organic acid. When the ozonisation is carried out in a hydrocarbon or a halogen derivative, peroxidised fillers with grafted ozonide peroxide groups are obtained, with the general formula

At increased temperatures, these mineral carriers initiate the process of heterogeneous radical polymerisation.

Active polymerisation centres can also be produced on the surface of inorganic fillers by various mechanical and physical treatments of the fillers. Thus the activating effect of thermal treatment and thermal vacuum treatment, and also mechanical grinding[27,28], are familiar in heterogeneous catalysis. The appearance of active centres when various oxides are heated may also be related, for example, to the formation of compounds of the Lewis acid type on the surface, and also to the production of coordinatively unsaturated metal atoms.

Irradiation using different forms of radiation can also be employed to initiate on a surface centres for the polymerisation of such monomers as vinyl chloride, vinyl acetate, acrylonitrile[29], and others, polymerising by a radical mechanism. In addition, these centres can react with organometallic compounds or metal-containing monomers, leading to the formation of ion-coordination centres[30].

2. Regular Kinetic Features of the Polymerisation Filling Process

The regular kinetic features of the polymerisation filling of polyalkenes are determined by the characteristic features of the polymerisation processes on the solid surfaces. Organometallic catalysts, particularly catalysts based on compounds of transition metals in a higher oxidation state, are unstable, and this is revealed in the appreciably non-stationary kinetics of the polymerisation of alkenes in their presence. The fixing of organometallic catalysts on a filler surface usually leads to appreciable stabilisation of their activity with time, and this makes it possible to increase the temperature range in which these catalysts can be used in polymerisation processes[20,21,31] and to increase their efficiency.

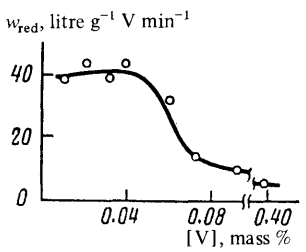


Figure 1. Dependence of the reduced rate of the gas-phase polymerisation of ethylene on the surface of perlite activated by VCl_4 and $Al(i\text{-}C_4H_9)_3$ on the quantity of vanadium fixed on the perlite surface; polymerisation temperature 87 °C, ethylene pressure 2.1 atm.[20]

Increase in the quantity of a transition metal (vanadium or titanium) fixed on a filler surface within the limits of the maximum possible number of reactive functional groups of the same type (for example up to ~6×10^{-6} mole M m^{-2} in the case of swollen perlite) is accompanied by a proportionate increase in the rate of polymerisation of ethylene; the specific activity of the catalyst remains constant (Fig.1). The similarity in the nature of the active centres produced with increase in the surface concentration of the catalyst to the limit given is also indicated by the fact that the observed rate constants of the deactivation of the active centres practically coincide (Table 1).[20,21]

With increase in the surface concentration of the fixed transition metal compound above the limit indicated, the formation of the solid catalyst phase begins, leading to a decrease in the specific catalytic activity of the system in the polymerisation of ethylene (see Fig.1). This is due on the one hand to a change in the nature of the active centres and on the other hand to a simultaneous decrease in the degree of utilisation of the transition metal in the polymerisation process.

Table 1. Kinetic characteristics of the gas-phase polymerisation of ethylene on the surface of inorganic fillers activated by VCl_4; cocatalyst $Al(i\text{-}C_4H_9)_3$.[21]

Catalytic system	[V], mass %	T, °C	w_{red}, litre min^{-1}g^{-1} V	E_{eff}, kcal mole^{-1}	k_d, min^{-1}
VCl_4/perlite	$7.1 \cdot 10^{-3}$	87	38	11.0	$1.8 \cdot 10^{-1}$
VCl_4/perlite	$3.6 \cdot 10^{-2}$	87	43	11.3	$1.5 \cdot 10^{-1}$
VCl_4/aluminosilicate	$8.5 \cdot 10^{-3}$	82	52	11.6	$4.8 \cdot 10^{-2}$
VCl_4/aluminosilicate	10^{-1}	82	16	11.8	$4.5 \cdot 10^{-2}$

Symbols: [V] is the quantity of fixed V, w_{red} the rate of polymerisation, related to the concentration of the monomer and the quantity of catalyst, E_{eff} the effective activation energy of the polymerisation of ethylene, and k_d the rate constant of the deactivation of the active centres in the initial section of the kinetic curve.

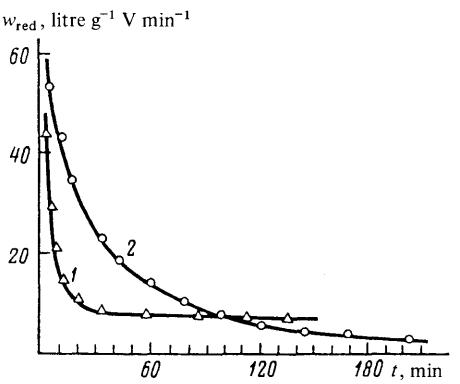

Figure 2. Kinetic curves for the gas-phase polymerisation of ethylene on the system VCl_4/perlite (5.9×10^{-6} g-atom V m^{-2} perlite) (1) and VCl_4/aluminosilicate (8.8×10^{-6} g-atom V m^{-2} aluminosilicate) (2); cocatalyst $Al(i\text{-}C_4H_9)_3$; molar ratio Al/V = 9.2, polymerisation temperature 87 °C, ethylene pressure 2.1 atm.[20]

The mineral materials used as polymer fillers generally have a complex chemical composition. For example, fillers based on SiO_2 or Al_2O_3 contain traces of the oxides of a number of other metals, and this should naturally influence the catalytic properties of the systems formed when catalysts for polymerisation processes are attached to these fillers. As shown in Fig.2, in the gas-phase polymerisation of ethylene

on VCl_4 fixed on perlite and on an aluminosilicate, at similar surface concentrations of vanadium, other conditions of the process being equal, the maximum specific rates of polymerisation have similar values. The stabilities of the catalytic systems formed on perlite and on an aluminosilicate differ considerably, however. For perlite, after an initial non-stationary region, the rate of polymerisation remains constant for a long time, and the kinetics of polymerisation can be described assuming the existence of two types of centre, one of which is deactivated by a first-order reaction, while the second is stable. When an aluminosilicate is used as a filler, the active centres in the initial range are deactivated much more slowly (see also Table 1), the stationary state in general is not reached, and the deactivation law is more complex[20,21].

The increased stability of fixed metal-complex catalysts compared with colloidally dispersed catalysts makes it possible to synthesise polymerisation-filled polyethylene at higher temperatures than usual, up to at least 100 °C.[21] The effective activation energy of the polymerisation of ethylene on the surface of fillers activated by titanium and vanadium compounds is 11.0–11.8 kcal $mole^{-1}$ for both the gaseous and the suspension methods of carrying out the process. As shown by a published analysis[21], the decrease in the rate of polymerisation with time, observed in the processes studied, is not related to diffusion restrictions in the transport of the monomer through the polymer covering to the active surface of the filler, but is due to chemical factors. The transformations leading to the deactivation of the active centres are generally reactions of first order with respect to the active centres. Bimolecular disappearance of the active centres fixed on a surface is seldom observed in the polymerisation of alkenes.

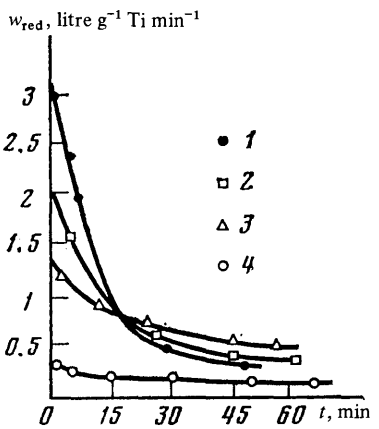

Figure 3. Kinetic curves for the polymerisation of propylene in the liquid monomer for different methods of producing the catalyst on the perlite surface (cocatalyst concentration $[(C_2H_5)_2AlCl] = 4 \times 10^{-3}$ M, polymerisation temperature 70 °C); *1*) β-$TiCl_3$ (reduction of $TiCl_4$ on perlite treated with $(C_2H_5)_2$.AlCl, at 20 °C, 1.5 mass % Ti); *2*) $TiCl_3$ (reduction of $TiCl_4$ on perlite from the complex $TiCl_4$–$(C_2H_5)_2AlCl$, at −45 °C, 2.4 mass % Ti); *3*) $TiCl_3$ (obtained from catalyst 1 by subsequently heating to 180 °C, 1.5 mass % Ti); *4*) $TiCl_3$ (reduction of $TiCl_4(C_2H_5)_2AlCl$ at 180 °C without treatment with $(C_2H_5)_2AlCl$, 1 mass % Ti).[14]

For the polymerisation of propylene on filler surfaces, fixed phase catalysts based on MCl_3 (M = Ti, V) are used[14]. Studies have shown that the level of activity achieved, and the nature of the kinetic curves, depend on the conditions of the formation of the catalyst on the surface of a given filler and on the conditions of the propylene polymerisation process. This is effectively illustrated by the data given in Fig. 3.

The activity of catalysts for the polymerisation filling of polypropylene for a number of fillers studied was found to be higher than that of finely dispersed crystalline titanium trichloride[14].

As in the polymerisation of ethylene, the nature of the filler has a significant influence on the catalytic properties shown by the resulting fixed systems in the propylene polymerisation process[14,32]. The results obtained using graphite as filler are particularly noteworthy[32]. The catalyst $TiCl_3$, deposited on graphite, has a higher activity than $TiCl_3$ deposited on other fillers such as perlite, talc, and chalk (Fig. 4). The polypropylene formed in this case has molecular mass of 1.5×10^6. The introduction of hydrogen into the reaction zone makes it possible to control the molecular mass over a wide range without change in the rate of polymerisation, and this makes it possible to obtain extruded and cast forms of filled polypropylene.

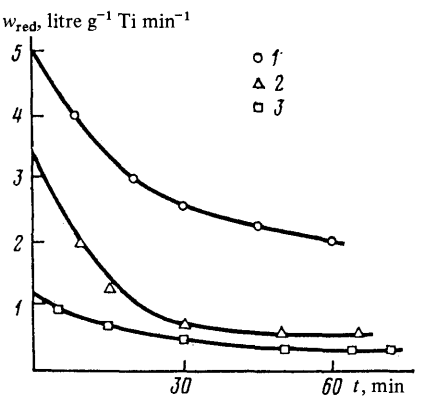

Figure 4. Influence of the nature of the filler on the kinetics of the polymerisation of propylene in the liquid monomer (fixed $TiCl_3$–$Al(C_2H_5)_3$ catalyst, where $[Al(C_2H_5)_3] = 4 \times 10^{-3}$ M, polymerisation temperature 70 °C); *1*) graphite, [Ti] = 0.14 mass %; *2*) perlite, [Ti] = 0.24 mass %; *3*) $TiCl_3.0.33AlCl_3$ (finely dispersed)[32].

The specific activity of a catalyst, based on vanadium and deposited on a filler, in the polymerisation of propylene, as in the case of a catalyst fixed on polymeric catalysts, depends on the surface concentration of the vanadium compound on the filler[33], and this dependence is extreme in character.

Metal-complex catalysts, modified by electron-donating additives and fixed on a surface, can be used to initiate the polymerisation of not only alkenes but also derivatives of vinyl monomers (for example vinyl chloride), whose polymerisation usually takes place by a radical mechanism with the aid of peroxide initiators. This type of polymerisation of vinyl chloride has been carried out[20] using fixed catalysts based on vanadium and titanium chlorides; tri-isobutylaluminium was used as cocatalyst, and diethyl ether was

used as an electron-donating additive. As in the polymerisation of alkenes, the fixing of the catalysts on the surface of the fillers leads to a sharp increase in the efficiency of the polymerisation of vinyl chloride.

The polymerisation of vinyl chloride at first takes place in non-stationary fashion; subsequently, a practically constant rate is established for a long period[20]. The initial non-stationary sections of the kinetic curves, irrespective of the surface concentration of the catalyst, the molar ratio Al/V, and the polymerisation temperature, become complete straight lines on coordinates $1/w-t$. This indicates that the disappearance of the active centres is bimolecular in the polymerisation of vinyl chloride on metal-complex catalysts fixed on a surface, in contrast to the polymerisation of alkenes, where, as shown above, the transformation of the active centres almost always takes place according to the law governing reactions of first order with respect to the active centres. The ratio of the rate constants of the bimolecular disappearance of the active centres and propagation (k_t/k_p) is $(2-3) \times 10^3$, which is characteristic, in principle, of radical polymerisation. The activation energy of polymerisation, determined from the initial reaction rate, is 5.8 kcal mole^{-1}, which is also similar in magnitude to the activation energy of growth in the polymerisation of vinyl chloride by a radical mechanism. On going to the stationary part of the curve, the activation energy of the polymerisation increases considerably (to 11 kcal mole^{-1}), that is to a value characteristic of the ion-coordination polymerisation of vinyl monomers. The polymer formed in the early stages of the polymerisation of vinyl chloride in the production of a polymer covering on the filler particles is characterised by a unimodal molecular-mass distribution (MMD). With further increase in the quantity of polymer in the composite, a second maximum appears on the polydispersion curves in the range of higher molecular masses, and the proportion of the high-molecular-weight polymer increases considerably with time.

The appearance of the bimodal molecular-mass distribution during the process, and the change to stationary polymerisation, might be related in principle to the hetero-phase character of the polymerisation of vinyl chloride in the mass. The second mode, characterising the high-molecular-weight fraction of the polymer, appears, however, even in the initial non-stationary stage of the process, and the ratio of the rate constants k_t and k_p remains constant with time. The observed characteristic features of the kinetics of the polymerisation of vinyl chloride on metal-complex catalysts fixed on filler surfaces can apparently be attributed to the presence of two types of active centre for polymerisation—radical and ion-coordination.

Thus the kinetic studies carried out have established that the catalytic and initiating power of transition metal complexes or organometallic compounds, fixed on a filler surface, is greater than that of the analogous non-fixed systems. This makes it possible to decrease the consumption of catalysts or to obtain a given degree of filling in a short time. Naturally, in the synthesis of highly filled and superhighly filled compositions, the consumption of catalyst per unit weight of the polymer increases. The general regular kinetic features of polymerisation filling are similar to those of the polymerisation of the analogous monomers. The specific features of reactions on a surface, however, raise the question of the reactivity of the associates of the active centres and the transition metal clusters in these systems.

3. Technological Aspects of Polymerisation Filling

Technological studies of the production of polymerisation-filled polyethylene have now been carried out[6,34-36]. Various general questions can be considered. The composition of the material (the degree of filling ϕ) formed in the polymerisation is given by the simple expression[12]

$$\varphi = \frac{P \cdot 100}{\int_0^t w_t dt + P}$$

where P is the quantity of filler introduced into the reaction vessel, and

$$\int_0^t w_t dt —$$

the quantity of polymer formed in the reactor in time t. Thus the degree of filling is determined by the quantity of added filler and the rate and time of polymerisation. The productivity of a continuous reaction vessel g with respect to the overall product will be given by

$$g = \frac{\alpha(P')\bar{y} + P'}{V}$$

where V is the volume of the reactor, P' the quantity of filler added to the reactor in unit time, $\alpha(P')$ the quantity of catalyst on the filler surface, and $\bar{y}$ the specific yield of polymer per unit of catalyst in unit time.

The addition of the filler to the reaction vessel increases the yield of the overall product, and a given concentration of the suspension (Π_p) is reached for a shorter average residence time τ_{av} of the particles in the reaction vessel.

$$\tau_{av} = \frac{\Pi_p}{g} = \frac{\Pi_p \cdot V}{\alpha(P')\bar{y} + P'} .$$

A significant feature is that the productivity of the reactor with respect to the overall product can increase in polymerisation filling without an increase in the heat liberated in the system. If the productivity of the reactor is limited by the limiting concentration of the suspension, it can be seen from the given relationships that this limit is reached in a shorter time when the filler is added to the reactor.

The technological process of polymerisation filling can be carried out under conditions of both gas-phase and suspension polymerisation, and also by polymerisation in the mass of the monomer. The stage of activation of the filler—the fixing of the catalyst or the polymerisation initiator on the filler particles—can also be carried out from the vapour phase of the catalyst in a vacuum or in a stream of an inert gas carrier, or from solution in an organic solvent. Thus the addition of the filler to the polymer at the stage of its synthesis can be organised technologically in such a way that it is entirely gas-phase, entirely suspension, or a mixed version. Necessary requirements for obtaining a product of good quality in all conditions are uniform deposition of the catalyst on all the particles of the filler, and the suppression of the processes of agglomeration of the filler at the stage of catalyst fixing and polymerisation. The latter is important not only from the viewpoint of obtaining the necessary physicomechanical properties of the final material but also to ensure stability of operation of the polymerisation reactor under continuous conditions. The apparatus design for the processes of polymerisation filling is practically the same for the polymer synthesis process. Thus the synthesis of pilot-plant batches of polyethylene–kaolin compositions has been carried out using a technological line for the preparation of high-density polyethylene in the Gur'ev chemical plant[34,36]. A basic diagram of the technological line is shown in Fig. 5. The polymerisation was carried out at 70–80 °C to give 80–70 mass % of polyethylene relative to the added kaolin. The principal parameters of the technological process are given in Table 2.

Analysis of the results of the industrial synthesis of filled polymers has shown that the use of continuous mixing flow reactors has a number of important technological and economic advantages (easy transportation of the suspension, effective removal of the heat of the reaction, the possibility of using existing technological units, etc.). In this case, however, at the outlet from the reaction vessel there will be a certain proportion of particles on which a polymer covering has not been able to form, because of the short residence time in the reactor. The experimental data indicate that the presence of particles not covered by polymer has a significant influence on the quality of the composition, leading to a deterioration in its properties and making processing difficult. This unsatisfactory feature can be eliminated by introducing a grader into the technological line[37]. A mathematical analysis of the possibility of using continuous mixing reactors with pulse introduction of the original reagents and removal of the polymerisation product has been carried out[38]. The analysis showed that this reactor makes it possible to guarantee a given value of the minimum covering of the filler particles by the polymer.

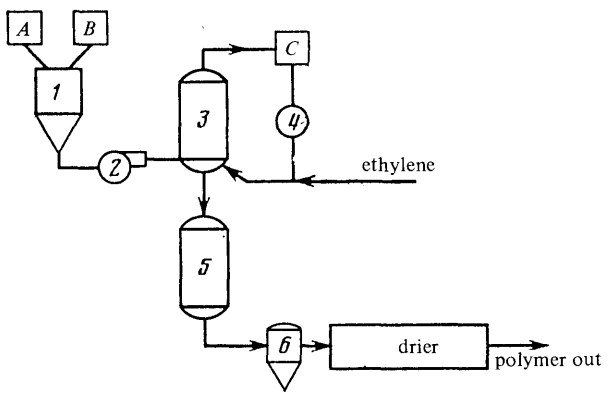

Figure 5. Basic technological scheme for producing a polyethylene–kaolin composition: *1*) vessel for depositing the catalyst on the kaolin surface; *2*) centrifugal pump; *3*) reactor; *4*) gas blower; *5*) product collector; *6*) centrifuge; *A,B*) equipment for metering the components of the catalyst; *C*) cooler[34].

Table 2. Parameters of the technological process[34].

T, °C	τ, h	$P_{C_2H_4}$, kg cm^{-2}	$Q_{C_2H_4}$, kg	c_{H_2}, vol.%
72—80	4.0	2.4—3.2	900	—
70—82	2.0	3.0	550	—
76—78	3.5	2.1—4.0	900	1.2—1.7
73—79	3.0	2.2—3.2	750	6.8

Symbols: τ is the average polymerisation time, $P_{C_2H_4}$ the ethylene pressure in the reactor, $Q_{C_2H_4}$ the quantity of ethylene absorbed, and c_{H_2} the hydrogen concentration in the gas mixture.

The principles of the technological process for the synthesis of porous plastics in the gas phase have been examined[39]. Studies of the kinetic parameters of the process and the removal of heat showed that the gas-phase synthesis of a polyethylene–perlite composition can be carried out under stable conditions.

III. THE STRUCTURE AND PROPERTIES OF POLYMERISATION-FILLED THERMOPLASTICS

1. Some Characteristic Features of the Structure of Polymerisation-Filled Polyalkenes

One of the principal factors determining the properties of filled polymer systems is the nature of the adhesion interaction between the surface of the filler and the polymer. Thus in the production of composite materials the problem is to achieve a strong bond between the polymer matrix and the filler. It is for this purpose, that is to improve the adhesion of the polymer to the filler, that modifying treatment of the fillers and matrix polymers is carried out. There is an extensive literature on the study of the structure and properties of the boundary layers at the surface of separation between the polymer and filler phases, since in the final analysis these determine the principal properties of composite materials[40]. An important contribution to the development of ideas in this field has been made by the work of Lipatov and co-workers[41].

As noted above, in the polymerisation introduction of a filler into a polymer, the centres initiating polymerisation are situated on the surface of the filler particles, and the polymer crystallises directly on the surface or in the pores of the carrier. In a composite material, a chemical bond may be formed between the macromolecules and the surface of the filler[42], or an effective adsorption interaction may be established between them, and this determines the nature of the packing of the macromolecules in the surface layer and the characteristic features of the structure of the boundary layer, and has a significant influence on the physicomechanical properties of the final material.

As a result of polymerisation on the surface, the particles of the filler are covered by a layer of polymer of controlled thickness. Studies carried out by scanning electron microscopy and X-ray spectroscopy[43,44] have shown that the polymer coverings formed under the optimum technological conditions for carrying out the process are uniformly distributed over the surface of the particles, and are compact and continuous. This makes it possible to obtain a fairly homogeneous distribution of the particles of the filler in the polymer matrix in the final composite material.

To increase the area of contact between the filler and the polymer matrix, attempts are usually made to decrease the size of the filler particles, down to fractions of a micron. The processes of agglomeration of the finely dispersed particles of the filler, which always take place, are different for the polymerisation method of introducing the filler and for the mechanical mixing of the prepared components. Thus the optimum dimensions of the particles of the original filler for achieving the required properties of a composite material are determined by the conditions of the process and the nature of the catalytic systems or their components. Thus organometallic compounds and transition metal derivatives may bring about agglomeration or deagglomeration of the particles of the filler during the synthesis of the composite[11].

In polymerisation on the surface of filler particles, the polymer is also formed within the pores, micro-cracks, and defects, so that there is a considerable increase in the area of contact between the filler and the polymer matrix and an increase in the strength of their mechanical interaction.

This is confirmed by scanning electron microscopy, which has been used to study the surface produced by the breakdown of composite specimens[45]. According to the data obtained[45-48], the polymer layer produced during polymerisation on the surface of a filler has an increased density.

It has been shown[45,46] that for identical degrees of filling, composites based on polymerisation-filled polyethylene have a lower coefficient of linear expansion than composites based on mechanical mixtures. This is apparently due to the more compact packing of the macromolecules in the intermediate layer at the polymer–filler boundary in the polymerisation-filled materials. The existence of a compact layer of polyethylene round the particles of filler in norplastics has been demonstrated by other workers[47,48].

X-Ray structural analysis[49] has shown that as a result of the cooperative growth of macromolecules on the surface of fillers, in a number of cases, orientation phenomena are observed in the resulting polymer layer, and the direction of orientation of the molecules corresponds to the normal to the filler surface. These orientation phenomena may be fairly clearly defined. Thus for polypropylene obtained on the surface of organic and inorganic fillers, the extent of the orientation corresponds to that of a polypropylene fibre elongated by a factor of 4–5. The observed orientation phenomena influence the density of packing of the macromolecules in the surface layer and the properties of the boundary layer as a whole.

Calorimetry and X-ray structural analysis indicate that materials based on polyethylene filled during synthesis have a degree of crystallinity which is on the average 10% greater than that of mechanical mixtures with similar compositions and identical characteristics of the polymer matrix[45,46].

These characteristic features of the structure of composite materials based on norplastics are apparently helping to ensure the improvement of the properties of composites relative to mechanical mixtures.

2. Compositions Based on Polyethylene

The use of catalytic systems based on the surface of fillers leads to the formation of high- or superhigh-molecular-weight polymers in the polymerisation process. Polymerisation filling is therefore used to synthesise composites based on a high-molecular-weight polyethylene matrix. Methods have been developed for synthesising polyethylene–kaolin compositions[34,36]. The kaolin was activated using catalysts based on titanium or vanadium in the presence of organoaluminium compounds. Polyethylene–kaolin compositions with a polymer molecular mass of $(1.3-5) \times 10^6$ and containing 30–50 mass % kaolin have good physicomechanical properties. These compositions have no fluidity, and articles are produced by sintering, hot pressing, or extrusion. Superhigh-molecular-weight polyethylene has recently been attracting increasing interest as a material with unique properties, and also as a substitute for Fluoroplast. Polymerisation-filled superhigh-molecular-weight polyethylene has a higher wear-resistance and a higher modulus of elasticity than these polymers. Since it is unlikely that alternative methods for obtaining filled compositions based on superhigh-molecular-weight polyethylene by methods involving mixing will be found, the development of the technology for the synthesis of these compositions by polymerisation filling is an important direction of development in this field.

The molecular mass of the polymer matrix in compositions based on polyethylene (PE) is controlled by the usual methods, by adding hydrogen or other chain transfer agents to the system. Thus in the polymerisation filling of polyethylene by kaolin activated by complex vanadium catalysts, the introduction of 15 vol.% hydrogen leads to a decrease in the molecular mass (MM) of the polyethylene matrix from $(2-3) \times 10^6$ to $(1.2-1.6) \times 10^4$.[50] The fluidity index of a molten polyethylene–kaolin composition with a degree of filling of 30 mass % increases from zero (in the absence of H_2) to 10 when $Al(i\text{-}C_4H_9)_3$ is used as cocatalyst. Thus polymerisation filling using an additive which controls the MM of polyethylene gives composites which can be worked by extrusion.

With decrease in the molecular mass of PE, its degree of crystallinity increases, leading to an increase in the rigidity of the polymer and the composition as a whole, to an increase in the modulus of elasticity and the yield point on elongation, and to a decrease in the relative elongation at the yield point[51].

The extent of the decrease in various physicomechanical characteristics with decrease in the molecular mass of the polymer matrix of a composition depends on the nature of the surface of the filler and on its dispersion composition. For various fillers, compositions have been developed which can be worked by casting and extrusion, and articles with good physicomechanical properties have been obtained ($\sigma_t = 25$ MPa), $\varepsilon = 50-400\%$).

Polymerisation has been used[50] to obtain composites with different concentrations of kaolin over a wide range of MM of the polymer matrix (from 3000000 to 125000). When superhigh-molecular-weight polyethylene with MM $> 10^6$ was used as the matrix, the introduction of a filler into the composition in concentrations up to 50 mass % did not lead to any loss of plasticity by the material. The composite deformation curves show high values of the deformational-strength characteristics. For polyethylene–kaolin compositions containing 0, 30, and 50 mass % filler, the limiting tensile strength (σ_t) is 46, 44, and 23 MPa, ε_t decreases from 260 to 240 and 150%, and the modulus E_t increases from 900 to 1900 and 1900 and 2900 MPa respectively. The filling of low-molecular-weight PE leads to the loss of plasticity by the composite at degrees of filling lower than those for superhigh-molecular-weight PE.

Table 3. Properties of heat-insulating materials obtained from norplastics containing swollen perlite and polyethylene[12].

Material	c_p, mass %	σ_c, MPa	σ_b, MPa	m, kg m^{-3}	λ, kcal m^{-1}s^{-1}K^{-1}
Norplastic perlite–PE	10—12	5—9	3	120—150	0.03—0.04
Perlite–phenol-formaldehyde resin*	70	3—5	3	120—150	0.03—0.05

Symbols: c_p is the polymer concentration, σ_c the compressive strength, σ_b the bending strength, m the volume mass, and λ the thermal conductivity coefficient.

*The properties of a heat-insulating material based on perlite and produced in industry at present are given for comparison.

Polymerisation filling can be used not only to obtain finished composites with a given concentration of filler but also to modify the surface of a filler. This is achieved by producing thin polymer coverings during polymerisation on the particles of the filler, and the process can be regarded as a form of finishing of the surface, using macromolecular chains.

These polymerisation-modified fillers or norplastic "concentrates" can be used as independent superhigh-filled composition materials containing up to 80–95 mass % of a mineral component, for example for the production of heat-insulating materials (Table 3).[12]

In addition, norplastic "concentrates" can be introduced as modified fillers by mixing with a prepared industrial polymer of similar character; in particular, this represents one possible way of obtaining cast and extruded composite products[43,45,52–56]. The use of norplastic "concentrates" is promising, since it makes it possible to obtain materials having better physicomechanical properties than mechanical mixtures with analogous composition. For polyethylene composites, these differences are revealed particularly clearly in the values of the specific impact ductility: this property is 1.5–2 times greater for composites based on polymerisation-modified fillers than for mechanical mixtures[43,56].

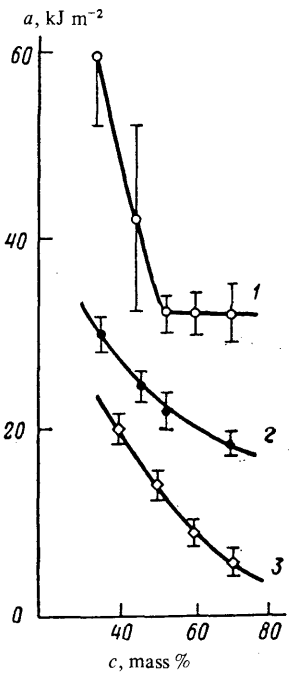

Figure 6. Dependence of the specific impact ductility (a) on the tuff concentration (c) for compositions based on HDPE and tuff (average particle size of the tuff 8.6 μm): *1*) HDPE–norplastic concentrate; *2*) HDPE–tuff–SHMPE mechanical mixture; *3*) HDPE–tuff mechanical mixture[56].

Fig.6 gives the dependence of the specific impact ductility for composites based on high-density polyethylene (HDPE) and a norplastic concentrate containing 87.5 mass % tuff and 12.5 mass % superhigh-molecular-weight polyethylene (SHMPE) on the concentration of tuff in the composite[56]. For comparison, data are given for mechanical mixtures of the matrix polymer and tuff and for mechanical mixtures with the addition of SHMPE in the same quantities as were added in the form of the norplastic "concentrate" to the composites based on norplastics. Results showing differences of a similar scale have also been obtained for composites based on other fillers[43].

The dependence of the tensile strength and the static bending strength on the degree of filling in the composites studied is extremal in character[45,56], and the optimum value lies in the range corresponding to 30–50 mass % filler, depending on the nature of the filler. Fig.7 gives comparative data on the dependence of the maximum tensile strength on the degree of filling for composites with the same composition as in Fig.6. Fig.7 shows that the strength of the composites based on norplastics is much greater than that of the materials obtained by mixing. The use of polymerisation filling also leads to an increase in the rigidity of the resulting material, compared with mechanical mixtures[43].

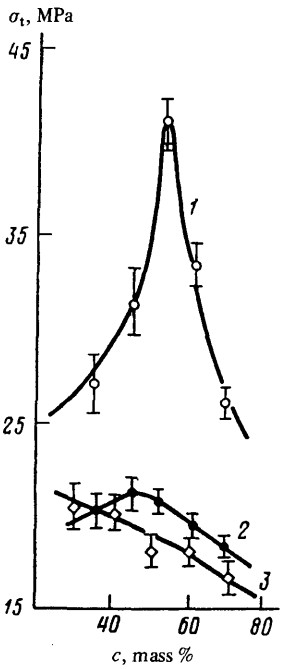

Figure 7. Dependence of the maximum tensile strength (σ_t) on the concentration of filler for compositions based on HDPE and tuff: *1,2,3*) see caption to Fig.6; rate of deformation $\bar{\nu}_\varepsilon = 1.04 \times 10^{-1}$ min^{-1}, σ_t for HDPE = 21.3 ± 1.4 MPa.[56]

Increase to a definite limit in the thickness of the polymer covering which is formed on the particles of the filler and which consists of superhigh-molecular-weight PE leads to an improvement in the strength properties and rigidity of materials based on norplastic "concentrates" for a given concentration of the mineral filler (Fig.8). Fig.8 shows that for the compositions studied, this limit corresponds to ~30 mass % PE in the "concentrate" or ~9 mass % in the composite, for a perlite concentration of 30%. The addition of SHMPE in the same quantities to mechanical mixtures of the matrix polymer and the filler also leads to an increase in the strength of the material, but the properties of the composites obtained in this way are considerably inferior to those of the composites based on norplastics.

3. Compositions Based on Polypropylene

The use of polymerisation filling to introduce fillers into polypropylene (PP) has given new materials with an unusual set of physical and mechanical properties. The structure of polypropylene formed on the surface of a filler is determined to a large extent by the nature of the filler and by the conditions under which the catalyst is prepared and the process is carried out[14,32]. An interesting feature is that the use of graphite as a filler gives the highest degree of isotactic character in PP (up to 94–96%).

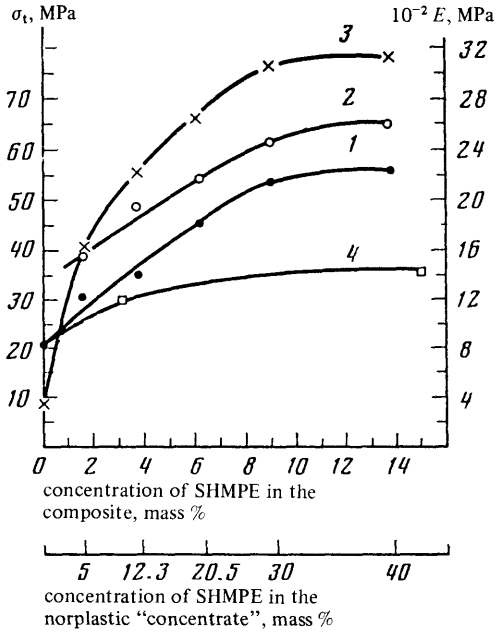

Figure 8. Influence of the concentration of SHMPE in a norplastic concentrate based on SHMPE and swollen perlite on the tensile strength (*1*), the static bending strength (*2*), and the tensile modulus of elasticity (*3*) for compositions based on HDPE and a norplastic "concentrate"; concentration of swollen perlite in all compositions 30 mass %; $\bar{v}_\varepsilon$ = 0.87 min^{-1}; *4*) change in tensile strength for HDPE–perlite–SHMPE mechnical mixtures[43].

The study of the electrical conductivity of polypropylene–graphite compositions has shown that polymerisation filling provides a new and promising method for obtaining heat-conducting and electrically conducting compositions[57–59]. Comparison of the specific resistance of composites obtained by polymerisation filled and mechanical mixtures of polypropylene and graphite shows that for the same degrees of filling, the mechanical mixture has a much lower conductivity (Fig. 9). The conductivity differences are particularly marked (by a factor of 10^7) at low concentrations of the filler $c \leq 8$ vol.%. To obtain by mechanical mixing a composition with the same conductivity, it is necessary to add 30 vol.% graphite, and this leads to a decrease in the tensile strength and compressive strength by factors of 1.5. Composites based on PP and graphite have a high uniformity, as indicated by the linear dependence of σ on the length and thickness of the specimen. In the temperature range 4.2–300 K, the values of σ for polymerisation-filled compositions are independent of temperature (for composites containing 8–61 vol.% graphite)[57] (Fig. 10). For these compositions, a conductivity constant with time was observed for graphite concentrations $c \geq 8$ vol.%, whereas for the compositions obtained by mixing this was observed only at $c \geq 20$ vol.%.

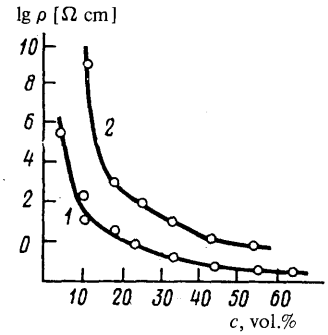

Figure 9. Dependence of the bulk specific electrical resistance (ρ) of compositions based on polypropylene and graphite on the graphite concentration: *1*) polymerisation filling, *2*) mechanical mixture of polypropylene and graphite[57].

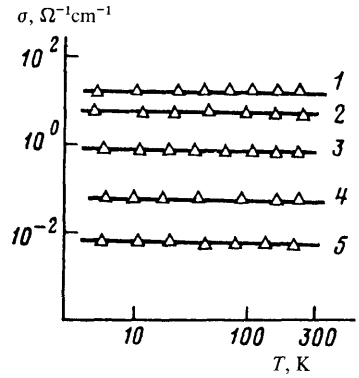

Figure 10. Temperature dependence of the conductivity of polymerisation-filled composites based on polypropylene and graphite for different volume concentrations of graphite: *1*) 0.61, *2*) 0.4, *3*) 0.35, *4*) 0.1, *5*) 0.08.[57]

The materials obtained show another remarkable property, namely their retention of plasticity and mechanical strength after repeated cooling and heating cycles from 300 K to 4.2 K. A scanning electron microscope study of the surface of pressed specimens of norplastics based on polypropylene and graphite showed that the norplastic (for identical original graphite particle sizes) contains graphite particles of smaller dimensions, uniformly distributed in the polymer matrix, compared with the mechanical mixtures, and the distance between the particles of the filler is much smaller in the norplastic.

These composites based on polypropylene and graphite are promising for applications in many branches of technology, as elements in electric-heating assemblies, coverings for screens in radio-electronic apparatus, strain gauges at low temperatures, highly stable resistors, antistatic coverings, and electric filters[60].

The strength properties of norplastics based on PP with a degree of filling of 30–40% are similar to those of non-filled isotactic polypropylene[32]. The presence of an atactic polypropylene fraction in the composite (up to 10–15%) has a plasticising influence and improves the deformational properties of the compositions.

Isotactic polypropylene has a low resistance to cold. To improve this property, rubber is added to polypropylene, or copolymerisation with ethylene is carried out. The use of polymerisation to introduce fillers into PP has made it possible to produce, on the basis of filled polypropylene, materials having a high resistance to cold (brittleness temperature between −35 °C and −45 °C) and a high impact strength (up to 18 kJ m^{-2}) at a concentration of filler (tuff, kaolin) of 40–50 mass %.[5]

4. The Thermo-Oxidative Degradation and Stabilisation of Norplastics

The kinetics of the thermo-oxidative degradation of polymerisation-filled polyethylene and mixed compositions at temperatures of 160–200 °C and oxygen pressures of 24×10^3–27×10^3 Pa have been studied[61]. Inhibitors were introduced into the powdered composite from a solution in ethanol or toluene, after which the powder was dried in a vacuum. The principal rapid method used to estimate the effect of the inhibitors was a volumetric method involving the measurement of the absorption of oxygen by the specimen on heating under static conditions. As with polyethylene, irrespective of the nature of the filler, the introduction of the inhibitor leads to a significant increase (by a factor of 3–7) in the induction period, and a decrease (by a factor of 1.5–3) in the rate of oxidation of the composite. The greatest increase in the induction period and decrease in the rate of oxidation were observed at concentrations of Irganox 1010 corresponding to 0.1–0.15% of the total mass of PE in the composite. The best results for composites containing any filler, however, were obtained using a synergic mixture of Irganox 1010 and Irganox PS 802. When fillers containing metallic components are used, and with specimens used at high temperatures in contact with a metal surface, it is necessary to add metal deactivators to the inhibitor mixture.

5. Compositions Based on Other Polymers

Among other thermoplastics, the polymerisation filling of polyvinyl chloride (PVC) is of greatest interest. The grafting of PVC macromolecules to the surface of fillers during radical polymerisation makes it possible to obtain "concentrates" which when mixed with PVC give a composite with much better properties than compositions based on non-modified fillers[42]. Both the technological properties and the strength characteristics are improved. In addition, the chemical grafting of PVC to the surface of fillers may be an important factor in obtaining composites with long-term strength.

Problems related to the radical mechanism of polymerisation initiated on the surface of a solid phase and to the characteristic features of radical copolymerisation taking place on the surface of solid particles have been examined[25,26]. The studies established that it is possible to vary widely the characteristics of the graft polymers: the molecular mass, the density of grafting, and the ratio of the grafted and non-grafted polymers in relation to the parameters and methods of polymerisation. When there are no reactions of chain transfer, it is possible to obtain polymerisation-filled compositions in which practically all the macromolecules are grafted to the surface of the dispersed filler. As a consequence of the formation of the chemical bond between the polymer and the filler, these polymerisation-filled polymers have higher wear-resistance, creep-resistance, and strength properties, compared with polymers filled by traditional methods. The industrial production of polymers filled by polymerisation under radical-polymerisation conditions can be carried out in existing equipment used for polymer synthesis[7].

The development of methods for the polymerisation filling of reactive carbo-chain polymers is also important. These include polymers obtained by the homo-polymerisation of propadiene and acetylene derivatives, and their copolymerisation with alkenes. Propadiene polymerises in the presence of metal-complex catalysts[62] based on vanadium, titanium, nickel, and rhodium. The use of transition metal salts as catalysts makes it possible to use polar solvents such as water and alcohol for the polymerisation of propadiene. In the presence of a catalyst based on rhodium acetylacetonate carbonyl in a medium of ethanol, the polymerisation is non-stationary (Fig. 11). After an induction period, the reaction rate increases and reaches a maximum value, after which almost complete deactivation of the catalyst takes place. The deposition of this catalyst on the surface of swollen perlite leads to an increase in the activity and stability of the catalyst. The rate of the polymerisation of propadiene is higher when the deposited catalyst is used, and remains unchanged for a long time. The increase in the stability of the catalyst deposited on the filler surface is due to a decrease in the rate of the reactions involving the disappearance of the active centres taking place in the solutions.

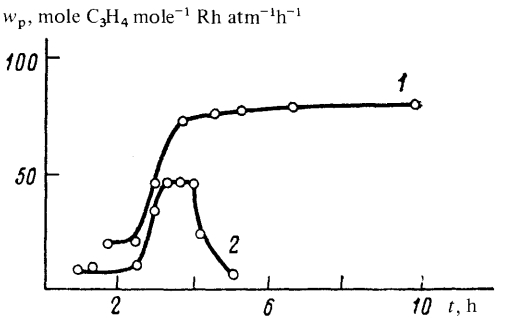

Figure 11. Change with time in the rate of polymerisation of propadiene on $Rh(AcAc)(CO)_2$ fixed on perlite (*1*) and $Rh(acac)(CO)_2$ in C_2H_5OH (*2*).[62]

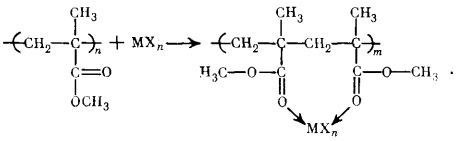

Similar kinetics are observed in the polymerisation of phenylacetylene in the presence of $MoCl_5$ fixed on kaolin, talc, and aluminium and magnesium oxides[63]. The fixing of $MoCl_5$ on mineral carriers leads to an increase in the lifetime of the catalyst and to an increase in the degree of transformation of phenylacetylene. The nature of the mineral carrier influences the stereospecificity of the catalyst and the molecular mass of the polymer.

The products obtained by the polymerisation filling of propadiene and acetylene derivatives can subsequently be cross-linked by various methods.

6. Polymer–Polymer Compositions

The immobilisation of metal-complex catalysts on carbo-chain polymers makes it possible, by using a polymer carrier as filler, to synthesise polymer–polymer compositions (PPC) at the stage of the polymerisation or copolymerisation of alkenes, and this represents a further development of the method of polymerisation filling[64]. The polymeric fillers used include polyvinyl chloride, polyvinyl acetate, polymethyl methacrylate (PMMA), polyformaldehyde, cellulose, and other polymers.

The fixing of MX_n to the surface of such polymers as polymethyl methacrylate or polyvinyl acetate can be represented as follows:

The process is accompanied by a displacement of the carbonyl group stretching frequency from 1740 cm^{-1} to 1650 cm^{-1}.[64] The fixing of MX_n to polyvinyl acetate takes place similarly. The mechanism of the interaction of MX_n with cellulose is more complex, and leads to cross-linking of the cellulose molecules.

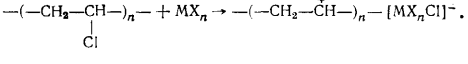

Table 4. Physicomechanical properties of PE–PMMA polymer–polymer compositions and the original components (upper values—data for the synthetic PPC, lower values—data for the mechanical PPC).[64]

Parameter	PMMA*/PE	[PMMA], vol.%			
		4	7	14	29
ρ, kg m^{-3}	1.190 / 0.948	0.959 / 0.962	0.968 / 0.965	0.983 / 0.965	1.019 / 1.017
σ_y, kg mm^{-2}	5.0 / 2.50	3.20 / 2.70	3.15 / 1.20	3.50 / 1.15	—
ε, %	2—3 / 370	250 / 80	210 / 70	180 / 45	—
T_g, K	383 / 203	217 / —	224 / 224	224 / 224	225 / 224

Symbols: ρ is the density, σ_y is the yield point, ε the elongation at rupture, and T_g the temperature of glass formation.

*This column gives the corresponding values of the parameters of the original components of the polymer composition.

Of particular interest is the fixing of MX_n on the surface of polymeric carriers containing a mobile halogen atom: copolymers of PVC, polyvinylidene chloride (PVDC), polytetrafluoroethylene (PTFE), copolymers of styrene with α-bromostyrene, etc. In these cases, the fixing involves the formation of ionic products:

The synthesis of PPC based on polymers activated by these methods is carried out by ordinary polymerisation methods. The physicomechanical properties of synthetic and mechanical PE–PMMA and PE–PVC compositions are compared in Tables 4 and 5. Increase in the volume fraction of PMMA in the composition with PE is accompanied by a decrease in the relative elongation and an increase in the yield point of the compositions. The synthetic PPC have much better physicomechanical properties than the corresponding mechanical compositions. The difference is particularly marked at high values of ϕ.

Table 5. Various properties of PE–PVC polymer–polymer compositions and the original components (upper values—data for the synthetic PPC, lower values—data for the mechanical PPC).[64]

Parameter	PE*/PVC	PE/PVC, mass %				
		83/17	77/23	70/30	56/44	45/55
σ_t, MPa	30.1 / 42.0	22.0 / 24.2	16.2 / 14.4	21.3 / 5.0	20.3 / —**	16.8 / —

r, kN m^{-1}	52 / 30	19 / 3.0	30 / 3.5	17 / 3.5	25 / —	31 / —

Symbols: σ_t is the limiting tensile strength, ε the relative elongation, and r the tear-resistance.

*Corresponding values of the parameters of the original components of the composition.
**Brittle specimens; the properties could not be determined.

In PPC obtained by mechanical mixing, the intermediate layer is formed by the mutual diffusion of the polymers. In the synthetic PPC, the production of the intermediate layers involves not only physical but also chemical interactions.

According to a model[64] in which there are no interactions at the boundary of separation between the phases, the following relationship should be observed between the yield point of polyethylene (σ_0), σ_{PPC}, and the volume fraction of polyethylene ϕ:

$$\sigma_{PPC}/\sigma_0 = 1 - \varphi^{2/3}.$$

Fig. 12 shows that in mechanical PPC based on polyvinyl chloride and polyethylene, there is satisfactory agreement between the experimental data and the theoretical relationship. This relationship is not observed for the synthetic compositions, indicating the existence of specific interactions between PE and PVC. One factor responsible for chemical interaction between the two polymers may be the grafting of polymer chains during the synthesis of the PPC. The presence of grafted chains in synthetic PE–PMMA and PE–PVC compositions has been established by physicochemical and extraction methods[64]. Mechanical PPC may undergo complete breakdown into the original components. The concentration of grafted polymer chains in the synthetic PPC depends on the type and volume fraction of the polymers. For example, with increase in the volume fraction of the vinyl polymer, the degree of grafting increases in the PE–PMMA system, and decreases in the PVC–PE system[64]. The mutual grafting of chains during the synthesis of polymer–polymer compositions may take place at the initiation stage, at the growth stage by the copolymerisation of unsaturated units,

and by reactions involving chain transfer at the surface of the basic polymer.

The formation of the intermediate layer may be influenced by the physical interweaving of the linear macromolecules with the open network of the surface. An X-ray diffraction study of synthetic polymer–polymer compositions based on PMMA–PE and PVC–PE has revealed changes in the values of the interplanar distances in the structures of synthetic compositions[65]. This indicates a reaction between the PE and the other polymers in synthetic compositions at the molecular level.

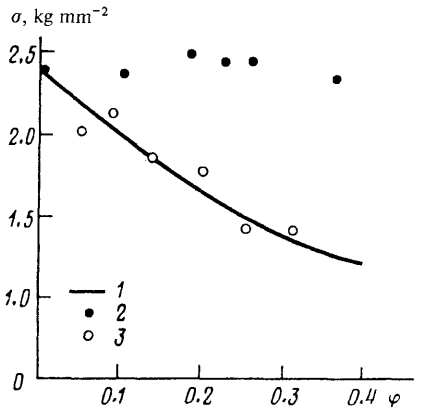

Figure 12. Dependence of the yield point of PPC based on PE and PVC on the volume fraction of the latter: *1*) theoretical curve; *2*) mehcnical PPC; *3*) synthetic PPC.[64]

Thus the synthetic method for preparing PPC makes it possible, at the stage of the synthesis of the polyalkene component, to increase the compatibility of the components as a result of the characteristic treatment of the surface, and to some extent to restrict or suppress the negative effects characteristic of mechanical methods for prepared PPC. This method can be used to obtain composition materials based on polymers which are not readily compatible under ordinary conditions.

IV. CONCLUSION

Examination of studies carried out up to the present, and the results obtained, shows that the method of polymerisation filling extends considerably the possibilities for creating composite materials for different purposes, including constructional purposes, on the basis of the filled polymers.

This is determined by many factors, including the wide synthetic possibilities of the method, the possibility of controlling over a wide range the composition of the products with the achievement of exceptional uniformity of the distribution of the particles of the fillers in the polymer matrix, the possibility of fine control of the structure of the compositions, and the improvement of the adhesion interaction at the surface of separation between the filler and the polymer phases, either as a result of chemical bonding between the macromolecules and the surface of the filler or as a result of the development of an effective adsorption interaction between them. Essentially, Enikolopov and his school have developed a new branch of macromolecular chemistry, involving the study of the specific features of the kinetics of polymerisation on solid surfaces, the characteristic features of the structure of the polymeric layer formed on the surface of fillers during polymerisation, the characteristic features of the physicomechanical properties of composites, and the working of these materials.

A number of promising ways of using the polymerisation filling of thermoplastics have now been established: the synthesis of highly-filled compositions based on superhigh-molecular-weight polyethylene, the synthesis of "concentrates" containing ~10% of the polymer matrix, and the synthesis of highly conducting and cold-resistant compositions based on polypropylene. New phenomena requiring further intensive study have been observed. The production of a composite material with given properties naturally requires the solution of complex problems both in the synthesis of the polymers and in the physics and mechanics of the compositions. Specific fields of application of polymerisation-filled materials and realistic possibilities for the development of industrial processes for their production have already been pointed out, however.

Metalloporphyrins as Catalysts of Chain Transfer in Radical Polymerisation and Stereoselective Oxidation

L.V.Karmilova, G.V.Ponomarev, B.R.Smirnov, and I.M.Bel'govskii

The results of studies on the catalysis of the chain transfer reactions in radical polymerisation and stereoselective olefin oxidation reactions in the presence of metalloporphyrins are surveyed. The problems of the synthesis of metalloporphyrins for catalytic studies are discussed.
The bibliography includes 43 references.

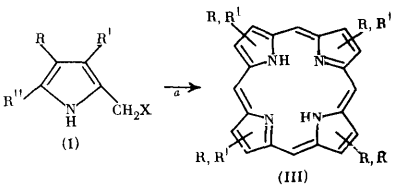
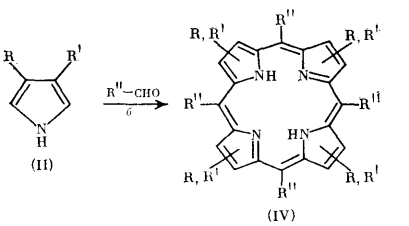
I. INTRODUCTION

Studies of the catalytic properties of porphyrins and related macrocyclic compounds have developed vigorously in recent years. The interest in these compounds is due primarily to the fact that their metal complexes are involved in the most important processes in living nature—photosynthesis and the transport, fixation, and activation of oxygen.



The principal results of studies, carried out under the overall supervision by N.S.Enikolopov, on the synthesis of porphyrins, the catalytic methods for the regulation of radical polymerisation with the aid of metal complexes, the synthesis and properties of immobilised catalysts, and the catalysis of stereoselective oxidation are summarised in this review.

II. THE SYNTHESIS OF PORPHYRINS FOR CATALYTIC STUDIES

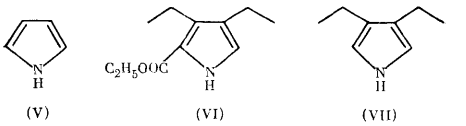


The advances in physicochemical and biological researches into metalloporphyrins as well as the possibility of their practical employment as catalysts of various processes, dyes, medicinal preparations, etc. have been to a large extent determined by the level of synthetic developments in this field. Towards the beginning of the 1980's, extremely advanced methods were developed for the synthesis of asymmetric porphyrins based on the successive addition of pyrrole fragments with subsequent cyclisation, which made it possible to obtain compounds with virtually any specified structure. The achievements in this field of the porphyrin chemistry have been summarised in a review by Evstigneeva[1] and in a fundamental work edited by Dolphin[2]. However, compounds simplified to the maximum extent rather than complex multifunctional compounds are required for the purposes of the photochemistry, electrochemistry, analytical chemistry, kinetics, catalytic action, and the study of the reactivity of tetrapyrrole macrocycles. These compounds must contain a definite set of alkyl or aromatic substituents and must be readily soluble in water or organic solvents. The principal requirements which must be met in the synthesis of compounds to be used for practical purposes is ready availability of the starting materials and the existence of a technological procedure for the synthesis and purification of the required porphyrins.

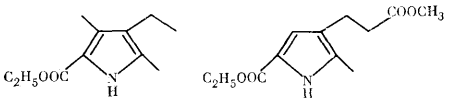
The development of studies in the field of the synthesis of porphyrins as potential catalysts proceeded via the preparation of derivatives with functional substituents, based on simple and ready available octa-alkylporphyrins and meso-tetra-arylporphyrins, and also via the improvement of technological schemes for the isolation and modification of porphyrins from readily available natural sources—haemin and chlorophyll.

Symmetrically substituted porphyrins are usually synthesised in a single stage via the cyclotetramerisation of 2,5-disubstituted pyrroles (pathway *a*) or via the condensation of 2,5-unsubstituted pyrroles in the presence of aldehydes (pathway *b*)[2]:

R, R' = Alk; R'' = H, COOH; X = OH, NH_2, $N(CH_3)_2$



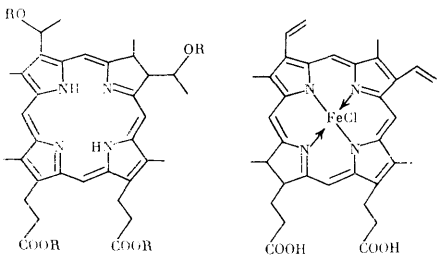
R, R' = H, Alk, R'' = Alk, Ar, 4(3)-pyridyl



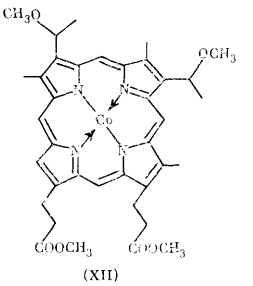
The exact positions of the groups R and R' in the porphyrins are not indicated in view of the formation of a racemic mixture of isomers when $R \neq R'$.

The synthesis of octa-alkylporphyrins (III) from the pyrroles (I, R, R' = Alk, R'' = COOH, X = OCH_3) is possible via pathway *a* with a yield of 70–80%. Pathway *b* leads to porphyrins (IV) in 70–80% yield when R, R' = Alk and R'' = H and 50–60% when R'' = Ar.

For practical requirements, it is possible to confine oneself to an extremely small number of initial pyrroles, whose employment makes it possible to solve the majority of problems in the synthesis of simple porphyrins. One such compound is the pyrrole (V), from which the preparation of *meso*-tetra-aryl(pyridyl, alkyl)porphyrins does not present special difficulties. The pyrroles (VI), (VII), and (VIII) are necessary for the synthesis of octaethylporphyrin and aetioporphyrin isomers—the most convenient models in a wide variety of physicochemical studies, while the pyrrole (IX) is used to model porphyrins with the natural structure.

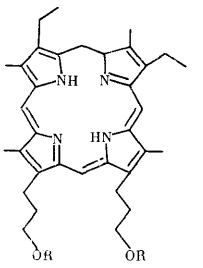


(V) (VI) (VII)



(VIII) (IX)

For an extensive investigation of the catalytic properties of porphyrins and related macrocycles, it was necessary to synthesise porphyrins and metalloporphyrins which would be highly soluble in organic non-polar or weakly polar solvents. For this purpose, an improved method was developed[3] whereby one could readily obtain the "tetra-alkyl ether-esters" (X) of haematoporphyrin, which consists in the successive treatment of the natural haemin (XI) with a solution of HBr in acetic acid accompanied by the addition of the corresponding alcohol to the reaction mixture.

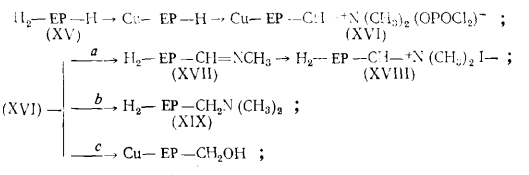


(X) (XI)

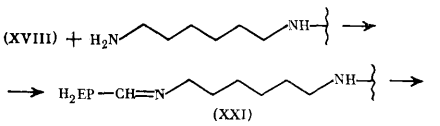
(XII)

The metal complexes of the "tetraether-esters", in particular the cobalt complex (XII), are readily soluble in the majority of hydrocarbons and other organic solvents, which made it possible to carry out extensive tests of the catalytic activity and to discover a new phenomenon in the radical polymerisation reactions—the catalytic chain transfer from the radical to the monomer[4].

However, the low stability of the metal complexes of the tetraether–esters significantly hindered their practical employment. A method was therefore developed for the synthesis of the more stable porphyrin (XIII) directly from haemin in yields up to 80%. The interaction of the porphyrin (VIII) with aliphatic acid chlorides, for example, with caprylic acid, makes it possible to obtain the corresponding esters soluble in any non-polar organic solvent and the reaction with acryloyl chloride yields the ester (XIV) which can be used for copolymerisation with methyl methacrylate and other acrylates in order to obtain porphyrin-containing polymers with catalytic activity.

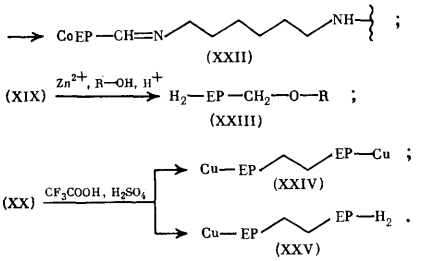


(XIII) R = H
(XIV) R = $COCH{=}CH_2$



Another branch of studies in the synthesis of porphyrins in order to create catalytic systems involved the preparation of derivatives based on simple and readily available octa-alkylporphyrins and *meso*-tetra-arylporphyrins with functional group substituents.

The presence of a functional group as a substituent makes it possible to vary within wide limits the chemical properties of the porphyrin and also to graft metalloporphyrins to the surface of a solid carrier. Such immobilisation of porphyrin complexes makes it possible not only to create catalysts capable of being used repeatedly but also to increase greatly their concentration, preventing the precipitation from solution of sparingly soluble metal complexes. It has been shown that the use of the Vilsmeier reaction in relation to porphyrins leads to considerable possibilities for the synthesis of a wide variety of compounds containing a functional group substituent in both *meso*- and β-positions in the macroring. The optimum version of the Vilsmeier reaction is not the synthesis of the formylporphyrins themselves but the preliminary preparation of intermediate reactive "phosphate complexes", which are then used to prepare a wide variety of porphyrins with functional group substituents[5–10].



Examples of various reactions of one of the representatives of octa-alkylporphyrins, namely aetioporphyrin-1 (H_2-EP-H) (XV), which are of interest for the synthesis of catalysts, are presented below:

(XX)

(XXI)

Three main versions of the modification of the "phosphate complex" are possible. Pathway *a* permits the synthesis of a wide variety of Schiff bases under mild conditions and with a high yield. For example, the demetallation of compound (XVI) with concentrated H_2SO_4 and subsequent treatment with aqueous methylamine lead to the Schiff base (XVII), whose methiodide (XVIII) readily reacts with aliphatic amines to form Schiff bases in 85–95% yield. The interaction of compound (XVIII) with the "Separon" macroporous gel containing hexamethylenediamine residues leads to the immobilisation of the porphyrin on the surface of the carrier, as in the system (XXI). After the introduction of a cobalt ion into the porphyrin (XXI), a heterogeneous catalyst (XXII) was obtained and its properties were investigated comprehensively[8]. An analogous attachment of a porphyrin was achieved on glass beads and was completed by a finishing treatment with triethoxyaminopropylsilane.

Pathway *b* has not so far been tested in practice, but it is also of interest for the modification and immobilisation of metalloporphyrins. It has been found that the porphyrin (XIX), obtained from the complex (XVI) by reduction with $NaBH_4$ and demetallation in concentrated H_2SO_4, readily reacts with alcohols and CH acids (acetone, acetylacetone, nitromethane, and cyanoacetic or nitroacetic esters) to form the ethers (XXIII) and other compounds.

Finally, pathway *c* makes it possible to obtain the ethane-bisporphyrins (XXIV) and (XXV), containing one or two metal atoms in the molecule, from the complex (XX), formed in quantitative yield after the successive treatment of the complex (XVI) with aqueous alkali and $NaBH_4$. Similar compounds may be of interest in the study of the catalytic activation of simple molecules of the type of O_2, N_2, CO, and CO_2.

Thus, several reliable methods of synthesis of metal complexes of porphyrins, readily soluble in various organic media, are at present available to investigators. This creates extensive possibilities for the comprehensive study of the catalytic properties of such compounds in polymerisation, oxidation, dehydrogenation, and other reactions.

III. CATALYTIC REGULATION OF RADICAL POLYMERISATION

The vast majority of methods for the regulation of radical-chain polymerisation processes are based on the introduction of various inhibitors, moderators, and chain-transfer agents, reacting with the chain carrier radical in stoichiometric proportions close to unity[11]. Thus the regulation of the molecular weight (MW), for example, is achieved as a result of chain transfer reactions via a mechanism involving the abstraction by a macroradical $R_n^{\cdot}$ of individual atoms or fragments from the molecule of the chain transfer agent SX:

$$R_n^{\cdot} + SX \rightarrow R_nX + S^{\cdot} .$$

The radical $S^{\cdot}$ formed interacts with the monomer M and regenerates the kinetic chain:

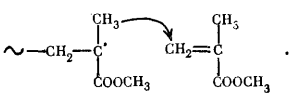
$$S^{\cdot} + M \rightarrow SR_1^{\cdot} .$$

The mechanism of the action of polymerisation inhibitors can be analogous, the difference consisting in the fact that the inhibitor radical cannot regenerate the chain owing to its low reactivity.

New pathways leading to the regulation of the polymerisation process have been discovered—catalysis of the reaction involving chain transfer to the monomer (CCT) and catalysis of inhibition[12–19]. As a result of the discovery of CCT, it has been possible to regulate the MW of the polymers and catalytic inhibition made it possible to regulate the rate of polymerisation.

The CCT phenomenon has been observed in the presence of cobalt complexes of porphyrins (PCo). Catalytic inhibition is manifested in the presence of model porphyrins–cobalt-phthalocyanines (PcCo).

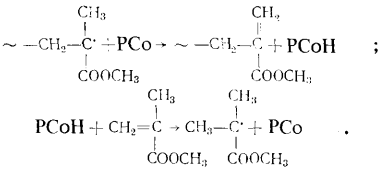
At the present time CCT has been thoroughly investigated in relation to the polymerisation of methyl methacrylate (MMA) initiated by azobisisobutyronitrile in the presence of the tetramethyl derivative of cobalt-haematoporphyrin[12–15]. Kinetic studies showed that CCT is a highly selective process, as a result of which the catalyst hardly influences the rate of polymerisation in the concentration range 10^{-6}–10^{-4} M, regulating the MW of the polymer in accordance with the familiar Mayo equation



$$\frac{1}{\bar{P}_n} = \frac{1}{\bar{P}_{n0}} + C_n \frac{[M]}{[PCo]} ,$$

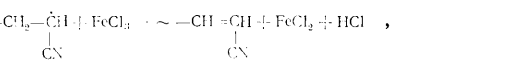
where $\bar{P}_n$ and $\bar{P}_{n0}$ are the average degrees of polymerisation in the presence and absence of the catalyst, $C_t = k_t/k_p$ is the chain transfer constant, k_t and k_p are the rate constants for chain transfer and propagation, and [M] and [PCo] are the concentrations of the monomer and the catalyst respectively.

The activity of the catalyst, estimated from the ratio of the chain transfer constants for the catalytic and non-catalytic reactions, is 10^8. The number of times each catalyst molecule is employed in the chain transfer steps reaches 10^5–10^6. Since the rate-limiting stage is the chain transfer to the metal complex and the regeneration process is fairly rapid, it was impossible to accumulate the intermediate in the catalytic reaction at concentrations sufficient for the investigation of its nature and reactivity.



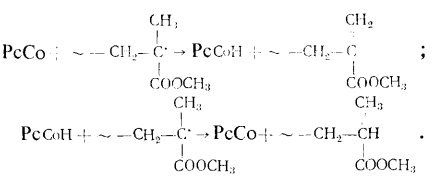
Information about the chain transfer mechanism was obtained with the aid of the NMR spectra of the oligomers[15]. Two alternative processes involving chain transfer to the monomer were analysed: via the transfer of a hydrogen atom from the radical to the monomer and via the transfer of a hydrogen atom from the monomer to the radical.

Analysis of the ratio of the intensities of the signals of the terminal and pre-terminal groups of the MMA oligomers, comparison of the average degrees of polymerisation determined from the NMR spectrum and by gel chromatography, and also analysis of the NMR spectra of the oligomers obtained from MMA deuteriated in the CH_3 group established that the chain transfer to the monomer takes place via the transfer of a hydrogen atom from the methyl group of the radical to the methylene group of the monomer:



In order to explain the CCT phenomenon, the hypothesis was put forward that the active intermediate in the reaction is cobalt-porphyrin hydride. In order to demonstrate the hydride mechanism of the catalysis, the cobalt-porphyrin

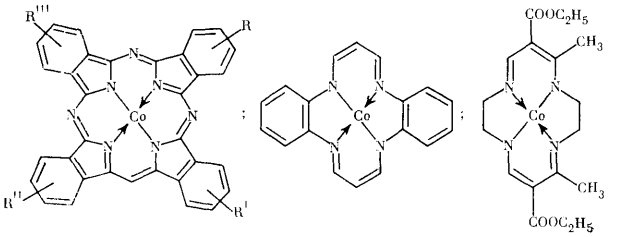
hydride was synthesised[16] and in its presence MMA gave rise to an oligomer having the identical MW and structure to those of the oligomer obtained under CCT conditions. It has thus been established that the catalyst activates the polymeric radical during chain transfer and that CCT can be described by a scheme comprising concerted reactions involving the dehydrogenation of the radical and the hydrogenation of the monomer:



It had been known previously that the transition metal complexes interact with polymeric radicals via the oxidative abstraction mechanism[21], for example:

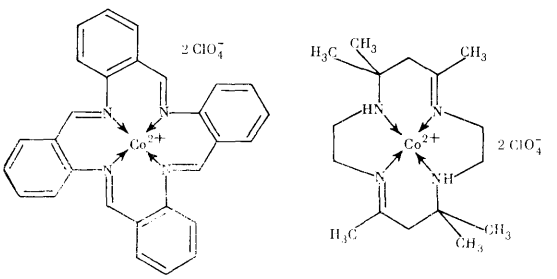
with rate constants in the range 10^5–10^6 litre mol^{-1} s^{-1}. Similar values of k_t, in the range (1–5) × 10^6 litre mol^{-1} s^{-1}, have been observed for cobalt-porphyrins[12]. However, one should note that only the presence of coordinated cobalt in a macroring with a specified structure constitutes the condition for the manifestation of CCT.

CCT has been observed also in the polymerisation of styrene and butyl acrylate[22,23], but in the former case its manifestation was complicated by the occurrence of side processes. In the polymerisation of butyl acrylate the rate-limiting stage is apparently the catalyst regeneration reaction and the process can therefore be regarded as reversible inhibition. One cannot rule out the possibility that the catalyst is regenerated via a mechanism involving the homolytic cleavage of the Co–C bond and not a mechanism with the dehydrogenation of the radical and subsequent transfer of the hydrogen to the monomer.



The study of the catalytic inhibition showed that the reaction proceeds via the following scheme:

The number of times each PcCo molecule is used in the course of a single polymerisation cycle is 10^2.



The CCT effect is manifested only when certain requirements are met by the structure of the catalyst molecule. The replacement of cobalt in the chain transfer catalyst by other metals, namely Cu, Fe, Ni, Zn, Rh, Mn, Pd, Mg, Pt, Sn, and U or by hydrogen leads to the complete loss of catalytic properties. Cobalt acetate, stearate, naphthenate, and acetylacetonate, cobalt-formazan, salcomin, and certain other cobalt complexes are inactive in the CCT to the monomer[19,23]. On the other hand, substituents in the macroring of the chain transfer catalyst do not play a decisive role in catalysis. When they are varied, the constant k_t changes within the limits of an order of magnitude[13].

It follows from the foregoing that the activity of the chain transfer catalyst is determined by the nature of the metal ion and the adjoining ligand environment and that the most important role is in this instance due to the π-electron system of the macroligand. The known chain transfer catalysts, namely the cobalt complexes of porphyrins, phthalocyanines (XXVI), tetra-azoporphyrins, and tetrabenzoporphyrins, hydroxycobalamin, and compound (XXVII), have an extensive π-conjugation system in the macroligand, which embraces almost its entire perimeter and which is quasi-aromatic in character.

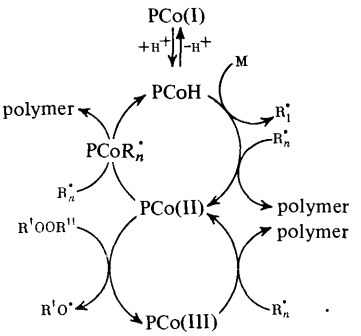
(XXVI) (XXVII) (XXVIII)

Cobalt complexes with a less extensive π-electron conjugation system along the perimeter of the macroligand, namely compounds (XXVIII) and (XXX), cobalt-formazan, etc., or a non-conjugated π-electron system, namely compound (XXIX), are incapable of catalysing chain transfer.

(XXIX) (XXX)

The observed characteristics of the molecular structure of the chain transfer catalyst made it possible to carry out a specific search for new promising catalysts and to discover them. Chain transfer catalysts with $k_t \cong 10^5$–10^8 litre mol^{-1} s^{-1}, readily available for extensive industrial application, have now been obtained. The rate of chain transfer in the presence of the catalyst is 10^{10} times greater than the rate of the non-catalytic reaction and CCT under the influence of metalloporphyrins is no less efficient than enzyme catalysis.

Although porphyrin complexes can contain cobalt(III), cobalt(II), or cobalt(I), only the cobalt(II)-containing forms are active, which is consistent with the hydride mechanism of the chain transfer catalysis. The Co–H bond in cobalt-porphyrins is polarised and the hydrides of the cobalt complexes behave as weak acids[25]:



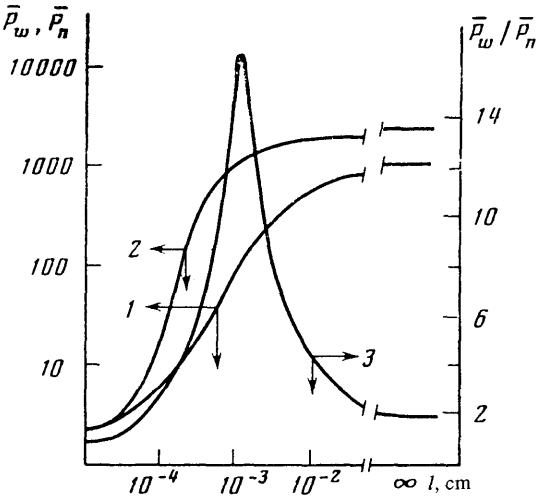
If the PCo(I) complex is fairly stable, for example, in the presence of amides, and the PCo(II) concentration in the polymerisation system is insignificant, then k_t is reduced by an order of magnitude. This is accompanied by a simultaneous increase of the rate of the catalytic chain termination reaction. Analogous effects have been observed in the presence of other porphyrin-like cobalt complexes.

Catalysts containing cobalt(III) are inactive in CCT, but under polymerisation conditions cobalt(III) is usually reduced to cobalt(II). The reduction reaction proceeds under the influence of chain propagation radicals via the oxidative chain termination mechanism[26,27] and is controlled by the axial ligand which determines the tervalent state of the cobalt atom. The addition to the polymerisation system of oxidants (benzoyl peroxide or cumenyl hydroperoxide), which selectively oxidise cobalt(II) to cobalt(III) in many catalysts,

leads to a decrease of the PCo(II) concentration and hence to a decrease of the rate of chain transfer.

The foregoing can be illustrated by the following scheme of the cyclic transformations of the catalysts in radical polymerisation:

One must note that the metal complexes investigated have many advantages compared with the familiar chain transfer agents. Thus, since the chain transfer constants in their presence are higher by 2–3 orders of magnitude than for the usual chain transfer agents, they can be introduced into the system at significantly lower concentrations in order to obtain polymers with a specified MW. The polymers thus obtained contain no fragments other than the monomer units, which is especially important in the synthesis of oligomers; on the other hand, the oligomers obtained, for example, by radical telomerisation, contain up to 15–20% of telogens, which impairs their operating properties.



IV. KINETICS OF THE HETEROGENEOUS CATALYSIS OF CHAIN TRANSFER TO THE MONOMER

The idea of immobilising the chain transfer agent on the surface of an inert carrier in order to create catalysts capable of being regenerated was put forward immediately after the discovery of CCT.[18] Experimental and theoretical studies in recent years have now elucidated the fundamental possibilities and have led to the formulation of the main problems of heterogeneous catalysis using metalloporphyrins[8,28-30]. It has been shown that the catalytic properties of the metal complexes are not retained for all modes of addition to the surface. Thus the grafting of aetioporphyrin, attached in the *meso*-position by a single covalent bond to the "Separon" macroporous gel, leads to a catalytically active system after the introduction of cobalt. However, heterogeneous catalysts based on the *meso*-porphyrin-(II) and *meso*-porphyrin-(IX) dibasic acids have no catalytic activity. These catalysts were synthesised both by chemisorption on alumina and by grafting via amide bonds to the surface of porous glass treated with aminopropyltrichlorosilane[28].

It became evident that the covalent grafting of the metal complex onto the surface via a fairly flexible, long, and polar chain is necessary to ensure catalytic activity. This procedure was realised in the study of Pashchenko et al.[8] Subsequently the cobalt complex of tetraphenylporphyrin, which also possessed catalytic properties, was immobilised on the surface of "Separon" together with the cobalt complex of aetioporphyrin-(IX). The initial tests of the heterogeneous catalyst were carried out using the model MMA polymerisation reaction[14].

Since chain transfer in the presence of the heterogeneous catalyst takes place only on its surface, the problem arises of the role of the size of the unit cell, the reactant concentration, the viscosity of the medium, etc. in the regulation of the molecular weight distribution (MWD) in the product. The corresponding kinetic calculation of the rate of polymerisation and MWD was therefore carried out[29,30] for a model of the heterogeneous catalysis of chain transfer to the monomer. The process was modelled by the system of kinetic equations for radical polymerisation taking into account the diffusion of the reactants to the catalyst surface.

Calculations of the MWD and of the rate of polymerisation as a function of the reactant concentrations and the size and shape of the unit cell of the macroreactant explained both the common features and the fundamental kinetic differences between the CCT in the homogeneous and heterogeneous versions. In the former case the regulating factor is the volume concentration of the catalyst-chain transfer agent (PCo) and in the latter it is the linear size of the unit cell of the reactant (l).

An example of the calculated dependence of the MWD parameters and the polydispersity of the products on the linear size of the microreactor cell[44]: 1) $\bar{P}_n$; 2) $\bar{P}_w$; 3) $\bar{P}_w/\bar{P}_n$.

Whereas in the homogeneous version the polydispersity ($\bar{P}_w/\bar{P}_n$) of the product changes monotonically from 2 to 1 on increase of the catalyst concentration[17], in the heterogeneous version the polydispersity passes through a maximum as l diminishes (see Figure) and the fraction of the low-molecular-weight component of the MWD corresponding to polymerisation in a boundary layer increases. When the weight contributions of the low- and high-molecular-weight fractions are approximately the same, the maximum polydispersity of the product is observed.

In both homogeneous and heterogeneous catalysis of the chain transfer to the monomer, the overall rate of polymerisation becomes dependent on the efficiency of the transfer. The diffusion control of the disproportionation of the radicals leads to a decrease of the short chain termination constant, decreasing the rate of polymerisation.

A new geometrical factor, lowering the rate of polymerisation, appears in heterogeneous catalysis. It is the stationery gradient of the radical concentrations in the reaction cell.

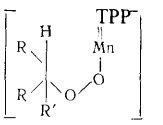
The catalysis of chain transfer on the wall leads to a redistribution of the radical concentrations in space and the overall concentration of the active centres and hence the rate of polymerisation decrease at the same time. Numerical calculations for specific model variants on a computer confirmed this fully[30]. A 30% decrease of the rate of polymerisation in heterogeneous catalysis has been recorded experimentally[8], while the corresponding concentration of the cobalt complex of the porphyrin, dissolved in the monomer, did not lead to an appreciable decrease of the rate of polymerisation under analogous conditions. Experimental measurement of the rate of polymerisation in heterogeneous catalysis therefore not only constitutes a simple quantitative test of the efficiency of the catalytic properties of the surface but can also become a fundamentally new method for the investigation of the dependence of the elementary kinetic radical polymerisation constants on the length of the chain in macroradicals.

V. CATALYSIS OF OXIDATION AND HYDROXYLATION REACTIONS

It is known that metalloporphyrins catalyse the oxidation reactions of various organic and inorganic compounds. Oxygen is then coordinated to the central metal ion and one or two electrons are transferred to the oxygen with formation of superoxo- or peroxo-complexes which interact with the substrate and initiate its free-radical oxidation[31].

The processes involving superoxide complexes of porphyrins include the oxidation of adrenalin, which has been shown[32-34] to be catalysed by tetra-*p*-sulphophenylporphyrincobalt(PCo). It has been demonstrated that PCo forms a charge-transfer complex with oxygen which can dissociate to give a superoxide ion:

$$PCo + O_2 \rightleftarrows [PCo^{+}O_2^{\cdot-}] \rightleftarrows PCo + O_2^{\cdot}.$$



The interaction of $O_2^{\cdot}$ with adrenalin involves a complex mechanism and the first stable product is adrenochrome. The system described is highly effective in an aqueous medium at biologically important pH and each catalyst molecule participates in at least 100 oxidation steps.

The oxidation reactions initiated by superoxide proceed via a radical-chain mechanism with formation of a large set of products[32]. In the presence of an excess of the reductant, metalloporphyrins can catalyse also non-chain oxidation which is both regioselective and stereoselective. Thus the oxidation of olefins by molecular oxygen takes place extremely effectively in the presence of the manganese complex of *p*-methoxytetraphenylporphyrin (TPPMnCl) and an excess of sodium tetrahydroborate. This system models the action of mono-oxygenating enzymes, the haem prosthetic group of which incorporates metalloporphyrins in most cases. In living organisms monoxygenases catalyse the processes involving the incomplete incorporation of oxygen. One of the components of hydroxylase systems, cytochrome P-450, initiates the hydroxylation and epoxidation of steroid and aliphatic olefins, aliphatic acids, and alkanes. A characteristic feature of the action of hydroxylases is that the oxidation is by molecular oxygen and the presence of a reductant is necessary for the functioning of the system.

It is known that the porphyrin complexes of manganese(II), obtained by the reduction of manganese(III), activate molecular oxygen and catalyse the oxidation of various olefins[35-37]. This model hydroxylase system contains an excess of reductant, is insensitive to the action of radical inhibitors, and a set of products uncharacteristic of radical oxidation is formed in its presence. Saturated alcohols and ketones have been detected among the olefin oxidation products.

The oxidation of aliphatic (ethylene, propene, hex-1-ene, hex-2-ene) and steroid (androstene and cholesterol) olefins has been investigated at room temperature in dimethylformamide and a 1:1 benzene–ethanol mixture by molecular oxygen in the presence of the TPPMnCl–$NaBH_4$ system and it has been shown that mono- and di-substituted olefins are oxidised with formation of a mixture of ketones and alcohols[38,39]. Ketones and secondary alcohols are formed from asymmetrically substituted olefins (propene and hex-2-ene), i.e. the process is regioselective. The rate of oxidation of olefins depends on the substituent at the carbon atom involved in the double bond and varies in the sequence ethylene < propene < hex-1-ene < hex-2-ene. Tri-substituted steroid olefins are oxidised regioselectively and stereoselectively at a higher rate and with nearly 100% conversion, forming only 5α-substituted alcohols.

The formation of tertiary alcohols from trisubstituted olefins and of ketones and secondary alcohols from mono- and di-substituted olefins apparently proceeds via the same mechanism involving the reduction of TPPMnCl to a manganese(II) complex of TPP as the first stage with subsequent formation of a complex with molecular oxygen: TPP = Mn^{+}–O_2. In this complex manganese(II) and O_2 are located to one side of the plane of the porphyrin ring[40] and the electrophilic addition of the complex to the double bond of the olefin leads to the formation of a cyclic intermediate complex analogous to complexes involving monoxygenases[41]:

The reductive cleavage of the C–Mn bond by $NaBH_4$ leads to an intermediate product of the peroxide type, the mode of the subsequent cleavage of which depends on the structure of the substituents R and R' at the double bond. The formation of ternary metalloporphyrins–oxygen–olefin complexes has been observed experimentally[42]. Within the framework of the mechanism involving the formation of complexes of this type, it has been possible to formulate a kinetic scheme for the oxidation of olefins and to calculate the constants for the individual stages[43].

The effective charge of the metal ion and hence the degree of polarisation of the reactants in the formation of their complexes with the catalyst may be influenced by the presence of extraneous ions in solution. The introduction of neutral salts into the O_2 + TPPMnCl + $NaBH_4$ system inhibits the oxidation of cholesterol and the magnitude of the effect depends on the nature of the salt and the solvent.

As already mentioned, the catalytic system described above exhibits certain properties characteristic of monoxygenases: a non-radical character and hence the selectivity of the process catalysed, which proceeds via the formation of a cyclic intermediate complex, a high specificity of action, and inhibition by neutral salts. By altering the nature of the reducing agent, it is probably possible to change the direction of the process, obtaining, for example, epoxides as the primary

products, and, by altering the nature of the substrate, it is possible to achieve a higher affinity of the latter for the catalyst and hence a higher rate of oxidation.

The Polymerisation of Solid Monomers Under Conditions of Deformation at a High Pressure

A.A.Zharov

The polymerisation of solid monomers deformed under high pressure has been examined. The anomalously high reactivity of the substances under these conditions, and the reasons for it, have been discussed. The possibilities provided by the methods of formal kinetics for the description and study of the mechanism of polymerisation have been demonstrated for the polymerisation of acrylamide.
The bibliography contains 56 references.

IV. Conclusion 147

I. INTRODUCTION

The formation of macromolecular compounds with shear deformation of the solid monomers under a high pressure was first detected by Enikolopov, Zharov, and Kapustyan in 1964.

In the first studies[1], for ten monomers of different character, it was shown that shear deformation and high pressures (SD + HP) are powerful factors stimulating the polymerisation of solid monomers. In a short time, studies in this field have extended and have led to considerable progress in the investigation of the reactivity of solid monomers and the regular features of polymerisation under SD + HP conditions. Compounds of various classes have now been studied: alkene derivatives, compounds of the acetylene series, nitriles, heterocyclic compounds, aromatic hydrocarbons, etc., corresponding to more than one hundred individual substances. Most of these substances can form macromolecular compounds under SD + HP conditions[1-25]. The study of the polymerisation has revealed unusual features in the chemical processes, for example the anomalously high reaction rates and the dependence of the kinetics of polymerisation on the magnitude of the shear deformation.

About one hundred papers have been published on the formation of polymers under SD + HP conditions. Most of the work in this field has been carried out by Soviet scientists. In recent years, a number of studies in this area have been carried out by the Japanese workers Ogo and Okuri[11,12,16].

II. CHARACTERISTIC FEATURES OF THE TRANSFORMATIONS AND REACTIVITY OF ORGANIC COMPOUNDS DEFORMED AT HIGH PRESSURES

Experiments under SD + HP conditions are carried out on an apparatus of the anvil type[26-28], whose operational principles were first realised by Bridgman, and which is based on the fact that the compression of a solid specimen between two plates does not lead to flow of the substance if a sufficiently thin specimen is taken. A version of this apparatus is given in Fig.1. The solid reaction mixture is placed between the anvils, which are made of ball-bearing steel or VK-6 hard alloy and which have the form of truncated cones. The thickness of the specimen depends on the nature of the substance and the area of the working surface of the anvils; for an anvil area of 1 cm^2, the weight of the original specimen is 5–10 mg. The anvils are compressed by means of a press capable of creating a load of up to 100 tons; a pressure of up to 10 GPa is produced in the specimen. After the pressure has been established, the specimen is deformed by rotating the lower anvil, which is on a platform placed on a supporting ball bearing. The platform is rotated by an electric motor and reducing gear. The shear forces are measured using an assembly consisting of a spring element, levers, and a mechanotron, the signal from which is passed to a recorder. The anvils can be kept at a constant temperature in the range 77–500 K.

Experiments have shown[1-25] that under SD + HP conditions, polymers can be formed by organic compounds of various classes: a) compounds with one $-C{=}C-$ bond: hydrocarbons (ethylene, styrene, α-methylstyrene, etc.), esters (alkyl acrylates, alkyl methacrylates), acids (acrylic, methacrylic, crotonic, etc.)[1,7], anhydrides[6], amides, imides[5], and nitriles[17,20], chloro-compounds (dichloro- and trichloropropenes, etc.)[15]; b) compounds with conjugated double bonds: butadiene, cyclopentadiene[7,14], 1,1,2-trichlorobutadiene[15], etc.; c) compounds with a triple bond: derivatives of acetylene (*p*-diethynylbenzene, tolan[1], derivatives of diacetylene[16], etc.), nitriles (malononitrile, cyanacetamide, terephthalodinitrile, 4-cyanopyridine, etc.)[17-19]; d) heterocyclic compounds: trioxan, hexamethyltrisiloxane[1,7], thiophene, pyridine[20,21]; e) aromatic compounds: benzene[25], napthalene, anthracene, phenanthrene[19,20,22], quinones, etc.[23,24]

The study of a large number of organic compounds indicates that if the molecules of a substance contain the groups $-C{\equiv}C-$, $-C{=}C-$, $-C{=}N-$, heterocyclic rings, or aromatic rings, then the conditions produced when the specimen is deformed can induce the formation of macromolecular compounds. Compounds with different reactivities can react: monomers which readily form polymers by different mechanisms in both the liquid and solid phases (acrylamide, styrene, etc.[1,30]); compounds which in other conditions do not give macromolecular products in the solid state (methyl methacrylate[8], maleic anhydride[1,6]); and substances which polymerise with difficulty (nitriles[20], derivatives of acetylene[1,7], whose polymerisation takes place only under severe conditions at high temperatures.

Parallel transformations in addition to the main reaction are often observed under SD + HP conditions. Polymerisation may be accompanied by Diels–Alder reactions[14], and the substances may react with atmospheric oxygen and moisture at the moment of deformation. If the compound contains two or more functional groups capable of reacting under SD + HP conditions, cross-linked insoluble polymers are formed[14,15,18,29]. The influence of side reactions can be decreased by selecting a range of pressures at which polymerisation takes place without complications; the products are analogous to the polymers synthesised under ordinary conditions. Styrene, methyl methacrylate, and trichlorobutadiene are converted into polymers which have the same structures as the corresponding polymers obtained by radical polymerisation[8,15,30]. Trioxan forms a polymer whose infrared spectrum is identical to that of polyoxymethylene obtained by radiation polymerisation[7]. Derivatives of maleimide give polymers corresponding to those obtained by radiation polymerisation[5].

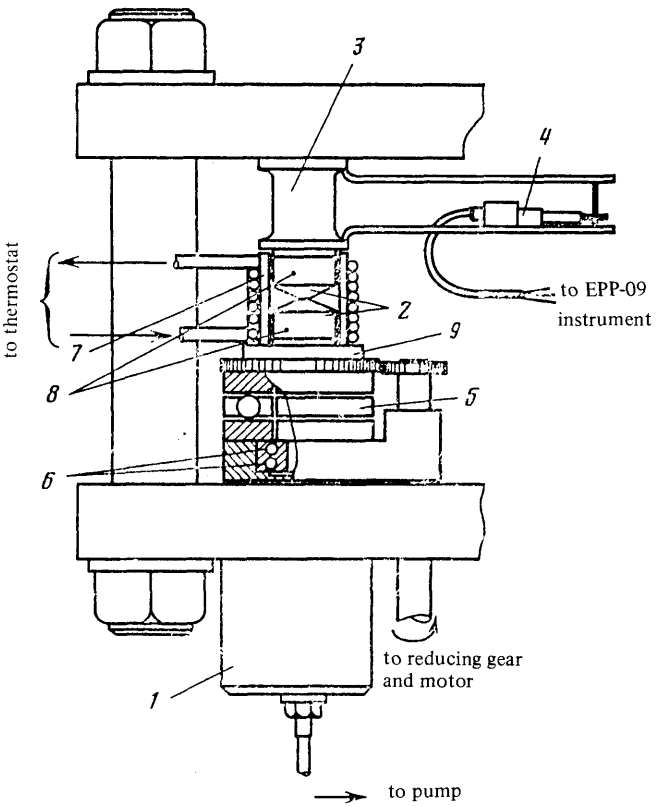

Figure 1. Apparatus for studying the transformations of substances under SD + HP conditions[28]: *1*) cylinder of hydraulic press; *2*) anvils; *3*) spring element; *4*) mechanotron; *5*) supporting ball bearing; *6*) radial ball bearing; *7*) constant-temperature jacket; *8*) positions for thermocouples; *9*) step bearing of heat insulator.

The reactivity of compounds under SD + HP conditions is such that high degrees of transformation are achieved in anvil rotation times measured in seconds[3,4,7]; the deformation of the solid specimen is a necessary condition for the chemical reaction. Treatment of the reaction mixture at the same pressures for times which are 10^2–10^3 times the duration of the experiments under SD + HP conditions does not lead to any significant transformation[1,7].

A general feature of chemical processes under SD + HP conditions is that the extent of the transformation depends on the magnitude of the shear deformation (usually expressed in terms of the angle of rotation of the anvil). The nature of the curves giving the dependence of the degree of conversion on the angle of rotation may vary, but the conversion always increases with increase in the deformation (Fig.2). The yield of reaction products increases with increase in pressure. With decrease in temperature, the rate of transformation decreases; the temperature coefficient of the reaction is small, however, and polymerisation can take place even at liquid-nitrogen temperature (acrylamide, butadiene, etc.)[6,7,14,31].

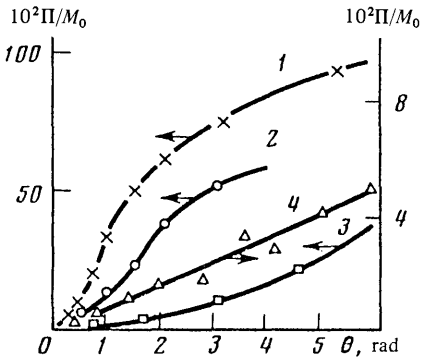

Figure 2. Dependence of the yield of polymer (Π/M_0) on the angle of rotation (θ) of the anvils (2000 MPa, 293 K)[7]: *1*) acrylamide, *2*) methacrylamide, *3*) maleic anhydride, *4*) trioxan (1000 MPa).

Other characteristic features of the formation of macromolecular compounds under SD + HP conditions are conveniently considered for specific examples.

1) *Acrylamide.* This monomer polymerises readily under SD + HP conditions, beginning at a pressure of several hundred MPa[4,6,31,32]. The study of the transformations of this monomer has resolved the question of when polymerisation takes place: whether the polymer is formed at the moment of deformation, or whether the growth of the polymer chains takes place after the SD + HP experiment is complete, as a result of the initiation of active centres, accumulated in the substance during its deformation. Which of these possibilities is realised was established[32] by measuring the shear stress of the specimen during deformation. Fig.3 gives the observed dependence of the shear stress (τ) on the angle of rotation of the anvil (θ) and on the quantity of polymer formed in the specimen (Π/M_0). The curves in Fig.3 show the accumulation of polymer in the specimen at the moment of deformation. Moreover, according to the results of the same study[32], for the mixture of acrylamide and polyacrylamide prepared by mechanical mixing or partial polymerisation, the values of τ correspond to the dependence of Π/M_0 given in Fig.3*b*. Thus polymerisation takes place at the moment of deformation of acrylamide, and the contribution of post-polymerisation is insignificant or non-existent.

2) *Styrene*[30]. The structure of the polymer obtained by the deformation of solid styrene at a pressure of 1000 MPa is extremely close to that of the polymer synthesised by radical polymerisation. With increase in pressure, however, the structure of the polymer formed under SD + HP conditions changes: there is a decrease in the proportion of units in the regular, predominantly syndiotactic, groups characteristic of ordinary polystyrene, and an increase in the proportion of units in short and irregular blocks. This phenomenon may be related to "head to head" connection or chain branching, and may be the consequence of the rupture of benzene rings. Side reactions taking place in parallel at pressures above 4000 MPa give a product made up of short polystyrene blocks, which are joined to one another by groups with an irregular structure.

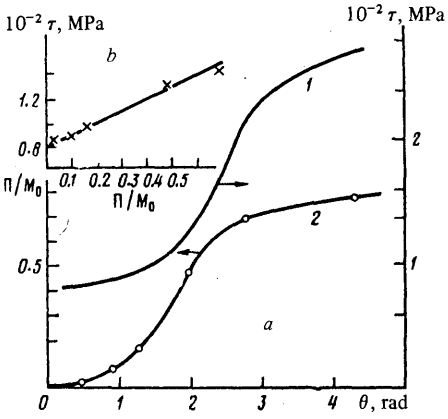

Figure 3. Relationship between the shear stress of the specimen τ, the degree of transformation Π/M_0, and the angle of rotation of the anvils θ;[32] *a*) dependence of the shear stress and the degree of transformation on the angle of rotation; *b*) dependence of the shear stress on the concentration of polymer in the specimen.

Thus with increase in pressure in SD + HP experiments there may be a change in the structure of the resultant macromolecular compound as a result of side reactions which are not revealed at low pressures.

3) *Trioxan*. The study of the polymerisation of trioxan has shown[7] that this monomer is polymerised with great difficulty under SD + HP conditions. At pressures of 3000–4000 MPa and θ = 4–5 rad, the yield of polymer did not exceed 1%. At lower pressures (1000–1500 MPa), no polymer was detected. If however trioxan is treated beforehand with ionising radiation, that is if ionic active centres are introduced, then this monomer polymerises readily on deformation even at a pressure of 1000 MPa to give polyoxymethylene (see Fig. 2).

The formation of polyoxymethylene under SD + HP conditions from trioxan containing ionic active centres indicates that the formation of the macromolecules is not due only to the production of the active centres and that it is the deformation of the solid monomer than ensures the necessary conditions for the chain process of growth of the polymer molecules.

Compounds whose polymerisation is difficult or not detected at all under ordinary conditions are of particular interest.

1. Polymerisation of Nitriles and Aromatic Compounds

Nitriles under ordinary conditions undergo poly-addition either under the influence of large doses of ionising radiation or in the presence of Lewis acids with cocatalysts. The passivity of the cyano-group with respect to polymerisation is explained by the fact that the formation of sequences of $-C=N-$ bonds in many cases is a thermodynamically unfavourable process[33].

Under SD + HP conditions, however, solid nitriles can react to form sequences of $-C=N-$ bonds; the polymers obtained are brown or black, and give an EPR signal in the form of the singlet characteristic of polyconjugated systems[19]. The change in the colour of the nitriles on polymerisation made it possible to use a micro-apparatus with transparent diamond anvils to follow visually the transformations of the nitriles during deformation[18]. These observations, made for tetracyanoethylene, malononitrile, and terephthalodinitrile, made it possible to record the breakdown of the crystalline blocks in the field of the shear stresses, to observe the displacement zones in the substance, and, which is most important, to detect the development of the polymerisation process as the deformation of the specimen increased[18].

The transformations of other nitriles under SD + HP conditions was studied using ordinary apparatus[17–20]. The reactivity of these compounds varies over a wide range[7,18]. The least reactive are derivatives of compounds of the aliphatic series: stearonitrile and palmitonitrile do not react even at 10000 MPa; succinonitrile is polymerised at this pressure, but at higher values of the deformation. Increase in the number of CN groups in the molecule, and additional functional groups such as $-C=C-$, NO_2, aromatic rings, etc. increase the reactivity of a compound to a considerable extent: benzonitrile reacts at 8000 MPa, *p*-nitrobenzonitrile at 5500 MPa, fumaronitrile at 3000 MPa, malononitrile at 1000 MPa, etc.[18] Under deformation conditions, both functional groups often react. Thus 4-cyanopyridine and benzonitrile react both at the $C\equiv N$ group and with opening of the aromatic ring. If the molecule contains a group more reactive than CN, for example the $-C=C-$ group in acrylonitrile, the polymerisation takes place primarily through this group[20].

Thus the transformations of nitriles are accompanied by the formation of products with a high molecular mass. The production of the structure of the polymeric molecules in the general case, however, is due not only to the successive attachment of CN groups to one another but also to the reaction of other functional groups ($-C=C-$, amide, NO_2, etc.)[18].

Aromatic hydrocarbons under SD + HP conditions undergo unusual transformations, whose chief characteristic is the opening of the aromatic rings[4]. It is known that aromatic fragments of molecules are among the most stable in chemical reactions. Very high pressures of tens of thousands of MPa generally do not bring about the transformation of aromatic hydrocarbons[34].

Benzene, pyridine, and thiophene are classical examples of aromatic compounds. All these substances at 8000–10000 MPa under shear deformation conditions undergo transformations accompanied by rupture of the aromatic ring and the formation of macromolecular compounds[9,20,35,36]. For example, benzene is converted into a brown polymer which does not melt and which is insoluble in common solvents; the infrared spectrum of the product does not contain absorption bands characteristic of aromatic derivatives, and is identical to the spectrum of the polyacetylene obtained on Ziegler–Natta catalysts, that is under SD + HP conditions, benzene is converted into a polymer made up of sequences of $-C=C-$ bonds[25,36]. The formation of polyene structures under SD + HP conditions is unique. The opening of the benzene rings under other conditions has been reported; it can take

place, for example, under the influence of radiation[37], ultrasonic waves[38], and shock waves[39], but the formation of sequences of −C=C− bonds is not observed.

Polynuclear compounds with isolated or condensed rings (naphthalene, biphenyl, anthracene, phenanthrene, etc.) under SD + HP conditions also form macromolecular compounds by rupture of the aromatic ring[20,36]. As with nitriles, the pressures at which aromatic compounds begin to react are characteristic of each substance[7]. Thus anthracene begins to polymerise at a pressure of 2000 MPa and above, naphthalene at 4000 MPa, biphenyl at 8000 MPa, and bibenzyl at 2,3-dimethylnaphthalene at 10000 MPa (durene does not react at these pressures[36]).

The reactivity of hydrocarbons under SD + HP conditions depends on the number of aromatic rings in the molecule, on the way in which they are connected, and on the nature of the substituents[35,36]. The stability of an aromatic derivative decreases with increase in the number of rings (benzene is more stable than naphthalene, naphthalene is more stable than anthracene, and biphenyl is more stable than terphenyl). For a given number of rings, the reactivity of the hydrocarbons depends on the way in which the rings are connected; anthracene reacts at lower pressures than phenanthrene, and phenanthrene reacts before terphenyl. Compounds with isolated rings are more stable than those with condensed rings: biphenyl is more stable than naphthalene, etc. The reactivity is influenced strongly by aliphatic groups. Dimethylnaphthalene, bibenzyl, and durene are much more stable in SD + HP conditions than their non-substituted analogues. The stability of these compounds in a field of mechanical stresses cannot be explained within the framework of the usual concepts of organic chemistry, since CH_3 or CH_2 groups have practically no influence on the stability of an aromatic ring. It has been suggested[7,35] that mechanical stresses may be "concentrated" in chemical bonds in different ways; mobile aliphatic groups prevent the "concentration" of the mechanical stresses in the molecule or its fragments, leading to a decrease in the reactivity of the substances under SD + HP conditions.

2. Estimation of the Rate Constants of Polymer Chain Growth

Chemical reactions under SD + HP conditions take place in times measured in seconds or fractions of a second, that is the reaction rates are very high. In a number of cases it has been possible to estimate the lower limit of the reaction rate constant[7,42].

Table 1. Rate constants for the growth of polymer chains (mole litre^{-1} s^{-1}) calculated for the liquid phase and observed for DS + HP.

Monomer	p, MPa	T, K	t, s	P	k_p (calc.)	k_p (SD + HP)	Refs.
Styrene	1000	195	1	1000	1.6	$\geqslant 10^2$	[7, 30]
Acrylamide	1000	150	1	1000	1.5	$\geqslant 10^2$	[3, 7]
Butadiene	2000	150	1	200	10^{-3}	$\geqslant 20$	[7, 29]

The lower limit of the rate constant is calculated using the obvious inequality[7]:

$$k_p \geqslant P/M_0 t$$

relating the rate constant of the propagation of the polymer chains (k_p, litre mole^{-1} s^{-1}) to the concentration of monomer (M_0, M), the degree of polymerisation (P), and the reaction time (t, s). By substituting the experiment time and the degree of polymerisation in the inequality obtained, it is possible to calculate the lower limit of the rate constant of polymer chain propagation. These estimates have been carried out for various polymerisation reactions (Table 1). The examples given in Table 1 indicate that under SD + HP conditions, the polymerisation rate constants are greater by 2–5 orders of magnitude than the corresponding rate constants for polymerisation in the liquid phase. In other words, on deformation of the solid monomers the reaction of the double bonds with the radicals is stimulated.

Table 2. Degree of transformation, yields of product, and rate constants for the dimerisation and trimerisation of cyclopentadiene[42].

T, K	p, MPa	t, h	$10^2 M/M_0$	$10^2 2M_2/M_0$	$10^2 3M_3/M_0$	k_d, litre mole^{-1}s^{-1}	k_t/k_d
Experiments in the liquid phase*							
353	500	1	8.35	91.3	0.32	$2.4\cdot10^{-3}$	$1.5\cdot10^{-3}$
353	0.1	5	31.7	68.2	0.076	$9.0\cdot10^{-5}$	$1.05\cdot10^{-3}$
293	0.1	170	56.9	43.1	0.0021	$7.2\cdot10^{-7}$	$6.7\cdot10^{-1}$
Experiments under SD + HP conditions**

* 10% solution in toluene used.
** Pure cyclopentadiene.
*** Angle of rotation of anvils equal to 2.6 rad.

The reaction rate constants under SD + HP conditions were also estimated quantitatively in a study of the dimerisation of cyclopentadiene[42]. In the liquid phase this reaction is accompanied by the formation of small quantities of oligomers, mainly trimers, so that the kinetics of dimerisation are described by equations which take account of the formation of the trimers[29,42]:

$$-\frac{dM_1}{dt} = \frac{1}{2}\frac{dM_2}{dt} = k_d M_1^3 \quad , \tag{1}$$

$$\frac{dM_3}{dt} = k_t M_1 M_2 \tag{2}$$

where M_1, M_2, M_3 are the concentrations of the monomer, dimer, and trimer, M; and k_d and k_t are the dimerisation and trimerisation constants respectively. Some of the experimental results, and also the constants k_d and k_t calculated using the equations obtained by solving the differential equations (1) and (2)[7,29], are given in Table 2. When the reaction is carried out under SD + HP conditions, the trimerisation rate constant increases considerably relative to the dimerisation rate constant. Comparison of the dimerisation rate constants calculated for the liquid phase and observed under SD + HP conditions gives an interesting result. k_d for the liquid-phase reaction (at the temperature and pressure of the SD + HP experiment) was calculated from the known values of the activation energy[40] and the volume effect of the formation of the activated complex[41]. The calculated rate was 2×10^{-9} mass % min^{-1}, whereas the rate observed under SD + HP conditions is not less than 15–20 mass % min^{-1}, that is it is 10^{10} times greater[42].

Thus the estimates of the reaction rate constants under SD + HP conditions indicate that the substances show an anomalously high reactivity under conditions of deformation in the compressed state.

3. The Role of Heat Production Under SD + HP Conditions

The deformation of solid specimens involves considerable mechanical work, most of which is converted into heat; the solution of the problems related to the estimation of the heat production in a substance is therefore important for the interpretation of the results of SD + HP experiments, and in particular for the determination of the factors responsible for the high reactivity. Calculations and direct measurements of the temperature of specimens have shown[7,49] that the total heat production in a substance on deformation in an apparatus of the anvil type is slight, and cannot be responsible for the high rate of the chemical transformations.

Another mechanism which can be introduced to explain the high reactivity of the compounds is based on the concept of "hot spots". It is suggested[7] that at the moment of deformation in the specimen there exist zones in which there is a sharp increase in temperature as a consequence of the non-uniformity of the specimen, the separation of the plastic flow of the substance, or other factors. The size of these zones is obviously greater by many orders of magnitude than that of the molecules, and the temperature in these "hot spots" cannot exceed the melting point of the substance at the given pressure[44].

To resolve the question of the existence of these molten zones under SD + HP conditions and their role as places where the reactions take place, a study was made of the influence of pressure on the rate constants of the iso- and syndiotactic addition of the growing polymer radical to the double bond of methyl methacrylate (k_i and k_s) in the liquid-phase polymerisation[45] and the polymerisation of this monomer under SD + HP conditions[8]. The difference in the volume effects of activation $\delta\Delta V^{\neq} = \Delta V_i^{\neq} - \Delta V_s^{\neq} = -0.3$ cm^3 mole^{-1} (liquid-phase polymerisation, pressure range 8000–1050 MPa) and the difference in the activation energy $E_i - E_s$, which was found to be 1.1 kcal mole^{-1} at both ordinary and high pressures, were determined. For SD + HP conditions, it was found that $\delta\Delta V^{\neq} = -0.08$ cm^3 mole^{-1}.[8] The values of $\delta\Delta V^{\neq}$ and $E_i - E_s$ obtained were used to verify the concept of "hot spots".

If the reaction takes place in the zones of the molten monomer, the change in lg (k_i/k_s) with change in pressure under SD + HP conditions should be determined by the quantity $|\delta\Delta V^{\neq}| > 0.3$ cm^3 mole^{-1}, since increase in pressure is accompanied by an increase in the temperature of the molten zones as a result of the increase in the melting point with increase in pressure. Thus the value $\delta\Delta V^{\neq} = -0.08$ cm^3 mole^{-1} found under SD + HP conditions does not agree with the suggestion that molten zones exist.

The applicability of the concept of "hot spots" can also be verified by another method, by comparing the values of k_i/k_s. This ratio is appreciably higher under SD + HP conditions than for polymerisation in the liquid phase[7]. To explain this difference, it is necessary to assume that the heat production in the monomer on deformation takes place up to a temperature ~ 100 K higher than the melting point of methyl methacrylate at the given pressure, but this contradicts existing ideas about local heat production[44]. Thus under SD + HP conditions, either no local molten zones of monomer are produced, or this phenomenon does not make a significant contribution to the chemical process.

4. Copolymerisation Reactions

A number of studies have been carried out for reaction mixtures consisting of two monomers[46–49]. When specimens of mixtures of acrylamide and methacrylamide with the eutectic composition (87% acrylamide and 13% methacrylamide) were deformed, a reaction was observed, accompanied by the formation of polymeric products (pressure range 500–1500 MPa, temperature 293 K). Gel-permeation chromatography indicated that copolymers are formed[46]. An interesting feature is that the rate of the copolymerisation of acrylamide and methacrylamide is greater than the rates of polymerisation of pure acrylamide and methacrylamide.

The study of the copolymerisation of mixtures of maleic anhydride and acenaphthene under SD + HP conditions[47,49] showed that the nature of the dependence of the composition of the copolymer on the composition of the original mixture is the same as that for the liquid-phase copolymerisation of the same monomers in acetone solution. The composition of the copolymer remains unchanged with change in the composition of the original mixture (with increase in the proportion of maleic anhydride from 20% to 85%). This was attributed[47] to the reaction of maleic anhydride and acenaphthene to form a charge-transfer complex, which polymerises rapidly and forms a copolymer of definite composition.

Copolymerisation reactions are often sensitive to both the mechanism of polymerisation and the phase state of the original mixture of the monomers. These reactions include the copolymerisation of styrene and methyl methacrylate, so that this reaction has been studied in detail under SD + HP conditions[6,48,49]. The experiments were carried out at 2000 MPa, 195 K, and angles of rotation of the anvils to give a yield of copolymer not exceeding 10%. Studies of the infrared and NMR spectra of copolymers of styrene and methyl methacrylate (obtained under SD + HP conditions, in the liquid phase, and with radiation-initiated polymerisation of the solid monomers), fractionation of the polymeric products, and subsequent analysis of the fractions gave the following results[48]: 1) under SD + HP conditions, mixtures of styrene and methyl methacrylate react to give copolymers; 2) the nature of the distribution of the units of styrene and methyl methacrylate is the same for the copolymer macromolecules obtained by radical copolymerisation and the copolymers obtained under SD + HP conditions; 3) the copolymers obtained by solid-phase polymerisation show a distribution of the units approaching that found for a mixture of homopolymers of styrene and methyl methacrylate; 4) the dependence of the yield of copolymer on the composition of the original mixture, obtained under SD + HP conditions, is close to that for the liquid-phase copolymerisation (the form of this dependence is quite different for the solid-phase copolymerisation).

Thus in spite of the fact that the original solid mixtures of monomers are non-uniform, their deformation is accompanied by effective mixing of the components and the formation of copolymers with uniform compositions. Moreover, the composition of the copolymers and the distribution of the monomeric units in the polymer chain are close to those which are observed in the copolymers obtained by liquid-phase radical polymerisation. From these factors, it was concluded[48] that the state of a substance under SD + HP conditions, according to a number of its properties, is close to the liquid state (a quasi-liquid state).

III. KINETICS AND MECHANISM OF POLYMERISATION UNDER CONDITIONS OF SHEAR DEFORMATION AND HIGH PRESSURES

To determine the mechanism and characteristic features of the kinetics of polymerisation reactions with SD + HP, a series of investigations was carried out, involving the detailed study of the polymerisation of acrylamide, and including studies of the physical state of the substance

during its deformation[50-52,54] and a series of kinetic measurements and calculations undertaken to investigate the mechanism of polymerisation[3,32] and to find the rate constants of the elementary stages of the polymerisation of acrylamide[7,53,55].

These studies established a number of general regular features of polymerisation under SD + HP conditions. It was found that the yield of polymer at constant pressure and temperature depends on the magnitude of the deformation and is independent of the rate of deformation of the specimen[3,7]. The kinetic curves are *S*-shaped (Fig.4), and the point of inflection corresponds to the range in which there is a change from internal displacement of the layers of substance to the surface slip of the anvils over the specimen[7]. It can be seen from Fig.4 that with increase in pressure, the position of the point of inflection is displaced to the range of higher degrees of conversion, due to the increase in the strength of the adhesion of the specimen to the material of the anvils. The calculations were carried out using data relating to the range in which the angle of rotation of the anvils corresponded to the magnitude of the deformation of acrylamide[7]. The molecular mass of polyacrylamide at first increases with increase in the deformation, reaches a maximum for 2–8% conversion (depending on the conditions of the experiment), and then decreases (Fig.5).

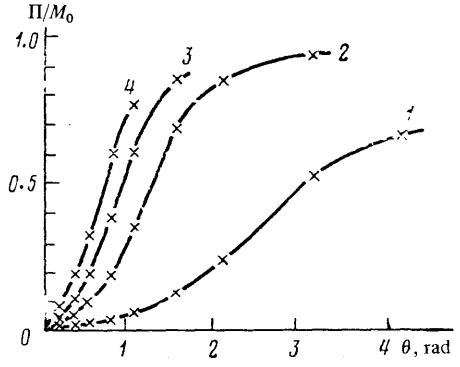

Figure 4. Dependence of the yield of polyacrylamide on the angle of rotation of the anvils at 293 K and different pressures[7]: *1*) 1000, *2*) 2000, *3*) 2500, *4*) 3000 MPa.

A study of the kinetics of the dependence of the polymerisation of acrylamide on the radical acceptors added to the monomer and experiments with previously irradiated specimens (treatment with γ-rays from a ^{60}Co source)[32] indicated that the polymerisation of acrylamide takes place by a radical mechanism. The increase in the rate of polymerisation is proportional to the increase in the concentration of polymer in the specimen[32]. The mechanism of the increase in the rate of polymerisation with increase in the concentration of the polymer is not clear. The appearance of polymer leads to an increase in the shear stress applied to the specimen (see for example Fig.3a), and this may lead to an increase in the reaction rate, since the shear stress applied to the reaction mixture under SD + HP conditions influences the rate of the chemical process[56]. It is also extremely probable that the appearance of polymer molecules in the specimen facilitates the production of regions in which the mechanical stresses leading to the generation of active centres for polymerisation are concentrated[32].

On the basis of the regular features observed, a mechanism was proposed for the polymerisation of acrylamide[7,53,55]; the following assumptions were made: a) all the elementary stages of polymerisation (initiation, propagation, and bimolecular termination of the chain) take place during the deformation of the specimen; the collision of the reagent molecules takes place only as a result of the movement of the layers of the substance relative to one another on shear deformation. Thus the independent variable in the equations describing the elementary stages should be not time but the magnitude of the deformation of the substance; b) the production of active centres (radicals) takes place mechanochemically in a medium of the monomer in regions where mechanical stresses are concentrated, and the number of such regions is proportional to the quantity of polymer formed. The differential equations are written as follows[53]:

$$\frac{dR}{dx} = k_i' M_0 + k_i \Pi - k_t R^2 \qquad (3)$$

$$-\frac{dM}{dx} = \frac{d\Pi}{dx} = k_p M_0 R \qquad (4)$$

where x is the magnitude of the shear deformation ($x = r\theta/z$); r the radius of the differential zone of the specimen, cm; θ the angle of rotation of the anvil, rad; z the height of the specimen, cm; M, Π, and R the concentrations of the monomer, polymer, and radicals, M; k_i' and k_i the rate constants of the initiation in the pure monomer and in the presence of polymer; and k_p and k_t the rate constants of the propagation and termination of the polymer chains.

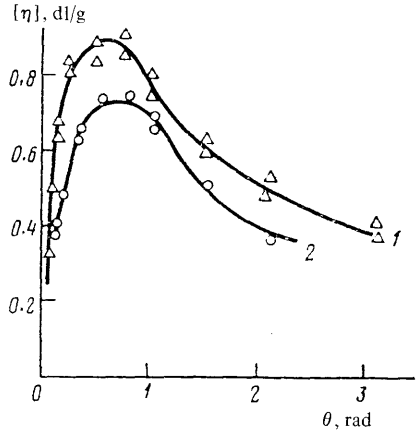

Figure 5. Dependence of the characteristic viscosity [η] of polyacrylamide on the angle of rotation of the anvils at 293 K[7]: *1*) 1000, *2*) 2000 MPa.

Solution of Eqns.(3) and (4) using the principle of stationary character gives the expression[7,53]:

$$\frac{\bar{\Pi}}{M_0} = \frac{k_p^2 k_i}{8k_t} M_0 \frac{(r_2^2 + r_1^2)}{z^2} \theta^2 \qquad (5)$$

where $\bar{\Pi}$ is the average concentration of the polymer in the annular zone of the specimen bounded by the radii r_1 and r_2.

Fig.6 gives the dependence on θ obtained at different pressures for different radial zones of the specimen. The experimental data obtained lie effectively on straight lines on these coordinates.

Eqn.(5) has been used[53] to verify the dependence of the yield of polymer on the radius of the anvil. Fig.7 gives the dependence of $(\Pi/M)^{1/2}$ on θ, obtained by averaging the results of 16 experimental series for anvils with diameters of 10 mm and 20 mm. The slopes of the straight lines corresponding to experiments with anvils of different diameter differ by a factor of two, and the yields of polymer differ accordingly by a factor of four. According to Eqn.(5), the yields of polymer for a fixed angle of rotation and the same specimen thickness should also differ by a factor of four; thus these results indicate good agreement between theory and experiment.

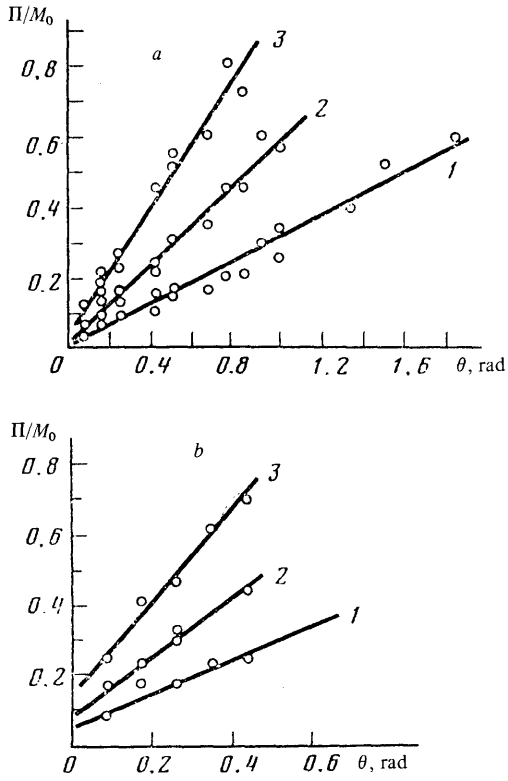

Figure 6. Dependence of (Π/M_0) on θ, obtained for different zones of the specimen at different pressures[53]: *a*) 1000, *b*) 3000 MPa; *1, 2, 3*) radial zones of specimens with diameters from 0 to 10 mm, from 10 mm to 15 mm, and from 15 mm to 20 mm respectively.

In the work cited[53], the experimental data on the molecular masses were treated using an equation relating the mean-molecular mass of the resulting polymer M_m to the angle of rotation of the anvils θ. The degree of polymerisation $\bar{P}$, the average for the entire specimen, is defined as $\bar{P} = G/N$, where G is the mass of the polymer, and N the total number of polymer particles. Solution of this equation[7] gave the equation:

$$\frac{1}{\bar{p}} = \frac{4}{15}\frac{k_i\theta\rho}{z} \qquad (6)$$

where ρ is the radius of the working surface of the anvil.

Fig.8 gives the dependence of $1/M_m$ on θ for pressures of 1000 MPa and 2000 MPa and for temperatures of 293 K and 195 K. Data corresponding to degrees of transformation of 3% and above[53] were used, that is the descending branch of the dependence of the molecular mass on the angle of rotation of the anvil was treated. According to Eqn.(6), the slope of the straight lines is proportional to k_i; thus the rate of formation of the radicals in the specimen increases with increase in pressure and temperature.

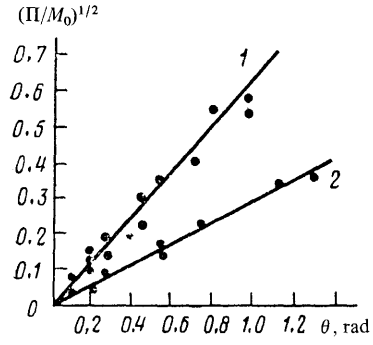

Figure 7. Dependence of (Π/M_0) on θ, obtained on anvils of different diameter[53] at 1000 MPa and 293 K: *1*) 20 mm, *2*) 10 mm.

Table 3. Rate constants and their ratio for the elementary stages of the polymerisation of acrylamide for SD + HP[7].

Conditions	$10^4\, k_p k_i/k_t$	$10^4\, k_i$	k_p/k_t
2000 MPa, 293 K	0.59	0.75	0.88
1000 MPa, 293 K	0.48	0.52	0.58
1000 MPa, 195 K	0.42	0.2	0.45

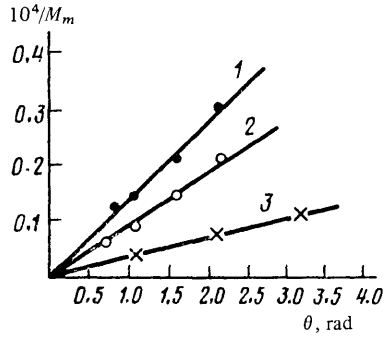

Figure 8. Dependence of the reciprocal of the molecular mass of polyacrylamide on the angle of rotation of the anvils under different conditions[53]: *1*) 2000 MPa, 293 K; *2*) 1000 MPa, 293 K; 3) 1000 MPa, 195 K.

The proposed mechanism of polymerisation and the mathematical m treatment of the experimental data carried out using the principle of stationary character make it possible to describe the dependence of P on θ and of π/M_0 on θ. This mechanism makes it possible to explain why the molecular mass of the polymer decreases at degrees of transformation greater than 3–5%; the decrease in molecular mass is due to the rapid increase in the concentration of active centres for polymerisation as the reaction proceeds[7].

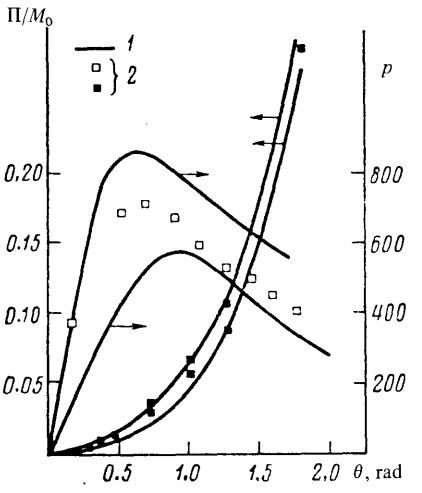

Figure 9. Dependence of the yield and degree of polymerisation of polyacrylamide on the angle of rotation of the anvils[7]: *1*) calculated curves, *2*) experimental data.

Eqns.(5) and (6) made it possible to calculate the rate constants of the elementary reactions and their ratios[7,53] (Table 3). Although Eqns.(5) and (6) describe the principal kinetic data satisfactorily, they do not explain, even qualitatively, the production of the maximum on the curves giving the dependence of the molecular masses on θ. It has been suggested[7,55] that the increase in the molecular mass of the polymer at low degrees of deformation is related to the non-stationary character of the process in the initial stage of the polymerisation. To verify this suggestion, the system of equations was solved without using the principle of stationary character[7,55]. The differential equations (3) and (4) were solved by numerical methods using the experimentally determined values of k_i and k_p^2/k_t (see Table 3) with variation of the quantity k_t/k_p. It was necessary, using the values of k_p^2/k_t and k_i, to select k_t/k_p to obtain curves giving the dependence of Π/M_0 on θ, of P on θ, and of P on Π/M_0 close to the experimental curves.

Fig.9 gives the experimental and calculated dependence of Π/M_0 on θ and of P on θ.[7] The theoretical curves calculated for $k_t/k_p = 10–20$ coincide to within 20–30% with the experimental curves for all degrees of conversion. Thus the results confirm that the polymerisation is non-stationary in the early stages of the deformation of acrylamide.

IV. CONCLUSION

The experimental data obtained indicate that under shear deformation conditions at a high pressure, solid organic compounds of different classes can polymerise at anomalously high rates, and can react by reaction paths which are not followed under ordinary conditions.

Measurements and calculations indicate that the rate constants of polymerisation with SD + HP may be 10^5 or more times the analogous constants characterising the liquid-phase reactions at the same temperatures and pressures. Under deformation conditions there may be a marked change in the selectivity of the chemical process. In a number of cases, side reactions which do not take place to a significant extent under ordinary conditions take place at rates comparable with that of the main reaction.

The reasons for the high reactivity of substances under SD + HP conditions have been insufficiently studied. Nevertheless, it should be noted that the dependence of the principal kinetic parameters (the degree of transformation, the concentration of radicals, the molecular mass of the polymer, etc.) on the shear deformation indicates that the duration of the elementary stages of the reaction of the interacting particles is very short, and the number of elementary acts is a function of the shear deformation. To explain this characteristic feature of processes under SD + HP conditions, two alternative mechanisms can be proposed. According to the first, under SD + HP conditions, strained and hence chemically activated bonds are produced in the reagent molecules and subsequently react with other molecules or their fragments in collisions, brought about by the motion of the substance on deformation. In the other possible mechanism, the bond, molecular fragment, molecule, or micro-region of the solid reagent, strained as a result of deformation, on subsequent deformation "ejects" the stored energy (relaxation); the potential energy of elastic deformation is converted into the vibrational energy of the molecules and individual bonds, which consequently show a high reactivity.

It is difficult at present to decide which of these mechanisms predominates under SD + HP conditions, since both explain the anomalously high rates of transformation and the weak temperature dependence of the reaction rate. In the first case, the mechanical stress applied to the bond can lower the activation energy of the reaction, and in the second case the high vibrational temperatures ensure high rates of transformation and are revealed in low values of the apparent activation energies. The elucidation of the mechanism responsible for the high reactivity of substances, and the determination of the reasons for the mixing of heterogeneous solid mixtures under SD + HP conditions at a level close to the molecular level, are important tasks in physicochemical studies under SD + HP conditions.

Another important problem is the determination of the types of chemical transformation which can take place during the deformation of solid reagents. At the present time, about twenty types of chemical reaction have been detected under SD + HP conditions. These include the addition to a $-C{=}C-$ bond of small molecules and functional groups (water, ammonia, the carboxyl group, the amide group, etc.), Diels–Alder reactions, the decomposition of peroxides, esterification, etc. These studies have shown that there are chemical processes favoured by SD + HP conditions, and on the other hand there are types of transformation which take place with difficulty or not at all on deformation of the compressed reagents. The reactions for SD + HP conditions are favourable include primarily the synthesis of macromolecular compounds. The largest number of studies carried out with SD + HP have been devoted to transformations of

this type. For these reasons, the results of the study of polymerisation processes with SD + HP are providing (and undoubtedly will continue to provide, in further extensions of these studies) a phenomenological and theoretical base for the development of the chemistry of solid organic compounds under conditions of deformation at high pressure in the compressed state.

Problems of Non-isothermal Character in Polymerisation Processes

S.P.Davtyan, P.V.Zhirkov, and S.A.Vol'fson

The results of the study of the radical polymerisation of vinyl monomers taking place under non-isothermal conditions, namely under purely adiabatic conditions, with transfer of heat to the surrounding medium, under the conditions of propagation of the polymer front, and the influence of hydrodynamics on the kinetics of polymerisation, have been reviewed. Various data on the ionic polymerisation of lactams, where the spontaneous heat production in the reaction is determined not only by the chemical source of heat release but also by the crystallisation of the resulting polymer, have been analysed. The results of the study of the condensation of epoxide compounds under the influence of amines under adiabatic conditions and under conditions of propagation of the polymer front have been discussed briefly.

I. INTRODUCTION

Many processes in the synthesis of polymeric materials are characterised by highly exothermic reactions and low values of the coefficient of thermal conductivity of the monomer–polymer mixture. This combination of thermophysical characteristics of the polymerisation medium together with the reaction rates actually observed in practice often leads to superheating of the reaction mass and the appearance of a non-uniform space–time distribution of the temperature and the extent of the reaction. A consequence of the formation of these non-uniform fields is the difficulty of controlling the process and in a number of cases a deterioration in the properties of the polymeric materials formed.

Spontaneous heat production in a polymerising system may lead to a change in the thermal conditions such as a change from bulk polymerisation to a self-propagating polymerisation front, or may influence the concentration of macroradicals and the intensity of the manifestation of the gel effect, or may lead to "burn-out" of the initiator long before the consumption of the monomer, and to the start of polymerisation by thermal initiation. Effects of this kind lead to a significant change in the regular kinetic features and properties of the materials formed. The development of new energetically rational processes, and the intensification of existing processes, must involve the analysis of the kinetic characteristics of non-isothermal polymerisation.

The traditional approach to the study of the kinetics of polymerisation processes involves an analysis under isothermal conditions. At the same time, in practical technological problems, it is usually necessary to deal with non-isothermal conditions as such or with departure of the reaction from isothermal conditions as a result of the influence of various factors.

In the last ten years, at least two factors have led to an increased interest in polymerisation reactions under non-isothermal conditions. The first of these is the deeper knowledge of the inter-relationship between the conditions of synthesis and the structure and properties of polymers, which has led, in particular, to a sharp increase in the number of studies of the control of the molecular-mass distribution (MMD) and the influence of the MMD on the properties of polymers. The second factor is the trend towards the use of non-isothermal conditions to intensify industrial polymerisation processes in reactors of different type, and also to harden oligomeric systems and to obtain cross-linked structures directly in articles.

The present review examines and summarises for the most part work carried out in recent years by Enikolopov and co-workers.

II. FREE-RADICAL POLYMERISATION

Polymerisation by a radical mechanism, which is the simplest and has been studied in most detail, has become the principal object of study in the investigation of non-isothermal effects. This process can be carried out in practically all known thermal conditions, and the analysis of the consequent problems is important for practical applications.

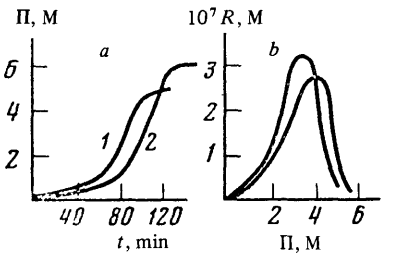

Figure 1. Change in the yield of polymer (П) (*a*) and the concentration of macro-radicals R (*b*) during adiabatic polymerisation[1]: *1*) quasi-stationary solution, *2*) exact solution; $I_0 = 10^{-3}$ M, $T_0 = 350$ K.

1. The Kinetics of Polymerisation Under Adiabatic Conditions

In the adiabatic polymerisation of vinyl monomers, depending on the difference between the activation energies for the decomposition of the initiator and for the termination of the chains, an adiabatic increase in the temperature of the polymerisation medium should mainly be reflected in the increased rate of decomposition of the initiator. Thus at sufficiently high rates of change of temperature, the use

of the principle of quasi-stationary concentrations (QSC) in the classical sense may become incorrect. In fact, numerical computer analysis of a kinetic scheme including initiation, propagation, and bimolecular termination shows[1] that there is a fairly marked difference between the quasi-stationary and the true solutions (Fig.1), the discrepancy between which depends chiefly on the magnitude of the heat of polymerisation (Q), the activation energies (E_i, E_t), and the pre-exponential factors (k_{i0}, k_{t0}) of the rate constants for initiation (k_i) and termination (k_t).

If in the equation for the concentration of macroradicals (R)

$$\frac{dR}{dt} = k_i(t)\,I(t) - k_t(t)\,R^2 \qquad (1)$$

the relative deviation of the true concentration of macroradicals from the quasi-stationary concentration ($\bar{R}$) is denoted by the quantity $\Delta = R/\bar{R} - 1$, then[2]:

$$\frac{d\Delta}{dt} = -\Delta(1+y)\,a(t) + \frac{1+\Delta}{2}\,\Psi(t) \qquad (2)$$

where

$$a(t) = \sqrt{k_i(t)\,k_t(t)\,I(t)};\quad \Psi(t) = \frac{1}{RT^2}(E_t - E_i)\frac{dT}{dt} + k_i(t);\quad y = R/\bar{R}$$

$I(t)$ is the concentration of the initiator, and T the temperature.

Analysis of Eqns.(1) and (2) shows that if $ta(t) \gg 1$ and $k_i(t)/a(t) \ll 1$, then $\Delta \to 0$, that is under non-isothermal conditions it is possible to use the QSC principle. In fact, the numerical solution of the system of kinetic equations for the adiabatic polymerisation of styrene, methyl methacrylate, and n-butyl methacrylate shows that for $ta(t) \geq 10^2$ and $k_i(t)/a(t) \leq 10^{-3}$ the QSC method can be used with sufficiently high accuracy.

Subsequently, the QSC principle was developed for cases in which it is possible to have the gel effect during adiabatic polymerisation; the conditions for the use of the QSC principle for the theoretical study of molecular masses and the MMD for the formation of the polymer were also studied[3].

The kinetics of radical polymerisation under adiabatic conditions when the QSC method is applicable have been studied theoretically[1,4,5]. The influence of various methods of initiation—photo- or radiation (W_i = const), thermal ($W_i = k_M M^2$), material ($W_i = k_i I$), complex ($W_i = k_{i1} I_1 + k_{i2} I_2$), and mixed ($W_i = k_i I + k_M M^2$) on the kinetics of formation and yield of the polymer were studied; here, W_i is the rate of initiation, and M the monomer concentration.

For the first three cases of initiation, the original kinetic equations can be solved in analytical form; the graphical representation of these solutions is given in Fig.2, which shows that for radiation (curve 2) or thermal (curve 3) initiation, the polymerisation gives 100% conversion, whereas for material initiation (curve 1) the conversion is much lower. The reason for the low yields for material initiation is that during the adiabatic increase in the temperature of the reaction mixture, complete "burn-out" of the initiator takes place long before the monomer is used up. The experimental study[6-11] of the kinetics of the radical polymerisation of styrene, methyl methacrylate, and n-butyl methacrylate under the influence of various peroxide initiators has shown that in accordance with theory, the yield of polymer formed does not exceed 40–50% of the original monomer concentration. Under specially selected conditions during the initiated adiabatic polymerisation of methyl methacrylate and n-butyl methacrylate, there is a gel effect[12], and in spite of the "burn-out" of the initiator, the yield of polymer may correspond to the practically complete consumption of the monomer. Since the realisation of this situation depends on the nature of the monomer, from the practical viewpoint, increasing the yield of polymer with material initiation is of considerable interest. For this purpose, a theoretical study was made[1] of the dependence of the yield of polymer on the initial conditions, the kinetic parameters, and the thermophysical characteristics of the monomer–polymer mixture. A significant increase in the yield can be achieved by using mixtures of initiators with different activation energies of decomposition.

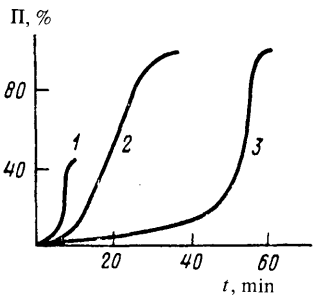

Figure 2. Kinetics of the adiabatic polymerisation of styrene for material (*1*), radiation (*2*), and thermal (*3*) initiation[1].

The influence of mixtures of different initiators on the kinetics of the polymerisation of styrene and methyl methacrylate using dicyclohexyl peroxydicarbonate (CPC), benzoyl peroxide (BP), t-butyl peroxide (tBP), cumyl peroxide (CP), and isobutyrodinitrile as initiators has been studied experimentally[13].

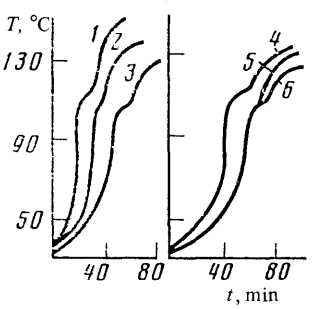

Figure 3. Kinetic curves for the polymerisation of methyl methacrylate under the influence of a mixture of initiators[13]: *1*) M_0 = 5.7, [CPC] = 0.22, [tBP] = 0.5; *2*) M_0 = 5.1, [CPC] = 0.2, [tBP] = 0.5; *3*) M_0 = 4.7, [CPC] = 0.22, [tBP] = 0.2; *4*) M_0 = 4.7, [CPC] = 0.1, [tBP] = 0.09; *5*) M_0 = 4.7, [CPC] = 0.05, [tBP] = 0.15; *6*) M_0 = 4.7, [CPC] = 0.05, [tBP] = 0.21 M.

The kinetics of the change in temperature during the reaction for initiation by a mixture of CPC and tBP are shown in Fig.3. The addition to the polymerisation system

of a second initiator (tBP) characterised by a higher activation energy leads to a change in the nature of the kinetic curves. A noteworthy feature is that the kinetic curves, in agreement with the theoretical results, show two inflections, indicating separate initiation in this system.

Comparison of the yields of polymethyl methacrylate and polystyrene obtained for initiation by a mixture of CPC with tBP or with CP with the yields for initiation by these initiators separately shows that in the first case the conversion increases by 60%, whereas the use of BP with other initiators is not effective, because of induced decomposition[14].

Under the conditions of adiabatic polymerisation, because of the continuous increase in temperature, the role of thermal initiation increases. For high degrees of transformation and high initial concentrations of monomer, thermal initiation may become the principal source of primary radicals. In fact, when the polymerisation of n-butyl methacrylate is carried out[11] without a solvent at higher temperatures (curve *1* in Fig.4*a*), the kinetic curves show a second abrupt change in temperature, due to thermal initiation. Dilution levels out the thermal polymerisation (curve *2* in Fig.4*a*), because of the low residual concentration of the monomer.

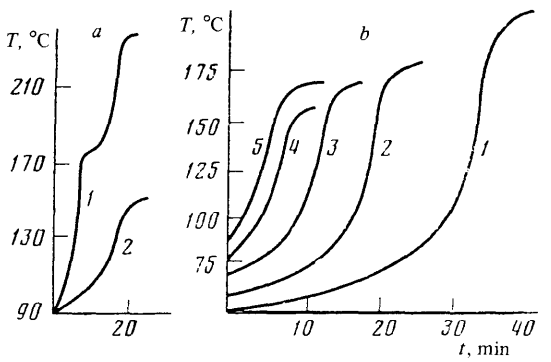

Figure 4. Kinetic curves for the adiabatic polymerisation of n-butyl methacrylate in the block (*a*, curve *1*; *b*, curves *1–5*) and in solution (*a*, curve *2*) for different initial temperatures[11,12].

The kinetics of the thermal polymerisation of styrene under adiabatic conditions was the subject of a special study[15] involving variation of the initial temperature and concentration of the monomer. To obtain a quantitative description of the kinetic curves, the authors cited carried out kinetic calculations assuming unimolecular, bimolecular, and termolecular mechanisms of initiation, and good agreement with experiment was obtained only for second-order kinetics.

In polymerisation under adiabatic conditions, complete decomposition of the monomer may be observed not only for thermal polymerisation but also when there is a gel effect. In fact, in a study of the polymerisation of n-butyl methacrylate in the bulk at an initial temperature of 50 °C,[12] an adiabatic increase in temperature was observed, corresponding to the practically complete consumption of the monomer (curve *1* in Fig.4*b*). With increase in the initial temperature of the reaction, there is a decrease in both the yield of polymer (at temperatures of 50, 70, 80, and 90 °C, the yields of polymer are 6.3, 4.5, 3.25, and 2.9 M respectively) and the final temperature of the system. The observed complete consumption of n-butyl methacrylate at 50 °C can in principle be attributed to an additional source of radicals, capable of bringing about thermal polymerisation. In this case, however, increase in the initial temperature of the reaction should lead to an increase in the rate of the thermal polymerisation itself, and hence to the complete consumption of the monomer, irrespective of the initial temperature of the reaction.

Thus this behaviour of the kinetic curves can be explained only by the gel effect in the reaction mixture. Comparison of experiment with calculations based on a kinetic model of the process makes it possible in this case to study the dependence of the rate constant of chain termination on the extent and temperature of the reaction.

The alternation of initiation and thermal polymerisation under adiabatic conditions is of methodological interest for the study of the mechanism of thermal initiation. In these cases, in the initial stage of the reaction, "burn-out" of peroxide impurities takes place, and all the subsequent information contained in the kinetic curves relates only to thermal polymerisation. Thus more reliable information on the mechanism of thermal initiation can be obtained by studying the polymerisation of vinyl monomers under adiabatic conditions, as was done for n-butyl methacrylate and styrene[12,15].

From the viewpoint of the determination of the elementary rate constants, a fact of considerable methodological interest is that at the moment of burn-out of the initiator, the quasi-stationary character with respect to the macroradicals breaks down, and post-polymerisation takes place; the latter can be studied using ordinary non-isothermal methods for determining elementary constants[16–21].

2. Nature of the Change in the Molecular Masses and the MMD in Adiabatic Polymerisation

The use of familiar methods (Laplace transformation, generating function method, etc.) for calculating the MMD function for radical polymerisation processes under adiabatic conditions involves considerable mathematical difficulties, because of the change in the rate constants with increase in the reaction temperature. Another limiting factor in the use of ordinary methods is that in adiabatic polymerisation, at the moment of "burn-out" of the initiator, the quasi-stationary character with respect to the macroradicals breaks down, so that to take detailed account of the characteristic kinetic features determined by the MMD of the final product, it is necessary to study the polymerisation without using the QSC method.

The nature of the change in the molecular masses and the MMD of the resulting polymer during the polymerisation under conditions when the QSC method is applicable or when this method is not applicable has been studied[1] in relation to the method of initiation.

For a constant rate of initiation up to high degrees of transformation, the mass-average ($\bar{P}_w$) and number-average ($\bar{P}_n$) molecular masses increase linearly with increase in the degree of transformation, but at the end of the reaction they decrease slightly, because of the consumption of the monomer. There is an analogous change in the ratio $\bar{P}_w/\bar{P}_n$, which is a measure of the polydisperse character of the resulting polymer. For thermal initiation, the ratios $\bar{P}_w/\bar{P}_n$ and $\bar{P}_z/\bar{P}_n$ ($\bar{P}_z$ is the *z*-average molecular mass) increase before the end of polymerisation.

For initiation by a material initiator, the values of $\bar{P}_w/\bar{P}_n$ and $\bar{P}_n$ decrease during the reaction as a result of an increase in the rate of decomposition of the initiator and a decrease in the lifetime of the macroradicals. In the initial stages of the reaction, $\bar{P}_n$ and $\bar{P}_w$ change in the same sense,

but subsequently, $\bar{P}_n$ decreases more rapidly than $\bar{P}_w$, since the formation of the low-molecular-weight polymer makes a more significant contribution to the first moment of the MMD function. For the same reason there is a slight broadening of the MMD of the resulting polymer.

For complex initiation (two initiators, initiator + thermal initiation), the curve giving the change in the instantaneous number-average molecular mass has several extremal points, due to the successive "burn-out" of the initiators or an increase in the role of thermal initiation with increase in the temperature of the system.

The moment of "burn-out" of the initiator has a fairly strong influence on the nature of the change in the MMD and the molecular masses, since the lifetime of the growing "live" chains may increase without limit. In this case, for a quantitative description of the adiabatic polymerisation, it is obviously necessary to analyse the MMD without using the QSC principle. For this purpose, the system of differential equations for the moments of the distribution of the "live" and "dead" polymers was solved numerically using a computer[1]. Analysis of the results shows that at low degrees of polymerisation, where the rate of bimolecular termination by a disproportionation mechanism is low because of the low concentration of macroradicals, the number-average molecular masses of the "live" and "dead" polymers increase and then decrease, and at the end of the polymerisation a new moderate increase in $\bar{P}_n$ for the "dead" polymer and a fairly intense increase for the "live" chains are again observed. For the "live" polymer, almost up to the end of the polymerisation, the ratio $\bar{P}_w/\bar{P}_n = 2$, after which, as the initiator is used up, it decreases to 1, due to the increase in the lifetime of the growing macromolecules, that is a change to "live" polymerisation.

The ratio $\bar{P}_w/\bar{P}_n$ for the "dead" polymer is close to 1.5 practically up to the end of the polymerisation, and it increases sharply only after the initiator has been used up. The increase in the polydisperse character of the "dead" polymer is also due to the "burn-out" of the initiator, so that the decrease in the rate of termination at the end of polymerisation leads to an increase in the length of the "live" chains by several orders of magnitude, and this has a stronger influence on the value of $\bar{P}_w$.

The results of the experimental study of the nature of the change in the MMD and the molecular masses in the adiabatic polymerisation of n-butyl methacrylate show complete agreement with these regular features[11].

As already noted, the determination of the MMD function using a Laplace transformation or a generating function involves considerable mathematical difficulties, and these methods can be used successfully only in those cases where the MMD function can be found analytically.

A method of finding the MMD function which eliminates these difficulties and is particularly effective in the analysis of non-isothermal polymerisation is therefore of interest[22,23]. The method involves essentially the reduction of the original system of differential equations for the "live" macromolecules to one equation in partial derivatives

$$\frac{\partial R(x,t)}{\partial t} + \frac{\varphi_2(t)}{N}\frac{\partial R(x,t)}{\partial x} = \varphi_1(t)R(x,t) \qquad (3)$$

where $x = j/N$; the number N is related to the chosen scale with respect to x, $\phi_1(t) = k_p(t)M$, $\phi_2(t) = \phi_1(t) + k_t(t) + k_t'(t)$, and k_t and k_t' are the rate constants for termination by recombination and disproportionation respectively. Eqn.(3) is solved by the method of characteristics.

The mass-average molecular mass and the ratio $\bar{P}_w/\bar{P}_n$ calculated by this method on a computer for the adiabatic polymerisation of styrene are given in Fig.5, where the points give the experimental data. The theoretical calculations show good agreement with experiment.

It should be noted that the maximum rate of polymerisation, corresponding to the maximum concentration of macroradicals, and the minimum value of $\bar{P}_n$, are reached for the same degree of polymerisation. The subsequent decrease in the concentration of macroradicals and increase in their lifetime leads to an increase in the molecular mass and a decrease in the rate of the process.

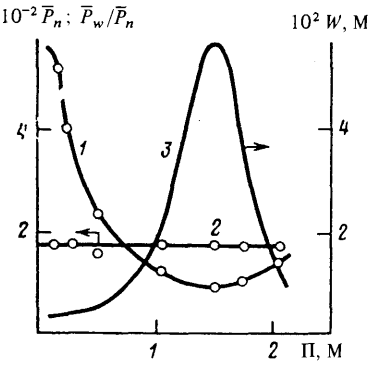

Figure 5. Change in the number-average molecular mass of polymerisation ($\bar{P}_n$, curve *1*), the width of the MMD ($\bar{P}_w/\bar{P}_n$, curve *2*), and the rate of polymerisation (W, curve *3*) during the adiabatic polymerisation of styrene[22]; $M_0 = 4.36$ M, $T_0 = 36$ °C; continuous curves—theory; points—experiment.

3. The Influence of Heat Removal on the Kinetics of the MMD

A periodic-action ideal-mixing reactor can be considered[24]. By changing the conditions of heat exchange at the walls of the reactor, it is possible to change the polymerisation conditions from isothermal to adiabatic. An indication of the non-isothermal character of the polymerisation process is provided by the Semenov parameter κ. For reactions with a high exothermicity and a high activation energy there is a sharp distinction, according to the Semenov parameter, between low-temperature (quasi-isothermal heating not more than 15–20 °C) and high-temperature (quasi-adiabatic, heating to 60–200 °C) polymerisation conditions. The intermediate zone is extremely narrow, and it is possible to speak of a critical value of the parameter κ. The intermediate zone becomes broader only for a low exothermicity and low activation energy of the process.

The change from one set of conditions to another is effectively illustrated by the dependence of the instantaneous number-average degree of polymerisation γ_n of the "live" polymer on the degree of transformation (α) (Fig.6).

For isothermal polymerisation, the quantity γ_n usually decreases monotonically with the degree of transformation (curve *1* in Fig.6). The appearance of heat production leads to a sharp decrease in the degree of polymerisation, since the activation energy of initiation is generally much greater than the effective activation energy of polymerisation. The change in γ_n may then be non-monotonic, and under low-temperature conditions, for example, the increase

in γ_n for the "live" polymer in the central phase of the process takes place as a result of cooling of the reacting mass (curve *2* in Fig.6).

The physical reason for the increase in the number-average chain length under high-temperature conditions is different. The rapid progressive increase in heating leads to the complete "burn-out" of the initiator, as a result of which the rate of initiation tends to zero, and $\bar{P}_n$ tends to infinity. Only macroradicals remain in the system, and very long polymer chains are formed (curve *3* in Fig.6).

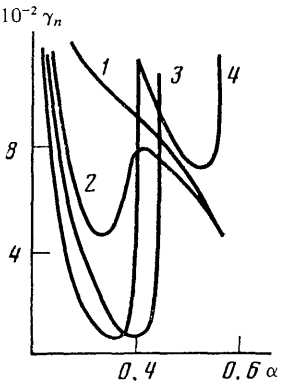

Figure 6. Dependence of the degree of polymerisation on the degree of transformation with heat removal under isothermal (*1*), low-temperature (*2*), and high-temperature (*3*) conditions and with thermal initiation (*4*).[24]

The qualitatively different changes in the degree of polymerisation during the reaction are responsible for the fundamentally different MMD under low-temperature and high-temperature conditions. Under the first conditions for degrees of conversion up to 0.5, the chain length is long and close to the initial quasi-stationary value, the distribution is narrow, and the heating increases the width of the MMD by not more than 5–20%. Under high-temperature conditions, the number-average molecular mass of the final polymer is much smaller (by factors of 3–10) than the quasi-stationary value, and the distribution is 2–3 times broader than the isothermal distribution (Fig.7). It should be emphasised that the narrow intermediate zone becomes broader only in the case of thermal "degeneration" of the process, that is for a small exothermicity of polymerisation or for a weak increase in the reaction rate with temperature.

Study of the detailed polymerisation kinetic scheme shows that allowance for chain transfer smooths out the differences in the polydisperse character between the quasi-isothermal and quasi-adiabatic conditions. With decrease in the degree of polymerisation under both sets of conditions, a marked decrease in the width of the distribution under high-temperature conditions is observed (curve *2* in Fig.7).

The existence of thermal initiation leads to separation of the process under high-temperature conditions into two quite distinct stages. At first, the initiator "burns-out" completely, and the heating of the system "includes" the thermal polymerisation mechanism. An interesting feature is that 100% conversion of the monomer is achieved only in the adiabatic case, and even with slight heat exchange, the consumption of the monomer leads to cooling of the reagents, and the reaction stops at $\alpha < 1$.

By itself, heat production in the reaction only broadens the MMD, but produces no qualitative changes in the nature of the distribution. A bimodal MMD may be produced, however, even in the simplest polymerisation kinetic scheme, if the heat exchange of the reactor is separated into two stages, and the temperature of the surrounding medium in the second stage is 30–40 K higher than that in the first.

In a continuous-acting ideal-mixing reactor, the constant supply of fresh reagents is responsible for a number of characteristic physical features of the processes[5], the most important of which is the possible existence of several stationary states of the reactor for the same values of the parameters. As in a periodic-action reactor, in this case also there are low-temperature and high-temperature conditions with corresponding types of MMD, determined by the kinetic scheme of the reaction.

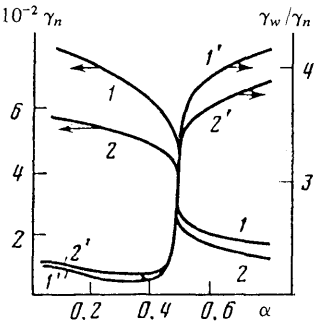

Figure 7. Influence of chain transfer on the degree of polymerisation (*1*, *2*) and the width of the MMD (*1'*, *2'*);[24] the curves were calculated without (*1*) and with (*2*) allowance for chain transfer.

4. Polymerisation During Propagation of the Thermal Wave

A classical example of the propagation of the front of an exothermic chemical reaction is provided by the burning of a flame in gaseous media. The comprehensive experimental and theoretical examination of this phenomenon is much in advance of the study of processes of this kind in condensed media. The analogy existing between the propagation of the front of exothermic reactions in gases and condensed media makes it possible to apply the results of classical theory to condensed systems.

The problem of the stationary velocity of the front of a chemical reaction was first examined in the theory of the combustion of gases by Zel'dovich and Frank-Kamenetskii[25–28]. The essential feature of this theory, namely the assumption that the coefficients of diffusion and temperature conductivity are equal, establishes a relationship between temperature and concentration, and makes it possible to reduce the system of two equations for diffusion and thermal conductivity to one equation, which unambiguously relates the rate of heat liberation to temperature. Because of the temperature dependence of the kinetic constants, the solution of the boundary problem requires additional assumptions, one of which is the assumption that the reaction zone is narrow and the chemical reaction takes place chiefly at temperatures close to those of the adiabatic

heating. In this case the boundary problem breaks down into two Cauchy problems: one in the range in which the reaction rate can be neglected, and the other in the range where the convective term in the thermal conductivity equation is neglected. The "joining" of the solutions for the two ranges makes it possible to obtain an analytical expression for the stationary velocity of the reaction front.

For the propagation of the front of a chemical reaction in a condensed medium, it is obviously impossible to assume that the coefficients of diffusion and thermal conductivity are equal, since they may differ by several orders of magnitude, and in most cases diffusion can be neglected.

The propagation of the front of an exothermic reaction in a condensed medium has been examined in a different formulation of the problem by a number of authors[29-37]. The conditions of existence and the unique character of the solution were studied, and various approximate methods for calculating the stationary velocity of the front were proposed. The method proposed in Ref.30 is based on the assumption that the reaction zone is narrow. It can be readily seen that for the general form of the dependence of the rate of heat liberation on the degree of transformation and temperature, the system of kinetic and thermal conductivity equations has a solution.

The approximation of a narrow reaction zone is based on the fact that, because of the high activation energy of the chemical reaction, most of the transformation takes place in a narrow range at temperatures close to the adiabatic heating of the reaction mixture. This makes it possible to replace the temperature by its maximum value in the equation for the temperature gradient in the reaction zone.

The approximation of a narrow reaction zone is not always applicable, however, even for high values of the activation energy of the chemical reaction. An important factor which restricts the applicability of this assumption in a number of cases is the nature of the dependence of the reaction rate on the degree of transformation. It has been shown[32,33], in particular, that for orders of reaction greater than unity, the assumption that the reaction zone is narrow is not correct. When there is retardation of the reaction, this approximation is unjustified even for high values of the activation energy.

An interesting characteristic feature of exothermic polymerisation reactions is the possible development of the process by a mechanism analogous to the propagation of a flame in a gas mixture. This was first pointed out in Ref.38. In subsequent studies[39-42] of the polymerisation of methyl methacrylate and triethylene glycol γ,ω-dimethacrylate under the influence of BP at a pressure of up to 5000 atm, propagation of the front of the polymerisation wave was established experimentally. Estimation of the velocity of the front showed that this phenomenon cannot be attributed to diffusion of active centres from the reaction zone into neighbouring layers with subsequent initiation of the reaction in these layers, since in this case the values of the velocity of the front should have been much lower than the experimental values. This gives grounds for assuming that the propagation of the polymerisation front in a cold mixture is thermal in character, that is it is similar to the normal propagation of a flame.

Special measurements[41] showed that there is no temperature gradient in the central part of the transverse cross-section of the reaction mixture. This means that under the conditions of the experiment, adiabatic propagation takes place, that is the front of the polymerisation wave is planar; the measured rate of displacement of the front is normal to this plane. The measured values of the rate of propagation of the thermal wave lie in the range 1–3 cm min^{-1}, depending on various parameters of the polymerisation mass. The structure of the front of the polymerisation wave, the influence of the concentration and nature of the initiator on the process of polymerisation propagation, and the role of pressure and the initial temperature have been studied[41,42]. It has been shown, in particular, that the stationary rate of propagation of the front of the polymerisation wave (u) increases with increase in the initial concentration of the initiator according to the law $u \sim I_0^{0.38}$.

Analysis of the thermodynamic characteristics shows that at atmospheric pressure, the boiling point of the monomer is reached for many monomers even at low degrees of transformation ($\leq$30%). Thus the propagation of the polymerisation reaction in this case must be accompanied by foaming of the polymerisation mixture[42]. Thus there exists a limiting pressure, below which stationary propagation of the polymerisation front is impossible.

When polymerisation is carried out under the conditions of propagation of the thermal wave with the reactor in a horizontal position and with mixtures having a low viscosity, convection is generally produced as a result of the existence of the heating zone. Convection cannot be eliminated even by using high pressures (up to 4000 atm). When the polymerisation reaction is carried out from above downwards in a column of liquid, convection is produced by the dropwise descent of the polymer formed. The experimental data show that in this case, for example with methyl methacrylate, breakdown of the front is not observed when a pressure above 1500 atm is used. Thus the prevention of convective breakdown of the front and boiling of the polymerisation mass is an important consequence of the use of high pressure in the propagation of the radical polymerisation reaction.

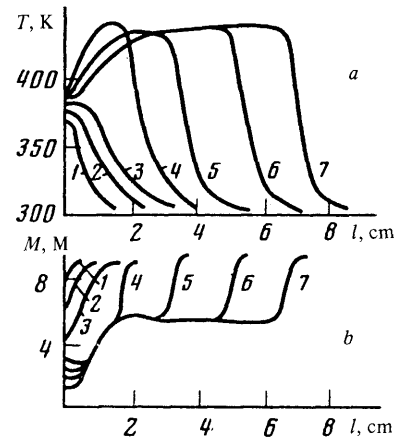

Figure 8. Profiles of the change in temperature (a) and the monomer concentration (b) along the direction of the reaction front after different times (s): *1*) 200, *2*) 800, *3*) 1600, *4*) 2400, *5*) 3000, *6*) 3600, *7*) 4200.[48]

The stationary propagation of the planar front of radical polymerisation with allowance for the specific characteristic features of the kinetics of the process has been studied theoretically by a number of authors[43-49]. The results of a numerical analysis[48], carried out without using the QSC method, show (Fig.8) that for material initiation in the presence or absence of the gel effect, the main mass of the

monomer reacts in a narrow temperature range at temperatures close to adiabatic heating. This result subsequently made it possible to use the approximation of a narrow reaction zone to find the stationary velocity of the front in analytical form.

The kinetic equations can obviously be simplified using the method of QSC with respect to the macroradicals. The study of this possibility for processes taking place under polymerisation wave propagation conditions[50,46] showed that with material initiation and assuming a narrow reaction zone, the conditions for quasi-stationary character have the form

$$\frac{k_t}{k_p} \gg 1; \quad \left(\frac{I_0 k_t}{k_i}\right)^{\frac{1}{2}} \gg 1$$

where the reaction rate constants are taken at the temperature of adiabatic heating.

The approximation of a narrow reaction zone made it possible to obtain analytical expressions for the stationary velocity of the polymerisation front with consumption of the initiator[46,47] and also for conditions under which its concencentration is constant[43]. In the first case, the analytical dependence of the limiting degree of transformation on the initial concentration of the initiator was obtained, and the width of the reaction zone estimated. The stationary rate of propagation of the polymerisation front is proportional to the initial concentration of the initiator to the power 0.4, which shows complete agreement with the experimental data. Comparison of the theoretical and experimental values of the stationary rate of propagation of the front and the limiting degree of transformation α_{lim} shows marked lack of agreement, however (Fig.9). Thus experiment showed practically complete consumption of the monomer, whereas the theoretically predicted degree of transformation is 0.6—0.7 (curve *1* in Fig.9*b*).

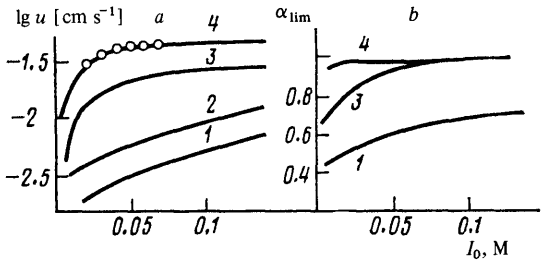

Figure 9. Dependence of the stationary velocity of the wave propagation front (u, cm s^{-1}) (*a*) and the limiting degree of conversion (*b*) on the initiator concentration; *1*) without allowance for pressure and the gel effect[44], *2*) with allowance for pressure, *3*) with allowance for the gel effect, *4*) with allowance for pressure and the gel effect[49]; points—experiment[41].

This lack of agreement between the experimental[39-42] and theoretical[43-46] results can be attributed to the existence of thermal polymerisation or the effect of high pressures and an extremely marked gel effect, not taken into account in the theory.

Allowance for polymerisation by thermal initiation should obviously lead to complete conversion. Published data[51] show, however, that the contribution of thermal polymerisation to the stationary velocity of the front is small (up to 3.5×10^{-3} cm s^{-1}). Thus a necessary step forward in the understanding of the nature of the discrepancy between theory and experiment was the study of the influence of pressure and the gel effect on the stationary velocity of the polymerisation front and the yield of polymer formed[49]. Fig.9*a* (curve *2*) shows that allowance for pressure leads to an increase in the magnitude of the stationary rate, but it still remains appreciably lower than the experimental value, and the limiting degree of transformation (curve *3* in Fig.9*b*) corresponds to complete consumption of the monomer only at values of I_0 equal to 0.1—0.15 M. The theoretical data show good agreement with experiment only when simultaneous account is taken of pressure and the gel effect (curves *4* in Fig.9*a* and 9*b*), and estimates for these conditions give a reaction zone width of 0.2 cm, which also shows good agreement with experiment.

As already noted, at high temperatures, thermal initiation may become the main source of radicals. At the same time, there have been practically no studies of its role in processes of radical polymerisation taking place under conditions of polymerisation wave front propagation, apart from a theoretical analysis of the influence of thermal initiation on the stationary rate of polymerisation, which shows that when there is no gel effect, for a reaction of first order with respect to the monomer, more acceptable values of the stationary rate are obtained in the approximation of a narrow reaction zone (curves *1* and *2* in Fig.10). When there is a gel effect, this approximation can also be used for higher orders of the reaction (curves *3* and *4* in Fig.10).

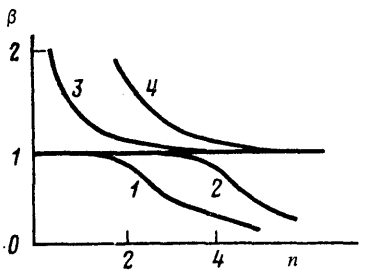

Figure 10. Ratio of the rates obtained from the results of analytical and numerical calculations of the rate of propagation of the front ($\beta = u_{anal}/u_{num}$) as a function of the kinetic order of the reaction (n);[51] the curves were calculated in the approximation of Ref.30 (*1*, *2*) and without it (*3*, *4*).

The kinetics of non-isothermal radical polymerisation in a periodic reactor without mixing have been studied theoretically and experimentally[52-54]. The results of numerical calculations and the analytical solution of the problem indicate that in these systems, for definite values of the parameters, values analogous to those for frontal polymerisation are observed. In fact, in the radical polymerisation of MTF-9 acrylate polyester, which has a high viscosity ensuring throughout the entire process heat transfer takes place by a purely conductive mechanism, the authors cited observed "layer" polymerisation conditions at atmospheric pressure[54].

There have been practically no experimental studies of the molecular masses and MMD in radical polymerisation under conditions of reaction front propagation. A theoretical analysis of the change in the molecular masses,

polydisperse character, and MMD of the resulting polymer has been carried out[47,51]. The calculations show that the average molecular masses decrease sharply behind the front of the thermal wave, but at the same time the decrease in the values of $\bar{P}_w$ and $\bar{P}_n$ is not the same, so that the polydisperse character of the resulting polymer at first increases because of the "burn-out" of the initiator (Fig.11*b*), but remains practically constant behind the wave front.

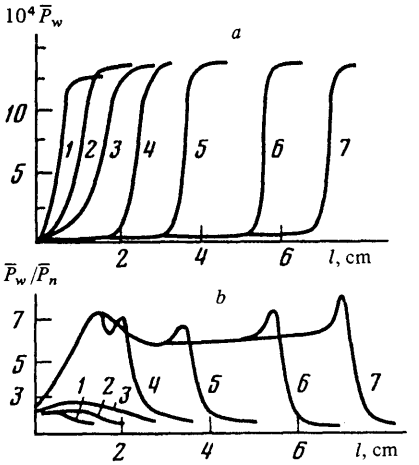

Figure 11. Change in $\bar{P}_w$ (*a*) and the width of the MMD (*b*) under front propagation conditions during the polymerisation of styrene[48]; $I_0 = 10^{-2}$ M, $T_0 = 300$ K, starting temperature 380 K; the numbering of the curves is the same as in Fig.8.

A broad MMD is a characteristic feature of polymerisation under reaction front propagation conditions. It should be remembered that for polymerisation under adiabatic conditions, the ratio $\bar{P}_w/\bar{P}_n$ for the final polymer is always appreciably greater than two, but for adiabatic polymerisation a narrow MMD may be preserved by stopping the polymerisation at the moment when the initiator "burns-out". This procedure is obviously impossible in principle for polymerisation under reaction front propagation conditions.

Chain transfer to the monomer or the solvent for frontal polymerisation leads to a decrease in the width of the MMD, and when this reaction is sufficiently intense, the MMD remains the most probable until the end of polymerisation.

5. Non-Isothermal Polymerisation in Tubular Reaction Vessels

The most important macrokinetic feature of polymerisation—the increase in the viscosity by several orders of magnitude—has a particularly marked influence on the course of the process in a tubular reactor. This influence is two-fold: firstly, there is appreciable distortion of the reagent flow rate profile, and secondly, there is a qualitative change in the integral characteristics of the process, primarily the pressure–flow rate characteristic, that is the dependence of the pressure drop (Δp) on the flow rate (q). The study of the process in the simplest one-dimensional version makes it possible to study the pressure drop–flow rate relationship, the longitudinal temperature profiles, and the influence of these parameters on the kinetics of polymerisation and the MMD of the products.

Polymerisation can take place under low-temperature or high-temperature conditions. In the absence of heat sources other than chemical sources, and when thermal conductance is negligible, increase in the consumption of the reagents leads to a proportionate displacement of all the points of the longitudinal profiles of temperature and concentration along the axis of the reactor. The temperature peak under high-temperature conditions ("hot spot"), with increase in the consumption, moves to the outlet from the reactor and may even leave the reactor[55]. There is then a unique relationship between the value of the flow rate of the reagents and the longitudinal temperature profile.

If the thermal conductivity in the axial direction is high (high thermal flux along the metal walls of the reactor), the relationship between the stationary states of the reactor and the flow rate become ambiguous. There exists a range of change in the flow rate within which one set of parameters corresponds to three different states of the reactor: low-temperature, high-temperature, and an intermediate unstable state. The arrival at specific reactor operating conditions depends on the initial conditions. In this case there is a complete analogy between the process of polymerisation in a tubular reactor and the process of combustion. With change in the consumption, flare-up or quenching of the process is observed, that is there is a change from low-temperature to high-temperature conditions and vice versa, and these changes show hysteresis. The range of non-unique solutions may consist of two separate regions of change in the flow rate, and there exists a range of values of the flow rate in which only high-temperature conditions are realised[56].

Heat liberation as a result of internal viscosity (dissipation of energy) may also lead to a non-linear change in the longitudinal temperature profiles. The mechanical source of heat increases in proportion to the square of the flow rate and to the viscosity of the liquid. Its contribution may naturally be particularly marked in polymerising systems. Studies have shown[57] that mechanical heat liberation plays the role of "trigger" for the change from low-temperature to high-temperature conditions, if the conditions of the process are close to the critical conditions for this change. Otherwise, the dissipation of mechanical energy has no qualitative influence on the operation of the reactor.

An important characteristic of a tubular reactor is the relationship $\Delta p(q)$, called the pressure–flow rate characteristic of the reactor. The form of this relationship is determined by the change in the distribution of the average (with respect to cross-section) viscosity along the length of the reactor with increase in the flow rate. The pressure–flow rate characteristic itself determines a number of regular features of the operation of the reactor, including qualitative features. For a polymerisation reactor, the $\Delta p(q)$ relationship is particularly complex. In the first place, the viscosity of the reacting mixture increases sharply during the reaction, and also changes with change in temperature. In the second place, as noted above, with change in the flow rate, non-linear changes take place in the longitudinal temperature profiles, and hence in the degree of transformation of the monomer. The viscosity undoubtedly depends on the molecular mass of the resulting polymer, but essentially no analysis of the effect of this factor has been published.

These characteristic features define the form of the $\Delta p(q)$ relationship. The marked increase in the viscosity is the reason for the basically non-monotonic character of this relationship. For very low values of the flow rate, the whole reactor is filled with very viscous polymerisation

products. Increase in the flow rate leads to the removal of products and to filling of a part of the reactor with less viscous reagents. The average viscosity in the reactor decreases rapidly, and the pressure drop $\Delta p \sim q \int_0^{\alpha} \mu(x)dx$ decreases. As a result, the $\Delta p(q)$ relationship at very low flow rates shows a clearly defined maximum[58], which is more marked, the greater the increase in the viscosity during the polymerisation. The flow rates corresponding to the maximum pressure drop also correspond to the almost complete transformation of the monomer at the outlet from the reactor ($\alpha \sim 0.95$).

A non-monotonic $\Delta p(q)$ relationship is also observed for the non-isothermal flow of an inert liquid, whose viscosity decreases rapidly with temperature. The decrease in the pressure drop with increase in the flow rate may take place as a result of the displacement of colder liquid, which has been able to cool during flow, by hotter and consequently less viscous liquid[59], or as a result of an increase in the dissipative heating[60]. Both of these effects, however, take place at extremely high values of the flow rate, much greater than those which can be realised in technological polymerisation processes.

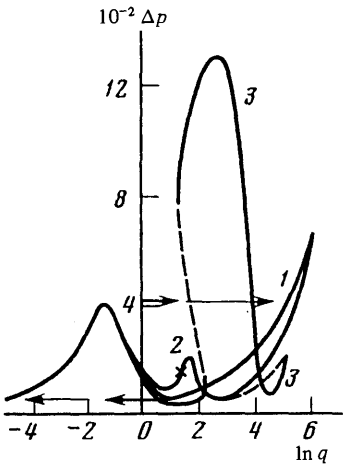

Figure 12. Pressure–flow rate characteristics of a tubular polymerisation reaction[60]: *1*) low-temperature conditions (the arrows indicate the hysteresis changes with change in the pressure drop); *2*) change from a dissipative source for the process to high-temperature conditions (the asterisk marks the point of change); *3*) high axial thermal conductivity (the broken lines are the branches of the curve for the unstable intermediate solution).

The above-mentioned change from low-temperature to high-temperature conditions for the process as a result of a mechanical source of heat may take place at comparatively low values of the flow rate. The form of the pressure–flow rate curve changes qualitatively, and new extremal points appear on it (curve *2* in Fig.12), since a complete rearrangement of the temperature and concentration profiles takes place. There is a sharp increase in both the heat production and the degree of transformation, so that there is competition between the temperature and concentration dependence of the viscosity, and either the former (in the case of solutions) or the latter (for bulk polymerisation) may predominate. The specific form of the $\Delta p(q)$ relationship may be extremely complex.

The situation is even more complicated when a decisive role is played by axial thermal conductivity. In addition to the maximum under low-temperature conditions (low values of the consumption), the pressure–flow rate characteristic shows a much larger peak under high-temperature "combustion" conditions, determined by the movement of the "front" along the reactor (curve *3* in Fig.12). In addition, branches of the $\Delta p(q)$ curve corresponding to stationary unstable states of the reactor exist.

In the experimental realisation of the process, it is possible to keep the flow rate or the pressure drop constant. In either case, several different stationary reactor operating conditions are possible, corresponding to the same value of the fixed parameter. With change in the parameter (for example the pressure drop in Fig.12), abrupt changes from one branch of the solution to another are possible. The points of the changes do not coincide, that is hysteresis is observed, and for Δp = const it is not thermal (as in combustion processes) but purely hydrodynamic.

The study of the flow rate profiles is possible only for a two-dimensional arrangement. The process has been studied for low-temperature conditions (or for the isothermal case).[61–63] As a result of the adhesion of the liquid to the walls of the reactor for an initial parabolic flow rate profile, the layers of liquid next to the wall are in the reactor for an extremely long time. The reaction in these layers takes place to a high degree of transformation, that is very viscous polymerisation products are formed, and the rate of flow at the wall decreases. Since the consumption is constant, there is a corresponding increase in the flow rate in the axial zone. The residence time of the reagents close to the axis decreases, so that there is a decrease in the degree of transformation of the monomer and the viscosity of the liquid, leading to an even greater increase in the rate of flow in the axial zone, etc.

This leads to the production of two quite distinct flow zones: a layer of very viscous slow-moving reaction products next to the wall, and a stream of reagents with low viscosity in the axial zone of the reactor, penetrating through the products (Fig.13). The ratio of these two zones depends on the flow rate, that is on the rate of supply of the reagents. To obtain uniform products at the outlet, it is necessary to have flow rates which are sufficiently low, so that the stream of unreacted liquid does not move out of the reactor. As a result of the "extension" of the flow rate profiles (Fig.13), the flow rate at the axis may be several tens of times greater than the average rate. As a result, there is a decrease in the flow rate (or an increase in the length of the reactor) necessary for complete polymerisation, compared with that calculated from the average residence time.

A study of the influence of the deformation of the flow rate profile on the MMD for "live" polymerisation[64] showed that the existence of two flow zones (essentially two fractions with markedly different molecular weights) may lead to the formation of a bimodal MMD at the outlet from the reactor.

An analysis of high-temperature polymerisation conditions in a tubular reactor with allowance for the distribution with respect to the cross-section of the velocity, temperature, and concentrations indicates that these conditions are unstable[65–67]. Within a definite range of change in the flow rates in the reactor, a polymerisation front is formed.

There exists a front stabilisation stage in which the rate of supply of the reagents is equal to the rate of "combustion". In the experiment, the duration of the stabilisation stage reached several tens of minutes. In this time interval, accumulation of viscous reaction products takes place ahead of the front, primarily with an increase in their viscosity, leading to an increase in the rate of flow in the axial zone. The rate of supply of the reagents becomes greater than the rate of "combustion", the front is deformed, and its central part is displaced towards the outlet from the reactor. The flow rate in the axial zone increases, with an increase in the rate of supply of the colder products to the less hot (as a result of curvature) front. The front cools and leaves the reactor.

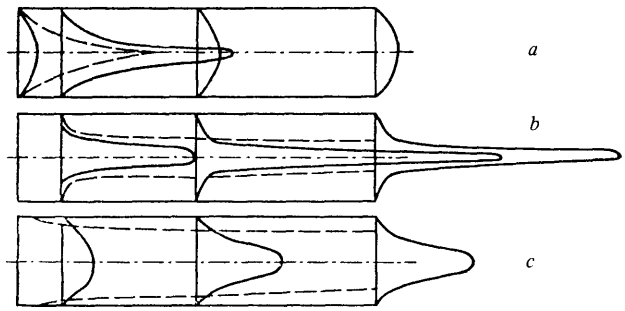

Figure 13. Profiles of the axial rates of flow in a tubular polymerisation reactor for different values of the flow rate: *a*) $q = 1$, *b*) $q = 10$, *c*) $q = 50$;[63] the broken line indicates the boundary of the layer of viscous products.

III. VARIOUS OTHER POLYMERISATION PROCESSES UNDER NON-ISOTHERMAL CONDITIONS

Many chemical reactions, although having smaller thermal effects and activation energies, are capable of taking place with spontaneous thermal acceleration under certain conditions. These reactions include various processes of ionic polymerisation, polycondensation, and vulcanisation (cross-linking).

Fairly reliable data on non-isothermal kinetics have been published for the anionic activated polymerisation of lactams and the polycondensation of epoxide compounds under the influence of amines, and these are examined in the present section. The non-isothermal kinetics of these processes make it possible to separate the common and distinctive features for various types of reaction taking place under non-isothermal conditions.

1. Anionic Activated Polymerisation of ε-Caprolactam

The anionic activated polymerisation of lactams (AAPL) opens up extensive possibilities for preparing constructional materials by "chemical" forming, that is directly from the monomers. The simplicity of the "monomer–article" technological scheme realised in the case of AAPL, however, hides major problems. These difficulties are related on the one hand to the complexity of the process itself and on the other hand to the spontaneous heat production in the reaction mixture. In spite of the fact that the exothermicity of the polymerisation of ε-caprolactam, for example, is only 3.2 kcal mole^{-1}, the adiabatic heating of the monomer–polymer mixtures may reach 70–90 K. In addition, the polymerisation of the lactam is accompanied by the simultaneous crystallisation of the resulting polyamide with a heat release of 6 kcal mole^{-1}, which also contributes to the increase in temperature. The spontaneous heating in AAPL is due not to high thermal effects of the chemical and physical processes taking place but to the high rate of the chemical reaction and the low values of the coefficients of thermal conductivity of the polymerising mixture.

The non-isothermal AAP of ε-caprolactam has been reported by a number of authors[68–73], who established that under adiabatic AAPL conditions for an initial polymerisation temperature of 150 °C and above, the polymerisation and crystallisation take place separately, whereas below 150 °C a combined process is observed. To exclude the influence of crystallisation on the kinetics of polymerisation, the process was studied either in the initial stages[74] or at temperatures above 150 °C.[75]

The development of experimental methods for separating information on the separate processes of polymerisation and crystallisation from the overall kinetics of the increase in temperature is obviously of interest.

A number of almost simultaneous papers[73,76,77] pointed out this new direction in the study of the kinetics of the AAP of lactams, chiefly ε-caprolactam. These papers described methods for the separate study of the kinetics of polymerisation and crystallisation taking place in parallel. Of these methods, the simplest and most reliable is the method[73] based only on experimental data. The results of this work can be examined briefly.

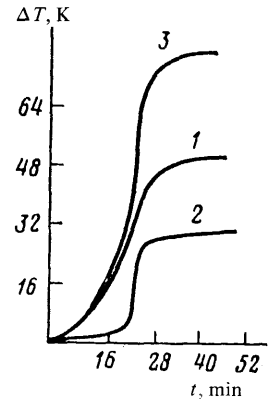

Figure 14. Kinetics of the change in temperature in the activated anionic polymerisation of ε-caprolactam;[73] *1*) polymerisation, *2*) crystallisation of the polymer, *3*) overall curve.

Independent experiments carried out at initial temperatures of 150 °C and 125 °C show that the actual temperature (T) of a reaction satisfies the respective equations:

$$T - T_0 = M_0 \frac{\Delta H_p}{c\rho} \alpha$$

$$\frac{T - T_0}{\alpha} = M_0 \frac{\Delta H_p}{c\rho} + \frac{\Delta H_{cr}}{c\rho} \eta$$

Here, M_0 is the initial concentration of the monomer, α and η are the extents of the polymerisation and crystallisation, ΔH_p and ΔH_{cr} the heats of polymerisation and crystallisation, c the heat capacity, and ρ the density.

Gravimetric determination of the yield of polymer during the polymerisation and use of the known value $M_0\Delta H_p/c\rho = 52$ made it possible to separate from the overall kinetic curve (curve *1* in Fig.14) the increase in temperature due only to polymerisation (curve *2* in Fig.14), and from the difference between curves *1* and *2* the change in temperature as a result of crystallisation (curve *3*). The limiting heating due to crystallisation obtained in this way agrees with the degree of crystallinity determined experimentally from the density[78].

A series of kinetic curves for polymerisation and crystallisation during the AAP of ε-caprolactam, obtained by this method, is given in Figs.15*a* and 15*b*.[79]

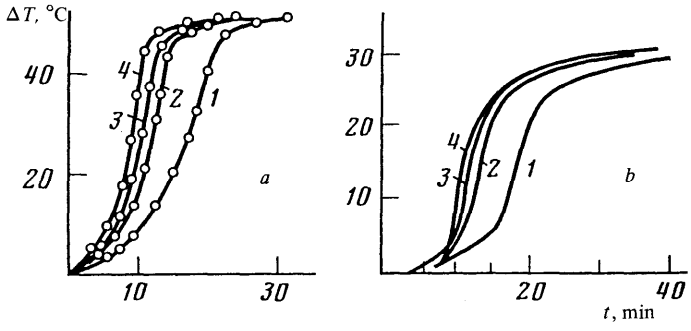

Figure 15. Kinetic curves for the polymerisation of ε-caprolactam (*a*) and the crystallisation of the polyamide (*b*) at different activator concentrations, M: *1*) 3.35×10^{-2}; *2*) 4.78×10^{-2}; *3*) 5.74×10^{-2}; *4*) 6.70×10^{-2}; $T = 125$ °C, concentration 3.35×10^{-2} M.[79]

The kinetic curves for the crystallisation of the resulting polyamide show three regions of increase in temperature: a slow increase, a range corresponding to a high rate of change in temperature, and the stage corresponding to the slow completion of the crystallisation process. The existence of three regions on the crystallisation kinetic curves, confirmed by the form of the dependence of η on α, is due to the sequence of stages involving nucleation, crystal growth, and secondary crystallisation, as confirmed by microscope studies of the morphology of the resulting polymers[80,81].

The methods developed for separating the kinetics of polymerisation and crystallisation make it possible not only to carry out a qualitative analysis of the kinetics of polymerisation and crystallisation but also to obtain a quantitative description of the kinetics of these complex processes[78,82-85].

Adiabatic thermometry is also of interest in the study of composition in combined polymerisation. The method is more valuable for copolymers having restricted solubility. A thermometric method has been proposed[86] for determining the composition of copolymers for the case of the anionic activated copolymerisation of ε-caprolactam with ω-dodecalactam.

Using published data[87] and assuming that in the adiabatic copolymerisation of ε-caprolactam with ω-dodecalactam the product $c\rho$ remains constant (the increase in the heat capacity is compensated by the decrease in the density), the authors cited obtained the equation

$$\Delta T_{cop} = \Delta T_{cl} N_1 + \Delta T_{dl} N_2 \qquad (4)$$

where ΔT_{cop} is the total increase in temperature due to adiabatic copolymerisation, ΔT_{cl} and ΔT_{dl} the adiabatic heating due to the polymerisation of caprolactam and dodecalactam, and N_1 and N_2 the mole fractions of the monomers in the copolymer.

By taking account of the fact that the values of the adiabatic heating for ε-caprolactam and ω-dodecalactam are 52 K and 20 K respectively and measuring the degree of transformation, it is possible, from the kinetic curves for the increase in temperature and a modification of Eqn.(4), to determine the composition of the copolymers formed for different initial ratios of the monomers.

Fig.16 gives the change in the composition of the copolymer during the reaction, together with data on the composition, obtained by ^{1}H NMR and elemental analysis. The good agreement of the values obtained indicates that the approach developed for the determination of the composition of the copolymers from adiabatic thermometric data is correct.

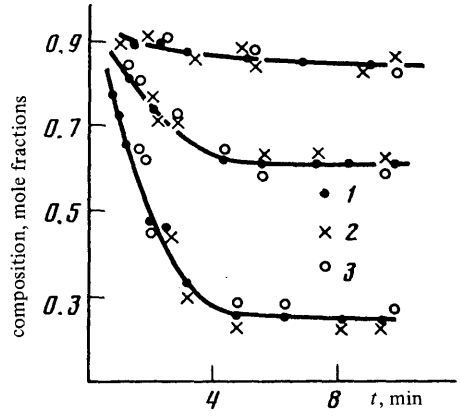

Figure 16. Kinetics of the change in the composition of the copolymer during the adiabatic copolymerisation of ε-caprolactam and ω-dodecalactam from data obtained by thermometry (*1*), ^{1}H NMR (*2*), and elemental analysis (*3*).[86]

There are no published experimental data on AAPL under the conditions of the propagation of a polymerisation wave. Studies of this kind may be of practical interest, in relation to the development of new methods for obtaining thick-walled monolithic articles based on polyamides.

A number of theoretical studies[88,89] showed the existence of a single thermal wave for combined processes of polymerisation and crystallisation. These results make it possible to formulate the conditions for carrying out frontal polymerisation experimentally for AAPL processes.

2. The Polycondensation of Epoxide Oligomers With Amines

The kinetics of the hardening of epoxide oligomers with different molecular masses under the influence of *m*-phenylenediamine (*m*PDA) under adiabatic conditions have been studied[90,91]. For the same initial reaction conditions,

increase in the molecular mass of the original oligomer leads to an increase in the rate of hardening. The authors cited attribute this to the catalytic effect of the hydroxyl groups, whose concentration increases with increase in the molecular mass of the oligomer. A quantitative description of the kinetic data was proposed.

Subsequently, on the basis of this approach, it was shown possible to harden epoxide oligomers under conditions of reaction front propagation[92].

Characteristic profiles of the change in temperature with time in the reactions of the epoxide oligomer ED-20 with *m*PDA and of ED-20 with polyethylenepolyamine are given in Figs. 17*a* and 17*b* respectively. After the thermal wave reaches stationary conditions, both the current reaction rate and the limiting temperature are the same in different layers. This means that the same quantity of epoxide groups reacts in each layer.

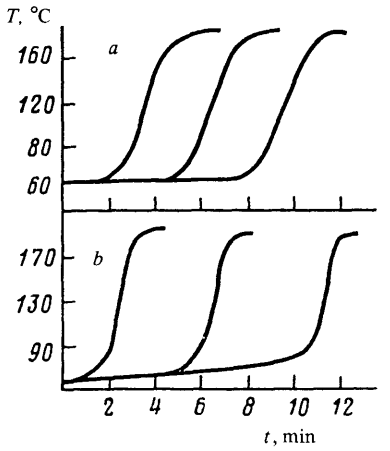

Figure 17. Temperature–time profiles for the hardening of epoxide resins in the presence of amines under thermal wave conditions[92]; temperature 60 °C (*a*) and 30 °C (*b*).

Special measurements showed that the temperatures at the surface of the thermal wave are the same, that is adiabatic propagation of the reaction front takes place in the experiment. Studies of the influence of the initial concentrations of the amine (A_0) and the epoxide groups (E_0) on the stationary rate of propagation of the wave show that $u \sim A_0^{0.63} E_0^{0.73}$. Increase in the initial temperature of the reaction mixture leads to an increase in both the maximum rate and the stationary rate, but since the maximum reaction rate increases more rapidly than the stationary rate, degeneration of the hardening front was observed at temperatures greater than 40 °C for PEPA and 80 °C for *m*PDA. This degeneration of the thermal wave, that is the change from frontal hardening conditions into volume hardening conditions is generally due to low values of the activation energy of the reactions taking place (8–10 kcal mole^{-1}).

The dynamics of the hardening of epoxide compounds by amines under conditions of thermal wave propagation have been studied by numerical methods[93].

Analysis of the solutions obtained shows that there are two reaction front propagation zones. The first corresponds to non-established conditions, and the second to established conditions, that is to stationary propagation of the hardening front.

An important conclusion from the comparison of the temperature and conversion profiles is that under stationary conditions the temperature profile is considerably in advance of the conversion profile. This means that the main mass of the product under conditions of stationary propagation of the thermal wave is formed in a narrow temperature range close to the adiabatic heating of the reaction mass. The influence of the initial concentrations of epoxide groups (E_0) and amine (A_0) and the kinetic and thermophysical parameters on the rate of propagation of the wave has also been analysed. The observed relationship, $u \sim A_0^{0.65} E_0^{0.8}$ is confirmed experimentally[92].

The approximation of a narrow reaction zone has been used[94] to find an analytical expression for the stationary velocity of the hardening front, and this again shows good agreement with experimental data.

* *
*

The material examined in the present review on polymerisation processes of different type taking place under non-isothermal conditions shows that the interpretation is complicated by the need to take account of the thermophysical characteristics of the system, the temperature dependence of the parameters, and a number of other factors.

The development of the theory of processes of this kind is making it possible, however, to use these complications to achieve a marked increase in the amount of kinetic information extracted from the kinetics of the process being studied.

A most important aspect of the study of non-isothermal kinetics is the rational allowance for the dynamics and distribution of the heat of reaction; this is necessary when planning polymerisation processes in large systems, for example in the chemical forming of large models. The approaches described in the present review provide a basis for developing new energetically rational processes, and also for intensifying existing technological processes.

The Formation, Structure, and Properties of Epoxide Matrices for High-strength Composites

B.A.Rozenberg and E.F.Oleinik

The results of studies of the kinetics and thermodynamics of the formation, and the structure and properties, of epoxide cross-linked polymers, carried out in the last 7-8 years in the Institute of Chemical Physics of the Academy of Sciences of the USSR, have been reviewed. The molecular, topological, and supermolecular structures of epoxide polymers have been examined, and the relationship between the properties shown by these polymers in the vitreous and rubber-like states and their structure has been analysed. The progress made in the directed modification of the physicomechanical properties of epoxide binding agents have been discussed. The characteristic features of the structure and properties of epoxide polymers formed at the boundary with a solid surface have been examined.
The bibliography contains 136 references.

V. Characteristic features of the structure and properties of epoxide polymers at the boundary with a solid surface 169

I. INTRODUCTION

A central problem in the design and production of articles of composite materials is the need to choose a polymer matrix ensuring the maximum realisation of the possibilities provided by the high-strength reinforcing fibres. This problem has many facets; one of its most important aspects is the relationship between the structure of a polymer matrix and its properties on the one hand, and the relationship between the conditions of synthesis and the structure on the other.

The present review examines the principal results of work carried out under the general direction of N.S.Enikolopov and directed towards the solution of the above problems. Densely cross-linked epoxide polymers, whose applied and technological properties at present make them the most promising binding agents for high strength composites, were examined in these studies. Individual aspects of these studies have already been summarised in a monograph[1] and a number of reviews[2-15].

The structure of polymers is usually classified as molecular and supermolecular. In the analysis of the structure of cross-linked polymers, in contrast to linear polymers, it is necessary to introduce another level of structural organisation of polymers, which has been called the topological; it characterises the degree of connectedness of the elements of the polymeric system. The terms linear, branched, ladder, or cross-linked polymer characterise the topological level of its organisation, a quantitative measure of which is provided by the distribution function of the corresponding element of the structure of the polymer system: branching between the chains, rings, etc.

The different levels of structural organisation of a polymer determine its various properties. There is in principle no unique simple relationship between all the levels of structural organisation, but a change in structure at any of the levels considered may have a significant influence on the properties of a polymer.

For an understanding of the various physicomechanical properties of a polymer it is first necessary to have a detailed and adequate description of each of its levels of structural organisation, and the practical problems of present-day materials science require a quantitative description. Progress in theory makes possible in most cases a quantitative description of the molecular and topological levels of structural organisation, but unfortunately this usually cannot be done at the supermolecular level.

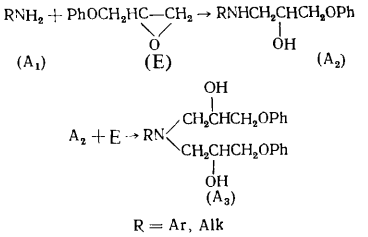
The possibility of a quantitative description of the molecular and topological structure of a polymer, however, does not eliminate serious difficulties, related primarily to the fact that the relationship between the micro-characteristics, which adequately describe the molecular structure and topology of the polymer, and the macroscopic properties of the material in many cases is unknown. This is characteristic chiefly of polymer matrices in the vitreous state, which is the main working state of the polymer in a composite. Thus the search for the regular features establishing this relationship is one of the most important directions in present-day studies in the field of polymers and composites based on them.

II. STRUCTURAL ORGANISATION OF EPOXIDE NETWORKS

1. Molecular Structure

It is first of all necessary to find the characteristics of the molecular structure of the original epoxide oligomers, which are usually synthesised by condensing epichlorohydrin and compounds containing a mobile hydrogen atom—phenols, alcohols, acids, amines, amides, etc.

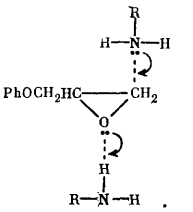
The most widely encountered are epoxide oligomers based on diphenylolpropane, the output of which makes up more than 90% of the total production of epoxide resins. It is for this compound and corresponding model compounds that the most important regular kinetic features of the formation of epoxide oligomers have been studied, and the mechanism of the process established.



Epoxide oligomers are usually obtained by the reaction of epichlorohydrin with phenol; the epoxide ring of epichlorohydrin reacts with the phenolic hydroxyl group[16-18]. The reaction takes place by an ionic mechanism and is catalysed by bases. As a result of this reaction there is an increase in the molecular mass of the oligomer, and an excess of epichlorohydrin in the reaction system ensures the production of final oligomers which are bifunctional with respect to the epoxide groups. The main reaction, however, is always

accompanied by side reactions, involving mainly the consumption of epoxide groups in solvolysis and addition to internal secondary hydroxyl groups of the oligomers[19], leading to a change in the functionality and molecular structure of the final oligomer. The products sought are formed mainly in the first stage of the synthesis[20,21], whereas in the later stages an increasing contribution is made by side reactions[22,23].

Studies carried out have established the molecular structure of epoxide oligomers, produced kinetic models of the processes involved in their synthesis, which describe the process quantitatively[24–27], and developed new methods for carrying out the synthesis, which make it possible to increase the proportion of the main reactions in the production of the structure and functionality of the oligomers and to decrease the rate of side reactions[28–31]. The establishment of the relationship between the molecular structure and the molecular-mass distribution (MMD) of the resulting oligomers and the conditions of the process has made it possible to control the process to obtain epoxide oligomers with a given molecular structure and given properties[32]. The method of carrying out the process developed by N.S.Enikolopov and co-workers has formed the basis of an industrial method for the synthesis of diane epoxide oligomers by a continuous technological scheme.



An extensive cycle of studies has also been carried out to establish the molecular structure of cross-linked epoxide polymers, obtained by hardening thoroughly purified and characterised epoxide oligomers and individual bifunctional monomers. In the course of these studies it has been possible not only to solve the principal problem being tackled, namely the production of binding agents with the required set of properties[1–12,33–36], but also to determine the principal regular kinetic features of the processes involved in the hardening of epoxide oligomers by various hardening agents[37–62], to establish a number of previously unknown details of the mechanism of these processes[7–12,36,39,41,44–52], to obtain a quantitative description of these processes and to determine the values of the thermodynamic and kinetic parameters[8,12,14,63–68], to establish the relationship between the reactivity and the chemical character of the reagents[50,69–71], to develop the principles of the rational choice of a hardening system and to control the molecular structure of the resulting three-dimensional network, and to establish scientifically based principles for selecting the hardening conditions to ensure intensification of the process and the production of materials with required properties[8,14,63].

In this cycle of studies, particular attention has been paid to the investigation of the kinetics and mechanism of the processes involving in the hardening of epoxide oligomers under the influence of amines, which are widely used in practice as hardening agents. The main reactions† taking place in this process can be represented by the following scheme:

† For simplicity, the reactions for the monofunctional compounds are given.

Before these studies, the mechanism of the opening of the epoxide ring under the influence of nucleophilic reagents was disrupted; it was not clear whether this reaction took place directly, or whether electrophilic cooperation was necessary. The studies[7,8,10,12,39] showed that the opening of the epoxide ring under the influence of nucleophilic reagents requires electrophilic cooperation, that is preliminary activation of the epoxide as a result of its reaction with some nucleophilic reagents. The idea of the need for activation is the key to the understanding of the regular kinetic features of the reaction of epoxide compounds with various nucleophilic compounds, including amines. This viewpoint makes it possible to understand the observed possibility of the non-catalytic reaction of epoxide compounds with primary or secondary amines and the second order of the reaction with respect to the amine[10,23,36]. In this case, one amine molecule acts as the nucleophile reagent, and the other as the proton donor. The transition state can be represented as follows:

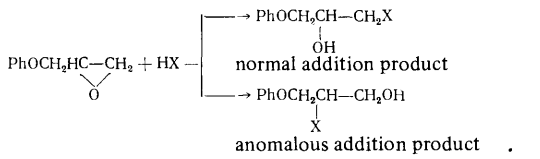
A second important conclusion about the mechanism of the reactions studied is that the components of the reacting system, that is the starting materials and reaction products, are combined in hetero- and homo-complexes, characterised by different reactivities. The formation of these complexes may be both intermolecular and intramolecular; their existence has been reliably proved, and the thermodynamic parameters of complex formation determined[7,8,10,12,41,52,53,64,68].

It is only on the basis of ideas about complex formation in these systems that it is possible to understand such characteristic features of the kinetics of the reactions of epoxy-compounds with primary and secondary amines as the extremely unusual simultaneous reactions of self-acceleration and self-inhibition, the catalytic and inhibiting action of various solvents, the clearly defined *ortho*-effect of a number of substituents in aromatic amines, etc.[7–12,37,44,45,52,54].

The mechanism of the processes involved in the hardening of epoxide oligomers under the influence of amines is extremely complex; to a first approximation it can be described by a kinetic scheme which takes account of all the electron-acceptor interactions of the original reagents and the reaction products with one another. The kinetics of the processes of the hardening of epoxide oligomers under the influence of aromatic amines (at moderately high temperatures $t < 150$ °C) and the molecular structure of the resulting polymer are described almost completely by this scheme. At higher temperatures, condensation of the hydroxyl groups formed with unreacted epoxide groups and with one another also takes place, leading to the formation of additional cross-linking sites[59].

When primary or secondary aliphatic amines or aromatic amines with a nitrogen-containing heterocyclic ring are used as hardening agents, the polycondensation reactions are accompanied by anionic polymerisation of the epoxide oligomers under the influence of tertiary amines[10,12,36,46–49]. This gives a polymer which has the chemical structure of a simple polyether and which contains as terminal groups

double bonds of the vinylidene type, hydroxyl and alkyl groups, or a tertiary amino-group. These terminal groups are obtained by the decomposition of the active growing centre—the quaternary ammonium alkoxide—in several directions and subsequent secondary initiation[12,46-48].



If the tertiary amine used is a nitrogen-containing heterocyclic compound such as pyridine and its derivatives, a new reaction takes place, leading to opening of the pyridine ring[46-48]. In this case the resulting polyene structure becomes a fragment of the polyether chain. The molecular structure of the polymer obtained is very complex; nevertheless, it can be reliably predicted if the detailed reaction mechanism is studied and the kinetic characteristics of the elementary stages of the process determined.

Analogous investigations directed towards the study of the kinetics and mechanism of the reactions and in the final analysis the establishment of the molecular structure of the resulting epoxide polymers are now being carried out with other hardening agents—phenols, alcohols, carboxylic acids, acid anhydrides, etc.[16-29,33,56,57]

The first results obtained in these studies confirmed the basic ideas about the important role of complex formation and the need for electrophilic cooperation in the reactions of nucleophilic addition of reagents to an epoxide ring. In contrast to amines, however, in a number of cases the reaction can also take place by an ionic mechanism.

A characteristic kinetic feature of the condensation of phenols and carboxylic acids with epoxides is that the product of the addition of a second molecule of the epoxide compound to the hydroxyether can be formed not only in succession, but also in parallel, by the direct reaction of two molecules of the epoxide–phenol (or carboxylic acid) complex[56,57].

Finally, new data on the determination of the direction of the opening of the epoxide ring are of considerable interest. A detailed study carried out by different NMR methods[33,36] showed that, contrary to the widespread view that normal addition takes place preferentially in nucleophilic attack at the epoxide ring, an appreciable proportion (up to 50%) corresponds to the anomalous addition of the nucleophilic residue X:

A number of studies have been devoted to the determination of the stability of epoxide polymers to the action of high temperatures and atmospheric oxygen. A detailed study of the thermal[72] and thermo-oxidative[73] degradation of cross-linked polymers based on the diglycidyl esters of diphenols with aromatic and aliphatic amines has been carried out by field mass spectrometry. Analysis of the products of the thermal and thermo-oxidative degradation of low-molecular-weight compounds[74] modelling the structure of the polymers studied showed that the weakest are the bonds $C^{\beta}-C^{\alpha}N$ in the hydroxypropylene bridge HC–CN in the aliphatic amine and $C-C_6H_4$ in the diphenylolpropane part of the chain, and the entire degradation process is described by a radical-chain mechanism. The process is initiated by the oxidation of the aliphatic parts of the polymer by atmospheric oxygen and the subsequent decomposition of the hydroperoxides formed. Chain transfer to heteroaliphatic parts of the polymer gives aminyl, alkyl, and aroxyl macro-radicals, whose decomposition gives derivatives of phenols, acetaldehyde, acetone, formaldehyde, and $H_2C{=}NCH_3$.[75]

With longer exposure to oxygen there is a decrease in the temperature of the appearance of those degradation products which are identical to the products of the thermal decomposition of the polymers in a vacuum. The thermo-oxidative degradation gives a large quantity of heavy products with masses 1.5–2.5 times the mass of the original model compound. The oxidation of secondary NH groups, which have not reacted with the epoxide, in the derivatives of aromatic amines gives stable aminyl and nitroxyl radicals, which inhibit the degradation, and in the derivatives of aliphatic amines gives the aminyl radical $\sim CH_2CH_2\dot{N}CH_2CH_2(OH)\sim$, which is actively involved in chain transfer. The dehydration process is the highest-temperature process both under conditions of the action of oxygen and in the subsequent degradation of the polymer in a vacuum.

2. Topological Structure

Analytical methods for describing the topological structure of cross-linked polymers suffer from the significant disadvantage that they do not make it possible to take account of the existence in the networks of rings of different size and complexity[1]. It is this feature, however, that determines the topological structure of the polymer network. Ring formation has a significant influence on the proportion of elastically active chains, which determine the mechanical behaviour of the polymer networks above the vitrification temperature. Allowance for this feature in different versions of the kinetic theory of high elasticity is usually made by introducing an empirical parameter—the front factor[1]. These difficulties have been successfully overcome by the development of a statistical topological model of the structure of cross-linked polymers, which has made it possible to establish a quantitative relationship between the chemical structure of the starting materials, the mechanism and conditions of the process of network formation, and the topological structure and various mechanical properties of networks in the highly elastic state[1,6-8,60,61,76-80].

The model of the structure of a densely cross-linked polymer was based on the view of a network as a set of randomly connected rings with a certain size distribution. The ring, that is a minimal closed contour in the network structure, was taken as the elementary structural unit. This approach made it possible to make specific the problem of describing the topology of the network structure and to reduce it to the determination of the distribution of the rings with respect to size. The process of formation of the network structure by the condensation of bifunctional molecules of diepoxide and tetrafunctional molecules of diamine was modelled on a computer by the Monte Carlo method. The scheme for the model process took account of intramolecular cross-linking (ring formation) both in the pre-gel region and in the later stages of the reaction, beyond the point of gel formation. The algorithm of the calculation made it possible to examine the influence on the kinetics of formation and topology of the network of such factors as monocyclisation, different ratios of the original reagents, differences in the reactivities of the functional groups of the reagents, and the change in reactivity during the reaction. Experimental analysis of the gel and sol fractions of the hardened systems confirmed the adequacy of the model of a real network system[78].

Berling and Oshmyan[81] were the first to describe the regular kinetic features of network formation; in particular, they predicted and detected a decrease in the reaction rate constant in the kinetic range in the later stages of the hardening reaction as a result of the high topological complexity of the system. The increase in the topological complexity of the system during the process leads finally to a non-trivial

physical effect. In stoichiometric mixtures, the reaction in principle does not go to completion, in spite of the presence in the system of a sufficient number of functional groups, capable of reacting. This limit of the reaction (yield < 100%), called the topological limit[77], appears because the reactive groups, which during the process have entered different topological formations in the network, cannot meet and react with one another even in the complete absence of diffusion restrictions.

The statistical model developed made it possible to carry out a quantitative analysis of the equilibrium elasticity of a network polymer in the rubber-like state. Because of the small dimensions of the chains between the nodes in the systems studied, this analysis could not be carried out within the framework of the traditional concepts of the kinetic theory of high elasticity. In the rubber-like state, the equilibrium elasticity of the network is determined by the elasticity of the chain between the nodes and by the topology of the network polymer. It has been shown[79] that by applying a mechanical stress to the boundaries of a model polycyclic network it is possible, by a numerical method on a computer without the use of any empirical parameters, to find the distribution function of the stresses in the chains between the nodes and the equilibrium modulus of elasticity of the network with allowance for the details of its molecular structure. Experimental verification of the theory showed excellent quantitative agreement between the results of the calculation and the experimental data, that is the proposed model provides an adequate description of the structure and equilibrium elastic properties of the networks. The observed agreement in the values of the modulus of elasticity indicates that all the non-uniformity of a real network lies within the limits of the statistical scatter. Spatial non-uniformity in the distribution of the reagents, for example as a result of micro-synergesis, would obvious lead to a decrease in the value of the equilibrium modulus of high elasticity E_∞. This conclusion is confirmed by an analysis of the topological structure and the equilibrium elasticity of the network systems, which show a conformational tendency to undergo monocyclisation reactions[60,61].

The topological model of a network polymer has been used successfully in a theoretical analysis of the durability and the nature of the breakdown of the network in the highly elastic state[79]; the undoubted advantage of this model for solving this problem lies in the possibility of taking account of the non-uniform character of the unloading of the chains between the nodes as a result of the topological non-uniformity of the network. Numerical modelling also made it possible to obtain information on the conformational characteristics of the short chains between the nodes in densely cross-linked networks. The dependence of the elasticity of the short chains on the elongation is stepped in character, and their conformational behaviour differs significantly from the generally adopted approximations of Langevin and Gauss[80].

In addition to the creation of the above statistical topological theory of the formation of polymer networks, work has continued on the development of traditional statistical methods for describing network polymers by means of the mathematical apparatus of the theory of branching processes[82-85]. In particular, a new parameter of the theory has been proposed—the probability of the termination of the chain of network development—whose magnitude determines not only the kinetics of the process of gel formation but also the topological structure and hence the properties of the cross-linked polymer in the highly elastic state; information on the structure of the gel can be obtained from the sol fraction of the polymer, which is easily analysed experimentally. When side reactions causing network growth to stop take place, the sol fraction contains the products of these reactions, including the monocyclisation reaction.

3. Supermolecular Structure

The next level of structural organisation of a polymer, reflecting the relative arrangement of its chain in space, must be characterised by the type of intermolecular interaction of the chains and their degree of ordered character. The first characteristic influences the magnitude of the free volume and the density of packing, which reveals itself in the morphological characteristics of the polymer[1,3,4,6].

Extensive systematic studies of the morphology of densely cross-linked (>10^{21} nodes cm^{-3}) epoxide polymers[1,3,4,6] have shown that the typical structural elements in these systems, which can be detected by electron microscopy, are globules. An important characteristic of these systems is that any attempts to change the nature of the globular structure by varying the chemical structure of the original epoxide oligomers and hardening agents, by changing the hardening conditions, or by the action of thermal and mechanical fields on the already formed network polymer did not lead to any significant change in the morphology of the system; in all cases it remained globular, and only the size of the globules changed.

These studies indicated that the fairly widespread view that globules are more highly cross-linked formations than the cross-linked polymer in the space between the globules is in general incorrect. Thus theories in which the variations in the mechanical properties of cross-linked polymers in the vitreous state are attributed to differences in the density of cross-linking of the globules cannot be correct.

The difference in the densities of the globules and the polymer in the space between the globules was extremely small, ~0.1%.[86] The physicomechanical characteristics of epoxide cross-linked polymers show extremely little sensitivity to the preliminary action of thermal, mechanical, and electromagnetic fields on the prepared polymer over a wide range of conditions. The variation in the properties of the polymers in this case does not exceed 20%. At the same time, even slight changes in chemical structure lead to fairly marked changes in the physicomechanical characteristics of the polymer.

These results are fundamental, since they show that the topological and supermolecular structures of the polymer, formed during the hardening process, are fixed by the three-dimensional network and cannot subsequently be changed by conformational rearrangement of the chains between the nodes without the rupture of chemical bonds.

The above observations led to the important conclusion that densely cross-linked polymers are characterised by a closer relationship between the different levels of their structural organisation, compared with linear polymers. The higher levels of the structure—topological and supermolecular—are determined to a considerable extent by the primary molecular structure of the polymer[1,3,6]. As a result, different external preliminary treatments of the prepared polymer, capable of producing radical changes in the properties of linear polymers, have a much less significant influence on the properties of densely cross-linked polymers, which to a large extent are determined by their molecular structure[87-98].

Studies of the density of epoxide polymers in the vitreous state have shown that the coefficient of molecular packing was unexpectedly high (K = 0.71–0.72), and appreciably higher than that for vitreous linear polymers[6,87,91]. This means, on the one hand, that the formation of chemical cross-linkages does not impose any kinetic restrictions on

the packing of the elements of the network, and on the other hand that the chains between the nodes, in spite of their considerable length (8–12 framework atoms), have a flexibility sufficient for closest packing to be produced. Subsequent experimental studies of the molecular mobility of epoxide polymers completely confirmed this conclusion.

Interesting and important results were obtained in an experimental and theoretical study of the kinetics and mechanism of the formation of the supermolecular structure of epoxide polymers[1,43,51,86].

An extremely general mechanism of the production of the supermolecular organisation of an amorphous polymer has been formulated, taking account of the kinetic characteristics of the process of its formation and its molecular mobility, and a mathematical model of the process has been developed. In this model, the size of the polymer cluster formed is greater, the greater the self-acceleration factor of the hardening process (irrespective of its specific mechanism) and the lower the molecular mobility of the polymer[98].

III. PHYSICOMECHANICAL AND RELAXATION PROPERTIES

Another important problem is the establishment of the relationship between the properties of cross-linked epoxide polymers in the vitreous state and the characteristic features of their structure. As indicated above, the equilibrium mechanical properties of cross-linked epoxide polymers in the rubber-like state is described completely by their topological structure and the conformation characteristics of the chains between the nodes. On going to the vitreous state, however, the situation changes radically[1,3–6,91,97]. The polymer matrices in high-strength composites are used at temperatures below the vitrification temperature, so that the study of the properties of epoxide polymers under these conditions is of particular interest; moreover, in general the properties of polymers in the vitreous state represent one of the least studied fields of polymer physics.

In view of the practical aspects of the application of polymer matrices, it is natural that the mechanical properties of these polymers were studied first. A cycle of studies carried out with epoxide cross-linked polymers with different chemical structures investigated the static and dynamic mechanical properties, the relaxation of stress, creep, various problems of the durability and breakdown and the relationship between these properties and the molecular and topological structures of the epoxide networks[1,3–6,71,87,88,94,96,99–107].

Study of the $\sigma-\varepsilon$ (elongation, compression, shear) diagrams has shown that in most epoxide polymers, in spite of the presence of a high concentration of chemical cross-linkages, at temperatures more than 100 K below T_g and moderate rates of deformation, plastic (induced–elastic) deformation is realised, and the frequently observed brittleness of specimens is due to their macroscopic defect character[1,3,6,91]. The limiting deformations at breakdown may be extremely high (10–15%). This conclusion is important, since it refutes the extremely widespread view that systems with such a high density of cross-linking cannot show plasticity.

Measurements of Young's modulus and the shear modulus, and also the yield limit, have shown that these important mechanical properties are practically independent of the topological characteristics of the network (the density of the nodes, the concentration of mono-rings[1,3,6,91,97]); only the strength was found to be sensitive to the concentration of mono-rings[1,3,95,97]. At the same time, as noted above, the mechanical properties of the networks in the highly elastic state are determined completely by their topological structure[1,6,8,60,61,78,79].

These results are fundamental, since they show that the properties of cross-linked polymers in the vitreous state must be related to the characteristic features of their packing[1,6,89,91,93,108], that is that the behaviour of networks, even when densely cross-linked, does not differ in this sense from that of linear polymers. The liquid–glass transition during the production of the network has a significant influence on the physicomechanical properties of the resulting polymer[91,97]. The slower the vitrification of the polymer during hardening (at low temperatures), the better its mechanical properties in the vitreous state, in spite of the lowered values of the degree of conversion at low hardening temperatures. At the same time, the values of the coefficient of molecular packing for specimens of a given polymer with appreciably different mechanical properties were found to be similar[91,97].

A possible explanation for these facts may be that the properties of a vitreous polymer are determined not only by the total fraction of the free volume in it but also by the nature of its distribution in the specimen. Direct measurements of the dependence of the free volume for epoxide systems on the concentration of chemical cross-linkages provides evidence in support of this suggestion[1,3,89,93,108].

The characteristics of the deformation and breakdown of epoxide polymers in the vitreous state have been studied[99–105]. In spite of the high density of chemical cross-linkages, in epoxide polymers, as in linear polymers, when a crack is propagated through the material, appreciable plastic deformations, irreversible under the given conditions, are observed in the opening of the developing crack. It is these deformations, preceding the rupture of chemical bonds, that to a large extent determine the stability of the material to the propagation of cracks, and hence its strength. These observations indicate that the extremely short bonds between the nodes in epoxide polymers are sufficiently flexible, and are able to undergo conformational rearrangements under deformation conditions.

The size of the plastic zone along the axis of elongation for films of densely cross-linked polymers (plane-stressed state) is equal to the thickness of the film, and this made it possible to formulate criteria for their breakdown[104].

The deformation of densely cross-linked polymers at values of the deformation close to or equal to the yield limit is accompanied by the rupture of chemical bonds[99–102]. This local breakdown of bonds during deformation long before the breakdown of the entire specimen is apparently due primarily to the short length of the chains between the nodes and the non-uniform distribution of stresses in the chains between the nodes. This mechanical degradation may be one explanation for the effect of the "anomalous" relaxational and deformational strengthening of densely cross-linked polymers, detected by various workers[3,99–102]. The essential feature of the phenomenon is that in contrast to linear polymers, during the successive relaxations of the stress or during deformation, the relaxation properties of the densely cross-linked polymers improve (the relaxation time decreases).

The practical result of the studies carried out was the development of epoxy-amine binding agents with record values of the modulus of elasticity (600–700 kg mm^{-2}) and yield limit (17 kg mm^{-2}) at room temperatures and ordinary rates of loading[3,6,91,96].

One of the most important characteristics of a binding agent is its heat resistance. A series of studies[1,3,6,34,35,89,91,109,110] established that the vitrification temperature T_g is determined unambiguously by the molecular and topological structures of the epoxide network. T_g for an epoxide polymer can be increased by high-temperature treatment (>150 °C) as the result of the reaction of unreacted (as a consequence of the topological limit) epoxide groups with

hydroxyl groups of the chains between the nodes[59]. This method of increasing the heat resistance of epoxide matrices for composites is hardly a promising technological technique, because the increase in the thermal stability and a definite but small increase in the value of the Young's modulus are accompanied by a marked increase in the brittleness of the polymer is also observed.

The unique relationship between the molecular structure of the network polymer and T_g makes it possible to use the method of increments to calculate *a priori* T_g for polymers with different chemical structures. This approach made it possible to propose and later to synthesise a number of highly heat-resistant epoxide binding agents.

The study of the vitrification temperature and mechanical behaviour of epoxide networks led to a non-trivial result of practical importance. It was found that important characteristics of the binding agents, such as the heat resistance and the mechanical properties, are determined by different structural parameters, in the first case by the chemical structure of the network, and in the second case by the packing of the chains in the polymer glass. This makes possible the directed and to some extent independent control of these properties of polymer binding agents.

The solution of these problems also made it possible to shed light on various general fundamental problems of the theory of the vitreous state of a substance. In particular, a fluctuational theory of vitrification[111] and a diffusion model of the volume relaxation of glasses have been developed. It was proved experimentaly for the first time[112] that the relaxation of the free volume in polymer glasses takes place not only by a local elasticity mechanism but also by a diffusion mechanism, which is revealed in two new non-trivial effects: the scale effect of the density of epoxide films and the scale effect of their rate of annealing.

A new effect, not yet understood, has also been detected, namely that the relaxation of the free volume in polymer glasses, taking place by a diffusion mechanism, is accompanied by ordering of the structure of the surface layers of the polymer[113].

Important information on the structure of network epoxide polymer glasses has been obtained in studies of their molecular mobility[1,3,6,64,87-95,106,108-110,114-123]. The use of a wide range of methods—mechanical and dielectric relaxation, dilatometry, thermally stimulated depolarisation, NMR, EPR, and calorimetry—established that in densely cross-linked epoxide polymers there is the entire spectrum of molecular movements characteristic of linear polymers. At the same time the molecular movements in these systems are characterised by a number of important features[1,3,6,89,90,92,109,110,114,119]:

1) the chemical units of the epoxide networks (their type and concentration) have no significant influence on the kinetic parameters of the local movements of all types;

2) the half-widths of the α-transitions in cross-linked polymers are usually much smaller than those in linear polymers;

3) the activation energy of the segmental mobility is always lower than that for linear polymers, and decreases with increase in the density of the cross-linkages, whereas the vitrification temperature increases.

The last two facts indicate on the one hand that there is a more uniform distribution of the segments with respect to length in a cross-linked polymer, and on the other hand that they are less extensive than the segments of linear polymers. Direct experimental measurements confirmed this conclusion, and showed that the segment in a network formed from individual diepoxides and diamines is a chain between two neighbouring chemical units[123].

IV. THE MODIFICATION OF EPOXIDE BINDING AGENTS

One of the traditional methods for producing a directed change in the properties of binding agents is by their chemical and physical modification. A series of studies[3,6,71,88,94,95,106,107,110-121,124-129] investigated the physicomechanical and relaxational properties of epoxide compositions over a wide range of chemical structures of the epoxide oligomers and hardening agents. Studies have been made of the properties of epoxide compositions whose chemical structure had been changed in directed fashion by carrying out copolycondensation reactions or by simultaneously carrying out reactions in the hardening system involving the polycondensation and polymerisation of a monomer or monomers of different kinds, or by other methods. Particular attention was paid to the study of the physicochemical modification of epoxide binding agents by the addition of low-molecular-weight rubbers[3,107,124-128]. This method made it possible to increase by almost two orders of magnitude the value of the effective surface energy of breakdown of the epoxide binding agents; this is extremely important for increasing their resistance to impact[107]. Extensive thermodynamic and kinetic studies of the production of the phase structure of epoxide polymers with inclusions of rubbers of different chemical character are making it possible to approach an understanding of the relationship between the chemical nature of the components and the conditions of the preparation of compositions and the phase structure of the composition material.

The phase equilibrium in the original epoxide–rubber systems is described satisfactorily by the Flory–Huggins theory[128]. A thermodynamic analysis of the change in the phase state of hardening epoxide–rubber systems showed that during hardening, the thermodynamic affinity between the epoxide polymer and the rubber decreases, leading finally to the exhaustion of their mutual solubility.

The kinetic condition of the production of the phase structure of epoxide–rubber compositions are determined by the ratios of the rates of the chemical reaction of hardening and the mutual diffusion of the components[124-128]. On the basis of these studies, ideas were developed about the mechanism of the production of the phase structure of epoxide–rubber compositions, a characteristic feature of which is the growth of the nuclei of the new phase under conditions of constantly changing coefficients of mutual diffusion of the components. The ideas developed make it possible to explain why the original thermodynamic compatibility of the components and the width of the distribution of the particles of the dispersed rubber phase with respect to size change in the opposite sense. They also make it possible to understand the frequently observed polymodal distribution of the particles of the dispersed phase with respect to size.

The proposed[124-128] model of the production of the phase structure is apparently of general value for any dispersed-reinforced polymer compositions, whose formation is related to the phase separation of the initially homo-phase mixture of the original components, and makes it possible to influence their phase structure, and hence their useful properties, in directed fashion.

V. CHARACTERISTIC FEATURES OF THE STRUCTURE AND PROPERTIES OF EPOXIDE POLYMERS AT THE BOUNDARY WITH A SOLID SURFACE

The relationship between the physicomechanical properties of epoxide binding agents in the vitreous and rubber-like states and the different levels of their structural organisation was examined above. The processes involved in the

hardening of binding agents in a composite material, however, often taken place in thin layers, in close contact with the filler surface. A large number of studies have shown that a filler may have a significant influence on a matrix, and so-called "boundary layers" are formed in it, with properties different from those of the block polymers[131,132]. The production of these boundary layers is usually attributed to the chemical influence of the solid surface of the filler on the production of the binding agent, the selective sorption of the components of the reaction system, the orienting influence of the surface on the molecules of the reagent and reaction product, etc. The large thickness of the boundary layers (up to tens and even hundreds of microns), however, can hardly be explained in terms of existing thermodynamic concepts.

Published data on this topic are extremely contradictory, apparently because there are kinetic factors, not previously taken into account, which are decisive in determining the observed changes in the properties of the matrix formed on the solid surface.

Various model experiments[133-136] have indicated that this decisive factor may be the internal stresses produced directly during the formation (hardening) of the polymer matrix in the composite. The internal stresses (shrinkage and thermal) arise unavoidably during the hardening of the binding agent in the composite. An important role in the production of composite materials may be played by other sources of internal stresses: 1) stresses produced by the relaxation of the volume of the previously deformed filler, and 2) stresses produced by a change in volume as a result of a phase transformation in the filler. The last two types of stress are easily modelled. Thus the appropriate experiments have been extremely informative from the viewpoint of the determination of the role of internal stresses in the production of composite materials with an epoxide matrix.

Studies involving the extensive use of various relaxation methods and the photoelasticity method have made it possible to investigate the kinetics of the production of internal stresses, their spatial distribution close to the boundary of an inclusion, the gradient of properties (T_g) of the matrix close to an inclusion, and the influence on these parameters of the nature of the adhesion interaction between the matrix and an inclusion, the conditions of hardening, and other factors. A distinct correlation has been noted between the observed gradient of the properties of a matrix at a previously deformed inclusion and the gradient of the developing stresses. Analogous results have been obtained in other model experiments. These data indicate a clearly defined causal relationship between the changes in the properties of a matrix formed on a solid surface and the internal stresses produced.

In addition to the decrease in T_g of a polymer produced in a field of mechanical forces, this polymer also shows an increase in the proportion of the sol fraction, a decrease in the equilibrium modulus of high elasticity, and the production in the specimen of structural stresses, that is residual stresses which are not annealed under any conditions. All these changes in the matrix are greater, the greater the stresses operating in the hardening process.

The observed changes in the properties of the matrix can readily be understood if it is assumed that the process of hardening of the matrix is accompanied by mechanodegradation of the chains of the network[134,135]. The data obtained lead to the following picture of the processes involved in the mechanodegradation of hardening polymer systems under the influence of mechanical stresses. In the range of pre-critical degrees of transformation, when the hardening system remains liquid and has a low viscosity, the applied stress relaxes. In the range of gel formation, when the viscosity of the system increases sharply, the rate of relaxation decreases, and although the stresses operating are extremely weak, they may nevertheless be comparable with the destructive stresses, since the number of elastically active chains, that is chains "holding" the load, in the network in the range of gel formation is also small, and the strength of this system is low. After the point of gel formation, the number of elastically active chains and hence the strength of the polymer increase sharply, and the system can now withstand a load (external or internal) without breakdown.

Thus during the formation of a cross-linked polymer there is a narrow range of degrees of transformation, close to the point of gel formation, in which the cross-linked polymer is very vulnerable to mechanical loads. The degree of damage to the polymer evidently depends on the level of stresses operating and on the kinetics of the hardening process, which determine the time for which the forming polymer is in the "danger" zone.

Although the qualitative picture appears quite satisfactory, quantitative agreement is not observed. Calculations show that the number of degraded chains between the nodes, required to explain the observed changes in the vitrification temperature of the polymer, is one hundred times that determined experimentally by the inhibitor method. Additional studies are therefore necessary to reach a final conclusion about the mechanism of the influence of internal stresses on the structure and properties of polymer matrices in a composite.

Nevertheless, it has already become clear that it is kinetic factors (the nature of the production and relaxation of internal stresses and the excess free volume) that are decisive in determining the observed changes in the properties of polymer matrices produced in contact with a solid surface. An understanding of these regular features is extremely important for the directed control of the properties of composite materials.

---o0o---

To summarise this extensive cycle of studies, it can be stated that they essentially form the basis of a branch of the physical chemistry of macromolecular compounds which is of practical importance but which has not been developed theoretically, namely the field of densely cross-linked polymer systems.

High-strength and High-modulus Reinforced Plastics

E.S.Zelenskii

Studies of the formation, structure, deformation, and fracture of polymeric composite materials reinforced with long fibres are reviewed. The main factors which determine the strength and the elastic modulus of reinforced plastics under short-term static load are discussed.
The bibliography contains 110 references.

I. INTRODUCTION

Plastics reinforced with an oriented array of long, high-strength, and high-modulus fibres are a new class of polymeric composite materials characterised by a marked anisotropy in physico-mechanical properties, depending on the type of fibres used, their mutual orientation, and the relative content of fibres in the matrix.

Because of the ease of controlling (between wide limits) the strength and the deformability of these materials, as well as some of their physicochemical properties (density, resistance to chemicals and to water, thermal and electrical conductivity, etc.), reinforced plastics can be used as constructional materials for a variety of applications, including highly stressed units and components.

We shall not attempt to discuss the structure, properties, and special features of reinforced plastics of various types, which have been recently reviewed in both Soviet and foreign publications[1-7], and we shall only examine the problems of retaining (or exploiting) the strength and the elastic modulus of the fibres in an oriented layer of reinforced plastic stressed in the direction of the fibres.

It is important to define correctly the initial characteristics of the strength members, i.e. the characteristics of the fibres when first prepared. The direct measurement of the properties of the fibre is complicated by the danger of damaging the sample (mechanically or physicochemically), thus degrading its properties while preparing the measurement samples[8]. These difficulties are most marked in the determination of the strength of the fibres, since in this case the measurements are affected not only by the sample preparation conditions but also by the scale factor, by the strain rate, and by the method of clamping the sample in the tensile tester. The measurement of the elastic modulus is usually straightforward, but in the case of organic fibres it may be influenced by several factors.

With oriented samples carefully prepared under laboratory conditions several workers have obtained characteristics corresponding to the initial properties of the fibres. This success makes it even more important to develop methods of quantitative analysis of the influence of various structural defects in real reinforced plastics on the mechanical properties of the components made from them.

Information on the adhesive strength of the fibre–polymeric matrix system is essential in studies of interactions in this system. Special models have been developed to calculate the adhesive strength, to identify the special features in the formation of the adhesion couple, and to give a quantitative formulation of the effect of the adhesive strength on the behaviour of the plastic under different stress conditions.

In addition to a strong adhesion the polymer matrix should offer a set of elastic and mechanical characteristics which ensures a uniform distribution of the stress over the system of fibres experiencing deformation under load. Theoretical work on this problem has been published both in the Soviet Union and abroad[9-12]. The use of epoxy polymer matrices in composite materials is reviewed by Rozenberg and Oleinik in the present issue of this Journal (see p.164).

The strength and elastic modulus of an oriented material under axially symmetrical load can be increased by increasing the relative content of reinforcing fibres. Therefore one of the problems in the design of reinforced plastics is the production of systems having a high packing density, with a regular hexagonal packing (in the case of fibres with a circular cross-section) and a minimum number of defects.

The materials known as hybrid polymer composites have attracted much attention during the past ten years. By combining within the same composite two or more types of fibre, or more than one matrix, we are able to control the properties of reinforced plastics between much wider limits, and in some cases we can achieve synergetic effects. It is also possible to vary the properties of the material in a prescribed way in the bulk across the cross-section of the item.

Another important area of research is concerned with the phenomena associated with the frontal or the uniform solidification of polymers and composite materials. Studies of stressed and strained states created during the formation, cooling, and storage of the material and of the residual stresses and strains (after relaxation) should lead to improved technological processes for the production of components from reinforced composite materials having the required properties.

We shall not attempt in this review to survey the whole of the current work on the development of high-strength reinforced plastics and on studies of their deformation and fracture and of their behaviour under practical conditions. The discussion will be confined mainly to the aspects developed by Enikolopov and his co-workers.

II. REINFORCED PLASTICS WITH AN ORIENTED STRUCTURE

1. Effect of the Strength and Length Distribution of the Elementary Fibres and Filaments on the Strength of Oriented Reinforced Plastics

One of the main problems in the study of the tensile strength of oriented composite materials is the determination of the initial strength of the fibres. Existing models of fibre structures can be used to calculate the elastic modulus

but are almost useless for predicting the strength characteristics of fibres[13].

The effect of the scale factor on the strength of elementary organic fibres (Vniivlon, Kevlar-49, Terlon) has been studied[14], and it was found that their strength characteristics are adequately described by the statistical theory of strength with a distribution function whose parameters are determined by the structure of the fibre. For Kevlar-49 and Terlon the strength distribution histogram was bimodal, due to the presence of various types of defect associated with the amorphous–crystalline structure of polymers showing a "shish-kebab" morphology[15].

The theory of the strength of a bundle of unattached fibres has been discussed[16] by assuming a Weybull distribution of fibre strengths. The high-grade physico-mechanical characteristics of reinforced plastics are the result of the simultaneous deformation of high-strength fibres interconnected by the polymeric binder. According to the statistical theory of fracture proposed by Rosen[11] the strength of an oriented composite material is equal to that of a bundle of non-interacting fibres of appropriate length (called the ineffective length, l_{ineff}). Experimental studies of the dependence of the strength of the bundle on the scale factor and comparisons with the strength of microscopic samples of plastic based on single fibres or braids (small bundles of fibres connected by the polymeric binder) have confirmed that the strength of a micro-plastic is the same as that of a bundle of unattached fibres of length l_{ineff}. This length can be calculated from the relative hardness of the components (according to Rosen) or from data on the adhesive strength in the fibre–polymer matrix system[17].

However, studies of reinforced plastics have brought to light a number of factors which are incompatible with Rosen's theory: 1) the dispersion of the strength of the fibres and of the micro-plastics is approximately an order of magnitude greater than the calculated value[14]; 2) the strength of the micro-plastics is dependent (albeit slightly) on the length of the sample, and falls off markedly when the standard ring specimen is replaced by real mechanical components and mass-produced items. These discrepancies are due to inhomogeneities and defects in the structure of real materials which are ignored in Rosen's idealised model. Among the most important of these effects is the instability of the properties of the fibres used, for example, in the windings of reinforced plastics.

Detailed studies have been made of the properties of filaments based on organic fibres: the scatter of the elastic moduli was relatively slight (variation coefficient $\nu_E \approx 4\%$), but the strength of the individual fibres within a braid covered a range of 20–25%, with a variation coefficient of 6–12% (depending on the length of the sample). The dispersion of the Weybull parameter β, which describes the effect of the scale factor, was also found to be relatively large[16].

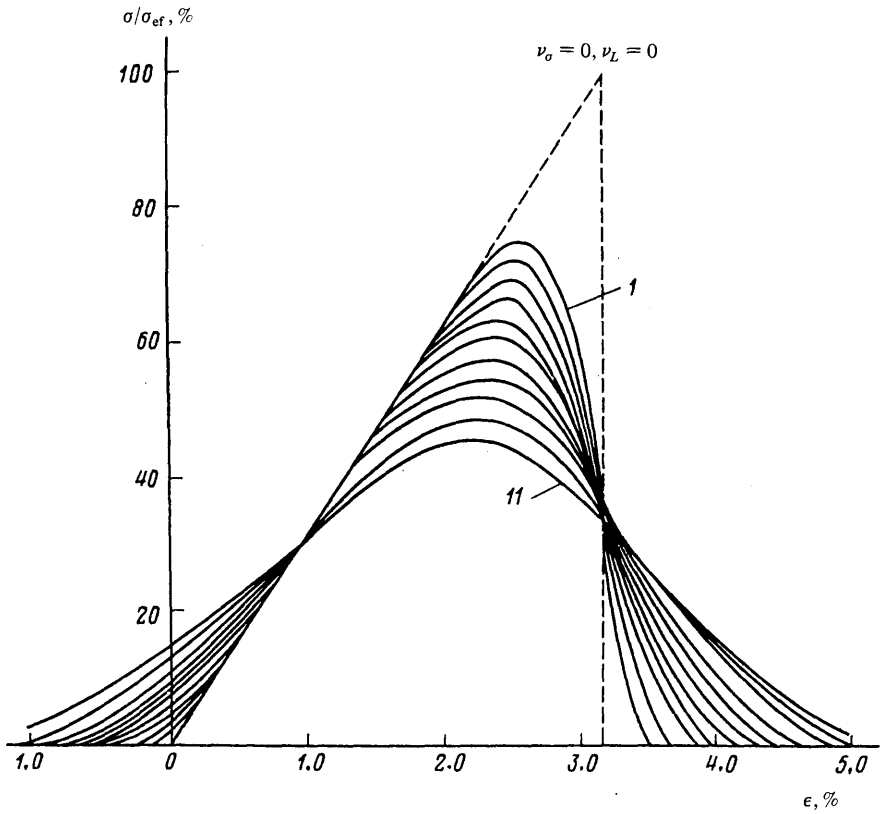

Figure 1. Tensile diagrams ($\sigma/\sigma_{ef}-\varepsilon$) calculated for bundles of organic fibres with different length dispersion: curves *1–11* correspond to variation coefficient of length (ν_L) between 0 and 1% in steps of 0.1%; σ is the strength of the bundle, σ_{ef} is the mean strength of the elementary fibre[18].

The interaction between the elementary fibres in the filaments, resulting from their partial adhesion during the production of the filament or from the twist in the filament, can be described by an appropriate ineffective length (for organic filaments, 20–150 mm), or alternatively by the ratio of the Weybull coefficients for the filament and for the elementary fibre respectively ($\beta_f/\beta_{ef} = 1.3–2.0$). The interaction between the fibres resulting from the presence of the polymer matrix causes l_{ineff} to decrease and β_f/β_{ef} to increase. For a micro-plastic based on Vniivlon filaments and an epoxy polymer matrix $l_{ineff} = 0.1–0.3$ and $\beta_{mp}/\beta_{ef} = 10–20$.

The $\sigma-\varepsilon$ tensile diagrams of the filaments for loads near the maximum for each sample usually include a non-linear region (due to a gradually increasing number of broken fibres, which produces a decrease in the aggregate cross-section of unbroken fibres). Micro-plastics under load break almost instantaneously, and a non-linear portion is not observed in the $\sigma-\varepsilon$ diagram, i.e. their behaviour under load is the same as that of elementary fibres.

However, because of the dispersion in the strength of the filaments themselves, which produces a dispersion in the strength of the resulting micro-plastics, a real reinforced plastic (for example, the ring samples with a uniform orientation) can be treated as a bundle of micro-plastics having different strengths. The breaking of one member of such a system creates a large-scale defect (a stress concentrator), which weakens the structure more markedly than the breaking of an individual fibre. This is one reason for the failure to exploit the initial strength of the elementary fibres in real reinforced plastics (as opposed to micro-plastics).

Another important contribution to the sequential breaking of the elementary fibres in real materials is the dispersion of the length of the fibres in filaments and in braids. Length inequality of the fibres in filaments occurs even at the fibre production stage, due to chemical and thermal fluctuations in the reaction region; dispersion of the length of fibres in braids occurs in the textile filament production processes (spinning and twisting), and also on the reeling machine.

A mathematical model[18] of the breaking of fibre bundles (filaments, or braids) which allows for the dispersion of the fibre length in terms of the variation coefficient ν_L has recently been proposed. The $\sigma-\varepsilon$ tensile diagrams calculated for braids in which ν_L varies from 0 to 1% are shown in Fig.1, and the dependence of the breaking stress of the braids on the parameter ν_L is shown in Fig.2. The broken lines are the tensile diagram for a single fibre or for a bundle with $\nu_\sigma = 0$ and $\nu_L = 0$.

The dispersion of the length of filaments in braids is usually studied by direct measurement of the filament lengths. No attempt is made to measure the dispersion of the fibre length within the filament. A method of measuring both the dispersion of the fibre length in the filaments and the overall dispersion of the fibre length in the braids was proposed in Ref.18. It relies on an analysis of the non-linear part of the $\sigma-\varepsilon$ tensile diagram for a filament, on the assumption that the non-linearity is due to the sequential involvement of the fibres in the deformation of the filament. The fractional number of fibres under load at a given deformation of the filament can be determined by comparing the measured stress of the filament with the stress calculated by Hooke's law. Differentiating the $\sigma = F(\varepsilon)$ dependence with respect to deformation gives the fibre length distribution curve and the variation coefficient ν_L.

Within a single filament the dispersion of the strength of organic fibres (ν_L) is usually found to be less than 0.12%, and for braids of these filaments it increases to 0.15–0.25%, which can lower the strength of a bundle (or braid) of these filaments by approximately 10% (see Fig.2); an analogous decrease was found in studies of the strength of micro-plastics based on braids in which the length dispersion was artificially modelled by previously applying different loads to the braid. When the problem is put in the elastic formulation a given dispersion of the stress is equivalent to a dispersion of the length of the filaments in the braid: experimental studies of the effect of the modelled dispersion of filament length in braids on the strength of the micro-plastics prepared from them agree very well with calculations (see Fig.2).

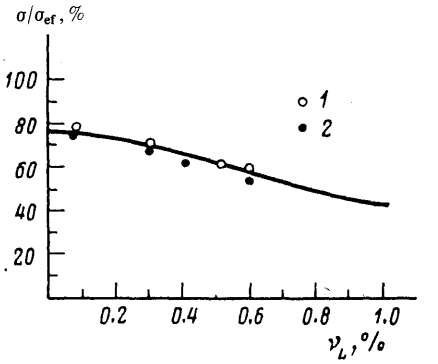

Figure 2. Reduced strength of the bundle of fibres σ/σ_{ef} against the variation coefficient of the length of fibres ν_L; the curve shows the theoretical dependence for a bundle of unattached organic fibres; the experimental points were obtained in tests on bundles or braids (*1*) and on micro-plastics (*2*).[18]

We note that the adverse effect of the dispersion of the length of fibres in filaments or in braids on the strength of reinforced plastics can be most marked in materials based on carbon or boron fibres, whose breaking strain is often less than 1%.[1]

2. Interaction of the Polymer Matrix with the Surface of the Reinforcing Fibres and Effect of the Adhesive Strength on the Mechanical Characteristics of Reinforced Plastics

The properties of composite materials depend not only on those of the components (fibres and matrix) but also on the interactions between the components, and especially on the strength of adhesion at the interface, which determines the effectiveness of the transmission of stresses through the phase boundary.

In spite of the obvious importance of studies of the adhesive strength in the development of reinforced plastics little was known for a long time on the changes in adhesive strength at the fibre–polymer interface: studies of adhesion have been traditionally confined to large-scale samples (prisms, plates, etc.). It was not clear to what extent the results obtained for flat surfaces could be transferred to cylindrical surfaces 10–100 μm in diameter (i.e. in the range of diameters of the fibres used in reinforced plastics). We should also note that for most of the high-strength reinforcing fillers used at present (carbon, organic, boron) the direct measurement of the adhesive strength in the fibre–polymer system is the only way of assessing the strength of

the coupling, since large test samples (plates, prisms, etc.) with the same fibre area cannot be prepared.

The apparatus and procedures which have been developed for preparing polymer–fibre composite samples, the adhesion testers for studying these samples at temperatures between −195 and +200 °C at different loading rates and in different atmospheres, and the new methods of treating the results of experiments on competitive (adhesional and cohesional) breaking processes have allowed the dependence of the adhesive strength in the fibre–polymer system on various factors to be studied systematically. The factors include the cooling and storage conditions, the measurement temperature, the rate of application of the stress, the composition of the binder, the type of fibre, the treatment of the fibre surface, etc.[18–34].

The most characteristic feature of adhesion couples is clearly seen in polymer–fibre systems: a non-uniform distribution of stresses at the interface, resulting from differences in the physico-mechanical characteristics of the components. This produces a strong dependence of the measured adhesion strength on the shape and size of the sample, and we must define the criteria for the most rational choice of numerical values of the adhesion strength. The local adhesion strength τ_{loc} has been proposed as the characteristic least sensitive to geometric factors: this parameter is determined by extrapolating the experimental results to zero length of the adhesion couple[26]. The τ_{loc} value can be used as a measure of the interaction at the interface, and also in studies of the nature of the adhesion and of the mechanism of the adhesion failure[27,28].

Studies of the dependence of the local adhesion strength of epoxy polymers on temperature and hardening rate have shown that under isothermal conditions τ_{loc} varies with the degree of hardening in the same sense as the hardness of the binder, tending towards an asymptotic value[27]. From studies of the kinetics of the development of adhesional strength during hardening it was found that the adhesion of these binders to steel and boron fibres is mainly due to chemical bonds[27].

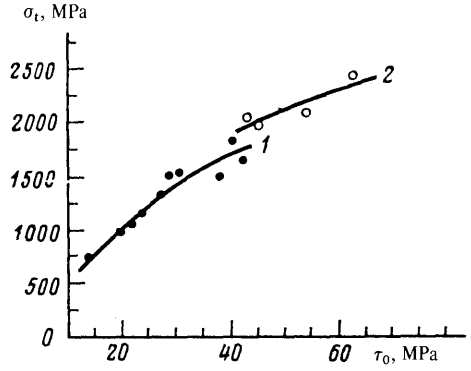

Figure 3. Dependence of the tensile strength of singly oriented glass fibre composites on the adhesion strength of the appropriate polymer–fibre system: *1*) for alkali-free glass fibres, *2*) for fibres of VMP grade[33].

Work on the dependence of the adhesive strength of polymer–fibre systems on temperature and loading rate has shown that below the glass transition region of the adhesive the local adhesive strength falls off linearly with increase of temperature and increases linearly with the logarithm of the loading rate[28–30]. This suggests that the adhesive failure of components (like their cohesive failure) takes place by a thermal fluctuation mechanism.

Refs.28, 31, and 32 describe a quantitative study of the relationship between the adhesive strength and the strength of the sample under tensile stress, compression, bending, and shear. The parameter used as a measure of the adhesive strength in this work was the quantity τ_0, defined for the final length of the sample, since it is affected by all the forces acting on the elementary cell of the reinforced plastic and therefore it can reflect more accurately than τ_{loc} the conditions of adhesion failure at the interface in real composites.

In oriented glass fibre composites prepared from various binders the tensile strength of the material σ_t increases with the adhesion of the binder to the fibre (see Fig.3). At high values of the adhesive strength we note a tendency for the plot of σ_t against τ_0 to reach a saturation level.

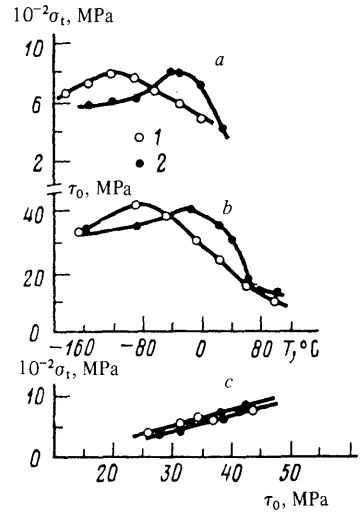

Figure 4. Effect of temperature on (*a*) the tensile strength σ_t of uniformly oriented glass fibre composites and (*b*) the adhesion strength τ_0 of the polymer–fibre system; (*c*) are the correlation curves; the binder is *1*) butvar-phenol, *2*) epoxy-phenol.

Changes in the same sense of the adhesive strength τ_0 and of the strength of the glass fibre composite σ_t are observed also in studies of temperature effects (Fig.4). Since both the strength of the glass filaments and the strength of the binder increase monotonically as the temperature T decreases, the observed correlation between the shape of the σ_t–T and τ_0–T curves suggests that in these composites the weakest member is the phase boundary, and therefore that the fracture of these materials begins at this boundary.

The most meaningful information on the relationship between the adhesion at the interface and the properties of the material is obtained from experiments in which the fibre and the binder material are kept constant, but the adhesion is varied by modifying the surface of the fibrous filler. Work of this type has shown[31,32] that changes in the adhesive interaction are accompanied by corresponding

changes in the strength of composites with a single orientation (both pressed and wound). The changes are in the same sense for all types of test (in tension, shear, compression, and bending, see Fig.5).

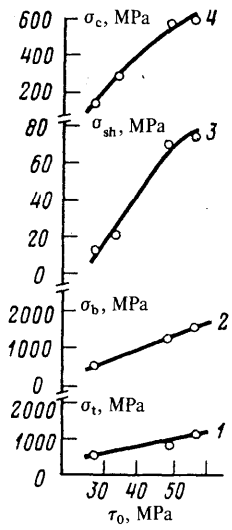

Figure 5. Strength of uniformly oriented glass fibre composites prepared from fibres with a pristine or a modified surface against the adhesion strength; EDT-10 binder, *1*) tension, *2*) bending, *3*) shear, *4*) compression[32].

Thus recent work shows that in glass fibre composites the adhesive strength of the polymer–fibre system is one of the factors mainly responsible for the mechanical characteristics of the material. The fracture of these materials (under tensile load) also reflects the level of adhesion at the interface: we observe a transition from failure at the interface (for small values of τ_0) to fracture by the increase in the number of broken fibres (for large values of τ_0). In the latter case the statistical model of fracture proposed by Rosen is applicable to the glass fibre composite.

In high-strength composites based on organic fibres of the Vniivlon type no correlation is observed between the adhesive strength and the strength of the material: for all the binders examined (covering a range of τ_0 from 40 to 60 MPa) the strength of the material under tension, compression, bending, and shear remained constant. This suggests a fracture mechanism controlled by the weak bond between the fibrils of which the fibre is composed[1].

In glass fibre composites (based on existing binders) a search for methods of modifying the glass surface so as to improve the adhesive strength should yield reinforced materials with enhanced mechanical properties.

In organic fibre composites based on highly oriented fibres of the Vniivlon type surface treatment aimed at strengthening the interaction of the fibre with the binder cannot by itself improve the physico-mechanical properties of the composite, and we must seek to modify the structure so as to enhance the transverse strength of the fibres under tension, i.e. to strengthen the bond between the fibrils.

3. Reinforced Plastics with a High Relative Content of Fibres

One method of raising the strength and the elastic modulus of reinforced plastics is to increase the relative content (by volume) of high-modulus and high-strength fibres, i.e. the reinforcement coefficient K_a. Traditional winding methods give materials containing only 65–70 vol.% of fibres, as compared to the theoretical K_a value of 90.7% for hexagonal close packing of fibres of equal diameter.

Various workers have reported a maximum on the plots of the physico-mechanical properties of reinforced plastics against the relative fibre content, usually in the region of 60–65%.[3,35] We can attribute the decrease in strength of the plastic at high fibre contents to an increase in the porosity of the samples and to the difficulty of producing uniformly thin (less than 1 μm) and yet continuous layers of the polymeric matrix. An indirect confirmation of this conclusion comes from the reported shift of the maximum towards higher values of K_a when the fibre diameter is increased[36].

The technological difficulties which prevent the incorporation of a high density of fine fibres are due mainly to the friction between the fibres during the formation of the material, which opposes their redistribution into the optimal hexagonal configuration. Furthermore, the dispersion of the fibre diameters lowers the theoretical limit of packing density (except for some special relationships between average fibre diameters in the case of a bimodal distribution).

To overcome these difficultes we must first of all optimise the structural order of the reeled element consisting of filaments or braids, i.e. create a close packing at the stage preceding the fixing of the positions of the filaments. Equally important is the achievement of a uniform distribution of the polymeric binder between the fibres[37]. This is done by repeated steeping of the filaments and braids in the binder during the winding of oriented reinforced plastics, by stretching them by friction (without slippage) on tensioning pulleys, and by forming an ordered, thin tape from a number of filaments or braids in a special profiling stacker. Some workers have applied ultrasonic vibrations to the stacker in order to lower the friction and to achieve a closer packing of the filaments in the tape, as well as a uniform penetration of the binder into the fibrous material. These new technological processes have given ring samples of glass or organic fibre composites in a single orientation containing up to 85 vol.% of fibres, i.e. approaching the theoretical limit, coupled with a negligibly small porosity of the samples (less than 1%).

When thermoplastic organic fibres are used the fibre content of the reinforced composite can be as high as 90 to 100 vol.%.[38,39] These high packing densities are achieved through irreversible thermal deformation of the fibres normally to their axis, which changes the fibre cross-section from a circular to an arbitrary shape, imposed by the contact with the neighbouring fibres. To prepare these maximally reinforced organic fibre composites the technological parameters must be chosen so as to retain as far as possible the initial strength and stiffness of the fibres in spite of their thermal deformation. A strong bond between the profiled fibres can be obtained from the self-adhesion forces (by direct interaction of the fibres) or by interposing thin layers of binder between the fibres.

If the porosity is kept to a minimum (less than 1%) the elastic modulus E and the tensile strength of the samples show a linear increase (as required by the additivity principle) up to the highest volume contents of fibres of different types. These results are illustrated (Fig.6) by plots (in relative units) of the characteristics of glass fibre reinforced plastics based on fibres 9–11 μm in diameter and an epoxy-diane binder. Increasing the fibre content of the glass fibre

composites increases their strength under compression more markedly than under tension: this is explained by the specific effect of the close-packed array of fibres, which prevents the loss of strength.

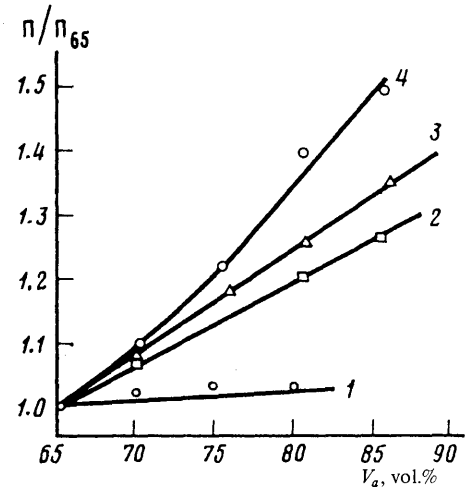

Figure 6. Effect of the fibre content by volume on the physico-mechanical characteristics of glass reinforced composites; П is a characteristic of the glass fibre composite for any value of the fibre content V_a, $П_{65}$ is the same characteristic for a 65% fibre content, *1*) τ_{sh}, *2*) σ_t, *3*) *E*, *4*) σ_c.[37]

4. Hybrid Polymeric Composite Materials

The preparation of hybrid polymeric composite materials (HPCM) by combining two or more types of reinforcing fibre (glass, organic, carbon, or boron) is a promising area of research in materials science, because of the prospect of controlling the properties of these materials between much wider limits.

The most important influence on the physico-mechanical behaviour of HPCM (especially under tension) is from the difference in the limiting deformations of the fibres present in the material. Organic–glass and carbon–boron plastics have been studied as HPCM based on fibres with similar deformation characteristics. The physico-mechanical properties of these materials are exactly described by the additivity principle.

An entirely different behaviour is observed in studies of HPCM containing fibres with substantially different deformation properties. In HPCM with alternate reinforcing elements having a low linear density or with alternate layers less than 0.1 mm thick the different fibres in carbon–organic, carbon–glass, boron–glass, and boron–organic composites do not break simultaneously under tension. Fig.7 shows as an example the tensile diagrams of carbon–glass composites with different ratios of carbon to glass fibres. In the initial region *I* (Fig.7) the carbon and the glass fibres are being deformed together. At a relative deformation of 0.7–1.0% we observe the fracture of samples containing more than the critical amount of carbon fibres (25 vol.%, curves *1* and *2*). At lower contents of carbon fibres this deformation does not cause breaking. In region *II* (Fig.7) curves *4* and *5* are non-linear, indicating the gradual breaking of the long carbon fibres into progressively shorter lengths. The presence of a "quasi-plastic" region (*II*) in the tensile diagram of the HPCM gives an increased breakdown energy, impact strength, and fatigue and dynamic strength in these materials. Beyond this region the almost linear region *III* extends up to the limiting deformation of 3–4%. On increasing the content of glass fibres the deformation at break of the carbon fibres in carbon–glass composites increases from 0.7 to 1.5%. This synergistic effect is apparently due to the repeated breaking of the carbon fibres into progressively shorter pieces, and to the avoidance of macroscopic cracks and premature failure of the material in glass fibre composites.

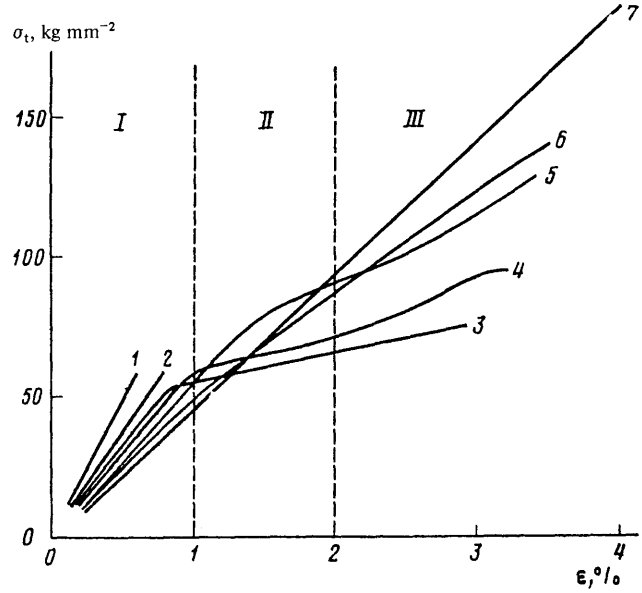

Figure 7. Tensile diagrams for uniformly oriented ring samples of carbon and glass fibre composites with different ratios by volume of carbon and glass fibre contents (%): *1*) 100:0, *2*) 78:22, *3*) 58:42, *4*) 41:59, *5*) 26:74, *6*) 12:88, *7*) 0:100.[52]

Under compression the dependence of the strength on the content of fibres with different elastic moduli is almost linear in HPCM. The elastic modulus stays linear after repeated (up to 10 times) load applications. This means that the carbon and the organic fibres when present in a matrix of glass and boron fibre composites can retain their strength at deformations (and therefore also at stresses) 2–3 times greater than in the simple carbon and organic fibre composites. These synergetic effects allow us to increase the elastic modulus of glass or organic fibre composites by small additions of carbon fibres, and to increase the compressive strength of carbon fibre composites by combining carbon and glass fibres.

An interesting possibility in the development of HPCM is the production of components with variable properties by varying the relative amount of different fibres in different parts of the article. This feature should allow us to control

the stress field in mechanical components both during assembly and in service. It should also be possible to solve the inverse of the traditional problem, i.e. given the most favourable stress field in the component, determine the required material structure. The effectiveness of this approach has been demonstrated for thick-walled vessels under external or internal pressure. Hybrid composite materials have attracted a great deal of interest in both the Soviet and the foreign scientific literature[40-48], but the reported experimental results are not always easy to compare because of the failure on the part of authors to quote the parameters of the material structure, the extent to which the components are kept discrete in the hybrid material, and the relative configuration of the reinforcing elements. The results reported by Phillips[46,47] appear to be the closest to ours[44,45].

We should note that although the theory of the construction and of the behaviour of hybrid composites is still in its early stages these materials have already been widely used in practical applications ranging from aviation components to sports equipment[48].

III. DEFORMATION AND FRACTURE OF MATERIALS WITH COMPLEX REINFORCEMENT

Recent component designs rely on multi-layer polymeric composite materials (PCM) with different and often complex patterns for the orientation of the reinforcing elements. The choice of reinforcement, of binder, and of orientations is determined by the function of the component and by its conditions of service. Materials having identical reinforcing elements and binders and differing only in the pattern of the reinforcement are entirely different materials as regards their mechanical properties. We therefore need theoretical models of the PCM to predict their behaviour with different orientation schemes of the reinforcement from a minimum of experimental information.

Studies of this type have been reported for glass, carbon, and organic fibre composites prepared by the winding method and for hybrid materials based on glass and carbon fibres[49-66].

Tube samples are used for experimental studies of the mechanical behaviour of materials produced by the winding method with complex reinforcement patterns. Special test methods had to be developed for tubular PCM samples under different loading conditions[49,61-63], because there are no standard test methods for this sample geometry.

Purely phenomenological studies of strength as a function of the angle of the reinforcement[57] have shown that in both carbon and glass composites the shear strength can be described by a formula which follows from the Gol'denblat–Kopnov strength criterion. Hence the calculation requires a knowledge of three experimental values of the torsional strength for three known winding angles[64].

A simpler dependence of the strength on the reinforcement angle was obtained[56] from a different phenomenological criterion, which allows for the structure of the material by formulating the failure condition for the plane where fracture is most likely. This criterion gave formulae for the dependence of the strength under uniaxial extension and of the torsional strength on the reinforcement angle in terms of the strength observed experimentally (under the same loading conditions) for a single, arbitrarily chosen winding angle. These theoretical formulae are satisfactorily consistent with experimental curves for glass and carbon fibre composites with winding angles of $\pm 20° \leq \alpha \leq \pm 80°$.[63] The results of experiments on the mechanical behaviour of carbon fibre composites under shear, together with data on the influence of various factors on the shear characteristics, have been used to design new types of component with a weight saving of up to 20%.[64,65,67]

The latest technological method of preparing multi-layer PCM relies on the use of a monolithic packet of uniformly oriented reinforcing layers which is itself oriented in different directions. The mechanical properties of multi-layer PCM are largely determined by those of the uniformly oriented reinforcing material. Hence it is relevant to examine theoretical models of the PCM able to predict the strength and the deformation behaviour of the multi-layer material from experimental data on the elasticity and strength of the uniformly oriented material. Both Soviet and foreign publications describe various models of this type which allow for a number of effects accompanying the deformation and fracture of the PCM and ignored in the purely phenomenological approach based on the linear elasticity theory of isotropic solids[68-75].

Experimental studies of the breaking of glass and carbon reinforced PCM have shown that the ultimate failure of these materials is preceded by various impairments (peeling, cracking) which do not exhaust the load bearing the capacity of the composite. It is important to know the types of stress and the stages in loading responsible for the appearance of these initial impairments as well as those responsible for the ultimate mechanical failure.

By combining theoretical models which allow for the layer structure of the material with the maximum stress criteria, and by comparing calculations with experimental results, the principles which determine the breaking of glass reinforced plastics under axial compression, extension, and torsion have been determined for various regions of winding angles[76]. The cause of the disintegration of the binder during the initial deformation and of the final failure of the material under axial extension and torsion has been identified (for different types of glass and carbon fibre reinforced plastics) by using a phenomenological model of the structure of a multi-layer PCM [74] in which a uniformly oriented monolayer is treated as the basic element. By generalising experimental data and various models of the deformation of uniformly oriented composite materials Zinov'ev and Tarakanov[74] have developed a generalised model of the deformation of a uniformly oriented monolayer within a packet of layers which assumes that the matrix of the mechanical characteristics of the uniformly oriented material can have one of eight possible values, depending on the magnitude and sign of the components of the stress tensor and on the sign of the deformation increments. An algorithm for computer calculations was developed from this model. The validity of the results was confirmed by the agreement between theoretical and experimental tensile diagrams[76,77]. It was also shown[69,70] that the torsional fracture of carbon and glass reinforced plastics is induced by compressive stresses along the fibres except in the glass fibre composites with a winding angle $\alpha = \pm 45°$, which break as a result of tensile stresses in a layer at right angles to the fibres. The disjoining stresses in this layer are also responsible for the breaking of glass fibre composites with angles $\alpha = \pm 60°$ and $\pm 75°$ under uniaxial extension. In a glass fibre composite with $\alpha = \pm 45°$ under uniaxial tensile stress the formation of cracks leading to the loss of load bearing capacity is caused by shear stresses. Samples with $\alpha = \pm 45°$ have the highest deformability: their tangential modulus (i.e. the slope of the finite part of the deformation curve) is small on the experimental diagrams and zero on the theoretical. According to this model after the loss of continuity the deformation grows at constant load (assumed to be equal to the limiting load); the proposed algorithm can be used also for loads higher than this limit. In the final stages of deformation we

find a marked increase in the tangential modulus due to the change in the reinforcement angle produced by the deformation, but this does not cause the fibres to break. In glass fibre composites with $\alpha = \pm 60°$ and $\pm 75°$ there is no increase in the tangential modulus, though a high deformability and an increase in deformation at practically constant load are again observed.

Torsional deformation of glass and carbon fibre composites with angles $\alpha = \pm 60°$ and $\pm 75°$ reveals disintegration of the binder as a result of disjoining stresses acting at right angles to the fibres, and of tangential stresses acting along the fibres. The causes of the large-scale failure of the material defined by the criteria given in Refs.74 and 76 for the various winding angles are effectively the same. Because of the special behaviour of $\alpha = \pm 45°$ materials under simple types of load their mechanical behaviour has to be studied with different types of complex loading approximating those experienced by composite materials under field conditions.

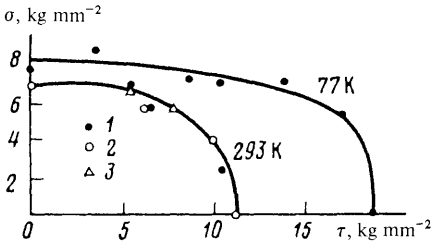

Figure 8. Breaking diagram for an organic fibre plastic at room temperature and at low temperature: *1*) torsion + tension, *2*) proportional deformation, *3*) tension + torsion[78].

Tubular samples of organic and glass fibre composites have been studied[78] for $\alpha = \pm 45°$ and the same epoxy binder under linear deformation conditions under simultaneous axial (tensile) load and torsional moment and with a complex load application curve: tension was used to bring the sample to a prescribed value of σ_i, and torsion was then applied to break the sample at the stress τ_i. The experiment was then repeated in the opposite sequence: a torsional moment was applied to bring the sample to a stress close to τ_i, and then the sample was broken under tension. Breaking diagrams for organic fibre composites loaded in different ways at room temperature and by the complex loading trajectory at low temperature (77 K) are shown in Fig.8. It was found that the experimental values of strength lie on the same breaking diagram for all types of load application. A decrease in temperature produces a marked increase in the strength of organic fibre composites, especially under shear.

IV. PHYSICO-MECHANICAL PHENOMENA IN THE POLYMER FORMATION AND REINFORCEMENT PROCESSES

In this Section we shall review the studies of mechanical phenomena in frontal and in uniform solidification processes, in the heat treatment of polymeric and composite materials, and in their practical applications. Studies of the mechanism of formation of defects and of residual stresses and deformations will also be discussed. The ultimate aim of this group of investigations is to develop favourable technological processes for the large-scale production of thick-walled monolithic components from polymeric or composite materials[79,108,109].

Studies of the chemical kinetics of the solidification of these components have shown[80-86] that the process can be frontal, i.e. spatially non-uniform. Therefore it is important to study the mechanical phenomena accompanying the frontal solidification of articles made from polymers and from reinforced plastics, since defects may be formed or residual stresses may be created.

The problem was solved by postulating[84-90,93] a two-step solidification front, with steps in the liquid and the solid state. This model allows most of the solutions to be obtained in a closed form clearly related to the physical nature of the phenomena and suitable for analysis[93]. Two limiting models were developed for composites: one in which the reinforcing fibres are fully immersed in the liquid binder and a capillary model in which the filler can form a system of capillaries.

By solving various problems in the mechanics of deformation and in hydrodynamics, and by using experimental results, it has been shown that defects can take the form of discontinuities or of residual stresses during frontal solidification[93,94].

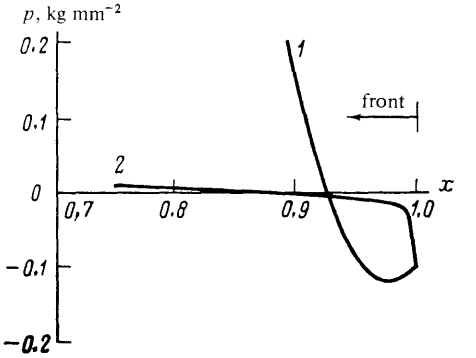

Figure 9. Changes in pressure ahead of the solidification front for a cylinder of reinforced plastic on an elastic mandrel as a function of the position of the front: *1*) stiff mandrel, *2*) stiffness of mandrel reduced by two orders of magnitude; p is the pressure ahead of the front, $x = r/R$ where r is the coordinate of the front and R is the radius of the outer surface of the shell[93].

Fig.9 shows a plot of the changes in pressure ahead of the solidification front in a thick-walled cylindrical shell of reinforced plastic: the front is moving from the outer surface ($x = 1$) towards the mandrel, and the binder is liquid ahead of the front. The fall in pressure ahead of the front to zero or even to "negative" values (i.e. to isotropic expansion stresses) suggests the possibility of slippages or breaks in the continuity of the liquid binder, and the formation of holes and pores (curve *1*); a decrease in the hardness of the mandrel by two orders of magnitude largely avoids the danger of defect formation (curve *2*).

A similar approach can be used to analyse the mechanical phenomena in polymers and in reinforced plastics during a frontal liquid–solid transition, and also in other systems (e.g. liquid–polycrystal, liquid–monocrystal, adhesive–substrate, etc.).

The next stage in the formation of components is heat treatment. This usually consists in cooling the article from the solidification temperature to the storage or application temperature, though additional heat treatment is sometimes applied in order to modify some of the properties of the material. Furthermore, materials and components are often used under conditions of variable temperature, which cause thermal stresses.

The mechanism of formation and development of thermal stresses in polymers was studied with samples consisting of amorphous polymers, both linear [poly(methyl methacrylate)] and with a network structure (epoxy resin)[91-93]. The dependence of the thermal stresses in amorphous polymers on the rate of change of temperature, the quasi-irreversibility of the stresses associated with cyclic changes in temperature, and the increase in stress during isothermal relaxation processes have been demonstrated experimentally and justified theoretically[91-93]. For polymers all these processes are strongly non-linear[93].

Problems of thermal stresses in polymers and reinforced plastics can be solved theoretically by using the full system of equations from classical mechanics which describes the stressed and the strained state, and also the functional relationship between the components of the stress and deformation tensors and time. Phenomenological relationships of the heredity equation type are most widely used. So far little work has been done on the use of physical non-linear coupling equations to describe thermal and residual stresses. A non-linear physical generalisation of the Aleksandrov–Gurevich–Lazurkin equation has been used[93,100] as the coupling equation to describe thermal stresses and relaxation phenomena in polymers by allowing for the first two terms in the spectrum of relaxation times and for the temperature dependence of the elastic and relaxation constants. The validity of this coupling equation in non-isothermal processes has been demonstrated[93] by comparing theoretical results with experimental data.

It has been shown[93-99] that the additional heat treatment applied to amorphous polymers to improve their strength and their relaxation time and to stabilise their properties allows the frozen (residual) bulk and linear deformations produced by the solidification and cooling of the polymer to relax. The influence of frozen linear highly elastic deformations has been used to explain the "well" and "hump" effects on the dilatometric curves of polymers.

Cracks or weaknesses in articles made from reinforced plastics can appear not only during solidification and cooling but also during subsequent storage under static conditions. To account for this phenomenon the thermal stresses and the relaxation phenomena have been studied[93,100,101] in components made from reinforced plastics. A theoretical model of anisotropic materials was developed to explain the relaxation behaviour of the polymer matrix and its interaction with the filler, and a coupling equation for the reinforced plastic under non-isothermal conditions was obtained. This equation is outwardly similar to the Aleksandrov–Gurevich–Lazurkin equation for homogeneous isotropic polymers, but in this case the highly elastic deformation has a different meaning, since it is explicitly temperature-dependent, suggesting interactions between the matrix and the filler[93, 100,101]. Relaxation phenomena in relatively thin articles (for example, made from glass fibre composites) can produce dangerous radial tensile stresses during isothermal storage, thus increasing the probability of crack formation at this stage[100,101]. In thick cylinders relaxation effects cause a substantial decrease in stress during the cooling and storage stages[101].

The influence of residual stresses and deformations on the mechanical behaviour of reinforced plastics and adhesives has been studied with the aid of discrete models of the reinforced plastic[102-107]. This required the development of an approximate theory of the boundary layer, applicable to contact problems in the mechanics of composites. The approach relied essentially on the postulated presence of an intermediate (boundary) layer between the adhesive and the substrate. Its main advantage is the possibility of obtaining "elastic" solutions in a closed form, accurately satisfying all the boundary conditions. Residual stresses created in the model by a layer of polymer during solidification, cooling, swelling, etc. can easily be calculated. This theory can explain the dependence of the measured mean strength of some model reinforced plastics (for example, glues and adhesives) on the geometry and on the experimental conditions (length and area of the joint, thickness of the layer of binder, fibre diameter, stiffness of the adhesive and of the substrate, degree of solidification, shrinkage, measurement temperature, etc.). Methods of calculating correctly the true strength of these composites have been proposed[105-107].

The problem of optimising the cooling conditions of thick-walled articles made of reinforced plastics by the winding method has been examined as a practical application of the theory of thermal stresses. In the formulation of the problem realistic account was taken of the possibilities offered by industrial production plant[110]. The method chosen to avoid crack formation was to use a non-uniform temperature field during the solidification and cooling of the sample[108-110]. This is a problem in non-linear programming with restrictions: the main difficulty in its solution is the non-linearity of the restrictions on the calculated radial stresses at each point in space and time[110].

The effect of various parameters of the problem on the final result has been analysed. A general feature of all the optimisation regimes obtained for articles made from typical reinforced plastics is the more rapid cooling of the outer than of the inner surface. Most of the regimes are monotonic, a very convenient feature in practice. In comparison to the traditional regimes they offer a saving in time of a factor of 4 or better, and they allow the construction of monolithic articles with a wall thickness 5–6 times greater than previously.

Physical and Physicochemical Effects on the Rheological Properties of Polymers during Processing

M.L.Fridman and E.V.Prut

New principles and processes for the treatment of polymers and polymer-based composites are discussed. The controlled effects of physical and mechanical fields on the rheological properties of polymers are analysed as a promising method of developing new component forming techniques. The following topics are discussed: solid-phase extrusion and hydro-extrusion, the cyclic deformation of melts in shear, the interaction of transverse and longitudinal ultrasonic vibrations, and the preparation of ultra-strong films and fibres.
The bibliography contains 64 references.

I. INTRODUCTION

Developments in the chemical technology of plastics during the past 25 years have included some important advances in the application of physicochemical principles in the synthesis of polymers. For example, the method of synthesis of isotactic polypropylene (PP) has suggested possible ways of obtaining other stereoregular polymers; ultra-high molecular weight polymers with a molecular mass (MM) greater than 10^6 have been produced; the polyamide industry can now offer polydodecaneamide (PA-12); new chlorinated thermoplastics have been developed. Lastly, in the Soviet Union the scientific basis of a new production technology for composite materials has been developed: it consists in chemical filling by polymerisation, giving highly filled polymeric composite materials (HPCM) by direct synthesis. These HPCM are called Norplasts (see Refs.1–3 and the review by D'yachkovskii and Novokshonova on p. of this issue).

The conversion of polymers into articles has been carried out by traditional methods (mainly extrusion, injection moulding and pressing). Developments in manufacturing technology have been in scale rather than in kind: larger-diameter extruders have been produced, and the maximum injection volume and speed of rotation of the feed screw in automated thermoplastic production units have been increased. Equipment now available can produce sheet material in widths of 24 m or more, it can mould articles weighing 10 or even 20 kg, it can draw oriented films 2–5 μm thick now and < 1 μm when current developments have been completed, and it can extrude sheets and slabs more than 20 mm thick. However, these achievements have brought the traditional methods close to their ultimate capabilities, and it is evident that a further increase in the size (and hence in power and raw material consumption) of conventional polymer plant cannot be cost-effective.

Further progress in polymer production is likely to result from intensive rather than extensive developments, relying on new methods of forming the wanted articles with much better productivity and product quality and a saving in raw materials and power consumption. The successful realisation of these aims requires the application of the latest advances in the physical chemistry and mechanics of polymers, in the rheology of continuous media, gas-containing media, and dispersed system, and in mathematical modelling and process optimisation methods. We believe that only this approach can offer the substantial improvements in plastics processing techniques which have for many years been the aim of the large teams of specialists working on these important and complex problems in scientific and industrial laboratories.

This paper reviews the scientific basis of some of the new methods of polymer treatment developed under the general direction of N.S.Enikolopov and in many cases from his personal work and ideas.

II. CONTROLLED INTERACTION OF PHYSICAL (MECHANICAL) FIELDS WITH POLYMERS AS A POSSIBLE WAY OF DEVELOPING NEW PROCESSING METHODS

The processing of polymers usually consists in converting the material into a state capable of viscous flow, giving it the required shape, and fixing this shape by cooling (or hardening) of the melt. The production processes include many physical and chemical transformations of the material, such as degradation and cross-linking of polymers, melting, crystallisation, visco-elastic flow, etc. The analysis and control of the process are further complicated by the simultaneous occurrence of most of these changes, with "overlapping" and mutual interaction, so that the individual effects are very difficult to separate and to study.

The properties of polymeric materials and of the articles prepared from them by traditional methods are controlled by two basic and well understood methods: the addition of a plasticiser, and varying the temperature and formation rate regime. Each of these methods has a number of weaknesses. For example, the control of the rheological and technological properties of the basic material by introducing a plasticiser is limited to a relatively small range of polymers by the loss of strength and increase in cost of the finished article: no satisfactory plasticiser has yet been found for the most important of all thermoplastics (polyolefins). Raising the temperature and formation rate can be considered only if the material is stable towards thermal and mechanical degradation, and the danger of loss of quality of the finished article is ever present. The development of new polymers and the ever-growing range of HPCM have created additional problems, arising from the poor thermal stability and very high viscosity of some of the melts, which limit and often preclude the use of standard methods of component production.

Recent work has shown that an effective method of controlling the properties of the polymer during the production process and of optimising the yield of high-quality articles can be based on the controlled action of physical (mechanical) fields on the material, leading to changes in the parameters of the micro- and macro-stresses in the state of the system[4-8]. By controlling the properties of polymers and of composite materials with an appropriate mechanical stress field at the formation stage we can organise the manufacturing processes in an entirely new way and produce articles with a set of properties not accessible by the conventional technology. There are many new methods of forming, but all are based on the same physical principle: the application of controlled mechanical actions on polymers during the formation process. Under these conditions an additional shear stress contributes to the basic flow of the polymer, and the material develops a complicated stress pattern. This deformation scheme can be applied to both solid and liquid substances.

1. Solid-phase Extrusion and Hydro-extrusion

The extrusion of polymers in the solid state by the simultaneous application of high pressure and shear stresses is being intensively studied[9-11] as a method of producing highly oriented materials. Its advantages over alternative methods of producing such materials include the production of articles with a cross-section of unusual shape and a high rigidity and strength from standard industrial polymers. Thus Enikolopov and co-workers[12] have prepared fibres having a strength and stiffness close to the theoretical maximum by extrusion and drawing of PE and PP polymer mixtures. However, because of the wide molecular mass distribution (MMD) of the initial polymers of technical grade a wide range of strength and stiffness parameters was obtained. A more selective specification of initial polymers, with optimum values of the MM, yielded fibres with mechanical properties almost indistinguishable from the theoretical values.

Solid-phase extrusion followed by drawing has been used[13] with a mixture of two high-density polyethylenes: ultra-high molecular weight (MM = 2×10^6) and ordinary (MM = 6.7×10^4). Fibres with a tensile elastic modulus of $E = 222$ GPa were obtained, equivalent to ~ 92% of the E value for the crystalline polyethylene lattice[14].

The structure and properties of the resulting articles are strongly influenced by the basic parameters of the extrusion process (pressure, temperature, etc.). Therefore one of the most essential contributions to this new method is a detailed study and description of the dynamics of the process in the two basic operating regimes: at constant feed rate and at constant pressure. In the first case the extrusion of solid polymers can be likened to the bulk pressing of metals. However, attempts to apply the theory of metal pressing[15,16] to polymer extrusion proved fruitless, because the model does not allow for the special features of plastic flow and orientation strengthening in polymeric materials.

We have recently proposed[9] a model of the extrusion of amorphous–crystalline polymers which assumes a power law for the increase in strength of the material. The following relationship between the extrusion pressure (p_{ext}) and the maximum elongation of the polymer (λ_{max}) was obtained:

$$p_{ext} = \sigma_0 \frac{1 + k \cot \psi}{m + k \cot \psi} (\lambda_{max}^{m+k \cot \psi} - 1) \qquad (1)$$

where σ_0 is the fluidity limit of the polymer before hardening, k is the coefficient of friction at the metal–polymer interface, 2ψ is the feed angle, i.e. the angle at the apex of the conical draw plate, and m is the hardening coefficient of the polymer.

Eqn.(1) satisfactorily describes the experimental results. We note that the extrusion pressure is strongly dependent on the friction at the metal–polymer boundary. Thus very low pressures are needed in the extrusion of Teflon (a polymer with a very small value of k).

Several ways of lowering the boundary friction (and hence the energy consumption) in solid-phase extrusion can be suggested. Firstly, the inner surface of the forming device can be coated with a layer of fluorinated polymer[17]. Secondly, the hydro-extrusion principle is applicable in principle to solid-phase extrusion. The provision of an intermediate hydro-layer lowers the friction between the forming channel and the polymer being processed. However, the practical use of hydro-extrusion is complicated by the tendency of the liquid (especially at high pressures) to diffuse in the surface layer of the polymer where it can cause undesirable changes in properties[11]. Two other approaches to this problem have been suggested in recent years: the application of high-frequency vibrations to the forming device and the provision of a stratified (two-layer) flow of polymer. We know[18,19] that the coefficient of friction can be markedly decreased by applying vibrations of high enough frequency to one of the contacting surfaces of a friction couple. The application of low-amplitude shear vibrations at ultrasonic frequencies (~ 2×10^4 Hz) to the forming device lowers the dry friction almost to zero[19]. This effect offers a substantial improvement in the quality and speed of solid-phase extrusion, giving high-grade products.

The stratified flow of polymers is the basis of the co-extrusion of two-layer and multi-layer sheets, films, filaments, and fibres. The theoretical foundations of co-extrusion were developed in Refs.8 and 20–23. A new way of exploiting two-layer flow[8,24] has been used successfully to accelerate the formation of highly viscous polymer systems (for example, PE with a MM $\geq 10^6$, and HPCM such as Norplasts). Two-layer or pseudo-two-layer flow is created in the forming device, with the layer of low-viscosity component (~ 200–300 μm thick) in contact with the channel wall while the high-viscosity core constitutes the main material. This flow geometry can be achieved by different methods, for example by injecting a low-molecular-weight polymer into the "dead" zones of the input side of the forming device (the "dead zone supply" method), or by adding a low-molecular-weight component to the polymer composition and pressing the low-viscosity component towards the wall of the forming channel (see Fig.1). As a result, the hydrodynamic resistance of the forming device (apparent, or effective viscosity of the system) is greatly reduced, but the properties of the resulting articles are determined by the main material. The formation process in this case can be treated as a special type of hydro-extrusion in which the liquid is replaced by a melt of low-molecular-weight polymer, by a liquid oligomer, or other low-viscosity substances.

An example of pseudo-two-layer flow is given by the production technology of HPCM based on Norplasts. As often reported[25-27], the low-molecular polyethylene into which the Norplast is injected as a filler concentrate is effectively pressed towards the wall of the forming channel, so that the finished articles consist of a "core" of Norplast and an outer "skin" with a low concentration of filler.

The two-layer and pseudo-two-layer flow method could also usefully be applied to solid-phase extrusion to increase the speed of the process and lower its energy consumption. However, experimental tests are needed to identify possible side effects and to characterise the rheologically important changes in flow patterns.

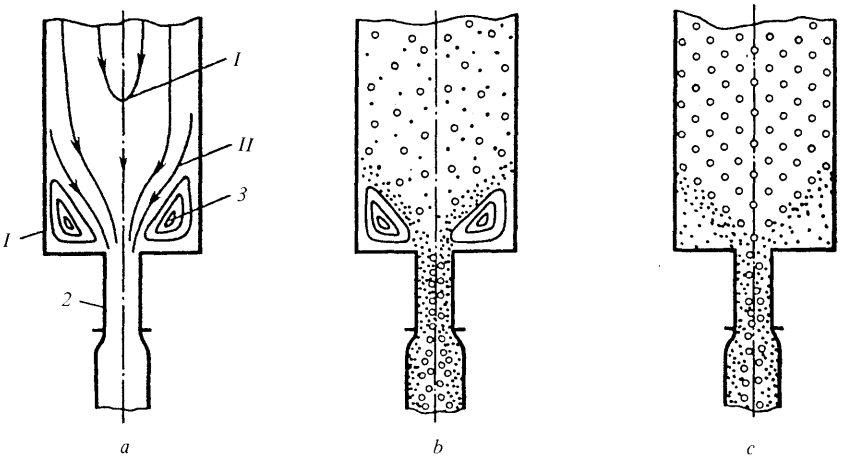

Figure 1. Generation of a two-layer flow in the forming of thermoplastics: (*a*) "dead" zones in the corners of the viscometer cup, (*b*) creation of two-layer flow by introducing a low-viscosity component into the "dead" zone, (*c*) formation of pseudo-two-layer flow by expressing the low-viscosity component from the mixture; *1*) reservoir (or "bomb"), *2*) capillary, *3*) "dead" zone; *I*) line of maximum tensile stress, *II*) line of maximum shear stress[8].

Further developments in solid-phase extrusion should also be aimed at increasing the formation pressure and lowering the formation temperature. These changes should yield materials with improved mechanical properties.

2. Cyclic Shear Deformation of Polymer Melts

Recent work has shown[4-7,28,29] that the complex stress patterns produced in melts by the imposition of additional shear on the basic flow can lower the viscosity of polymeric and dispersed systems. Complex shear can be produced in melts by rotation or by vibration (longitudinal or transverse with respect to the extrusion axis) of the elements of the forming device.

The simplest example of imposed shear is the screw (helical) flow created by forcing the substance through an annular orifice under a constant pressure drop while rotating the cylinders at constant speed (or one of the cylinders, for example the nozzle or the shaft of the extrusion head). An analysis[5,8,30] of helical flow based on the theory of viscous flow[31] has yielded the basic equations for the rheological characteristics of abnormally viscous liquids in terms of the flow conditions and of the geometry of the flow device. The influence of the elasticity of the polymer melts on the extrusion parameters under cyclic shear deformation conditions has been calculated[8,25,30]. The construction and application of extrusion systems with an imposed shear generated by reciprocating rotations of the elements of the forming head (i.e. by low-frequency vibrations of relatively large amplitude) have been discussed in detail[30,31].

Whatever the chosen method of applying the additional shear (rotation of the shaft, reciprocating large-amplitude rotational vibrations, with the moving element located in the pre-inlet chamber or in the forming head itself, and with the vibrations normal to the main flow or coaxial with it) very similar rheological and technological effects are obtained: for a constant drop in pressure in the channels and a constant temperature the viscosity of the polymer and its post-extrusion swelling decrease, and the consumption of liquid and the critical parameters for the onset of unstable flow increase very markedly. For example, in the extrusion of PP reciprocating rotational vibrations of the forming device with an angular amplitude of 22.3° and a frequency of 25 Hz increase the throughput of the extrusion head by a factor of 1.3–1.4,[29] increase the critical flow parameters by 2–5, and lower the swelling coefficient by 1.3–1.5.

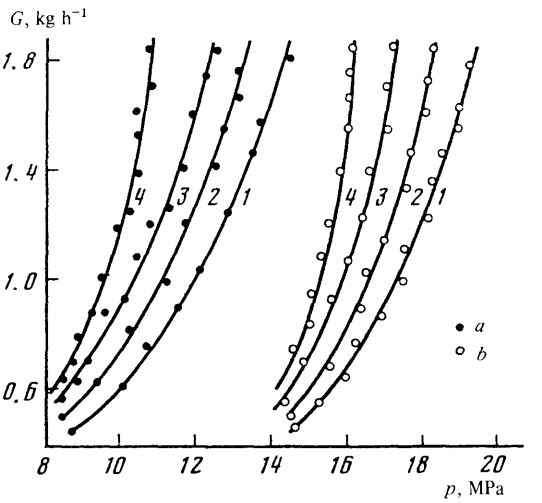

Figure 2. Operating characteristics of the apparatus (plots of the throughput G against the pressure drop in the extrusion head p) for the processing of PP filled with 10 wt.% of chalk (*a*) and 20 wt.% of asbestos (*b*) at 210 °C and different shaft vibration amplitudes: *1*) 0°, *2*) 4.8°, *3*) 11.5°, and *4*) 22.3°[32].

The use of imposed shear is even more effective in high-viscosity systems (for example, filled thermoplastics). Thus in filled polyolefins (30–40 wt.% chalk, carbon black, or asbestos) a 40–80% increase in productivity can be achieved, or if the throughput is kept constant the pressure in the extrusion head can be decreased by at least 20–30% (see Fig.2). Longitudinal vibrations in these melts enhance the orientation effects and produce a slight hardening of the article in the extrusion direction. Reciprocating vibrations of the shaft give a product with isotropic properties, but because of the better homogenisation of the melt the mechanical properties are slightly better (in both directions) than those of the conventionally extruded articles.

We should stress that in spite of the expenditure of power in creating the additional shear by rotation or vibration of the forming elements the overall power consumption of the polymer processing plant is lower (at the highest forming rates) than the power needed to rotate the worm screw in the extrusion through a head (draw plate) with a fixed shaft. Thus forming in the presence of imposed shear may even cause a saving in specific energy consumption[8,29,30]. This effect is most marked in highly filled thermoplastics (for example, asbestos-filled PP[29,32]).

3. Effect of Ultrasonic Shear Vibrations on Polymer Melts

In polymer melts strong vibrational effects can be induced relatively easily by applying high-frequency (ultrasonic, US) vibrations from rod or disk emitters mounted in place of the normal elements of the extrusion head. High-frequency techniques are recommended because the rheological properties of visco-elastic materials are affected by vibrations only above a critical amplitude of the rate of deformation $\varepsilon'_0 = \varepsilon_0\omega$ (where ε_0 is the amplitude of the deformation and ω is the angular frequency), so that at high frequencies we can expect a substantial decrease in effective viscosity[33]. Therefore by using high frequencies we can obtain the desired effect from small-amplitude periodic deformations.

The effect of shear US vibrations has been discussed repeatedly[34–36]. It was shown[37] that the decrease in the largest Newtonian viscosity coefficient of thermoplastic melts produced by US vibrations can be described by the formulae

$$\eta_0 = \eta_{0,0}\exp(-\varepsilon_0/k_1)$$

$$\eta_0 = \eta_{0,0}\exp(-\varepsilon_0'/k_2)$$

Here $\eta_{0,0}$ and η_0 are the largest values of the Newtonian viscosity coefficients in the absence of vibrations (i.e. for $\varepsilon_0 = 0$ and $\varepsilon'_0 = 0$) and in the presence of ultrasound respectively (at a frequency of ~ 20 kHz); k_1 and k_2 are effectiveness coefficients whose value is approximately $k_1 = 1.1 \times 10^{-2}$ and $k_2 = 1100\ s^{-1}$ for a large group of industrial thermoplastics (PVC, PS, PE, and PP).

Using the criterion for the onset of elastic turbulence ($\gamma'_{cr} \cdot \theta_r$) = const (where γ'_{cr} is the critical shear rate and θ_r is the characteristic relaxation time) we can reduce the role of the vibrations to a lowering of the parameter η_0, and hence of θ_r, which allows the parameter γ'_{cr} to rise. Data obtained for polyolefins[8,32,38] confirm that $1/\eta_0$ and γ'_{cr} vary with ε'_0 in the same sense (Fig.3): this conclusion is consistent with the explanation of the effect of vibrations on the rheological properties of melts in terms of a controlled change in the relaxation characteristics, and it also confirms the validity of the assumption that unstable flow is due to a relaxation transition in the polymer.

The use of shear US vibrations in polymer processing technology has been described in detail[8,37,38], and it was pointed out that the new processing method is especially useful in the production of thin sleeve films (up to 10 μm thick) by stabilising the process and giving a product of uniform thickness.

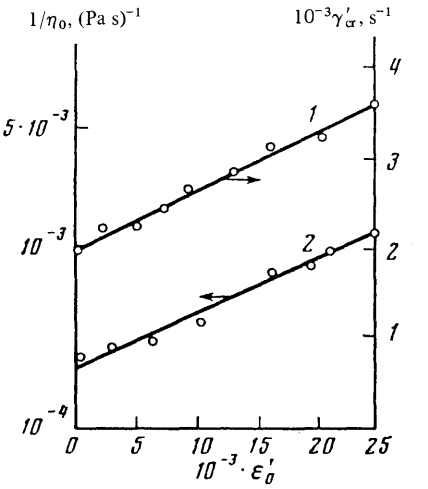

Figure 3. Dependence of the lowest fluidity $1/\eta_0$ and of the critical shear rate γ'_{cr} on the rate of deformation ε'_0 for polyethylene[37].

4. Acoustic Cavitation Phenomena in Fluid Polymers and Compositions Based on Them

The acoustic cavitation (AC) phenomenon is well known in low-molecular liquids, especially in water. However, it has been studied also in solutions of polymers[39–41], and mechanical degradation of the polymer molecules and other secondary effects have been reported for cavitation in low-viscosity solutions. As the viscosity of the liquid increases, we observe a decrease in the mean size and in the rate of growth and collapse of the cavitation bubbles, and the strong secondary effects of cavitation disappear. It was shown both theoretically and experimentally that when the viscosity of the liquid is higher than 1.5–2.0 Pa s the secondary effects of the acoustic cavitation are no longer detectable, i.e. the cavitation is fully suppressed[42,43]. For this reason the acoustic cavitation of polymer melts was not discussed in published papers until recently.

Work carried out between 1978 and 1983 has shown[44–48] that acoustic cavitation can be produced and studied in detail in melts of both model and industrial polymers. It was pointed out that in order to induce cavitation in a melt of a high-molecular polymer the sound pressure level should exceed the bulk strength of the material. Since the strength of a polymer is a minimum in a triaxially stressed state it was reasonable to expect that acoustic cavitation can be excited only by volume US vibrations (as opposed to the shear vibrations considered in the previous Section). For example, in a polymer such as polybutadiene (with a narrow molecular weight distribution and a viscosity coefficient of 10^6 Pa s) the bulk tensile strength is less than 1 MPa,[49] i.e. of the same order as the static bulk strength of ordinary low-viscosity liquids such as water[39], in which AC is relatively easily induced.

By using a special viscometer (with provisions for the application of ultrasound to polymer melts) acoustic cavitation has been detected and its properties have been studied systematically, noting that because of the marked viscoelastic properties of the melts the conditions of formation and the growth and collapse dynamics of the cavitation bubbles are not the same as those in low-molecular low-viscosity liquids.

The AC phenomenon has been observed not only in melts of model polymers (monodispersed polybutadienes) but also in high-pressure and low-pressure PE, PS and PP, and also in HPCM (polyethylene filled with kaolin, chalk, perlite, or glass spheres of average diameter 50 μm[44–48]). Visual observation in ordinary (non-polarised) light and high-speed photography have revealed the formation and growth in an acoustic field of cavitation bubbles which disappear when the source of ultrasound is switched off.

An important experiment was carried out with fluid high-molecular polymers. A small sound pressure detector was embedded in a sample of rubber and connected to an ultrasonic frequency spectrum analyser. It was found that the spectrum of the signal contained, in addition to the fundamental frequency of 17.8 kHz, higher harmonic and subharmonic multiples of this frequency. This phenomenon has been observed many times in ordinary low-viscosity liquids[43], and is typical of AC. It is consistent with the formation in the polymeric liquid of bubbles of resonant size, which suffer strong deformation by the acoustic field and nonlinear changes in the fundamental vibration frequency.

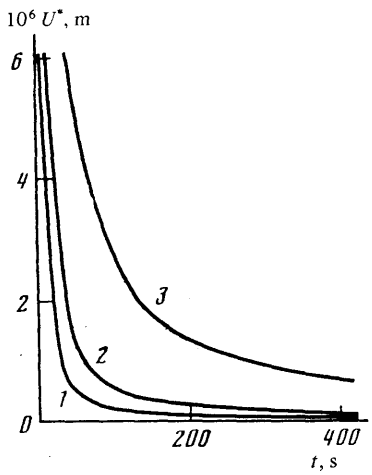

Figure 4. Threshold amplitude of the acoustic vibrations U^* against processing time t of monodispersed polybutadienes of molecular mass MM = 1.6×10^5 (*1*), 3.5×10^5 (*2*), and 5.3×10^5 (*3*)[47].

The following properties and secondary effects of acoustic cavitation in polymer melts have been identified[44–48]. Firstly, the AC is a threshold phenomenon, i.e. each polymer has a characteristic amplitude of acoustic vibrations (U^*) at which cavitation sets in. The parameter U^* depends on time t (see Fig.4), and it is analogous to a long-term strength (durability) function for the polymer[49]. Increasing the MM of the polymer increases its stability towards the formation of AC. The dependence of U^* on t (Fig.4) is described satisfactorily by a power law at low amplitudes of the bulk US vibrations and by an exponential function at relatively large amplitudes:

$$t = A_1 (U^*)^{B_1}$$
$$t = A_2 \exp(B_2 U^*)$$

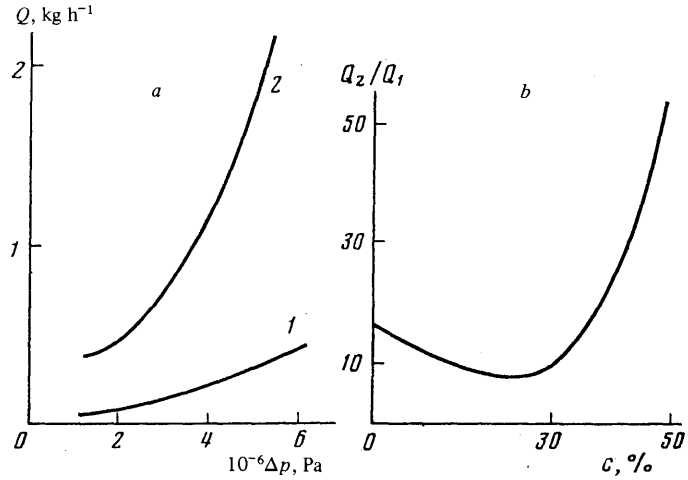

Figure 5. Pressure–flow characteristics of high-density polyethylene (HDPE) melts: (*a*) unfilled HDPE at 264° and acoustic vibration amplitude 0 μm (*1*) and 8 μm (*2*); Q is the flow, Δp is the pressure drop; (*b*) relative flow Q_2/Q_1 (where Q_2 is for the presence and Q_1 for the absence of acoustic vibrations) in HDPE filled with perlite as a function of filler concentration c (temperature 240 °C, amplitude of acoustic vibrations 8 μm)[47].

Secondly, by inducing AC in melts of industrial polymers we can lower the effective viscosity of melts of thermoplastics and HPCM based on them (Fig.5). Depending on the nature of the polymer, on the U^* value, and on other factors, the viscosity can be lowered 5–100-fold, giving a sharp, irreversible increase in the fluidity of the material exposed to the acoustic field. However, this explanation applies only to a part of the increased fluidity (i.e. to the increased throughput). There is a change in the nature (and therefore also in the mechanism) of the flow: the flow collapse phenomenon in the extrusion of the material before exposure to ultrasound is replaced by bubble flow.

Thirdly, in addition to mechanical degradation and changes in the nature of the flow, both of which produce a large decrease in the viscosity of the melt, AC also produces marked changes in the structure of the extruded articles: a decrease in the average characteristic length of the structure elements and a narrower size distribution[48,50], and in the case of filled systems the filler particles become smaller and more uniformly dispersed in the polymer matrix[46,47].

We should stress that the combined effect of these favourable aspects and of the unfavourable mechanical degradation of the polymer matrix caused by the acoustic cavitation is a slight improvement (by 10–20%) in the tensile strength and

in the elongation at break of the extruded articles in comparison to similar articles produced under ordinary conditions[47].

Further studies are needed on the technological aspects of this new phenomenon, which has important consequences in the physics, mechanics, and processing technology of polymers.

5. Production of Ultra-strong, High-modulus, and Ultra-thin Films and Fibres

The preparation of thin and ultra-thin films with the highest possible strength and elasticity from flexible-chain polymers is currently of interest[51]. The main problem is to straighten out the macromolecular chains as far as possible, because this configuration should give an elastic modulus close to the theoretical maximum, though the strength may fall well short of the maximum owing to defects in the structure. Various approaches are possible: multistage film drawing to give an oriented array of chains with the optimum structure, directional crystallisation, setting up a liquid-crystal state in thermoplastics, etc.[51,52].

By developing the concept of orientation by deformation and by applying it in practical systems Enikolopov and coworkers prepared PP films 30–40 μm thick with values of the tensional elastic modulus close to the theoretical maximum[53]: for example, for $\lambda = 28–30$ the mechanical parameters of the films were $\sigma_r = 1.3–1.5$ GPa and $E = 36–43$ GPa.

These results were confirmed by measurements of the velocity of ultrasound (ν_{us}) in polypropylene films prepared with different values of λ.[64] Thus, for $\lambda = 33.7$ and a temperature of 93 K, ν_{us} was 8700 m s^{-1}, a value not previously achieved in oriented flexible-chain polymers. For comparison we note that the ν_{us} value of steel lies between 5 and 6 × 10^3 m s^{-1}, i.e. well below the value for highly oriented polypropylene. The specific elastic modulus E/ρ (where ρ is the density of the polymer) was three times greater for these films than for steel.

These abnormally high mechanical parameters in highly oriented PP can be explained in several ways: the high degree of orientation of the macromolecular chains, the difference in structure between crystalline and amorphous regions (the through chains being more numerous in the latter as well as having a different conformational spectrum), etc.

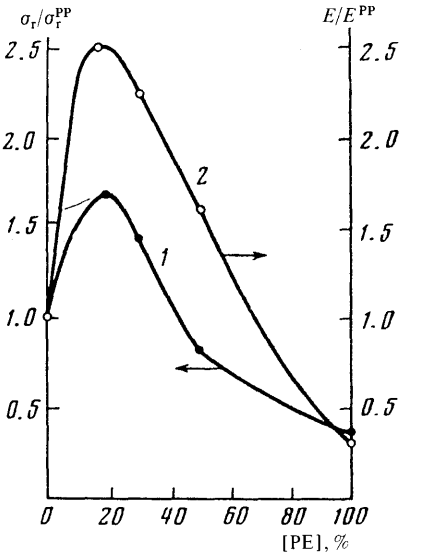

Figure 7. Tensile strength σ_r (*1*) and elastic modulus E (*2*) against composition of PP–HDPE samples for an elongation $\lambda = 15$; temperature of elongation 120–130 °C, σ_r^{PP} and E^{PP} are the tensile strength and the elastic modulus of PP.

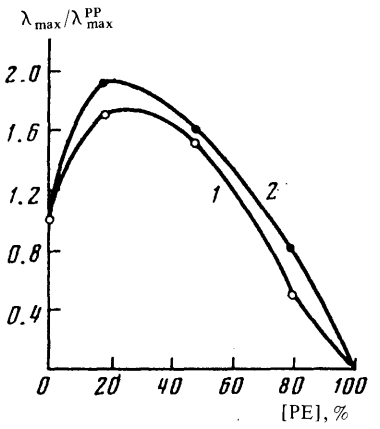

Figure 6. Effect of the composition of PP–HDPE samples on the maximum elongation λ_{max} at different temperatures: *1*) 125, *2*) 145 °C; λ_{max}^{PP} is the maximum elongation of PP.

Polymer–polymer composite materials (PPCM) are another class of potentially useful materials for preparing high-strength, high-modulus thin films. In these films the dependence of the maximum elongation λ_{max} on the composition of the PPCM goes through a maximum (Fig.6). For example, in PP–PE compositions the highest value of λ_{max} is obtained for a PE content of 20–30%. Since the elastic modulus E and to some extent the tensile strength σ_r of the material are monotonic functions of the degree of elongation λ (see, for example, Fig.7) we can expect films with higher values of E and σ_r from PPCM than from single-phase systems.

III. PHYSICOCHEMICAL METHODS OF CONTROLLING THE PREPARATION AND PROPERTIES OF COMPONENTS MADE FROM POLYMERS

Almost any technological process applied to polymer materials is accompanied by a complex set of physical and physicochemical phenomena. This is specially the case when we are concerned not merely with the formation of articles but with developing materials with new and prescribed properties. The approach developed by Enikolopov and his coworkers involves stimulating chemical and physicochemical

changes in the materials by new (non-traditional) methods and studying these changes in polymers and in composite materials under extreme processing conditions.

1. Modification of the Properties of Polymers by High Pressure and Shear Deformation

The processes accompanying plastic flow in polymers under high pressure and shear deformation have been studied extensively in recent years (see the review by Zharov on p.140 of this issue).

One of the most important aspects of this essentially new area in the physical chemistry and mechanics of the solid state is polymer modification. Traditional methods of polymer modification have been reviewed in detail[54,55]. However, the processing of mixtures of polymers and reactive monomers under the combined influence of high pressure and shear deformation offers new possibilities of producing composite materials and articles having specified properties by grafting growing macromolecules onto the polymer matrix. The method can be used, for example, to prepare graft copolymers not available by conventional methods. Thus a conversion of the monomer of ~ 75% has been obtained in studies of the polymerisation kinetics of *N,p*-tolylmaleic imide in a PP matrix, with up to 90% of the resulting polymer grafted to the matrix. As a result of the modification ~ 40% of the composite material was found to be insoluble in boiling tetralin.

It was also shown that forming polymers under these conditions is accompanied by various structural changes (for example, amorphisation and changes in the crystallinity of the lattice[56]), as well as by a large decrease in the molecular weight of the polymer produced by mechano-chemical degradation[57].

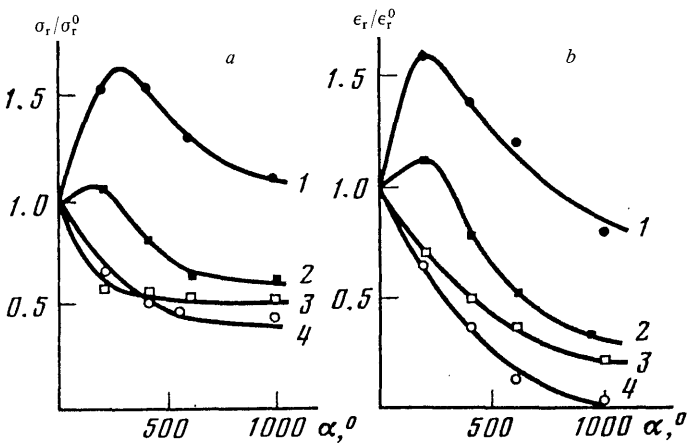

Figure 8. Relative changes in tensile strength (*a*) and in elongation at break (*b*) of samples from PP–SKEP (*1*) and PP–HDPE mixtures (*2*), HDPE (*3*), and PP (*4*), deformed at 10 kbar pressure, as a function of the angle of rotation of the anvil α [58].

The kinetics of these processes are reasonably well described by the relationships usually applied to mechanical degradation processes[41]. We should note, however, that marked differences exist between different polymers: thus in PE mechanical degradation is observed only at pressures above 10 kbar, whereas in PP it sets in at 5 kbar. Lowering the MM of the polymers produces a sharp decrease in fluidity (σ_t), tensile strength (σ_r), and relative elongation at break (ε_r), which converts the fracture from a necking process to a brittle fracture[58].

A very interesting result was obtained in the study of the plastic flow of a mixture of polymers under combined pressure and shear: mixtures of thermodynamically incompatible polymers were found to form a homogeneous system in the amorphous phase under these conditions[59]. As a result the changes in the mechanical properties of the material are not the same as for the homopolymers (Fig.8). We note from curves *1* and *2* of Fig.8 that σ_r and ε_r go through a well defined maximum as a function of the shear deformation in these mixtures for rotation angles of the anvils of 200–300°. The height of the maxima is different in the different polymer systems: for example, in PP–SKEP mixtures the increase in the parameters near the maximum is 60%, but in a PP–PE mixture it is much smaller. We may assume that this marked improvement in the physico-mechanical properties of the mixtures of polymers (as compared with the homo-polymers) is the result of the formation of much smaller and more uniformly distributed heterogeneous phase regions.

The improved understanding of the plastic flow of polymer mixtures under pressure led to the production of high-strength and high-modulus fibres (see above).

To conclude this Section we note that from many points of view (mechanical degradation, decrease in size of the structure elements, amorphisation of the polymers, increased structural uniformity and homogeneity) the effect of combined pressure and shear on polymeric materials is similar to the effect of vibrations, especially the effect of ultrasound in the acoustic cavitation regime. This is consistent with the general principle of using strong physical (mechanical) fields for processing polymers and composite materials.

2. Physico-mechanical and Rheological Properties, and Processing of Polymerisation-filled Plastics (Norplasts)

The principle of polymerisation (or chemical) filling consists in polymerising the appropriate monomer on the surface of a filler (which can be of almost any type: dispersed or filamentary, mineral or organic) after activating its surface with a complex catalyst. This method can be used to produce materials with any desired ratio of polymeric component to filler[1,2].

The wide practical application of these materials (Norplasts) must be preceded by a detailed study of their physico-mechanical, rheological, and technological properties: a series of investigations under the direction of N.S.Enikolopov[25–27,60–63] marks the beginning of this area of research. Because of the multiplicity of the types of material in this new class, of the complexity of their structure, and of their unique properties, extensive and sustained studies are still needed, but some important aspects of the structure and properties of Norplasts have already been established, and the following recommendations for the processing of Norplasts can be formulated.

Whatever the nature of the mineral component, Norplasts are obtained as powders of different particle size. The particles are agglomerates produced by the growing together (or interlinking) of the polymeric coating formed on the

separate particles of the filler. In the Norplasts, therefore, the mineral particles are surrounded by a layer of macromolecules firmly bound to the filler surface by chemical or physical forces. The thickness of this layer is much greater than the thickness of the strengthened surface layers in ordinary filled systems prepared by mechanical mixing of the components followed by granulation on the extruder. The region affected by the presence of the particle of mineral filler is much more extensive in Norplasts than in mixed composites of a similar composition.

At very high filler contents (> 80 wt.%) the Norplasts with a polymeric component of MM $\cong 10^6$ show only elastic deformation. The material develops a tendency to flow only if the amount of "coat" is increased to 40–60% (depending on the MM of the polymer), but a further increase in the amount of polymer (to 80%) does not affect the viscosimetric and extrusion behaviour of Norplasts.

Some interesting effects were observed in studies of the thermal expansion of Norplasts. The temperature dependence of the linear expansion coefficient $\alpha = \Delta l/(l\Delta T)$ (where l is the length of the sample, Δl and ΔT are the increments in length and temperature respectively) includes two maxima: the first at 125–135 °C, corresponding to T_m for the polymeric material, and the second at 180–190 °C. The height of the first peak decreases when the amount of polymer in the Norplast is decreased, and the height of the second peak increases; furthermore, the first peak corresponds to an endo-effect, and the second to an exo-effect. The nature of the second maximum in the $\alpha(T)$ curves is still not fully understood, but we may assume it to be related to the detailed structural features and morphology of the polymeric "coat"[27].

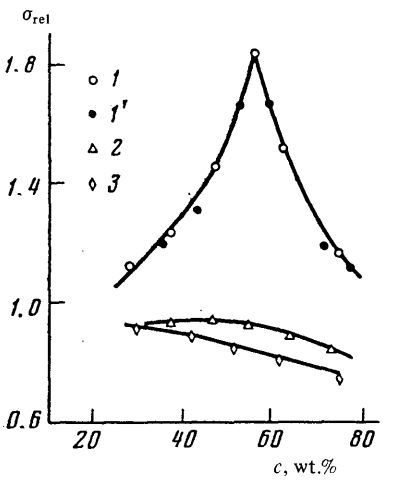

Figure 9. Relative strength ($\sigma_{rel} = \sigma_c/\sigma_m$) of materials as a function of the content of tuff c; compositions with Norplasts containing 12.5 wt.% PE and tuff of average particle size 8 μm (*1*) and 17.2 wt.% PE and tuff of average particle size 80 μm (*1'*); *2*) are model compositions prepared by mixing PE, filler, and ultra-high-molecular-weight PE, 3) are ordinary mechanical mixtures[27].

Structural and morphological studies of the intermediate layers near the filler particles and near the particles of Norplast introduced into a matrix of polyethylene by mechanical mixing have revealed the changes in the number and size of the crystals as a function of distance from the particle surface. In composition containing the pure filler the size of the perturbed region was comparable to the effective radius of the particle, whereas for Norplast it was comparable with the size of the bonded polymer layer. We note that similar effects are observed when the surface of ordinary fillers is treated with dressing compounds. In this sense the Norplast can be described as a filler dressed with a high-molecular-weight polymer of the same nature as the matrix of the main polymer. Since the wear of the equipment is not decreased but is actually made worse by ordinary dressing compounds this method of "dressing" by polymerisation is to be preferred in polymer processing.

The use of Norplasts containing 80–90 wt.% of mineral component as fillers for thermoplastics in the production of HPCM may be technologically preferable to the direct synthesis of the material with the required filler content.

Data obtained so far justify the following conclusions[27]:

a) irrespective of the nature of the mineral filler and of the PE matrix, in Norplast compositions the strength (maximum tensile stress) goes through a maximum as a function of filler content (Fig.9);

b) the strength of the Norplast composites is equal to or greater than the strength of the basic PE over practically the whole range of filler concentration in the material (30–70 wt.%);

c) the relative elongation at break of a HPCM containing Norplasts is close to that of the basic polymer at the fluidity limit, whereas it is lower in ordinary mixed compositions;

d) for a fixed content of the mineral component in composites the strength characteristics increase with the amount of polymeric component (i.e. with the thickness of the "coat") in the Norplasts;

e) the specific shock viscosity of materials filled with Norplasts is higher than for ordinary mixtures of the same composition;

f) the wear of the parts of the processing plant is much lower for HPCM containing Norplasts than for mechanical mixtures with conventional fillers.

A systematic study of the rheological (viscous, and viscoelastic) properties of these new materials[25,27,60–62] has shown that for a fixed shear stress (τ) the relative viscosity of the compositions $\eta_{rel} = \eta_c/\eta_m$ (where η_c and η_m refer to the composition and the matrix polymer respectively) is uniquely determined by the content by volume of Norplast in the mixture, and that for a fixed filler content the viscosity of the system increases with the amount of polymeric component in the Norplast used as a filler concentrate.

We note that undesirable "blocking" effects (with formation of a "stopper" of filler at the mouth of the forming channel) do not take place during the extrusion of Norplasts, though they are common in the pressing of ordinary HPCM mixtures.

The addition of fillers to linear polymers produces flow collapse (Fig.10) even if the effect is absent in the base material[26,27,60]. Increasing the concentration of filler or decreasing the length of the channel and the volume of material in front of the channel tends to convert the pressure–flow curves from characteristic hysteresis loop curves into flow curves with a break. The effective value of the stress τ_{cr} or of the flow Q_{cr} corresponding to the onset of collapse decreases as the concentration of filler in the system increases, but the effect is slight and for practical calculations the parameter τ_{cr} can be assumed to have the constant value 2.5×10^5 Pa.

Lastly, in all HPCM (whatever the nature of the matrix and of the filler) a sharp increase in the pressure drop at the inlet is observed over a well defined range of temperature and strain rate (the Bagley correction). In the case of the Norplasts the increased loss of inlet pressure for a given concentration of mineral filler sets in at lower extrusion rates, as shown in Fig.11. Typically, the sudden step in the loss of inlet pressure occurs at τ values corresponding to the flow collapse in linear PE.

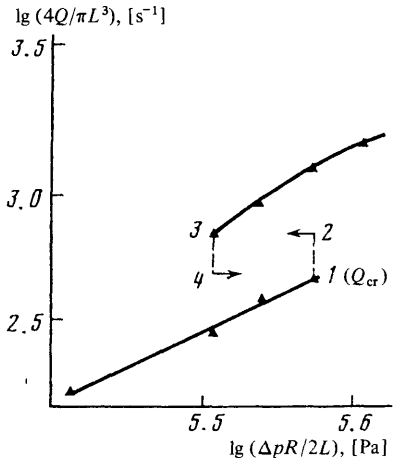

Figure 10. Flow curve for a PE composition containing 30 wt.% of perlite introduced as a Norplast; capillary size 1 mm × 30 mm, temperature 200 K. Point *1* (Q_{cr}) corresponds to the onset of pressure self-oscillations of amplitude equal to the distance between lines *1–2* and *3–4*; the arrows denote the onset of flow collapse (Q is the flow, Δp is the pressure drop, R is the channel radius, and L is the channel length)[27].

The addition of Norplasts to compositions lowers the swelling of the extruded product very considerably, thus assisting the production of shaped articles with improved dimensional tolerances.

Equations and procedures for predicting the viscosity properties of composites filled with Norplasts have been proposed[25–27,61].

Thus recent work has demonstrated the value of Norplasts as components of HPCM offering a prescribed set of properties. This allows us not only to improve the strength characteristics but also to decrease the wear on the extrusion devices (as compared with similar compositions prepared from mechanical mixtures by the traditional technology). The processing of these materials should be carried out in equipment with forced feed (single-screw extruders with a channelled sleeve in the load region, or double-screw extruders) with an attachment for degassing the melt. As in the processing of mixed compositions, the extrusion machinery must have a high-power drive as compared to the extruders for pure polymers.

Further work on these materials should be aimed at the structural and morphological properties of composites containing Norplasts and at determining their long-term stability. We can hope that new materials with a high long-term stability (durability) will emerge from current work on polymerisation filling.

There is little doubt that important advances in the industrial treatment of plastics can be expected from the more general application of mechanical and acoustic fields to polymers in the viscous liquid or the solid state.

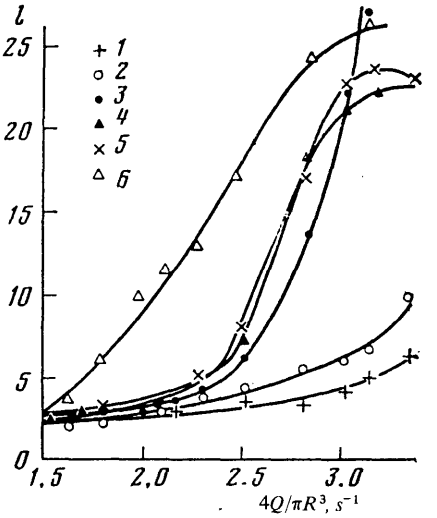

Figure 11. Dependence of the inlet effect (length of the inlet region l) on the normalised volume flow for PE–Norplast (perlite) compositions with different concentrations of filler: *1*) 0, *2*) 10, *3*) 20, *4*) 25, *5*) 30, *6*) 40 wt.%; temperature 180 °C[27].

The Combustion of Polymers and the Mechanism of Action of Fire-proofing Agents

N.A.Khalturinskii, T.V.Popova, and A.A.Berlin

The sequence of stages involved in the combustion of polymers—ignition, flame propagation, and burn-out—has been examined. The limits of existence of the flame and the role of radiation in combustion processes have been discussed. The influence of halogen- and phosphorus-containing fire-proofing agents on the combustion processes has been analysed. The promising possibilities provided by micro-encapsulated fire-proofing agents have been demonstrated.
The bibliography contains 130 references.

I. INTRODUCTION

Polymers are finding increasing application in various branches of the national economy, but in a number of fields the increase in their use is being held back because of the increased fire hazard associated with materials based on them. This applies particularly to polymers in building, transport, the electrotechnical industry, and other fields. Thus the problem of decreasing the combustibility of polymers and the development of non-combustible materials based on them is one of the most important tasks in polymer chemistry.

Most work aimed at lowering the combustibility of polymeric materials has been and is being carried out on the basis of an empirical search for fire-proofing additives. In recent years, under the direction and with the active participation of Academician N.S.Enikolopov, fundamental studies have begun and are being successfully continued in the Soviet Union in the field of the combustion of polymers and the mechanism of the action of inhibitors. The results of these studies make it possible to formulate the principal ways to reduce the combustibility of polymers and to create non-combustible materials based on them.

The sequence of phenomena in the combustion of polymers can be represented by a scheme which shows that the combustion of polymers is a complex multi-stage process which maintains itself and is controlled by mass and heat transfer[1-4]. The products of the transformation and gasification of polymers are various hydrocarbons[1], so that the diffusion combustion of polymers is largely analogous to the combustion of gaseous and liquid hydrocarbons.

The combustion of polymers is a process that develops with time. Five basic stages in the development of this process can be distinguished: ignition, flame propagation, combustion itself, smoke formation, and collapse of the flame[5]. It is possible to distinguish provisionally five spatial zones in the combustion of polymers: a polymer heating zone, a zone

of chemical transformations in the condensed phase, a zone under the flame, the flame itself, and a zone of reaction products and oxidant[1].

From the above qualitative scheme for the combustion of polymers, it is possible to reach preliminary conclusions about the paths leading to a lowering of the combustibility of polymeric materials. These are primarily an increase in the heat of gasification L, a decrease in the supply of heat to the polymer by increasing the heat losses or by decreasing the heat of combustion Q or by lowering the temperature of the flame by diluting it with non-combustible thermal degradation products[1,3]. It is usually assumed that the formation of a carbonised residue insulates the polymer from heating by the flame[4]. Smoke formation indicates incomplete combustion of the fuel and a decrease in the heat of combustion, and also makes it possible to reach qualitative conclusions about the degree of combustibility of polymers[6,7]. The chemistry of the processes taking place in a polymer gas flame is extremely complex, and has still been insufficiently studied. This question has been dealt with in a number of recent publications[1,8].

The mechanism of the influence of inhibitors on the various stages of the combustion of polymers has not yet been finally resolved. Generally speaking, only qualitative schemes for the action of fire-proofing agents have been published. In this connection, the study of the regular features of the combustion process, and the influence of fire-proofing agents and gas-phase inhibitors on this process and on reactions in diffusion flames in general, is of considerable scientific and practical interest. The aim of the present review is to examine work published up to the present on this problem, and to summarise the results obtained.

II. PROCESSES INVOLVED IN THE IGNITION OF POLYMERIC MATERIALS

The development of theories of flame production and ignition began with the thermal theory of explosion developed by Frank-Kamenetskii[9]. Because of the variety of polymeric materials and the conditions of their application, it is possible in practice to have ignition processes of different types, which do not fit into the framework of a single sufficiently simple theory. The ignition process is often determined by an induction period, during which the surface layer of a substance is heated to a temperature determined by the conditions of stationary combustion, with simultaneous initiation of the combustion of the gaseous products of the thermal decomposition of the polymers.

Since up to 80% of fires arise from low-calorie sources[1], it is appropriate to pay particular attention to the ignition of polymers by these sources. At the present time there are many theories of ignition to describe systems reacting in the condensed phase[10], but these theories cannot explain the observed practical dependence of the ignition process on the conditions of the surrounding gaseous medium and do not take account of the probability of endothermic reactions involving degradation of the polymer in the condensed phase. The models of ignition in the gas phase published up to the present are one-dimensional models in which the source of the oxidant is the surrounding gaseous medium, and the source of the fuel is the products of the gasification of the solid polymer.

The ignition process is initiated by the transfer to the polymer of the heat from the source, which may be an electric discharge, a heated body, a burner flame, etc. In contrast to theories of the ignition of a condensed fuel, in the case of the ignition of polymers it is necessary to bear in mind that: 1) when a thermal flux acts on a polymer, its gasification begins at a rate which depends on the thermal flux power[14]; 2) the temperature at the polymer surface (T_s) is determined by the thermal decomposition conditions[11]; 3) the products of the thermal decomposition of the polymer mix with the oxidant, forming a "previously mixed" mixture; 4) when the gaseous phase reaches critical conditions, ignition of the mixture takes place[12], that is exothermic oxidation reactions are initiated; 5) the relaxation time of the processes taking place in the gas phase τ'' is extremely short compared with τ', that is the relaxation time (the time of the change in the heat distribution in the condensed phase): $\tau'/\tau'' \cong 10^4$;[13] 6) the time of ignition delay, that is the attainment of conditions in which ignition has taken place in the gas phase and the polymer specimen is able to burn in the absence of the source, is determined by the time taken to create the necessary heated layer in the condensed phase[14].

When an ignition source acts on a polymer and the resulting mixture of oxidant and thermal decomposition products, the initiation of the wave of the chemical reaction in the gas phase takes place in accordance with the theory of the ignition of a hot mixture by heated surfaces[12] in the case where the removal of heat from the heated surface (q_*) reaches a critical value, defined by the relationship

$$q_*^2 = 2\lambda'' \frac{RT_s^2}{E} Qk_s e^{-E/RT_s}$$

where λ'' is the thermal conductivity of the gas phase, T_s the temperature of the heated surface, E the effective activation energy of the reactions, Q the heat of the reaction in the gas phase, and k_s the pre-exponential factor in the expression for the rate constant of the chemical reaction. The right-hand part of the expression for the thermal flux contains the kinetic characteristics of the chemical reaction taking place in the gas phase; the quantity q_* is determined by the conditions of heat exchange between the hot wall and the surrounding gas. As a rule, when polymers are ignited by heated solids, there is produced (as a result of natural convection) a stream of gas which flows over the heated surface. The field of flow of the gas stream is determined by the rate of flow and the shape and characteristic dimensions of the solid.

Table 1. Values of the parameters of the ignition process for a number of polymers*.

Polymer	T_i, °C	OI	T_{fp}, °C	T_{sfp}, °C
Polyformaldehyde	975	15.1	—	—
Polystyrene	1002	18.1	296	491
Polymethyl methacrylate	1050	17.5	280—300	450—462
Polyethylene	1055	17.4	341	349
Polyamide	1075	25	421	424
Polycarbonate	1176	28	—	—
Polyvinyl chloride	1260	45	391	454

*T_i values from Ref. 13; OI, T_{fp}, and T_{sfp} from Ref. 16.

Table 1 gives experimental data on the temperature of the surface of a heated solid $T_s = T_i$, where T_i is the temperature at which ignition of the degradation products of the

polymers takes place under conditions of identical heat exchange. For comparison, Table 1 gives the values of the oxygen index (OI), the temperature of flame production T_{fp}, and the temperature of spontaneous flame production T_{sfp}. The limiting characteristics, that is the OI values characterising the combustion process, change in the same sense as T_i, which determines the kinetics of the chemical reactions in the gas phase. The values of T_{fp} and T_{sfp} are apparently integral characteristics which include the thermophysical characteristics of the material, the geometric dimensions of the specimen and the compartment, the flow rate, etc., so that there is no direct correlation between these values and T_i.

Since in some branches of industry polymeric materials are used at increased concentrations of oxygen in the atmosphere, it is important to discuss the dependence of the ignition temperature on the oxygen concentration. The data in Fig. 1 [13,14] show that in mixtures enriched in fuel, the ignition temperature decreases with increase in the oxygen concentration; at an oxygen concentration in the mixture greater than the stoichiometric concentration, T_i is independent of the oxygen concentration ($[O_2]$).

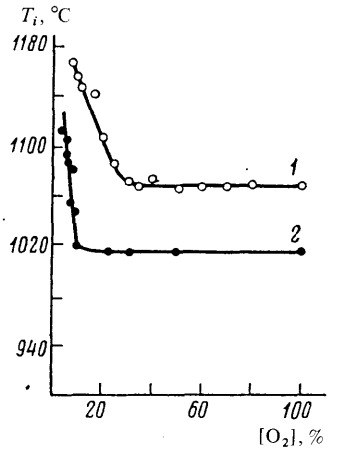

Figure 1. Dependence of the ignition temperature of the polymer on the oxygen concentration: *1*) polymethyl methacrylate[13,14]; *2*) polyoxymethylene[13].

Another characteristic determining the ignition of the material is τ_i, the time taken to create a heated layer, or the ignition delay time. With the assumption that the condensed phase is chemically inert[15], the necessary condition for ignition was found, namely that at the temperature of the polymer surface T_s the temperature gradient should not be greater than that given by the expression:

$$\frac{dT}{dx} = \frac{\rho' C_p''}{\lambda'} \frac{2RT_s^2}{E} \cdot \frac{u'}{e}$$

The ignition delay time[15] is given by

$$\tau_i = \frac{(T_s - T_0)\, EC_p'}{2RT_f^2 C_p''} \cdot \frac{\varkappa' e^2}{(u')^2}$$

where C_p'' and C_p' are the heat capacities of the gas and condensed phases respectively; ρ', λ', and $\varkappa'$ the density, thermal conductivity, and temperature conductivity of the condensed phase respectively; T_f the flame temperature, and T_0 the temperature of the polymer.

The heat required to create the heated layer is calculated using the equation

$$q_i = \frac{(T_s - T_0)^2 C_p'}{2RT_f^2 C_p''} \cdot \frac{\rho' e}{u'}$$

The regular features observed[15] cannot be transferred completely to the case of the combustion of a polymer, since, firstly, no account was taken of the endothermic reaction of thermal decomposition in the condensed phase and, secondly, during ignition the ignition source (for example a heated body) is present in the flame zone.

The conditions of existence of a stationary combustion front have been found[17] from an examination of the conditions of preservation of the mass fluxes of the oxidant and the fuel and the preservation of the thermal flux. The model examined includes a diffusion flame in the gas phase, the endothermic reactions of thermal decomposition in the condensed phase, and the production of the heated layer. Using these data[17], the present authors found that the ignition delay time is proportional to the temperature conductivity of the polymer $\tau_i \cong \text{const}\, \varkappa_1$, as in the expression obtained in Ref. 15. In addition, the data[17] were used to obtain the dependence of the ignition delay time on the oxygen concentration in the surrounding medium:

$$\ln \tau_i \simeq -2 \ln [O_2] + \text{const}$$

These conclusions are confirmed by experimental data on the dependence of the ignition delay time on the thermophysical characteristics of the polymers and the concentration of oxidant in the stream[13,18,19].

III. REGULAR FEATURES OF THE COMBUSTION OF POLYMERS

After stationary combustion conditions have been established close to the ignition source, depending on the conditions of the surrounding medium (the oxygen concentration, pressure, temperature, the velocity of the incoming flux), the thermophysical and thermochemical properties, the geometry of the specimen, etc., two cases may be realised. The flame either is localised or extends over the surface of the polymeric material, leading to an increase in the combustion region and the complete covering of the burning material by the flame. Since the consequences of a fire depend on the size of the combustion region, considerable attention has been paid in the literature to the separate topic of flame propagation[20-33].

Since an exact solution of the two-dimensional problem of flame propagation is not possible, a number of approximate models exist. The problem of the propagation of a flame over the surface of a polymeric material is usually divided into two cases. The first case corresponds to the propagation of the flame over the surface of a specimen of the polymeric material, the thickness of which is much greater than the thickness of the heated layer. These materials are usually classified as thermally thick fuels. The second case is when the thickness of the polymer specimen is comparable with the thickness of the heated layer; these are thermally thin materials. In addition, the exchange of heat between the flame and the polymer surface depends markedly on the direction on the rate of flow of oxidant relative to the rate of flame propagation[20,21].

Thus in De Ris' model[28], flame propagation over thermally thin and thermally thick fuels is examined with the assumption that for thermally thin fuels, heat transfer from the flame through the gas phase predominates, and that for thermally thick fuels, heat transfer takes place through the condensed and gas phases without allowance for the radiation from the flame. For thermally thin layers, the rate of propagation of the flame reaction is inversely proportional to the thickness of the layer of fuel

$$v = \frac{\sqrt{2\lambda'}}{\rho' C_p' \delta} \cdot \frac{T_f - T_s}{T_s - T_0}$$

where 2δ is the thickness of the layer of fuel. For thermally thick specimens, the following expression was obtained:

$$v = \frac{\rho'' C_p'' \lambda'' v_a}{\rho' C_p' \lambda'} \left(\frac{T_f - T_s}{T_s - T_0} \right)^2$$

where v_a is a parameter defining the rate of the incoming flow of oxidant.

Subsequently, models of flame propagation were proposed[29,32], in which the solutions of the equations of heat and mass cotransfer for the gas and condensed phases are examined, and subsequently combined; the dependence of the rate of flame propagation on the parameters of the medium and the characteristics of the polymer obtained in this way are given below. For thermally thin polymers:

$$v = \frac{\lambda' Q_c [O_2] f(p, [O_2])}{L \rho' C_p' (T_s - T_0)}$$

For thermally thick polymers:

$$v = \frac{[\lambda'' Q_c [O_2] f(p, [O_2])]^2}{\lambda' \rho' C_p' C_p''^2 (T_s - T_0)^2}$$

Here, Q_C is the heat of combustion of the polymer, p the pressure, and $[O_2]$ the oxygen concentration in the stream. These empirical relationships were confirmed experimentally[33]; the relationships obtained do not make it possible to obtain a physical picture of the process, however.

Solution of the equations of the thermal balance in the edge of a propagating flame (with the assumption that the transfer of heat from the flame to the polymer takes place as a result of convective heat exchange and radiation) [30,34] gave the following expressions for the rate of propagation of the flame over thermally thin fuels[34]:

$$v = \frac{1}{C_p' \rho'} \left(\frac{\lambda'}{\beta \delta} \right)^{1/2} \left[\frac{2(T_f - T_s) + Q_r}{T_s - T_0} \right]^{1/2}$$

and thermally thick fuels:

$$v = \frac{\alpha (T_f - T_s) + Q_r}{\beta \rho' [L + C_p' (T_s - T_0)]}$$

where α is the heat exchange coefficient, L the heat of gasification of the polymer, Q_r the thermal flux of radiation from the plane, and β a coefficient relating the rate of propagation of the flame to the rate of linear thermal decomposition in the nose of the flame. The expressions obtained contain in explicit form the dependence of the rate of propagation of the flame on the parameters of the external medium and the characteristics of the polymer. Although this model is approximate, it effectively describes the published experimental data.

To characterise the combustion of polymers under the conditions of the stationary (relative to the surface) diffusion edge of a flame (for example the combustion of polymers in a counter-current of gaseous oxidant, when a planar flame is created), Spalding introduced the parameter B (the Spalding number), which characterises the intensity of heat and mass exchange in the system and arises in the solution of the equations of heat and mass transfer at the phase boundary[1]. In the case of convective and molecular heat transfer, the parameter B is defined by the equation

$$B = \left\{ \frac{[O_2]}{r} \cdot Q_c - C_p'' (T_s - T_0) \right\} / L$$

where r is the stoichiometric coefficient of the oxidation reaction.

The rate of diffusion combustion ($\dot{m}$) in this case is given by the expression

$$\dot{m} \simeq \ln(1 + B)$$

The parameter B is an important characteristic for estimating the degree of combustibility of materials, and methods have been developed for calculating it for various materials by the treatment of experimental data on combustion for the configuration of a planar flame with sweeping by the oxidant from above downwards in a counter-current flame[35-38]. The values of the parameter B have been determined[37] for various polymers with sweeping of the flame by a stream of oxidant, and account has been taken of the contributions of various mechanisms of heat transfer to the quantity B for combustion in air and in oxygen (see Table 2).

Table 2. Values of the transfer parameter B for various polymers[37].

Polymer	Parameter B	
	in air	in oxygen
Polymethyl methacrylate	1.38	13.6
Nylon 6-6	1.2	14.0
Polyvinyl chloride	0.9	7.0
Polypropylene	0.67	11.6
Polystyrene	0.6	9.4
Low-density polyethylene	0.58	10.3
High-density polyethylene	0.55	9.7
Untrated cardboard	0.51	4.5
Cardboard containing 16% inhibitor	0.41	3.8
Cardboard containing 25% inhibitor	0.17	2.2
Maple	0.16	2.1

IV. LIMITS OF EXISTENCE OF A DIFFUSION FLAME FOR POLYMERS

A number of studies have shown that the products of the transformation of polymers and gaseous and liquid hydrocarbons in the zone under the flame are practically the same[1,40-44]. Collapse of the polymer flame takes place in the gas phase for the same reasons as in gaseous diffusion flames.

The foundation of the theory of diffusion combustion was laid by Burke and Schumann[12], who were the first to examine the problem of the combustion of coaxial parallel gaseous streams of fuel and oxidant. It is suggested that the chemical reaction in the flame takes place infinitely rapidly (much more rapidly than diffusion), and the form of the flame is determined by the rate of diffusion. In this model, the flame represents an infinitely thin surface with the oxidant on one side and the fuel on the other; the fluxes of oxidant and fuel reaching the flame are in the stoichiometric ratio. Hottel and Hawthorne[45] were the first to confirm experimentally the concept of the flame as a combustion surface with the fuel on one side and the oxidant on the

other. The calculated temperature of the flame in the reaction zone coincides with the adiabatic temperature of the previously mixed mixture of fuel and oxidant.

The conclusion that limits of a diffusion flame exist was first reached by Zel'dovich[46], who solved the one-dimensional problem of the combustion of complex streams of fuel and oxidant moving in opposite directions. With increase in the intensity of the fluxes of fuel and oxidant reaching the flame zone, the latter becomes broader (assuming a single-stage chemical reaction with a finite rate) and the temperature of the flame zone decreases to the minimum possible value (T_f^*):

$$T_f^* = T_f - 3RT_f/E$$

Collapse of the diffusion flame takes place because the chemical reaction, whose rate is exponentially dependent on temperature, is not fast enough to process the substance (fuel, oxidant) reaching the flame and cooling it, and this leads to further cooling and extinction of the flame. Collapse of a diffusion flame may take place similarly with a constant flux of oxidant and decrease in the concentration of oxygen in it. In practice, a diffusion flame is colder than predicted by theory[12], since an important role in the thermal balance is played by heat losses as a result of radiation into the surrounding medium, not usually taken into account in the theory.

In the analysis of the limiting conditions of a diffusion flame, it is convenient to use the parameter: $\mathrm{Dam} = \tau_d/\tau_c$, where Dam is the Damkohler number, τ_d the characteristic diffusion (convection) time, and τ_c the characteristic time of the chemical reaction[12].

A simplified form of the expression for the Damkohler number for a diffusion flame has been given[8]:

$$\mathrm{Dam} = \tau_d \cdot [\mathrm{F}] \cdot [\mathrm{O_2}] \cdot \frac{B}{[\mathrm{O_2}]} \cdot e^{-E/RT}$$

where τ_d has the same order of magnitude as the ratio l/w in the case of forced convection (l is the characteristic dimension, and w the rate of sweeping) or l^2/D in the case of diffusion; D the coefficient of mutual diffusion of the fuel and the oxidant; and [F] the concentration of the fuel. Collapse of the flame takes place at $\mathrm{Dam} = \mathrm{Dam}_{cr}$.

This expression, in particular, leads to a number of possible methods for inhibiting combustion by collapse of the flame[8]: 1) isolation of the fuel and a consequent decrease in its concentration in the flame; 2) decrease in the concentration of oxidant; 3) cooling of the condensed fuel and oxidant; 4) inhibition of homogeneous and heterogeneous reactions; and 5) increase in the rate of sweeping of the flame by the oxidant.

All these methods in the final analysis are directed towards a decrease in the flame temperature; instead of the condition for collapse of the flame $\mathrm{Dam} = \mathrm{Dam}_{cr}$, where Dam_{cr} is the value of the Damkohler number at the combustion limit, it is possible to consider the condition $T_f = (T_f)_{cr}$, where $(T_f)_{cr}$ is the flame temperature at the combustion limit[8]. On the basis of this equation, in the case where the value of $(T_f)_{cr}$ and the other necessary parameters of the system are known, it is possible to calculate the limiting conditions for the flame from the thermal balance equations[8].

The theory of the limits of a diffusion flame was subsequently developed[41-44] for polymers undergoing degradation and gasification without a residue, for the configuration of a planar diffusion flame. It was shown[47-51] that there is a relationship between the limiting conditions of combustion of polymeric materials and heat losses of different kinds. Equations were obtained, describing the influence on the critical conditions of convective and conductive heat losses and heat losses due to radiation, and the phenomenon of "break-through" of the fuel and oxidant through the flame zone as a result of incomplete combustion was calculated theoretically.

Another approach to the determination of the limiting conditions of the combustion of polymers, based on the thermal balance equation, is possible. Thus a model of the candle-like combustion of polymers has been examined[52] and made the basis of an experimental method for determining the limiting minimum oxygen concentration supporting candle-like combustion under conditions of natural convection.

V. HEAT TRANSFER BY RADIATION AND ITS INFLUENCE ON THE COMBUSTION OF POLYMERS

The role of radiation in diffusion combustion was first pointed out by Blinov and Khudyakov[53], who studied the dependence of the rate of combustion of the fuel under conditions of natural convection in air on the characteristic dimension of the combustion region. Beginning from a diameter of the combustion region of ~20 cm, the mechanism of the transfer of heat from the flame to the fuel changes from convective to radiative heat transfer[8]. Radiation from the flame on the one hand leads to increase in the supply of heat to the polymer and to an increase in the rate of combustion of the polymer and the rate of flame propagation, and on the other hand to a decrease in the flame temperature as a result of heat losses to the surrounding medium, a decrease in the width of the flame zone, and a decrease in the conductive and convective heat transfer.

Table 3. Various parameters* of the combustion of polymers in air under conditions of natural convection[55].

Polymer	T_f, K	$Q_{r.f}$, W cm^{-2}	Q_{con}, W cm^{-2}	$Q_{r.s}$, W cm^{-2}	$10^4 m$, g cm^{-2}s^{-1}	γ
Polyoxymethylene	1400	5	17.5	6.7	6.5	1.0
Polymethyl methacrylate	1400	20.1	7.62	10.7	10.5	0.85
Polyacrylonitrile	1350	28.7	6.84	18.2	8.5	0.87
Polystyrene	1190	37.2	2.9	14.6	14.5	0.57

Notation: $Q_{r.f}$ is the radiation heat flux to the polymer, Q_{con} is the convective heat flux from the flame to the polymer, $Q_{r.s}$ is the thermal radiation from the polymer surface, and γ is the degree of completeness of combustion.

There have been a number of studies of the influence of radiation on the combustion of polymers. Thus the influence of radiation on the combustion of polymethyl methacrylate in air has been analysed theoretically for the case of a one-dimensional flame of small dimensions[54]. An important role is played by radiation from the polymer surface, which is responsible for heat losses and heating of the flame. Completeness of combustion has practically no influence on the rate of burn-out of the polymer, since with decrease in the completeness of combustion there is a simultaneous decrease in the stoichiometric coefficient of the oxidation. The influence of the oxygen concentration in the stream on the intensity of the radiation from the flame has been analysed[56]. Table 3 shows that polystyrene, which is characterised by the lowest degree of completeness of combustion and the greatest radiation from the flame, burns

much more rapidly than other materials. For all polymers except polyoxymethylene, heat transfer to the polymer by radiation predominates; an important role in the combustion process is played by the re-emission of heat from the polymer surface. Because of the large heat losses due to radiation, the flame temperature for polystyrene has the lowest value.

Radiation from the surface also plays an important role in the case of polymers which burn with the formation of carbon. The temperatures in the condensed phase during the combustion of wood under the conditions of a planar counter-current flame have been measured[8]. A temperature of 1870 K is developed on the surface of hot wood with sweeping by an oxidant mixture containing 53% oxygen at a rate of 115 cm s^{-1}. Under these conditions, the chief mechanism of the losses, as in the combustion of coal, is thermal loss by radiation from the polymer surface, which leads to a decrease in the combustion rate. Usually, a temperature of 700–800 K is developed on the surface of wood under fire conditions, and the radiation power can reach 0.6 W cm^{-2}.

VI. MECHANISM OF THE INHIBITION OF DIFFUSION FLAMES BY HALOGEN-CONTAINING INHIBITORS

The diffusion flames of hydrocarbons are convenient model systems for the study of the mechanism of the inhibition of the combustion of polymers in the gas phase. Up to the present, however, there has been no unified view of the nature of the inhibition of diffusion flames of hydrocarbons by various chemical additives. It has been correctly pointed out[57] that the kinetics of a reaction in a flame of a mixture of gases and in a diffusion flame of the same gases are not necessarily identical. The basic difference in a diffusion flame is the existence of zones under the flame and after the flame. The zone under the flame is characterised by a relatively low concentration of oxygen (or its absence), a high concentration of fuel, a sufficiently high temperature, and a diffusion flux of free radicals from the flame. As a result, conditions are created in the region under the flame which are characteristic of gas mixtures rich in fuel, in which various processes are possible, leading to a change in the actual composition of the fuel and the inhibiting additive passing into the flame zone. When the oxidant contains additives, analogous processes of their transformation with the participation of radicals diffusing from the flame zone are possible. This may explain the difference, with respect to the reaction of inhibiting additives, in the behaviour of a diffusion flame and a previously mixed flame.

The action of halogen-containing additives can be considered in detail, since the amount of published data is greatest on this topic. There are two approaches to the explanation of the action of halogen-containing additives in flames—chemical and physical[58]. The chemical approach was first proposed by Fryburg[59]. A typical scheme for the chemical mechanism of inhibition[58] is given below for the addition of HBr to a previously mixed flame, where the radical H$^\cdot$ (O$^\cdot$, OH$^\cdot$) is replaced by the less active radical Br

$$\text{Fuel} + O_2 \rightarrow CO_2 + CO + H_2O + Q$$

Chain propagation and branching

$$OH^\cdot + CO \rightarrow CO_2 + H^\cdot$$
$$OH^\cdot + CH_4 \rightarrow H_2O + CH_3^\cdot$$
$$CH_3^\cdot + O_2 \rightarrow CH_2O + OH^\cdot$$
$$H^\cdot + O_2 \rightarrow OH^\cdot + O^\cdot$$

inhibition:

$$HBr + OH^\cdot \rightarrow H_2O + Br^\cdot$$
$$HBr + O^\cdot \rightarrow OH^\cdot + Br^\cdot$$
$$HBr + H^\cdot \rightarrow H_2^\cdot + Br^\cdot$$
$$HBr + CH_3^\cdot \rightarrow CH_4 + Br^\cdot$$

regeneration of inhibitor

$$Br^\cdot + CH_4 \rightarrow CH_3^\cdot + HBr$$

The efficiency of the action of halogen-containing inhibitors increases in the order F < Cl < Br < I.[58] This provides evidence in support of the chemical mechanism of inhibition. A large number of studies of mixed systems have shown that small quantities of added halogen-containing inhibitors (several mole %) decrease by a factor of ten or more the rate of propagation of the flame and have a marked influence on the limit of flame production[60].

The inhibiting action of halogen-containing compounds is generally related to the formation of the compounds HX (where X is a halogen atom) and their subsequent participation in inhibition according to the scheme given above. It has been pointed out[58], however, that the introduction of small quantities of a halogen-containing inhibitor into a polymer has little influence on the limiting conditions of combustion of the polymer (on the magnitude of the oxygen index OI). A decrease in the OI of the polymer by several units requires the introduction of up to 15–20 mass % of halogen-containing inhibitors[61].

Larsen and Ludwig[58] give data which support the so-called "physical" mechanism of inhibition, that is simple dilution of the hot system by the inhibitor and decrease in the temperature of the flame. Experiments to determine the minimum quantity of inhibitor which must be added to a previously mixed gaseous mixture of air and hydrocarbons to prevent flame propagation in this mixture showed that the concentration of halogen in the mixture is ~70 mass %, irrespective of the type of inhibitor and fuel. F, Cl, Br, and I were found to be equally effective in this comparison, in contrast to the usual method of comparison from the number of moles of inhibitor required for collapse of the flame. These results were confirmed for diffusion flames[62]. Petrella and Sellers[62] determined the concentration of inhibitor from the mass at the combustion limit; the measurements showed that, irrespective of the type of inhibitor (CF_2Cl_2, CF_2ClBr, CF_3Br) and fuel (C_3H_8, n-C_4H_{10}), the halogen concentration was 76.9 ± 2.2 mass %. This result indicates that in a comparison of the concentration of halogens in the flame from the mass, different halogens are almost equally effective, and that the mechanisms of the inhibition coincide to a large extent for mixed and diffusion flames.

The role of halogen-containing inhibitors introduced into a polymer reduces to increasing the mass of polymer which must be gasified to obtain the same fuel flux[58]. A number of studies have shown, however, that it is impossible to attribute the action of inhibitors entirely to an inert diluent, that is to a decrease in the adiabatic temperature of the flame. Thus the efficiency of many inhibitors depends on the total pressure in the system, although a number of exceptions to this rule have been found[63].

Studies of the action on the diffusion flames of halogen-containing inhibitors added to the gas phase are examined below. There are two familiar flame configurations in these experiments—with a parallel stream (Burke–Schumann burner) and with a counter-current of fuel and oxidant.

These configurations differ in the gas-dynamic parameters of the flame. Systems with a parallel stream are characterised by long residence times of the fuel in the zone below the flame, and lower convection in the direction of the flame; in these systems, however, the existence of partial mixing of the fuel with the oxidant at the point of origin of their boundary, that is at the cold wall, is not excluded. In counter-current systems, there is always convection in a direction perpendicular to the flame, which influences the concentration of the reagents and the distribution of temperature in the flame. When allowance is made for these possible differences, the conclusions from the experiments of the two types show fairly good agreement.

The inhibition of diffusion flames by halogen-containing compounds was first studied by Simmons and Wolfhard[64]. The critical concentration of CH_3Br added either with the fuel or with the oxidant, leading to collapse of the flame, was determined under conditions of a coaxial stream of fuel. The number of molecules of inhibitor at which collapse of the flame begins was ~20–30 times smaller when the inhibitor was added with the air than when it was added with the fuel. Studies of the influence of inhibitors on a flame with a coaxial configuration[65,66] confirmed the conclusion[64] that the efficiency of an inhibitor is greater when it is added with the air than when it is added with the fuel.

Friedman and Levy[67] give the dependence of the volume concentration of an inhibitor added with the fuel to a flame at the combustion limit on the rate of flow of the oxidant. In this comparison, the efficiency of the inhibitors decreased in the order $CF_3Br > CH_3Br > CCl_4 > CH_3Cl \gg N_2$. Comparison of the volume concentrations of combustion inhibitors should be supplemented by a comparison of the heat capacities of the fluxes of the gases introduced into the flame, as was done in Ref.58.

The influence of halogen-containing inhibitors on hydrocarbon and hydrogen flames has been studied spectrographically[68]. The introduction of the inhibitor decreases the luminescence of the OH and HCO radicals and increases the luminescence of the C_2 radical and carbon black, and the temperature of the flame decreases with increase in the concentration of the inhibitor.

A counter-current method has been used to compare the efficiency of different inhibitors[69] by determining the dependence of the concentration of inhibitor (mole %) in the air or the fuel required for collapse of the flame on the rate of sweeping of the flame. The fact that in this comparison CF_3Br is slightly more effective than CF_2ClBr, in spite of the higher heat capacity of the latter, indicates that the action of the inhibitors is chemical in character.

The influence of the inhibitor CF_3Br on the diffusion combustion of polymethyl methacrylate and its monomer under conditions of sweeping by a counter-current of the flame has been studied[44]. The inhibitor was introduced with the oxidant. The authors' suggestion that a better model of the diffusion flame of a polymer is obtained when the inhibitor is introduced with the oxidant appears doubtful, since in the combustion of a polymer, an inhibitor moving in the gas phase reacts with the gasified fuel in the zone under the flame. The introduction of CF_3Br into the flame with the oxidant led to the appearance of a luminous flame zone on the fuel side, and the colour of the flame changed from blue to bluish-green. This was due to the radiation of the carbon black and its precursor C_2 (emission in the green range, in accordance with Ref.64). An important result obtained by Seshadri and Williams[44] was the detection of the presence of oxygen at the boundary of a luminous flame. The introduction of an inhibitor into the flame increased the break-through of oxygen into the zone under the flame. The increase in carbon black formation, in the authors' opinion, is due either to the products of the transformation of the inhibitor or an increase in the concentration of oxygen under the flame. The increase in the break-through of oxygen through the flame may be due to a decrease in the temperature of the flame and the consequent decrease in the reaction rate in the flame zone. In the presence of CF_3Br, however, there is practically no decrease in temperature at the combustion limit.

The influence of C_2H_5Br, CCl_4, and $CHCl_3$ on a previously mixed and diffusion counter-current acetylene–air flame has been studied spectrographically[70]. The introduction of inhibitors into a diffusion flame increases in the spectrum the intensity of the emission bands of C_2 and decreases the intensity of the OH bands. The following mechanism has been proposed for the action of Cl-, Br-, and I-containing inhibitors[63]. The inhibitors introduced into the flame increase the formation of carbon black, on whose particles absorption of molecular oxygen can subsequently take place. In fact, this should decrease the concentration of oxygen in the flame and lead to a decrease in the reaction rate, and a decrease in the parameters of the limiting conditions. The authors cited[63] did not observe a change in the concentration of the OH radical in the flame in the presence of inhibitors, and this does not agree with published data. Moreover, their hypothesis that there is a decrease in the oxygen concentration in the flame is not confirmed experimentally and is contradicted directly by the data in Ref.44.

In a number of papers on the combustion of polymers (for example Refs.71–74) it is suggested that halogen-containing inhibitors "operate" in the gas phase in the same way as in gas flames. The action of halogens on combustion was attributed[73,75] to a decrease in the rate of the reactions and a decrease in the flame temperature. However, in Ref.76, which gives data on the combustion of mixtures of polymethyl methacrylate and chlorinated polyethylene, it was established that (in contrast to the gas phase, where Cl plays the role of inert diluent[58]) with the participation of Cl in the degradation processes in the condensed phase, carbon black, apparently formed by the removal of Cl in dehydrochlorination reactions, may accumulate on the polymer surface.

VII. PHOSPHORUS-CONTAINING COMBUSTION INHIBITORS

In addition to compounds of the halogens, compounds of P, B, N, and various metals of the type Sb and As are used as combustion inhibitors. Phosphorus compounds are more frequently used than the others; the possible mechanisms of their effect on the combustion of polymers, formulated in a review[77], are given below.

1. The effect on processes in the condensed phase, an increase in the non-burning residue, and a decrease in the quantity of fuel reaching the flame; the influence on the heterogeneous oxidation of coke.
2. The formation of a surface vitreous or viscous molten layer of high-boiling phosphoric acids, which prevent the processes of diffusion of the fuel and heat transfer.
3. Inhibition of gas-phase reactions.

The specific mechanism of the action of phosphorus-containing fire-proofing agents depends on the nature of the polymers. Thus when introduced into polyethylene, which does not form a residue on degradation, phosphorus compounds operate in the gas phase, but in epoxide compositions they operate by the first two of these mechanisms[78,79]. Some authors suggest that only phosphorus(V) compounds are active inhibitors[77], although other data[80] indicate that

amorphous red phosphorus is also a fire-proofing agent. The efficiency of inhibitors has been related to the way in which they are introduced into the polymer[81].

Analysis of published data shows that although the mechanism of the action of phosphorus-containing compounds in the condensed phase on the whole is not clear, its principal characteristics can be distinguished. Thus in cellulose materials in the presence of fire-proofing agents there is an increase in the yield of carbon as a result of dehydration[1]. Coke is formed according to the following hypothetical scheme:

$$(C_6H_{10}O_5)_x \rightarrow 6xC + 5xH_2O \quad .$$

A gas-phase mechanism of the action of phorphorus compounds in the combustion of polymers has been proposed[81,82]. Thus it has been suggested[82] that in the flame there is heterogeneous destruction of radicals on P_2O_5 particles formed during combustion; this lowers the reaction rate in the flame and leads to a decrease in its temperature.

On the whole, the question of the mechanisms of the action of phorphorus-containing inhibitors remains open. A number of effects have not yet been explained. For example, it has been shown[82] that in spite of the increase in the limiting characteristics of the combustion of polymethyl methacrylate inhibited by phorphorus compounds, the rate of burn-out of the material away from limiting conditions increases. None of the published mechanisms of the inhibition of the combustion of polymers can explain this fact. As noted in a number of publications, in the inhibition of the combustion of polymers by halogen- and phosphorus-containing compounds there is an increase in carbon black formation, smoke formation, or coke formation. Smoky sooty flames are highly luminous, and in them an important role is played by heat transfer by radiation[8]. In the combustion of carbon-forming polymers, a change from a gaseous diffusion flame to heterogeneous oxidation is possible; high temperatures are developed in the upper layer of the condensed phase of the burning polymer[37], and this may also lead to powerful radiation from the surface of the burning polymer.

VIII. CARBON BLACK FORMATION IN THE COMBUSTION OF POLYMERS

The mechanism of the formation of carbon black in diffusion flames is attracting the attention of many research workers[83-92]. A general scheme of the processes leading to the formation of carbon black in flames has been described[1]. Five stages in this process have been distinguished [90]: 1) the formation of nuclei of carbon black (the radicals $C_2^{\cdot}$ and $C_2H^{\cdot}$, polyaromatic radicals) as a result of thermal decomposition reactions in the zone under the flame with the participation of $H^{\cdot}$, $O^{\cdot}$, and $OH^{\cdot}$ radicals from the flame; 2) the formation of larger carbon black nuclei by a mechanism of the radical polymerisation and recombination type; 3) aggregation of the carbon black nuclei to form larger particles; 4) the development of surface growth of the carbon black particles; and 5) heterogeneous burn-out of the carbon black particles in the flame.

Stages 1 and 2 take place by a radical-chain mechanism. In stages 3 and 4, an important role is played by ionic processes[91]. There are other models of carbon black formation, but for these there is less experimental justification[93]. In the last stage, an important role is played by the degree of dispersion of the carbon black formed in the zone under the flame. The more finely dispersed the carbon black, the greater its surface area and the more actively it is oxidised in the flame.

The diffusion flames of methane and ethane at the combustion limit are blue, and carbon black is not formed; with increase in the oxygen concentration in the oxidant, there is an increase in the temperature of the flame, leading to an increase in the thermal decomposition of the fuel and carbon black formation[56]. This effect is also observed in the combustion of polymers, and the degree of completeness of the combustion of the fuel in the flame decreases with increase in the oxygen concentration[94]. The influence of various Br and Cl compounds on the formation of carbon black in diffusion flames of hydrocarbons has been studied[85,86]. Br compounds, when supplied to the diffusion flame with the fuel or with the oxidant, facilitate carbon black formation, but Cl compounds do not lead to any significant increase in carbon black formation. The apparent mechanism of this effect[85] is that the introduction of halogens into the flame lowers the concentration of $OH^{\cdot}$ radicals, and this in turn leads to an increase in the concentration of carbon black nuclei. The participation of the halogen-containing compounds in the stage involving the initiation of carbon black formation is not excluded. A similar effect is observed for various phosphorus compounds, for example $POCl_3$.[95]

IX. MICRO-ENCAPSULATED FIRE-PROOFING AGENTS

The most widely encountered fire-proofing agents, phosphorus- or halogen-containing compounds, are in most cases extremely toxic substances, which volatilise or seep from the material during its processing and use. It is for this reason that in recent years a new and promising method has been developed for introducing fire-proofing agents into polymeric materials in the form of micro-capsules. As a result of micro-encapsulation, the fine particles of liquid, solid, or gaseous fire-proofing agents introduced into a polymer covering are isolated from the surrounding medium, but retain the properties of combustion inhibitors.

By using an appropriate covering material, it is possible to stabilise and even improve the physicomechanical properties of a polymer composition, since the fire-proofing agent in this case simultaneously acts as a modifier. The use of micro-encapsulated fire-proofing agents (MFA) makes it possible to create materials with a working surface enriched in the fire-proofing agent, which increases its fire-resistance without a significant change in the physicomechanical properties. In addition, it becomes possible to use as fire-proofing agents substances which in non-encapsulated form are unsuitable for these purposes, for example water, and also substances with a low boiling point or a high toxicity. Moreover, it is possible to use in micro-encapsulated form fire-proofing agents which in the usual form are incompatible with the polymer matrix.

Micro-encapsulation methods are provisionally classified as chemical and physical. Phase separation methods are based on phase transformations in polymer solutions. The encapsulated substance is dispersed in the polymer solution, after which phase separation is initiated by changing the temperature, the pH of the medium, or the concentration of the components. As a result, the polymer separates from solution and is adsorbed on the particles of encapsulated substance, forming a micro-covering round them. Polymer encapsulation methods are based on the polymerisation or polycondensation of monomers or pre-polymers on the particles of the substance being encapsulated. Physical methods of micro-encapsulation use centrifuges, spray apparatus, etc. Phase separation and polymerisation methods are usually employed for the micro-encapsulation of fire-proofing agents.

The best known fire-proofing agent, containing phosphorus and halogen atoms, is tris(2,3-dibromopropyl) phosphate

$$(BrCH_2—\underset{\displaystyle Br}{\underset{|}{CH}}—CH_2—O—)_3—PO$$

which is a toxic liquid, obtained by brominating allyl alcohol and the subsequent reaction of the 2,3-dibromopropanol with $POCl_3$. This is one of the most widely encountered fire-proofing agents, used for polyalkenes, polyesters, polyurethanes, and polystyrene[96]; a number of methods for its micro-encapsulation have been patented[96–101]. The micro-capsules are obtained by aqueous-phase separation (covering material melamine–formaldehyde[97], urea–formaldehyde[97], polysiloxane[100], dextrin[96]) or by polymerisation, again in an aqueous medium (covering material polyurethane[98–100] or copolymers of ethylene with methacrylyl chloride[100] or of styrene with divinylbenzene[101]). Micro-capsules of tris-(2,3-dibromopropyl) phosphate have been used in fire-resistant carpets[97], paints, and polyurethane foam[102,103], and to impregnate fabrics to increase their fire resistance[100].

Methods for the micro-encapsulation of tris(2,3-dichloropropyl) phosphate[98,99], tris(1-chloro-3-bromoisopropyl) phosphate[101], and tris(1-bromo-3-chloroisopropyl) phosphate[101] have been patented. Methods have also been described for micro-encapsulating tricresyl phosphate, red phosphorus, ammonium phosphate, and other phosphorus-containing compounds. Tricresyl phosphate, an oily liquid, is micro-encapsulated in polyurethane[98,99,101], polymethyl methacrylate[101], and gelatin[104] coverings. Red phosphorus, which has found extensive application as a fire-retarding agent in many polymeric materials, has the disadvantage that at the temperatures of the processing of plastics in the presence of residual moisture it is capable of forming the toxic phosphine. The use of this fire-proofing agent in micro-encapsulated form prevents the formation of phosphine; a number of methods exist for the micro-encapsulation of red phosphorus[105–108].

When 10% of micro-encapsulated phosphorus is introduced into a polymer, the OI of the polyamide† increases by five units, and that of polyterephthalate, polypropylene, and polystyrene by approximately two units[106].

Of the halogen-containing fire-proofing agents, compounds containing chlorine and bromine have been most widely used. Bromine-containing compounds are generally more effective, although they are more toxic[96]. On the one hand, they bring about better initiation of the decomposition of the polymer chain, and on the other hand the hydrogen halides formed in the region before the flame are inert diluents and lower the flame temperature. Moreover, halogens can intensify carbon black formation in the flame. The following are now used in micro-encapsulated form: 1,1,2,2-tetrabromoethane[96,97,99] to obtain self-extinguishing polyurethane foam, 1,2-dibromoethane[96], and chloroalkanes containing 12–72% chlorine[102,110], which are used as fire-extinguishing additives to polyalkenes, polystyrene, natural rubbers, etc.

Micro-encapsulation makes it possible to use as fire-proofing agents substances which cannot be used at all in non-encapsulated form. These are primarily compounds with a low boiling point—Freons and low-boiling hydrocarbons. Methods have now been developed for micro-encapsulating tetrafluorodibromoethane, trichlorotrifluoroethane, and tetrachlorodifluoroethane, by aqueous-phase separation[103,111].

†The OI was determined by the published method[109].

The micro-encapsulation of water and aqueous solutions of fire-proofing agents is of particular interest. The method of phase separation in ternary water–oil–water emulsions and the method of interphase condensation and polymerisation are most frequently used for these purposes. Water is micro-encapsulated in the form of dilute solutions of salts such as sodium and potassium aluminates, borates, etc.[112–122] to obtain a stable double covering, or in the form of concentrated solutions of water-soluble fire-proofing agents (ammonium phosphates, chloride, and bromide). Micro-encapsulated water or its solutions are used as filler to decrease the combustibility of fibres, films, etc. The micro-capsules obtained, with diameter ~5 μm, contain 68 to 75 mass % water, and its concentration remains unchanged after treatment under normal conditions for one week or on heating to 100 °C for 1 h;[20] the external appearance of the micro-capsules also remains unchanged.

The conditions of the processing of polymeric compositions containing MFA (temperature, pressure) should be such that the covering of the micro-capsules does not break down in the process. The material of the covering should be inert with respect to the components of the polymer composition, or should react with the polymer or its components, leading to an increase in the strength of the coverings of the micro-capsules and in the strength of their attachment to the polymer.

The addition of polystyrene micro-capsules containing water or sodium metaphosphate has been recommended for the production of fire-resistant polyurethane[119]. Micro-encapsulated Freon-113 has been recommended for this purpose[123]. A method has been developed for obtaining fire-resistant cast polymer compositions containing an encapsulated inorganic filler and micro-capsules containing water[124]. These compositions are used to prepare plastics with a high mechanical strength, which can be used as constructional materials.

The migration of a fire-proofing agent from a polymer matrix has been studied in specimens containing dextrin micro-capsules with a 90% concentration of 1,1,2,2-tetrabromoethane[96]. When the specimens were kept at 100° for 20 h, the concentration of MFA decreased by 5%, and that of the non-encapsulated fire-proofing agent decreased by 99% (that is it volatilised practically completely).

The combustibility of an epoxide binding agent based on ED-20 epoxide resin, hardened by polyethylene polyamine and containing MFA, has been studied[125]. The fire-proofing agents used were tris(2,3-dibromopropyl) phosphate and Freon-$318B_2$ (polyvinyl alcohol covering). Micro-capsules with a diameter smaller than 200 μm were used; the mass fraction of the fire-proofing agent in the micro-capsules was 85–98%. Estimation of the fire-extinguishing action of the fire-proofing agents studied[125] showed that their efficiency decreases in the order: tris(2,3-dibromopropyl) phosphate > Freon-$318B_2$ > Freon-$114B_2$. The value OI = 40 is reached on the addition of 50, 60, or 70 mass % of these additives respectively, and the limiting oxygen concentration c_{lim} = 40% is reached for 65–74 mass % of the additive. The action of tris(2,3-dibromopropyl) phosphate as an MFA is shown in the condensed phase in the same way as in the case of the non-encapsulated fire-proofing agent[126].

To determine the mechanism of the action of MFA, the influence of the type of fire-proofing agent, the material of the covering, and the size of the micro-capsules on the temperature at which they open in pure form and in a polymer matrix was studied[127–129], and the efficiencies of the action of fire-proofing agents added to the polymer matrix in the free form and as micro-capsules were compared. The fire-proofing agents studied were carbon tetrachloride,

trichloroethyl phosphate, tris(2,3-dibromopropyl) phosphate, Freons 114-B_2 and 318-B_2, water, etc. Polyvinyl alcohol, gelatin, and polyurea were used as the covering of the micro-capsules, and an epoxide matrix was usually employed as the polymer matrix.

At a heating rate of 10 K s^{-1}, the temperature at which the micro-capsules open coincides with the temperature at which intensive decomposition of the material of the covering begins. Irrespective of the type of fire-proofing agent and the size of the micro-capsules, the temperatures at which they open for coverings of polyvinyl alcohol, polyurea, and gelatin are 210–240, 200, and 70–85° respectively[129], and the range of temperatures in which opening of 80% of the micro-capsules of fractions of the same size takes place does not exceed 10 K.

Fire-proofing agents can be divided into two classes, according to the type of opening of the micro-capsules. The first class consists of low-boiling liquids such as Freons, CCl_4, H_2O, etc., which are characterised by the fact that at the moment of opening, the liquid in the covering is greatly superheated, and when the opening temperature of the micro-capsules is reached they "explode", accompanied by a sharp decrease in the mass of the specimen; the second class consists of high-boiling liquids [fire-proofing agents such as tris(2,3-dibromopropyl) phosphate, trichloroethyl phosphate, etc.] or solid substances. A characteristic feature of MFA of the second class is that with increase in the temperature of the specimen, a smooth decrease in its mass takes place.

The mechanism of action of fire-proofing agents of the second class, added to a polymer matrix, will be considered first. When the material is heated, the micro-capsules open, and the fire-proofing agent is transferred to the polymer melt in the surface layer of the specimen. The presence of the fire-proofing agent in the thermal decomposition zone intensifies the process of carbon formation on the surface of the burning polymer, and this in turn leads to a change in the conditions of heat and mass exchange between the polymer surface and the flame. When the thermal balance is broken down, the combustion of the polymer stops. With increase in the concentration of the fire-proofing agent there is a smooth increase in the OI. The efficiency of MFA of this class is the same as that of the same fire-proofing agents in the free state. A significant increase in the OI values for these systems can be obtained only by adding large quantities of fire-proofing agent (up to 30–40 mass %) to the polymer composition. The addition of this quantity of fire-proofing agent in the free form is not possible, since it would seep from the polymer matrix; the use of MFA solves this problem.

For MFA of the first class, for which the opening of the covering of the micro-capsules is accompanied by critical phenomena ("micro-explosions"), the liquid at the moment of opening of the micro-capsules is highly superheated. The stable superheated state of the liquid inside the covering is apparently due to the absence of nuclei for vapour formation. When the decomposition temperature of the material of the covering is reached, defects are produced in it, leading to breakdown of the micro-capsule. The "micro-explosion" which accompanies the breakdown of the micro-capsule is stronger, the greater the superheating of the liquid. If the liquid in the capsule is not superheated and its boiling point is higher than the temperature at which the material of the covering begins to decompose, gradual decomposition of the latter takes place, with slow evaporation of the liquid.

Fig.2 shows that the addition of low concentrations of a low-boiling MFA to the polymer does not lead to a change in its decomposition temperature. A sharp decrease in the temperature at which decomposition starts takes place at a concentration of ~2 mass % MFA in the specimen. At this concentration, the so-called dispersion effect begins to appear. The size of the dispersed particles of the polymer and the rate of their removal depend on the strength of the "micro-explosion". In the "micro-explosion", the particles of the polymer are torn from the main mass and removed from the flame zone, without burning. For an increase in the MFA concentration by more than 3%, the temperature of the start of the decomposition remains constant and equal to the temperature at which the degradation of the covering of the micro-capsule begins, and is independent of the type of matrix[129].

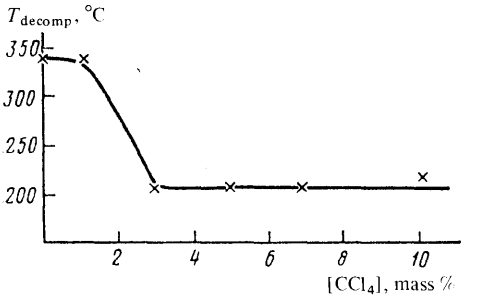

Figure 2. Influence of the concentration of micro-encapsulated fire-proofing agent (CCl_4) on the temperature of the start of the decomposition of the polymer matrix T_{decomp}.[129]

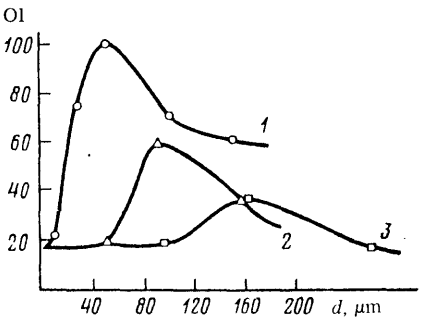

Figure 3. Influence of the size of the micro-capsules (d) and the type of MFA on the efficiency of the inhibition of the combustion of the epoxide composition ED-20 + polyethylenepolyamide: *1*) CCl_4, *2*) Freon-318B_2, *3*) Freon-114B_2, MFA concentration 7 mass %.[128]

A study of the combustibility of epoxide polymers in the presence of MFA using the published methods for determining the OI [109] and for estimating the minimum ignition

energy[130] showed that with increase in the percentage dispersion of the polymer there is an increase in its OI and ignition temperature, that is a decrease in the degree of combustibility. It was also established that the size of the micro-capsules has a significant influence on the efficiency of the decrease in the combustibility of the polymer in the presence of the MFA (Fig.3), and the maximum value of the OI is observed for different diameters of the micro-capsules, depending on the type of fire-proofing agent[127]. In spite of the complexity of the physical mechanism of their action, the use of fire-proofing agents in micro-encapsulated form provides an extremely effective method for reducing the combustibility of polymeric materials, and there is no doubt that the development of this field of the chemistry and technology of polmers is promising.

Thus an analysis of the data given in the present review indicates that in the development of methods for decreasing the combustibility of polymers it is necessary to pay particular attention to the structure of the polymer and the interaction of the inhibitor with the polymer and to take account of the reactions involved in the degradation in the condensed phase of the polymer and the inhibitor and the transformations in the gas phase.

Published data indicate the following principal ways of reducing the combustibility of polymers: 1) the addition of carbon-forming catalysts to the polymer. Depending on the type of polymer, these may be metal salts, phosphorus-containing compounds, halogen-containing compounds with antimony oxide, etc. When carbon is formed on the surface of a burning polymer, there is a deterioration in the heat and mass exchange between the flame and the polymer surface and a decrease in the flow of fuel into the flame zone, and the flame is extinguished; 2) the use of polymers combined with non-combustible materials with a high heat capacity and heat conductivity (filled, or in constructions); 3) the addition to the polymer of additives whose thermal decomposition adds inert diluents to the gas phase, decreasing the temperature of the flame and leading to its extinction; and 4) the addition to the polymer of additives whose decomposition leads to the appearance in the gas phase of active inhibitors of the gas-phase oxidation reactions (bromine-containing compounds are the most effective), again leading to collapse of the flame.

A new trend, namely the use of micro-encapsulated fire-proofing agents, is very interesting and promising. In this case, there are several simultaneous effects: dispersion of the polymer from the surface, leading to a decrease in the degree of combustion of the polymer (up to 50 mass % of the polymer is removed from the flame zone); physical dilution of the flame, leading to a decrease in its temperature; and chemical inhibition of the reactions in the flame in the case of the micro-encapsulation of effective gas-phase inhibitors.

New Advances in the Chemistry of Methane

E.A.Grigoryan

The review deals with new reactions of methane in the presence of organometallic catalysts. The available data on deuterium-hydrogen exchange between methane and the methyl groups of the catalyst and on the reactions involving the addition of methane to low-valence transition metal complexes and to unsaturated hydrocarbons are surveyed. Certain other aspects of the chemistry of methane of theoretical and applied interest are considered.
The bibliography includes 70 references.

III. The activation of methane by low-valence transition metal compounds 212
IV. The "alkanolysis" of the transition metal-carbon bond 217
V. The addition of methane to unsaturated hydrocarbons 217

I. INTRODUCTION

Petroleum processing products constitute at present the main raw material source for the preparation of the majority of organic compounds and polymeric materials. This is the reason for the continuing increase in the rate of extraction and processing of petroleum during the last decades, which has led to the danger of exhaustion of its available resources. According to the estimates of specialists, if the present rate of development of the petroleum processing industry is maintained, the world petroleum reserves will be virtually completely exhausted after 30–40 years. The continuously increasing deficiency of petroleum and petroleum products is already facing chemists with the task of creating a new raw material source for the manufacture of organic substances and polymeric materials.

In nature there are two sources available for organic chemistry, with enormous reserves still available, namely coal and natural gas. The possibility, in principle, of obtaining hydrocarbon raw materials and natural liquid fuel from coal has been known for a long time but the imperfection of the coal processing technology, the severe conditions required for this purpose, and other, including purely economic, factors have created serious obstacles to the realisation of this process in industry. The conversion of natural gas into a hydrocarbon raw material, for example, the preparation of acetylene, have long been achieved on an industrial scale. These processes also proceed at high temperatures and pressures with very low yields and very low selectivity.

On the other hand, it is well known that enzymes exist in nature which oxidise methane (the principal component of natural gas) to methanol under the usual conditions with a high selectivity. The progress in the chemistry of alkanes in recent years is due to the endeavour to create new highly efficient and selective ways of processing natural gas.

The work of Enikolopov and Nalbandyan has made an enormous contribution to the development of the chemistry of saturated hydrocarbons. As early as the 1950's, they investigated in detail the kinetics and mechanism of the gas-phase oxidation of methane by molecular oxygen[1-19]. Since these classical studies have been described in detail in other reviews and monographs[19-21], in the present article the gas-phase reactions of methane will not be considered.

The activation of alkanes under mild conditions in the presence of soluble platinum complexes was first observed by Shilov and co-workers in 1969.[22] It was established, in particular, that the activation of the C–H bond in alkane can lead to deuterium–hydrogen exchange involving the alkanes and their chlorination or oxidation[23-26]. The publication of these studies attracted much interest to the chemistry of paraffinic hydrocarbons and new catalysts for the activation of the CH bonds in saturated hydrocarbons, mainly based on the complexes of Group VIII elements, were soon discovered [27-30].

Comparative analysis of the physicochemical characteristics of hydrogen, methane, ethylene, and other hydrocarbons indicates the possibility of employing Ziegler–Natta organometallic catalysts for the activation of the C–H bonds in the methane molecule. Table 1 presents the bond energies D, the ionisation potentials IP, the electron affinities EA, and the proton affinities PA of methane, hydrogen, ethylene, acetylene, and benzene[26]. It is seen that the C–H bond energy in methane is approximately the same as the H–H bond energy in the hydrogen molecule, but is lower than the C–H bond energies in acetylene, benzene, and ethylene. The ionisation potential of methane is higher than those of benzene, ethylene, and acetylene, but is lower than the ionisation potential of hydrogen. Methane has a smaller proton affinity than benzene and ethylene but higher than hydrogen.

In terms of the characteristics considered, methane thus occupies an intermediate position between hydrogen and ethylene. This factor led to the hypothesis that the activation of methane and its chemical reactions can be achieved in the presence of catalysts capable of activating hydrogen and ethane molecules, although methane should then manifest a lower reactivity than hydrogen owing to steric hindrance. The hydrogenation catalysts and olefin polymerisation catalysts of the Ziegler–Natta type are known to belong to this class.

Table 1. The physicochemical characteristics of hydrocarbon and hydrogen molecules[26].

Molecule	D(R-H), kcal mol^{-1}	IP, eV	EA, eV	PA, eV
H_2	104	15.4	−3.60	4.4
CH_4	104	12.7	—	5.3
C_2H_4	106	10.5	−1.81	6.9
C_6H_6	109	9.2	−1.10	7.5
C_2H_2	120	11.4	—	—

When hydrogn interacts with organometallic catalysts of this type under the usual conditions, the transition metal (M)–carbon bond undergoes hydrogenolysis:

$$M{-}R + H_2 \rightarrow M{-}H + RH \quad .$$

In the absence of the monomer, the reaction results in the evolution of alkane and the formation of a transition metal hydride derivative. In addition, it has been shown[31] that, under these conditions, D_2 molecules enter into deuterium–hydrogen exchange with the alkyl groups of the catalyst. The hydrogenolysis of the M–C bond plays a decisive role also in the hydrogenation reactions of unsaturated hydrocarbons. Analogous reactions of methane with organometallic catalysts have been observed recently for the first time.

Deuterium–hydrogen exchange reactions in methane, the addition of methane to unsaturated hydrocarbons and low-valence transition metal complexes, and reactions involving the exchange of alkyl groups between alkanes and organometallic complexes of 3*d* transition elements have been discovered in recent years. These reactions are especially interesting, because they proceed under mild conditions and in non-polar solvents such as heptane and benzene.

This review describes in detail the studies by Enikolopov's school on the activation of methane in the presence of organometallic complexes in hydrocarbon media and analyses the causes of the relatively high reactivity of methane compared with heavier homologues.

II. THE INTERACTION OF DEUTEROMETHANE WITH ZIEGLER–NATTA CATALYSTS

The interaction of methane can be conveniently studied in the presence of Ziegler–Natta catalysts in which far-reaching transformations of the system components, leading to the reduction of the transition metal with evolution of gaseous products, do not occur. It is therefore useful to employ catalytic systems containing organoaluminium components which have the weakest reducing properties but can alkylate transition metal compounds. It is known[32] that such requirements are met fairly satisfactorily by dimethylaluminium chloride. Its interaction with transition metal salts results in the formation in most cases of an alkylated complex exhibiting catalytic activity and stable in the absence of monomers[33].

The interaction of deuteromethane with catalytic systems based on titanium tetrachloride, biscyclopentadienyltitanium dichloride, diacetylacetonatiotitanium dichloride, vanadium trichloride, and vanadium triacetylacetonate in combination with dimethylaluminium chloride has been investigated in the temperature range 20–70 °C and in the pressure range 0.4 to 10 atm.[34] The results of the mass-spectrometric analysis of the products have shown that the interaction of deuteromethane with the above catalysts results in deuterium–hydrogen exchange between methane and the alkyl groups of the catalytic system. Dideuteromethane is then formed preferentially; however, mono- and tri-deuteromethane are also found in the products together with CH_2D_2. It is noteworthy that, in the presence of deuteromethane, fairly large amounts of methane are found in the gas phase. Fig.1 shows that the amount of methane in the gas phase increases with time almost linearly, while the accumulation of di- and trideuteromethane takes place after an appreciable induction period. The evolution of methane evidently occurs in the stage involving the formation ot the active centres responsible for the deuterium-hydrogen exchange.

The accumulation of methane in the presence of deuteromethane can be caused by the reversibility of the intramolecular or intermolecular disproportionation of the methyl groups bound to the transition metal atom:

$$\rangle M\langle^{CH_3}_{CH_3} \rightleftarrows M{=}CH_2 + CH_4 \quad ;$$

$$2\,\rangle M{-}CH_3 \rightleftarrows \rangle M{-}CH_2{-}M\langle + CH_4 \quad .$$

The formation of carbene complexes in such systems has now been rigorously demonstrated[35,36]. In the catalytic systems investigated these equilibria are apparently displaced largely to the left under the usual conditions. The hypothesis of the reversibility of the disproportionation of the alkyl groups[34] makes it possible to explain not only the accumulation of methane in the presence of an excess of deuteromethane but also the formation of di- and tri-deuteromethanes. Indeed the addition of deuteromethane to the carbene complexes of transition metals should lead to the formation of deuteromethyl derivatives whose disproportionation leads to the formation of di- and tri-deuteromethanes, for example, in accordance with the mechanisms

$$\rangle M{=}CH_2 + CD_4 \rightarrow \rangle M\langle^{CH_2D}_{CD_3} \rightarrow \begin{cases} \rangle M{=}CD_2 + CH_2D_2 \quad ; \\ \rangle M{=}CHD + CHD_3 \quad ; \end{cases}$$

$$\rangle M{-}CH_3 + 2CD_4 \rightarrow 2\,\rangle M{-}CD_3 + CH_2D_2 \quad .$$

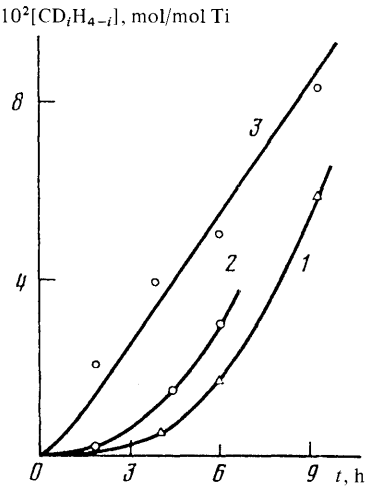

Figure 1. Kinetics of the deuterium–hydrogen exchange between CD_4 and the $TiCl_4$–$Al(CH_3)_2Cl$ catalytic system[34]: 1) dideuteromethane; 2) trideuteromethane; 3) methane; 20 °C, 3 atm, $[TiCl_4] = 5 \times 10^{-2}$ M, Al/Ti = 4.

The formation of monodeuteromethane can be readily explained by taking into account the possibility of the exchange of the methyl groups bound to the transition metal and the aluminium atom[37]; however, the possibility of the direct interaction of deuteromethane with the transition metal complex containing the M–CH_3 σ-bond is of greatest interest[34]:

$$\rangle M{-}CH_3 + CD_4 \rightarrow \rangle M{-}CD_3 + CH_3D \quad .$$

This reaction, which takes place most readily in the case of vanadium catalysts, is analogous to the hydrogenolysis of the M–C σ-bond.

It must be emphasised that the interaction of gaseous deuterium with the $TiCl_4$–$Al(CH_3)_2Cl$ system under identical conditions also results in the formation of the same deuteromethanes as in the reactions of deuteromethane with this system (Table 2)[31]. The identical proportions of the deuteroproducts in the interaction of gaseous deuterium and deuteromethane with Ziegler–Natta catalysts indicates the similarity of the mechanisms of the activation of the hydrogen and methane molecules in the coordination sphere of the transition metal. In the presence of small amounts of pyridine the deuterium–hydrogen exchange involving methane is fully suppressed. Evidently pyridine enters into the coordination sphere of the transition metal, forming a stable complex and preventing thereby the coordination and activation of methanes.

Table 2. The yields Q of the gaseous products of the interaction of deuterium with the $TiCl_4$–$Al(CH_3)_2Cl$ catalytic system[31]*.

τ, h	10^2Q, mol/mol Ti			
	CHD_3	CH_2D_2	CH_3D	CH_4
2	0.2	0.1	0.4	2.3
4	0.4	1.7	0.3	3.6
8	1.9	6.5	—	11.0
10	2.9	7.2	—	14.7

*Solvent—heptane; 50 °C; $[TiCl_4] = 2.5 \times 10^{-2}$ M; Al/Ti = 4.

The validity of the above ideas about the mechanism of the interaction of deuteromethane with Ziegler–Natta catalysts has been confirmed by the results of mass-spectrometric analysis of the gaseous products of the hydrolysis of the catalytic system where mono-, di-, and tri-deuteromethanes were detected[34]. The formation of deuterated methyl groups in the catalytic systems is possible only as a result of the activation of the C–D bond in the deuteromethane molecule when the latter interacts with the active centres of the catalyst. Thus the above results indicate the activation of the methane molecule in the coordination sphere of the transition metal.

The proposed mechanism of the deuterium–hydrogen exchange presupposes two possible pathways in the interaction of methane with organometallic complexes: (1) the reaction which is the reverse of the disproportionation of alkyl groups and (2) the exchange of alkyl groups between methane and the organometallic compound. Recently it has been possible to obtain direct evidence for the possibility of the occurrence of that reaction with participation of methane.

III. THE ACTIVATION OF METHANE BY LOW-VALENCE TRANSITION METAL COMPOUNDS

The disproportionation of alkyl groups containing a β-carbon atom in dialkyl compounds of transition metals proceeds via the scheme

$$\rangle M\langle^{C_2H_5}_{C_2H_5} \rightarrow \rangle M + C_2H_6 + C_2H_4 ,$$

according to which the oxidation state of the metal changes at once by two units and an alkane and an alkene are formed[33,37].

A reversible reaction can be achieved in the oxidative addition of an alkane to a complex of a transition metal in a low oxidation state. The analogous reaction with hydrogen is well known and takes place under the usual conditions at a high rate, for example, in the hydrogenation of olefins[38]:

$$\rangle M + H_2 \rightarrow \rangle M\langle^{H}_{H} \xrightarrow{C_2H_4} \rangle M\langle^{H}_{C_2H_5} \rightarrow \rangle M + C_2H_6 .$$

It is easy to estimate that the oxidative addition of methane should be less exothermic by ~10 kcal mol^{-1} than the addition of hydrogen. Steric hindrance may be an additional obstacle in the case of methane.

The oxidative addition of methane to low-valence transition metal complexes should entail the formation of alkyl hydride derivatives:

$$\rangle M + CH_4 \rightleftarrows \rangle M\langle^{H}_{CH_3} .$$

Under the usual conditions, this equilibrium is known to be displaced to the left[39], so that the isolation of the product of the oxidative addition of methane is not a simple task and the occurrence of the reaction can be inferred only from the results of the study of isotope exchange involving methane.

The possibility of the oxidative addition of alkanes to platinum(II) has been postulated by Shilov and co-workers[26]. Recently the same workers were able to isolate and investigate the σ-aryl complexes of platinum(IV) from a solution of hexachloroplatinic acid and hydrocarbons in a CF_3COOH + H_2O mixture, although the mechanism of the formation of the Pt–R bond was not rigorously demonstrated[40–44].

It has been established[45–47] that deuterium–hydrogen exchange between methane and deuterium takes place in a benzene solution of vanadocene (Cp_2V), leading to the formation of CH_3D, CH_2D_2, CHD_3, and CD_4 in the proportions 1.0 : 0.2 : 0.3 : 0.12. The yield of deuteromethanes (for a methane content in the initial mixture of 35% and a pressure of 250 mmHg) after 24 h is 2–6%. Here one should note that repeated deuteration of the solvent (benzene) takes place simultaneously with formation of hexa- and penta-deuterobenzenes.

The formation of methanes deuterated to different extents in the isotope exchange between D_2 and CH_4 may be due to the oxidative addition of methane, for example, via the mechanism

$$\rangle M + CH_4 \rightleftarrows \rangle M\langle^{H}_{CH_3} ;$$

$$\rangle M\langle^{H}_{CH_3} + D_2 \rightarrow \begin{cases} \rightleftarrows \rangle M\langle^{D}_{CH_3} \rightleftarrows \rangle M\langle^{H}_{CH_2D} \\ \rightarrow \rangle M\langle^{H}_{D} + CH_3D \end{cases} .$$

The preferential formation of monodeuteromethane may be associated with the simultaneous occurrence of the oxidative addition of deuterium:

$$\rangle M + D_2 \rightarrow \rangle M\langle^{D}_{D} \xrightarrow{CH_4} \rangle M\langle^{D}_{H} + CH_3D .$$

The oxidative addition of methane becomes thermodynamically more favourable when the process is accompanied by the simultaneous rupture of the double bond in the olefin (for example, ethylene) molecule in the coordination sphere of the metal. In this case a methyl derivative should be formed in which the disproportionation reaction, leading to

the reformation of methane and ethylene, is faciliated:

$$>M\leftarrow\overset{CH_2}{\underset{CH_2}{\|}}+CH_4\rightleftarrows >M\langle^{CH_3}_{C_2H_5}\,.$$

On the other hand, if one of the hydrocarbons contains deuterium atoms, the reversibility of this reaction leads to deuterium–hydrogen exchange between methane and ethylene.

Table 3. The products of the deuterium–hydrogen exchange between C_2D_4 and CH_4 under the influence of Cp_2V.[45]*

C_2D_4/CH_4	Yield, mol/mol Cp_2V

Table 3 presents data for the isotope exchange between methane and ethylene in the presence of vanadocene at 70 °C. Evidently benzene is also involved in the exchange reaction and in the methane–deuteroethylene–benzene system the deuterium–hydrogen exchange results in the formation mainly of fully deuterated benzene and "light ethylene", while methane gives rise to simple exchange products. Table 4 shows that the multiple deuterium–hydrogen factor is on average 1.7 for methane, while under the same conditions it reaches 5.9 for benzene and 4.0 for ethylene[47].

It follows from the data of Shestakov et al.[47] presented in Table 5 that less than 10% of the benzene employed and up to 44% of the ethylene participate in the deuterium–hydrogen exchange reactions. On this basis, one may claim that in the presence of Cp_2V the benzene and ethylene molecules are involved in multiple exchange reactions.

The deuterium–hydrogen exchange between methane and benzene in the absence of ethylene proceeds much more slowly. This fact together with the results of the study of the H–D exchange in the C_2D_4–CH_4–C_6H_6, C_2H_4–CD_4–C_6H_6, and C_2D_4–C_6H_6 systems (Tables 5 and 6) shows that benzene is deuterated as a result of its reaction with deuteroethylene, while methane is involved in exchange with ethylene in a parallel pathway[46].

In the C_2H_4–CD_4–C_6H_6 system the ethylene molecule transfers deuterium atoms from methane to benzene. Indeed the rate of deuteration of benzene in this system is much higher than in the system where the deuterating agent is deuterethylene and the multiple exchange factor is the same in both cases.

Table 5. The yields of deuterohydrocarbons and the specific rates of isotope exchange ν_{sp} in various systems in the presence of vanadocene[47].

System	Amount of hydrocarbons involved in exchange, mole %			$10^2\nu_{sp}$, litre $mol^{-1}h^{-1}$

*Solvent—benzene; 70 °C; 2.5 atm; 100 h.

Presumably the formation of deuterocarbons is due to their metathesis reaction involving the dissociation of the C=C double bond in ethylene. Indeed the methyl hydride complex formed in the oxidative addition of methane[26,45] can be converted into a carbene complex[48], which is the active centre of metathesis according to the authors[49]. The formation of deuterated hydrocarbons can then be represented schematically as follows:

$$>M+CH_3\rightleftarrows \underset{H}{\overset{|}{>M}}\langle^{CH_3}_{H}\rightleftarrows >M{=}CH_2+H_2\,,$$

$$\underset{D_2C=CD_2}{\overset{M=CH_2}{\diagup\!\!\diagdown}}\longrightarrow >M{=}CD_2+H_2C{=}CD_2\,.$$

When [^{13}C] methane was used, the transfer of carbon-13 atoms to the ethylene molecules should have been observed: however, mass-spectrometric studies showed that the interaction of the C_2H_4, $^{13}CH_4$, and C_6H_6 hydrocarbons with Cp_2V

does not lead to the isotope exchange of carbon between the system components[47]. The replacement of methane by [^{13}C]-methane hardly affects also the rate and degree of the deuterium–hydrogen exchange between deuteroethylene and methane. These data show that in the system investigated there are no metathesis reactions and that the hydrocarbons are deuterated due to the isotope hydrogen–deuterium exchange.

It is noteworthy that, on passing from benzene to deuterobenzene or from methane to deuteromethane, the rate of deuterium–hydrogen exchange with ethylene falls appreciably other conditions being equal. The kinetic isotope effect k_H/k_D is 3.6 for benzene and 3.1 for methane. The occurrence of a significant isotope effect confirms that the dissociation of the C–H bond in the benzene and methane molecules takes place in the rate-determining stage of the process[45–47].

Table 5 lists the specific rates of the deuterium–hydrogen exchange defined as the numbers of steps in the H–D exchange adjusted to unit concentrations of the catalyst and the corresponding hydrocarbon, i.e.

$$\nu_{sp} = \frac{\sum i d_i}{[Cp_2V]\,[RH]\,\tau},$$

where $\Sigma i d_i$ is the number of steps in the deuterium–hydrogen exchange in the given hydrocarbon, $[Cp_2V]$ the amount of the catalyst in moles, [RH] the molar concentration of the hydrocarbon, and τ the experimental time (h).

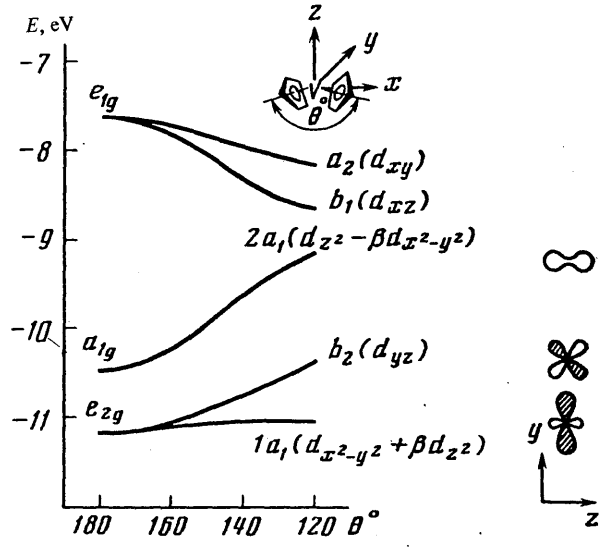
It is of interest that, in the presence of vanadocene under the conditions of the experiments presented in Table 5, the specific rates of the deuterium–hydrogen exchange between methane and benzene, on the one hand, and the deuteroethylene, on the other, are almost equal and in certain cases ν_{sp} for methane is actually higher (Table 6). The anomalously high reactivity of methane compared with benzene is evidently due to the specific features of the mechanism of the activation of the C–H bond in these hydrocarbons by vanadocene.

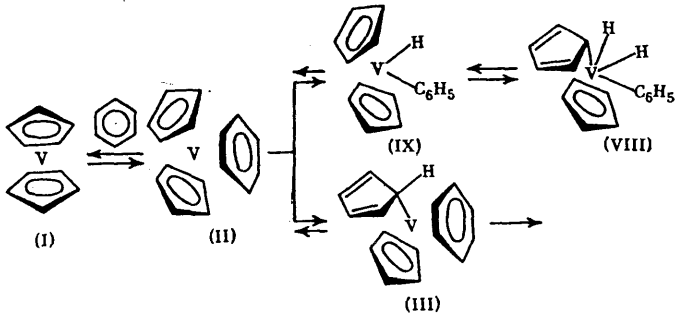
The cyclopentadienyl rings of the catalyst also participate in the H–D exchange reactions. Table 4 shows that methane is hardly involved in this exchange, while benzene exchanges with the cyclopentadienyl groups only in the absence of ethylene.

The H–D exchange between benzene and C_5D_5 rings results in the formation mainly of hexadeuterobenzene and small amounts of C_6H_5. When ethylene is present in the system, the isotope exchange between benzene and C_5D_5 rings is fully inhibited and there is exchange between the latter and ethylene, which results in the formation of mainly $C_2H_2D_2$. Although the factor associated with the multiple exchange of methylene and benzene with the C_5D_5 rings separately is fairly large, the contribution of this exchange is insignificant in both cases. This is also indicated by the observed satisfactory deuterium atom balance in the exchange between the hydrocarbons investigated in the presence of "light" Cp_2V.[47]

The principal experiment data indicating the multiple character of the H–D exchange between benzene and deuteroethylene in the presence of vanadocene with the preferential formation of C_6D_6 and C_2H_4 show that the coordination of the benzene and ethylene molecules in these intermediate complexes ensures the equivalence of the C–H bonds. The residence time of the benzene and ethylene molecules in the intermediate complexes should then be sufficient for the exchange of all the hydrogen atoms. For example, the complex $(\eta^5\text{-}C_5H_5)_2(\eta^6\text{-}C_6H_6)(\eta^2\text{-}C_2H_4)V$, which has the required symmetrical coordination of benzene and ethylene molecules, can be considered as the intermediate; however, its existence is doubtful for both steric and electronic reasons, because 23 electrons should be present in the transition metal orbitals.

The electronic structue of the complex Cp_2V has been considered[47] for different angles θ between the directions of the V–Cp bonds. Fig. 2 illustrates schematically the positions of the d levels of Cp_2V for different values of θ found by calculations based on the extended Hückel method[50,51].





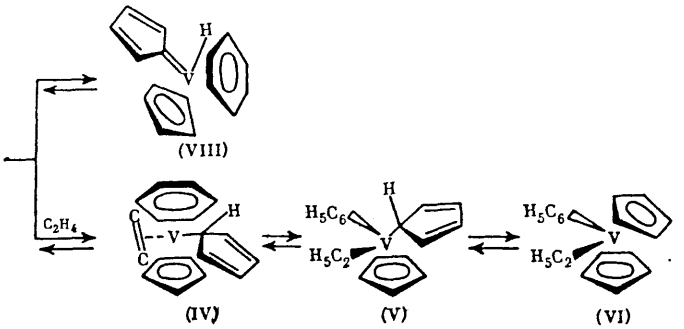


Figure 2. Schematic illustration of the variation of the energy of the d levels in the complex Cp_2V as a function of the variation of the angle θ between the axes of the Cp rings[47].

The distorted Cp_2V complex has three low lying weakly antibonding orbitals: $1a_1$, b_2, and $2a_1$,[47,51,52] which are responsible for the formation of bonds between Cp_2V and ligands of the σ or π type. The sterically accessible electron density maxima in all three orbitals are located in the zy plane. The $1a_1$, b_2, and $2a_1$ orbitals can then ensure the formation of a σ-bond at angles of ±90°, ±45°, and 0° relative to the z axis respectively. The b_2 and $1a_1$ orbitals are suitable for the π interaction at angles of 0°, ±90°, and ±45° relative to the z axis respectively.

The following scheme has been proposed to interpret the main experimental facts observed in the study of deuterium exchange between benzene, on the one hand, and ethylene and Cp rings, on the other[47]:

The first stage is the addition of benzene to Cp_2V; the possibility of complex formation is ensured by the interaction of $2a_1$ and b_2 orbitals of Cp_2V with the orbitals of a_{2u} and e_{1g} of benzene respectively (Fig. 3). The overall energy gain is not very great, since it is made up of the decrease of the energies of two orbitals occupied by four electrons and the increase of the level of one one-electron orbital. Furthermore, there exists also definite steric hindrance to the accommodation of three rings around the vanadium atom.

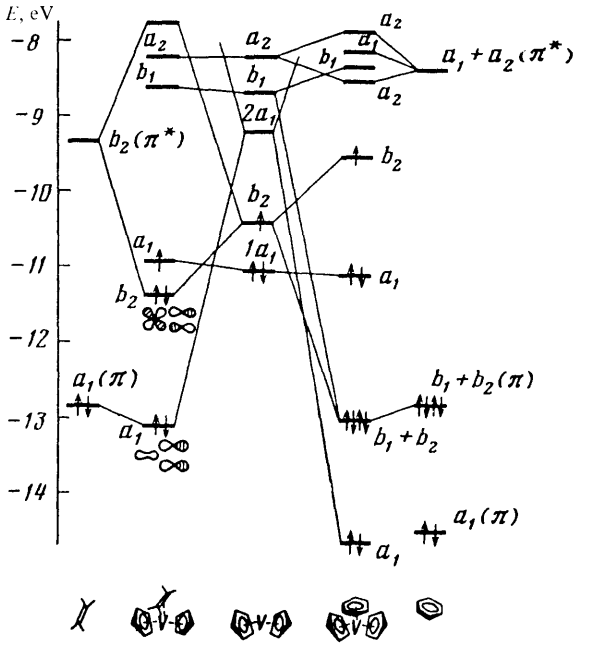

Figure 3. Energy scheme for the interaction of the complex Cp_2V with ethylene and benzene molecules[47].

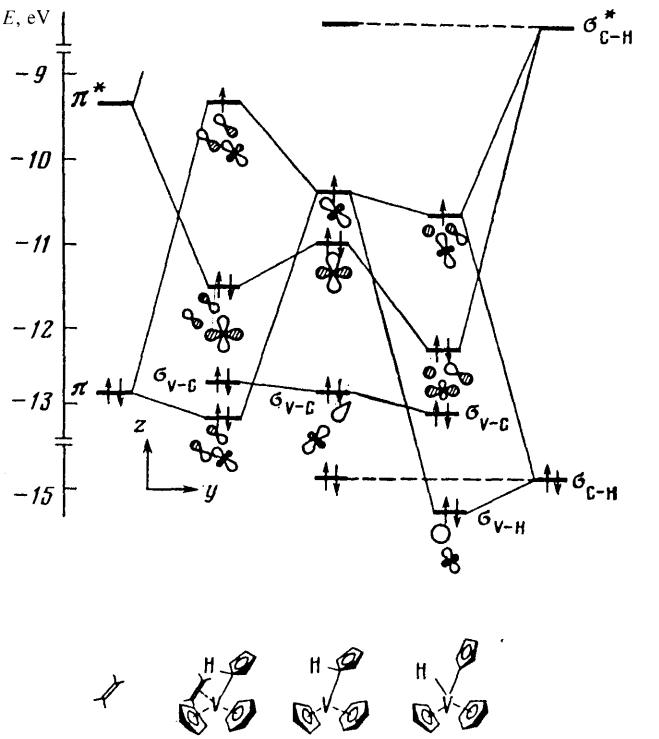
The presence of a *d* electron in the complex (II) in a high antibonding orbital renders it unstable and reactive, in particular, it tends to be oxidised. The easiest way of employing the reactivity of the complex (II) and of removing an electron from the antibonding *d* orbital consists in attack by the positively charged vanadium atom on the negatively charged rings with formation of the complex (III) or (IX). Attack on the cyclopentadienyl ring is preferred both from the standpoint of the larger negative charge an in view of the possibility of a smooth conversion of η^5-Cp into η^1-Cp via η^3-Cp; this reaction pathway is simplified because there is no need for the dissociation of a C–H bond.



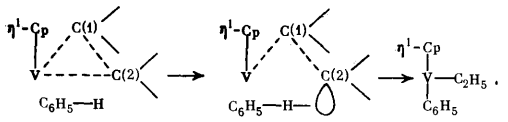


Figure 4. Energy scheme for the interaction of the complex $(\eta^1\text{-Cp})(\eta^5\text{-Cp})(\eta^6\text{-}C_6H_6)V$ with an ethylene molecule and the rearrangement of the orbitals of the complex when a hydrogen atom migrates from η^1-Cp to the vanadium atom[47].

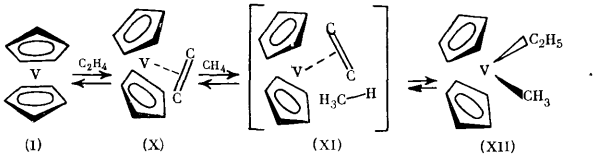
The corresponding low lying orbitals are used for the formation of the $V-\eta^1$-Cp or V–H and $V-C_6H_5$ σ-bonds in the final products of the rearrangement—the complexes (III) and (IX) (Fig. 2). The remaining electrons (three or one) are accommodated in orbitals not involved in interactions with the ligands and for this reason there is no destabilising contribution to the energy in the complex (III) and (IX), in contrast to the initial complex (II). The complex (IX) is apparently thermodynamically somewhat more stable than the complex (III); the latter has orbitals ensuring the σ- and π-binding of C_2H_4 as a result of its interaction with the π and π* orbitals (Fig. 4).[47] A symmetrical coordination of benzene and ethylene obtains in the complex (IV) formed (provided that their rotation in the coordination sphere of the vanadium atom is unhindered). According to calculations by the extended Hückel method, the carbon atoms in the coordinated C_2H_4 molecule are not equivalent. This non-equivalence of the C(1) and C(2) atoms should lead to a difference between the bond lengths, i.e. $l_{V-C(1)} > l_{V-C(2)}$, which facilitates the abstraction of a hydrogen atom from the benzene ring in

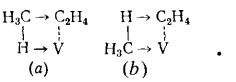


accordance with the scheme[47]

This mechanism agrees with the observed considerable kinetic isotope effect. The complex (V) formed can apparently be converted into the more stable complex (VI) via the shift η^1-Cp → η^3-Cp → η^5-Cp. The reverse transition (VI) → (V) is favoured by the steric hindrance due to the fairly large C_2H_5 and C_6H_5 ligands. The ease of rotation of the fragment η^6-C_6H_6 in the complex (IV) is fairly evident. The possibility of the rotation of the C_2H_4 fragment in the complex $Cp_2V.C_2H_4$ about the V–C_2H_4 axis is due to the electronic factor, since rotation by an angle of 90° results in the disappearance of the stabilising interaction of the b_2 orbital of the vanadium atom with the π* orbital of ethylene (Fig.2). In the complex (IV) there is no symmetry plane owing to the non-equivalence of the five- and six-membered rings and the b_1 and b_2 states are therefore partly mixed. This ensures some stabilisation of the occupied level on rotation of the ethylene molecule by 90° and thereby a decrease of the barrier to the rotation. The results of a semiempirical quantum-mechanical calculation thus confirm a significant decrease of the barrier to rotation.

The occurrence of deuterium exchange between benzene and the C_5D_5 rings, also with the preferential formation of C_6D_6, can be accounted for within the framework of the proposed scheme by the conversion of the complex (III) into the carbene complex (VII).[47]

The difference between the characters of the deuterium–hydrogen exchange reactions of benzene (multiple exchange) and methane (simple exchange) with ethylene supports the view that the proceeds in parallel reactions via different mechanisms. In the case of methane the following scheme appears the most natural:



(I) (X) (XI) (XII)

The complex (X) should be fairly stable because Cp_2V has orbitals suitable for the effective π and σ binding of the ethylene molecule (Fig.3). It is evident from the above scheme that, on passing from CH_4 to CD_4, a considerable kinetic isotope effect should be observed.

The sequence of the C_2H_4 and CH_4 addition steps illustrated in the scheme follows from the sharp difference between the coordination properties of these molecules and the instability of the allyl hydride sandwich complexes[48]. In the transition (X) → (XI) → (XII) the cleavage of the double bond in the ethylene molecule facilitates additionally the loosening of the stable C–H bond in methane.

The replacement of methane by benzene immediately precludes the (X) → (XI) stage owing to the steric hindrance, since in the presence of the C···H–C_6H_5 and V···C_6H_5 interactions the ethylene and benzene molecules occupy such a considerable proportion of the space around the vanadium atom that either benzene or ethylene must fall within the region of the van der Waals contact between the Cp rings, which is impossible without a significant increase of the Cp–V bond length and hence without an appreciable energy expenditure[47].

Two possible versions of the addition of the methane molecule can be postulated in the intermediate complex (XI) in conformity with thermodynamics (for the direct abstraction of a hydrogen atom from a CH_4 molecule by the vanadium complex):

(a) (b)

Higher aliphatic hydrocarbons (C_3, C_4, etc.) could not be detected by chromatographic and mass-spectrometric methods in the $Cp_2V + CH_4 + C_2H_4 + C_6H_6$ reaction products. This finding shows that the addition of type (b), in which the interaction between the vanadium atom and a carbon atom is significant, is preferred. The methane molecule should apparently be subjected to preliminary thermal activation and should be made to assume an excited conformation with a partial increase of the H–C–H angle due to deformation vibration. A donor orbital is then formed along the second-order axis of the distorted CH_4 molecule, which determines the interaction with the electropositive vanadium atom.

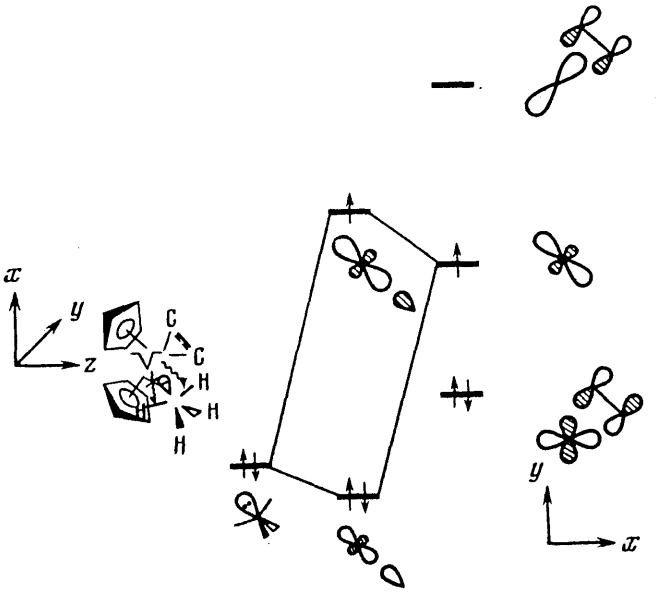


Figure 5. The interaction of the orbitals of a conformationally excited methane molecule with the complex $Cp_2V.C_2H_4$.[47]

The formation of the C_2H_4–CH_3 bond is possible only when the vanadium atom attacks a C–H bond remote from ethylene. However, Fig.5 shows that the presence of a hydrogen atom between the carbon atoms of methane and ethylene gives rise to steric hindrance. When the methyl group is bound to the vanadium atom, this hindrance eliminated, since an H atom from CH_4 naturally adds to C_2H_4. The rotation of the methane molecule about the V–CH axis, which could, in principle, ensure conditions for the formation of a propyl hydride derivative, is energetically unfavourable owing to the considerable increase of the repulsion of methane from the Cp rings and the lack of suitable orbitals for the formation of

the V–H bonds outside the bisector plane. The absence of the above obstacles favours the addition of methane to ethylene, which is apparently characteristic of the $Ti(OR)_4$–AlR_3 system, where the formation of propane from methane and ethylene has been observed[53].

It is natural to expect that ethylene remains in the coordination sphere of the vanadium atom longer than methane. Therefore, and also in view of the asymmetry of the addition of methane relative to ethylene, only mono- and di-deuteromethanes should be observed in the deuterium exchange products, which is consistent with experimental data[45–47] (Table 6).

Comparison of the mechanism of the parallel deuterium–hydrogen exchange reactions between methane and ethylene and between benzene and ethylene shows that the formation of an active centre in the case of benzene requires a longer expenditure of energy. This is in fact the reason for the observed high reactivity of methane compared with benzene in the exchange reaction of ethylene. The hindrance of the H–D exchange following the replacement of methane by heavier alkanes is also to be expected from these ideas.

It follows from the data presented above for the mechanism of the oxidative addition of methane that a decrease of the catalytic activity should be observed in the series of 3*d* transition metal metallocenes with enhancement of the electron-donating properties of the metal atom. The results of a study of the H–D exchange between deuteroethylene and methane and benzene in the presence of different metallocenes (Table 6) show that a sharp decrease of the rate of the H–D exchange involving methane is observed with enhancement of the electron-donating properties of the 3*d* transition metal atom in the sequence Ti > V > Mn > Fe > Co > Ni, while the multiple exchange factor changes insignificantly.

These results confirm yet again that the isotope exchange between methane and ethylene takes place as a result of the oxidative addition of methane to the transition metal complex of ethylene, i.e. as a result of the reaction which is the opposite of the disproportionation of the alkyl groups bound to the metal atom.

IV. THE "ALKANOLYSIS" OF THE TRANSITION METAL–CARBON BOND

The studies by Enikolopov and co-workers of the activation of methane by organometallic Ziegler–Natta catalysts demonstrated for the first time that, by analogy with hydrogen, methane can also participate in the dissociation of the transition metal–carbon σ-bond[34,53].

As mentioned above, the hydrogenolysis of the M–C bond plays an important role in the hydrogenation reactions of unsaturated hydrocarbons[38] and in the processes involving the regulation of the molecular weight of polyolefins during their synthesis in the presence of Ziegler–Natta catalysts[54]. In this case the reaction leads to the formation of the corresponding alkane and a metal–hydride linkage.

The reaction of methane with the M–C σ-bond leads to the formation of a methyl derivative of the transition metal and an alkane molecule:

$$\rangle M{-}R + CH_4 \rightarrow \rangle M{-}CH_3 + RH \quad .$$

By analogy with hydrolysis, hydrogenolysis, alcoholysis, etc., this reaction can be called "alkanolysis" (although for other alkanes a reaction of this type has not so far been observed) or the hydromethylation of the M–C bond.

"Alkanolysis" is observed in various catalytic systems based on $TiCl_4$, Cp_2TiCl_2, VCl_4, $V(acac)_3$, $Fe(acac)_3$, and many other transition metal derivatives in combination with various organoaluminium compounds. The rate of the process depends on the nature of the transition metal, the length of the hydrocarbon group bound to it, and other factors.

The most convincing demonstration of the occurrence of "alkanolysis" was achieved in the study of the interaction of methane, carefully freed from traces of moisture and oxygen, with catalytic systems. It is known[3] that in the interaction of the components of Ziegler–Natta systems containing triethylaluminium or diethylaluminium chloride the evolution of ethane and ethylene is observed, the amount of the latter being much smaller than that of ethane. Fig. 6 presents as an example data for the kinetics of the evolution of ethane in the $Fe(acac)_3$–$Al(C_2H_5)_3$ catalytic system[53].

Fig. 6 shows that ethane is evolved in an amount almost equivalent to the initial iron content over a period 5–10 min in the absence of methane; subsequently the evolution of ethane ceases. In the presence of methane the "alkanolysis" of the Fe–C_2H_5 σ-bond results in the evolution of a much larger amount of ethane. Trideuteromethane (CD_3H/Fe = $2{,}2 \times 10^{-4}$) is detected in the products of the hydrolysis of the catalytic system treated with tetradeuteromethane, which indicates the formation of a methyl derivative of iron in the "alkanolysis" of the Fe–C_2H_5 bond. According to preliminary data, the rate constants for the "alkanolysis" of the M–R bond are smaller by a factor of 30–50 than the rate constants for the hydrogenolysis of the same bond. "Alkanolysis" is a reaction which can already find an important practical application, for example, in the manufacture of polyolefins.

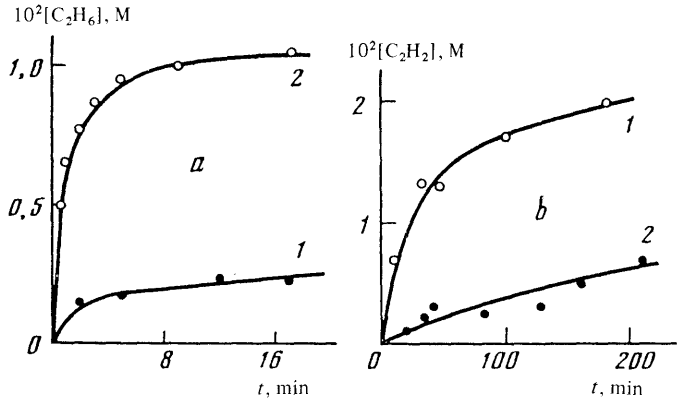

Figure 6. Kinetics of the accumulation of ethane (*a*) and of the absorption of acetylene (*b*) in the $Fe(acac)_3$–$Al(C_2H_5)_3$ catalytic system in the absence (curves *1*) and presence (curves *2*) of methane[53].

V. THE ADDITION OF METHANE TO UNSATURATED HYDROCARBONS

The discovery of the deuterium–hydrogen exchange reaction involving methane and of the "alkanolysis" of the M–C bond, which proceeds analogously to the corresponding reactions of hydrogen with organometallic catalysts, led to the task of finding new ways for the transformation of methane.

The most characteristic and important reaction of hydrogen in the presence of Ziegler–Natta catalysts is hydrogenation of unsaturated hydrocarbons. The mechanism of the hydrogenation reaction involves stages in which the transition metal–carbon bond undergoes hydrogenolysis and a hydrocarbon molecule is inserted in the metal–hydride bond formed[38]. For example, the mechanism of the hydrogenation of ethylene can be represented schematically as follows:

$$\rangle M{-}R + H_2 \rightarrow \rangle M{-}H + RH\ ,$$
$$\rangle M{-}H + C_2H_4 \rightarrow \rangle M{-}C_2H_5 + H_2\ ,$$
$$\rangle M{-}C_2H_5 + H_2 \rightarrow \rangle M{-}H + C_2H_6\ .$$

The discovery of "alkanolysis" led to the idea that hydrogen may be replaced by methane in the hydrogenation reactions of ethylene and acetylene[53 55]. Indeed, the "alkanolysis" of the M–R σ-bond in the catalytically active complex results in the formation of a new $M{-}CH_3$ σ-bond. It is known[33] that the insertion of an ethylene molecule in the bond results in the formation of a propyl derivative of the transition metal:

$$\rangle M{-}CH_3 + C_2H_4 \rightarrow \rangle M{-}C_3H_7\ .$$

This reaction is much faster than the insertion of ethylene in an M–H bond[53]. The "alkanolysis" of the $M{-}C_3H_7$ bond obtained should result in the formation of a propane molecule—the product of the addition of methane to ethylene:

$$CH_4 + C_2H_4 \rightarrow C_3H_8\ .$$

The possibility, in principle, of the occurence of this reaction was first demonstrated in the presence of the $Ti(C_4H_9O)_4{-}Al(C_2H_5)_3$ catalytic system in benzene at 20 °C and a pressure of 1 atm.[55] Under these conditions, in the absence of methane, ethylene dimerises with formation of but-1-ene. The subsequent addition of the monomer, leading to the growth of the polymer chain, is hardly observed in this system[57].

If the catalytic system is maintained in an atmosphere of ethane in the absence of ethylene, then ethane, the product of the "alkanolysis" of the $Ti{-}C_2H_5$ bond, accumulated in the gas phase[55,58]. As a result of this reaction, a small amount of the methyl complex of titanium is formed in the system. After the supply of ethylene to the system in proportions $CH_4/C_2H_4 > 10$, its absorption with formation of propane is observed. This is accompanied by the simultaneous formation of a small amount of but-1-ene, whose yield can be reduced by increasing the molar ratio of methane and ethylene or by altering the conditions in the treatment of the catalyst with methane. Under the conditions indicated, the yield of propane after 10 h is 15–20% of the amount of ethylene in solution. It is noteworthy that the efficiency of the catalyst is not high and that approximately 1 mole of propane is formed in the presence of 4–5 moles of the initial titanium[55].

The formation of propane is not observed in the absence of methane or ethylene. When methane is replaced by deuteromethane, tetradeuteropropane $C_3H_4D_4$ is detected mass-spectrometrically in the gaseous products[55]. Thus there is no doubt about the formation of propene from methane and ethylene.

In order to achieve the addition of methane to acetylene, i.e.

$$CH_4 + C_2H_2 \rightarrow CH_3{-}CH{=}CH_2\ ,$$

studies were made of various catalysts of the hydrogenation of acetylene based on titanium(IV), iron(III), cobalt(II), and nickel(II) complexes in combination with organoaluminium compounds[53]. Among these, catalytic activity in the reaction involving the addition of methane to acetylene was shown only by the $Fe(acac)_3{-}Al(C_2H_5)_3$ system in benzene solution. It is known from the literature[59] that acetylene polymerises in the presence of this catalyst. However, after the treatment of the catalytic system with carefully purified methane, the polymerisation of acetylene is not observed and the rate of its absorption falls significantly[53] (Fig. 6b).

Thus, by interacting with the active centres of the catalyst, methane converts them into a form inactive for polymerisation. Bearing in mind that ethane is evolved in this process, the decrease of the catalytic activity can be attributed to the formation of a methyl derivative of the transition metal with a much lower reactivity in the initiation of the polymer chain[33,37]. Evidently the presence of the relatively inactive $M{-}CH_3$ bond in an excess of methane ($CH_4/C_2H_2 \geq 30$) ensures the necessary condition for the single insertion of an acetylene molecule in this bond and the formation of propene in the system[53].

In a dilute solution of the catalyst propene accumulates after an appreciable induction period whose duration depends on the catalyst concentration. Table 7 shows that the yield of propene increases with time and with temperature. With increase of the molar ratio Al/Fe, the yield of propene falls and, when Al/Fe > 8, whereupon the rate of exchange of the alkyl groups bound to the iron and the aluminium atoms increases significantly, its formation is not observed and acetylene polymerises[53].

Table 7. The yields of propene Q in the reaction of methane and acetylene under the influence of the $Fe(acac)_3{-}Al(C_2H_5)_3$ catalytic system[53]*.

10^3[Fe(acac)$_3$], M	T, °C	t, min	$10^2 Q$, mol/mol Fe	10^3[Fe(acac)$_3$], M	T, °C	t, min	$10^2 Q$, mol/mol Fe
1	14	240	1.6	1	30	51	1.6
1	20	100	—	10	20	40	0.5
1	20	135	0.4	10	20	70	0.8
1	20	255	1.0	10	20	95	0.9
1	20	280	2.8	10	20	240	1.0

*Solvent—benzene; pressure 640 mmHg; $[CH_4] = 1.93 \times 10^{-2}$ M; $[C_2H_2] = 0.6 \times 10^{-2}$ M; Al/Fe = 4.

In the absence of methane or acetylene, propane is not formed, while the replacement of methane by deuteromethane, results in the detection of deuteropropene in the reaction products. It was noted above that, after the hydrolysis of the catalytic system treated with tetradeuteromethane, trideuteromethane is formed in small amounts ($CD_3H/Fe = 2.2 \times 10^{-4}$).[53] This fact shows that the fraction of the active centres responsible for the addition of methane to acetylene, relative to the total amount of iron in the system, is small. This is evidently the reason for the observed low yield of propene relative to the initial amount of the catalyst.

Enikolopov presented for the first time the results of studies on reactions involving the addition of methane to unsaturated hydrocarbons (ethylene and acetylene) in the 1979 Medvedev lectures. This fundamentally new reaction of paraffinic hydrocarbons aroused much interest not only in our country but also abroad. Studies on the activation of alkanes by non-platinum metal complexes are being vigorously prosecuted in many laboratories at the present time.

The formation of propene in the H_2–CH_4–C_2H_4–C_2H_2 mixture in the presence of a catalytic system based on nickel(II) stearate, naphthenate, and naphthenehydroxamate, deposited on the surface of nickel hydroxide, in combination with triethylaluminium or di-isobutylaluminium hydride has also been reported by Noskova and co-workers[60,61]. In the presence of these catalysts it is possible to obtain propene in higher yields. However, unfortunately, owing to the complexity of the system proposed in these investigations, the role of methane in the formation of the propene molecule has not so far been unambiguously established. The situation is also complicated by the fact that the formation of a small amount of propene in the system is observed also in the absence of methane, apparently as a result of the metathesis of ethylene. Despite this, the above studies merit special attention, since there is no doubt about the activation of methane in these systems.

---o0o---

Analysis of the literature data on the catalytic activation of alkanes indicates a vigorous development of the chemistry of saturated hydrocarbons. In the presence of 3*d* transition metal complexes, a fundamentally new type of reactions of methane, namely addition reactions, has been discovered. By adding methane to unsaturated hydrocarbons (in particular to acetylene), it is possible to obtain the most important petroleum processing products from a non-petroleum raw material—natural gas. The possibility of the practical application of this process arises owing to the development of highly active catalysts, which make it possible to increase sharply the yield of the product (for example, propene) per unit mass of the catalyst. We believe that, under the conditions of the vigorous development of the research in this field, the practical application of the available results is a matter for the near future.

The possibility, in principle, of achieving the hydromethylation of various compounds with the aid of methane leads to new ways of synthesising various organic compounds using the side products from the processing of petroleum, natural gas, and coal. The range of thermodynamically feasible reactions involving methane is fairly wide. These reactions include, for example, the hydromethylation of allene, leading to the formation of butenes, the formation of ethyl methyl ketone from methane, carbon monoxide, and ethylene (analogously to the hydroformylation reaction), the synthesis of acetaldehyde from methane and carbon monoxide at elevated pressures, and many others. The search for the selective catalysts of these and other most important reactions of alkanes (oxidation, chlorination, dehydrogenation, etc.) is being actively prosecuted in various countries[22–31,40–47,60–70]. One must note that studies of Soviet investigators have played a leading role in the catalytic activation of alkanes; these investigations have already significantly enriched the chemistry of alkanes.

Russian Chemical Reviews

March 1984

Review articles by scientists at the Nesmeyanov Institute of Organoelemental Compounds of the USSR Academy of Sciences (awarded the Order of Lenin), founded thirty years ago in 1954 from a number of branches of the Zelinskii Institute of Organic Chemistry of the USSR Academy of Sciences on the initiative of the outstanding Soviet chemist Academician A.N.Nesmeyanov, are collected in this issue of the Journal. During the past years, this Institute, which is the first one in the world to deal with the chemistry of organoelemental compounds, grew into a major scientific research establishment and acquired great authority in world science. This authority is due to the fundamental studies by Academicians A.N.Nesmeyanov, K.A.Andrianov, M.I.Kabachnik, I.L.Knunyants, V.V.Korshak, I.V.Obreimov, O.A.Reutov, and A.V.Fokin, as well as the Corresponding Members of the USSR Academy of Sciences M.E.Vol'pin, D.N.Kursanov, and R.Kh.Freidlina.

A.N.Nesmeyanov discovered the phenomenon of metallotropism, investigated the properties of sandwich compounds, and devised new methods for the synthesis of the σ- and π-complexes of transition metals—organometallic chelates. Important discoveries such as those of the rearrangement of radicals in solution with 1,2-migration of chlorine and the fixation of molecular nitrogen by transition metal complexes under mild conditions have been made in the Institute. A new allotropic modification of carbon, namely carbyne, has been discovered, and a new synthetic method, ionic hydrogenation of unsaturated compounds, has been proposed.

The modern chemistry of organic derivatives of phosphorus, fluorine, and silicon, the synthetic chemistry of polymers, and many other branches of chemical science have been developed.

In view of its major services to chemical sciences and in the training of scientific cadres, the Nesmeyanov Institute of Organoelemental Compounds of the USSR Academy of Sciences was awarded the Order of Lenin in 1967.

Modern Problems of Homolytic Telomerisation

R.Kh.Freidilina, F.K.Velichko, and A.B.Terent'ev

The results of studies in homolytic telomerisation during the last decade at the Institute of Organoelemental Compounds of the USSR Academy of Sciences are surveyed. The synthetic possibilities which have arisen as a result of initiation by metal carbonyls are demonstrated. The prospects for the practical utilisation of telomerisation are discussed.
The bibliography includes 173 references.

I. INTRODUCTION

Telomerisation is understood as a radical chain process in which a molecule of any kind of saturated compound (telogen) combines with several molecules of an olefin or another unsaturated compound. Formally, the reaction can be expressed by Eqn.(2) of Scheme 1; it fills the "gap" between addition and polymerisation:

Scheme 1

(1) $X-Y + C=C \longrightarrow X-C-C-Y$ (addition),

(2) $X-Y + n\,C=C \rightarrow X-(C-C)_n-Y$ (telomerisation; $n = 2$-20)

Telomers

(3) $X-Y + n\,C=C \rightarrow X-(C-C)_n-Y$ (polymerisation; $n \rightarrow \infty$).

This comparatively new field began to develop in the postwar years. At the present time systematic and extensive researches into telomerisation are prosecuted in the USSR, the USA, Japan, Italy, the Federal Republic of Germany, and France.

Telomerisation is a typical organic reaction; it makes it possible to synthesise under similar conditions homologous series of polyfunctional compounds of different classes by selecting appropriate telogen–monomer pairs. The studies by Soviet investigators, and in particular by the team at the Institute of Organoelemental Compounds of the USSR Academy of Sciences, have in many respects enriched the theoretical and practical aspects of telomerisation and have led to its transformation from a purely laboratory reaction into a process suitable for technological application[1-3].

Two monographs and a number of reviews[1,4], among which we shall mention only those published in recent years[5-12], have been devoted to telomerisation. The concept of telomerisation has been included in an encyclopaedia[13] and in textbooks of organic chemistry[14]. The rate of development of researches in this field is so great that it has now become necessary to write new reviews and monographs.

New important branches of telomerisation have developed extensively in recent years and its applications in organic synthesis, in the study of general problems of radical chemistry, and in practice have been greatly expanded.

This includes the discovery of fundamentally new initiators and initiating systems which made it possible to involve in telomerisation many new types of telogens and monomers as well as their new combinations which had been previously believed to be ineffective in this process. Instances of telomerisation accompanied by the rearrangement of growing radicals have been extensively studied. Investigations have been developed into stepwise telomerisation and the cotelomerisation of two monomers with one telogen. Practical applications in which telomerisation makes it possible to solve important problems have been found. New methods have been developed for the isolation of telomers as well as schemes for demonstrating their structure by methods of physical organic chemistry. The most important advances achieved in the field of telomerisation during the last decade are considered in this review.

II. GENERAL PROBLEMS OF TELOMERISATION

Monomers. In principle any unsaturated compound capable of radical polymerisation can be used in free-radical telomerisation; ethylene, alk-1-enes, vinyl chloride, vinylidene chloride, perfluoroethylene, chlorofluoroethylenes, allyl and acrylic compounds, and diene hydrocarbons and their derivatives have been studied in greatest detail and are frequently used.

Telogens. Substances containing bonds which readily undergo homolytic dissociation are used as telogens:

The types of such bonds whose dissociation leads to telomerisation are presented below:

C—H	B—H	SO_2—Hal
C—C	N—Hal	Si—H
C—Cl	P—H	Sn—H
C—Br	S—H	Cl—H
C—I	S—Hal	Br—H
	S—S	I—H

Reaction mechanism. The generally accepted mechanism of telomerisation initiated by radical-forming substances is presented in Scheme 2.

Scheme 2

(1) Initiator $\rightarrow$ R$^{\cdot}$
(2) R$^{\cdot}$ + X—Y $\rightarrow$ RX + Y$^{\cdot}$ } (initiation)

(3) Y$^{\cdot}$ + CH_2 = CHR $\rightarrow$ $YCH_2\dot{C}HR$
(4) $YCH_2\dot{C}HR + n CH_2 = CHR \xrightarrow{k_p} Y(CH_2CHR)_nCH_2\dot{C}HR$ } (growth of radical)

(5) $Y(CH_2CHR)_nCH_2\dot{C}HR$ + X—Y $\xrightarrow[\text{telomers}]{k_{tr}}$ $Y(CH_2CHR)_{n+1}X$ + Y$^{\cdot}$ (chain transfer)

(6) Radicals $\rightarrow$ inactive products (chain termination)

Here k_p and k_{tr} are the chain propagation and chain transfer constants respectively and $n = 1,2,3, \ldots$

In most instances the telomerisation reactions initiated by peroxides, azo-compounds, and light proceed in accordance with this scheme in which chain transfer directly to the telogen [stage (5) of scheme 2] takes place. However, many examples of telomerisation in which Scheme 2 does not hold have now accumulated. The importance of Scheme 2 consists in the fact that in many cases of smooth telomerisation under rigorously controlled conditions it is possible, knowing the distribution of the telomers in terms of the number of monomer units to estimate comparatively simply the relative rates of the intermediate stages—for example, the partial chain transfer constants C_n can be determined from the Mayo equation[15]:

$$C_n = k_{tr}/k_p = Q \cdot \left(T_n \Big/ \sum_{n+1}^{\infty} T_i \right) ,$$

where Q is the molar ratio of the monomer and the telogen and T_n the molar yield of the telomer incorporating n monomer units. A characteristic feature of the partial constants C_n, in contrast to the general chain transfer constants C_∞ determined from radical polymerisation data, consists in the fact that they reflect the influence of the fragment Y of the telogen on the radical centre in the telomer-radicals $Y(CH_2CHR)_n^{\cdot}$. For many telomerisation processes, the constants C_n increase as n increases from 1 to 4–5 (Table 1) and only then assume constant values. They make it possible to estimate the reactivities of the intermediate radicals, telogens, and monomers.

Initiation. The independence of C_n on the nature of the radical-forming compound and, within certain limits, of its concentration (at the same temperature) shows that the initiator is not involved in the chain propagation and transfer stages. The initiation of telomerisation by radical-forming substances such as acyl and alkyl peroxides, azo-compounds, and similar compounds is restricted to a fairly narrow class, since the reaction proceeds only with telogens containing an *E–E'* bond readily susceptible to homolytic dissociation. For example, peroxides and azobisisobutyronitrile successfully initiate the telomerisation of olefins with CCl_4 but are incapable of initiating the analogous reactions involving the C–Cl bond with compounds of the type RCH_2CCl_3.[9] On the other hand, the major influence of polar affects on the course of telomerisation has been discovered. When the polar effects of the telogen and the monomer are of the same kind, even extremely reactive compounds do not react via the telomerisation mechanism under the conditions of the method of initiation indicated. Thus, on initiation with peroxides, azo-compounds, or ultraviolet light, acrylic monomers are not telomerised by the esters of α-bromo-substituted acids, chloroform, and carbon tetrachloride[10]; instead of undergoing telomerisation, the monomer polymerises. Nevertheless, these initiation methods retain fully their importance for telomerisation, particularly telomerisation involving the dissociation of a C–H bond.

A new important procedure involves the use of metal carbonyls for the initiation of telomerisation. Carbonyls were employed for this purpose for the first time in the Laboratory of Organoelemental Synthesis at the Institute of Organoelemental Synthesis of the USSR Academy of Sciences in 1959–1961.[13] As will be shown below, when halogen-containing telogens are used, the initiation of the telomerisation by mononuclear metal carbonyls can be described by Scheme 3:

Scheme 3

$$M(CO)_n \rightleftarrows M(CO)_{n-1} + CO ;$$

$$\rangle C—Hal + M(CO)_{n-1} \rightarrow \rangle C^{\cdot} + HalM(CO)_{n-1} .$$

(A)

Next the reaction proceeds via stages (3)–(6) of Scheme 2 (Y = $\rangle C^{\cdot}$) or, in contrast to the initiation of the telomerisation by radical-forming substances, the intermediate metal carbonyl halide (A) participates in the chain transfer stage, transferring the halogen to the growing radical via Scheme 4 (where $m = 0,1$):

Scheme 4

$$(A) + Y(CH_2CHR)_m CH_2\dot{C}HR \rightarrow Y(CH_2CHR)_{m+1}Hal + M(CO)_{n-1} .$$

The metal-containing species $M(CO)_{n-1}$ arising in this stage participates in the transfer of the kinetic chain, abstracting the halogen from the telogen, as shown in Scheme 3.

This is a very flexible initiation procedure, since, by varying the nature of the metal carbonyl, it is possible to achieve reactions which proceed with very great difficulty. It has now been found that the complexes of metal carbonyls with various ligands, i.e. $M(CO)_{n-1}L$, as well as the combination of the metal carbonyl and the ligand taken separately, i.e. $M(CO)_n$ + L are even more active telomerisation initiators. Subsequently, both in the studies in the Laboratory of Organoelemental Synthesis at the Institute of Organoelemental Synthesis of the USSR Academy of Sciences and in the studies by foreign investigators, a wide range of initiating systems were applied, including various transition metal compounds (carbonyls, halides, chelates, and π-complexes) in combination with various activating additives (co-initiators)—alcohols, amines, amine hydrochlorides, nitriles, carboxylic acid esters, phosphorous acid esters, dimethylformamide (DMF), etc.[13]

Chain transfer. A wide variety of forms of chain transfer in telomerisation have now been discovered. Apart from the reactions with chain transfer by the growing radicals to the telogen [stage (5) of Scheme (2)]. reactions have been found in which chain transfer proceeds via the fragmentation of the growing radical (Scheme 5), via the oxidation of the growing radical (Scheme 6), and via the transfer of the halogen from metal carbonyl halides (Scheme 4). For example, for the telomerisation of ethylene by tetrachloroethylene (initiator—t-butyl peroxide (TBP)], we suggested[16] that chain transfer takes place via the fragmentation of the growing radical in accordance with Scheme 5:

Scheme 5

$$CCl_2{=}CCl_2 + n CH_2{=}CH_2 \xrightarrow{TBP} Cl(CH_2CH_2)_nCCl{=}CCl_2 ;$$

(1) (TBP) $\rightarrow$ 2R$^{\cdot}$;

(2) R$^{\cdot}$ + $CCl_2{=}CCl_2 \rightarrow RCCl_2\dot{C}Cl_2 \rightarrow RCCl{=}CCl_2 + Cl^{\cdot}$;

(3) Cl$^{\cdot}$ + n $CH_2{=}CH_2 \rightarrow Cl(CH_2CH_2)_n^{\cdot}$;

(4) $Cl(CH_2CH_2)_n^{\cdot} + CCl_2{=}CCl_2 \rightarrow Cl(CH_2CH_2)_n CCl_2\dot{C}Cl_2$ (B) ;

(5) $Cl(CH_2CH_2)_nCCl_2\dot{C}Cl_2 \xrightarrow{\text{fragmentation}} Cl(CH_2CH_2)_nCCl{=}CCl_2 + Cl^{\cdot}$.

There is no doubt that the chain transfer by the radical (B) to the telogen does not occur both as a consequence of the low reactivity and considerable stability of this radical and owing to the low probability of the abstraction of a chlorine atom from tetrachloroethylene. The radicals (B) undergo fragmentation with formation of the final products and the elimination of the chain propagating chlorine atom. Such telomerisation is accompanied by the formation of a number of side products; in particular, extensive chlorination takes place with evolution of hydrogen chloride, which is also consistent with the hypothesis of the intermediate formation of atomic chlorine.

A new type of telomerisation, in which there is undoubtedly no usual chain transfer to the telogen, has been found[17-21]; it was shown that contrary to the literature data, under the conditions of the Meerwein reaction it is possible to achieve the telomerisation of ethylene, acrylonitrile, and vinylidene chloride by arenediazonium chlorides (Scheme 6):

Scheme 6

$$ArN_2Cl + nCH_2=CHX \xrightarrow[CH_3COONa]{CuCl_2/CuCl} Ar(CH_2CHX)_nCl + N_2 ;$$

(1) $ArN_2Cl \xrightarrow{CuCl} Ar^{\cdot}$;

(2) $Ar^{\cdot} + CH_2=CHX \rightarrow ArCH_2\dot{C}HX$;

(3) $ArCH_2\dot{C}HX + nCH_2=CHX \rightarrow Ar(CH_2CHX)_n^{\cdot}$;

(4) $Ar(CH_2CHX)_n^{\cdot} + ArN_2Cl \not\rightarrow$ (do not react);

(5) $Ar(CH_2CHX)_n^{\cdot} + CuCl_2 \rightarrow Ar(CH_2CHX)_nCl + CuCl$;

$Ar = C_6H_5$, n-$NO_2C_6H_4$, o-$CH_3C_6H_4$; X = H, CN, $COOCH_3$; $n = 1, 2$.

All the stages of this reaction, except stage (3), had been proposed earlier. We were able to obtain telomers and demonstrate thereby that stage (3) can take place[21]. In this case direct chain transfer via stage (4) is undoubtedly ruled out; the growing radical is stabilised in the oxidation-reduction reaction with $CuCl_2$ via stage (5).

Certain examples in which the telomerisation does not obey the usual mechanism with chain transfer to the telogen were enumerated above. However, the reactions of the usual type (Scheme 2) have been most thoroughly investigated, including investigations by kinetic methods.

Chain termination is the least investigated stage in the telomerisation mechanism. It has been frequently suggested that chain termination takes place as a result of the dimerisation or disproportionation of radicals. However, tests in relation to the telomerisation of cyclohexene, heptene, and propene by trifluoroiodomethane[22] and carbon tetrachloride[23] did not confirm this hypothesis. In the case of carbon tetrachloride[23] the formation of hexachloroethane was not observed, but the hydrides of the intermediate radicals, obtained as a result of the "allyl termination", were found. Instances (for example, in the telomerisation of isobutene by aliphatic acids[24]) where the recombination and cross-recombination reactions of radicals play a significant role and the yield of the corresponding compound is comparable to that of the telomers have been discovered in recent years.

Thus a wide variety of reactions with different types of initiation and chain transfer and termination mechanisms, depending on the structure of the telogen and the monomer and also on the nature of the initiating system, can be achieved at the present time by the telomerisation method. This has greatly extended the scope of the utilisation of telomerisation for synthetic purposes.

III. METAL CARBONYLS AS INITIATORS OF A NEW TYPE

Interesting features have been discovered in telomerisation using initiators of a new type—variable valence compounds and carbonyls of Group VI–VIII metals. Freidlina and Belyavskii showed in 1959[25,26] that iron, chromium, molybdenum, and tungsten carbonyls effectively initiate the homolytic telomerisation of ethylene with CCl_4, $CHCl_3$, and CCl_3COOR. Since then initiating systems based on transition metal carbonyls have been widely used in homolytic chain reactions involving both telomerisation[9,10,12,27] and polymerisation[28,29]. The data accumulated suggest that in this case we are dealing with a new branch of homogeneous catalysis—the metal carbonyl-initiated homolytic chain reactions. The study of the application of redox initiators (the character of the initiating action of which resembles in many respects that of metal carbonyls), mainly iron and copper halides and complex cyanides[30-32] as well as chlorine-containing iron complexes of the type $[L_4Fe^{III}Cl_2]_2[Fe^{II}Cl_4]$, where L = DMF or dimethyl sulphoxide (DMSO), and $[(CH_3CN)_6Fe^{II}][Fe^{III}Cl_4]_2$ in telomerisation was prosecuted simultaneously[33]. Both these large groups of metal-containing initiators are combined[12] in the broad concept of coordination initiators, whose application significantly expands the synthetic scope of telomerisation, namely (1) it makes it possible to regulate the composition of the telomerisation mixture, driving the telomerisation reaction towards the formation of lower telomers up to 70–80% yield of the adduct relative to the sum of the telomers, (2) it directs telomerisation selectively to the C–Hal bond in the presence of reactive C–H and C–Hal bonds in the telogen, (3) it makes it possible to introduce into the telomerisation reaction telogens with the trichloromethyl group which is inert under the conditions of peroxide initiation, (4) it permits the telomerisation of readily polymerisable monomers such as acrylic compounds, styrene, and vinyl chloride, (5) it leads to a simple way of synthesising branched telomers in accordance with a stepwise telomerisation scheme (see Section VI), and (6) it increases the selectivity of the photoinitiation driving the reaction towards the rupture of the C–Hal bond.

Metal carbonyls are the most promising initiators. Differing appreciably (depending on the metal) in their activity in the initiation stage and in their ability to participate in the chain transfer stage, suitably selected metal carbonyls make it possible to achieve any of the synthetic possibilities in telomerisation enumerated above or to obtain a combined result.

In terms of their interaction with the telogen, the monomer, the co-initiator, and finally the growing radical, metal carbonyls effective in telomerisation can be divided into three groups. The first group includes carbonyls capable of abstracting a halogen atom from the telogen in the initiation stage and of transferring it to the growing telomer radical, regenerating at the same time the halogen abstracting species. In other words, these carbonyls are capable of participating in the chain transfer stage without interrupting the kinetic chain. This group includes $Fe(CO)_5$ and its derivatives with the ligand L in the coordination sphere of iron $[L_nFe(CO)_{5-n}]$.

The second group comprises carbonyls capable of abstracting a halogen atom from the telogen in the initiation stage but incapable of transferring it to the growing telomer radical. It includes chromium, molybdenum, and tungsten hexacarbonyls.

The third group is made up of dinuclear carbonyls with a metal–metal bond, for the initiating capacity of which the conditions in the homolytic dissociation of the metal–metal

bond are of decisive importance; their interrelations with the components of the reaction mixture are frequently manifested in an extremely complex manner. This group includes $Re_2(CO)_{10}$, $Mn_2(CO)_{10}$, and $[Cp_2Fe(CO)_2]_2$, as well as, apparently, $[CpW(CO)_3]_2$ and $[CpMo(CO)_3]_2$, which are capable of forming metal-centred radicals[34].

The addition of chloroform to alk-1-enes can serve as a test reaction for the classification of metal carbonyls[35-38]. Chloroform is able to react with dissociation of both C–Cl and C–H bonds in different sequences depending on the character of the initiation (Scheme 7).

Scheme 7

(1) $CCl_3{-}H \rightarrow \dot{C}Cl_3 \xrightarrow{-C=C-} CCl_3\dot{C}{-}\dot{C}- \xrightarrow{CCl_3-H} CCl_3C{-}\dot{C}H$;

(2) $Cl\,CH{-}Cl \rightarrow \dot{C}HCl_2 \xrightarrow{-C=C-} CHCl_2\dot{C}{-}\dot{C}- \xrightarrow{CCl_3-H} CHCl_2C{-}\dot{C}H$;

(3) $Cl_2CH{-}Cl \rightarrow \dot{C}HCl_2 \xrightarrow{-C=C-} CHCl_2\dot{C}{-}\dot{C}- \xrightarrow{CHCl_2-Cl} CHCl_2C{-}CCl$.

Eqn.(1) represents the peroxide type of initiation: the C–H bond is dissociated in the initiation and chain transfer stages and the initiator is not involved in the chain transfer stage. Eqn.(2) represents a mixed type of initiation: the metal carbonyl participates in initiation but not in chain transfer; the initiation involves the C–Cl bond and the chain transfer involves the C–H bond. Eqn.(3) represents metal carbonyl initiation where the carbonyl participates in the initiation and chain transfer stages; the initiation and chain transfer take place with dissociation of the C–Cl bond.

In the case of iron pentacarbonyl, which, depending on the conditions, can either react directly via reactions of types (2) and (3) of Scheme 7 or indirectly via a reaction of type (1) (forming a radical $R^{\cdot}$ capable of abstracting a hydrogen atom from chloroform), in each specific reaction it is necessary to take into account the tendency of $Fe(CO)_5$ to form complexes with the monomer[39] and the co-initiator[40-42]. In the case of a weakly polar monomer exhibiting a small capacity for complex formation with iron carbonyl (for example, ethylene), the metal carbonyl is not involved in the chain transfer stage when $Fe(CO)_5$ is used in small amounts (< 5 mole %) without an initiator and the distribution of the telomer homologues in the telomerisation of CCl_4 or $CHCl_3$ with C_2H_4 does not differ from their distribution in peroxide initiation[26,27].

It has been shown for monomers forming comparatively stable complexes with $Fe(CO)_5$ (propene and specially vinyl chloride) in relation to telomerisation with CCl_4 and $CHCl_3$ [39,40] that, at a low $Fe(CO)_5$ concentration and for a long kinetic chain, only the initiating activity of the carbonyl is manifested in the reaction, i.e. it is able to generate $\dot{C}Cl_3$ radicals and the chain transfer constants do not differ from those in the peroxide initiation. With increase of the $Fe(CO)_5$ concentration, the content of the adduct in the mixture of telomers increases appreciably and C_1 can be significantly greater than in the peroxide initiation, i.e. the involvement of the initiator in the chain transfer stage becomes appreciable (a halogen atom is transferred from the telogen to the growing radical via an iron carbonyl intermediate—see Table 1). It has been found[39] that in the initiation by $Fe(CO)_5$, the reactivity of olefins in telomerisation with CCl_4 varies in parallel with the thermal stability of the complexes (C=C).$Fe(CO)_4$ (C=C is the monomer). Apparently a maximum $Fe(CO)_5$ concentration exists above which C_1 and C_2 no longer increase[43] and in addition self-inhibiting properties of the carbonyl make an appearance[27]. Accordingly the content of the adduct in the mixture of telomers passes through a maximum as a function of both the $Fe(CO)_5$ concentration and the reaction time at $[Fe(CO)_5]_0 = \text{const}$.[42,44,45]

The character of the initiation of the telomerisation by iron pentacarbonyl changes sharply in the presence of a nucleophilic co-initiator—an alcohol, a tertiary amine, DMF, DMSO, hexamethylphosphoramide (HMP), and *N,N*-dichloramide[27]. The first two members of the series predominate in the mixture of telomers. The chain transfer rate constant C_1 increases greatly (Table 1), which can be explained by the fact that, in the presence of a nucleophilic co-initiator incorporated in the coordination sphere of iron (this has been demonstrated by EPR[46,47]), the iron-containing species $(Fe)^nCl$, formed as a result of the abstraction of a chlorine atom from the chlorine-containing telogen (CCl_4), transfers the chlorine atom to the growing radical at a much higher rate than in the direct interaction of the growing radical with the telogen.

Table 1. The telomerisation of ethylene by carbon tetrachloride with different methods of initiation[5]*

$CCl_4 + C_2H_4 \rightarrow CCl_3(CH_2CH_2)_nCl$

Initiator	Composition of mixture of telomers, mole %					C_n			
	$n=1$	$n=2$	$n=3$	$n=4$	$n=5$	C_1	C_2	C_3	C_4
Azobisisobutyronitrile	3.1	36.2	30.9	17.2	12.5	0.15	2.8	4.9	5.5
$Fe(CO)_5$	5.4	47.3	29.0	12.7	5.9	0.20	3.6	5.7	7.9
$Fe(CO)_5 + CH_3OH$	66.7	23.7	7.8	1.8	0	6.0	7.7	13.3	—

* Temperature 100 °C; $[C_2H_4]_0/[CCl_4]_0 \cong 4$.

The rate constant for chain transfer via $Fe(CO)_4Cl$ for the adduct-radical in the telomerisation of CCl_4 with C_2H_2 and C_3H_6 using CH_3OH as the co-initiator proved to be 100 times higher than in the peroxide initiation, i.e. than in the direct interaction of the growing radical with the telogen[48,49]:

$$CCl_4 + Fe(CO)_{5-n}(CH_2OH)_n \rightarrow \dot{C}Cl_3 + ClFe(CO)_{4-n}(CH_3OH)_n + CO \ ;$$
$$\dot{C}Cl_3 + CH_2 = CH_2 \rightarrow CCl_3CH_2\dot{C}H_2 \ ;$$

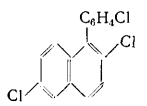
$$CCl_3CH_2\dot{C}H_2 + ClFe(CO)_{4-n}(CH_3OH)_n \xrightarrow{k_{tr} \geqslant 4 \times 10^5 \text{ litre mol}^{-1}\,s^{-1}}$$
$$\rightarrow CCl_3CH_2\dot{C}H_2Cl + \dot{F}e(CO)_{4-n}(CH_3OH)_n \ ;$$
$$CCl_3CH_2\dot{C}H_2 + CCl_4 \xrightarrow{k_{tr} = 0.39 \times 10^4 \text{ litre mol}^{-1}\,s^{-1}} CCl_3CH_2CH_2Cl + \dot{C}Cl_3 \ .$$

Nucleophilic co-initiators act in two ways. On the one hand, they increase the overall rate of reaction, the rate constant increasing in parallel with the increase of their dielectric constants; on the other hand, they influence C_1, i.e. they facilitate the involvement of the initiator in the stage where the halogen is transferred from the telogen to the growing radical and can be arranged in a sequence corresponding to the increase of their electron-donating capacity[45].

The majority of systems based on $Fe(CO)_5$ effectively initiate telomerisation by chlorine-containing telogens at a temperature above 100 °C[12]. However, there exist co-initiators which significantly reduce the initiation temperature. Thus, in the presence of *N,N*-dichlorosulphonamides $XC_6H_4SO_2NCl_2$, iron pentacarbonyl effectively initiates the reaction of CCl_4 with alk-1-enes at a temperature as low as 50 °C and at 25 °C the reaction proceeds to the extent of 1–2% in 6 h.[50] In certain cases when the dissociation of the C–Hal bond is sufficiently easy, as, for example, in the case

of CBr_4 and CCl_3Br, the reaction with acrylic monomers in the presence of the usual $Fe(CO)_5$ + DMF system begins already at room temperature and takes place exothermically[51]:

$$CCl_3Br + CH_2{=}CHCOOCH_3 \xrightarrow[20-80^\circ]{Fe(CO)_5+C_6H_5N(CH_3)_2} CCl_3(CH_2\underset{\displaystyle COOCH_3}{\underset{|}{C}}H)_nBr \ ;$$



$$n = 1\,(37\%);\ n=2\,(12\%)\ .$$

It may be that in this case the carbonyl is activated by the telogen incorporated at the same time in the coordination sphere of the iron.

The use of initiating systems of the type of $Fe(CO)_5^+$ co-initiator made it possible to introduce into telomerisation compounds with the CCl_3 group[9,12,52] and benzyl chloride (via the C–Cl bond)[55]. These systems are effective in the initiation of telomerisation with participation of compounds having a CCl_2 group activated by electron-accepting substituents[53,54] and compounds with the CBr_3 and CBr_2 groups[10,56-58].

Using initiating systems based on $Fe(CO)_5$, it is possible to telomerise by polychloro- and polybromo-derivatives polymerisable monomers such as acrylic compounds[10,53,59,60], vinyl chloride[43,55,57,61], vinylidene chloride[62], and 1,3-dienes[63,64]. The familiar ability of $Fe(CO)_5$ to promote dehalogenation and dehydrohalogenation has been used in telomerisation to convert linear chain compounds into cyclic and aromatic compounds. Such are, for example, the lactonisation reactions in the telomerisation of unsaturated compounds by esters of α-halogeno-substituted acids[10] and the formation of ring-chlorinated phenylnaphthalenes in the telomerisation of DDT with vinyl chloride[65]:

$$(ClC_6H_4)_2CHCCl_3 + CH_2{=}CHCl \xrightarrow[\text{coinitiator}]{Fe(CO)_5}$$

Substituted 2,2,6-trichloro-1-(chlorophenyl)tetrahydronaphthalenes are formed in the telomerisation of ethylene, methyl acrylate, and styrene with DDT[66-68]. Thus initiators based on $Fe(CO)_5$ lead to extensive possibilities in telomerisation (see Table 6 for further details).

The representatives of the second group of metal carbonyls–chromium, molybdenum, and tungsten hexacarbonyls–give rise to an initiating metal-centred radical $\dot{M}(CO)_5$ or $L_n\dot{M}(CO)_{5-n}$; the latter abstracts a halogen atom from the telogen in the initiation stage and produces a species [for example, $ClM(CO)_5$], which is not involved in the subsequent development of telomerisation. The partial chain transfer constants C_n for the reactions of CCl_4 with ethylene and propene hardly change on passing from peroxide initiation to initiation by the carbonyls $Cr(CO)_6$, $Cr(CO)_5[P(C_6H_5)_3]$, $Mo(CO)_6$, or $W(CO)_6$[69-72] (Table 2). The formation of $\dot{C}Cl_3$ radicals in the photochemical interaction of chromium, molybdenum, and tungsten hexacarbonyls with polychloroalkanes has been demonstrated by EPR using spin trapping agents[74]. The formation of the radicals $Cl\dot{C}r(CO)_5$ by the abstraction of chlorine from CCl_4 under the influence of $Cr(CO)_6$ has also been reliably established by EPR[75,76]. The co-initiators which usually facilitate the involvement of the carbonyl-containing species in the chain transfer stage naturally do not influence the proportions of the telomers in the mixture in the given instance (where such involvement does not occur).[71] The chain transfer constants C_n are in such cases close to the "cross" constant (Table 2).

The use of co-initiators in combination with $Cr(CO)_6$ does not affect appreciably the yield of adducts and telomers in the reactions of CCl_4 and $CHCl_3$ with olefins[71,77], although the rate of initiation in the presence of a co-initiator increases (for low degrees of conversion of the telogen)[70-72]. The insertion of an active ligand of the type of $P(C_6H_6)_3$ in the ligand sphere of the metal carbonyl can increase significantly the initiating activity of the carbonyl, as has been observed for $Cr(CO)_5[P(C_6H_5)_3]$.[70] The insertion of HMP in the coordination sphere of chromium with displacement of CO and the formation of the complex $ClCr(CO)_3$(HMP) in the presence of CCl_4 has been observed by EPR[76]. Apparently metal carbonyls of this type are most effective in the initiation of telomerisation reactions which are distinguished by a long kinetic chain, because these carbonyls do not regenerate the initiating species during telomerisation.

Table 2. Partial chain transfer constants C_n for the telomerisation of propene by carbon tetrachloride with different methods of initiation (at 120 °C)[69-72].

Initiator	C_1	C_2
Peroxide*	2.65	33.0
$Cr(CO)_6$	2.63	34.9
$Mo(CO)_6$	2.03	39.2
$Mn_2(CO)_{10}$	1.79	26.4
$Cr(CO)_6$ + HMP	1.51	26.7
$Cr(CO)_6$ + DMF	1.60	28.2
$Cr(CO)_6 + CH_3CN$	1.59	22.3
$Cr(CO)_6 + CH_3OH$	1.51	23.2
$Mn_2(CO)_{10}$ + DMF	1.95	27.2

* The values obtained by interpolating the data for 95°, 105°, and 145 °C.[73]

Among the representatives of dinuclear metal carbonyls, $Mn_2(CO)_{10}$ has been studied in greatest detail in telomerisation[38,59,78-82]. The stage preceding initiation (and possibly determining the rate of reaction as a whole[27,34]) is in this instance the dissociation of the metal carbonyl at the metal–metal bond, which takes place either thermally (120–130 °C) or under the influence of ultraviolet light. The metal-centred $\dot{M}n(CO)_5$ radicals formed are capable of abstracting a chlorine atom from the telogen and of initiating telomerisation. The formation of $\dot{C}Cl_3$ from CCl_4 and of $\dot{C}Cl_2CCl_2H$ under the influence of $\dot{M}n(CO)_5$ has been demonstrated by EPR[74]. The radicals $\dot{M}n(CO)_5$ cannot then be attached to a spin trapping agent, which indicates a high reactivity in the abstraction of chlorine from the telogen[74]. The partial chain transfer constants for the telomerisation of ethylene and propene with CCl_4, initiated by $Mn_2(CO)_{10}$, are close in magnitude to the chain transfer constants for the same reaction initiated by peroxides[82] (Table 2). The relative isomerisation constant in the reaction of methyl chloroacetate with ethylene, initiated by $Mn_2(CO)_{10}$, is almost the same as under the conditions of peroxide initiation[38]. The main process stabilising the growing adduct and telomer radicals is abstraction of hydrogen by the latter from the components of the medium [pathway (2), Scheme 2].

Thus the available data show that $Mn_2(CO)_{10}$ does not participate in the stage involving the transfer of the halogen from the telogen to the growing radical[38,59,80-82]. It does not initiate the addition of CH_3OCOCH_2R to hex-1-ene which takes place effectively in the presence of peroxides[81] whence it follows that $\dot{M}n(CO)_5$ does not participate in the transfer of hydrogen from the substrate to the growing radical, accompanied by the dissociation of a C–H bond. (This does not apply to processes involving the homolysis of other E–H bonds, for example Si–H.) It has been found that $Mn_2(CO)_{10}$ initiates fairly readily reactions with both CCl_4 and $RCCl_3$[59,79,80], since in its presence telomers with the CCl_3 group are

capable of further reactions of the type of stepwise telomerisation (see Section VI). This property of $Mn_2(CO)_{10}$ apparently explains the maxima on the curve describing the time variation of the yields of the lower telomers[80].

A characteristic feature of $Mn_2(CO)_{10}$ as an initiator is that nucleophiles not only do not activate it but in many instances actually reduce the effectiveness of initiation[79,80]. Microadmixtures of iron compounds exert a considerable influence; therefore, when telomerisation initiated by $Mn_2(CO)_{10}$ is carried out in metallic reactors, i.e. under conditions close to those obtained in the industrial process, one can obtain a mixture of telomers with an increased content of lower telomers, which is reflected in the chain transfer constant determined[36,83].

It is noteworthy that, in the telomerisation of ethylene by methyl chloroacetate, initiation proceeds with abstraction of the chlorine atom by the $Mn(CO)_5$ radicals, but the overall reaction product is almost wholly a mixture of telomers formed as a result of the dissociation of a C–H bond in the telogen[38]:

$$\left.\begin{array}{l} CH_3OCOCH_2Cl \xrightarrow{Mn_2(CO)_{10}} CH_3OCO\dot{C}H_2 \xrightarrow{nC_2H_4} \dot{T}_n \\ \dot{T}_n \xrightarrow{CH_3OCOCH_2Cl} CH_3OCO\dot{C}HCl \end{array}\right\} \text{(initiation);}$$

$$\left.\begin{array}{l} CH_3OCO\dot{C}HCl + n\,H_2C=CH_2 \rightarrow CH_3OCOCHCl(CH_2CH_2)_n\dot{} \\ CH_3OCOCHCl(CH_2CH_2)_n\dot{} + ClCH_2COOCH_3 \rightarrow \\ \rightarrow CH_3OCOCHCl(CH_2CH_2)_nH + CH_3OCO\dot{C}HCl \end{array}\right\} \text{(main kinetic chain).}$$

The telomerisation of ethylene[38,80–82] and propene[82] with CCl_4, of ethylene with CCl_3COOCH_3[38] and $ClCH_2COOCH_3$[38,81], and of 1,1,1,3-tetrachloropropane with methyl acrylate[59] can be initiated with the aid of $Mn_2(CO)_{10}$.

IV. STEPWISE TELOMERISATION

A telomer having a group reactive in telomerisation (CCl_3, CBr_3) can play the role of a telogen, having entered into a secondary reaction with the monomer. Such a process has come to be called stepwise[12] or secondary[4] telomerisation, in contrast to the usual chain telomerisation. The products of the stepwise telomerisation can have the same structure as the telomers obtained by the usual (chain) telomerisation if the carbon atom which carries the unpaired electron in the growing radical is attacked in the secondary reaction[84]:

$$CH_3I \xrightarrow{C_2H_4} CH_3CH_2CH_2I \xrightarrow{C_2H_4} CH_3(CH_2)_4I \text{ etc.}$$

The synthetic value of this reaction consists in the fact that any telomer-homologue can be obtained from preceding members of the series by consecutive monomer addition steps.

The structure of the product of the stepwise telomerisation can, however, differ from that of the telomers obtained by the usual telomerisation when there are several reactive centres in the telomer and the radical attack is not directed to the carbon atom carrying the unpaired electron in the growing radical[85]:

$$CH_3OCOCH\underset{\downarrow}{Br}_2 \xrightarrow{CH_2=CHCl} CH_3OCOCH\underset{\downarrow}{Br}CH_2CHClBr \xrightarrow{CH_2=CHCl} \rightarrow CH_3OCOCH(CH_2CHClBr)_2 .$$

(The arrow indicates the point of attack.) This version of the stepwise telomerisation makes it possible to synthesise branched telomers†. The greatest synthetic possibilities in this version arise from the application of coordination initiators (including metal carbonyls), which initiate selectively the reaction at the most reactive C–Hal bond in the telogen[12]. However, stepwise telomerisation is also not ruled out for peroxide initiation[56,86]:

$$CBr_4\ (\text{or } CHBr_3) \xrightarrow[BP]{C_2H_4} CBr_3CH_2CH_2Br \xrightarrow[BP]{C_2H_4} (BrCH_2CH_2)_2CBr_2 ,$$

where BP is benzoyl peroxide. 1,1,1,3-Tetrachloroalkanes enter into the stepwise telomerisation initiated by the $Fe(CO)_5$ + co-initiator systems[9,87,88], for example:

$$ClCH_2CH_2CCl_3 + C_2H_4 \rightarrow (ClCH_2CH_2)_2CCl_2 .$$

When the esters of α-halogeno-substituted acids are used as telogens, the stepwise telomerisation makes it possible to obtain α-substituted lactones[89], including spiro-dilactones, which are difficult to obtain by other procedures[90]:

$$CHCl_2COOCH_3 + 2\,C_2H_4 \rightarrow \begin{array}{l} H_2C\text{——}CClCH_2CH_2Cl \\ \quad|\qquad\quad| \\ H_2C\quad C{=}O \\ \quad\diagdown O\diagup \end{array} ;$$

$$(C_2H_5OCO)_2CBr_2 + 2\,RCH=CH_2 \rightarrow \begin{array}{l} \quad\quad\quad\quad\quad\quad\quad\quad O \\ \quad\quad\quad\quad\quad\quad\quad\quad \downarrow \\ RHC\text{—}C\quad\quad C\text{—}O \\ \quad|\quad\quad\quad\quad| \\ O\text{—}C\quad\quad C\text{—}CHR \\ \quad\quad\diagdown\quad\quad\diagup\ (\ H_2) \\ \quad\quad\quad C \\ \quad\quad\quad\quad O \end{array} .$$

Thus the stepwise scheme expands the synthetic possibilities of telomerisation.

1. Determination of the Structure of Halogen-containing Telomers

In all cases of telomerisation with participation of polyhalogeno-telogens, it is necessary to solve problems involving the determination of the structure of the telomers, which are sometimes by no means simple, bearing in mind the possibility of rearrangements in the growing radicals, of the disproportionation of the halogens in the chlorine- and bromine-containing adducts and telomers[91], and the probability of stepwise telomerisation. Studies in the Laboratory of Organoelemental Synthesis at the Institute of Organoelemental Synthesis of the USSR Academy of Sciences[92–99] have established that ^{13}C NMR is a reliable method for the determination of the structures of polyfunctional halogen-containing telomers. The regions in which the signals of various polychloro-groups[92–95] and polybromo-groups[95–97] appear have been investigated in detail, the characteristic interactions of the vicinal and geminal halogen atoms have been discovered, and a scheme has been developed using the additive increments due to chlorine and bromine in the chlorine- and bromine-containing fragments[98,99], which makes it possible to calculate the chemical shifts of the polyhalogeno-groups in the ^{13}C NMR spectra.

V. TELOMERISATION ACCOMPANIED BY THE REARRANGEMENT OF THE RADICALS

Oxygen-containing telogens reacting as a result of the dissociation of a C–H bond are of special interest in the telomerisation reaction. These include carboxylic acids, alcohols, ketones, and their various derivatives (Table 3). These telogens have been investigated in reactions with a wide range of monomers, which has led to the discovery of the characteristics of the telomerisation with their participation, involving the rearrangement of the growing radicals.

† In this case the usual telomers have the structure $CH_3OCOCHBr(CH_2CHCl)_nBr$.

As a result, the growing radical in this group of reactions participates simultaneously in three competing processes—chain propagation, chain transfer, and isomerisation. The study of the characteristics of such reactions has demonstrated extensive possibilities in their employment for research and synthetic purposes[11,100,101].

* Here R is an alkyl group appearing in the α-position relative to the functional group as a result of the rearrangement of the radicals and chain propagation in accordance with Scheme 8.

1. Reaction Conditions

The low effectiveness of the telogens reacting as a result of the dissociation of a C–H bond as chain transfer agents in the reaction makes it necessary to employ as initiators mainly alkyl or acyl peroxides, which give rise to RO· radicals on decomposition (t-butyl peroxide, dicyclohexyl peroxydicarbonate) in the temperature range 50–150 °C. These reactions are characterised by relatively low degrees of conversion of the telogen (1–10%) and sometimes the formation of a considerable amount (15–60%) of unidentified higher telomers. In order to reduce the content of the latter, the telomerisation must be carried out at comparatively low pressures (25–50 atm). Analytical and preparative gas–liquid chromatography and ^1H and ^{13}C NMR spectroscopy are widely used to analyse the mixtures, to obtain the telomers in a pure form, and to demonstrate their structure.

2. Telomerisation of Ethylene

It was demonstrated for the first time in 1964 that the telomerisation of ethylene by acetic acid (Table 3, No.2) is accompanied by a rearrangement of the growing radicals with 1,5-migration of the hydrogen atom, which leads to the formation of two series of telomers[102]. Subsequently, it was possible to show in relation to a wide range of reactions with ethylene that such rearrangement is a fairly common phenomenon for reactions with comparatively ineffective telogens[103] (Scheme 8). The radicals (C) formed in the initiation stage react with ethylene to produce the growing radicals (D), which are converted into telomers of the non-rearranged series T_n, having transferred the chain to the telogen:

Scheme 8

$$\underset{(T_0)}{RCH_2CO_2CH_3} + R'O^{\cdot} \rightarrow \underset{(B)}{R\dot{C}HCO_2CH_3}\ ;$$

$$\underset{(C)}{\cdot} + n\,CH_2=CH_2 \rightarrow \underset{(D)}{\cdot(CH_2CH_2)_n\,CHRCO_2CH_3}\ ;$$

$$(D) \xrightarrow{T_0} H(CH_2CH_2)_nCHRCO_2CH_3\ ;$$

$$\dot{C}H_2CH_2CH_2CH_2CHRCO_2CH_3 \xrightarrow{1,5\text{-H-rearrangement}} \underset{(F)}{CH_3CH_2CH_2CH_2\dot{C}RCO_2CH_3} \rightarrow$$

$$\xrightarrow{C_2H_4} CH_3(CH_2)_3CRCO_2CH_3 \xrightarrow{T_0} \underset{T_m}{H(CH_2CH_2)_m\,CRCO_2CH_3}\ .$$

$$\quad\quad\quad

It has been shown[103] that in the given system the growing radical (D) ($n = 1$) does not rearrange with 1,3-migration of hydrogen. It might have been supposed that telomers with a branched structure T'_m are obtained via the stepwise telomerisation mechanism from the telomers formed (see Section IV). However, detailed investigations yielded much evidence showing that here we are in fact dealing with a rearrangement of radicals[11]. One of the most convincing pieces of evidence is the high process selectivity—only one series of branched telomers containing the butyl group in the α-position is formed. Special tests demonstrated the absence of comparable amounts of α-ethyl-substituted telomers, which should have been produced as a result of the secondary reaction of the first telomer $CH_3CH_2CHRCO_2CH_3$ with ethylene[11].

The influences of various factors on the course of telomerisation and on the degree of rearrangement have been estimated quantitatively in relative terms and compared using the method of relative kinetics, within the framework of which the partial chain transfer constants $C_n = k_{tr}/k_p$ and the relative isomerisation constants $C_i = k_i/k_p$ have been estimated (Table 3).[103] For the same monomer, when the radical centre is sufficiently remote from the functional group and the substituent R, the reactivity of the radicals $\dot{C}(CH_2CH_2)_nCHRCO_2CH_3$ is independent of the nature of R. The difference between the values of C_n with $n \geq 3$ for reactions involving different telogens $RCH_2CO_2CH_3$ is then determined solely by the difference between the efficiencies of the telogens as chain transfer agents for the reaction (Table 3). Thus $C_{n\geq 3}$ can serve as a relative measure of the efficiency of the given telogen in the chain transfer stage. The data in Table 3 show that the telogens investigated in telomerisation with ethylene, which react at the C–H bond, are characterised by extremely low values of $C_{n\geq 3}$ (from 0.04 to 0.20) and only methyl bromoacetate (Table 3, No.6), which reacts as a result of the dissociation of the C–Br bond, can be classified as an extremely effective telogen.

The corresponding radicals differ much more as regards the degree of rearrangement C_i. $C_i = 0$ has been obtained for methyl bromoacetate, which is highly effective in telomerisation. Comparison of data for methyl acetate and methyl bromoacetate (Table 3, Nos.3 and 6 respectively), where the growing radicals are the same, has shown that a higher value of C_i corresponds to the less effective methyl acetate. Thus the comparatively low efficiency of the telogen in the chain transfer reaction constitutes an important condition for the rearrangement of the radicals.

However, this is a necessary but not a sufficient condition. Thus the values of $C_{n\geq 3}$ for methyl chloroacetate (No.5) and methyl propionate (No.8) are higher than for methyl acetate (No.5) and the degree of rearrangement is in this case also higher (see Table 3). In the given instance, the difference between the stabilities of the initial and rearranged radicals plays a significant role and it is naturally higher in the presence of a substituent R = Cl or CH_3, different from hydrogen, at the radical centre of the rearranged radical (F) (Scheme 8). Here the polar nature of the substituent R does not play a fundamental role: for both electron-donating (CH_3) and electron-accepting (Cl) substituents, the degree of rearrangement is higher than for R = H.

On the other hand, the increase of the chain length of the substituent in the α-position relative to the carboxy-group (Table 3, No.10) results in a decrease of the degree of rearrangement, which can be explained by the appearance of steric hindrance in the intramolecular chain transfer stage. At the same time the nature of the initiating system [peroxides and complex initiators based on $Mn_2(CO)_{10}$ and $Fe(CO)_5$] hardly affects the rearrangement with migration of hydrogen in the telomerisation reaction[36,62,82].

3. Telomerisation of Propene

The replacement of ethylene by propene led to new prospects for the investigation of telomerisation (Scheme 9). In the study of the telomerisation of propene by carboxylic acids and their derivatives, it was shown[11] that, together with the 1,5-migration of hydrogen in the radical (H), there is also a high degree of the 1,3-migration of hydrogen in the radical (G) containing one monomer unit. This results in a sharp increase of the content of telomers with two substituents in the α-position and among the higher telomers there are virtually no compounds of the non-rearranged series[112–114] (Table 3, Nos.23, 24, and 26).

Scheme 9

$$\underset{(G)}{CH_3\dot{C}HCH_2CHRCOOCH_3} \xrightarrow{1,3\text{-H}} \underset{(G')}{CH_3CH_2CH_2\dot{C}RCOOCH_3}\ ;$$

$$\underset{(H)}{CH_3\dot{C}HCH_2\overset{CH_3}{\overset{|}{C}}HCH_2CHRCOOCH_3} \xrightarrow{1,5\text{-H}} \underset{(H')}{CH_3CH_2CH_2\overset{CH_3}{\overset{|}{C}}H\dot{C}RCOOCH_3}.$$

Comparison of data for the reactions of propene with various telogens of the type $RCH_2CO_2CH_3$ (R = H, Cl, or CH_3)[112,113,115] shows that in this series too the lowest relative degree of rearrangement corresponds to methyl acetate (R = H), where the difference between the stabilities of the rearranged (H′) and non-rearranged (H) radicals is smallest (see Scheme 9). It has been shown in relation to the telomerisation of propene by methyl chloroacetate (Table 3, No.24)[114,116] that the decrease of the reaction temperature from 150 °C to 25 °C results in the disappearance of the telomers whose formation is associated with the 1,3-migration of hydrogen, while the 1,5-migration of a hydrogen atom, which is more favourable from the standpoint of the conformation of the transition state, proved to be much less affected by the change of temperature. This is yet another piece of evidence showing that we are in fact dealing with the migration of hydrogen, since in the case of the secondary reaction of telomers T_n of the type $H[CH(CH_3)CH_2]_nCHRCO_2.CH_3$ with propene there are no grounds for expecting markedly different reactivities for T_1 and T_2.

The rearrangement of the radicals with 1,3-migration of hydrogen in the case of propene is associated, in our view, with a favourable combination of polar factors—the nucleophilic radical centre attacks the electrophilic component of the radical in the intramolecular transfer range.

4. Other Monomers

The significant role of the polar characteristics of the growing radical in the rearrangement has been confirmed in the study of the telomerisation of vinyl chloride (Table 3, Nos.27 and 28), where the growing radicals have a pronounced electrophilic character. In this case the rearrangement of the radicals $Cl\dot{C}HCH_2(CHClCH_2)_nCHRCO_2CH_3$, where $n = 0$, 1, does not occur[117,118].

The influence of the nature of the monomer on the reaction has been manifested also in the comparison of the results obtained in the reactions of methyl propionate with vinyl acetate[119] and allyl acetate[120] (Table 3, Nos.33 and 34). In the former case only the 1,5-migration of a hydrogen atom takes place, while in the reaction with $CH_2{=}CHCH_2CO_2CH_3$, which can be regarded as a substituted analogue of propene,

the 1,3-migration of hydrogen takes place. The formation of two telomers with different structures containing two monomer units was also noted for the telomerisation of hex-1-ene[121] (Table 3, Nos.31 and 32) and trimethylvinylsilane[122] (No.35).

A number of interesting features distinguish the telomerisation of isobutene[24,122]. In this case there is no 1,3-migration of hydrogen in the radical $(CH_3)_2\dot{C}CH_2CHRCO_2CH_3$, although polar factors favour it (see Scheme 10). The absence of the rearrangement is apparently associated with the steric hindrance, which has a particularly marked effect in the stage involving the formation of the energetically unfavourable four-membered transition state, while the 1,5-migration of hydrogen in the radical (I) proceeds to a high extent:

Scheme 10

$$(CH_3)_2\dot{C}CH_2C(CH_3)_2CH_2CHRCO_2CH_3 \xrightarrow{1,5\text{-}H} (CH_3)_2CHCH_2C(CH_3)_2CH_2\dot{C}RCO_2CH_3$$

(I) (I')

$$(CH_3)_2C{=}CH_2 \longrightarrow CH_3C(\dot{\ })(=CH_2)_2 \ ;$$

$$(I') + CH_3C(\dot{\ })(=CH_2)_2 \longrightarrow (CH_3)_2CHCH_2C(CH_3)_2CH_2CRCO_2CH_3 \longrightarrow$$

$$\longrightarrow (CH_3)_2CHCH_2C(CH_3)_2CH_2CRCO_2CH_3 \ .$$

$$CH_2CH(CH_3)_2$$

Here the behaviour of the radical (I') is unusual. By virtue of the characteristic features of its structure, it is hardly involved in the chain propagation and transfer reactions and mainly recombines with the isobutenyl radicals, giving rise to an unsaturated compound. Subsequently the hydrogenation of the double bond makes it possible to obtain readily the saturated analogue.

5. Telomerisation of Olefins by Acetals

The study of the telomerisation of ethylene[124] and propene[125] by linear acetals led to the discovery of a new combination of rearrangements with 1,5- and 1,9-migrations of a hydrogen atom (Table 3, No.18). The reaction develops via the C–H bond of the methoxy-group with formation of long-chain acetals T_n. The intermediate growing radicals (Scheme 11) with one and three monomer units rearrange respectively with 1,5- and 1,9-migration of hydrogen. On the other hand, the radical with two monomer units does not rearrange with 1,7-migration of hydrogen. Such selectivity constitutes important evidence in support of an intramolecular character of the migration of hydrogen, because all three telomers T_n, where n = 1, 2, and 3, can participate to equal extents in secondary reactions. We may note that the 1,9-migration of hydrogen corresponds to two 1,5-transitions as regards the conformation of the transition state, which probably actually facilitates the occurrence of this rearrangement[126]:

Scheme 11

$$CH_3CH(OCH_3)_2 \xrightarrow{R\dot{O}} CH_3\dot{C}H(OCH_3)OCH_2 \ ;$$

(T_0)

$$CH_3\dot{C}H(OCH_3)OCH_2 + n\,CH_2{=}CH_2 \xrightarrow{T_0} CH_3CH(OCH_3)OCH_2(CH_2CH_2)_nH \ ;$$

(T_n)

$$CH_3CH(OCH_3)OCH_2(CH_2\dot{C}H_2)_n \xrightarrow[1,9\text{-}H(n=3)]{1,5\text{-}H(n=1)} CH_3\dot{C}(OCH_3)OCH_2(CH_2CH_2)_nH \ ;$$

$$CH_3\dot{C}(OCH_3)OCH_2(CH_2CH_2)_nH \xrightarrow[-CH_3\dot{O}]{} CH_3C(O)OCH_2(CH_2CH_2)_nH \ .$$

6. The Use of ^{13}C NMR for the Investigation of the Structure of Telomers

The processes described above and analogous reactions always result in the formation of extremely complex compounds having a branched structure and belonging to different classes—carboxylic acids and their esters, nitriles, halogeno-derivatives, substituted cyclic and linear acetals and their hetero-analogues, etc. ^{13}C NMR has been used widely and successfully to determine the structures of such compounds[121,127–131]. The characteristic groups and the corresponding chemical shifts of the signals as well as the rules governing the variation of the chemical shifts as a function of the structure of neighbouring units have been discovered for a large number of model compounds. For example, the ^{13}COO and $^{13}CH_3$–C signals are displaced downfield with increase of the number of substituents at the neighbouring carbon atom; the accumulation of substituents at the β-carbon atom leads to an upfield shift of the $^{13}CH_3$.CH_2C signal. Calculations based on an additive scheme taking into account corrections[128] and the regression equation proposed by ourselves, with the corresponding coefficients, which relates the chemical shifts of the key signals of the test compounds, in particular, the esters of polybranched acids, to the chemical shifts of the signals of the corresponding carbon atoms in isostructural hydrocarbons, have been widely used to assign the signals[121,129].

VI. COTELOMERISATION OF TWO MONOMERS WITH ONE TELOGEN

Cotelomerisation may imply the reactions of two monomers with one telogen, of two telogens with one monomer, or of two monomers with two telogens[4,12]. The study of cotelomerisation was begun only in recent years and concerns mainly different versions of the reactions of monomers with one telogen. The difficulties in the study of a complex mixture of homo- and co-telomers limit the development of this field. Examination of the simplest cotelomerisation scheme

$$\underbrace{X-Y}_{\text{telogen}} + \underbrace{mA + nB}_{\text{monomers}} \xrightarrow{\text{initiator}} \underbrace{XA_mB_nY}_{\text{cotelomers}} \ ,$$

shows that, for each value of the sum $m + n$, one may expect the formation of 2^{m+n} different structures if the growth of the radical chain takes place only via the "head to tail" mechanism. When $m + n = 1–3$, there is a possibility of the formation of 14 compounds; the absence of asymmetric atoms in the molecules of the products is then assumed.

Table 4. The cotelomerisation of two monomers* with one telogen.

* Conventional notation: $E = CH_2CH_2$, $P = CH_2CHCH_3$, $I = CH_2C(CH_3)_2$, $V = CH_2CHCl$, $V' = CH_2CCl_2$, $A = CH_2CHCN$, $F = CF_2CFCF_3$.
** All possible telomers have been obtained.

In view of the difficulties in the investigation, cotelomerisation was initially used only to obtain mixtures of oligomers with useful properties—fire resistance, thermal stability, high covering power, and compatibility with polymers. Numerous examples of the preparation of such oligomers have been published[4]; the molecular weights of a series of these, which varies in the range from 400 to 10000, were indicated.

The study of the structure of the lower cotelomers and the determination of the ratio of their yields and the yields of homotelomers as a function of the reaction conditions and the nature of the components are of great theoretical interest. Such study makes it possible to investigate the comparative reactivities of the monomers and radicals in competing reactions, to determine the sequence in which the monomer units are incorporated in the radical chain, and to observe the influence of the polar properties of the monomers, telogens, and growing radicals on the reactions. Cotelomerisation can apparently be used as a model for the solution of certain problems in copolymerisation.

The cotelomerisation of different pairs of monomers with telogens reacting both via a C–Cl bond (Table 4, Nos.1, 4, 6, 7, and 8), via a C–H bond (Nos.2, 3, and 5), or via an S–Cl bond (No.9) was investigated for the first time in the Laboratory of Organoelemental Synthesis at the Institute of Organoelemental Compounds of the USSR Academy of Sciences in relation to nine examples (Table 4) with identification of all the homotelomers and cotelomers formed, containing between one and three monomer units in the molecules. In examples 1–3 both monomers are olefins and are characterised by a polar effect of the same kind; in the remaining examples each two monomers differ markedly as regards the polar effect.

Table 4 shows that in all cases, except for Nos.7 and 9, both possible cotelomers, containing two monomer units, were obtained; the cotelomer whose formation is favoured by the polar effect in the chain transfer stage and by the higher reactivity of the radical centre in T_2 is then formed in a higher yield. When the polar effects of the two monomers act in the same direction and when the telogen is weakly electrophilic, all six possible cotelomers, containing three monomer units, are formed (Nos.2 and 3). In all the remaining cases the cotelomers T_2, for which the polar effect is unfavourable in the chain propagation or chain transfer stage (Nos.1 and 4–6), are not formed. Example 9 is a special case where the two monomers not only differ in their polarity but one of them ($CF_2=CF-CF_3$) is extremely inert in radical reactions; nevertheless it has been possible to involve perfluoropropene in this process. Here it is easy to observe the influence of the polar effects—the absence of groups of the type FSO_2F_n and FSO_2EFF.

VII. PROSPECTS FOR THE PRACTICAL APPLICATION OF TELOMERISATION

The study of the chemical reactions of the tetrachloroalkanes $CCl_3(CH_2CH_2)_nCl$ demonstrated the possibility of using them for the synthesis of ω-chlorocarboxylic acids on the basis of which methods have been developed for the preparation of a new polyamide fibre and synthetic perfumes[1,154]. The reaction of ethylene with tetrachloroethylene made it possible to synthesise 1,1,2-trichlorobutadiene, which readily polymerises via a radical mechanism; its polymers are readily soluble in organic solvents, are resistant to the action of inorganic acids in the cold, and are incombustible; their films exhibit an effective adhesion to metals, rubber, and synthetic materials[155].

The telomerisation of ethylene via the esters of halogenoacetic acids has served as the basis of a method for the synthesis of γ-aminobutyric and ε-aminocaproic acids; the former is an active psychotropic preparation (Gammalon) and the latter is an agent arresting the flow of blood (ε-Capron)[156,157].

The telomerisation of DDT in the presence of complex initiators with formation of derivatives of tetra- and dihydronaphthalenes constitutes one of the possible procedures for the chemical treatment of DDT.[158] Alkyl chlorides, which are essential for the manufacture of biologically degradable surfactants, are obtained by the telomerisation of ethylene by hydrogen chloride. Preparations have been made for the industrial application of this process[159].

The combination in a single process of telomerisation and the rearrangement of radicals made it possible, after a suitable selection of the monomers, telogens, and process parameters, to devise a simple single-stage method of synthesis of branched and polybranched monocarboxylic acids (VIK, PORK), which produce no chemical waste or waste water. The method makes it possible to obtain acids with a wide variation of their structures within the framework of a single universal technology. The preparation of branched

acids by the telomerisation method has been achieved on an industrial scale[160,161].

The VIK acids are highly effective substitutes of dietary and technical plant oils in the paint and varnish industry and other branches of the national economy. Fully oil-free high-quality ML-1121 autoenamels have been devised on their basis at the GIPI LKP, one tonne of VIK replacing up to one tonne of plant oils[162]. Oil-free drying agents have been obtained on an industrial scale on the basis of VIK[161]; the use of VIK makes it possible not only to save up to four tonnes of dietary oils per tonne of VIK but also to increase significantly the activity of the drying agents as a result of the higher concentration of the metal salt and hence their consumption can be reduced.

The VIK and PORK acids are also effective extractants for non-ferrous and rare metals. They make it possible to increase significantly the productivity of extraction processes in hydrometallurgy[163]. The higher fractions of the VIK and PORK acids constitute the basis for the preparation of foam fire extinguishers and de-emulsifying agents[164] and also serve as flotation agents, whereby one can increase by 3—4% the extraction of valuable components from mineral ores, which is extremely important bearing in mind the scale of the mining products processing industry[165]. The main effect of these studies has been the development of a simple technology, the high quality of the telomerisation products obtained, and the possibility of economising on large amounts of dietary and imported technical plant oils.

* Without co-initiator or in combination with iso-C_3H_7OH, DMF, or HMP (HMP = hexamethylphosphoramide and DMF = dimethylformamide).

** Without co-initiator or in combination with HMP, DMF, or CH_3CN.

*** In combination with cyclohexanol.

As a typical organic reaction, telomerisation gives rise to extensive synthetic possibilities. Tables 5 and 6 present examples of telomerisation, involving halogen-containing telogens and initiators of different kinds, achieved in the Laboratory of Organoelemental Synthesis at the Institute of Organoelemental Compounds of the USSR Academy of Sciences in 1977–1982.

Further study of this productive reaction will undoubtedly lead to the development of its new practical applications.

Fluorine-containing Imines

A.V.Fokin, A.F.Kolomiets, and N.V.Vasil'ev

Data on the methods of synthesis, certain physicochemical properties, and reactivities of fluorine-containing imines of known types are surveyed and the characteristic features of the variation of their properties due to the effects of the fluorine atoms and polyfluoro-substituents at the C = N bond are examined. The theoretical and applied aspects of the development of the chemistry of fluorine-containing compounds with a nitrogen-carbon double bond are discussed.
The bibliography includes 240 references.

III. Certain physicochemical properties 243
IV. The reactivity of fluorine-containing imines 245

I. INTRODUCTION

Imines of different structure, including azomethines (Schiff bases), hydrazones and azines, oximes, carbonylimines (iminoesters, amidines, and chloro- and dichlorocarbonylimines), nitrogen-containing heterocumulenes (isocyanates, isothiocyanates, keten imines, and carbodiimides) as well as substances of other types with a C=N double bond are close to alkenes as regards their importance. Their study is indissolubly linked with the foundation and development of organic chemistry as a science, the development of its methods and theory, particularly the stereochemistry of organic compounds and their reactions, tautomeric phenomena, isomerism, molecular rearrangements, the mechanisms of the stepwise and concerted reactions involving nucleophilic and electrophilic addition to a multiple bond, and cycloaddition reactions.

The applied importance of the chemistry of imines is inestimable. They are precursors or intermediates in the synthesis of many physiologically important substances of biogenic and abiogenic types. Imines are formed as intermediate species in the synthesis of many natural products, monomers for polymerisation, and precursors for other technically important materials. The chemistry of imines can be legitimately regarded as the foundation of the chemistry of heterocyclic compounds, which is vigorously developing and is of great practical importance. The study of the chemistry of imines and iminium salts throws light on processes involved in vital activity associated with the synthesis, metabolism, catabolism, and biocatalytic role of biogenic nitrogen-containing substances.

The first fluorine-containing imines were obtained more than 30 years ago and these compounds have been investigated vigorously during the last two decades. At the same time the extensive data accumulated over a short period on the fluorine-containing imines have made an important contribution to the general chemistry of compounds with a C=N bond.

The interest in fluorine-containing imines is due primarily to practical requirements. The development of components of high-energy fuel compositions, explosives, combustion accelerators, precursors for valuable lubricants and other materials, and intermediates in the synthesis of physiologically important substances constitutes a by no means complete list of problems in the solution of which the chemistry of fluorine-containing imines is involved. During recent years, the interest in the chemistry of fluorine-containing imines increased in connection with the appearance of unique fluorine-containing pesticides and medicinal drugs distinguished by the "suicidal" mechanism of action in relation to pyridoxal enzymes. The intensification of studies of the influence of the imine and iminium groups on the reactions of adjacent fluorine-containing substituents is due to this particular factor.

The available extensive data on fluorine-containing imines cannot be considered in a single article and this is not the aim of the present review. Here an attempt is made to summarise the most important information about fluorine-containing imines and to discover the characteristic features introduced by fluorine atoms of fluorine-containing substituents into various methods for the formation of compounds with an imine group and their properties.

The attainment of the aim formulated proved possible by virtue of the availability of monographs on the chemistry of imines[1-3] and the chemistry of organofluorine compounds[4,5], to which the reader is referred in order to become acquainted with the fundamental problems. It has also been promoted by the existence of data on specific problems in the chemistry of fluorine-containing imines. Thus data on *N*-polyfluoroalkylfluoro- and *N*-polyfluoroalkyldifluoro-carbonylimines (perfluoroaza-alkenes) have been examined by Knunyants and Gontar[6]. The chemistry of *N*-fluoroimino-compounds has been discussed in detail in a book[7], in reviews[8,9], and in an article of a review type[10]. An excellent review[11] deals with the chemistry of fluorine-containing keten imines. The existence of the above publications made it possible to reduce greatly the amount of factual data discussed here, the latter being limited to information in the field of fluorine-containing azomethines which had not been reviewed previously and the most important data on other fluorine-containing imines.

II. METHODS OF SYNTHESIS

Non-fluorinated imines are mainly synthesised by condensing amino-compounds with carbonyl compounds, by eliminating the vicinal substituents at the C–N bond in nitrogen-containing compounds, by the imine exchange reaction, by the condensation of nitroso-compounds with an activated methylene group in various substances, and also by the oxidation of secondary amines and their derivatives. The first method is the most general. Many specific methods for the synthesis of imines are also known. These include procedures based on the cleavage of unsaturated compounds by primary amines, on cycloaddition–decomposition reactions, on the isomeric transformations of unsaturated nitrogen-containing compounds, on the functional transformation of

compounds with an imine group, etc. Almost all these methods have been tested in the synthesis of fluorine-containing imines but by no means all proved suitable for this purpose.

It is believed[1] that the condensation of amines with non-fluorinated carbonyl compounds proceeds as a reversible process:

$$>C=O + H_2NR \rightleftarrows \left[>C\begin{matrix}OH\\NHR\end{matrix} \right] \rightleftarrows >C=NR \quad .$$

In neutral media the rate-limiting stage is the formation of the addition product—the corresponding hemiaminal. However, fluorine-containing carbonyl compounds, especially perfluoroketones, are such powerful electrophiles that they interact vigorously not only with amines, hydrazines, and hydroxylamines but also with weak nucleophiles such as acid amides and sulphonamides[12-23], forming stable geminal aminohydroxy-compounds:

$$R_FR_F'C=O + H_2NR \rightarrow R_FR_F'C\begin{matrix}OH\\NHR\end{matrix} \quad ;$$

$$R = H, Alk, Ar, OH, NR_2, C(O)R, SO_2R \quad .$$

The synthesis of fluorine-containing imines is therefore not limited by the first stage except for amino-compounds whose basicity is extremely low and which are sterically hindered[24,25]. In most cases the second stage of the reaction—the dehydration of the geminal aminohydroxy-compound formed—is rate-limiting.

As a result of the above feature, by no means all fluorine-containing imines can be obtained by the condensation of fluorocarbonyl compounds with amino-compounds, by analogy with the corresponding hydrocarbon compounds. Under the usual conditions in the absence of a catalyst or in the presence of weak dehydrating agents (inorganic and carboxylic acids), only the imines of partly fluorinated carbonyl compounds are formed, for example, the anils of trifluoroacetone[17,26,27], the anil of trifluoroacetophenone[28], the imines of aromatic polyfluoro-substituted ketones and aldehydes[29-33], and the hydrazones of partly fluorinated ketones[34-36]. Fluorine-containing aldimines are readily formed under the usual conditions; instead of polyfluoroaldehydes, it is possible to employ in this instance their hydrates and other derivatives[37-41].

Among the imines of highly electrophilic perfluoroketones, only the hydrazones have been obtained by the condensation of the polyfluoroketones with hydrazines in trifluoroacetic acid[42,43]. Other types of perfluoroketone imines are not formed under the usual conditions in view of the stabilisation of the C–O bond in geminal aminohydroxy-compounds by perfluoroalkyl and especially trifluoromethyl groups[12-18]. The stabilisation effects are so marked that the thermolysis of the adducts obtained by the addition of perfluoroketones to amino-compounds does not lead to their dehydration but results in various destructive transformations, which lead to the formation of either the starting materials[17,18,20,24-26], or the products of their oxidation-reduction reactions[15,44,45], or the products of the "haloform" decomposition[8,36,46-49].

The adducts of amino-compounds with asymmetric polyfluoroketones frequently undergo the "haloform" decomposition even under mild conditions[36,47]:

$$R_FR_F'C=O + H_2NR \rightarrow R_FC(O)NHR + HR_F' \quad .$$

These reactions can be sometimes prevented by regulating the pH of the medium. Thus the phenylhydrazone and the oxime of difluoronitromethyl methyl ketone, which is highly sensitive to bases, are formed only in a neutral medium[48,49].

The stability of the adducts of perfluoroketones with amino-compounds is reduced and the tendency towards decomposition into the initial reactants increases with decrease of the basicity of the amino-compounds employed[17,18,24-26,50-52]. Thus the hemiaminals of hexafluoroacetone are stable substances which can be distilled without decomposition. On the other hand, the hemiamidals of hexafluoroacetone, obtained from carboxylic acid amines, are stable up to 100 °C [20,52] and those obtained from perfluorocarboxylic acid amides are stable only up to 50 °C:[24] the adducts of hexafluoroacetone with the amides of perfluorodicarboxylic acids are stable at atmospheric pressure only in solutions in the presence of an excess of hexafluoroacetone and at a temperature below 0 °C.[25] Thus the properties of the adducts of amino-compounds with polyfluoroketones vary within extremely wide limits, which must hinder the development of a general method for their conversion into fluorine-containing imines.

At the same time, under the conditions of concerted reactions, almost all the fluorine-containing geminal aminohydroxy-compounds could be involved in reactions involving dehydration by mild dehydrating agents. Thus various imines[19], hydrazones, and azines of polyfluoroketones[53], *N,N'*-bis(hexafluoroisopropylidene)diamides of perfluorodicarboxylic acids[25], and *N*-hexafluoroisopropylideneamidines[54] have been obtained by dehydration with $POCl_3$ in pyridine. Hexafluoroacetone azine[55] and the perfluoroacylimines of hexafluoroacetone[24] have been synthesised with the aid of $POCl_3$ in quinoline. Trifluoroacetic acid anhydride in pyridine or quinoline proved to be effective in the synthesis of the acylimines of perfluoroketones[56] and the phosphoryl- and sulphonyl-imines of hexafluoroacetone[57,58]:

$$R_FR_F'C=O + H_2NR \rightarrow R_FR_F'C\begin{matrix}OH\\NHR\end{matrix} \xrightarrow{-H_2O} R_FR_F'C=NR \quad ;$$

$$R = H, Alk, Ar, NH_2, NR_2, N=CR_2, C(O)R, C(O)R_F, P(OR)_2, S(O)Ar \quad .$$

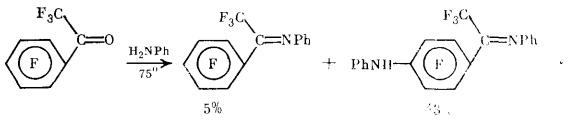
Other dehydrating agents also proved to be effective. Thus thionyl chloride converts smoothly and almost quantitatively the adducts of polyfluoroketones and sulphonamides into the corresponding sulphonylimines[21,22]. Asymmetric fluorine-containing azines have been obtained by heating the adducts with P_2O_5.[59,60] Oleum has been used successfully to synthesise the perfluoroacylimines and the azine of hexafluoroacetone[50,61]. Pentafluoro-2-azopropene in the presence of KF proved to be an effective dehydrating agent in the synthesis of hexafluoroacetone acylimines[62]:

$$R_FR_F'C=O \xrightarrow{H_2NSO_2R} R_FR_F'C\begin{matrix}OH\\NHSO_2R\end{matrix} \xrightarrow{SOCl_2} R_FR_F'C=NSO_2R \quad ;$$

$$R_F, R_F' = CF_3, ClCF_2, O_2NCF_2; \; R = Me, Ph, 4\text{-}MeC_6H_4 \quad ;$$

$$(CF_3)_2C=NNH_2 + O=CRR' \xrightarrow{P_2O_5} (CF_3)_2C=N-N=CRR' \quad ;$$

$$R, R' = Alk, Ar$$



$$(CF_3)_2CNHC(O)R \xrightarrow{SO_3} (CF_3)_2C=NC(O)R \xleftarrow[-CF_3NCO,\,-HF]{CF_3N=CF_2} (CF_3)_2CNHC(O)R' \quad ;$$

$$R = CF_3, C_4F_9; \; R' = Me, Et, Ar \quad .$$

The use of mild dehydrating agents made it possible to extend greatly the assortment of imines obtained by the reactions of polyfluoroketones with amino-compounds. The considerable prospects for the further improvement and development of this method are now quite evident.

The preparative value of the condensation of polyfluoroketones with various amino-compounds in the presence of dehydrating agents is not limited to the synthesis of fluorine-containing imines and is acquiring increasing importance as a method of synthesis of a wide variety of fluorine- and

nitrogen-containing heterocycles[34,39,51,54,60,63-71]. They are formed on dehydration of the adducts of polyfluoroketones with amino-compounds containing functional groups such as OH, SH, NH_2, COOH, C≡N, etc. in the α-, β-, or γ-position relative to the NH_2 group. It is noteworthy that, when these reactions are carried out in highly electron-donating protophilic media, it is possible to eliminate the use of dehydrating agents, using instead an excess of the highly electrophilic polyfluoroketone[65-68]. In conclusion of the discussion of the reactions of polyfluoroketones with amino-compounds, we may mention one of the features of the condensation of perfluoroaryl ketones with amines associated with the ability of the fluorine atom in the perfluoroaryl group to undergo readily nucleophilic substitution which results in the formation of an amino-derivative[30,31]:

This process was facilitated by carrying out the condensation in the presence of $AlCl_3$ or H_2SO_4,[30,31] which led to simple and selective methods of synthesis of polyfluorinated Schiff bases (see the review of Gerasimova and Fokin[72]).

The imine exchange reactions, which are widely used in the syntheses of imines of the hydrocarbon series, proved suitable also for the preparation of certain fluorine-containing imines. The characteristic features of this method are the high stability of the fluorine-containing aminals and aminoketals, which like the geminal aminohydroxy-compounds, are frequently isolated in a pure state[17-20,25,56,58,59,71]. The transamination of fluorine-containing imines is therefore carried out as a severe thermal process[17-20] and the imine exchange takes place at room temperature only in the presence of amine acceptors[17,26,59]:

$$R_F^1R_F^2C{=}NR \xrightarrow{H_2NR'} R_F^1R_F^2C\begin{matrix}NHR\\NHR'\end{matrix} \xrightarrow{\Delta(H^+)} R_F^1R_F^2C{=}NR' .$$

The characteristic features of these reactions have not so far been studied in detail. It has only been shown that hexafluoroacetone imines can be used for the selective synthesis of the corresponding oximes and hydrazones. The acyl- and sulphonyl-imines of hexafluoroacetone can probably be regarded as precursors of the corresponding anils.

Certain side reactions accompanying the transamination of fluorine-containing imines are known. The imines of asymmetric polyfluoroketones undergo the haloform decomposition in these reactions[17]. In a number of cases reactions in which fluorine- and nitrogen-containing heterocyclic compounds are formed take place instead of the imine exchange.

The transformations of fluorine-containing geminal aminohydroxy-compounds and aminals into the corresponding imines can also be regarded as processes involving the elimination of vicinal substituents at the C–N bond in saturated fluorine- and nitrogen-containing compounds. Similar reactions (dehydrofluorination and reductive dehalogenation) are used widely in the syntheses of *N*-fluoroimines (see the review of Fokin et al.[8]). Thermal transformations of amino- and amido-ketals of polyfluoroketones in the presence of phosphorus pentoxide also lead to fluorine-containing imines[18,37,73]:

$$F_3C\begin{matrix}OR''\\NHR'\end{matrix}R \xrightarrow{\Delta,\ P_2O_5} F_3C{=}NR' ;$$

R = H, CF_3; R' = NHC(O)NH_2, C(O)R_F, $SO_2C_6H_4CH_3$-*p* .

Cycloaddition–decomposition reactions have found extensive applications in the syntheses of fluorine-containing imines. This procedure proved to be one of the convenient methods for the preparation of difluorocarbonylimines[8], fluorine-containing keten imines, including compounds with perfluoroalkyl groups at the nitrogen atom[11], and also various fluorine-containing azomethines and acylimines of polyfluoroketones[15,17,20,26]. In many cases this method makes it possible to obtain imines which cannot be synthesised by other procedures. Thus the extension of the Staudinger reaction to fluorine-containing carbonyl compounds permitted the synthesis even of the imines of asymmetric ketones which undergo the "haloform" decomposition in other syntheses:

$$F_3C(R)C{=}O + Ph_3P{=}NR' \xrightarrow[-Ph_3PO]{\Delta} F_3C(R)C{=}NR' ;$$

R = Me, CF_3, O_2NCF_2; R' = H, Ph, C(O)Me, C(O)Ph, C(O)OEt .

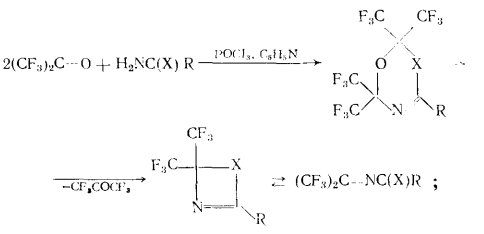
Decomposition with formation of difluoronitromethane and trifluoroacetyliminotriphenylphosphorane has been noted only in the reaction of triphenylphosphine imine with nitroperfluoroacetone[26].

A modification of the Staudinger reaction, in which isocyanates and catalytic amounts of triphenylphosphines oxide[26,74] or dimethylformamide[75] are used instead of iminophosphoranes, is extremely interesting:

$$O{=}C{=}NR \xrightarrow[150-180^\circ]{X=O} \left[\vphantom{\frac{1}{1}}\right. \text{cyclic intermediate} \xrightarrow[-CO_2]{} X{=}NR \left.\vphantom{\frac{1}{1}}\right] \xrightarrow[-X=O]{(CF_3)_2C=O} (CF_3)_2C{=}NR ;$$

X = Ph_3P, R = Ar; X = $(CH_3)_2NCH$, R = C_6F_5 .

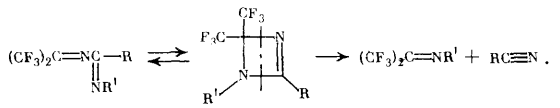
In the absence of catalysts, this reaction does not take place even under much more severe conditions.



The interaction of hexafluoroacetone with thionylimines in the presence of CsF [76] and the thermal reactions of octafluoroisobutene with nitrosobenzene[77] are apparently processes of the cycloaddition–decomposition type:

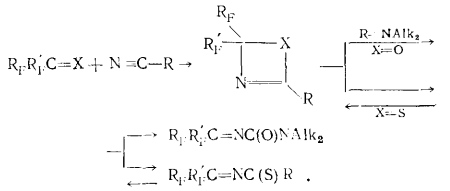
$$(CF_3)_2C{=}O \xrightarrow[-SO_2]{O{=}S{=}NAr} (CF_3)_2C{=}NAr \xleftarrow[-COF_2]{ON-Ph} (CF_3)_2C{-}CF_2 .$$

Many cyclodecomposition reactions, leading to fluorine-containing imines, have no analogues in the hydrocarbon series. Thus the nucleophilic cleavage of tetrakis(trifluoromethyl)-1,3-dithietan by amino-compounds leads to various hexafluoroacetone imines[78]. The yield of the reaction products is higher the lower the basicity of the amino-compound:

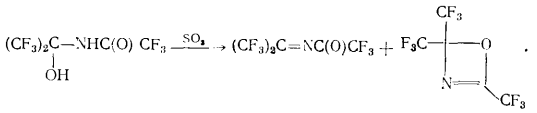


$$(CF_3)_2C\begin{matrix}S\\S\end{matrix}C(CF_3)_2 \xrightarrow{H_2N-R} (CF_3)_2C{=}NR .$$

2,2,6,6-Tetrakis(trifluoromethyl)-1,3,5-oxathiazines and the corresponding 1,3,5-oxadiazines are effective precursors of hexafluoroacetone thioacylamines[63,79-82] and hexafluoroisopropylideneamidines[54,83]. Thermolysis with elimination of hexafluoroacetone leads in these cases to the derivatives of 1,3-thiazete and 1,3-diazete, which are converted into imines under certain conditions:

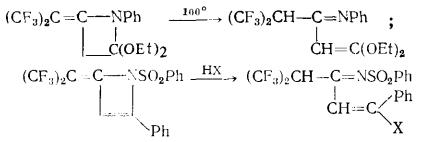


Derivatives of 1,3-thiazete proved to be extremely stable, undergoing electrocyclic reactions only on heating to 150 °C.[79] On the other hand, derivatives of 1,3-diazete

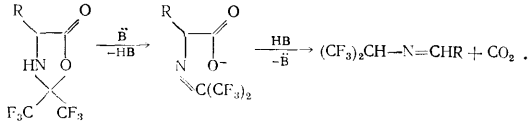


readily isomerise under the usual conditions to amidines and the presence of these compounds in the equilibrium mixture has been confirmed by the isolation of the products of their retro-[2 + 2]-cycloaddition[54]:

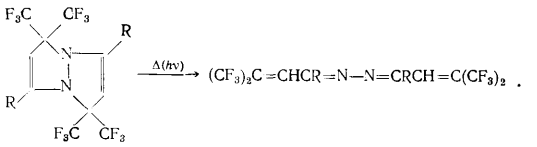
The formation of fluorine-containing 1,3-oxazetes and 1,3-thiazetes in [2 + 2]-cycloaddition reactions of polyfluoroacetones and hexafluorothioacetone with acid nitriles has been demonstrated recently[84]. In contrast to derivatives of 1,3-thiazete and 1,3-diazete, 1,3-oxazetes isomerise reversibly to acylimines:



It is noteworthy that the dehydration of the adduct of hexafluoroacetone and trifluoroacetamide by sulphur trioxide also leads to a four-membered unsaturated heterocycle—2,2,4-tris(trifluoromethyl)-1,3-oxazete, which was isolated in the form of a complex with SO_3.[50] The oxazete stabilised by three trifluoromethyl groups does not change at 150 °C and undergoes irreversible ring opening only in the presence of bases:

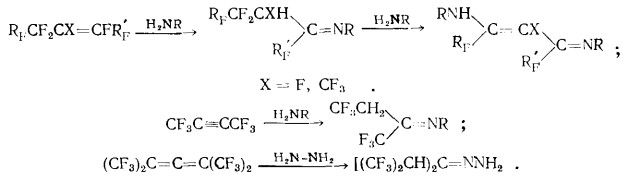


This indicates a concerted mechanism of the condensation of polyfluoroketones with acid amides in the presence of dehydrating agents and one may expect that, under certain conditions, the products of these reactions may be exclusively 1,3-oxazates.

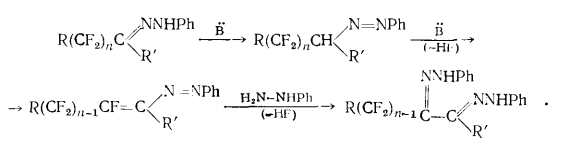


Among other electrocyclic reactions leading to fluorine-containing imines, mention should be made of the transformations of cyclic [2 + 2]-adducts of fluorine-containing keten imines with a ketenal or with acetylenes, ring opening being accompanied by a proton shift[85,86]:

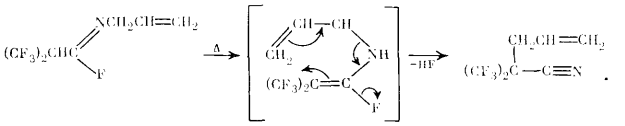
The anionotropic cyclodecomposition with formation of fluorine-containing imines in the catalysed reactions of 2,2-bis(trifluoromethyl)-1,3-oxazolidin-5-ones is of interest[87]:



The formation of symmetrical fluorine-containing azines in high yields in the thermal or photolytic decomposition of the adducts of hexafluoroacetone azine with acetylenes is likewise striking[88]:



The electrocyclic reactions described are distinguished by high selectivity, so that the formation of fluorine-containing imines in various heterocyclic reactions of fluorine- and nitrogen-containing compounds constitutes a kinetically and thermodynamically most favourable process.



Many methods of synthesis characteristic of fluorine-containing imines alone are based on the reactions of amino-compounds with polyfluoroalkenes. Terminal polyperfluoroalkenes are converted in these reactions into imidoyl fluorides, which are intermediates in the synthesis of keten imines[11], and into hydroxamoyl fluorides, amidines, hydrazidines, etc.[5]. The analogous reactions of amino-compounds with inner perfluoroalkenes, perfluorocycloalkenes, alkynes, and allenes initially lead in all cases to α-hydropolyfluoroketone imines[89–91] and, under conditions suitable for dehydrofluorination, the imines formed undergo further reactions with formation of iminoenamines[92–99], iminonitriles[91], and iminoketen imines[100], for example:

The characteristics of these reactions specified above show that prototropic shifts from C to N in CCN triad systems are less characteristic of fluorine-containing imines than of the imines of non-fluorinated carboxylic ketoacids. Triad prototropism of the enamine–imine and enehydrazine–hydrazone type therefore takes place extremely rapidly and the equilibrium is fully displaced to compounds with a C=N bond. However, the azo–hydrazone prototropism is achieved relatively easily, which has been manifested by the mild conditions in the conversion of fluorine-containing hydrazones into polyhydrazones[34,38–40,43,101]:

The conditions governing the thermal 1,3-sigmatropic transformations of *N*-allyl-2*H*-hexafluoroisobutyroimidoyl fluoride[102], which can be achieved only under the conditions of the C → N proton shift, may serve as a qualitative characteristic of the tendency of fluorine-containing imines to undergo triad prototropism of the imine–enamine type:

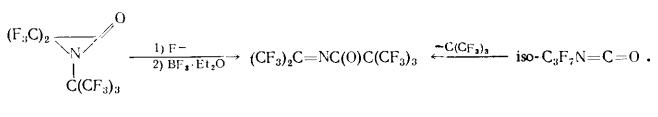
Since the "aza-Claisen" rearrangement of the compound takes place on heating above 120 °C, the energy barrier to the process must be estimated as more than 15 kcal mol^{-1}.

A large number of special methods for the synthesis of fluorine-containing imines, based on the anionotropic and free radical reactions of fluorine- and nitrogen-containing compounds, on cycloaddition reactions, etc., have been described.

Nonafluoro-t-butylpotassium readily reacts with chlorocarbonylimines to form products of the nucleophilic substitution of the chlorine atom[103]:

These reactions resemble the reactions of chlorocarbonylimines with organometallic compounds widely investigated in hydrocarbon chemistry.

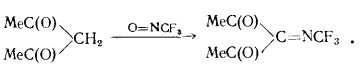
The alkylation of certain fluorocarbonylimines has been achieved with the aid of trialkyl phosphites[104]:



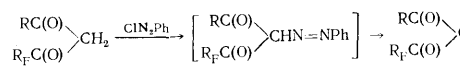
Fluorophosphoranes are apparently intermediates in this case.

Hexafluoroacetone perfluoroisopropylimine is formed on reaction of hexafluoroacetone with bromocyanogen or perfluoroisopropyl isocyanate in the presence of potassium fluoride[105]:

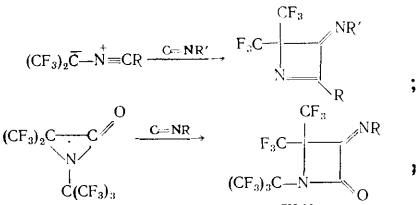
The reaction of nonafluoro-t-butylcaesium with perfluoroisopropyl isocyanate led to hexafluoroacetone nonafluoropivaloylimine[106]. An elegant synthesis of this compound has also been achieved by the nucleophilic opening of the ring of the corresponding perfluoro-α-lactam by the fluoride ion:



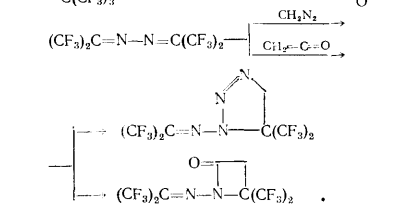
Benzophenone perfluoro-t-butylimine has been obtained by the nucleophilic deoxygenation of the corresponding oxaziridine[107]:



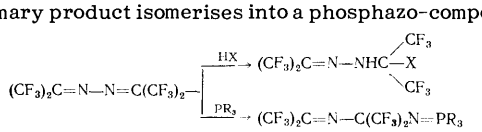
Analogous syntheses are also known for non-fluorinated imines.



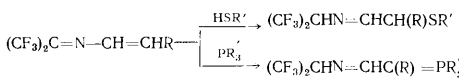
In the presence of bases, trifluoronitrosomethane reacts with acetylacetone, which made it possible to obtain diacetyl ketone trifluoromethylimine[108]:



This reaction can be regarded as an analogue of the condensation of nitroso-compounds via the activated methylene group of strong CH acids (the Ehrlich–Sachs reacton), which has been widely investigated in hydrocarbon chemistry. Like non-fluorinated β-diketones, fluorine-containing β-diketones react with benzenediazonium chloride[34,70]:



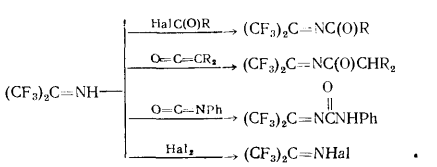
The [3 + 1]-,[81,109–113] [2 + 2]-,[86,114] and [2 + 3]-cycloaddition[115] reactions have been used successfully for the synthesis of cyclic fluorine-containing imines:



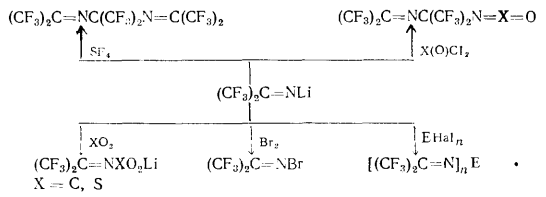
The trimerisation of fluorine-containing 1,3-diazadienes with a terminal methylene group also leads to similar compounds[54].

Selective reactions of fluorine-containing imines made it possible to achieve the synthesis of a large number of the compounds under consideration via functional transformations with retention of the C=N bond. For example, hexafluoroacetone azine combines smoothly with nucleophiles via one of the C=N bonds and is converted into hydrazones, while on interaction with trialkyl phosphites or tertiary phosphines the primary product isomerises into a phosphazo-compound[115–117]:

Hexafluoroacetone alkenylimines interact with nucleophiles via the 1,4-addition mechanism[118,119]:



In contrast to their non-fluorinated analogues, hexafluoroacetone alkylimines undergo the imine–imine prototropic shifts extremely readily even in the presence of triethylamine[120]:



In the hydrocarbon chemistry such reactions take place at a low rate only in the presence of extremely strong bases.

Hexafluoroacetone imine and hydrazone are precursors of a large number of fluorine-containing imines. They have been involved in acylation by acyl halides[60], ketens[19,73,121], and isocyanates[17,60]; the substitutional halogenation of hexafluoroacetone imine has been achieved in the presence of alkali metal fluorides[122]:

Hexafluoroacetone *N*-lithioimine proved to be more reactive in reactions with various electrophiles. On intense cooling. this compound is smoothly brominated[19], forms addition products with sulphur dioxide or carbon dioxide[123], forms substitution products on reaction with chlorotrimethylsilane, phosphorus trichloride, arsenic trichloride, sulphur dichloride, boron halides, sulphene chlorides, and sulphinyl chlorides[124], and sulphur tetrafluoride[125]:

Instances of the conversion of fluorine-containing oximes into imines are known. For example, hexafluoroacetone dichlorophosphorylimine has been obtained by the reaction of hexafluoroacetone oxime nitrite with phosphorus trichloride[126]:

$$(CF_3)_2C{=}NONO \xrightarrow{PCl_3} (CF_3)_2C{=}NP(O)Cl_2 \ .$$

Reactions involving the fluorination of amines, amides, imines, iminoesters, amidines, and guanidine and its derivatives by elemental fluorine as well as the reactions of unsaturated compounds with tetrafluorohydrazine, chlorodifluoroamine, and difluoroamine are widely used in the synthesis of *N*-fluoroimines with a fluorinated hydrocarbon group. In combination with the dehydrofluorination, reductive dehalogenation, and homolytic decomposition reactions of the substances formed, the above processes made it possible to devise a large number of specific methods for the synthesis of *N*-fluoroimines of different structure, which have been examined in detail in a number of communications[8-10, 127-129].

The reactions of electrophiles with nitriles have been used recently for the synthesis of *N*-halogenoimines. For example, halogenofluorosulphates react with the nitriles of perfluorocarboxylic acids under mild conditions[130]; on heating in the presence of a strong inorganic acid, polyfluoroalkyl hypochlorites add to nitriles[131]:

$$R_F{-}C{\equiv}N + HalOSO_2F \rightarrow R_F{-}C\!\!<\!\!\begin{matrix}NHal\\OSO_2F\end{matrix} \ ;$$

$$R_F{=}CF_3,\ NO_2CF_2,\ (NO_2)_2CF,\ n\text{-}C_3F_7 \ .$$

$$R_F{-}C{\equiv}N + ClOCH_2(CF_2)_4H \xrightarrow[110\text{-}115^\circ]{H^+} R_F{-}C\!\!<\!\!\begin{matrix}NCl\\OCH_2(CF_2)_4H\end{matrix} \ .$$

There are comparatively few data on homolytic reactions leading to fluorine-containing imines. At the same time the possibility, in principle, of employing for these purposes reactions based on the properties of carbenes and carbenoid species as well as the high tendency of the N–Hal bonds in halogenoimines towards homolysis have been demonstrated; the prospects of the synthesis of fluorine-containing imines via the pyrolytic reactions of fluorine- and nitrogen-containing unsaturated compounds have been assessed.

Thus bis(trifluoromethyl)diazomethane alkylates hexafluoroacetone imine fairly smoothly[132] and its pyrolysis in the presence of alkanes leads to hexafluoroacetone hydrazones[133] in a mixture with other substances:

$$(CF_3)_2CN_2 \begin{cases} \xrightarrow{HN{=}C(CF_3)_2} (CF_3)_2CHN{=}C(CF_3)_2 \\ \xrightarrow{\Delta,HR} (CF_3)_2C{=}NNHR \end{cases} .$$

Thermal reactions of bis(trifluoromethyl)diazirine lead to hexafluoroacetone azine[134], while heating in the presence of alkanes results in the formation of hexafluoroacetone alkylimines[133]:

$$(CF_3)_2C\!\!<\!\!\begin{matrix}N\\N\end{matrix} \begin{cases} \xrightarrow{\Delta} (CF_3)_2C{=}N{-}N{=}C(CF_3)_2 \\ \xrightarrow{HR,165^\circ} (CF_3)_2C{=}NR \end{cases} .$$

Isonitriles react smoothly with perfluoroalkyl iodides to form fluorine-containing iodocarbonylimines[135]:

$$RN{=}C + IR_F \rightarrow RN{=}C\!\!<\!\!\begin{matrix}R_F\\I\end{matrix} \ .$$

Many cyclic fluorine-containing imines have been obtained in reactions involving [1 + 4]-cycloaddition of isonitriles to fluorine-containing unsaturated compounds (see below).

It has been shown that *N*-halogenoimines are converted under the conditions of photolysis into the corresponding azines[19]; in the presence of metallic mercury, these compounds readily condense with sulphene chlorides and acyl chlorides[136]:

$$(CF_3)_2C{=}NHal \begin{cases} \xrightarrow[Hal=Br]{h\nu} (CF_3)_2C{=}N{-}N{=}C(CF_3)_2 \\ \xrightarrow[Hg]{HalX} (CF_3)_2C{=}NX \end{cases} ;$$

$$X = SCF_3,\ C(O)CF_3 \ .$$

The pyrolysis of hexafluoroacetone azine with alkanes or alkenes[137,138] leads to mixtures of substances containing hexafluoroacetone hydrazones:

$$(CF_3)_2C{=}N{-}N{=}C(CF_3)_2 \begin{cases} \xrightarrow{(CH_3)_2C{=}C(CH_3)_2} \\ \xrightarrow{HR} \begin{cases} \rightarrow (CF_3)_2C{=}NNHC(CF_3)_2CH_2C(CH_3)_2 \\ \qquad\qquad\qquad\qquad\quad | \\ \qquad\qquad\qquad\qquad\quad CH_3 \\ \rightarrow (CF_3)_2C{=}NNHC(CF_3)_2R \end{cases} \end{cases} .$$

When hexafluoroisopropylideneiminoxybis(trifluoromethyl)amine was heated with polyfluoroethylenes, the products of the insertion of an alkene in both N–O bonds were obtained[139]:

$$(CF_3)_2C{=}NON(CF_3)_2 \xrightarrow{CF_2{=}CFX} (CF_3)_2C{=}NCF_2CFXON(CF_3)_2 +$$

$$+ (CF_3)_2C{=}NOCF_2CFXN(CF_3)_2 \ ;$$

$$X = F,\ Cl \ .$$

The above data indicate the extremely wide variety of the methods of synthesis of polyfluorinated imines. They are formed as a result of anionotropic, cationotropic, and homolytic reactions, concerted and stepwise electrocyclic processes, and cycloaddition–decomposition reactions.

The formation of extremely stable intermediates, which are converted into the final imines as a result of severe stepwise or mild concerted processes, is characteristic of the majority of the methods. As fluorine atoms of polyfluoroalkyl groups accumulate at the C=N bond of the intermediate, the efficiency of the stepwise processes falls and that of the concerted processes increases. This apparently reflects a common feature of fluorine-containing imines—a marked increase of strain in the latter with increase of the number of fluorine atoms and polyfluoroalkyl groups at the C=N bond.

III. CERTAIN PHYSICOCHEMICAL PROPERTIES

The physicochemical properties of fluorine-containing imines have been little investigated. A broad set of characteristics has been established only for isolated compounds among *N*-fluoromines of practical importance[8]. For the remaining compounds, the boiling points and in certain cases the refractive indices and densities are known. The majority of the fluorine-containing imines have been characterised by their infrared spectra [ν(C=N)] and their ^{19}F and ^{1}H NMR spectra. The thermodynamic parameters have been determined only for certain *N*-fluoroimines; in a number of instances the geometrical parameters of the molecules of these compounds have been calculated[8].

The characteristics of the physicochemical properties of the compounds considered have been expressed most strikingly in the series of perfluoroketone imines whose parameters are partly compiled in the Table. It follows from the data presented that, in contrast to their hydrocarbon analogues,

fluorine-containing imines are relatively low-boiling liquids, while certain perfluoroimines are gases under the usual conditions. Low boiling points are characteristic even of amines with mobile hydrogen atoms in the molecule, which indicate extremely weak forces of dipole–dipole interactions, a low energy of the intermolecular $n\pi$ interactions, and a weak hydrogen bond between the molecules of fluorine-containing imines in the liquid state. These findings are correlated with the sharp decrease of the basicity and the "amphoteric" properties of the imine after the introduction of fluorine atoms or polyfluoroalkyl groups at the C=N bond.

*Relative to CF_3COOH.

It is noteworthy that the reduced basicity and weak "amphoteric" properties of fluorine-containing imines are responsible for their increased stability and their much smaller tendency towards oligomeric transformations than for the non-fluorinated analogues. This is the reason for the existence under the usual conditions of the fluorine-containing analogues of many aliphatic imines of the hydrocarbon series, which are unknown in their free state.

The high volatility of perfluoroketone hydrazones and especially their oximes, which are fairly strong acids, must be regarded as extremely interesting[141]. This can be explained by the weak *s* character of the hybrid state of the orbitals not only of the *p* electrons of the imine nitrogen but also of the *p* electrons of the heteroatom linked to the imino-group, which is possible only in the presence of additional many-centre molecular orbitals in the CNO and CNN triads of fluorine-containing imines. Data indicating the extremely high stability and the relative ease of formation of the oximes and hydrazones of fluorocarbonyl compounds compared with fluorine-containing azomethines are consistent with this finding.

The analysis of the vibrational spectra of fluorine-containing imines leads to a similar conclusion. Judging from these characteristics, the imine bond in the compounds considered is more sensitive to various effects of substituents than in the molecules of the hydrocarbon analogues. Thus the stretching vibration frequencies of the C=N bond in fluorine-containing imines are manifested in the region from 1770 cm^{-1} for hexafluoroacetone trimethylsilylimine (see Table) to 1553 cm^{-1} for the *N*-fluoroimine of the dinitrile of mesoxalic acid[8]. The corresponding range for the imines of the hydrocarbon series is from 1680 to 1600 cm^{-1}.[1] Even for the monosubstituted hexafluoroacetone anils, the stretching vibration frequency of the C=N bond varies from 1698 to 1592 cm^{-1} depending on the nature and position of the substituent in the benzene ring[140].

When the dependence of the vibrational spectra of fluorine-containing imines on structure is considered (see Table), it is striking that only in the presence of a pair of *p* electrons in the substituent at the imine nitrogen (*N*-halogenomines, oximes, hydrazones, azines, sulphenylimines, and sulphinylimines) are the vibrations of the C=N bond manifested in the region characteristic of the hydrocarbon analogues and the degree of displacement of this band towards lower energies is correlated with the increase of the overlap integral of the orbitals of the valence electrons of the imine nitrogen and the substituent. In the absence of substituents with a pair of *p* electrons, the energy of the stretching vibrations of the C=N bond of the fluorine-containing imine is much higher than in the hydrocarbon analogues and increases with enhancement of the electron withdrawing effects of the substituent at the imine nitrogen.

The dependence of the ^{19}F NMR spectra of hexafluoroacetone imines on structure is unusual (see Table). Substituents at the imine nitrogen having *p* electrons diminish the shielding of the fluorine nuclei of the CF_3 group in parallel with the increase of the overlap integral of the orbitals of the imine nitrogen and the substituent of this type. Analogous effects are introduced by other substituents of the *+E* type, which has been shown particularly clearly in the series of hexafluoroacetone anils[140] and in this case too a shift of the stretching vibration bands of the C=N bond towards lower energies has been observed simultaneously with diminution of the shielding of the fluorine nuclei. Such a complex dependence is possible only for the "acetylenic" type of π overlap via the C=N bond in the compounds considered, which is fully consistent with their enhanced electrophilic properties.

Additional information about the compounds considered is provided by the results of the study for the dynamics of the ^{19}F NMR spectra[142]. Two groups of signals due to non-equivalent polyfluoroalkyl groups usually appear in the spectra of imines of fluorine-containing symmetrical ketones having a fairly rigid C=N bond [14,19,59,122,140]. The study of the temperature variation of the spectra makes it possible to discover the energy barrier to the *Z*/*E* transition[14,59,74,143], which consitutes a quantitative measure of the rigidity of the imine linkage.

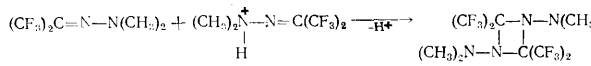
The energy barriers of the *Z*/*E* transitions ($\Delta G''$) have now been estimated for *N*-perfluoroisopropyldifluorocarbonylimine[1] (approximately 11 kcal mol^{-1}), hexafluoroacetone perfluoroisopropylimine[14] (13.4 kcal mol^{-1}), and hexafluoroacetone anils[74] (14.35–15.45 kcal mol^{-1}). According to the results of Dowson et al.[143], $\Delta G''$ for aliphatic hexafluoroacetone imines varies from 12.0 to 20.5 kcal mol^{-1} depending on the degree of branching of the alkyl group. Presumably the rigidity of the C=N bond in these compounds is determined by the hyperconjugation of the alkyl substituent. Thus hexafluoroacetone methylimine is distinguished by the maximum energy barrier to *Z*/*E* isomerisation (20.5 kcal mol^{-1}). For compounds with a secondary alkyl group (isopropyl and α-hydrohexafluoroisopropyl), the $\Delta G''$ are 17.5 and 18.5 kcal mol^{-1} respectively, while the values for compounds with a "tertiary" alkyl group (t-butyl, perfluoroisopropyl, and α-chlorohexafluoroisopropyl) are 12.0–13.7 kcal mol^{-1}.

Thus the C=N bond in perfluoroketone imines is much less rigid than in the imines of the hydrocarbon series, where the $\Delta G''$ are greater than 25 kcal mol^{-1} even for aliphatic

representatives[1,142]. The greatest increase of the rigidity of the imine bond in the compounds considered is apparently attained as a result of hyperconjugation effects; the barrier to the *Z*/*E* isomerisation of perfluoroketone imines is increased by substituents with positive mesomeric contributions and possibly substituents with a high *p*-electron density.

At the same time compounds are known among perfluoroketone imines for which the *Z*/*E* transformations are achieved under the usual conditions and even at −60 °C. Judging from the ^{19}F NMR spectra, the acylimines[19], perfluoroacylimines[24,144], sulphinylimines[58], and sulphonylimines[23] of perfluoroketones belong to compounds of this class.

IV. THE REACTIVITY OF FLUORINE-CONTAINING IMINES



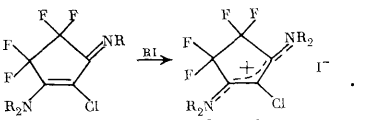
As unsaturated compounds with "amphoteric" properties, the non-fluorinated imines readily interact with electrophiles and nucleophiles. Under anhydrous conditions, they are readily protonated by acids with formation of iminium salts, interact with halogens and alkylating and nitrosating reagents, combine with alcohols, thiols, and amines, and react with organometallic compounds. Iminium salts interact particularly readily with nucleophiles.

As unsaturated compounds of the electron-donating type, imines enter into certain pericyclic reactions, particularly the [2 + 1]-, [2 + 2]-, and [2 + 3]-cycloaddition reactions. Azomethines, iminium salts, and acylimines are most reactive in these processes; compounds of the last type also possess dienophilic properties. The coordination-unsaturated character of the imine bond determines many isomeric and tautomeric transformations of imines of the hydrocarbon series.

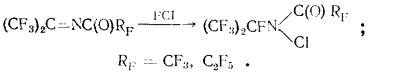
The reactivity of the fluorine-containing imines differs significantly from that of their non-fluorinated analogues. The differences are considered below in relation to reactions with electrophiles and nucleophiles and also cycloaddition reactions.

1. Reactions with Electrophiles

In most cases polyfluorinated imines are weak or even extremely weak bases. Under anhydrous conditions, they are therefore frequently indifferent to acids and do not manifest properties due to the formation of iminium salts. Only the hydrazones of fluorine-containing aldehydes and ketones are apparently protonated by strong acids, as shown by the electrophilic cooperative effect of sulphuric acid in the dimerisation of hexafluoroacetone dimethylhydrazone described by Wright and Zollinger[53]:

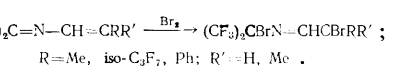


There are also data concerning the acid-catalysed reactions of partly fluorinated *N*-fluoroimines, which are attributed to the cleavage of the N—F bond by protic and Lewis acids[8]. Fully fluorinated *N*-fluoroimines do not interact even with sulphuric and fluorosulphonic acids[10]. Perfluoroketone perfluoroacylimines are indifferent to anhydrous acids on heating, which is used in their purification[50,61].

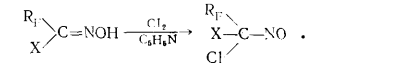


At the same time aqueous solutions of acids decompose fluorine-containing imines[85,86,89,96,99,101], which makes it possible to regard these compounds as convenient precursors of carbonyl and other compounds, for example[99]:

In view of their low basicity and weak nucleophilic properties, the alkylation of fluorine-containing imines has been hardly investigated. An example of such a reaction is provided only by the interaction of cyclic iminoenamines with alkyl iodides[93], where the alkylation is promoted by the additional stabilisation of the iminium ion by dialkylaminovinyl groups:



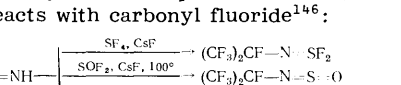
Among the halogens, only gaseous fluorine adds to the C=N bond of fluorine-containing imines. Thus perfluoroderivatives of saturated amines are isolated together with the perfluoro-derivatives of *N*-fluoroimines in the fluorination of nitriles and various imines in the gaseous and solid phases[8]. Chlorine fluoride, which readily adds to the C=N bond in *N*-fluorodihalogenocarbonylimines[8] and hexafluoroacetone perfluoroacylimines, have similar properties[144]:



It is noteworthy that exhaustive fluorination of imines frequently takes place in the presence of alkali metal fluorides, the most active of which is CsF. Thus hexafluoroacetone imine has been converted into the *N*-fluoroimine on fluorination in the presence of KF and into the perfluoroisopropyldifluoroamine in the presence of CsF.[122] In the presence of CsF, hexafluoroacetone *N*-fluoroimine combines with chlorine fluoride[8]:

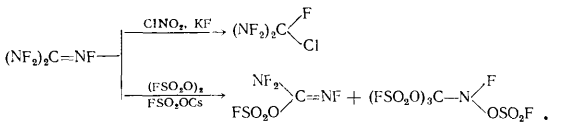
The chlorination and bromination of fluorine-containing imines do not usually take place in the absence of a catalyst. Only the interaction of bromine with hexafluoroacetone alkenylimines, leading to 1,4-addition products, has been described[119]:

However, many reactions of the compounds considered with halogens and other electrophiles have been achieved in the presence of bases. The interaction of perfluoroketone oximes and polyfluoroalkylhydroamoyl halides with chlorine in pyridine leads to nitrosoperhalogenoalkanes[141,145] (the Piloti reaction):



On chlorination in the presence of CsF and bromination in the presence of KF, perfluoroketine imines have been converted into the corresponding halogenoimines[122] (see above).

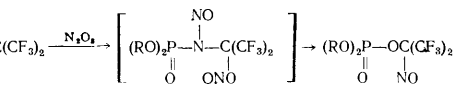
Chloropentafluoroacetone imine interacts smoothly with oxalyl chloride in pyridine, which leads to 1,2-dichloropentafluoroisopropyl isocyanate[146]:



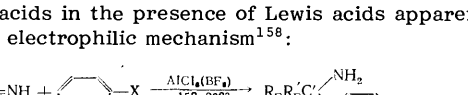
Hexafluoroacetone imine interacts with sulphur tetrafluoride[147] and thionyl fluoride[148] in the presence of caesium fluoride as the catalyst; in the presence of KF, hexafluoroacetone imine reacts with carbonyl fluoride[146]:

In the absence of catalysts, such reactions can be achieved only when the explosive hexafluoroacetone lithioimine is used (see above).

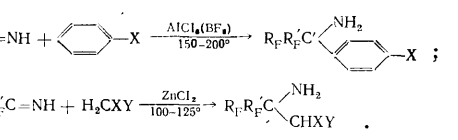
The interactions of pentafluoroguanidine with nitryl chloride catalysed by KF [149] and with peroxodisulphuryl difluoride in the presence of caesium fluorosulphate[150] have been described:



Non-catalysed reactions of electrophiles with fluorine-containing imines are also known. Thus hexafluoroacetone hydrazone is oxidised to bis(trifluoromethyl)-diazomethane on treatment with PCl_5:[60]



Substitutional fluorosulphonation of hexafluoroacetone imine by peroxodisulphuryl difluoride[151] and the reactions of halogenofluorosulphates with pentafluoroguanidine[152,153] and hexafluoroacetone fluoroimine[154] take place readily:



Hexafluoroacetone imine reacts with boron halides under mild conditions[155,156]:

The transformations of hexafluoroacetone dialkoxyphosphoryl-imines in the reactions with N_2O_3 are also of interest[157]:

The reactions of perfluoroketone imines with aromatic compounds or CH acids in the presence of Lewis acids apparently proceed via an electrophilic mechanism[158]:

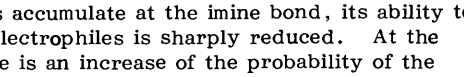
It is evident from the data presented that fluorine-containing imines possess an unusual ability to interact with electrophiles. The protonation, alkylation, acylation, and electrophilic reactions, which take place readily with the non-fluorinated analogues and usually proceed via three-centre transition states, are not characteristic of these compounds. Fluorine-containing imines interact fairly vigorously only with reagents capable of electrophilic addition via a four-centre transition state (nitrosating agents, boron halides, and probably halogenofluorosulphates). Analogous behaviour is to some extent characteristic also of the reactions of electrophiles with polyfluoroalkenes[159].

The available data also show that, as fluorine or polyfluoroalkyl groups accumulate at the imine bond, its ability to interact with electrophiles is sharply reduced. At the same time there is an increase of the probability of the reaction of fluorine-containing imines with electrophiles via a nucleophilic mechanism, which is also characteristic of polyfluoroalkenes[160]. The above finding suggests that one may expect an appreciable expansion of the range of reactions of fluorine-containing imines with electrophiles, many of which may acquire applied importance.

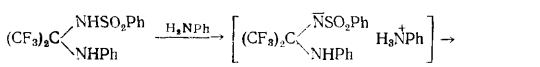
2. Reactions with Nucleophiles

In terms of the character of their reactivity with respect to nucleophiles, the fluorine-containing imines known at present can be divided into two groups. *N*-Polyfluoroalkyl-substituted mono- and di-fluorocarbonylimines, polyfluoroalkylhydroxamoyl fluorides, and certain *N*-fluoroimines should be included in the first group. All these compounds form predominantly or exclusively products of the substitution of the fluorine atom and the carbon atom of the imine group on interaction with nucleophiles of the type H–X. Numerous examples of reactions of this type have been published in a book[5] and in a review[6].

This character of the reactivity of the fluorine-containing imines of the first group is apparently associated with the increased asymmetry of the π orbital of the C=N bond due to the effects of the fluorine atom; this results in the elimination of the possibility of the concerted addition of the nucleophile and the process takes place in a stepwise manner.

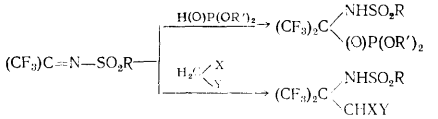


The absence of direct correlations between the nucleophilic properties of the reactants and the conditions of their reactions with *N*-trifluoromethyldifluorocarbonylimine (pentafluoro-2-azapropene) may be quoted in support of these ideas[6]. Proof of the impossibility of concerted reactions of compounds of this type has been obtained in a study of the interaction of polyfluoroalkylhydroxamoyl halides with triethylamine[161–165] where nitrile oxides should have been formed as a result of the concerted dehydrohalogenation. It was shown in the above studies that the mode of reaction depends little on the structure of the polyfluoroalkyl group and is determined exclusively by the nature of the halogen at the C=N bond. Thus, whereas the interaction of hydroxamoyl fluorides with triethylamine leads to oligomers under any conditions in the presence of dipolarophiles and in their absence[162], i.e.

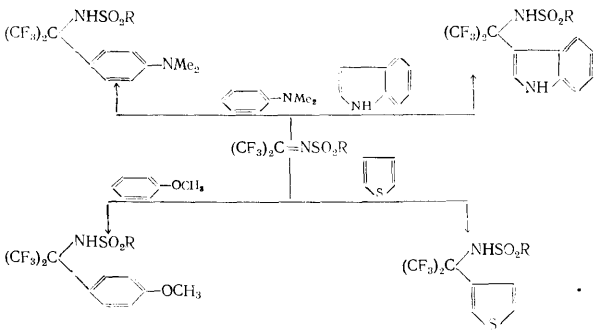


the corresponding hydroxamoyl chlorides and particularly hydroxamoyl bromides are converted by triethylamine under mild conditions into the corresponding nitrile oxides, detected by the presence of the [2 + 3]-cycloaddition products[163–165].

Acyl-, sulphinyl-, and sulphonyl-imines should be included in the second group of fluorine-containing imines, which react with nucleophiles to form addition products. Polyfluoroketone sulphonylimines have been most widely investigated in reactions with nucleophiles[166–173].



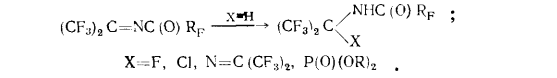
It has been shown[166–168] that polyfluoroketone methane- and benzenesulphonylimines interact vigorously with proton-containing nucleophiles and in many instances such reactions can be carried out unambiguously only in dilute solutions with cooling and slow introduction of the nucleophile into the reaction medium. Under optimum conditions, the reactions with aliphatic alcohols, α,β-unsaturated alcohols, ethylene chlorohydrin, and phenol (0–20 °C), thiols (−40 °C), amines (−50 to −40 °C), carboxylic acid amides (including their fluoro-derivatives), urea, and sulphonamides (50–60 °C) take place almost quantitatively:



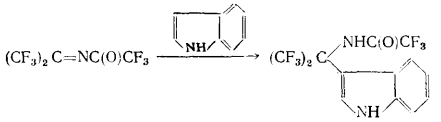
Polyfluoroketone sulphonylimines interact particularly vigorously with fairly strong bases. In this case there is a possibility of side reactions due to the appearance of an excess of the base in the reaction medium[166,167]:

The reactions of polyfluoroketone sulphonylimines with PH and CH acids such as dialkyl phosphites (20 °C),[169] malonic and acetoacetic esters, and acetylacetone (20–50 °C) take place under mild conditions in the absence of catalysts[170]:

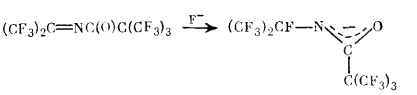
The π-electron-donating aromatic compounds, namely *N*,*N*-dimethylaniline (−40 °C),[171] indole (20 °C),[172] and anisole and thiophen (50–60 °C),[171,173] are unusually readily alkylated by polyfluoroketone sulphonylimines. The alkylation takes place regiospecifically at the site of maximum π-electron density in the ring:



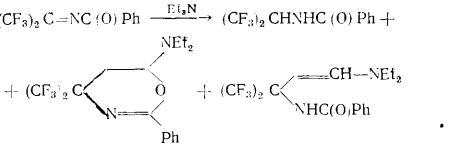
In all these reactions polyfluoroketone sulphonylimines behave as "mild" π-acids, which has been confirmed by the method of competing reactions[168]. This feature is responsible for the concerted mechanism of the addition reaction, which constitutes a significant difference between the sulphonylimines and the imines of the first group, for which many of the reactions described above either do not occur or require extremely severe conditions, for example[174]:



Hexafluoroacetone perfluoroacylimines, sulphinylimines, dialkoxyphosphorylimines, and acylimines, which are similar to sulphonylimines as regards the conditions of their reactions with nucleophiles, are distinguished by an extremely low energy barrier to *Z*/*E* transformations.

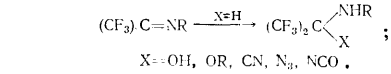


Hexafluoroacetone perfluoroacylimines are apparently even stronger π-acids than sulphonylimines. Together with the usual nucleophiles[24,108], they combine under mild conditions with hydrogen halides[144], hexafluoroacetone imine[73], and dialkyl phosphites[175] in the absence of catalysts:



Hexafluoroacetone trifluoroacetylimine alkylates indole exothermically (on cooling)[172]:

A single example of the interaction of acylimines with the fluoride ion is known. It has been shown[106] that hexafluoroacetone perfluoropivaloylimine combines with caesium fluoride in an exothermic reaction, forming a salt stable up to 130 °C:



According to the available data, hexafluoroacetone sulphonylimines react exothermically with alcohols, thiols, and amines[58], while hexafluoroacetone dialkoxyphosphorylimines undergo exothermic reactions with water and alcohols[57]. At 20 °C alcohols, amines, and sulphonamides add to trifluoroacetaldehyde sulphonylimines[176]. Polyfluoroketone acylimines are highly reactive in reactions with alcohols thiols, amines, and acid amides[20,56]. The electrophilic properties of hexafluoroacetone acylimines are so pronounced that they are capable of "abstracting" a hydride anion from a triethylamine molecule[177]:

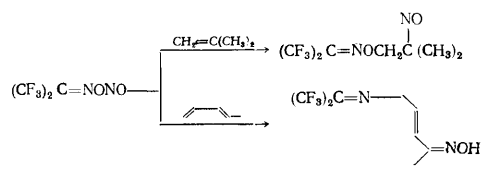
Other fluorine-containing imines are less reactive with respect to nucleophiles: polyfluoroketone imines unsubstituted at the nitrogen atom, aliphatic polyfluorinated azomethines, anils, hydrazones, azines, and *N*-fluoroimines. They constitute, as it were, an intermediate group of imines between difluoro- or fluoro-carbonylimines, on the one hand, and sulphonyl- or acyl-imines, on the other.

All these compounds combine vigorously with highly basic nucleophiles such as ammonia, amines, and hydrazines in the absence of catalysts, which has been demonstrated in relation to the reaction of hexafluoroacetone imines and anils[17,19,26,53,140], perfluoroguanidines, perfluoroamidines, and perfluoroketone *N*-fluoroimines[8,10], as well as hexafluoroacetone azine[115]. Thiols add to hexafluoroacetone anils[140] and alkenylimines[119] in the absence of catalysts and without heating. The conditions governing the interaction with hydroxy-compounds depend greatly on the nucleophilic properties of the latter and the electrophilic properties of the imine.

Thus hexafluoroacetone imine and its *N*-alkyl and *N*-aryl derivatives combine with lower alcohols on moderate heating or in the presence of catalysts without heating[17,26,78,140]. In the presence of basic catalysts, HCN, HN_3, HNCO, and acid alcohols interact with hexafluoroacetone imine[19,120]:

The addition is favoured by protophilic solvents capable of forming non-solvated anionoid species. Analogous features are characteristic also of the series of *N*-fluoroimines[8,10].

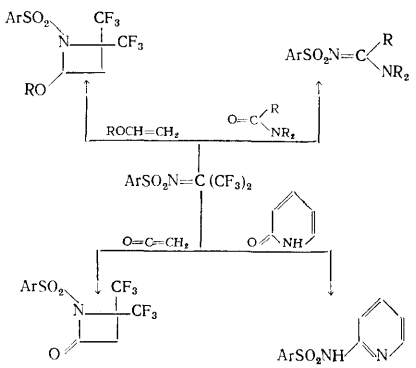
Even powerful electrophiles such as pentafluoroguanidine and pentafluoroamidines, which readily combine with lower alcohols, interact with weakly basic hydroxy-compounds only in the presence of nucleophilic catalysts[178,179]. Weaker electrophiles, for example polyfluoroketone *N*-fluoroimines, react even with aliphatic alcohols only in the presence of bases, forming adducts which are readily decomposed[8,10]:



The extremely strong influence of steric factors on the conditions and even the possibility of the addition of the reactant to the C=N bond, characteristic also of the imines of the hydrocarbon series, must be regarded as a characteristic feature of the properties of the intermediate group of fluorine-containing imines, apart from the marked dependence of the conditions in their reactions with nucleophiles on the basicity of the latter. The increase of the bulk of the substituent at the imine nitrogen atom or at the nucleophilic centre of the reactant leads to a sharp alteration of the reaction parameters, so that in many instances even highly basic amines do not form adducts with fluorine-containing imines.

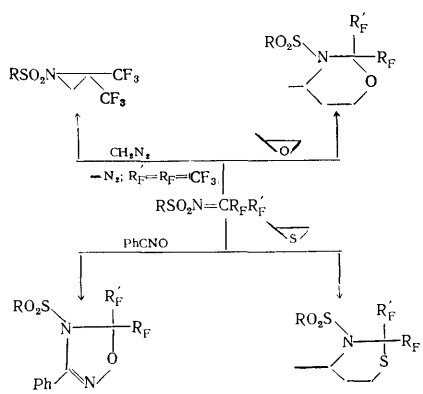
The next characteristic feature is that many of the fluorine-containing imines of this group are distinguished by an increased tendency towards the stepwise combination with nucleophiles. This determines the optimum conditions for their reactions with nucleophiles, the possibility of achieving the reactions with electrophiles with nucleophilic cooperation discussed above, and many unusual reactions of *N*-fluoroimines involving the formation of aza-anions[8]. In this respect the imines of the intermediate group, as it were, manifest the properties of difluoro- and fluoro-carbonyl-imines with the difference that they give rise to addition products instead of substitution products.

Thus a broad spectrum of the reactivities of the test compounds has been manifested in fluorine-containing imine–nucleophile systems: ranging from typical stepwise reactions to extremely mild concerted reactions. In the reactions of the first type one of the aspects of the reactivity of the dichlorocarbonylimines known in the hydrocarbon series is thrown into sharp contrast and is enhanced, while in the second type the unusual chemistry of iminium compounds is strongly manifested. At the same time the analogies noted above must be regarded as superficial. In reality the study of fluorine-containing imines as electrophiles led to the discovery of the most effective precursors of aza-anions, the strongest of the known "soft" π-acids, and a multiplicity of compounds with intermediate properties.



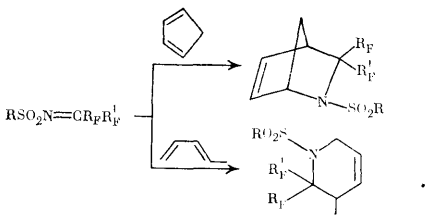
3. Cycloaddition Reactions

Various representatives of fluorine-containing imines have been investigated to unequal extents in cycloaddition reactions. Fluorine-containing oximes and their derivatives have not apparently been involved in cycloaddition hitherto. It has only been shown that in some of their reactions with unsaturated compounds, where one might have expected the formation of cyclic [2 + 2]- and [4 + 2]-adducts, acyclic substances were obtained. This happens on heating under severe conditions mixtures of hexafluoroisopropylidene-iminoxy-*N*,*N*-bis(trifluoromethyl)amine with polyfluoroalkenes[139] (see above). The nitrite of hexafluoroacetone oxime interacts analogously with polyfluoroalkenes at 180–190 °C [180] and with ethylenic compounds and 1,3-dienes at −50 to −15 °C:[181]



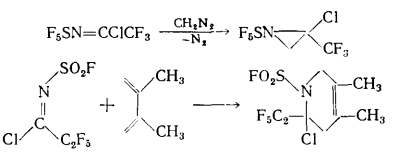
It may be that the many-centre π orbital of the derivative of the fluorine-containing oxime has no common symmetry elements with the π orbitals of alkenes and 1,3-dienes, i.e. the concerted [2 + 2]- and [4 + 2]-cycloaddition reactions are in this case prohibited.

Fluorine-containing azomethines are somewhat more reactive in cycloaddition processes than their hydrocarbon analogues and the tendency of these compounds towards cyclisation increases sharply with enhancement of the electron-accepting properties of the substituent at the imine nitrogen atom. Among the compounds of this series, polyfluoroketone sulphonylimines are the most reactive. It has been shown for hexafluoroacetone toluene-*p*-sulphonylimine that, under the conditions of intense cooling they react with keten and alkyl vinyl ethers to form cyclic [2 + 2]- adducts[21,22]. Hexafluoroacetone benzenesulphonylimine reacts vigorously with carboxamides via the cycloaddition–decomposition mechanism[182]:

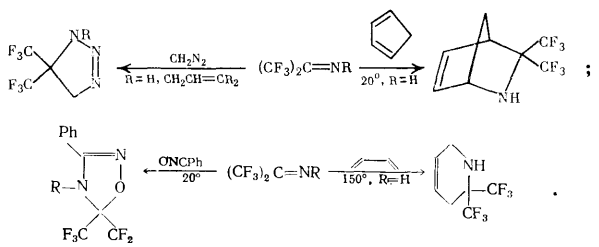


These data show that, as regards their tendency towards [2 + 2]-cycloaddition, fluorine-containing sulphonylimines have no equals in organic chemistry.

Polyfluoroketone sulphonylimines are extremely reactive also in [3 + 2]-cycloaddition. Their interaction with diazoalkanes takes place even at −60 °C and is accompanied by the elimination of nitrogen[168], which is characteristic of reactions of diazoalkanes controlled by the lowest unoccupied molecular orbitals (LUMO) of the imine and proceeds via a symmetrical transition state. Hexafluoroacetone benzenesulphonylimine readily interacts with benzonitrile oxide apparently via a stepwise pathway[161]. Polyfluoroketone sulphonylimines enter smoothly, under conditions typical for concerted reactions, into [3 + 2]-cycloaddition with oxirans and thi-irans[183,184]:



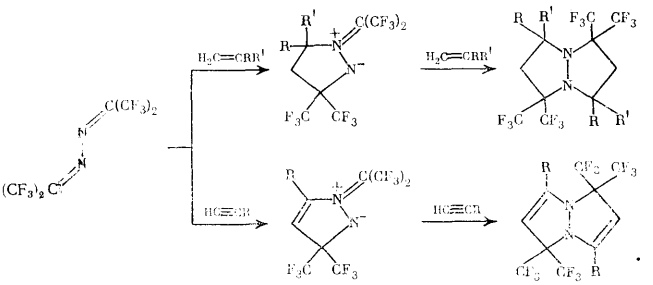
The [4 + 2]-cycloaddition of polyfluoroketone sulphonylimines takes place under unusually mild conditions[166]. They react smoothly with cyclopentadiene only with intense cooling (to −50 °C). *cis,trans*-Piperylene also enters into the reaction at a reduced temperature:



However, α,β-unsaturated aldehydes and ketones could not be involved in cycloaddition with polyfluoroketone sulphonylimines. The properties of polyfluoroketone sulphonylimines in [2 + 2]- and [4 + 2]-cycloaddition reactions described above are unusual and must be regarded as an exceptional case from the standpoint of the Woodward–Hoffman rules.

Other examples of the cycloaddition of highly electrophilic fluorine-containing imines are known. For example, trifluoroacetaldehyde toluene-*p*-sulphonylimine[37] readily forms a cyclic [4 + 2]-adduct with 2,3-dimethylbutadiene. Limiting cases of an unusually high tendency towards cycloaddition are known among fluorine-containing imines of other types, including halogenocarbonylimines[186,187]:

As the electron-withdrawing effects of the substituent and the imine nitrogen atom in fluorine-containing azomethines are reduced, their capacity for [2 + 2]-cycloaddition falls sharply. Thus hexafluoroacetone imine interacts with isobutene on heating above 200 °C to form a product of the "ene" reaction[188]. The reactivity in the [3 + 2]- and [4 + 2]-cycloaddition processes is reduced to a somewhat lesser extent[19,188–191]:



Attention should be drawn to the fact that diazomethane enters into these reactions as a 1,3-dipole[188,190] and not as a carbene precursor.

N-Fluoroimines are usually more reactive in cycloaddition reactions than fluorine-containing alkyl- and aryl-imines. They form fairly smoothly cyclic [3 + 2]- and [4 + 2]-adducts with diazomethane and 1,3-dienes respectively. Some of the compounds of this series, for example, perfluoroguanidines and amidines, are actually more reactive in [4 + 2]-cycloaddition reactions than polyfluoroketone sulphonylimines. However, in contrast to sulphonylimines, these compounds also give rise to [3 + 2]-cycloaddition products on reaction with diazomethane[8].

Fluorine containing hydrazones have been scarcely investigated in cycloaddition reactions. At the same time the spontaneous or acid-catalysed dimerisation of hexafluoroacetone *N*,*N*-dimethylhydrazone[53] (see above) under mild conditions constitutes important evidence indicating their capacity for cyclisation.

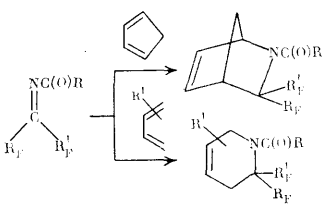
The pericyclic reactions of fluorine-containing azines and especially hexafluoroacetone azine occupy a special place in the chemistry of fluorine-containing imines. Attempts to involve this compound in [1 + 2]-cycloaddition lead either to the cleavage of the imine bond[109]:

or to products of the transformations of the primary cyclic [1 + 2]-adducts[55,116–119,192] (see above). Only keten[114] and diazomethane[115] could be involved in the reaction via the C=N bond with formation of cyclic [2 + 2]- and [3 + 2]-adducts respectively (see above). In other numerous reactions of hexafluoroacetone azine with unsaturated compounds, 1,5-diazabicyclo[3.3.0]octanes and 1,5-diazabicyclo[3.3.0]-octa-2,6-dienes are usually produced with the intermediate formation of cyclic azomethine-imines (see the communications by Tipping and co-workers[193,194] and Burger and co-workers[195,196] and the references quoted therein):

Thus the interaction of hexafluoroacetone azine with unsaturated compounds takes place as a two-stage cross [2 + 3]-cycloaddition. Ethylene, acetylene, monoalkyl- and monoaryl-substituted ethylenes and acetylenes, geminal dialkyl- and diaryl-ethylenes, alkyl vinyl ethers, alkoxyacetylenes, ynamines, certain cyclic alkenes, 1,3-dienes, acrylates, propiolates, etc. react with hexafluoroacetone azine via this pathway.

The intermediate azomethine-imines proved to be fairly stable in reactions of hexafluoroacetone azine with geminal dialkylethylenes, 1,3-dienes, alkoxyacetylenes, ynamines, etc. These compounds were isolated, their structure was demonstrated by spectroscopic methods and X-ray diffraction studies[193,196–200], and their properties were investigated. The intermediate products of these reactions served as precursors of 1,5-diazabicyclo[3.3.0]oct-2-enes, hexafluoroacetone alkenylhydrazones, and fluorine- and nitrogen-containing heterocycles (1,2-diazepines, pyrazoles, pyrazolines, pyrimidines, pyridine and triazine derivatives, etc.)[191–212].

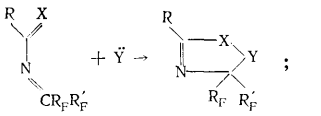
The study of the pericyclic reactions of hexafluoroacetone azine enriched organic chemistry in new examples of intramolecular 1,3-, 1,4-, and cascade proton shifts, unusual 1,4-sigmatropic transitions of the CF_3 group, and examples of unusual intramolecular electrocyclic reactions. However, the observed characteristic features of the reactivity of azines as 1,3-dipolar systems of atoms realised in the C=N=N=C four-centre fragment must be regarded as the most important outcome of the study of hexafluoroacetone azine. The observed charactersitics of its reactions with unsaturated compounds reflect the features of [2 + 3]-cycloaddition reactions of the LUMO-controlled type and are important in synthetic organic chemistry.



The studies of pericyclic reactions of fluorine-containing keten imines led to new advances in the chemistry of imines[11]. Their capacity for cycloaddition is greater than that of the known non-fluorinated triarylketen imines and, like the fluorine-containing azomethimes, increases appreciably as the

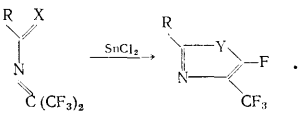
electron withdrawing effects of the substituents at the imine nitrogen atom become more pronounced. In contrast to triarylketen imines, fluorine-containing keten imines react exclusively at the imine bond in the [2 + 2]- and [3 + 2]-cycloaddition reactions with alkyl vinyl ethers, acetylenes, octafluoroisobutene, diazomethane, and nitrones. The dimerisation of fluorine-containing keten imines takes place analogously with nucleophilic cooperation by "soft" bases. Only dimerisation in the presence of "hard" bases and the epimerisation of these compounds involve the carbon–carbon bond. Thus the fluoroalkyl substituents in the cumulated C=C=N system exhibit more pronounced activating effects on the imine bond than on the carbon–carbon bond. The activating effects of perfluoroalkyl groups diminish the electron-donating properties of the imine group and hence the reactions controlled by the highest occupied molecular orbitals, characteristic of hydrocarbon keten imines, are replaced by the LUMO-controlled processes in the case of the fluorine-containing keten imines.

The appearance of unusual properties in the series of *N*-arylbis(trifluoromethyl)keten imines, where the imine group is linked to a conjugated system, proved to be an interesting consequence of the activating effect of the perfluoroalkyl groups. The primary pericyclic reactions are accompanied in this case by electrocyclic reactions involving aromatic systems. Formally both types of processes take place as [1 + 4]-cycloaddition in the presence of a carbenoid species and as [2 + 4]-cycloaddition in reactions with electron-donating alkenes or acetylenes. These mild reactions led to the prospect of the synthesis of hitherto inaccessible fluorine-containing derivatives of indole and quinoline and, in principle, they can be used also to synthesise other fluorine- and nitrogen-containing heterocycles[11].



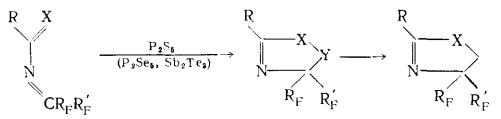
A large group of fluorine-containing imines, widely investigated in cycloaddition reactions, comprises the acyl-, thioacyl-, and iminoacyl-imines of polyfluoroketones. In contrast to azines, where the rigidity of the N–N bond prevents the formation of a four-centre π orbital in the molecule, free rotation of the acyl group at the nitrogen atom of the C=N bond is characteristic of compounds of this type, which creates conditions for the manifestation of the reactivity of both the isolated imine group and the conjugated C=N–C=X system.

The properties due to the isolated C=N bond have been investigated only in relation to the reactions involving the [4 + 2]-cycloaddition of cyclopentadiene and acyclic 1,3-dienes to polyfluoroketone acetyl- and perfluoroacyl-imines[213,214]:



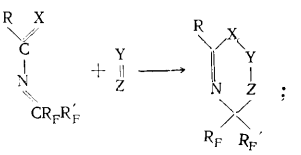
Perfluoroacylimines proved to be particularly reactive in these reactions. Cyclic adducts with cyclopentadiene can be isolated only when the reaction is carried out with intense cooling; perfluoroacylimines react at reduced temperatures even with acyclic 1,3-dienes. Hexafluoroacetone acetylimine enters into these reactions at room temperature.

The properties of polyfluoroketone acyl-, thioacyl-, and iminoacyl-imines as four-centre conjugated systems have been investigated much more widely. Carbenes, carbenoid species, and carbene precursors interact vigorously with these compounds via the [1 + 4]-cycloaddition mechanism:



X=O, S, NH, NR, NAr; Y=CH_2, CCl_2, $C(OMe)_2$, C=NR, $P(OR)_3$.

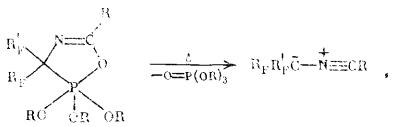
Diazomethane[21], dichloro- and dimethoxy-carbenes and complexes of carbenes with chromium pentacarbonyl[83,109,212–217], isonitriles[83,216–220], and trialkyl phosphites[73,87,221–224] were made to undergo this reaction. Stannous chloride reacts similarly to carbonoid species, but the primary adduct decomposes and 1,3-azoles are formed[225,226]:



The affinity of acyl-, thioacyl-, and iminoacyl-imines for sulphur, selenium, and tellurium atoms proved to be unusually high. When the imines are heated with phosphorus pentasulphide or pentaselenide and antimony telluride, cyclic [1 + 4]-adducts are formed and then undergo a further exchange reaction[79,82,227–229]:

Y=S, Se, Te .

Reactions involving the [2 + 4]-cycloaddition of unsaturated compounds to acyl-, thioacyl-, and iminoacyl-imines of polyfluoroketones take place in most cases under extremely mild conditions. Electron-donating alkenes[21], alkyl vinyl ethers[21,230], keten[21,231], sulphenes and alkoxyacetylenes[232], aromatic aldehydes[233,234], α,β-unsaturated aldehydes[214,235], carboxylic acid nitriles[234], cyanamides[84], various alkenyl cyanides[214,236,237], and sulphoxides[238] undergo these reactions:



X=O, S, NH, NR, NAr .

The dienophilic properties of the compounds enumerated usually become more marked with enhancement of their electron-donating properties, which indicates the operation of LUMO-controlled mechanisms of these reactions.

Among the heterodienes of the series considered, the maximum activity is shown by perfluoroacylimines, which form cyclic [1 + 4]- and [2 + 4]-adducts as a rule under the conditions of intense cooling. These compounds must be regarded as the most reactive heterodienes among those known at present in organic chemistry.

The studies of the pericyclic reactions of polyfluoroketone acylimines enriched organic chemistry in many new examples of sigmatropic transformations and electrocyclic reactions, apart from the reactions discussed above. The cyclic

[1 + 4]-adducts of acylimines with phosphites, whose pyrolysis leads to highly reactive fluorine-containing nitrile-ylides, proved to be particularly interesting[239,240]:

A unique feature of these 1,3-dipoles is their unusually high capacity for [2 + 3]-cycloaddition not only to electron-donating unsaturated compounds but also to the C=N bond in nitrogen-containing heterocycles with formation of fluorine- and nitrogen-containing condensed systems.

---o0o---

Numerous fluorine-containing analogues of imines of all known types have now been investigated on a fairly broad scale. These compounds proved in most cases to have more strained structures compared with their hydrocarbon analogues, which is the reason for their higher stability, the unique combination of their properties, and the specific features of the optimum conditions and pathways leading to their formation.

The introduction of fluorine and fluoroalkyl groups at the C=N bond usually suppresses the amphoteric character of the imines and imparts to them pronounced electrophilic properties, which depend in an unusually marked manner on the nature and positions of the fluorine-containing and other substituents at the imine bond. The effects resulting from the effect of the substituents at the highly polarisable C=N bond lead in this instance either to its marked inactivation or to a sharp increase of its ability to be involved in stepwise or concerted reactions. The chemistry of fluorine-containing imines therefore involves contrasting features. It is particularly rich in examples of extremely reactive and unreactive compounds with a C=N bond.

The above feature of the properties of fluorine-containing imines suggests that these compounds are ideal objects for theoretical studies. Comparative investigation of fluorine-containing imines and their non-fluorinated analogues at the electronic level constitutes at present one of the promising approaches to the creation of general molecular orbital models of organic compounds and their reactions.

Fluorine-containing azomethines, which reproduce many of the properties of non-fluorinated iminium salts, are of particular theoretical interest. The availability, stability, physicochemical properties convenient for investigations, and high reactivity suggest that the use of individual representatives of these compounds in the modelling of numerous biochemical reactions, involving the formation and metabolism of biogenic Schiff bases, is likely to be promising. Presumably more extensive studies of the steric effects and of the stereochemistry of reactions involving fluorine-containing imines will exert a fruitful influence on the understanding of the chemical nature of many processes involving vital activity.

The applied aspects of fluorine-containing imines have been associated for a long time only with the chemistry of the highly strained energy rich *N*-fluoroimines. However, during the last decade there has been a sharp increase of interest in various fluorine-containing imines as precursors of a wide variety of acyclic and alicyclic fluorine- and nitrogen-containing compounds. The data already accumulated at the present time suggest that fluoroimines can be usefully employed for the introduction of polyfluoroalkyl groups into a wide variety of specific structures, which leads to the possibility of their application in the syntheses of physiologically active substances and technically important products and also for the preparation of highly valuable materials. All these factors show that the advances achieved at the present time in the study of fluorine-containing imines constitute only the beginning of the development of an extremely rich field of the chemistry of organofluorine compounds with an electrophilic C=N bond.

The Chemistry of Perfluoroisobutene

Yu.V.Zeifman, E.G.Ter-Gabrielyan, N.P.Gambaryan, and I.L.Knunyants

The literature data on the methods of synthesis and reactions of the highly electrophilic perfluoroisobutene with nucleophiles as well as electrophiles are surveyed. The possibilities of employing this fluoro-olefin in organofluorine synthesis are discussed. The advances in the study of the perfluoro-t-butyl anion, generated from perfluoroisobutene and the fluoride anion, are considered in a special section.
The bibliography includes 199 references.

I. INTRODUCTION

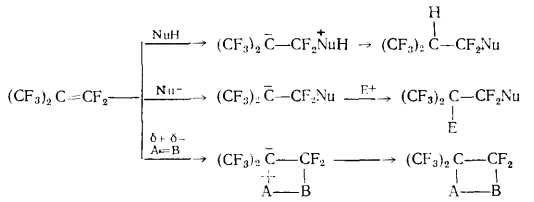
The ability of fluoro-olefins to react with nucleophiles, which distinguishes them radically from the hydrogen-containing analogues, is particularly pronounced in the case of perfluoroisobutene (PFIB), whose chemistry has developed vigorously since 1953. This fluoro-olefin is of special interest primarily because of its uniquely high electrophilic activity: PFIB reacts with almost all known nucleophiles and even the usual organic solvents, for example dimethylformamide or acetonitrile, are not sufficiently inert in relation to this compound. The properties of PFIB are close to those of activated olefins of the type of α,β-unsaturated carbonyl compounds or polycyano-olefins. At the same time the wide variety of the reactions of PFIB is determined by the lability of the fluorine atoms in the CF_3 group, characteristic of fluoro-olefins, and the possibility of further reactions of the addition products associated particularly with the high CH-acidity of the $(CF_3)_2CH$ group. All these factors, together with its ready availability, make it possible to employ PFIB widely in organofluorine synthesis.

The high electrophilicity of PFIB is due to the combination of the strong electron-accepting effects of the fluorine atoms and the CF_3 group on which is superimposed the capacity of the vinyl fluorine atoms for effective conjugation with the C=C bond. Indeed, the consecutive increase of the asymmetry of the molecule in the sequence $CF_2{=}CF_2 < CF_3CF{=}CF_2 < (CF_3)_2C{=}CF_2$ is accompanied by a gradual increase of the positive charge on the carbon atom of the CF_2 group, which has been confirmed by quantum-chemical calculations[1-3]. On the other hand, calculations for the molecules of PFIB and esters of perfluoromethylacrylic acid by the extended Hückel and CNDO methods[4] showed that their reactivity is determined by the dynamic properties of the distribution of electron density rather than the static distribution. The higher electrophilicity of perfluoromethylacrylate compared with PFIB can be explained by the greater ability of the alkoxycarbonyl group, compared with the CF_3 group, to stabilise the intermediate carbanions or carbanion-like transition states. From this point of view, the sharp increase of electrophilicity in the above sequence is caused in the first place by the growing stability of the carbanions: $NuCF_2\bar{C}F_2 < NuCF_2\bar{C}FCF_3 < NuCF_2\bar{C}(CF_3)_2$ (Nu is the nucleophile residue). Such variation of the state of the carbanion is evidently associated not only with the stabilising effect of the CF_3 group but also with the destabilisation of the carbanionic centre by the compact unshared electron pairs of the α-fluorine atoms.

The framework of the present review precludes a comparison of the electrophilic properties of PFIB and the lower fluoro-olefins in relation to specific examples. We shall only note that in all cases without exception PFIB is much more reactive in reactions with nucleophiles than, for example, hexafluoropropene. At the same time, the reactions of PFIB with electrophiles, if they occur at all, proceed with much difficulty. Nucleophilic catalysis therefore assumes special importance in such reactions, which reflects the change in the reaction mechanism from electrophilic in the case of non-fluorinated olefins and lower fluoro-olefins to nucleophilic for PFIB. Separate aspects of the chemistry of PFIB have already been discussed in a number of recent reviews[1-8]. However, the chemistry of this fluoro-olefin has not so far been fully considered.

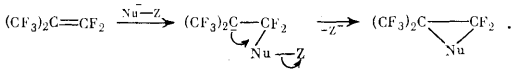
II. PHYSICAL PROPERTIES AND METHODS OF SYNTHESIS

PFIB is a colourless highly toxic† gas[9] with a boiling point of 6.5 °C, which can be readily identified from the infrared[10] and ^{19}F NMR [7] spectra. Its reduction potential at the platinum electrode is −2.65 V.[11]



The main methods of synthesis of PFIB include thermolytic processes, which indicates a high thermal stability of this compound. PFIB is obtained by the pyrolysis of Teflon[12], tetrafluoroethylene[13], hexafluoropropene[14], and perfluorocyclobutane[10,15] at 700–750 °C (see also other communications [16-18]). It has been suggested that the synthesis of PFIB by pyrolysis involves the intermediate formation of difluorocarbene[13,19]. In addition, PFIB can be obtained by the dechlorination of 1,2-dichloro-octafluoroisobutane by zinc in dioxane or acetone[20], but this reaction is of limited practical interest, since the dichloride itself is obtained only on chlorination of PFIB.

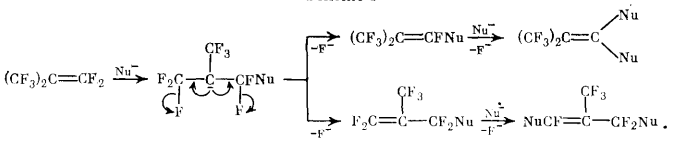
III. REACTIONS WITH NUCLEOPHILES



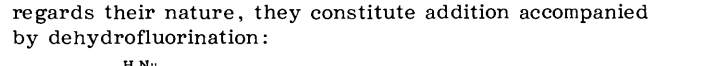
The chemistry of PFIB includes all the reactions with nucleophiles characteristic of fluoro-olefins. Addition to double bond of PFIB takes place when it interacts with

† PFIB is approximately 10 times more toxic than phosgene.

proton-donating nucleophiles. The conjugated nucleophilic addition reactions (the commonest instance is that of the reactions with participation of the F^- anion) as well as ionic cycloaddition of 1,2- or 1,3-dipolar compounds belong to the same type:



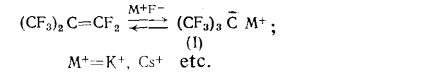
In those cases where the nucleophile is attached to a group Z capable of being split off in the form of an anion (or neutral molecule), the addition can be accompanied by intramolecular cyclisation [see Eqns.(3), (4), (6), and (7) below]:



When PFIB interacts with conjugated nucleophiles, the vinyl fluorine atom is usually substituted. The same process is frequently accompanied by the addition of nucleophiles to PFIB, which distinguishes it sharply from the lower fluoroolefins for which addition is more typical. In many cases the products of the "allyl" substitution resulting from the elimination of an F^- anion from the CF_3 group are formed. Both "vinyl" and "allyl" products are usually capable of further reactions with nucleophiles, which leads to geminal substitution of 1,3-disubstitution (Scheme 1):

Scheme 1

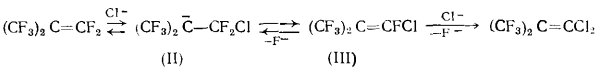
The relative contributions of the vinyl and allyl substitutions are determined by the nature of the entering nucleophile and also by the reaction conditions. The vinyl substitution is facilitated in the interaction with nucleophiles which ultimately give rise to a substituent with an unshared electron pair as a result of the reaction. In other cases allyl substitution competes with this process to some extent [see Eqn.(9) below].



In certain reactions of PFIB both vinyl and fluorine atoms are substituted by an alkylidene residue, the imino-group, or a sulphur atom. However, these processes, which lead to the formation of cumulenes or heterocumulenes, can be classified only formally as substitution reactions, since, as regards their nature, they constitute addition accompanied by dehydrofluorination:

1. Reactions with Halide Ions

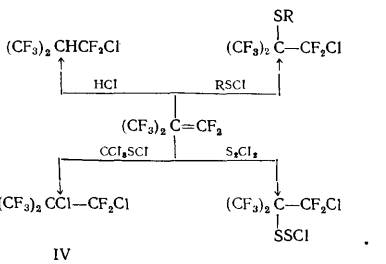
The Fluoride Ion



PFIB readily interacts with alkali metal fluorides (KF, CsF) in aprotic dipolar solvents with formation of the perfluoro-t-butyl anion (I). The reaction is reversible, so that the free fluoro-olefin is present in solution together with the anion (I).[7] The anion (I) is generated also in the reaction of PFIB with tetramethylformamidinium hydrogen fluoride[21] or hexamethylguanidinium fluoride[22] and in this case the equilibrium is displaced to a greater extent towards the anion (I), as shown by the ^{19}F NMR spectra:

In terms of their wide variety and importance for the chemistry of fluorocarbanions, the reactions of the anion (I) are of independent interest and will be considered in the concluding Section of this review. We shall only note that the anion (I) readily combines with a proton. Thus the interaction of PFIB with hydrogen fluoride in the presence of catalytic amounts of ammonium fluoride[23] or triethylamine[24] results in the formation of monohydroperfluoroisobutane $(CF_3)_3CH$. This reaction is important in the chemistry of PFIB because it accompanied the transformations of the latter in which the initial adducts are dehydrofluorinated.

The Chloride Ion



PFIB is also capable of combining with the Cl^- anion via the double bond with formation of the anion (II). This might have led to the exchange of chlorine for fluorine but under the usual conditions this reaction does not occur, since the equilibrium in the exchange is largely displaced towards the initial reactants. The exchange reaction was achieved in the presence of compounds which irreversibly bind the F^- anion. Thus fluorine is exchanged for chlorine in PFIB when the latter is treated with benzoyl chloride in the presence of pyridine; together with the monochloride (III), a certain amount of the *gem*-dichloride is formed under these conditions[25]:

(1)

The interaction of PFIB with phosphoryl chloride catalysed by triethylbenzylammonium chloride (TEBA) yielded the monochloride (III) and the dichloride $ClCF_2C(CF_3)=CFCl$.[25] Furthermore, TEBA or tertiary amines catalyse the hydrochlorination of PFIB [23] and the addition to the latter of aliphatic and aromatic sulphene chlorides[26] or sulphur monochloride[27]. It is of interest that the interaction of PFIB with sulphene chlorides containing electron-accepting groups, in the presence of the chloride ion, is of the halogenophilic type and leads to the chlorination of PFIB.[26] The dichloride (IV) has also been obtained on treatment of PFIB with chlorine under the conditions of nucleophilic catalysis[28] (Scheme 2):

Scheme 2

IV

In the absence of a catalyst, these reactions either do not occur at all or require very severe conditions [see Eqn.(13) below].

The Bromide Ion

Fluorine exchanges for bromine in PFIB on treatment of the latter with benzoyl bromide in the presence of pyridine. Together with the monobromide $(CF_3)_2C{=}CFBr$, disubstitution products are formed[25]. Under the conditions of nucleophilic catalysis, it has also been possible to achieve the hydrobromination of PFIB [23] and the addition of bromine to the latter[28] [see Eqn.(13)].

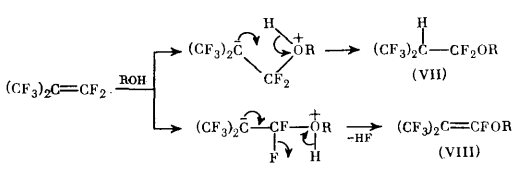
PFIB does not react with the iodide anion; hydriodic acid also does not add to PFIB under the conditions of nucleophilic reaction[23]. Iodoperfluoroisobutene has been obtained from the monochloride (III) by the exchange reaction with KI.[29]#

2. Reactions with *O*-Nucleophiles

Water and Hydrogen Peroxide

When PFIB reacts with water in acetone[30] or tetrahydrofuran (THF),[31] α-hydrohexafluoroisobutyric acid (V) is formed in a high yield. This is one of the most important reactions of PFIB in practice, particularly because the acid (V) is the starting compound for the synthesis of bis(trifluoromethyl)keten [32] and derivatives of perfluoromethacrylic acid[33]. Depending on the reactant ratio and the reaction conditions, the hydration of PFIB in the presence of triethylamine can yield the fluoride of the acid (VI), the acid (V), or its decarboxylation product—dihydroperfluoropropane[34]:

$$(CF_3)_2C{=}CF_2 \xrightarrow[-HF]{H_2O} \underset{(VI)}{(CF_3)_2CH{-}COF} \xrightarrow[-HF]{H_2O} \underset{(V)}{(CF_3)_2CH{-}COOH} \xrightarrow{-CO_2} (CF_3)_2CH_2 .$$

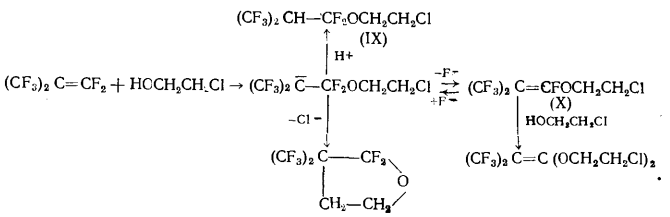


The alkaline epoxidation of PFIB leads to an epoxide[35-37] [see also Eqn.(4)], which has been suggested as a monomer[38,39]:

$$(CF_3)_2C{=}CF_2 \xrightarrow[NaOH]{H_2O_2} (CF_3)_2C(O{-}OH){-}CF_2 \xrightarrow{-OH^-} (CF_3)_2C(O){-}CF_2 . \qquad (3)$$

Alcohols

PFIB readily reacts with aliphatic alcohols[40-42] and cellulose[43]. The reaction results in the formation, apart from compound (VII), also of the vinyl ethers (VIII) (Scheme 3). It has been established that the saturated ethers (VII) are converted into the unsaturated ethers (VIII) under much more severe conditions than those in the reaction of PFIB with alcohols. On this basis, it is assumed that the ethers (VII) and (VIII) are formed independent of one another:

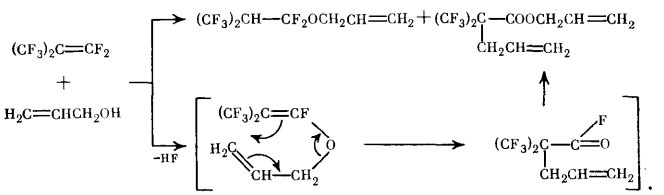


Scheme 3

Perfluoroisobutenyl derivatives of lithium and magnesium, which can be used to synthesise compounds containing the $(CF_3)_2CF{=}CF$ group, were obtained from chloro- and iodoperfluoroisobutenes[29].

The intermediate dipolar ion is stabilised mainly as a result of the protonation of the anionic centre but enhancement of the electron-donating properties of the residue R promotes the elimination of the F^- anion from the CF_2 group[40]. With increase of the acidity of the alcohols, their interaction with PFIB becomes more difficult. Thus CF_3CH_2OH, $HSCH_2CH_2OH$, and $ClCH_2CH_2OH$ react with PFIB under mild conditions only in the presence of basic catalysts[40], which tends to increase the fraction of the vinyl substitution products. For example, depending on the conditions, either the ethers (IX) and (X) or the acetal or bis(trifluoromethyl)keten can be obtained from PFIB and ethylene chlorohydrin[44,45]. The product of the intermolecular cyclisation of the intermediate carbanion is formed only under the conditions of thermodynamic control on interaction of the vinyl ether (X) with the F^- anion[45] (Scheme 4):

Scheme 4

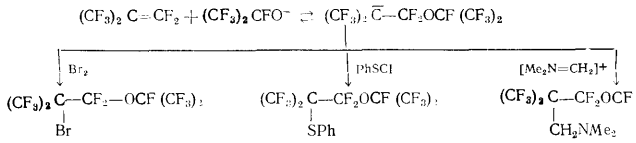


The addition of the enol of pentafluoroacetone to PFIB is catalysed by *N*-methylpyrrolidine or pyridine[46]:

$$(CF_3)_2C{=}CF_2 + CF_2{=}C(OH){-}CF_3 \rightarrow (CF_3)_2CHCF_2OC(CF_3){=}CF_2 .$$

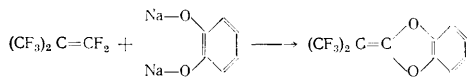
The reactions of PFIB with allyl alcohols are of special interest. Together with the addition products, the products of the Claisen rearrangement of allyl vinyl ethers and not the ethers themselves are formed (Scheme 5):[47,48]

Scheme 5



Propargyl alcohol and its homologues react analogously with PFIB and the migration of the propargyl group is accompanied by the acetylene–allene rearrangement[48]. It has been suggested that the products of all these reactions are formed as a result of the [3,3]-sigmatropic rearrangement of the intermediate fluorocarbanion[48].

The reactions of PFIB with sodium alkoxides in aprotic media lead to alkyl perfluoroisobutenyl ethers of bis(trifluoromethyl)keten acetals depending on the reactant ratio[49]. PFIB is apparently capable, in principle, of interacting also with alkali metal perfluoroalkoxides, but the reaction is reversible and the equilibrium is fully displaced towards the initial reactants (the perfluoroisopropoxide anion is a more effective leaving group than the fluoride anion). Indeed, in the presence of appropriate electrophiles it is possible to detect the formation of an intermediate carbanion and to obtain the products of the coupled perfluoroalkoxybromination or perfluoralkoxysulphenylation of PFIB. The alteration of the nature of the counterion leads to an analogous result: the interaction of PFIB with the salt $[Me_2N{=}CH_2]^+\bar{O}CF(CF_3)_2$

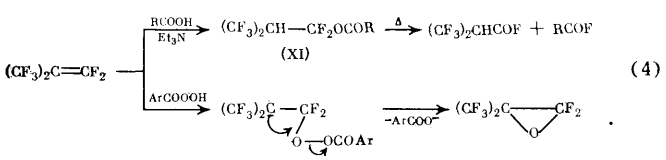


yields a fluorine-containing alkoxyamine as a result of the covalent binding of the intermediate carbanion to the methyleneimmonium cation (Scheme 6):[50]

Scheme 6

Phenols

On heating, PFIB reacts with phenol and resorcinol; only the addition products have been obtained as a result[51]. Like alkoxides, the phenoxides react in their turn with PFIB under mild conditions and give rise to the products of the vinyl monosubstitution[52,53] and disubstitution[54,55]. When PFIB reacts with the disodium salt of catechol, a cyclic keten acetal is formed[56]:



Acids and Peracids

In contrast to derivatives of perfluoromethacrylic acid[33], PFIB does not react with carboxylic acids in the absence of a catalyst. Acetic and benzoic acids add to PFIB only in the presence of triethylamine. The resulting adducts (XI) decompose into two acid fluorides on treatment with triethylamine[57] or on thermolysis[58].

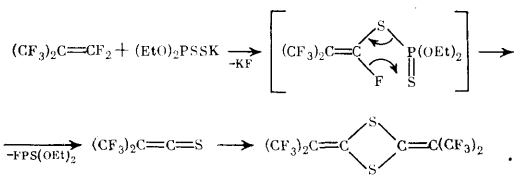
Despite the fact that the introduction of electronegative substituents into the olefin molecule usually hinders the Prilezhaev epoxidation, PFIB readily interacts with aromatic peracids to form an epoxide (Scheme 7). The reaction mechanism is apparently inverted in this case and the peracid functions as a nucleophile[59]:

Scheme 7

(4)

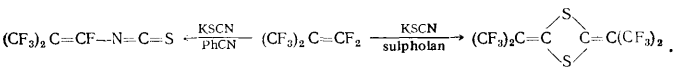
Derivatives of Hydroxylamine

PFIB readily comines with acetone[60] and hexafluoroacetone[61] oximes:

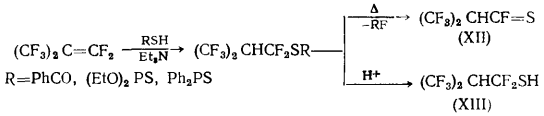


3. Reactions with *S*-Nucleophiles

The interactions of PFIB with benzylmercaptan[62], allylmercaptan[63], and thiophenol[26] lead mainly to addition products. Depending on the conditions, mono- or di-substitution products have been obtained in the reactions with mercaptides[64] and thiophenoxide[65]:



Disubstitution with formation of the bis(trifluoromethyl)-thioketen dimer takes place with PFIB reacts with potassium diethyl phosphorodithioate (Scheme 8):[66] the monosubstitution product could not be isolated owing to its spontaneous decomposition:



Scheme 8

This reaction is of preparative importance. The interaction of PFIB with the salts of other thiolo-acids leads to the same result[67-69]. It is of interest to note that, in the reaction of PFIB with KSCN, the thiocyanate ion exhibits the properties of an ambident nucleophile[70]:

Thiolo-acids add to PFIB in the presence of triethylamine as the catalyst. Like their oxygen analogues [see Eqn.(4)], the resulting adducts decompose on thermolysis with formation of the thioacid fluoride (XII). Acid hydrolysis of the adducts leads to the mercaptan (XIII) with two fluorine atoms in the α-position[58].

4. Reactions with *N*-Nucleophiles

PFIB readily reacts with ammonia and amines and the tendency towards the formation of unsaturated products is then enhanced.

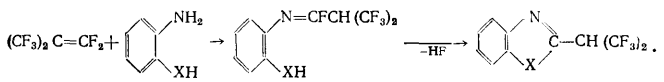
Ammonia

PFIB vigorously combines with ammonia. Subsequent dehydrofluorination leads to hexafluoroisobutyronitrile, the low yield of which can be explained by its extreme instability in relation to ammonia[41]:

The much lower reactivity of hexafluoropropene in this reaction permits the employment of the latter for the elimination of PFIB from hexafluoropropene[71].

Primary Amines

The interaction of PFIB with primary amines leads to α-hydrohexafluoroisobutyroimidoyl fluorides, the amidines derived from this acid, or bis(trifluoromethyl)keten imines (Scheme 9):[72,73]



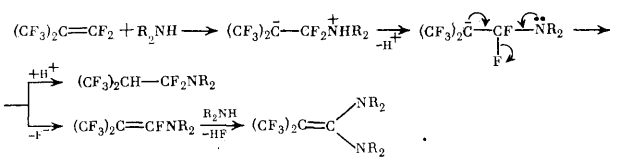
Scheme 9

$$(CF_3)_2C{=}CF_2 \xrightarrow[-HF]{RNH_2} (CF_3)_2CHCF{=}NR \begin{cases} \xrightarrow{-HF} (CF_3)_2C{=}C{=}NR \\ \xrightarrow{RNH_2} (CF_3)_2CHC(NR)(NHR) \end{cases} \quad (5)$$

In the reaction of PFIB with an excess of *p*-toluidine, the corresponding amidines undergo further reactions: derivatives of azetidine and quinoline were obtained under these conditions[74].

Keten imines can be obtained either by the direct interaction of PFIB with primary amines catalysed by triethylamine (in this case the PFIB–Et_3N system behaves simultaneously as the acceptor of the HF evolved) or with preliminary isolation of imidoyl fluorides and subsequent dehydrofluorination with powdered KOH in ether or with the adduct $BF_3.Et_3N$§. The interaction of PFIB with primary amines in the presence of CaF does not stop at the stage involving the formation of ketene imines but leads to their cyclic adducts with PFIB [see Eqn.(12) below].

When PFIB was allowed to react with *ortho*-substituted anilines, the products of the cyclisation of the intermediate imidoyl fluorides were obtained[56] (see also Nakai et al.[75]):

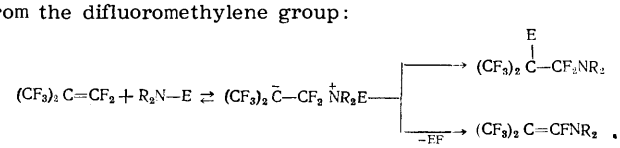


X=O, S, NH

Secondary Amines

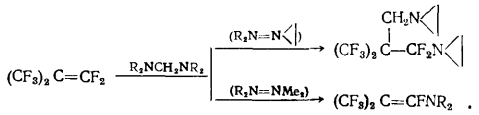
The interaction of PFIB with secondary amines leads to both addition products and unsaturated products (Scheme 10) and the available data do not permit a rigorous distinction to be made (as in the reaction with alcohols) between situations where the unsaturated products are formed as a result of direct vinyl substitution or as a result of the dehydrofluorination of the adducts formed initially[76–78]:

Scheme 10



It has been suggested[76] that the presence of electron-donating substituents at the nitrogen atom increases the ability of its electron pair to "expel" the fluoride ion from the intermediate carbanion. The reactions of PFIB with highly basic secondary amines therefore lead to unsaturated products, while the reactions with weakly basic amines lead to the formation of addition products. The interaction of PFIB with dimethylamine or piperidine in the presence of an excess of the base leads to bis(trifluoromethyl)keten aminals. The corresponding aminal could not be obtained by the reaction with diethylamine, apparently owing to the influence of steric factors in this reaction[79].

§ This reagent is particularly convenient in the synthesis of keten imines which readily dimerise in the presence of traces of bases.



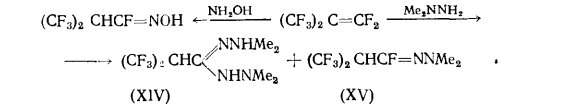
Tertiary Amines

The interaction of PFIB with tertiary amines leads to the formation of a dipole ion. When a group capable of cationoid abstraction is present at the nitrogen atom, the ion is stabilised either via the migration of this group to the carbanionic centre or via its elimination with a fluorine atom from the difluoromethylene group:

Thus, depending on the character of the substituents at the nitrogen atom, the insertion products or the products of the substitution of a fluorine atom by a dialkylamino-group have been obtained by the reaction of PFIB with tetra-alkyldiaminomethanes (Scheme 11):[80]

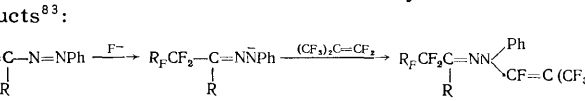
Scheme 11

The latter case evidently obtains also in the interaction of PFIB with *N*-trimethylsilylpiperidine[79].



The formation of a dipolar ion from PFIB and R_3N has been confirmed in the study of the reaction of PFIB with pyridine in the presence of bromine; this yielded a coupled addition product[28]:

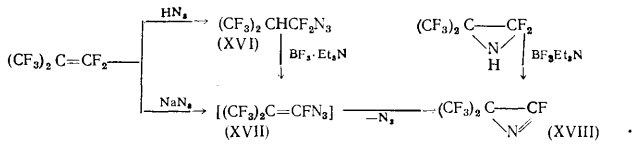
There exist many indirect data indicating the reversible addition of R_3N to PFIB. Thus the dimerisation of bis(trifluoromethyl)keten imines by tertiary amines is retarded in the presence of PFIB by a factor greater than 100.[72]



Hydroxylamine, Organic Derivatives of Hydrazine, and Hydrazoic Acid

When PFIB reacts with free hydroxylamine, the fluoride of α-hydrohexafluoroisobutyrohydroxamic acid is formed[81]. The reaction of PFIB with 1,1,-dimethylhydrazine gives rise to the hydrazine derivatives (XIV) or (XV), depending on the reactant ratio[82]:

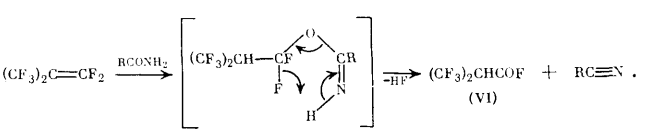
(XIV) (XV)



The interaction of PFIB with phenylazo-olefins in the presence of CsF results in the formation of vinyl substitution products[83]:

PFIB combines with 3,3-dimethylaziridine[84]. An addition product has been obtained from PFIB and hydrazoic acid, generated *in situ* from NaN_3 and sulphuric acid in dimethylformamide[85]. PFIB reacts even more readily with sodium azide[85,86]. The azirine (XVIII), formed as a result of the spontaneous decomposition of the unsaturated azide (XVII),

then polymerises under the influence of the nucleophiles present in the reaction mixture. However, it was obtained under neutral conditions by the dehydrofluorination of the saturated azide (XVI) or 3,3-difluoro-2,2-bis(trifluoromethyl)aziridine by the complex $BF_3.Et_3N$ (Scheme 12):



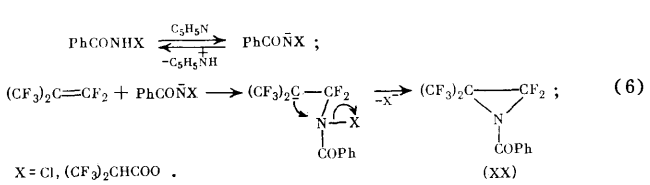
Scheme 12

Amides and Sulphonamides

The electrophilic properties of PFIB are sufficiently strong for it to react with carboxylic acid amides in the absence of bases[87]. When PFIB was allowed to react with acetamide or benzamide in diglyme, the acid fluoride (VI) and the corresponding nitriles were obtained (Scheme 13). Evidently in this case the amides undergo *O*-alkylation with formation of unstable iminoesters, which decompose subsequently like the acyl derivatives of α,α-difluoroalcohols [see Eqn.(4)]:

Scheme 13

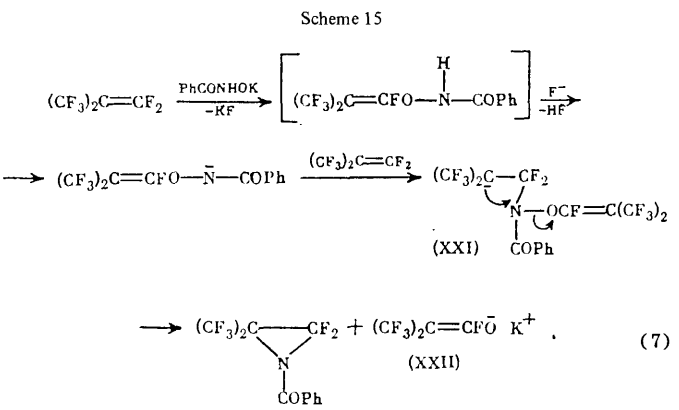
The much less basic benzenesulphonamide and urethane react with PFIB only in the presence of bases. PFIB readily reacts with the potassium salt of benzenesulphonamide to form the adduct (XIX) of *N*-phenylsulphonylketen imine with KF:[87]



The reaction of PFIB with urethane takes place in the presence of KF as the catalyst and leads to the adduct of the corresponding keten imine with PFIB [see Eqn.(12) below]

N-Nucleophiles Containing Leaving Groups

When PFIB interacts with *N*-chloro- or *N*-acyloxy-benzamide in the presence of bases, *N*-benzoylaziridine (XX) is formed in a satisfactory yield (Scheme 14). This reaction, which constitutes nucleophilic cyclisation of PFIB, is an example of the fixation of the amide anion formed as an intermediate in the Hofmann and Lossen rearrangements by the interaction with the electrophilic C=C bond[88]:

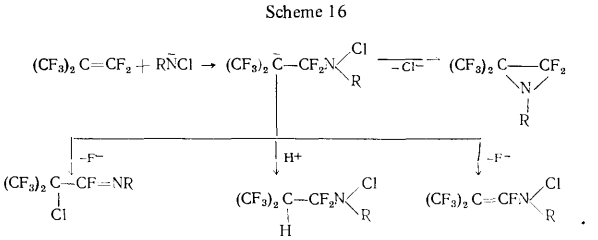


Scheme 14

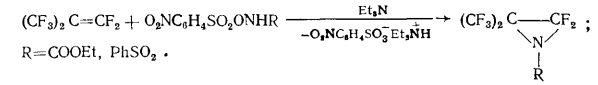
(6)

The reaction of PFIB with the potassium salt of benzohydroxamic acid proceeds via an analogous route (Scheme 15). In this case the carbanion (XXI) cyclises and the mesomeric anion (XXII) plays the role of the leaving group[88]:

Scheme 15



(7)

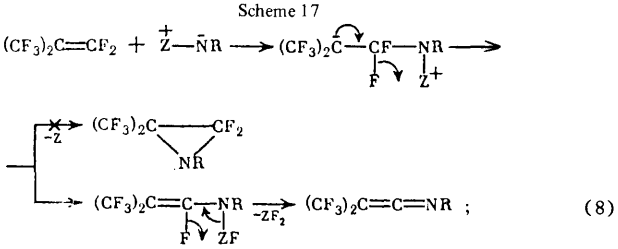


The formation of the aziridine (XX) was also detected in the reaction of PFIB with $Me_3\overset{+}{N}-\overset{-}{N}COPh$.[88]

When various *N*-chloroamides were involved in the nucleophilic cyclisation reaction, it was observed that products other than aziridines are also formed; this is associated with the low effectiveness of the Cl^- anion as the leaving group and also with the tendency of the chlorine in the *N*-chlorocompounds to undergo cationoid abstraction (Scheme 16):[89]

Scheme 16

The cyclisation of PFIB with the aid of *N*-(*p*-nitrobenzenesulphonyloxy)amides takes place much more unambiguously[89]:

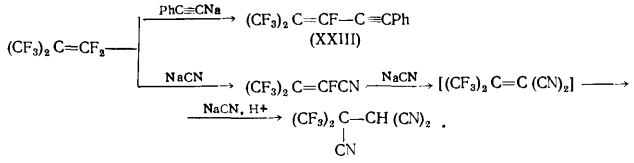


These reagents have been used successfully for the cyclisation of other highly electrophilic unsaturated fluorine compounds[89].

It has been established that PFIB does not form cyclic adducts with acylnitrenes generated by the photolysis of benzoyl[88] or alkoxycarbonyl azides[89]; this confirms the nucleophilic mechanism of the formation of the fluorine-containing aziridines.

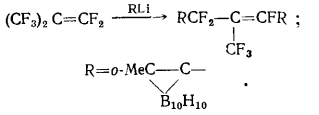
In the interaction of PFIB with iminophosphoranes[90] or iminosulphuranes[91], rings are not formed either. The only pathway in these reactions involves vinyl substitution in accordance with Scheme 17 accompanied by the β-decomposition of the intermediate fluorides [see Eqn.(11)]:

Scheme 17



(8)

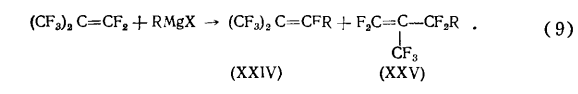
Z = Ph_3P, R = Ph; Z = Me_2S, R = COOEt.



5. Reactions with *C*-Nucleophiles

Organometallic Compounds

The replacement of the vinyl fluorine atom by the CN group is readily achieved by the reaction of PFIB with NaCN and the resulting nitrile is capable of further reaction with the cyanide[92]. The reaction of PFIB with sodium phenylacetylide in ether results in the formation of the enyne (XXIII):[93]



When PFIB was allowed to react with aryl-lithium compounds, a series of vinyl mono- and di-substitution products were obtained; the latter exhibit a high contraceptive activity[94,95]. PFIB reacts with 2-lithio-1-methyl-*o*-carbaborane to form a 1,3-disubstitution product[96]:

The corresponding derivative of *m*-carbaborane gives rise to the product of the usual vinyl substitution[97].

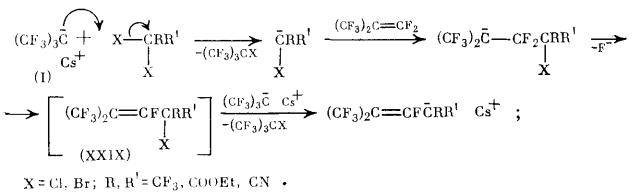
PFIB reacts readily with alkyl- and benzyl-magnesium halides with formation of vinyl and allyl substitution products[98–100]:

(9)

The terminal olefins (XXV) are readily converted into the inner olefins (XXIV) by Lewis bases¶ or acids. This apparently explains the finding that, when PFIB interacts with arylmagnesium halides, it is possible to identify only the inner olefins (XXIV). The corresponding terminal olefins should contain the highly mobile "benzyl" fluorine atom, a result of which they are converted into the olefins (XXIV) under the reaction conditions.

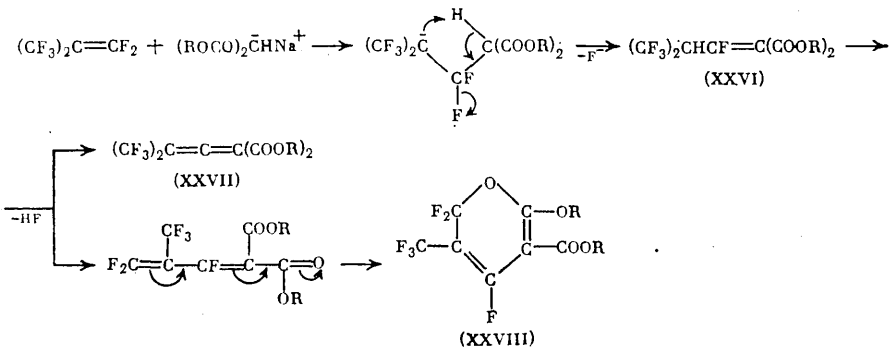
Compounds with Active Methylene and Methyl Groups

PFIB does not react with malonic ester in the absence of bases but, with catalysis by triethylamine, it gives rise to a mixture of products containing the alkylidenemalonic ester (XXVI), the allene (XVII), and the pyran (XXVIII).[101] The reaction of PFIB with sodiomalonic ester leads to the same result†. The allene and pyram are formed as a result of the dehydrofluorination of the alkylidenemalonic ester (XXVI) via two pathways: with elimination of the vinyl fluorine atom or the fluorine atom from the CF_3 group; in the latter case the 1,3-diene cyclises to a pyran (Scheme 18):[100]



The use of the complex $BF_3.Et_3N$ in the reaction of PFIB with malonic esters made it possible to achieve the preparative synthesis of the allenes (XXVII).[101] This complex not only activates the methylene group but at the same time it plays the role of the dehydrofluorinating agent.

The condensation of PFIB with active methylene groups in the presence of CsF has also been investigated. 3-Ethoxycarbonyl-3-phenyl-1,1-bis(trifluoromethyl)allene was obtained in this way from phenylacetic ester[103]. More reactive allenes, obtained from malonic acid derivatives, have been isolated in the form of stable adducts with CsF:[103]



Analogous adducts have been obtained also in the reaction of PFIB with certain compounds containing dihalogenomethylene groups[104]. In this case the attacking species is the α-halogenocarbanion, which is generated as a result of the halogenophilic reaction of the perfluoro-t-butyl anion with a *gem*-dihalide [see Eqn.(14)]. This carbanion substitutes the vinyl fluorine atom in PFIB with formation of the intermediate (XXIX), which is also dehalogenated by the anion (I) (Scheme 19):

Scheme 19

Scheme 18

¶ This rules out the possibility of obtaining the allyl substitution products in aprotic dipolar solvents containing the F^- anion (see the discussion in the communication of Zeifman et al.[87]).

† The condensation of PFIB with sodiomalonodinitrile afforded $(CF_3)_2CHCF=C(CN)_2$.[102]

In the presence of CsF and under comparatively mild conditions, PFIB condenses with acetonitrile to form the salt (XXX):[105]

$$(CF_3)_3\bar{C} \underset{}{\overset{MeCN}{\rightleftharpoons}} (CF_3)_3CH + \bar{C}H_2CN$$

$$(CF_3)_2C{=}CF_2 \xrightarrow[-F^-]{\bar{C}H_2CN} (CF_3)_2C{=}CFCH_2CN \xrightarrow[-(CF_3)_3\bar{C}]{(CF_3)_3\bar{C}}$$

$$\rightarrow (CF_3)_2C{=}CF\bar{C}H{-}CN \xrightarrow[-(CF_3)_3CH]{(CF_3)_2C=CF_2} [(CF_3)_2C{-}CF]_2\bar{C}{-}CN\ Cs^+ \quad .$$

(XXX)

PFIB reacts analogously with acetyl bromide in the presence of CsF.[7]

Vinyl substitution products have been obtained also in the condensation of PFIB with a number of other *C*-nucleophiles [100,106,107] catalysed by the F^- anion or tertiary amines:

$$(CF_3)_2C{=}CF_2 \longrightarrow \begin{cases} \xrightarrow{Me_2CHCOF} Me_2C(COF)CF{=}C(CF_3)_2 \\ \xrightarrow{(CF_3)_2CHCOOEt} (CF_3)_2C(COOEt)CF{=}C(CF_3)_2 \\ \xrightarrow[NaC(COOMe)_2]{Me} (CF_3)_2C{=}CFC(Me)(COOMe)_2 \quad . \end{cases} \qquad (10)$$

A similar product obtained from PFIB and chloroform is dehalogenated under the reaction conditions with formation of dichlorobis(trifluoromethyl)allene (isolated in the form of an adduct with furan):[108,109]

$$(CF_3)_3\bar{C} + H{-}CCl_3 \rightleftharpoons (CF_3)_3CH + \bar{C}Cl_3 ;$$

$$(CF_3)_2C{=}CF_2 \xrightarrow[-F^-]{\bar{C}Cl_3} (CF_3)_2C{=}C(F)C(Cl)_2 \xrightarrow{-[FCl]} (CF_3)_2C{=}C{=}CCl_2 \quad .$$

The reactions of PFIB with fluorocarbanions are described below in Section VI.

Nitroalkanes

The ambident anions of the salts of nitroalkanes attack the double bond in PFIB via the oxygen atom. The subsequent reactions according to Scheme 20 lead to the formation of the dioxazoles (XXXI).[110,111] The key stage of the reaction is apparently the migration of the perfluoroisobutenoxide anion [cf.Eqn.(7)] from the nitrogen atom to the carbon atom in the intermediate *O*-perfluoroisobutenylnitrone ether:

Scheme 20

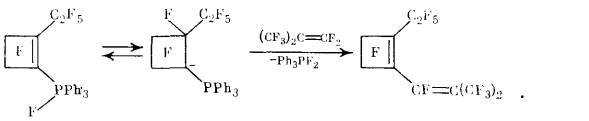
$$(CF_3)_2C{=}CF_2 + RCH{=}N(O)O^- \rightarrow [(CF_3)_2C{=}CFO{-}N{=}CHR(O)] \rightarrow$$

$$\rightarrow [(CF_3)_2C{=}CF\bar{O}CH{-}N{=}O(R)] \rightarrow [(CF_3)_2C{=}CFOCH{-}N{=}O(R)] \rightarrow$$

$$\rightarrow [(CF_3)_2C{=}CFOC{=}NOH(R)] \xrightarrow{-HF} (CF_3)_2C{-}C(O{-}N)(O{-}C{-}R) \quad .$$

(XXXI)

Phosphorus and Sulphur Ylides



The reaction of PFIB with the ylide (XXXII), leading to the cross-conjugated perfluorotriene (XXXIII),[112,113] has been investigated (for the mechanism, see the review of Tyuleneva et al.[114]):

$$(CF_3)_2C{=}CF_2 + (CF_3)_2C{=}C{=}PPh_3 \xrightarrow{-Ph_3PF_2} (CF_3)_2C{=}C(CF{=}C(CF_3)_2)(CF{=}C(CF_3)_2) \quad .$$

(XXXII) (XXXIII)

When PFIB was allowed to interact with the fluorophosphorane (XXIV), the fluorodiene (XXXVI) was obtained; the preliminary isomerisation of the phosphorane to the phosphorus ylide (XXXV) has been postulated (Scheme 21):[115]

Scheme 21

(XXXIV) (XXXV) (XXXVI)

In the reaction of PFIB with the S-ylide (XXXVII), the intermediate fluorosulphurane is dehydrofluorinated to the fluorine-containing ylide (XXXVIII).[91] As in the reaction of PFIB with α-halogenocarbanions discussed above, in this reaction the only pathway leading to the stabilisation of the intermediate fluorocarbanion involves the elimination of the F^- anion from the CF_2 group and not intramolecular cyclisation (Scheme 22). In this case vinyl substitution is specially preferred owing to the presence of the onium fragment [see Eqn.(8)]:

Scheme 22

$$(CF_3)_2C{=}CF_2 + \underset{(XXXVII)}{Me_2\overset{+}{S}{-}\bar{C}HCOOEt} \rightarrow (CF_3)_2\bar{C}{-}CF(F){-}CH(\overset{+}{S}Me_2)COOEt \rightarrow$$

$$\rightarrow [(CF_3)_2C{=}CF{-}CH(F{-}\overset{+}{S}Me_2)COOEt] \xrightarrow{-HF} \underset{(XXXVIII)}{(CF_3)_2C{=}CF{-}\bar{C}(\overset{+}{S}Me_2){-}COOEt} \quad . \qquad (11)$$

6. Reactions with *P*-Nucleophiles

PFIB readily reacts with trialkyl phosphites, forming trialkoxyfluoroperfluoroisobutenylphosphoranes (XXXIX).[115-117] The synthesis of the adducts (XXXIX) constitutes a rare instance of the isolation of pentacovalent (and not tetracovalent quasi-phosphonium) intermediates of the Arbuzov rearrangement. On heating, the adducts (XXXIX) decompose via two pathways:

$$(CF_3)_2C{=}CF_2 + P(OR)_3 \rightarrow (CF_3)_2C{=}CF{-}PF(OR)_3 \begin{cases} \xrightarrow{-R_2O} (CF_3)_2C{=}CF{-}P(F)(OR)(O) \\ \xrightarrow{-RF} (CF_3)_2C{=}CF{-}P(OR)_2(O) \quad . \end{cases}$$

(XXXIX)

The interaction of PFIB with bis(dialkylamino)chlorophosphines is complicated by the exchange of the substituents at the carbon and phosphorus atoms[118]:

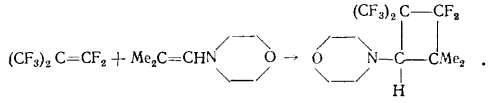
$$(CF_3)_2C{=}CF_2 + ClP(NR_2)_2 \rightarrow (CF_3)_2C{=}C(F){-}PF(NR_2)_2 \rightarrow (CF_3)_2C{=}C(Cl){-}PF_2(NR_2)_2 \quad .$$

PFIB reacts with di-isopropylphosphine to form a vinyl substitution product[119].

The reaction of PFIB with tertiary phosphines is unusual. It does not stop at the stage involving the formation of the vinyl substitution products—fluorophosphoranes $(CF_3)_2C{=}CF{-}PR_3F$; subsequent reactions yielded the perfluorodiene (XL) and the cross-conjugated perfluorotriene (XXXIII)[112,113] (for the reaction mechanism, see Tyuleneva et al.[114]):

$$(CF_3)_2C{=}CF_2 \xrightarrow[-R_3PF_2]{PR_3} (CF_3)_2C{=}CFCF{=}C(CF_3)_2 + (CF_3)_2C{=}C(CF{=}C(CF_3)_2)(CF{=}C(CF_3)_2) \quad .$$

(XL) (XXXIII)

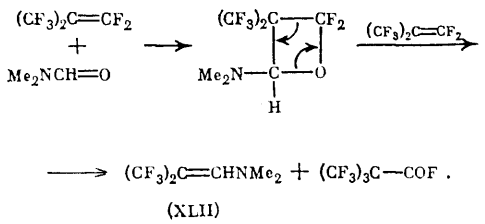


The rate and direction of the reaction depend greatly on the nature of the phosphine and the polarity of the solvent. Thus PFIB reacts with tributylphosphine in ether to form only products of the exchange of the ligands in the intermediate $(CF_3)_2C{=}CFPFBu_3$, namely the phosphoranes $(CF_3)_2C{=}CBuPF_2Bu_2$ and $(CF_3)_2C{=}CFPF_2Bu_2$, while in acetonitrile and diglyme the defluorodimerisation and defluorotrimerisation products are formed[113].

The observed characteristic features made it possible to extend the reaction of tertiary phosphines with PFIB to other fluoro-olefins and to establish it as a method of synthesis of fluorine-containing dienes[120].

7. Cycloaddition

PFIB enters into [2 + 2]-, [2 + 3]-, and [2 + 4]-cycloaddition reactions with various unsaturated compounds to form products with four-, five-, and six-membered rings, the first two types of cycloaddition being most characteristic of this fluoro-alkene. PFIB undergoes the Diels–Alder reaction only under very severe conditions (with cyclopentadiene at 150 °C and with butadiene at 200 °C) and produces a low yield of cyclic 1,4-adducts[121]. On the other hand, a cyclic analogue of PFIB, namely perfluoromethylenecyclopropane, is an active dienophile and forms an adduct with cyclopentadiene at a temperature as low as 0 °C.[122]

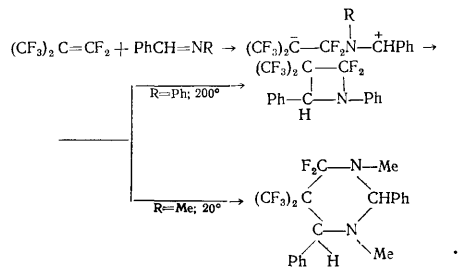


At the same time, PFIB readily undergoes cycloaddition reactions with multiple bonds enhanced nucleophilic properties. Such reactions include the formation of a derivative of cyclobutane when PFIB interacts with isobutenyl-morpholine[123]:

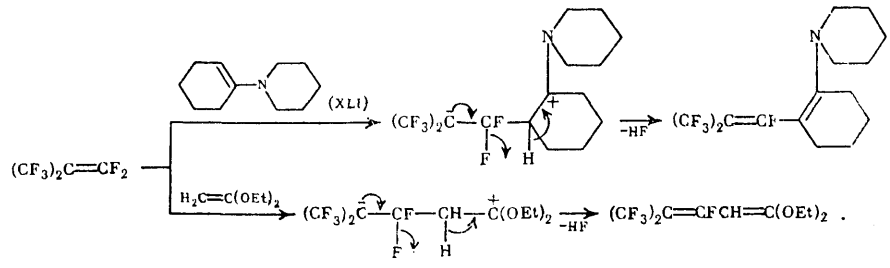
This reaction is accelerated with increase of the polarity of the solvent, which supports an ionic mechanism of the cycloaddition. Perfluoroalkenylation products have been obtained by the interaction of PFIB with the enamine (XLI)[123] or the keten acetal[100] (Scheme 23). Evidently the intermediate dipolar ions are stabilised not only by cyclisation but also by the elimination of the F^- anion and a proton:

PFIB probably reacts with dimethylformamide via the [2 + 2]-cycloaddition mechanism[124], but the unstable cyclic adduct decomposes with elimination of carbonyl fluoride, which leads to the fluoride of perfluoropivalic acid and the enamine (XLII) (Scheme 24):

Scheme 24



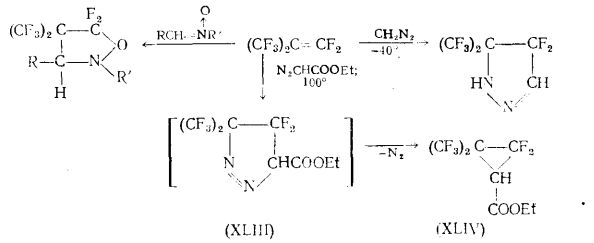
(XLII)



PFIB reacts in the same way with dimethylaminobenzaldehyde#[125], nitrosobenzene[61], and sodium nitrite[61], which lead to the olefin $(CF_3)_2C{=}CHC_6H_4NMe_2$ and the anil and oxime of hexafluoroacetone respectively.

A stable cyclic adduct has been obtained from PFIB and benzylideneaniline under severe conditions. The more nucleophilic benzylidenemethylamine reacts with PFIB much more readily; however, this involves the formation of a six-membered cyclic adduct incorporating two molecules of the imine (Scheme 25)[126]:

Scheme 25

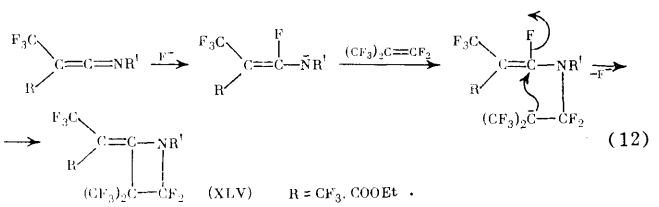


Scheme 23

In the absence of the activating dimethylamino-group, aromatic aldehydes react with PFIB only under the conditions of nucleophilic catalysis[125].

PFIB readily gives rise to 1,3-cycloaddition products on reaction with diazomethane[93] and nitrones[127,128]. Pyrazoline (XLIII) obtained from PFIB and diazoacetic ester eliminates nitrogen, which leads to the cyclopropane (XLIV) (Scheme 26):[91]

Scheme 26



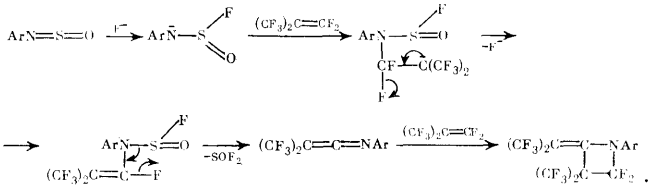
(XLIII) (XLIV)

The range of cycloaddition reactions with participation of PFIB has been expanded by employing nucleophilic catalysts. This approach made it possible to involve in the cycloaddition to PFIB compounds containing electrophilic multiple bonds.

We may note that the application of nucleophilic catalysis is of general importance in the chemistry of compounds with electrophilic multiple bonds and in particular such catalysis is used widely for the dimerisation and trimerisation of isocyanates[129], ketens[130], keten imines[72], and activated olefins[131]. The application of nucleophilic catalysts makes it possible to achieve also mixed cyclodimerisation, for example, in the case of hexafluoroacetone and ketens[132] or isocyanates[133].

In the presence of alkali metal fluorides or tertiary amines, PFIB reacts with fluorine-containing keten imines under mild conditions in accordance with Scheme 27 to form cyclic adducts—the azetidines (XLV).[134] The role of the catalyst evidently consists in converting the electrophilic keten imine into a nucleophilic mesomeric anion capable of adding to the double bond of PFIB. Such addition is accompanied by cyclisation and regeneration of the catalyst:

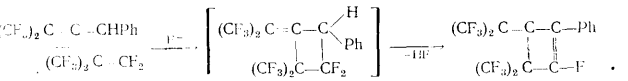
Scheme 27



(12)

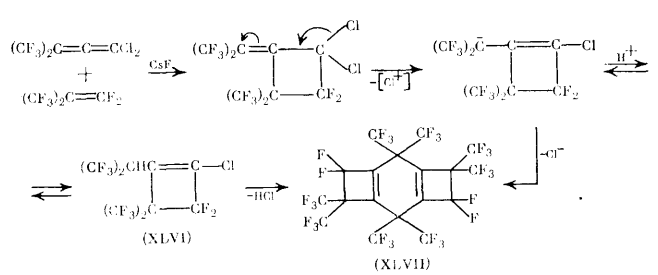
(XLV) R = CF_3, COOEt.

The azetidines (XLV, R=CF_3) are also formed in the reaction of PFIB with primary amines in the presence of the same catalyst[134], since the keten imines themselves are obtained from PFIB and primary amines [see Eqn.(5)]. It is striking that the rate of addition of RNH_2 to PFIB is higher than the rate of the subsequent reactions, including the formation of imidoyl fluorides and keten imines. By selecting the appropriate reactant ratio and the catalyst, this makes it possible to control the reaction by arresting it at any stage. Such control cannot be achieved in the reaction of PFIB with the weakly basic urethane. In this case the first stage is the slowest and the only product isolated is therefore the corresponding *N*-epoxycarbonylazetidine[134].



The azetidines (XLV, R=CF_3) are also formed in the reaction of PFIB with *N*-sulphinylamines in the presence of CsF (Scheme 28).[135] Evidently vinyl substitution and β-elimination of SOF_2 and not cycloaddition take place initially in this reaction; the keten imines thus formed combine with a further PFIB molecule:

Scheme 28

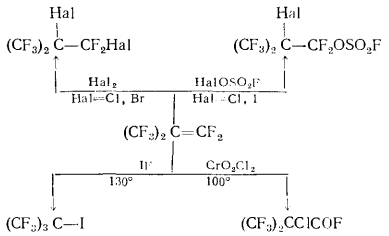


This Scheme confirms that the reaction of PFIB with *N*-sulphenylbenzenesulphonamide leads to *N*-benzenesulphonyl-bis(trifluoromethyl)keten imine, which gives rise to a stable adduct with CsF, analogous to the adduct (XIX).[87]

The application of nucleophilic catalysis also made it possible to achieve the cycloaddition of PFIB to allenes[10]:

PFIB apparently interacts via the analogous Scheme 29 with dichlorobis(trifluoromethyl)allene. The reduction of the intermediate cyclic adduct by the $(CF_3)_3C^-$ anion results in the formation of the cyclobutene derivative (XLVI), whose dehydrochlorination leads to the tricyclic compounds (XLVII):[108,109,136]

Scheme 29

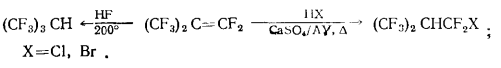


(XLVI) (XLVII)

IV. REACTIONS WITH ELECTROPHILES

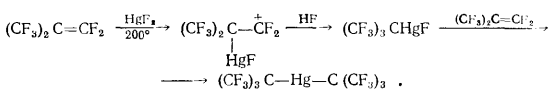
As already mentioned above, in reactions with electrophiles PFIB is much less reactive than lower fluoro-olefins and these reactions require as a rule extremely severe conditions.

The addition of halogens to PFIB via a radical mechanism can be achieved photochemically or thermally in the presence of catalysts. Thus PFIB is chlorinated in the gas phase at 128 °C over $FeCl_3$ on activated charcoal (AC).[137] The heat of chlorination of PFIB is ΔH = 42.2 kcal mole^{-1}, while for tetrafluoroethylene ΔH = 57 kcal mole^{-1}. PFIB is not brominated under illumination; the method of elimination of unsaturated impurities from PFIB is based on this property of the latter. However, in the presence of catalytic amounts of acetamide, PFIB combines with bromine under ultraviolet irradiation[10]. The addition of iodine fluoride to PFIB [14] and its reaction with chromyl chloride[138] on heating have also been described.



Highly reactive chlorine and iodine fluorosulphates add to PFIB at a temperature as low as 20 °C:[139]

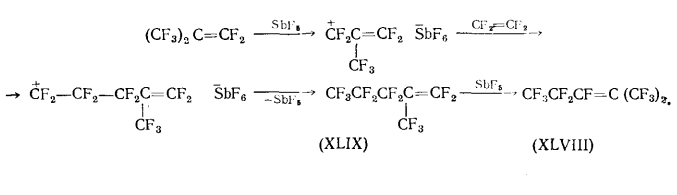
(13)



PFIB exchanges fluorine for chlorine under severe conditions on treatment with $AlCl_3$ and, in contrast to the exchange reaction with the Cl^- anion [Eqn.(1)], the polysubstitution products $ClCF_2C(CF_3)=CCl_2$ and $Cl_2FC(CF_3)=CCl_2$ are formed in this case together with monochlorides and dichlorides[25].

The addition of hydrogen halides to PFIB in the gas phase takes place only on heating, in contrast to nucleophilic hydrohalogenation [Eqn.(2)]:[140]

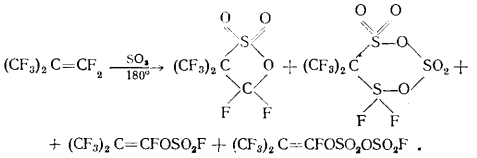
X=Cl, Br .



Mercuration of PFIB in anhydrous HF or AsF_3 yields bis-(perfluoro-t-butyl)mercury:

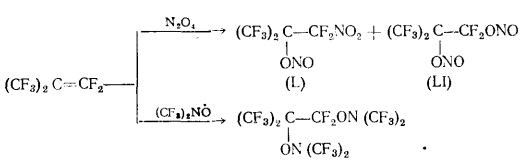
It has been suggested that the reaction proceeds as a result of the attack by the metal cation on the double bond of PFIB or via a four-centre cyclic transition state[141]. The nucleophilic mercuration of PFIB takes place under much milder conditions[7].

In the presence of SbF_5, it is impossible to achieve the interaction of PFIB with elemental sulphur. The attacking agent is apparently the doubly charged sulphur cation formed when sulphur is oxidised by SbF_5.[142] The reaction of PFIB with bis(pentafluorophenyl) disulphide has also been studied[143]:



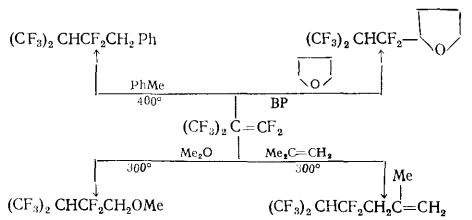
The condensation of PFIB with fluorinated ethylenes has also been achieved in the presence of SbF_5 under extremely mild conditions[144,145]. The primary step in these reactions is the formation of the perfluoromethylallyl cation (detected by ^{19}F NMR):

Together with the 1 : 1 adduct (XLVIII), the 1 : 2 adduct $C_3F_7C(CF_3)=CFC_2F_5$ is formed in the reaction via the intermediate isohexene (XLIX).



PFIB reacts via an analogous mechanism with perfluoroazapropene, giving rise to a high yield of the perfluoroenamine $(CF_3)_2NCF=C(CF_3)_2$.[146]

The electrophilic addition of sulphur trioxide to PFIB at 180 °C leads to the corresponding β-sultone and pyrosultone together with the products of their further reactions[147]:



The nitration of PFIB by nitrogen oxides proceeds via a radical mechanism (Scheme 30): approximately equal amounts of the nitronitrite (L) and the dinitrite (LI) were obtained in this reaction[148]. PFIB also combines with bis(trifluoromethyl)amine oxide:[149,150]

Scheme 30

The fluoroalkylation of tetrahydrofuran by PFIB takes place with initiation by benzoyl peroxide (BP).[151] On heating, PFIB is also inserted in the C–H bonds of isobutene, toluene[152], and dimethyl ether[153]:

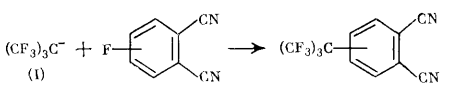
V. OTHER REACTIONS

PFIB is readily oxidised by potassium permanganate in water[10]. This reaction constitutes a convenient laboratory method for the synthesis of hexafluoroacetone[154]. Among its side products, hexafluoro-α-hydroxyisobutyric acid[155] and monohydroperfluoroisobutane[10] were identified:

The formation of hexafluoroacetone has also been established in the reaction of PFIB with sodium nitrite in dimethylformamide[61] and with hydrogen peroxide in aqueous alkali[35]. The interaction of PFIB with fluorine oxide gives rise to the epoxy-derivative of PFIB.[38]

The hydrogenation of PFIB in the presence of a palladium catalyst leads to dihydroperfluoroisobutane (LII) as the only product[56]. When nickel is used, the main hydrogenation product is 1,1,1-trifluoro-2-trifluoromethylpropane[157]:

Traces of dihydroperfluoroisobutane have also been detected in the products of the reaction of PFIB with the Hantzsch ester[23].



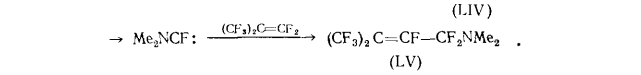
It has been shown that PFIB does not form homopolymers on radical initiation and γ-irradiation. However, the formation of copolymers with certain acrylates on initiation by acetyl peroxide has been noted[158,159]. The copolymer with tetrafluoroethylene, obtained on γ-irradiation, includes 4% of PFIB.[160] Studies of the kinetics of the copolymerisation of PFIB with tetrafluoroethylene have been described by Isamukhamedov et al.[161] and Gafurov et al.[162]

VI. REACTIONS OF THE PERFLUORO-t-BUTYL ANION

The study of the methods of synthesis and reactions of the perfluoro-t-butyl anion (I) is associated with the possibility of synthesising a wide variety of compounds containing the $(CF_3)_3C$ group and their practical employment. This Section includes the literature on the chemistry of this anion which has not been incorporated in a special review on this topic[7] published in 1976§. It is noteworthy that the chemistry of this anion differs from the chemistry of the primary and secondary fluorocarbanions not only by its wide variety but also by specific features associated with the increased stability of the anion. The anion (I) is a more effective leaving group than, for example, the perfluoroisopropyl anion. The ease of the decarboxylation of $(CF_3)_3C-COOH$ compared with $(CF_3)_2CF-COOH$ [163] and also the instability of perfluoro-t-butylmethanols in alkaline media are consistent with this finding[164].

For the same reasons, certain reactions known for primary and secondary fluorocarbanions cannot be carried out with the anion (I), since in the presence of the F^- anion these reactions are reversible and the equilibrium is displaced towards the initial compounds. This applies to the interaction of the anion (I) with benzoyl chloride[164,165] and dimethylaminotrifluorosulphurane[166]. Furthermore, as a consequence of its reversibility, the dimerisation of PFIB rarely accompanies its reactions initiated by the F^- anion[7]. It is remarkable that the pseudohalogen character of the perfluoro-t-butyl group makes it possible to employ compounds of the type CF_3C-X (X = Br, PhS, etc.) as electrophiles for the bromination, sulphenylation, and other similar reactions involving fluorocarbanions. It is also significant that the anion (I) in solutions is in equilibrium with free PFIB, so that the anionoid intermediates formed in the reactions of the anion (I) frequently interact with PFIB.

The anion (I) has been alkylated by $I(CH_2)_nI$ ($n = 1$ [104] and $n = 3$ or 4 [167]), $ClCH_2SCH_3$,[91] $(ClCH_2)_2O$, and $(ClCH_2)_3N$. The corresponding perfluoro-t-butyl derivative has been obtained from the anion (I) and α-chlorotetrahydrofuran[169]. The synthesis of perfluoro-t-butylphthalonitriles, which have been used to obtain phthalocyanines, has been described[170]:

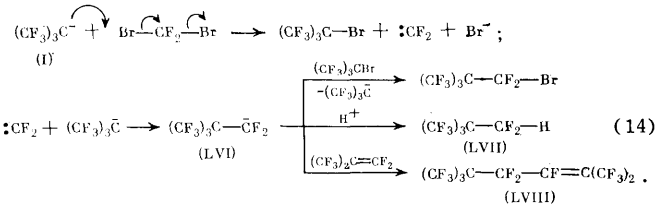


The interaction of PFIB with fluorotrimethylamine leads to the tertiary amine (LIII).[71] The anion (I) is probably formed in this case and the source of the fluoride ion is fluorotrimethylamine itself:

(LIII)

§ Except where stated otherwise, this Section deals with the reactions of the anion (I) generated by the addition of alkali metal fluorides to PFIB.

PFIB reacts in an unusual manner with α,α-difluorotrimethylamine. Fluoroamine adds reversibly under these conditions to the fluoro-olefin and compound (LIV) is formed; on heating, it decomposes into monohydroperfluoroisobutane and dimethylaminofluorocarbene, which adds to PFIB to form the amine (LV):[172]



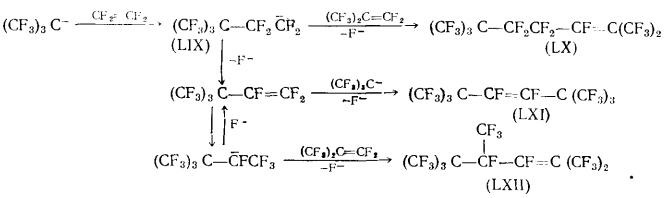
(LIV)

(LV)

When the anion (I) interacts with epichlorohydrin, the opening of the epoxide ring and dehydration are accompanied by the substitution of chlorine by the $(CF_3)_3C$ group[173] (for the description of the mechanism, see Gervits et al.[174]):

The replacement of bromine by the perfluoro-t-butyl group takes place in the reaction of the anion (I) with CF_2Br_2.[175] However, in contrast to the usual alkylation of the anion (I) where the halogen atom undergoes nucleophilic substitution, in this case the interaction proceeds via a completely different mechanism. The anion (I) is initially brominated by CF_2Br_2, which is accompanied by the generation of difluorocarbene to which the anion (I) and bromine are then added in a coupled reaction to form perfluoroneopentyl bromide. The hydride (LVII) and the olefin (LVIII) were detected as side products, which confirms the formation of the carbanionic intermediate (LVI):

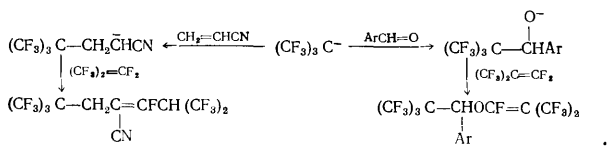
(14)



(LVII)

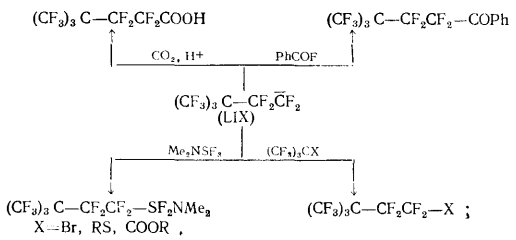
(LVIII)

The reaction of the anion (I) with chlorodifluoromethane, leading to compounds (LVII) and (LVIII), also proceeds via the intermediate formation of difluorocarbene[175]. Substitution of bromine by the $(CF_3)_3C$ group on treatment of $BrCF_2.CF_2Br$ by the anion (I) also proceeds via an elimination–addition mechanism [see Eqn.(15)].

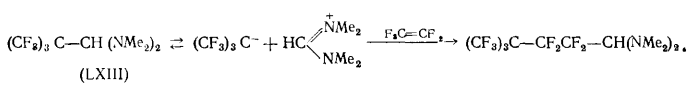


The main product of the reaction of the anion (I) with tetrafluoroethylene is the olefin (LX); the isomers (LXI) and (LXII) are formed together with this compound (Scheme 31)[176]. It is striking that the intermediate carbanion (LIX) is capable of being involved in the reaction with a second PFIB molecule in preference to the usual stabilisation pathway—the β-elimination of the F^- anion:

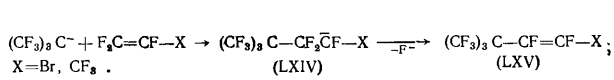
Scheme 31



(LIX) (LX) (LXI) (LXII)

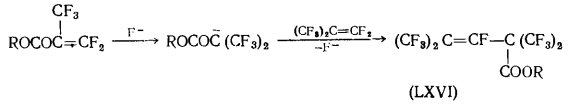


The *C*-anions[177] or *O*-anions[125], generated by the addition of $(CF_3)_3C^-$ to acrylonitrile or aromatic aldehydes respectively, are also capable of subsequent vinyl substitution reactions with PFIB:

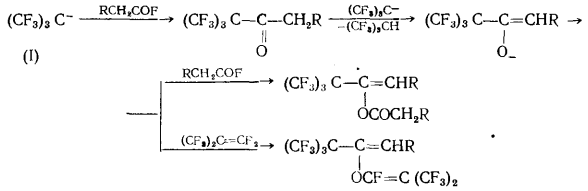


The reactions involving the coupled addition of the anion (I) to tetrafluoroethylene, which include the formation of the olefin (LX), are fairly general. Thus the intermediate carbanion (LIX) adds to the carbonyl group of CO_2 and substitutes the fluorine in benzoyl fluoride or in Me_2NSF_3.[178] It has also been possible to achieve the bromination, sulphenylation, and alkoxycarbonylation of the anion (LIX) in the condensation of PFIB with tetrafluoroethylene in the presence of CsF and compounds of the type of $(CF_3)_3CX$: [178,179]

A characteristic feature of the latter reactions is that the anion (I), participating in the initial stage where the intermediate (LIX) is generated, is liberated in the concluding stage and is not consumed in the reaction. Thus in fact the entire process constitutes the insertion of tetrafluoromethylene in the C–C, C–Br, or C–S bond catalysed by the anion (I). The anion (I) also catalyses the exchange of chlorine for fluorine in the vicinal chlorosulphide, $(CF_3)_2C(SPh)-CF_2Cl$ in its interaction with CsF.[179] Tetrafluoroethylene is also inserted in the C–C bond of the geminal diamine (LXIII) and in this case the addition of the anion (I) is not required, since the initial diamine is capable of dissociating into the anion (I) and the corresponding immonium cation[178]:

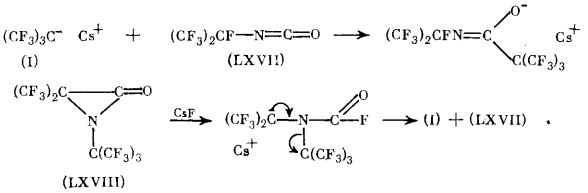


The interaction of the anion (I) with bromotrifluoroethylene[107] or hexafluoropropene[180] leads only to the vinyl substitution products (LXV). The intermediate fluorocarbanion (LXIV) is less reactive than the fluorocarbanion (LIX) and is stabilised only as a result of the β-elimination of the F^- anion:



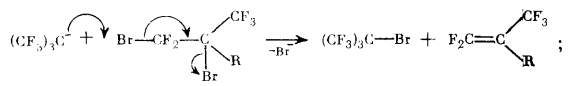
It is of interest to note that, under the conditions of thermodynamic control, the product is not the olefin (LXV, X = CF_3) but its isomer, namely the olefin $(CF_3)_2CFCF=C(CF_3)_2$ resulting from the interaction of PFIB with the perfluoroisopropyl anion[181]. On the other hand, the condensation of PFIB with perfluoroazapropene, catalysed by CsF, results in the formation of $(CF_3)_3C-CF=NCF_3$ regardless of the conditions[182,183].

The interaction of PFIB with perfluoromethacrylic acid esters in the presence of CsF leads to the unsaturated esters (LXVI).[107] In the given case, the reaction is propagated not by the anion (I) but by the C-anion of the hexafluoroisobutyric acid ester, apparently as a consequence of the greater ease of formation of the latter [cf.Eqn.(10)]:



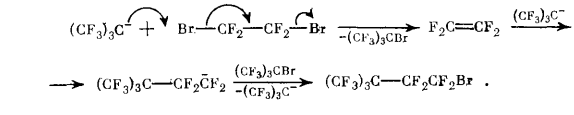
The interaction of the anion (I) with carboxylic acid halides is in general reversible because the carbonyl compounds formed are capable of decomposing in the presence of the F^- anion with reformation of the initial anion (I).[165] The equilibrium position is then determined by the electrophilic properties of the carbonyl carbon atom in the reaction products. Thus the anion (I) is acylated under mild conditions by carbonic acid derivatives[165,184,185]. However, perfluoro-t-butyl phenyl ketone cannot be obtained under the usual conditions of the generation of the anion (I); in this case the reaction equilibrium is fully displaced towards the initial compounds[165]. The benzoylation of the anion (I) has been achieved only using hexamethylguanidinium as the counterion[22].

When the anion (I) is acylated by aliphatic carboxylic acid halides containing an α-hydrogen atom, the equilibrium shifts towards the reaction products, since, on treatment with the anion (I), the intermediate alkyl perfluoro-t-butyl ketones give rise to the corresponding enolates, which are then converted into the *O*-acyl and *O*-perfluoroisobutenyl derivatives[21,186]:



The addition of the anion (I) to the carbonyl group of perfluoroisopropyl isocyanate via Scheme 32 leads to the stable adduct of perfluoropivaloylimine and CsF. It is remarkable that the same adduct is formed when the α-lactam (LXVIII) is treated with CsF. The driving force of the latter reaction is the ease of migration of the perfluoro-t-butyl anion from the nitrogen atom to the carbon atom[187]:

Scheme 32

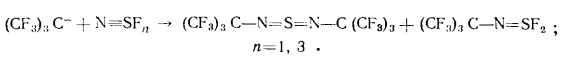


The anion (I) is brominated on treatment with elemental bromine[188]. It is of greater interest that $(CF_3)_3C-Br$ is formed also in the reactions of the anion (I) with certain compounds containing the C–Br bond. They include the *gem*-dibromopolyfluoroalkanes mentioned above. The anion (I) is also brominated when it reacts with vicinal dihalogenopolyfluoroalkanes[107]. The olefins formed together with $(CF_3)_3CBr$ undergo subsequent condensation with PFIB catalysed by the F^- anion:

R=F, COOEt .

In contrast to those reactions where the anion (I) behaves as a debrominating agent, its interaction with $CF_2BrCHFBr$ leads to the dehydrobromination of the latter[107].

The reaction of the anion (I) with dibromotetrafluoroethane constitutes a special case[107]. As a result of the debromination of the vicinal dibromide by the anion (I), the reaction leads to the formation of perfluoro-t-butyl bromide and tetrafluoroethylene, which reacts further via a coupled nucleophilic addition mechanism:



(15)

The anion (I) is smoothly sulphenylated by ethanesulphene, arenesulphene[189–191], and dialkylaminosulphene[189] chlorides. The reaction constitutes a convenient method of synthesis of perfluoroalkyl sulphides and perfluoroalkanesulphenamides. On the other hand, the interaction of the anion (I) with sulphene chlorides having electron-accepting substituents leads only to its chlorination[189]:

Areneselenyl chlorides react with the anion (I) analogously to arenesulphenyl chlorides[191]. Perfluoroalkylation at the nitrogen atom with the aid of the anion (I) was achieved when the latter reacted with thiazyl fluoride and thiazyl trifluoride[192]:

$n=1, 3$.

CF_3COONO has been proposed as the nitrosating agent for the anion (I).[193]

Thus it follows from the data examined that the reactions of the anion (I) constitute a fairly general method of synthesis of compounds containing the $(CF_3)_3C$ group. Certain compounds of this type have been suggested as gas-transferring media[167,194,195] and as monomers for the synthesis of thermostable silicone elastomers[196,197]. Compounds containing the $(CF_3)_3C-CF_2$ group have been synthesised by the reaction of the anion (I) with CF_2Br.[175] Reactions involving the coupled addition of the anion (I) to tetrafluoroethylene have led in their turn to a pathway towards the synthesis of the higher homologues—compounds with the $(CF_3)_3C-CF_2CF_2$ group. These compounds are of interest because they provide a method for the introduction of functional groups into fluoroolefins with a simultaneous increase of the length of their hydrocarbon chains[178].

---o0o---

The data presented in this review show that, in terms of its importance for the chemistry of organofluorine compounds, PFIB is fully comparable with the most important fluoroolefins such as tetrafluoroethylene and hexafluoropropene. Whereas the latter are industrially important and are manufactured on a large scale, PFIB has found extensive applications, despite the limitations associated with its high toxicity, in the laboratory synthesis of functional organofluorine com- of many types. The most important of these include hexafluoroacetone[198], derivatives of α-hydrohexafluoroisobutyric and perfluoromethacrylic acids[33], bis(trifluoromethyl)keten[32] and its imines[72], acetals[199], and aminals[79], allenes[103], and various heterocyclic compounds with *gem*-trifluoromethyl groups.

At the same time PFIB proved to be a convenient model compound for the solution of various problems associated with the nucleophilic reactions of fluoro-olefins such as the relative contributions of addition and vinyl and allyl substitution processes, the application of nucleophilic catalysis in addition and cycloaddition reactions, etc. Thus the development of the chemistry of PFIB has in many respects determined the general advances in the study of fluorine-containing compounds of various types, apart from purely practical results.

Some Rearrangements of Free Alkyl Radicals and Alkyl Cations in Solutions

O.A.Reutov

The results of studies of rearrangement reactions by the author and his co-workers during the last 20 years are described. A rearrangement of the n-propyl free radical in solutions as a result of the hydrogen 1,3-shift has been discovered and its characteristic features have been investigated (using carbon-14, deuterium, and tritium). The reaction involving the formation of organomercury compounds from mercury salts of carboxylic acids and peroxides has been studied and a mechanism has been proposed for it. New skeletal rearrangements in the thermal decomposition of cycloalkyl peroxides in benzene and bromoform have been discovered. It has been shown by the method of double ^{13}C NMR that some of the reactions involve the formation of species which manifest properties intermediate between those of free radicals and carbonium ions. The mechanism of the thermolysis of peroxides is considered.
The skeletal rearrangements and hydride shifts in the deamination and solvolysis of alicyclic compounds have been studied and a number of rearrangements with 1,2-migration of the halogen and in particular the isomerisation of acyloxybromopropanes in organic solvents, which takes place particularly readily, have been observed.
The bibliography includes 103 references.

I. THE ISOMERISATION OF THE n-PROPYL RADICAL

A quarter of a century ago the available information about the feasibility of the isomerisation of free alkyl radicals under mild conditions in the liquid phase as a result of hydrogen shifts was contradictory. Thus Voevodskii and Mardaleishvili[1] suggested that free radicals (n-propyl, primary isobutyl, and cyclohexyl), formed from the corresponding olefins and atomic hydrogen in the presence of deuterium, isomerise in the gas phase (the hydrogen 1,3-shift) at room temperature. This hypothesis explained the high (up to 50%) degree of deuteriation of the radical recombination products.

On the other hand, Kharasch et al.[2] showed that isomerisation with a change in the skeleton does not occur on decomposition of acyl peroxides in carbon tetrachloride:

$$CH_3-CH_2-CH_2^{\cdot} \rightleftarrows (CH_3)_2CH^{\cdot} .$$

Only n-propyl chloride is formed from butyryl peroxide, while only isopropyl chloride is formed from isobutyryl peroxide.

The possibility of the isomerisation of alkyl radicals in liquid-phase photochlorination has been studied[3]. Using deuterium-labelled isobutane, it was shown that the primary isobutyl radical does not isomerise to the tertiary radical:

$$CH_3-CD(CH_3)-CH_2^{\cdot} \rightleftarrows CH_3\dot{C}(CH_3)-CH_2D .$$

Model reactions in which the hydrogen 1,3-shift in the free radical formed initially should be thermodynamically favourable, i.e. should lead to the formation of more stable radicals, have been investigated[4-7]. However, the n-hexyl as well as the δ- and γ-phenylalkyl radicals did not isomerise. Only the non-isomerised chlorides were formed in all cases:

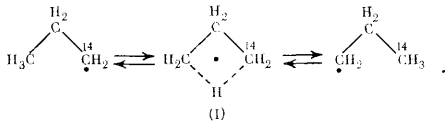
$$(CH_3-CH_2-CH_2-CH_2-CH_2-CH_2-COO)_2 \xrightarrow{CCl_4} \longrightarrow CH_3-CH_2-CH_2-CH_2-CH_2-CH_2-Cl ;$$

$$(Ph-CH_2-CH_2-CH_2-CH_2-COO)_2 \xrightarrow{CCl_4} Ph-CH_2-CH_2-CH_2-CH_2-Cl ;$$

$$(Ph-CH_2-CH_2-C(CH_3)H-COO)_2 \xrightarrow{CCl_4} Ph-CH_2-CH_2-CHCl-CH_3 .$$

However, we believe it to be extremely improbable that the free alkyl radicals, if such are formed as kinetically independent species, for example, in the decomposition of acyl peroxides in solutions, should be altogether incapable of isomerisation. It is well known that free radicals are capable of abstracting a hydrogen atom from the solvent molecule in solutions:

$$R^{\cdot} + H:C\swarrow\searrow \longrightarrow R-H + {}^{\cdot}C\swarrow\searrow .$$



There are no grounds for the assumption that in the presence of suitable steric conditions they cannot abstract hydrogen from their C–H group with a corresponding shift of the free valence. The degree of isomerisation of the radical depends on the ratio of the rates of isomerisation and substitution. It is to be expected that at moderate temperatures the degree of isomerisation is low and isomerisation can be detected only by highly sensitive experimental techniques.

We investigated the decomposition of n-butyryl peroxide, labelled with ^{14}C in the α-position, in boiling carbon tetrachloride[8,9]:

$$(CH_3-CH_2-{}^{14}CH_2-COO)_2 + 2CCl_4 \rightarrow 2CH_3-CH_2-{}^{14}CH_2-Cl + 2CO_2 + CCl_3-CCl_3 .$$

Analysis of the distribution of the radioactive label in propyl chloride showed that, together with the normal product ($CH_3-CH_2-{}^{14}CH_2-Cl$), an appreciable amount (4.0 ± 0.5%) of propyl chloride containing the label in the 3-position ($^{14}CH_3-CH_2-CH_2-Cl$) is formed.

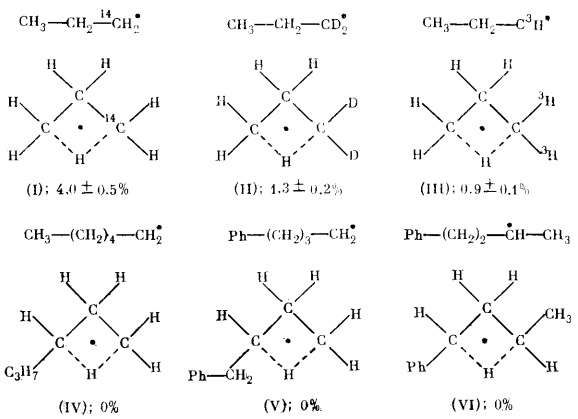
It is more likely that the isomerisation proceeds in a single stage via the four-membered cyclic transition state (I):

(I)

In the light of the results of the study of the isomerisation of the n-propyl radical in solution, it was of interest to consider the reason for the absence of isomerisation in the experiments of De Tar and co-workers[4-6] even when the hydrogen 1,3-shift could lead to a thermodynamically more stable radical of the benzyl type:

$$Ph-CH_2-CH_2-\dot{C}H-CH_3 \rightleftarrows Ph-\dot{C}H-CH_2-CH_2-CH_3 .$$

The author of this review can so far see no reasons, other than the high symmetry of the cyclic transition state in the case of the n-propyl radical, which may favour the 1,3-isomerisation.



Even a slight decrease of the degree of symmetry in the transition stage (I) appreciably reduces the degree of 1,3-isomerisation. Thus the substitution of two hydrogen atoms even for deuterium {decomposition of [α-D_2]butyryl peroxide in carbon tetrachloride} reduces the extent of isomerisation from 4.0 ± 0.5% to 1.3 ± 0.1%:[10]

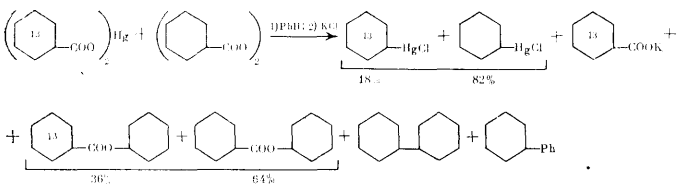
$$CH_3-CH_2-\dot{C}D_2 \rightleftarrows \dot{C}H_2-CH_2-CD_2H .$$

If tritium is employed instead of deuterium, the extent of isomerisation falls to 0.9 ± 0.1%.[11]

The proposed transition states for the β-isomerisation of the three free radicals (I)–(II) which we investigated and the free radicals (IV)–(VI) studied by De Tar and co-workers[4,5] are presented in Scheme 1.

Scheme 1

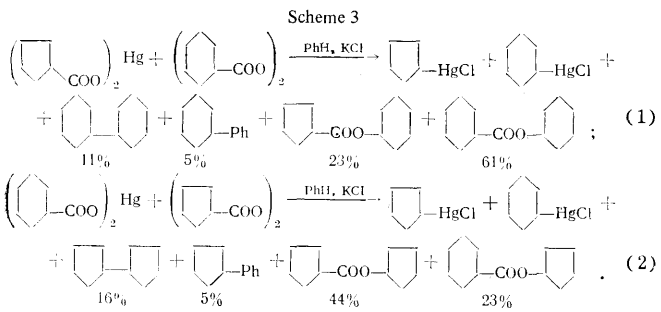
Since the free radical formed in solution can undergo two competing kinds of reactions—can abstract an atom from the solvent molecule or can isomerise—then naturally the faster the former process the lower the degree of isomerisation of the radical. It is known that the ease of abstraction of H, Cl, and Br atoms from the solvent molecule by the free radical increases in the sequence Cl < H < Br. Presumably, when CCl_4 is replaced by bromoform, the degree of isomerisation falls. This hypothesis has been confirmed in the study of the decomposition of [α-D_2]butyryl peroxide in bromoform. In chloroform the radical $CH_3-CH_2-\dot{C}D_2$ isomerised to the extent of 1.3 ± 0.1% and in bromoform only to the extent of 0.7 ± 0.1%.[12]



II. THE REACTIONS OF THE MERCURY SALTS OF CYCLOALKANECARBOXYLIC ACIDS WITH PEROXIDES

The reaction of the mercury salts of carboxylic acids with peroxides, leading to the formation of organomercury compounds, has been known for a long time[13]:

$$(R-COO)_2Hg \xrightarrow{(RCOO)_2} R-HgOCOR + CO_2 .$$



It was believed that the peroxide plays the role of a catalyst in this reaction. In reality the reaction mechanism proved to be more complex[14-16]. The study of the reaction between mercury cyclohexanoate labelled with ^{13}C in the ring and cyclohexanoyl peroxide established[14] that the peroxide is the source of the main product (Scheme 2):

Scheme 2

Since the results obtained were unexpected, we investigated additionally the[15] interactions of mercury cyclopentanoate with cyclohexanoyl peroxide [reaction (1)] and of mercury cyclohexanoate with cyclopentanoyl peroxide [reaction (2)]; both reactions were carried out in benzene at 80 °C under the conditions described by Shatkina et al.[14] The organomercury compounds obtained were converted into the corresponding bromides by the reaction with bromine in glacial acetic acid; the composition of the reaction products was determined by gas–liquid chromatography (GLC). The analytical data for the products formed in the reactions investigated are presented in Scheme 3 and in Table 1:

Scheme 3

It follows from Schemes 2 and 3 that hydrocarbons, namely bicycloalkyls and phenylcycloalkanes, are formed only from the alkyl groups in the corresponding peroxides: bicyclohexyl and phenylcyclohexane in reaction (1) and bicyclopentyl and phenylcyclopentane in reaction (2). The study of the mixture of esters showed that two esters are formed in each reaction, the alcohol component of which corresponds to the alkyl group of the peroxide employed while the acid component corresponds to the alkyl group of the peroxide or the mercury salt.

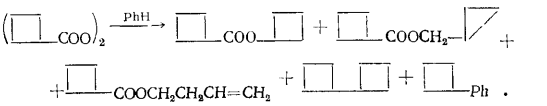
Table 1 shows that cyclohexylmercury chloride predominates in the mixture of organomercury compounds in reaction (1), which is consistent with the results obtained using mercury [^{13}C]cyclohexanoate.[14] However, cyclohexylmercury chloride also predominates in reaction (2), where the preferential formation of cyclopentylmercury chloride would have been expected by analogy.

Table 1. The composition in reactions (1) and (2) (%) (bromide fraction)*.

Reaction		
(1)	95	5
(2)	73	27

*Bromobenzene was detected in the mixture of bromide in both reactions.

Consideration of the results obtained by Shatkina et al.[14] suggests that two reactions predominate in the system investigated (mercury salts–peroxide): thermal decomposition of the peroxide leading to hydrocarbons and an ester and the reaction of the peroxide with the mercury salt. The latter probably begins with attack by the alkyl group of the peroxide on the mercury atom and the subsequent course of the reaction is determined by the ease of decomposition of the carboxylate radicals formed:

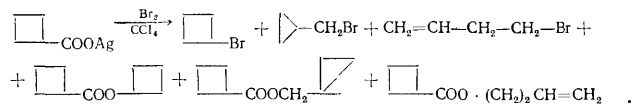


According to Ol'dekop et al.[16] and Hart and Wyman[17], cyclohexanoyl peroxide decomposes faster than cyclopentanoyl peroxide. This can in fact account for the preferential formation of cyclohexylmercury chloride in both reactions. Since there is an excess of cycloalkyl radicals derived from the peroxide in the reaction mixture, the carboxylate radicals formed recombine with them to produce two esters.

The absence from the products of both reactions of hydrocarbons containing the group derived from the mercury salt and also of esters containing the group derived from the mercury salt in the alcohol component suggests that the decarboxylation of the carboxylate radicals takes place in the complex of the mercury salt with the peroxide and is accompanied by a synchronous attack by the cycloalkyl radicals formed on the mercury atom.

III. THERMAL DECOMPOSITION OF ACYL PEROXIDES

The study of the reaction of mercury cyclobutanoate with cyclobutanoyl peroxide in boiling benzene established[18] the formation, together with other products, of esters whose alcohol component has been to a large extent rearranged as a result of the contraction or opening of the ring.



Subsequently a study was made[19] of the thermal decomposition of pure cyclobutanoyl peroxide in boiling benzene. The composition of the reaction products was determined by GLC. The esters were analysed by the chromatography of the reaction mixture and repeated chromatography of the alcohols obtained as a result of the alkaline hydrolysis of the ester fraction. This demonstrated the formation (apart from the cyclobutyl ester of cyclobutanecarboxylic acid) of rearranged esters, namely the cyclopropylmethyl and 3-butenyl esters of cyclobutanecarboxylic acid (the proportions of the products were 47 : 48 : 5). The hydrocarbons in the low-boiling fraction formed in the reaction were not investigated; the formation of bicyclobutyl and phenylcyclobutane was established:

Interesting results were obtained in the study of the thermal decomposition of cyclobutanoyl peroxide in bromoform[20].

In the literature there is a widely held view that the absence of the rearrangement is evidence for a free-radical mechanism and, conversely, that the presence of rearranged products indicates a carbonium ion mechanism. Thus a free-radical mechanism, based mainly on the absence of rearrangement products, has been proposed in studies[21,22] devoted to problems of the halogenodecarboxylation of acids by $Pb(OAc)_4$ and LiCl. In the catalytic decomposition of peroxides by copper complexes[23], the carbonium ion formed by the one-electron oxidation of the free radicals is believed to be responsible for the formation of the rearranged products.

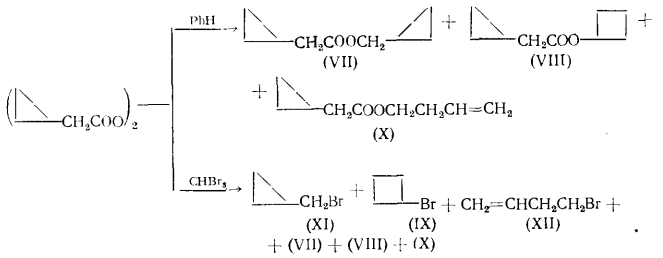
However, we showed[24] that rearranged bromides, namely cyclopropylmethyl and allylmethyl bromides, are formed in the reaction of silver cyclobutanecarboxylate with bromine (the Borodin–Hunsdiecker reaction) in addition to cyclobutyl bromide and the rearranged esters of cyclobutanecarboxylic acid (known from literature data[25]):

It might have been hoped that the analogous rearrangement would be observed also in the thermal decomposition of cyclobutanoyl peroxide. Indeed cyclobutyl bromide and rearranged bromides, namely cyclopropylmethyl and allymethyl bromides, in proportions of 85 : 5 : 10 on average, as well as a mixture of esters, namely cyclobutyl, cyclopropylmethyl, and 3-butenyl esters of cyclobutanecarboxylic acid in proportions of 65 : 30 : 5, were isolated on decomposition of this peroxide in bromoform at 140 °C. Thus a rearrangement, which is fairly likely to have a free-radical mechanism, has been observed[20].

A study has also been made of the problem of the possible formation of rearranged esters in the thermal decomposition of cycloalkylacetyl peroxides. According to Hart and Wyman[26,27], ring expansion products are not formed in the decomposition of aliphatic cyclic acyl peroxides (ranging from C_3 to C_6) in CCl_4. Such compounds have not been detected either in the products of the reaction of cyclobutylmethyl iodide with benzoyl peroxide or di(t-butyl) peroxide or in the reaction of cyclobutylmethyl chloride with Ph_3SnH.[28] Products formed as a result of ring opening have been isolated in the former reaction (the formation of 5-iodopentene has been demonstrated).

We detected[29] rearranged esters in the thermal decomposition of cyclobutylacetyl and cyclopentylacetyl peroxides in benzene at 80 °C. The composition of the main reaction products (esters and high-boiling hydrocarbons) was determined by GLC; the hydrocarbons in the low-boiling fraction were not investigated. The formation of 1,2-dicyclobutyl- and 1,2-dicyclopentyl-ethanes, benzylcyclobutane, and benzylcyclopentane was established. The

esters were analysed by chromatographing the alcohols obtained by the alkaline hydrolysis of the ester fraction; the composition of the esters is presented in Table 2.



The data in Table 2 show that, apart from esters having the usual structure, esters whose alcohol component has rearranged as a result of ring expansion are formed in the thermolysis of cyclobutylacetyl and cyclopentylacetyl peroxides, the tendency towards ring expansion being more pronounced in the case of cyclobutylacetyl peroxide.

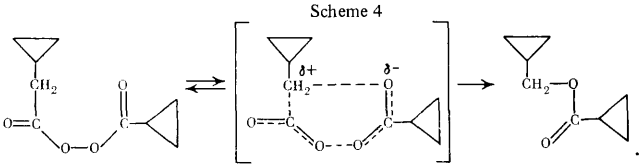
Table 2.

Initial peroxide	Composition of ester fraction	
$[(CH_2)_n CHCH_2COO]_2$	$(CH_2)_n CHCH_2COOCH_2 \cdot CH(CH_2)_n$	$(CH_2)_n CHCH_2 \cdot COOCH(CH_2)_{n+1}$
$n=3$	70	30
$n=4$	80	20

In the study of the thermal decomposition of bis(cyclopropylacetyl) peroxide[26,30], only the cyclopropylmethyl ester of cyclopropylacetic acid (VII) was found in the reaction products. After the decomposition of this peroxide in hexachloroacetone, cyclopropylmethyl chloride and the product of the homoallyl rearrangement of the cyclopropylmethyl radical, namely 3-butenyl chloride, were detected in addition to the ester (VII).[31]

In the study of the thermal decomposition of cyclopropylacetyl peroxide in $CHBr_3$ and in benzene at 65–70 °C [32] we observed for the first time the formation of the products of a rearrangement with ring expansion—cyclobutyl cyclopropylacetate (VIII) and cyclobutyl bromide (IX). Apart from compounds (VIII) and (X), cyclopropyl cyclopropylacetate, 3-butenyl cyclopropylacetate (X), cyclopropylmethyl bromide (XI), and 3-butenyl bromide (XII) are formed in $CHBr_3$; a mixture of the esters (VII) and (VIII) is produced in benzene. The bromides (IX), (XI), and (XII) are obtained in proportions of 7 : 84 : 9, while the esters (VII), (VIII), and (X) are formed in proportions of 80 : 19 : 1 in $CHBr_3$ and 70 : 13 : 17 in benzene:

The compositions and structures of the products were determined by GLC and ^1H NMR.



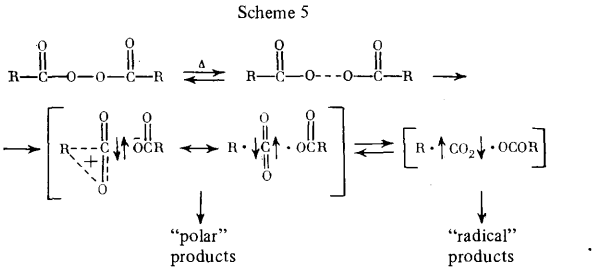
IV. THE MECHANISM OF THE THERMOLYSIS OF ALICYCLIC ACYL PEROXIDES

Analysis of the literature data shows that the thermal decomposition of acyl peroxides is a complex process; the products may be formed via both radical and non-radical (ionic or molecular) mechanisms. The contribution of each pathway depends on the structure of the peroxide and on the conditions of its decomposition.

Whereas there is at present no doubt about the radical pathway for the formation of hydrocarbons and halogenoderivatives in the decomposition of acyl peroxide, the mechanism of the formation of esters cannot be decided unambiguously in most cases. The employment of various investigators of the tracer atom (^{18}O) method[30,33] and of the method of optically active peroxides[34], the study of the influence of solvents[35] and polar additives[36] on the decomposition of peroxides, and investigation of the thermolysis kinetics[26] do not as a rule justify a conclusion concerning the true mechanism of the formation of the esters.

In their study of the kinetics of the decomposition of alicyclic peroxides in CCl_4, Hart and Wyman[26] concluded, on the basis of the observed anomalously high rate of decomposition of cyclopropylacetyl peroxide, that the formation of the corresponding ester has a cyclic mechanism (Scheme 4):

Scheme 4

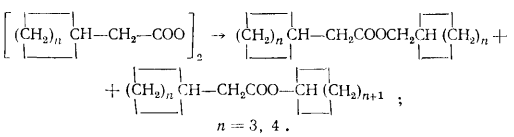


Oae et al.[30], who investigated the decomposition in CCl_4 of the same peroxide labelled with ^{18}O in the carbonyl group, found the complete distribution of the label with respect to both oxygen atoms in the ester and concluded that the ester is formed via a radical pathway. Some investigators[37,38] believe that the esters are the products of the decomposition of the carbonates formed initially:

An ionic mechanism of the decomposition of certain peroxides in polar solvents has been proposed in a number of studies: $RCOO^- {}^+OOCR$ (see, for example, Smid et al.[35]).

Another approach to the explanation of the mechanism of the thermolysis of acyl peroxides has been proposed by Walling[32]. According to Walling's mechanism (Scheme 5), the decomposition of acyl peroxides does not involve competing heterolytic and homolytic reactions, the "polar" and "radical" products being formed from a single intermediate radical-ion pair:

Scheme 5

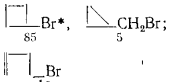


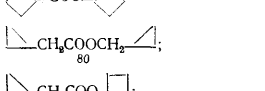
However, this scheme does not allow an objective solution of the problem of the pathway followed in the formation of particular products in these reactions. Thus Walling believes that there are "polar" products, while other investigators[40] who used Walling's mechanism, assigned them to "radical" products.

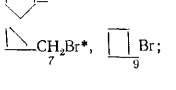
The method of chemically induced dynamic nuclear polarisation (CIDNP) now makes it possible to draw reliable inferences about the mechanism of the decomposition of acyl peroxides. The polarisation of esters is direct evidence for

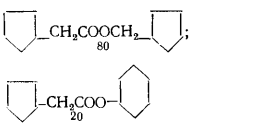
the radical pathway leading to their formation on decomposition of acetyl, benzoyl, cyclopropanoyl, etc. peroxides[41]. In other cases the problem of the mechanism of the formation of esters can be solved only tentatively.

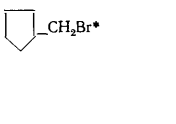
In the study of the thermal decomposition of alicyclic acyl peroxides, the formation of rearranged esters was demonstrated[42]. Thus the decomposition of cyclobutylacetyl and cyclopentylacetyl peroxides in benzene involves the formation, apart from esters having the normal structure (cyclobutylmethyl cyclobutylacetate and cyclopentylmethyl cyclopentylacetate respectively), of products rearranged as a result of ring expansion—cyclopentyl cyclobutylacetate and cyclohexyl cyclopentylacetate respectively:











$n = 3, 4.$

The formation of products rearranged as a result of the contraction or opening of the ring, both esters and bromides, was also observed in a study of the thermal decomposition of cyclobutanoyl peroxide in benzene and bromoform[19].

Lippmaa et al.[43] investigated the CIDNP in the thermal decomposition of primary and secondary peroxides in benzene and in a benzene + bromoform mixture, namely cyclobutanoyl peroxide (XIII), cyclopentanoyl peroxide (XI), cyclohexanoyl peroxide (XV), cyclopropylacetyl peroxide (XVI), cyclobutylacetyl peroxide (XVII), and cyclopentylacetyl peroxide (XVIII). According to Kaptein[44], who studied the CIDNP of the decomposition products of the peroxides (XIII)–(XVIII) in hexachloroacetone, cyclo-olefins and cycloalkyl chlorides are polarised, while the esters formed are not polarised; he did not detect rearranged products on decomposition of the peroxides (XIII) and (XVI).

Table 3. Products of the thermolysis of alicyclic acyl peroxides in $CHBr_3$.

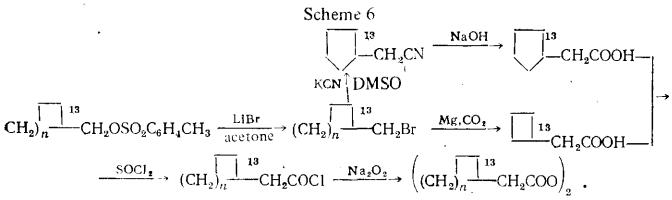
*Polarised products.

Lippmaa et al.[43] were interested primarily in the possibility of detecting the CIDNP in the rearranged products. The peroxides were thermolysed at 60–75 °C in the thermostatted cavity of an NMR spectrometer. The authors used 10% solutions of the peroxides in benzene and the same solutions with added 10% $CHBr_3$. Table 3 presents the main products of the decomposition reactions of the peroxides in bromoform (the same mixtures of esters are formed in benzene). Our results[43] of the study of CIDNP in the decomposition reactions of the peroxides (XIII)–(XV) are generally identical with those of Kaptein[44]: only cyclo-olefins and the corresponding bromides with a normal structure are polarised. The rearranged bromides and esters formed on thermolysis of the peroxide (XVII), which we detected, are not polarised.

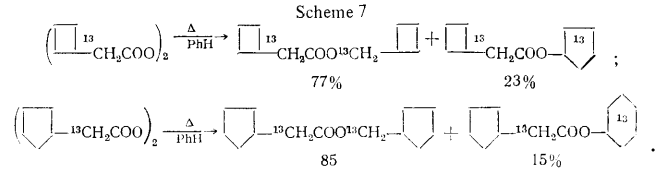
The thermolysis of the peroxides (XVI) and (XVII) is characterised by the formation of polarised unsaturated hydrocarbons (butene and pentene) and polarised bromides. The character of the polarisation of the hydrocarbons is consistent with the polarisation of the radical before ring opening. In the thermolysis of the peroxide (XVIII), an unsaturated hydrocarbon (hexene) is not formed, which is consistent with the greater thermodynamic stability of the five-membered ring. In the decomposition of the peroxide (XVI) in the benzene + bromoform mixture, 4-bromobutene—the product of the rearrangement of cyclopropylmethyl bromide—is polarised, while the esters formed are not polarised.



Our results and the literature data permit the conclusion that the CIDNP of esters is observed only in those cases where the decomposition of the peroxide results in the formation of comparatively long-lived radicals. In the remaining cases the absence of the polarisation of the esters can be explained by the fact that the latter are formed via a non-radical (polar) mechanism; or the decomposition of the peroxide proceeds via a radical pathway but there is no appreciable polarisation in the pairs of radicals RCOOR formed in view of the very short (less than 10^{-10} s) existence of the primary cage.

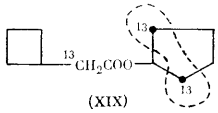
The lack of direct evidence for the free-radical pathway to the formation of esters (rearranged and non-rearranged) led us to test the possibility of the formation of the latter via a heterolytic mechanism[45]. It is known that skeletel rearrangements of alicyclic carbonium ions, formed in nucleophilic substitution reactions (deamination, solvolysis, transformation of alcohols into alkyl halides, etc.), which lead to ring expansion, are always accompanied by the migration of hydride ions in the ring[46–48]. If analogous carbonium ions are formed in the peroxide decomposition reactions which we investigated, one may expect isomerisation as a result of the migration of hydride ions in the expanded ester ring. The use of cycloalkylacetyl peroxides labelled with ^{13}C should show whether hydride shifts leading to the distribution of the ^{13}C atoms in the ring occur in the expanded ring†.

†The use of the ^{14}C label for the investigation of the mechanisms of organic reactions suffers from the significant disadvantage that the distribution of the label in the reaction products is determined by a very laborious degradation, which requires a long time (weeks and even months). Together with Lippmaa, the present author developed for the first time and used[72,73] a new method for the investigation of the rearrangements, consisting of the employment of the ^{13}C label and ^{13}C double nuclear magnetic resonance (DNMR). This method permits an enormous saving of time, since it does not require the degradation of the products; the distribution of the label in the final products is determined from the spectra in the course of several hours. At the present time this is the usual research technique generally accepted throughout the world.



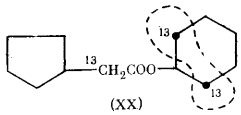
The initial cyclobutyl- and cyclopentyl-[^{13}C]acetyl peroxides were obtained in accordance with Scheme 6#:

Scheme 6



All the stages of the synthesis were tested to make sure that the position of the ^{13}C label is rigorously fixed. The peroxides were decomposed in benzene under the usual conditions[29]. The composition of the ester fraction was determined by GLC; the results of the analysis are presented in Scheme 7:

Scheme 7



The position of the ^{13}C label in the esters was determined by the ^{13}C double nuclear magnetic resonance; the following distribution of the ^{13}C atoms was found from the spectra:

(a) in the decomposition of cyclobutyl[^{13}C]acetyl peroxide:

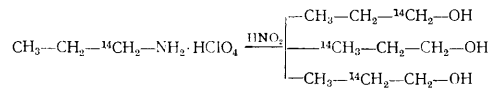
(XIX)

(b) in the decomposition of cyclopentyl[^{13}C]acetyl peroxide§:

(XX)

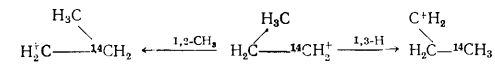
Evidently the alcohol components of both esters contain ^{13}C atoms (in equal amounts) only in the 2,5-positions in compound (XIX) and in the 2,6-positions in compound (XX), as should have been the case in the absence of ring isomerisation. In the cyclobutylmethyl and cyclopentylmethyl components of the corresponding esters, the entire ^{13}C is contained in the methylene group of the side chain.

Thus it has been established that *the esters formed in the thermolysis of cyclobutylacetyl and cyclopentylacetyl peroxides in benzene undergo a skeletal rearrangement leading to the expansion of the ring in the alcohol component of the molecule; there are no hydride shifts.*



It is known that esters are not formed at all in the photolysis of cyclopentylacetyl peroxide where the most favourable conditions are generated for radical reactions[49]. Taking this fact into account and also our data showing the absence of chemically induced dynamic nuclear polarisation in the esters and the presence of rearranged esters in the thermolysis of the peroxides, one may conclude that the free-radical pathway to the formation of the esters is unlikely. On the other hand, the absence of hydride shifts in the ring in the alcohol components of the rearranged esters rules out the possibility of the formation of at least the usual carbonium ions during the reaction.

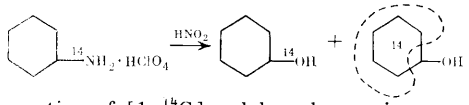
The results obtained suggest that the thermolysis of cycloalkylacetyl peroxides involves the formation in the transition state of a radical-ion pair in which species of the carbonium ion type undergo a skeletal rearrangement but do not possess sufficient energy and a sufficiently long lifetime for the occurrence of hydride shifts.



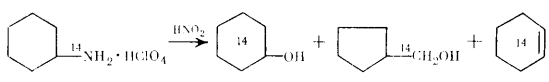
In other words, we encountered in these reactions species which are apparently intermediate between free radicals and carbonium ions.

V. THE ISOMERISATION OF CARBONIUM IONS IN DEAMINATION REACTIONS

In a series of studies[50-56] it was shown that the deamination of n-propylamine labelled with ^{14}C in the 1-position results in the formation of n-propyl alcohol containing ^{14}C (3–4% overall) not only in the 1-position but also in the 2- and 3-positions:

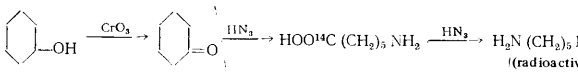


This result was explained either by the intermediate formation of an asymmetrically protonated cyclopropane or by the fact that two parallel reactions of the propyl cation take place: the 1,2-migration of the methyl group and the hydride 1,3-shift:[57]



Neither of these explanations can be regarded at the present time as fully justified experimentally.

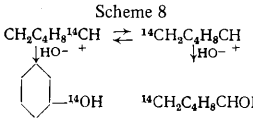
VI. THE HYDRIDE SHIFTS IN THE DEAMINATION REACTIONS OF ALICYCLIC AMINES



The study of the isomerisation of alkyl cations with migration of hydride ions[51,52,58] led to the hypothesis[51] that the hydroxy-group in the cyclohexanol molecules, formed on treatment of cyclohexylamine with nitrous acid, is not linked solely to the carbon atom to which the amino-group was attached in the initial cyclohexylamine molecule. This was confirmed in another investigation[59] with the aid of the radioactive ^{14}C label:

The interaction of [1-^{14}C]cyclohexylammonium perchlorate with nitrous acid leads to the formation of a mixture of cyclohexanol and cyclopentylmethanol:

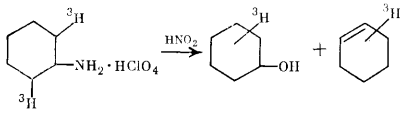
In order to establish the position of the ^{14}C atom in the cyclohexanol molecule, the latter was subjected to degradation:



#The initial tosylates were obtained analogously[44].

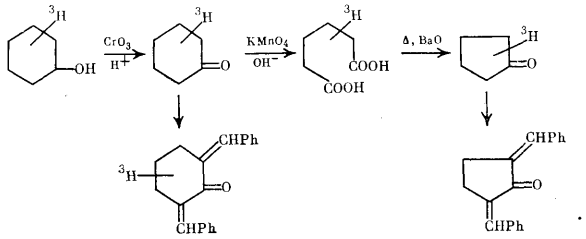
§The same result was obtained when the ^{13}C DNMR spectra of the alcohols (cyclopentanol and cyclohexanol), isolated after the alkaline hydrolysis of the mixture of esters, were measured.

The pentamethylenediamine proved to be radioactive¶, its radioactivity amounting to 3.7 ± 0.3% of that of the cyclohexanone. This implies that the hydroxy-group in certain cyclohexanol molecules is not linked to the carbon atom to which the amino-group had been attached in the initial cyclohexylamine molecule.



Thus the cyclohexyl cation isomerises in accordance with Scheme 8:

Scheme 8



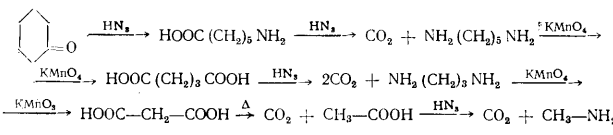
After the study of Reutov and Shatkina[59], it became clear that the mechanism of the Dem'yanov interconversion of alicyclic compounds is more complex than had been thought; *it is complicated by isomerisations involving a shift of hydride ions*.

The isomerisation of the cyclohexyl cation, formed on deamination, as a result of the hydride shift has been confirmed[61] using the tritium label. The products of the deamination of [2,6-^{3}H$_2$]cyclohexylamine are cyclohexene and cyclohexanol:

The degradation of [^{3}H]cyclohexanol was carried out in accordance with Scheme 9:

Scheme 9

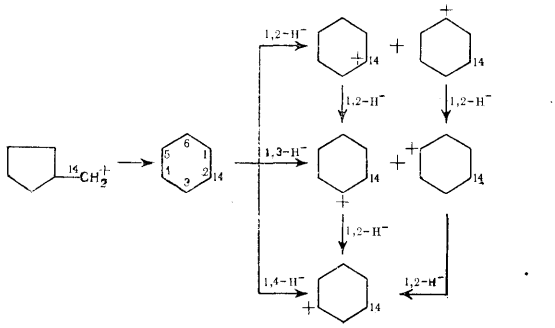
It was established that the extent of isomerisation of the cyclohexyl cation is 4.8 ± 0.3% and that the isomerisation is mainly due to the H$^-$1,2-shift (3.5%): the contribution of the H$^-$1,3-shift was 1.3% in this instance.



The hydride shift accompanying the expansion of the five-membered ring on deamination of [1-^{3}H]cyclopentylmethylamine have been investigated by the present author and his co-workers in Ref.62 and the isomerisation in the deamination of n-alkylamines has been studied in Refs.63–65.

The influence of anions with different nucleophilic properties on the degree of isomerisation of the [1-^{14}C]cyclohexyl cation formed on deamination of labelled cyclohexylamine has been investigated[66]. In the presence of the ClO_4^-, $H_2PO_4^-$, and CH_3COO^- anions, the degrees of isomerisation of this cation were 3.7 ± 0.3%, 5.0 ± 0.5%, and 3.7 ± 1.4% respectively. The absence of an appreciable influence of the change in the nucleophilic properties of the anions on the degree of isomerisation of the cation shows that the transition state is formed in all cases with participation of the molecules of the same substance derived from the solvent. This substance can apparently be only water. A change in the reaction temperature from 20° to 90 °C also does not affect the degree of isomerisation of the [1-^{14}C]cyclohexyl cation.

It is known that the reaction of aminomethylcycloalkanes with nitrous acid leads to cycloalkanols as a result of the rearrangement of cycloalkylmethyl cations to cycloalkyl cations. Thus, according to the data of Smith et al.[67], the reaction of aminomethylcyclopentane with nitrous acid leads to the formation, together with unsaturated hydrocarbons, of a mixture of alcohols whose main component is cyclohexanol:

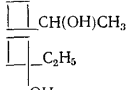


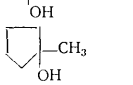
The question whether the cyclohexyl cation isomerises as a result of hydride shifts in the given reaction is of natural interest. In this connection a study was made of the reaction of aminomethylcyclopentane with nitrous acid using the ^{14}C isotope.[68] The reaction of aminomethyl[^{14}C]cyclopentane with nitrous acid was performed in an aqueous solution of sodium dihydrogen phosphate at 90 °C, as in the study of Smith et al.[67] The resulting mixture of alcohols was oxidised in order to isolate [^{14}C]cyclohexanone, which was subjected to degradation in accordance with the following scheme:

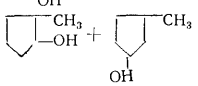
It follows from the radioactivities obtained that cyclohexanol contains ^{14}C not only in the 2-position but also in all the remaining positions, which indicates the isomerisation of the cyclohexyl cation. The cyclohexyl cation can isomerise as a result of hydride shifts from the 2,6-positions (the H$^-$1,2-shift), the 3,5-positions (the H$^-$1,3-shift), and the 4-position (the H$^-$1,4-shift) or as a result of consecutive shifts in accordance with Scheme 10:

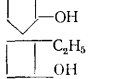
Scheme 10

The distribution of the label among all the positions of the six-membered ring can be caused, generally speaking, both by independent H$^-$1,2-, 1,3-, and 1,4-shifts and by a combination of consecutive H$^-$1,2-shifts (and also H$^-$1,3–1,2-shifts). Shatkina et al.[68] left this question open believing that the isomerisation proceeds via independent H$^-$1,2-, 1,3-, and 1,4-shifts.

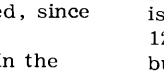






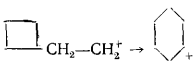


The difference between the relative radioactivities of cyclohexanone and pentamethylenediamine is 4.5%; according to Scheme 10, it corresponds to half the H$^-$1,2-shifts, whereas



¶The low degree of rearrangement of the cyclohexyl cation may be explained by the fact that it reacts very rapidly with the solvent to form cyclohexanol. The fact that the reaction of *cis*-[2-D]cyclohexylammonium perchlorate with nitrous acid leads to the formation of at least 94% of *cis*-[2-D]cyclohexanol has been explained analogously[60].

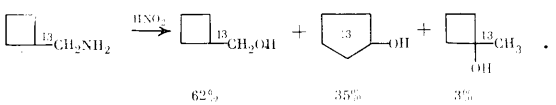
the cyclohexyl cation isomerises to the extent of 9% as a result of H^-1,2-shifts. The radioactivity of methylamine (1.2%) is caused by half the H^-1,3-shifts, so that the cyclohexyl cation isomerises to the extent of 2.4% as a result of H^-1,3-shifts. The degree of isomerisation due to the H^-1,4-shifts is equal to the difference between the relative radioactivities of trimethylenediamine and half the sum of the percentage isomerisations due to the H^-1,2- and 1,3-shifts; this difference is 1.2%. Thus the [2-^{14}C]cyclohexyl cation formed as an intermediate in the reaction of aminomethyl[^{14}C]cyclopentane with nitrous acid isomerises to the extent of 12.6 ± 1.0% due to the hydride shifts.



Interesting results were obtained in a study of the deamination of 1-cyclobutyl- and 2-cyclobutyl-ethylamines[69]†. The deamination was carried out in an aqueous solution of sodium dihydrogen phosphate at 90 °C; the results of the analysis of the reaction products are presented in Table 4.

Table 4. Deamination of 1-cyclobutyl- and 2-cyclobutyl-ethylamines.

Reaction products	Initial amine	
		
	37.4	4.4
	4.2	53.4
	17.4	6.9
	18.7	23.5
	14.3	7.6
	0.3	—
	17.4	6.9



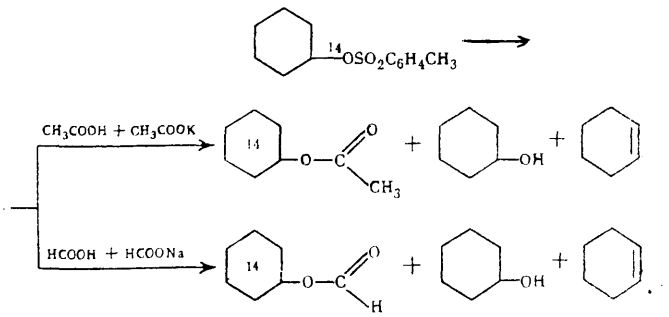
Inspection of the data in Table 4 shows that the deamination of 1-cyclobutyl- and 2-cyclobutyl-ethylamines entails the formation of a large amount of rearranged products. The set of alcohols isolated from the products of the first and second reactions is the same, but the degrees of rearrangement of the intermediate carbonium ions in the reactions investigated are different. The rearrangement accompanied by the expansion of the ring contributes 31–33% in both reactions. Apart from the skeletal rearrangement, the carbonium ions undergo a rearrangement as a result of the hydride ion shift. In the deamination of 2-cyclobutylethylamine the degree of rearrangement as a result of the migration of hydride ions, leading to products without ring expansion, is greater (39%) than in the case of 1-cyclobutylethylamine (20%). Evidently this was to be expected, since the primary carbonium ion () formed in the former case should rearrange to a much greater extent (to tertiary and secondary carbonium ions) than the more stable secondary carbonium ion () formed in the latter case.

The formation of large amounts of 1-, 2-, and 3-methylcyclopentanols in both reactions indicates a considerable tendency towards ring expansion in the intermediate cyclic carbonium ions. Ring expansion by two carbon atoms, leading to a cyclohexanol, takes place to a slight extent (0.3%) and only in the case of 2-cyclobutylethylamine. The absence of cyclohexanol from the deamination products of 1-cyclobutylethylamine indicates a one-stage rearrangement of the carbonium ion:

In the study of the deamination of aminomethylcyclobutane, we employed the ^{13}C DMNR method[71]. Dem'yanov and co-workers[74] showed that the deamination of aminomethylcyclobutane is accompanied by ring expansion and leads to the formation of cyclopentanol and the normal reaction products—cyclobutylmethanol; the yields and ratios of the products were not determined.

The earlier study of the deamination of aminomethyl[^{14}C]-cyclopentane and the demonstration of the rearrangement of the intermediate carbonium ion[68] made it of interest to study the deamination of aminomethyl[^{13}C]cyclobutane in order to observe the isomerisation of the carbonium ion leading to ring expansion. The deamination was carried out in an aqueous solution of sodium dihydrogen phosphate at 90 °C. The composition of the reaction products was determined by GLC and the distribution of the ^{13}C in the reaction products was found by the ^{13}C DNMR method[73]; the results of the analysis of the reaction products are presented below:

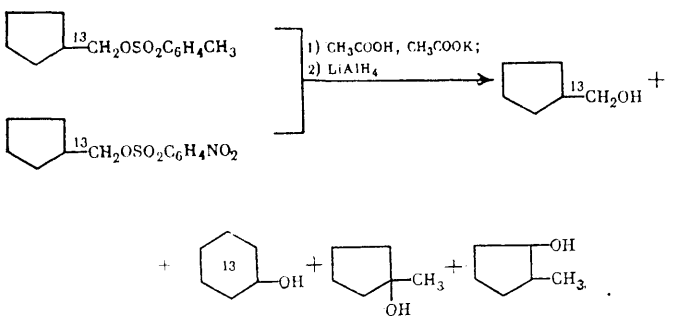
Inspection of the above data shows that the deamination of aminomethyl[^{13}C]cyclobutane results in the formation of a considerable amount of rearranged products. The contribution of the rearrangement accompanied by ring expansion is 35%. The formation of 1-methylcyclobutanol shows that, apart from the skeletal rearrangement, the carbonium ion isomerises due to the migration of the hydride ion, which leads to the formation of a tertiary cation.



The distribution of the ^{13}C label in the cyclopentanol molecule was found from the ^{13}C DNMR spectrum. It was established that cyclopentanol contains ^{13}C not only in the 2-position but also in all the positions, which indicates the isomerisation of the intermediate carbonium ion owing to the migration of the hydride ion in the ring. In carrying out a comparison with data[68] for the isomerisation of the carbonium ion formed on deamination of aminomethyl[^{14}C]cyclopentane, one should note an appreciably greater degree of isomerisation due to hydride shifts (45% compared with 12.5%) of the carbonium ion formed from aminomethylcyclobutane and its smaller capacity for ring expansion (35% compared with 75%).

The stereochemistry of the Dem'yanov rearrangement and the influence of conformational factors on the latter have been studied in a number of investigations[75–77].

† The formation of rearranged products in the deamination of [1-^{14}C]-2-cyclopropylethylamine has been demonstrated[70].



VII. THE ISOMERISATION OF CARBONIUM IONS IN SOLVOLYTIC REACTIONS

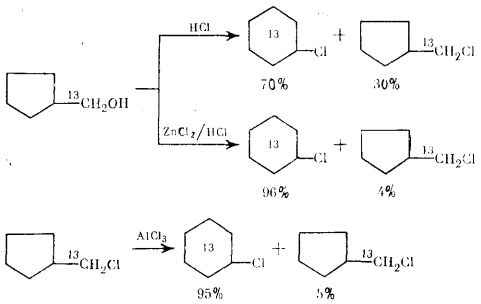
The isomerisation of the [1-^{14}C]cyclohexyl cation in acetolysis and formolysis has been studied[78]:

The solvolysis of [1-^{14}C]cyclohexyl toluene-*p*-sulphate was carried out by heating the latter with glacial acetic acid and potassium acetate at 50° and 100 °C or with anhydrous formic acid and sodium formate at 50 °C for 16 h. The cyclohexyl cation isomerises as a result of hydride shifts to the extent of 7% in acetolysis and 60% in formolysis. Analogous results were obtained in the study of the influence of the water content in the medium on the types of hydride shifts in the reaction of [2,6-D_2]cyclohexyl toluene-*p*-sulphonate.[79]

The acetolysis of cyclopentyl[^{13}C]methyl toluene-*p*-sulphonate and *p*-nitrobenzenesulphonate has also been studied[80]:

Analysis of the distribution of the label in the reaction products showed that the isomerisation due to hydride shifts takes place to the extent of 25% in the case of the toluene-*p*-sulphonate and 24% in the case of the *p*-nitrobenzenesulphonate.

The isomerisation of the cations formed as intermediates in the solvolysis of cyclopentylmethyl and cyclohexyl arenesulphonates labelled with ^{13}C or ^{14}C is significantly influenced by the ionising capacity of the medium and temperature; the influence of the leaving group is weak[81].



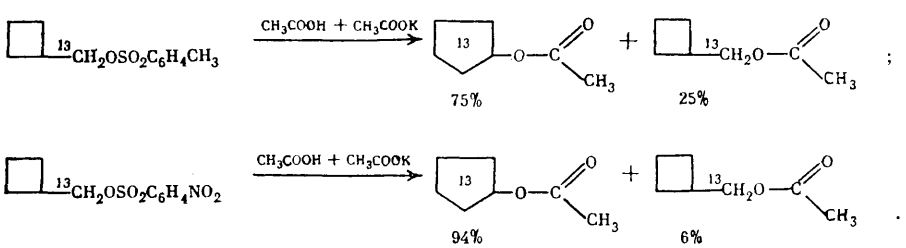
The following mixtures of products are formed in the acetolysis of cyclobutyl[^{13}C]methyl toluene-*p*-sulphonate and cyclobutyl[^{13}C]methyl *p*-nitrobenzenesulphonate:[82]

The distribution of ^{13}C in the cyclopentyl acetate molecule was determined by the ^{13}C DNMR method under the conditions of total uncoupling of the hydrogen nuclei[72]. The significant influence of the nature of the departing group on the rearrangement accompanied by ring expansion and conversely the absence of its influence on the isomerisation in the cyclopentane ring as a result of hydride shifts are noteworthy.

An analogous behaviour has been observed in the acetolysis of the corresponding 2-cyclobutylethyl arenesulphonates[83], as can be seen from the data in Table 5.

The hydride shifts were also investigated in the reactions of cyclic alcohols with the Lucas reagent ($ZnCl_2$/HCl).[84-88] Scheme 11 presents some of the reactions investigated, including the reaction with aluminium chloride[87]:

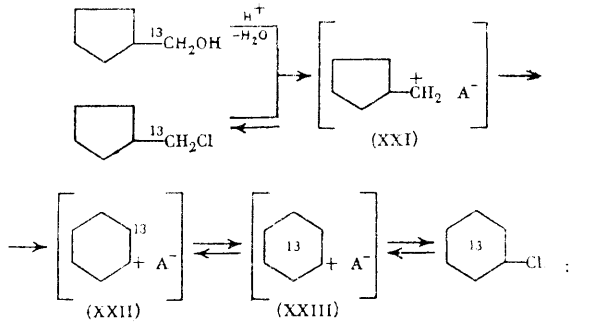
Scheme 11



(3) (4) (5)

Table 5. The products of the acetolysis (rel.%) of 2-cyclobutylethyl toluene-*p*-sulphonate and *p*-nitrobenzenesulphonate.

Initial compound			 cis-	trans-		Ring expansion, %
	23.0	22.0	20.0	33.0	2.0	77
	5.0	37.0	20.0	34.0	4.0	95

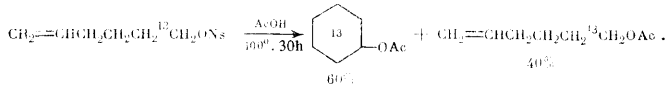


Note. Ns = *p*-nitrobenzenesulphonyl (Ed.of Translation).

The cyclohexyl chloride formed contains the label in all the positions in the cyclohexane ring and not only in the 2-position, as would have been the case in the absence of isomerisation. The virtually uniform distribution of the label in

the ring shows that the cyclohexyl cation undergoes the maximum possible isomerisation. One can imagine the following probable mechanism of the reactions: in the first stage the ion pair (XXI) is formed rapidly (as a result of the protonation of the carbinol with subsequent elimination of water or via the ionisation of cyclopentylmethyl chloride by the Lewis acids) and is in its turn irreversibly# converted into the ion pair (XXII) (Scheme 12):

Scheme 12

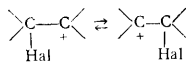


(XXI) (XXII) (XXIII)

$A^- = AlCl_4^-$, $ZnCl_3^-$, HCl_2^- .

The cyclohexyl cation stabilised by the complex anion is fairly stable and isomerises as a result of hydride shifts. Ion pairs of type (XXII) are formed and subsequently give rise to the reaction products.

The isomerisation of the cyclohexyl cation on heating cyclohexanol with boric acid has been investigated. The expansion of the cyclopentane ring to the cyclohexane ring has been discovered in the demercuration of cyclopentylmethylmercury acetate[90].

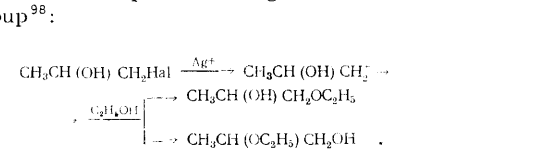


The acetolysis of [1-^{13}C]-5-hexenyl and cyclopentyl[^{13}C]methyl p-nitrobenzenesulphonates has also been investigated[91]. It has been found that the degree of cyclisation reaches 60% in the acetolysis of [1-^{13}C]-5-hexenyl *p*-nitrobenzenesulphonate after 30 h at 100 °C; the [^{13}C]cyclohexyl acetate formed has been fully isomerised, which has resulted in a uniform distribution of the label in the ring:

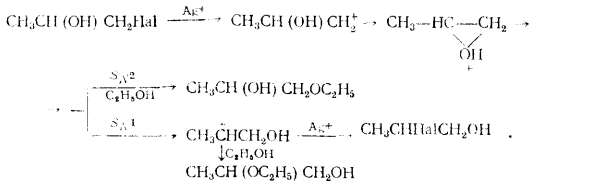
Analogous data have been obtained in the study of the acetolysis of cyclopentyl[^{13}C]methyl *p*-nitrobenzenesulphonate[80] under the same conditions in the absence of potassium acetate. A uniform distribution of the label was also obtained in the main reaction product, namely cyclohexyl acetate, which indicates the 100% isomerisation of the intermediate cation as a result of the migration of hydride ions. The equivalent results of these reactions suggest the formation of the same intermediate cation responsible for the isomerisation.

VIII. REARRANGEMENTS WITH THE 1,2-MIGRATION OF THE HALOGEN ATOM

Numerous rearrangements of carbonium ions due to the 1,2-migration of the halogen have been discovered in the study of a number of deamination and solvolytic reactions:



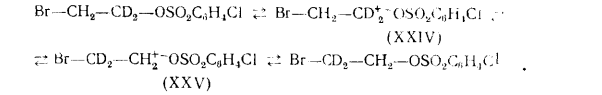
The simplest model reactions, namely the deamination of β-halogenoethylamines, have been studied using the ^{14}C label[92-96]:



X = OH, OCHO, $OCOCH_3$, $OCOCF_3$; Hal = Cl, Br .

The degree of isomerisaton varies in the range 5–27% for chlorine and 30–50% for bromine. For a survey of the rearrangements and deamination reactions, see Reutov and Gudkova[97].

The alcoholysis of 1-halogeno-2-propanols and 2-halogeno-1-propanols in the presence of silver nitrate apparently proceeds with the nucleophilic 1,2-migration of the hydroxy-group[98]:

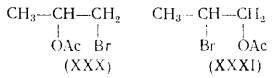


The authors quote the following hypothetical reaction mechanism:

In the solvolysis of the simplest model compounds, the degree of 1,2-migration of the halogen is as a rule higher than in the deamination reaction. Thus the degree of 1,2-migration of bromine reaches 50% in the course of the trifluoroacetolysis of [1-^{14}C]-2-bromoethyl arenesulphonates (Ar = Ph, *p*-ClC_6H_4, *p*-$CH_3C_6H_4$, or β-$C_{10}H_7$).[99] The acetolysis of 2-bromoethyl *p*-nitrobenzenesulphonate is accompanied by 40.8% 1,2-migration of the halogen[100]. As a rule, with the increase of the ionising power of the acid and with decrease of its nucleophilic properties, the degree of migration of the halogen increases[101,102]. Thus the degree of migration increases from 0 to ~4% for chlorine and from 33 to 56% for bromine in the solvolysis of [1-^{14}C]-2-halogenoethyl *p*-nitrobenzenesulphonates and *p*-bromobenzenesulphonates on passing from CH_3COOH to HCOOH and then to CF_3COOH.

In the acetolysis of halogenoethyl sulphonates in aprotic solvents, the degree of isomerisation increases with increasing polarity of the solvent. Thus the acetolysis of [1-^{14}C]-2-bromoethyl arenesulphonates in benzene is not accompanied by isomerisation at all, while in nitrobenzene the extent of the 1,2-migration of the halogen atom is 49%.

It is of interest to note that the isomerisation of the initial sulphonate, which had not reacted, was observed in the acetolysis of the [2,2-D_2]-2-bromoethyl *p*-chlorobenzenesulphonate. This isomerisation apparently takes place in the ion pairs (XXIV) and (XXV) with their reconversion into the covalent substrate:

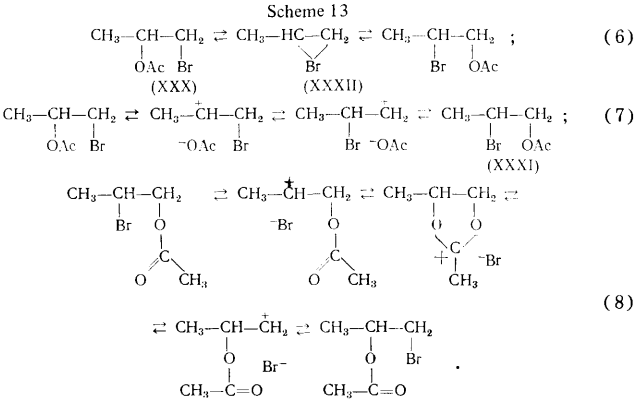


(XXIV) (XXV)

#The reversibility of this stage has been demonstrated by special experiments.

IX. THE ISOMERISATION OF ACYLOXYBROMOPROPANES

In the study of the products of the solvolysis of 1(2)-halogeno-2(1)-propyl tosylates $CH_3CH(OTs)CH_2Cl$ (XXVI), $CH_3CH(OTs)CH_2Br$ (XXVII), $CH_3CHClCH_2OTs$ (XXVIII), and $CH_3CHBrCH_2OTs$ (XXIX) in acetic acid, it was observed that the reaction products consist in each case of two halogenoalkyl acetates—unisomerised and isomerised as a result of the 1,2-migration of the halogen.



When these reactions are studied in the presence of sodium acetate, the picture becomes more complex[102]. For example, in the solvolysis of compounds (XXVII) and (XXIX), the products of secondary processes (1,2-dibromo- and 1,2-diacetoxypropanes) appear in addition to $CH_3CH(OAc)CH_2Br$ (XXX) and $CH_3CHBrCH_2OAc$ (XXXI), but the ratio of compounds (XXX) and (XXXI) remains the same as in the absence of added sodium acetate (70 : 30). These results led to the hypothesis that the acetoxybromopropanes formed undergo a reversible isomerisation owing to the 1,2-migration of bromine already in the acetolysis of the initial bromotosylates:

(XXX) (XXXI)

Indeed it has been shown[101] that, when pure compounds (XXX) and (XXXI) are heated in glacial acetic acid (for 30 h at 100 °C), the same equilibrium mixture, containing 70% of 1-bromo-2-propyl acetate and 30% of 2-bromo-1-propyl acetate, is formed. Three possible reaction mechanisms [(6), (7), and (8) in Scheme 13] were examined:

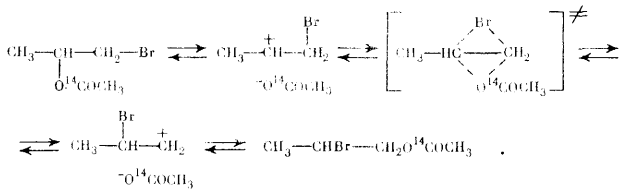
Scheme 13

(6)

(7)

(8)

In order to discover which is the true mechanism of the isomerisation, the tracer atom method was employed[102]. The isomeric acetoxybromopropanes (XXXa) and (XXXIa) labelled with ^{14}C in the acetoxy-group were synthesised:

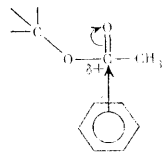


(XXXa) (XXXIa)

Each radioactive isomer was heated in glacial acetic acid for 30 h at 100 °C, i.e. until the attainment of equilibrium between the isomeric acetoxybromopropanes, after which the loss of radioactivity was compared with the degree of isomerisation. In both cases the isomerisation terminated with partial retention of the radioactive label in acetoxybromopropanes [16% for compound (XXXa) and 10% for compound (XXXIa)].

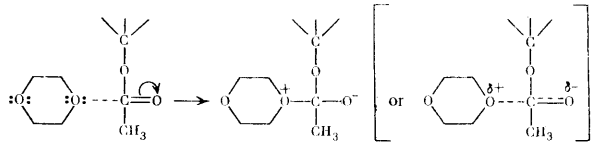
If the acetoxonium mechanism (7) operated, the complete retention of the radioactivity would have been observed, and in addition 1,2-diacetoxypropanes should have appeared in the reaction mixtures. The result of the isomerisation of the labelled compounds combined with the complete absence of 1,2-diacetoxypropane makes it possible to exclude the acetoxonium mechanism from consideration. If the reactions of compound (XXXa) and (XXXIa) with acetic acid proceeded via the S_N2 mechanism, the products would have been non-radioactive and non-isomerised acetoxybromopropanes. If the reaction proceeded exclusively via the formation of carbonium ions, an equilibrium mixture of acetoxybromopropanes with complete loss of radioactivity would have been formed.

Some retention of radioactivity can apparently be explained by the fact that the isomerisation proceeds at least partly in the stage involving the formation of contact or solvate-separated ion pairs. The isomerisation proceeds in this case via a synchronous mechanism as a consequence of the simultaneous migration of the bromine atom and the labelled acetoxy-group (Scheme 14):



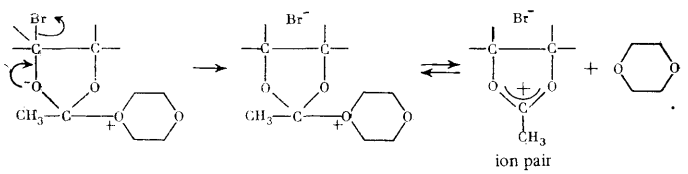
Scheme 14

The role of the main driving force leading to the formation of ion pairs in the given reaction is apparently assumed by the hydrogen bonds between the solvent molecules and the acetoxy-group in compounds (XXX) and (XXXI), although one cannot exclude *a priori* also the possibility that the dipole–dipole interaction between the molecules of acetic acid and the C–OAc bond plays a role.



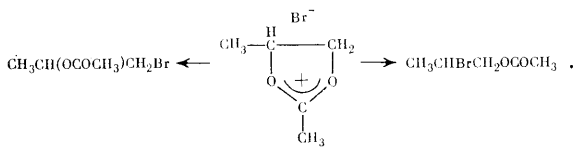
It is of interest that the isomerisation proceeds not only in acetic acid but also in benzene, toluene, and dioxane[101,102]. The isomerisation was carried out for 30 h at 100 °C and it was established that it proceeds only in those cases where the solvent molecules contain π or p electrons; the isomerisation does not occur in n-octane where such electrons are absent.

The isomerisation mechanism is apparently different from that in glacial acetic acid. Presumably in the case of aromatic solvents the main driving force of the reaction involves the interaction of the π-electron system of the benzene ring with the carboxyl carbon carrying a partial positive charge (the formation of a kind of π-complex):



If this hypothesis is adopted, one may expect that this kind of interaction can also occur in solvents of the type of dioxane containing atoms with free p electrons and can be more intense than the interaction due to π-electron systems. The above interaction creates favourable conditions for the operation of the oxolonium mechanism (Scheme 15):

Scheme 15



The carbonyl group activated in this way can probably play the role of an "internal" nucleophile in relation to the C—Br bond present in the molecule of the acetoxybromo-derivative:

ion pair

Next the ion pair can be stabilised by being converted into the isomeric acetoxybromopropanes:

The corresponding trifluoroacetoxybromopropanes do not isomerise. This is apparently due to the impossibility of the interaction of solvent molecules with the carboxyl carbon atom, examined above, owing to the steric hindrance generated by the three fluorine atoms. On the other hand, the corresponding trimethylacetoxybromopropanes (for which the steric hindrance is still greater) isomerise faster than acetoxybromopropanes and the reaction proceeds even in n-heptane. The stabilising influence of the t-butyl group on the acetoxonium cation formed apparently plays a decisive role in this case; the necessity for the activation of the carbonyl group by solvent molecules does not then arise.

* * *

We may note in conclusion that the development of the chemistry of alkyl radicals and alkyl cations can serve as a good illustration of the familiar postulate that science develops in jumps depending on the appearance of new research techniques. Thus qualitatively new results in the chemistry of carbonium ions are associated with the employment of superacid media, NMR, the tracer atom method, and in particular the ^{13}C double NMR. An equally great importance of the development and application of new research methods can be traced also in the chemistry of aromatic carbonium ions[103].

The Structure and Stereochemistry of Paramagnetic Metal Complexes of *o*-Quinones

M.I. Kabachnik, N.N.Bubnov, S.P.Solodovnikov, and A.I.Prokof'ev

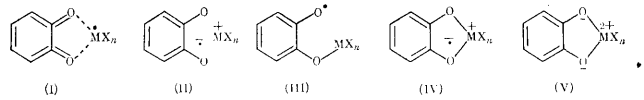
Data are presented on the EPR spectra of transition metal and Group IV metal complexes with *o*-semiquinone ligands. Analysis of the *g*-factors and the hyperfine coupling constants has been used to determine the structure of the complexes, the electronic configuration of the metal, and the ligand substitution processes.
The bibliography includes 56 references.

CONTENTS

I. Introduction 288
II. The electronic structure of paramagnetic manganese, rhenium, iron, molybdenum, tungsten, and chromium complexes of *o*-quinones 289
III. The stereochemistry of paramagnetic chelate complexes of Group IV elements with semiquinone ligands 299

I. INTRODUCTION

A new branch of the coordination chemistry of metals, associated with the extensive employment of *o*-quinone ligands, has arisen recently. As a result of the characteristic feature of the electronic structure of *o*-quinones, these ligands can function, depending on the conditions, as paramagnetic radical-anions, or diamagnetic catacholate dianions, or, in rare cases, as non-reduced *o*-quinone molecules. Thus, in contrast to the traditional task of coordination chemistry involving primarily the description of the electronic structure of the central metal ion, an additional task involving the determination of the degree of reduction of the ligand arises.

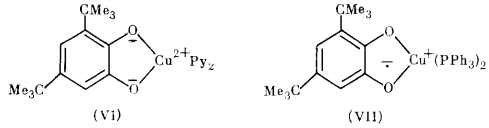


The interest in these systems at the present time is due to the exceptional wide variety of the electronic structures arising in such complexes. However, it was soon discovered that the complexes of *o*-quinones with certain transition metals are biochemically important. It was established that certain micro-organisms employ special substances—"siderophores"—as iron-binding agents.

One of these "siderophores", namely enterobactin, contains in its molecule three catechol groups joined via a macroring. The iron(III) complexes of enterobactin are exceptionally stable[1,2]. It is known that the conditions governing the growth of pathogenic bacteria are definitely related to the iron content in the human organism[3]. Thus the study of the formation and structure of variable-valence metal complexes of *o*-quinones has assumed practical importance.

Numerous studies of the structure of transition metal complexes of *o*-quinones by X-ray diffraction have been analysed in a review[4]. According to the latter[4], the length of the carbonyl bond C—O in the *o*-quinone is a characteristic quantity and makes it possible to estimate the degree of reduction of the ligand. The greatest number of stability constants of the complexes have been determined for the iron(III) ion. It was found that the iron(III) complex of enterobactin has the highest stability constant[5]. It was shown that the synthetic analogues of enterobactin and also of *o*-quinone, having a simple structure, form with Fe^{3+} complexes having high stability constants[5]. The chemical characteristics of transition metal complexes of *o*-quinones include their ability to undergo multistage oxidation and reduction with retention of their structure[4]. It can be assumed that donor—acceptor interactions constitute the basis of the reactions of these complexes with N_2, CO, and O_2. It has been found that the vanadium complexes of catechol actively fix molecular nitrogen under certain conditions[6]. The vanadium complexes also proved capable of reversible combination with O_2, NO, and CO.[7]

The formal examination of the electronic structure of metal complexes of *o*-quinones is usually carried out within the framework of the oxidation-reduction triad of the *o*-quinone. Taking into account the coordination, it is possible to postulate different structures of the complex of *o*-quinone with the organometallic fragment $\dot{M}X_n$ having an odd number of electrons. We shall consider paramagnetic complexes of precisely this type.



In principle, the *o*-quinone ligands can give rise to the following types of complexes:

(I) (II) (III) (IV) (V)

The formation of a particular structure depends on the nature of M and X and on the number *n*. Structure (I) corresponds to the coordination of the neutral *o*-quinone via the unshared electron pairs of the oxygen atoms. Structures (II)—(IV) correspond to the coordination of the semi-reduced form of the quinone—the semiquinone radical-anion—and differ in the distribution of the unpaired electron between the metal and the ligand. Structure (V) reflects the coordination of the fully reduced quinone—the catecholate dianion.

The change in the degree of oxidation of the copper atom and of the degree of reduction of the ligand in the following complexes can serve as a clear example of the transformation of the structures[8,9]:

(VI) (VII)

The energy differences between structures (VI) and (VII) are small and the replacement of pyridine by triphenylphosphine leads to a sharp alteration of the electronic structure of the complex. In certain cases the possibility of equilibrium between forms (VI) and (VII) has been postulated,

as, for example, in the case of the bipyridyl adduct of the cobalt complex of 3,5-di-t-butyl-*o*-benzoquinone.[10] However, such hypotheses must be accompanied by an indication of the character of the skeletal changes in the complexes without which no transitions between the "electronic isomers" are of course possible. A convenient method for the investigation of the above transitions involves the photochemical synthesis of the complexes of *o*-quinones with radical organometallic fragments. In contrast to other methods[11–14], it makes it possible to determine not only the final reaction products but also the unstable intermediate complexes.

The coordination chemistry of Group IV elements has developed to a much lesser extent than that of transition metals. The employment of semiquinone paramagnetic ligands leads to new possibilities for the study of the stereochemistry of the coordination compounds of silicon and tin. Electron paramagnetic resonance (EPR) and electronic absorption spectroscopy have been used as the main procedures for the investigation of the electronic structure of the *o*-quinone complexes.

The aim of the present review was to examine the characteristics of the structures of the complexes and the wide variety of the electronic configurations of the metal and the ligands and to demonstrate the possibilities of the EPR method from the standpoint of the solution of various stereochemical problems.

II. THE ELECTRONIC STRUCTURE OF PARAMAGNETIC MANGANESE, RHENIUM, IRON, MOLYBDENUM, TUNGSTEN, AND CHROMIUM COMPLEXES OF *o*-QUINONES

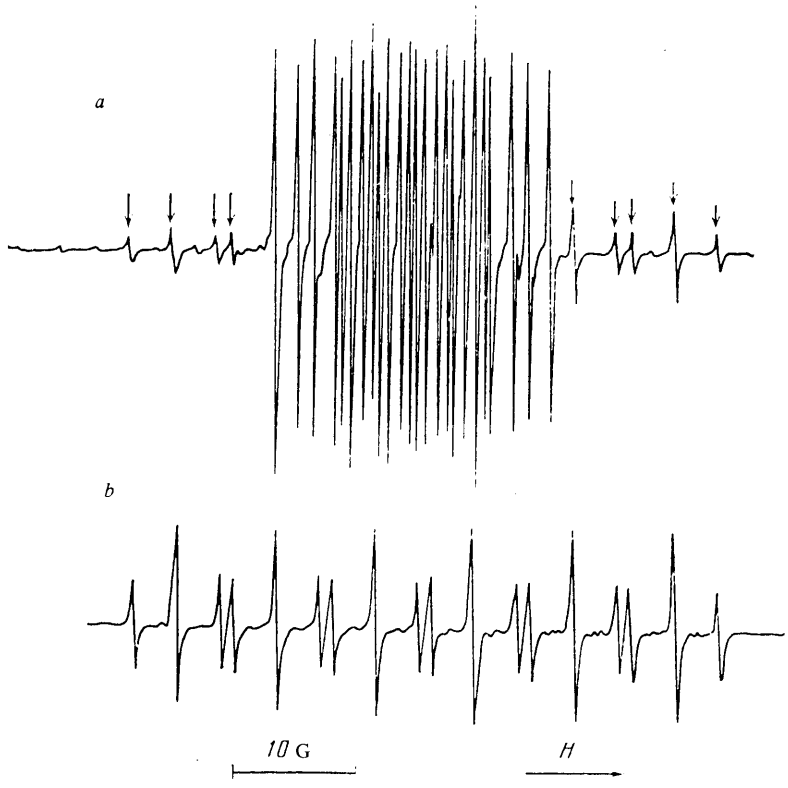
1. The EPR and Electronic Absorption Spectra of the Complexes of *o*-Quinones with Manganese and Rhenium Penta- and Tetra-carbonyls

It is known that the photolysis of manganese and rhenium decarbonyls leads to the formation of the corresponding radicals[13]:

$$(CO)_5M—M(CO)_5 \xrightarrow{h\nu} 2\dot{M}(CO)_5,$$

where M = Mn or Re. The interaction of these radicals with *o*-quinones leads to the formation of complexes having different structures depending on the temperature.

When manganese pentacarbonyl was allowed to react with *o*-quinones, it was possible to detect primary radicals which had not been found in previous studies[16–19], to determine their stabilities, and to measure the rate constants for their reactions[22]. The photolysis of $M_2(CO)_{10}$ in the presence of 3,6-di-t-butyl-*o*-benzoquinone and pentane at −80 °C leads to the appearance of a radical whose EPR spectrum corresponds to the interaction of the electron with the ^{55}Mn ($I = 5/2$) nucleus and with the two non-equivalent protons of the catechol ligand (Fig.1).



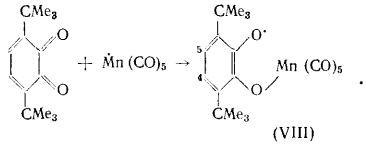


Figure 1. EPR spectra of the radicals (VIII) (*a*) and (IX) (*b*) in pentane at −80 °C (*a*) and 20 °C (*b*); the arrows indicate the lines of the radical (IX).[22]

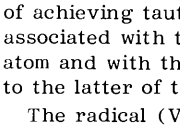
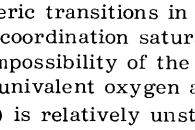
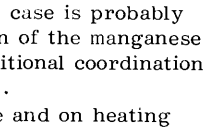


On the basis of the characteristics of the distribution of the unpaired electron density in the catechol ligand, a structure with the unpaired electron localised at the oxygen atom was attributed to the radical (VIII):

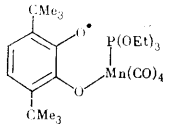


(VIII)

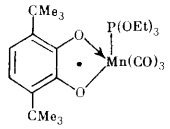
The larger hyperfine coupling contant (HFC) (5 G) is attributed to the ring proton in the 4-position relative to the univalent oxygen atom of the catechol ligand and the smaller constant (1.7 G) is attributed to the proton in the 5-position. In the temperature range from −100° to 20 °C, the alternation of the hyperfine structure (HFS) line widths is not manifested in the EPR spectra of the complex (VIII), which permits the conclusion that the $-M(CO)_5$ fragment does not migrate between the oxygen atoms of the catechol ligand in the radical (VIII) on the EPR time scale. The difficulty of achieving tautomeric transitions in this case is probably associated with the coordination saturation of the manganese atom and with the impossibility of the additional coordination to the latter of the univalent oxygen atom.



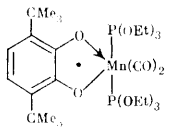
The radical (VIII) is relatively unstable and on heating above −80 °C is converted (in the absence of ultraviolet radiation) into the radical (IX), characterised by appreciable hyperfine coupling with the ^{55}Mn nucleus and with the two equivalent protons of the catechol ligand (Fig.1 and Table 1). Table 1 presents the spectroscopic characteristics of species having the following structures:



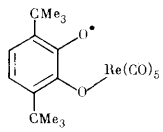
(IX)



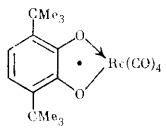
(X)



(XI)

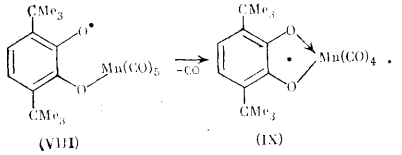


(XII)



(XIII)

(XIV)



(XV)

(XVI)

Because of the low stability of the radical (VIII), the latter was not detected in previous studies[16–19]. There is controversy concerning the structures of the radicals (IX), namely whether they contain the $Mn(CO)_5$ or $Mn(CO)_4$ fragments. It has been suggested[16,17] that the fragment $Mn(CO)_4$ is present in radicals of type (IX). The data obtained by Tumanskii et al.[22] constitute important evidence in support of this hypothesis and the radical (IX) is probably formed on elimination of one CO group from the primary radical (VIII):

(VIII) (IX)

Table 1. The spectroscopic parameters (G) of the primary and secondary radicals formed on interaction of *o*-quinones with manganese and rhenium pentacarbonyls.[22,23]

Radical	$a_{H(4)}$	$a_{H(5)}$	a_{Mn}	a_P
(VIII)	5.0	1.7	3.0	—
(IX)	3.4	3.4	7.7	—
(X)	—	—	2.8	—
(XI)	—	—	8.7	—
(XII)	5.1	1.7	2.2	6.0
(XIII)	3.15	3.15	10.1	43.0
(XIV)	2.7	2.7	16.1	54.0
(XV)	—	—	6.6	—
(XVI)	3.8	3.8	29.0	—

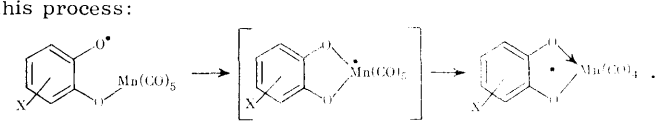
Note: a_{Cl} = 0.47 G [the average of the constants for the hyperfine coupling of the unpaired electron with the $^{35}Cl(^{37}Cl)$nuclei] was obtained for the radical (XI); the constants for the hyperfine coupling of the unpaired electron with the ^{185}Re and ^{187}Re nuclei are quoted instead of a_{Mn} for the radicals (XV) and (XVI).

To confirm the transformation of the radical (VIII) into the radical (IX), a study was made of the kinetics of the destruction of the radicals (VIII) and of the accumulation of the radicals (IX), the analysis of which indicates the unimolecular character of the conversion of (VIII) into (IX) and the extremely similar rate constants for the destruction of the radicals (VIII) (3.0×10^{-3} s^{-1}) and for the accumulation of the radicals (IX) (3.3×10^{-3} s^{-1}) at −30 °C show that the radical (VIII) is almost entirely converted into the radical-(IX). The general expression for the rate constant for the unimolecular conversion of the radical (VIII) into the radical (IX) is[22]

$$k(s^{-1}) = 2 \cdot 10^{15} \exp[-(17300 \pm 1000)/RT]$$

and $k(-20\ °C) = 0.017\ s^{-1}$.

The stability of the primary manganese-containing radicals investigated depends significantly on the structure of the *o*-quinone employed. In the case of *o*-chloranil, the primary radicals (X) (see Table 1), which differ from the secondary radicals (XI) by the constants for the hyperfine coupling with the ^{55}Mn and ^{35}Cl, ^{37}Cl nuclei, proved to be much less stable than the corresponding complexes with the 3,6-di-t-butyl-1,2-dihydroxybenzene ligands. The rate of destruction of the radicals (X) proved to be appreciably higher than the rate of accumulation of the radicals (XI), which shows that, apart from the elimination of the CO group, the primary radicals derived from o-chloranil participate also in other destruction processes. However, the activation energies for the destruction of the radicals (X) and the accumulation of the radicals (XI) proved to be approximately identical. The overall expression for the rate constant for



the transformaton of the primary radical (X) into the secondary radical (XI), determined from the curve for the accumulation of the secondary radical (XI), is

$$k(s^{-1}) = 5 \cdot 10^{8} \exp[-(7600 \pm 1000)/RT]$$

Triethyl phosphite (TEP) exerts a significant influence on the stability of the primary radicals. The photolysis of $M_2(CO)_{10}$ in the presence of 3,6-di-t-butyl-*o*-benzoquinone with added TEP leads to the appearance of a primary radical to which the structure (XII) was attributed (Table 1), with an asymmetric distribution of the unpaired electron density in the catechol ligand (this is indicated by the difference between the HFC constants for the ring protons) and with additional hyperfine coupling with the ^{31}P nucleus. The rate of conversion ($k = 0.0013\ s^{-1}$) of the radical (XII) into the secondary radical (XIII), characterised by the equivalent HFC constants for the ring protons and the much higher HFC constant due to the coupling with the ^{31}P nucleus, is appreciably lower than the rate of conversion of the radical (VIII) into the radical (IX) at −20 °C presented above[23].

After prolonged illumination of the reaction mixture in an excess of TEP, yet another CO group is substituted by a TEP molecule in the coordination sphere of manganese, and the radical (XIV), whose spectroscopic characteristics are listed in Table 1, is generated[23].

The large difference between the destruction constants of the primary radicals as a function of the structure of the ligands at the manganese atoms shows that the rate-limiting stage of the process is apparently intramolecular attack on the central manganese atom by the univalent oxygen atom of the catechol ligand. The electron-accepting properties of the ligand and the electron-donating properties of the manganese-containing fragment play an important role in this process:

The primary rhenium complexes (XV) and the secondary rhenium complexes (XVI), formed in the photochemical reacton of 3,6-di-t-butyl-*o*-benzoquinone with $Re_2(CO)_{10}$, have a much greater line width in the EPR spectra, in contrast to the analogous manganese-containing complexes, which leads in some cases to the blurring of the proton hyperfine structure. In the transition from (XV) to (XVI) a sharp increase of the constants for the hyperfine coupling with the ^{185}Re, ^{187}Re nuclei is observed (see Table 1).[23] It follows from Table 1 that the substitution of the CO group by a TEP molecule leads to an appreciable shift of the unpaired electron density from the *o*-quinone ligand to the manganese, rhenium, and phosphorus atoms.

Analysis of the EPR spectrum of the radical (VIII) demonstrates unambiguously the asymmetric addition of the *o*-quinone ligand to $\dot{M}n(CO)_5$. However, it is difficult to estimate the polarity of the bond between the ligand and $\dot{M}n(CO)_5$ from the difference $a_{H(4)} - a_{H(5)}$. To solve this problem, a study was made[20] of the electronic absorption spectra of the test complexes. Fig.2 illustrates the electronic absorption spectra of the manganese complexes (VIII), (IX), (XIII), and (XIV) in pentane. On heating from −100° to 20 °C, it is possible to observe a successive decrease of the intensity of the bands of (VIII) and an increase of the band of (IX). An analogous behaviour has been observed also in the transformation of the rhenium complexes. Table 2 presents the spectroscopic data for the complexes investigated. In the spectra of the complexes (VIII) and (XV), the primary complexes of manganese and rhenium, there are two absorption bands in the visible region: near 600 nm and a more intense band in the range 400–500 nm. The spectra of the complexes (IX) and (XVI), the secondary complexes of manganese and rhenium, contain one band in the visible region. A band in the ultraviolet region with $\lambda_{max} \approx$ 300 nm has been observed in the spectrum of a rhenium complex of type (XVI) with the 3,5-di-t-butyl-1,2-dihydroxybenzene ligand. The extinction coefficients of such complexes, determined by Gerber and Wan[21], amount to $\sim 10^3$ litre mole^{-1} cm^{-1}.

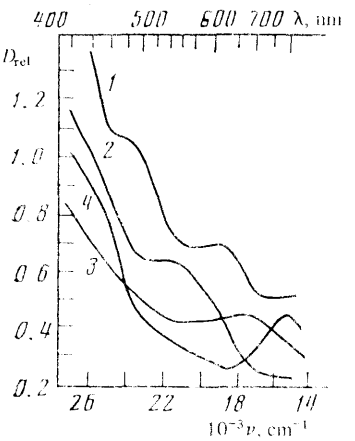


Figure 2. Electronic absorption spectra of manganese complexes in pentane: *1*) (VIII) at −100 °C; *2*) (IX) at 20 °C; *3*) (XIII) at −150 °C; *4*) (XIV) at 20 °C.

Table 2. The frequencies of the π–π* transitions in the electronic absorption spectra of the *o*-semiquinone complexes of manganese and rhenium carbonyls[20].

Notation: Q = 

Successive substitution of two CO groups in the complex (IX) by two TEP molecules[22,23] leads to a strong bathochromic shift of the band at 540 nm (Fig.2). When the reaction is carried out at temperatures between −20° and −15 °C, a band, corresponding to the complex (XIV), appears at 670 nm. On further heating, the 670 nm band disappears.

and a new band with λ_{max} = 800 nm appears; when the reaction is carried out at room temperature, this band appears at once. After the measurement of the spectra of (IX) and (XIV), part of the soluton was transferred to a tube for the investigation of the EPR spectra. The signal splittings due to the interaction with the nuclei of hydrogen, manganese, and phosphorus atoms, observed in the EPR spectra[22,23], confirm the assignment of the bands in the electronic spectra to species having the corresponding structure. Analogous shifts of the long-wavelength absorption band on substitution of the CO groups by TEP take place in the corresponding rhenium complexes (XVI). A bathochromic shift is observed also in the spectra of the complex (VIII) in the presence of tributylamine, which indicates the substitution of the CO group by an amine molecule.

The similarity of the spectroscopic characteristics of the manganese and rhenium complexes (VIII) and (XV) and the complexes (IX) and (XVI) is associated with the similarity of their structures and the fact that the chromophore responsible for their absorption in the visible region is an *o*-semiquinone ligand. Although the electronic absorption spectra of certain *o*-semiquinone radical-anions had been obtained earlier[24-26], the influence of coordination on the positions of the absorption bands had not been investigated. In order to consider the spectra of the manganese and rhenium complexes, a study was made of the influence of the coordination of the Na^+ cation and the *o*-semiquinone ligand on the spectrum of the corresponding sodium *o*-semiquinolate (O^-Na^+) in tetrahydrofuran (THF) and the electronic absorption spectrum of the radical (XVII), in which the catechol ligands are bound covalently to the central carbon atom, was measured:

(XVII)

Fig. 3 illustrates the spectra of Q^-Na^+ at 70° and −70 °C. At −70 °C the 770 nm band shows a shoulder at 660 nm, which disappears on heating and reappears on cooling. According to Prokof'ev[27], the fraction of contact ion pairs in THF increases with decrease of temperature (ΔH = 1.7 ± 0.2 kcal mol^{-1}) and for this reason we assigned the shoulder at 660 nm to two contact ion pairs. Thus the coordination of the ions in Q^-Na^+ leads to an appreciable hypsochromic shift and an increased time of contact between this complex and a sodium mirror results in the decolorisation of the solution associated with the formation of a diamagnetic dianion. The spectrum of the dianion has a single absorption maximum at 305 nm. For comparison, we shall indicate the positions of the absorption band maxima of the corresponding catechol derivative (270 nm) and the orthocarbonic ester of catechol, which is a precursor of the radical (XVII) (270 nm). When air is admitted into the cuvette containing the dianion, the characteristic blue colour of the radical-anion reappears and its spectrum is measured.

The electronic spectrum of the radical (XVII), obtained by oxidising the corresponding phenol with lead dioxide, contains a band with λ_{max} = 400 nm, on which there are two shoulders, at 380 and 420 nm.[20] It follows from these data that, in the presence of a covalent bond at the second oxygen atom, a larger hypsochromic shift of the absorption bands is observed in the spectrum of the radical than that of the bands due to the *o*-semiquinone radical-anion. Comparison of the spectra of the complexes (VIII) and (IX), on the one hand, and those of (XV) and (XVI), on the other, with the spectra of Q^-Na^+ (Fig. 3) demonstrates a great similarity both in the positions of the bands and their intensities. Such similarity indicates a high polarity of the metal–oxygen bond and that the ligand is present in the radical-anionic form[28].

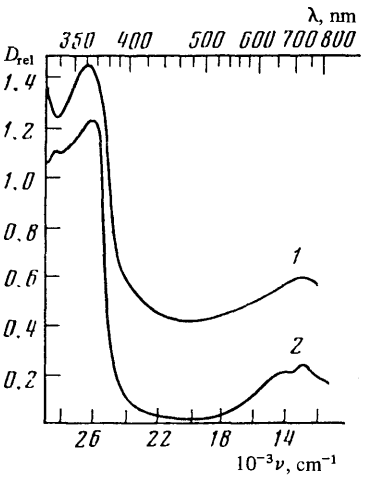

Figure 3. Electronic spectra of the radical-anion $Q^-(Na^+)$ in THF at 70 °C (curve *1*) and −70 °C (curve *2*).[20]

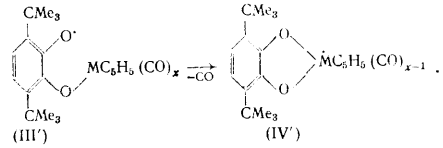
The involvement of the second oxygen atom in the bond with the metal in the complexes (VIII) and (XVI) leads to an appreciable hypsochromic shift of the bands in the absorption spectrum, which may be associated with a definite contribution of a covalent chelate structure, arising as a result of the effective exchange interaction between the d_{xz} and d_{yz} orbitals of the metal and the π electrons of the ligand[20].

2. The EPR Spectra of the *o*-Quinone Complexes of Iron, Molybdenum, and Tungsten Metallocenes

The substitution of the CO groups in iron, molybdenum, and tungsten carbonyls by the cyclopentadienyl ligand leads to an alteration of the even number of *d* electrons of the metal to an odd number, which results in the possibility of the formation of dinuclear complexes. It is believed that the cyclpentadienyl ligand in the dimeric complex $[Mo(CO)_3 . \pi\text{-}C_5H_5]_2$ has a negative charge, is a donor of three electron pairs, and occupies three coordination sites, the molybdenum atom having a formal +1 oxidation state and a coordination number of 7.[29] The photolysis of such dimers leads to the appearance of the corresponding metal-centered radicals, which react with *o*-quinones to form paramagnetic complexes[30].

The EPR spectra of the paramagnetic complexes arising on photolysis of $Fe_2(\pi\text{-}C_5H_5)_2(CO)_4$, $Mo_2(\pi\text{-}C_5H_5)_2(CO)_6$, and $W_2(\pi\text{-}C_5H_5)_2(CO)_6$ in the presence of 3,6-di-t-butyl-*o*-benzoquinone, 3,5-di-t-butyl-*o*-benzoquinone, and *o*-chloranil (3,6-Q, 3,5-Q, and Cl_4Q respectively) have been investigated[43]. The primary paramagnetic products detected in the temperature range −100° to −60 °C in a 2 : 1 pentane–toluene mixture have spectra whose common feature is an asymmetric distribution of spin density in the *o*-quinone ligand [$a_{H(4)} \neq a_{H(5)}$], which reflects the non-equivalent involvement of the oxygen atoms in the formation of a bond



between the ligand and the metal. The HFC constants and the g-factors are listed in Table 3.

Table 3. Parameters of the EPR spectra of the adducts of $FeC_5H_5(CO)_3$ and $WC_5H_5(CO)_3$ with o-quinones[43].

(XIX) (Cl$_4$Q)$_2$MoC$_5$H$_5$	—	—	38.8	1.965	1.991	1.976	1.941
(XIX) 3,6-Q(Cl$_4$Q)MoC$_5$H$_5$	—	—	—	—	1.990	1.975	1.945
(III′) 3,6-QWC$_5$H$_5$(CO)$_3$	6.9	0.8	—	1.999	—	—	—
(III′) 3,5-QWC$_5$H$_5$(CO)$_3$	—	3.8	—	2.001	—	—	—
(XIX) (3,6-Q)$_2$WC$_5$X$_5$	—	—	72.5	1.902	1.960	1.912	1.842
(XIX) 3,6-Q(Cl$_4$Q)WC$_5$H$_5$	—	—	—	—	1.960	1.923	1.824

Note: 3,6-Q = 3,6-di-t-butyl-1,2-dihydroxybenzene ligand; 3,5-Q = 3,5-di-t-butyl-1,2-dihydroxybenzene ligand; Cl$_4$Q = o-chloranil ligand. Compexes of type (III′) all have the structure of phenoxy-radicals, while complexes of type (IV′) have chelate structures with the predominant localisation of the unpaired electron at the metal atom (see text).

In contrast to the complexes of manganese and rhenium pentacarbonyls, the ligand-centered free radicals considered in this section are converted into new metal-centered free radicals (Table 3):

In the case of molybdenum and tungsten, the metal-centered free radicals undergo further changes associated with the substitution of the CO groups by the o-quinone.[43]

The EPR spectra of the liquid and solid solutions of the metal-centered free radicals are presented in Figs.4–6. The change in the g-factor in solution relative to its value for the free electron, the strong anisotropy of the g-factor and the absence of an appreciable hyperfine coupling with the hydrogen atoms of the ligands in solution show that the unpaired electron occupies the 3d(Fe), 4d(Mo), and 5d(W) orbitals of the corresponding metal atoms. Analysis of the EPR spectra of the solid solutions shows that the paramagnetic species are characterised by an overall spin $S = 1/2$ in all cases.

In the radicals of the type $\dot{M}(C_5H_5)(CO)_x$ the iron, molybdenum, and tungsten atoms should have the $3d^7$, $4d^5$, and $5d^5$ configurations respectively. The number of d electrons of the metal atom in the complex depends on the degree of

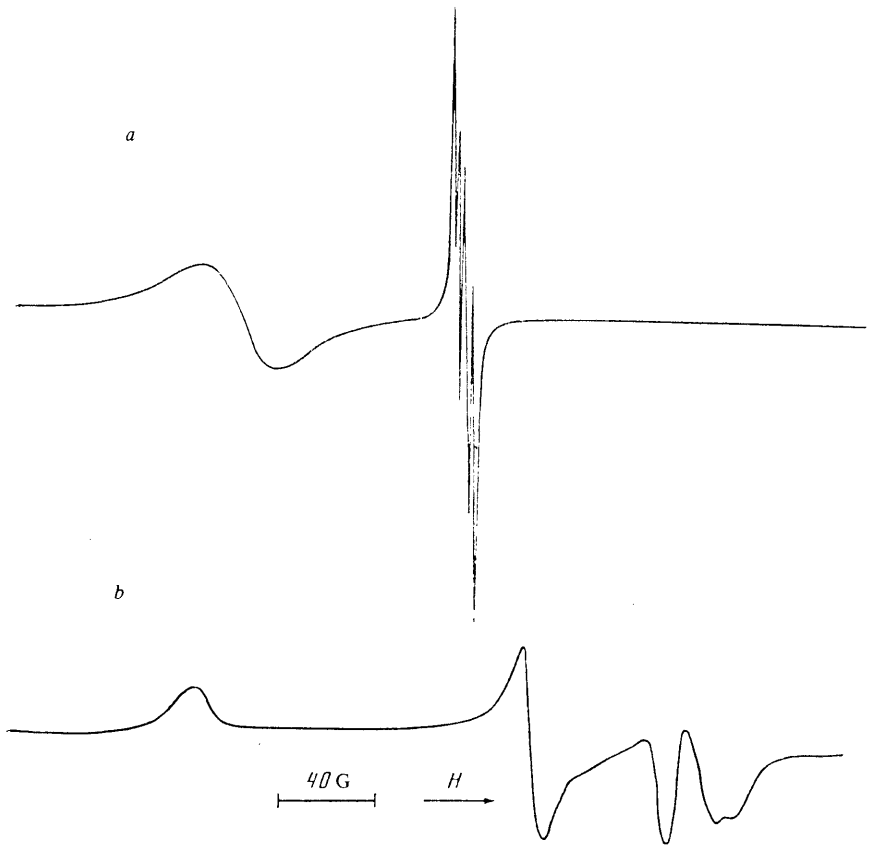

Figure 4. EPR spectra of 3,6-QFeC$_6$H$_5$CO: a) solution, −75 °C; b) solid solution, 155 °C.[43]

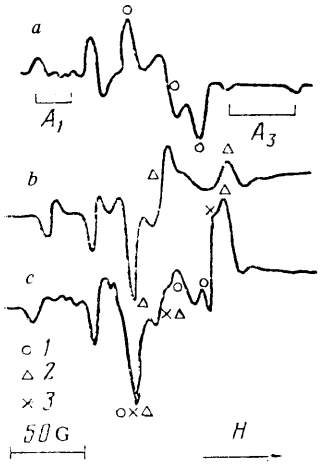
its oxidation by the *o*-quinone ligands. Depending on the degree of reduction of the *o*-semiquinone ligand (from semiquinone to the catecholate), the metal atom loses one or two electrons. When metal-centered free radicals are formed from $\dot{M}(C_5H_5)(CO)_x$ and *o*-quinones, a bond should be formed either by two electrons of the catecholate anion or by the unshared electron pairs of the oxygen atoms of the carbonyl groups in the non-reduced form of the quinone. The nature of the bond between the *o*-quinone ligands and metals has been investigated by X-ray diffraction[31,32].



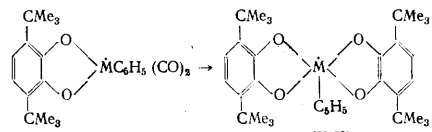


Figure 5. EPR spectra of solid solutions of molybdenum complexes: *a*) $(3,6\text{-Q})_2\dot{M}oC_5H_5$, −150 °C (*1*); *b*) $(Cl_4Q)_2.\dot{M}oC_5H_5$, −155 °C (*2*); *c*) mixture of $(3,6\text{-Q})_2\dot{M}oC_5H_5$ (*1*), $(Cl_4Q)_2MoC_5H_5$ (*2*), and $3,6\text{-QCl}_4\text{Q}\dot{M}oC_5H_5$ (*3*), −150 °C, 3,6-Q/Cl_4Q = 1; A_1 and A_3 are the components of the tensor of the hyperfine coupling with the ^{95}Mo(^{97}Mo) nuclei[43].

For the iron complexes, it is necessary to make a choice between the $3d^7$ and $3d^5$ electronic structures. For the $3d^7$ configuration, the non-reduced *o*-quinone is coordinated, while in the case of the $3d^5$ configuration the complex should have a catecholate linkage. According to Buchanan et al.[31], in the tris-*o*-quinone complexes of iron, all the ligands are reduced to the semiquinone state only. On the basis of these data, one can postulate that in the metal-centered complexes of 3,6-Q and 3,5-Q with $Fe(C_5H_5)(CO)_2$ the non-reduced form of the *o*-quinone is coordinated. It is of interest that the replacement of 3,6-Q and 3,5-Q by *o*-chloranil (Cl_4Q), which has more pronounced electron-accepting properties, leads solely to ligand-centered radicals characterised by a *g*-factor close to 2. Comparison of the spectra illustrated in Fig.6 with EPR spectra of arenecyclopentadienyliron,[33] in which the iron atom has the $3d^7a_{1g}^2e_{2g}^4.e^{*1}_{1g}$ configuration (d_{xz} and d_{yz} are the orbitals of the unpaired electron) demonstrates the similarity of the *g*-factors and of the degrees of their anisotropy. It may be that the presence of the cyclopentadienyl ligand in these two different complexes is responsible also for the analogous disposition of the *d* levels[33].

More complex reactions are observed for the molybdenum and tungsten complexes. The primary ligand-centered radicals are converted into metal-centered radicals of two types: the first has the structure (XVIII) and the second has the structure (XIX) (see Table 3):[43]

The radicals of type (XVIII) are unstable and are converted into the radicals (XIX) in the presence of an *o*-quinone. Complexes of type (XVIII) are characterised by $g < 2$, but the deviations from 2 are not as great as in complexes of type (XIX); the *g*-factor for the complex (XVIII) (M = Mo) is almost isotropic. The spectrum of this radical is characterised[43] by an HFC constant of 15.6 G corresponding to coupling with the ^{95}Mo(^{97}Mo)nuclei ($I = 5/2$) and with two protons of the catechol ligand. We may note the small (~1 G) splitting by the protons compared with the splitting of 3.5 G characteristic of the corresponding *o*-semiquinolates.

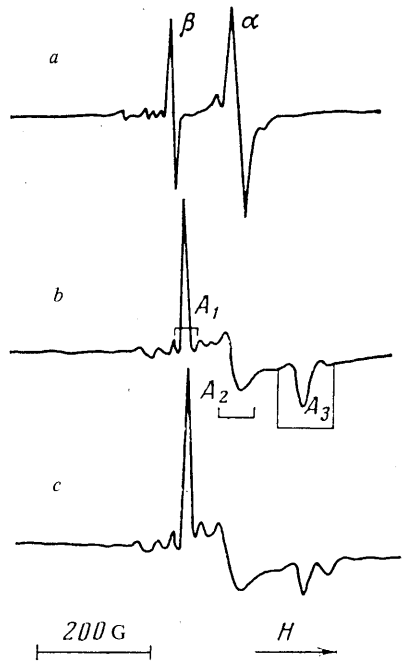

Figure 6. EPR spectra of tungsten complexes: *a*) $(3,6\text{-Q})_2.\dot{W}C_5H_5$ (α, the satellite lines due to ^{183}W are visible) at −20 °C (*1*) and $(3,6\text{-Q})_2\dot{M}oC_5H_5$ (β) present in solution as a consequence of a slight admixture of $Mo_2(C_5H_5)_2(CO)_6$ in the initial dimer $W_2(C_2H_5)_2(CO)_6$; *b*) $(3,6\text{-Q})_2\dot{W}C_5H_5$, −155 °C ($A_1$, A_2, and A_3 are the components of the tensor of the hyperfine coupling with the ^{183}W nuclei); *c*) mixture of $(3,6\text{-Q})_2WC_5H_5$ (*1*) and $3,6\text{-QCl}_4\text{Q}WC_5H_5$ (*2*), −155 °C.[43]

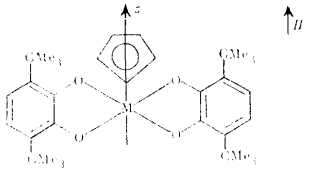
It is so far difficult to put forward a mechanism for the transfer of spin density from the metal atom and to estimate its value in the *o*-quinone ligand. One can only claim that in the secondary molybdenum complex there is one *o*-quinone ligand symmetrically attached to the molybdenum atom. The substitution of the remaining two CO groups in the radical (XVIII) (M = Mo) by the *o*-quinone ligand decreases the average *g*-factor and leads to the appearance of a considerable anisotropy of the latter (see Fig.5 and Table 3) and to an increase of the constant for hyperfine coupling with the ^{95}Mo(^{97}Mo)nuclei.[43]

The factors g_2 and g_3 proved to be sensitive to the structure of *o*-quinone following the replacement of 3,6-Q and 3,5-Q by Cl_4Q^-. The presence of two molecules of the *o*-quinone ligand in the complex (XIX) has been confirmed by the formation of mixed complexes. The interaction of $Mo(C_5H_5)(CO)_3$ with a mixture of 3,6-Q and *o*-chloranil produces, together with $(3,6\text{-Q})_2Mo(C_5H_5)$, also the complexes $(Cl_4Q)_2Mo(C_5H_5)$ and $(3,6\text{-Q})(Cl_4Q^-)Mo(C_5H_5)$.[43] The formation of $(3,6\text{-Q})(Cl_4Q)Mo(C_5H_5)$ was inferred from the appearance of a new line characterised by a value of g_3 different from that for the individual complexes of 3,6-Q and Cl_4Q. The relative intensities of the signals of the individual and mixed complexes depend on the ratio of the *o*-quinones 3,6-Q and Cl_4Q. The value of g_3 for the mixed complex is approximately equal to its average value for the individual complexes[43].

An analogous behaviour has been observed in the study of tungsten-containing complexes. The metal-centered radical (XVIII) is less stable and does not accumulate at high concentrations, being rapidly converted into the radical (XIX). The spectra of the tungsten complexes (XIX) exhibit larger shifts of the *g*-factor and a higher degree of anisotropy of the latter compared with the molybdenum complexes, possibly as a consequence of the larger spin-orbital coupling constant[34]. The interaction with a mixture of 3,6-Q and Cl_4Q results in the formation of mixed complexes characterised by smaller values of g_3 than for the 3,6-Q complex; the individual complex (XIX) with Cl_4Q is not formed. The parameters of the spin-Hamiltonian for the molybdenum complex (XIX) are close to the analogous parameters of the inorganic oxo-complexes described in the literature[35]. In the complexes $MoOX_4Y$ the molybdenum atom is located in the same plane as the ligands X_4; the complex has the C_{4v} symmetry, which is reflected by the axial symmetry of the *g*-factor, persisting even in mixed complexes of the type $MoOX_{4-i}Y_{i+1}$.[35] Presumably the absence of axial symmetry in the complexes investigated is associated, on the one hand, with the presence of the cyclopentadienyl ligand and, on the other hand, with the absence of the C_{4v} symmetry in the disposition of the oxygen atom relative to the $Mo-C_5H_5$ bond.

The electronic structure $4d^1$, with localisation of the unpaired electron in the d_{xy} orbital lying in the plane of the ligand X_4, is characteristic of the oxomolybdenum(V) complexes. The parameters of the spin-Hamiltonian of the oxo-complexes are extremely sensitive to the substitution of the ligand X_4.[35] In the oxo-complexes of *o*-quinones there is a catecholate linkage with the molybdenum(VI) atom[36]. All these factors suggest that the electronic configuration $4d^1$, with localisation of the unpaired electron in the d_{xy} orbital, is characteristic of the complex $Q_2MoC_2H_5$. An analogous hypothesis can apparently be put forward also for the tungsten complex in view of the similarity of the EPR spectra.



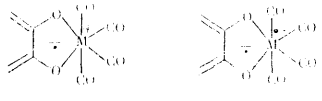
This hypothesis is confirmed by the analysis of the anisotropy of the *g*-factor and the anisotropic component of the HFC constant for the molybdenum and tungsten complexes. Having adopted the $4d^1$ state of the unpaired electron (the d_{xy} orbital) as the ground state and having neglected the delocalisation of the unpaired electron density over the ligand, we obtain the following expressions:

$$g_z = 2 - \frac{8\xi_M}{E_{d_{x^2-y^2}} - E_{d_{xy}}};\quad g_x = 2 - \frac{2\xi_M}{E_{d_{xz}} - E_{d_{xy}}};\quad g_y = 2 - \frac{2\xi_M}{E_{d_{yz}} - E_{d_{xy}}}.$$

Hence it follows that most probably $g_z = g_3$.

It follows from Figs.5 and 6 that there is no axial symmetry of the anisotropic hyperfine coupling either. The values $A_1 = 41$ G, $A_2 = 60$ G, and $A_3 = 112.5$ G for the tungsten complex (XIX) ($I^{183}W = 1/2$) can be determined from the EPR spectrum of a frozen solution, illustrated in Fig.6*b*. The value $\bar{A} = (A_1 + A_2 + A_3)/3 = 71.2$ G is close to $A_{iso} = 72.5$ G determined from the spectrum of the solution (Fig.6*a*). The values $A_1 = 66.0$ G and $A_3 = 65.0$ G for the complex $(3,6\text{-Q})_2MoC_5H_5$ can be determined from the spectrum; $A_2 = 113.0$ G has been calculated from the relation $A_{iso} = (A_1 + A_2 + A_3)/3$.

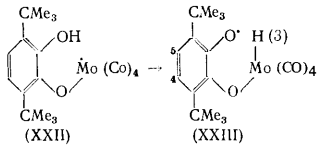
The dipole–dipole components of the HFC constant (A^P) can be determined from these data. For the molybdenum complex, we have $A_1^P = -2.0$ G, $A_2^P = 25.0$ G, and $A_3^P = 27.0$ G, while for the tungsten complexes the corresponding values are −31.5, −12.5, and 40.0 G. The identical signs of A_3^P and A_{iso}^P are consistent with the fact that the unpaired electron occupies the d_{xy} orbitals and the values of g_3 and A_3 correspond to the orientation of the *z* axis parallel to the external magnetic field[36].



On the basis of the above considerations concerning the electronic structure of the molybdenum and tungsten complexes of type (XIX), one can postulate that complexes of type (XVIII) should also have the $4d^3$ and $5d^3$ configurations.

Transition metal complexes with *o*-quinone ligands can be obtained by the photochemical reaction of *o*-quinones with metal carbonyls. The photolysis of $Mo(CO)_6$ in the presence of 3,5-di-t-butyl-*o*-quinone, *o*-chloranil, and phenanthrenequinone yields complexes of different compositions[4,14]. The compositions were established by X-ray diffraction and were found to be represented by the formulae $\{MoO[O_2C_6H_2\cdot(t\text{-Bu})_2]_2\}_2$ for 3,5-di-t-butyl-*o*-quinone,[36] $Mo(O_2C_6Cl_4)_3]_2$ for *o*-chloranil,[37] and $(PhenQ)_2Mo_2O_5(PhenQ)_2$ for phenanthrenequinone.[38]

There is at present not only no clear-cut idea about the mechanism of these reactions and about the dependence of the final products on the nature of the *o*-quinone but even the source of the oxygen atoms of the oxomolybdenum group is not known exactly. Although $MoO[O_2C_6H_2(t\text{-Bu})_2]_2$ was synthesised in an N_2 atmosphere, the possible role of the presence of traces of oxygen in the formation of the main reaction product has been assumed[36]. The application of the EPR method to the study of the reaction mechanism did not yield an umambiguous answer to the question of the structure of the paramagnetic species detected and of their role in the formation of the final diamagnetic products[4,28].

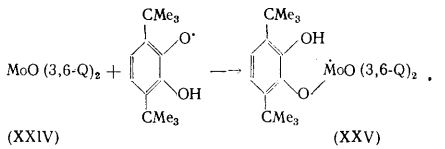


On the basis of the analysis of the EPR spectra of the semiquinone species arising in the photolysis of tungsten and molybdenum hexacarbonyls in the presence of phenanthrenequinone, formula (XX) was attributed to these species.

(XX) (XXI)

Here the metal is in the +1 oxidation state[28]. Since the unpaired electron of the ligand in compounds of type (XX) arises as a result of electron transfer from a metal atom having an odd number of electrons, in reality the metal atom should also carry an unpaired electron and the system as a whole should have a biradical character; formula (XXI) corresponds to this situation.

The reaction between $Mo(CO)_6$ and 3,6-di-t-butyl-*o*-quinone (3,6-Q) in pentane under vacuum conditions on irradiation with the light of a mercury lamp at room temperature is accompanied, as in the study of Weir and Wan[28], by the formation of the *o*-quinone radical-anions without any signs of hyperfine coupling with the molybdenum isotopes. Weir and Wan[28] present some arguments in support of the assignment of the measured spectra to a complex of type (XX) but, in view of the absence of hyperfine coupling with the magnetic molybdenum isotopes, this assignment cannot be regarded as unambiguous. When the above reaction is carried out at low temperatures, species whose EPR spectra are characterised by the following HFC constants are formed: $a_{H(3)}$ = 0.16 G, $a_{H(4)}$ = 3.8 G, $a_{H(5)}$ = 3.0 G, and a_{Mo} = 1.9 G.[54] The low constants for hyperfine coupling with one of the protons in the ^{95}Mo and ^{97}Mo isotopes enabled Sarbasov et al.[54] to propose the oxygen-centered structure (XXIII) for the species formed. The small difference between the constants for the hyperfine coupling with the protons in the fourth and fifth-positions of the aromatic ring shows that the bond between the central molybdenum atom and oxygen is polar under these conditions:



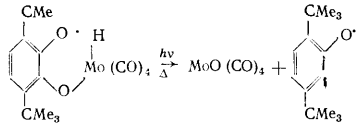
The formation of the radical (XXIII) should apparently be preceded by the formation of the metal-centered radical (XXII). The formation of these radicals is probably associated with the involvement of the semiquinone radical, functioning as a monodentate ligand. The participation of the semiquinone radical in the reaction is indicated by the increase of the concentration of the radicals (XXIII) when hydroquinone is added to the system.

Thus the reaction of the photoexcited quinone with hydrogen atom donors must be added to the primary photochemical step in the formation of the complexes, consisting in the elimination of the CO group from $Mo(CO)_6$.[28,29] After prolonged photolysis (~30 min) at a low temperature, a paramagnetic complex, in which the unpaired electron is localised at the molybdenum atom, accumulates gradually together with the unstable radical (XXIII).[54] When the reaction is carried out at room temperature, the radical (XXIII) is not formed at a concentration sufficiently high for measurement, but an increase of temperature does not affect the formation of the molybdenum-centered free radical. This radical is stable at room temperature *in vacuo* but disappears when oxygen is admitted into the tube.

The identification of the paramagnetic complex described as a molybdenum-centered free radical is based on the following spectroscopic data: the appreciable difference of the *g*-factor from 2, the appreciable anisotropy of the *g*-factor, and the large constants for splitting by the Mo nuclei[54].

According to the results of chemical analysis[36], one can postulate the formation of mainly the diamagnetic product $MoO[O_2C_6H_2(t\text{-}Bu)_2]_2$. The presence of the M=O bond in the photolysis product follows from the formation of the paramagnetic complex when the reaction mixture is treated with HCl,[54] because the *g*-factor and the HFC constant for the complex formed are fully consistent with the known values for $MoOCl_5$.[35] The similarity of the spectral parameters of the radicals listed in Table 4 is striking. On this basis, one can suggest that these spectra correspond to radicals arising via the reaction[54]

The interaction of (XXIV) and (XXV) with HCl leads to the formation of $MoOCl_5$.



It follows from Table 4 that the parameters of the EPR spectra depend on the solvent and on the structure of the *o*-quinone. The influence of THF is evidently associated with complex formation.

Table 4. The *g*-factors and the constants for the hyperfine coupling with the molybdenum nucleus in the hydroxy-molybdenum complexes of *o*-quinones[54].

Complex	a_{Mo}, G	$\bar{g}$	g_1	g_2	g_3
(XXV) in THF*	46.5	1.953	1.985	1.945	1.945
(XXV) in pentane	51.9	1.939	1.961	1.940	1.917
$MoOCl_5$ in THF	51.9	1.946	1.968	1.942	1.942

*Axial symmetry.

It follows from the analysis of the X-ray diffraction data that the *o*-quinone ligand in $(MoOQ_2)_2$ [36] accepts two electrons from the metal atom and is a catecholate dianion. The source of the oxygen atoms in the oxomolybdenum group remains unelucidated. The formation of the M–O bond *in vacuo* suggests that the source of the oxygen atoms is some kind of complex of the *o*-quinone whose cleavage gives rise to the M=O bond, for example:

The photolysis of $Mo(CO)_6$ in toluene in the presence of di-t-butyl peroxide also leads to the appearance of a signal with a slightly anisotropic *g*-factor (g = 1.931), tentatively identified as $t\text{-}BuOMo(CO)_4$.

3. The Electronic Structure of the Tris-3,6-di-t-butyl-*o*-quinone Complexes of Chromium

Numerous studies have now been devoted to the tris-*o*-quinone complexes of chromium[4,39]. They are believed to be the closest analogues of the bacterial iron complex of the siderphore enterobactin[40]. There is so far no unanimous view concerning the electronic structure of these complexes. On the basis of the analysis of the X-ray diffraction data for the tris-3,5-di-t-butyl-*o*-quinone complex of chromium, Downs et al.[41] concluded that the Cr^{3+} ion is coordinated to three semiquinone ligands. After analysing the same data, Sofen et al.[39] concluded that the Cr^{3+} ion is coordinated to non-reduced *o*-quinone molecules. The difference between the studies of Downs et al.[41] and Sofen et al.[39] is associated with the fact that the former authors estimated the degree of reduction of the ligand from the length of the C–O bond,

while the latter estimated it from the length of the C–C bonds in the ring. According to polarographic data, the complexes should reversibly accept and give up six electrons[39,41]. The electronic absorption spectra of the tris-3,5-di-t-butyl-*o*-quinone complex of chromium and of its mono-, di-, and tri-anions in the visible region have been recorded[39].

The EPR spectra of the radical-cations and radical-anions exhibit a surprising similarity, which is manifested in the similarity of the constants for hyperfine coupling with the ^{53}Cr nuclei and of the *g*-factors.[55] The appreciable deviation of the *g*-factor from 2.0023 and the large splitting by ^{53}Cr (20–30 G) show that an appreciable fraction of the unpaired electron in the radical-cations and radical-anions is localised at the chromium atom[4,41]. It has been suggested that, on passing from the radical-cation to the radical-anion, the levels of the metal and ligands are inverted, so that in both cases the d_{z^2} orbital of the chromium atom accommodates the unpaired electron[4].

Until recently, there were no data on the distribution of the unpaired electron density among the *o*-quinone ligands, without which the description of the distribution of the spin density is incomplete. Such data have been obtained in a study[55] of the EPR spectra of the radical-cations and radical-anions of the tris-3,6-di-t-butyl-*o*-quinone complexes of chromium. The corresponding radical-cation and radical-anion were obtained by oxidising the tris-3,6-di-t-butyl-*o*-quinone complex of chromium with I_2 and by reducing it with the sodium and potassium salts of n-Bu_4NOH in solution in THF. The radical-cation is reformed on treating the radical-anion with I_2. The reversibility of the reduction has been established by the EPR method and electronic absorption spectroscopy. Figs.7 and 8 present the EPR spectra of the radical-cations and radical-anions of the complexes. The EPR spectrum of the radical-cation is characterised by the following parameters: $g = 1.9689$, $a_{Cr} = 25.5$ G, and $a_H = 0.85$ G.

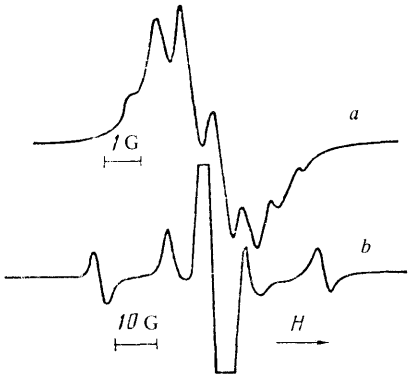


Figure 7. EPR spectrum of the radical-cation $Cr(3,6\text{-}Q)_3^+I^-$ in THF; spectrum *b* was recorded with tenfold amplification relative to spectrum *a*.[55]

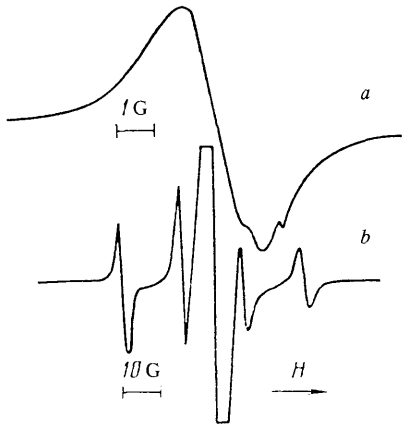
For the semiquinone type of distribution of spin density in the ligand, there is a splitting of 0.85 G which corresponds to a spin density of 0.7 in the three *o*-quinone ligands, since the corresponding splitting in the radical-anion of 3,6-di-t-butyl-*o*-quinone is 3.6 G. This implies that the maximum spin density, amounting to 0.3, corresponds to the chromium atom, while in an individual ligand it amounts to 0.23.

The EPR spectrum of the radical-anion is characterised by the following parameters: $g = 1.9707$, $a_{Cr} = 22.7$ G, and $a_H = 0.85$ G.[55] The main difference between the spectrum of the radical-anion and that of the radical-cation consists in a decrease of the hyperfine coupling with ^{53}Cr and an appreciable increase of the line width. The best resolution is observed in the temperature range from 0° to −20 °C. At these temperatures, one of the wings of the envelope curve in Fig.8 shows clearly three HFS components. Presumably the number of lines is not less than seven, i.e. the unpaired electron density is delocalised over three ligands in the radical-anion, as in the radical-cation. It has been observed that the HFS pattern is independent of the nature of the cation (sodium or potassium).



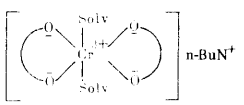


Figure 8. EPR spectrum of the radical-anion $Cr(3,6\text{-}Q)_3^-Na^+$ in THF; spectrum *b* was recorded with twentyfold amplification relative to spectrum *a*.[55]

Thus it follows from the data obtained that the distribution of spin density in the radical-anion is the same as in the radical-cation. Previously it had been assumed that in the paramagnetic chromium complexes the bulk of the unpaired electron density is located at the chromium atom[4]. We can now claim that the bulk of the spin density is in fact located in the ligands and not at the chromium atom.

The EPR spectra of the di-*o*-quinone complexes of chromium in the radical-cationic and radical-anionic forms have also been obtained[55]. These complexes are formed on prolonged treatment of the electrically neutral complex with oxidants and reductants and also as a result of the photochemical reactions of 3,6-di-t-butyl-*o*-quinone with $Cr(CO)_6$. In contrast to the tris-*o*-quinone complexes, the character of the distribution of spin density in the radical-cations and radical-anions of the di-*o*-quinone complexes of chromium is completely different. Five HFS components with a binomial distribution of intensities and the splittings $a_H = 0.85$ G and $a_{^{53}Cr} = 25.5$ G are clearly seen in the EPR spectrum of the radical-cation obtained by the prolonged treatment of $Cr(3,6\text{-}Q)_3$ with I_2. It follows from these data that the spin densities are 0.46 in the two ligands and 0.54 at the chromium atom[55].

After the reduction of $Cr(3,6\text{-}Q)_3$ with n-butyl alcohol, the EPR spectrum of the reaction mixture shows, apart from the signals due to the chromium atoms, $(3,6\text{-}Q)_3^{\bullet-}$, and $(3,6\text{-}Q)^{\bullet-}$, a narrow signal with chromium satellites (a_{Cr} = 16.0 G).[55] The narrow signal is apparently due to the radical-anion $Cr(3,6\text{-}Q)_2^{\bullet-}$, which is formed after the elimination of $(3,6\text{-}Q)^{\bullet-}$ from the initial radical-anion. The absence of hyperfine coupling with the ligand protons indicates the localisation of the unpaired electron at the chromium atom, which led to the assignment of the biscatecholate structure (XXVI) to these species:

(XXVI)

Analysis of the parameters a_{Cr} for the test complexes shows that they are influenced by the spin densities both at the chromium atom and at the oxygen atoms. The radical-cations described above are obtained on photolysis of 3,6-Q and $Cr(CO)_6$. In this case they are formed either under the influence of traces of O_2 or on irradiation[55].

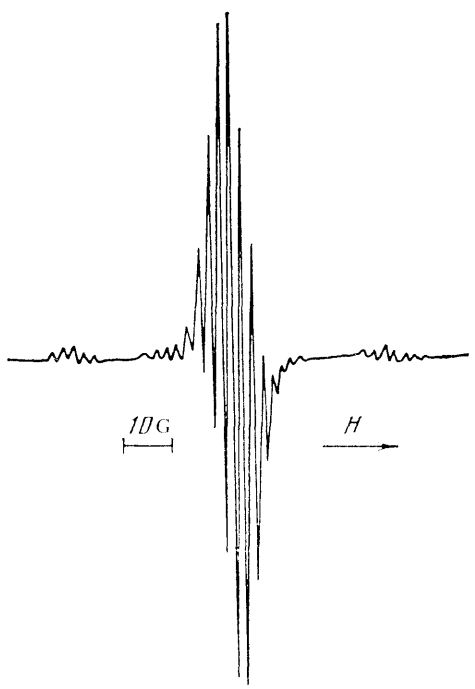

Figure 9. EPR spectrum of the radical cation $Cr(CF_3\text{–}\overset{O}{\overset{\|}{C}}\text{–}\overset{O}{\overset{\|}{C}}\text{–}CF_2CF_3)_2^{+\bullet}$.[42]

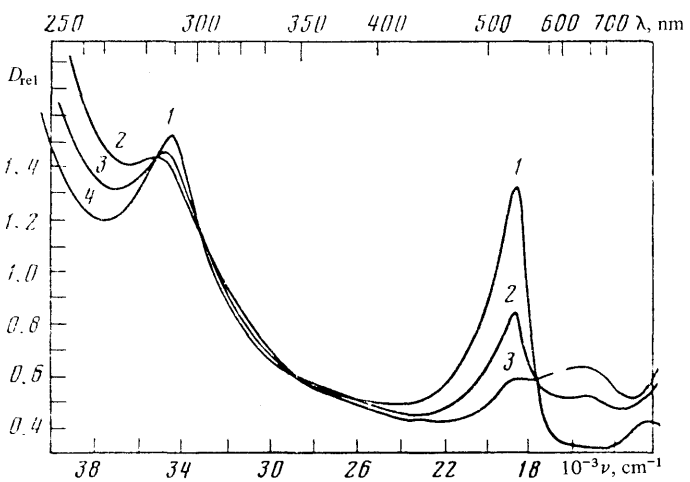
In addition to the tris-3,6-Q complexes of chromium, the di-*o*-quinone complexes of chromium are also formed in coordinating solvents (ether, THF, and alcohol). It is noteworthy that, after the photolysis of a solution of 3,5-Q and $Cr(CO)_6$ in toluene, the EPR spectrum exhibits a HFS corresponding to the three protons of the three *o*-quinone ligands; the splittings are $a_H \cong 1.00$ G and a_{cr} = 26.9 G, while g = 1.9731.[55]

Fig.9 presents the EPR spectrum obtained on photolysis of $CF_3\text{–}\overset{O}{\overset{\|}{C}}\text{–}\overset{O}{\overset{\|}{C}}\text{–}CF_2\text{–}CF_3$ in an α-diketone in the presence of $Cr(CO)_6$. Analysis of the HFS shows that there are two α-diketone ligands in the radical-cation complex (a_F = 2.8 G, a_{cr} = 27 G, and g = 1.9658). The parameter a_F = 8.8 G has been obtained for the corresponding semidione complex of $Mn(CO)_4$, where the unpaired electron is localised in the ligand[42]. It follows from a comparison of these data that 0.6 of the unpaired electron density in the radical-cation complex of chromium corresponds to the two ligands and 0.4 corresponds to the chromium atom. Presumably two coordination sites in the two-ligand complexes are occupied either by CO groups or solvent molecules.

Whereas the distribution of the spin density of the unpaired electron can be inferred from EPR data, the distribution of the charge can be postulated solely on the basis of indirect data. For the purpose of further study of the electronic structure of the complexes, their electronic absorption spectra were obtained. Previously Solodovnikov et al.[20] investigated the influence of coordination on the positions of the absorption bands of the semiquinone chromophore in relation to the carbonylmanganese and carbonylrhenium complexes of 3,6-Q. Comparison of the spectrum of $Cr(3,6\text{-}Q)_3$ with that of $Cr(3,5\text{-}Q)_3$ [39] showed the complete identity of the positions and intensities of the absorption bands in the visible regions: in the ultraviolet region[55], a band was recorded at 290 nm (Fig.10). Comparison of the positions and intensities of the absorption bands in the $Cr(3,6\text{-}Q)_3$ spectrum with the positions and intensities of the absorption bands in the spectra of $(3,6\text{-}Q)^{\bullet-}Na^+$ and $(3,6\text{-}Q)^{\bullet-}\,Mn^+(CO)_4$ [20] as well as other manganese and rhenium complexes leads to the conclusion that the electronic configuration of the complex is much closer to that of $Cr^{3+}(3,6\text{-}Q)_3^{\bullet-}$ than to the configuration of the complex $Cr(3,6\text{-}Q)_3$.[55]



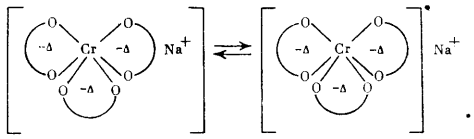


Figure 10. The changes in the electronic absorption spectra of $Cr(3,6\text{-}Q)_3$ during reduction by n-Bu_4NOH in THF: *1*) $Cr(3,6\text{-}Q)_3$; *2*) spectrum corresponding to the intermediate reduction stage; *3*) $Cr(3,6\text{-}Q)_3^{\bullet-}n\text{-}Bu_4N^+$.[55]

The reduction of the complexes *in vacuo* on a sodium mirror leads to a sharp decrease of the intensity of the 525 nm band and to the appearance of new absorption bands

at 520, 575, and 680 nm and a band with $\lambda_{max} > 800$ nm, which can probably be identified, on the basis of the study of Sofen et al.[39], as the 825 nm band. Measurement of the spectra in the course of the reduction of the complex revealed an isosbestic point; the spectrum *3* has been assigned to $Cr(3,6\text{-}Q)_3^{\bar{}}$.[55]

The large number of absorption bands in the spectrum of $Cr(3,6\text{-}Q)_3^{\bar{}}$ is striking. In view of this and also in view of the behaviour of the line width in the EPR spectrum of the complex $Cr(3,6\text{-}Q)_3^{\bar{}}Na^+$, the problem arises as to the form of the distribution of negative charge and spin density and of the influence of the cation on this distribution. In order to solve this problem, the complex was reduced by $n\text{-}Bu_4NOH$ (Fig. 10). The spectrum of $Cr(3,6\text{-}Q)_3^{\bar{}}n\text{-}Bu_4N^+$ differs from that of $Cr(3,6\text{-}Q)_3^{\bar{}}Na^+$ by the absence of the band at 575 nm.

The study of the influence of temperature on the spectrum of $Cr(3,6\text{-}Q)_3^{\bar{}}Na^+$ showed that the intensity of the 575 nm band diminishes appreciably when the temperature is reduced from 50° to −70 °C. This entails some increase of the intensity of the 680 nm band. Presumably the 575 nm absorption band is associated with the formation of a contact pair:

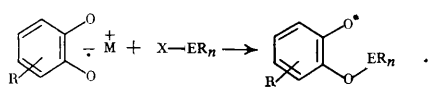
The temperature dependence of the width of the EPR line of the radical-anion may be partly associated both with the presence of this equilibrium and with the migration of Na^+ between the ligands in the contact and solvent-separated ion pairs. The use of $n\text{-}Bu_4N^+$ as the cation does not entail line narrowing. The subsequent reduction of $Cr(3,6\text{-}Q)_3^{\bar{}}Na^+$ on a sodium mirror leads to the disappearance of the 575 and 825 nm bands. The spectrum of $Cr(3,6\text{-}Q)_3^{2-}.2Na^+$ in the visible region consists of two bands at 516 and 720 nm. On reduction with atmospheric oxygen, the spectrum of the dianion gradually disappears and that of the radical-anion reappears; the radical-anion is stable in air for a long time.

The oxidation of the complex by oxidants such as I_2 and $AgBF_4$ is accompanied by a decrease of the intensity of the 525 nm band and the appearance of a new band at 365 nm in the electronic absorption spectra.

The experimental data presented yield a qualitative picture of the electronic structure of $Cr(3,6\text{-}Q)_3$ and its oxidised and reduced forms. We established that the degree of reduction of the ligand in $Cr(3,6\text{-}Q)_3$ is close to that in the semiquinone, while in the radical-cation and the radical-anion most of the spin density (0.7) is located in the ligands. On this basis, one can postulate that the number of electrons in the ligands of the radical-cation should be close to an odd number, for example 2.7; the number 1.7 no longer satisfies this condition. When the negative charge in the ligand is −2.7e, the charge on the chromium atom should be +3.7e. The number of electrons in the ligand of the radical-anion should be 4.7 and the charge on the cation should be +3.7e. Presumably in the electrically neutral complex the same charge of +3.7e on the chromium atom remains and the overall charge of the ligands is −3.7e. According to this picture, the charge on the chromium ion (+3.7e) in the complex does not change on oxidation and reduction.

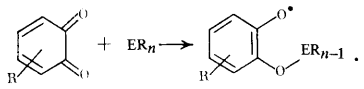
According to the proposed charge distribution in the ion pairs involving the radical-cations and radical-anions, a completely different interaction between the counterions should be observed: in the former case there should be a weak interaction owing to the shielding of the positive charge on the chromium atom by the negatively charged ligands and in the latter case there should be a strong interaction due to the high negative charge on the ligands. The differences between the widths of the EPR lines of the radical-cations and radical-anions, caused by the difference in the dynamics of the redistribution of the spin and charge densities between the ligands and the complex, may be associated with this factor.

In conclusion it is useful to compare the spin density on the chromium atom, which amounts to 0.3, with the spin density in the ligand (0.23). The localisation of the unpaired electron either in the ligand (Mn, Re) [22,23] or at the central metal atom (W, Mo) [43] is characteristic of the majority of the transition metal complexes with semiquinone or catechol ligands investigated hitherto. The similarity of the spin densities on the chromium atom and in one of the ligands indicated above demonstrates the approximately equal involvement of their orbitals in the formation of a bond. Thus one may conclude that the Cr=O bond is highly covalent. It may be that the high degree of covalence of the M−O bond is the cause of the high complex forming capacity of enterobactin towards Fe^{3+} and Cr^{3+}.



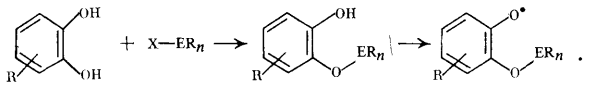
III. THE STEREOCHEMISTRY OF PARAMAGNETIC CHELATE COMPLEXES OF GROUP IV ELEMENTS WITH SEMIQUINONE LIGANDS

Within the framework of the electronic structures (I)–(V), the degree of reduction of the *o*-quinone ligand in the paramagnetic complexes of Group IV elements is −1. The main task of the study is to determine the coordination of the semiquinone ligand and the structure of the complex. Depending on the same variables (M, X, and *n*), not only are different types of coordination observed [structures (III) and (IV)] but also there is a significant variation in the geometrical disposition of the ligands X relative to the central atom M. Whereas the octahedral structure is characteristic of transition metal complexes of *o*-quinones, for the complexes of Group IV elements considerable variety of different types of environment of the central atom is observed. Analysis of the hyperfine coupling of the unpaired electron of the *o*-semiquinone ligand with the magnetic moments of the nuclei of the elements incorporated in the ligand X makes it possible to infer the geometrical disposition of these elements.



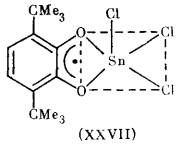
The different dispositions of the ligands relative to the plane (the nodal plane for the π orbitals of the unpaired electron localised in the *o*-semiquinone ligand) formed by the atom M and two oxygen atom is manifested by the equal values of the HFC constants. The non-equivalence of the oxygen atoms in the chelate coordination of the *o*-semiquinone ligand can arise in its turn in structures characterised by a trigonal-bipyramidal geometry of the disposition of the ligands X around the atoms M. This non-equivalence should be manifested by the inequality of the constants for the hyperfine coupling of the unpaired electron with different ring protons of the ligand [for example, $a_{H(4)} \neq a_{H(5)}$ in the case of the 3,6-di-t-butyl-1,2-dihydroxybenzene ligand].

Chelate *o*-semiquinone complexes of Group (IV) elements can be obtained from the following reactions.

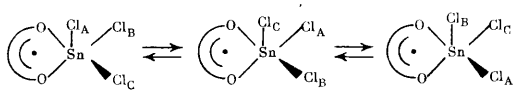


1. The interaction of alkali metal *o*-semiquinolates with organometallic halogeno-derivatives:

2. The interaction of *o*-quinones with organometallic compounds:



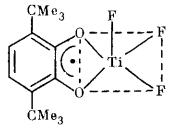
3. The interaction of catechols with halogeno-derivatives and subsequent oxidation of the hindered phenols formed:



1. Pentacoordinate Chelate Complexes

The *o*-benzosemiquinone complex (XXVII) has been obtained by the reaction of tin tetrachloride with 3,6-di-t-butyl-*o*-benzoquinone (3,6-Q) [44] in toluene. Hyperfine coupling with two equivalent protons [$a_{H(4)} = a_{H(5)} = 3.9$ G], one $^{35,37}Cl$ nucleus ($I = 3/2$, $a_{Cl} = 0.6$ G), and the magnetic isotopes ^{117}Sn and ^{119}Sn ($a_{^{117}Sn} = a_{^{119}Sn} = 7.2$ G) has been recorded for this compound at room temperature. The spectroscopic data obtained led to the conclusion that the complex (XXVII) formed has a chelate tetragonal-pyramidal structure (see Fig.11*a*):[44]

(XXVII)



This structure explains why hyperfine coupling with only one chlorine nucleus was recorded: the other two lie near the nodal plane of the π orbital of the unpaired electron and hyperfine coupling with them is not manifested in the spectrum. With increase of temperature in the range 40–80 °C, the HFS lines are broadened due to the coupling with the chlorine nucleus and above 100 °C each component of the proton triplet is split into ten lines (Fig.11*b*) due to the hyperfine coupling with the three equivalent chlorine atoms ($a_{Cl} = 0.3$ G). The temperature-induced changes are fully reversible and indicate the presence of a dynamic effect due to the rotation of the $SnCl_3$ group relative to the plane of the *o*-semiquinone ligand at an elevated temperature. This rotation can be considered from the standpoint of the "tourniquet" mechanism proposed for compounds with a pentacoordinate phosphorus atom[45,46]:

As a result of such rotation, all three chlorine nuclei become equivalent and the constant for hyperfine coupling with the $^{35}Cl(^{37}Cl)$nuclei diminishes by a factor of 2 which is typical for hyperfine coupling with the β-nuclei in free radicals when the unpaired electron is delocalised via a hyperconjugation mechanism. The frequency of rotation in the range 20–50 °C has been estimated and is described by the expression[44]

$$\nu_{wt}(s^{-1}) = 2.4 \cdot 10^{15} \exp[-(13000 \pm 1000)/RT]; \nu_{rot}(20^\circ C) = 6 \cdot 10^5 s^{-1}.$$

The complex (XXVIII), obtained by the interaction of titanium tetrafluoride with 3,6-Q in toluene, has an analogous tetragonal-pyramidal structure[56]. Triplet splitting by two equivalent protons [$a_{H(4)} = a_{H(5)} = 3.8$ G], a doublet due to the ^{19}F nucleus, located outside the nodal plane ($a_{^{19}F} = 4.7$ G), and a narrow triplet due to two fluorine nuclei, located in the vicinity of the nodal plane ($a_F = 0.6$ G) (Fig.12) are recorded in this case.

(XXVIII)

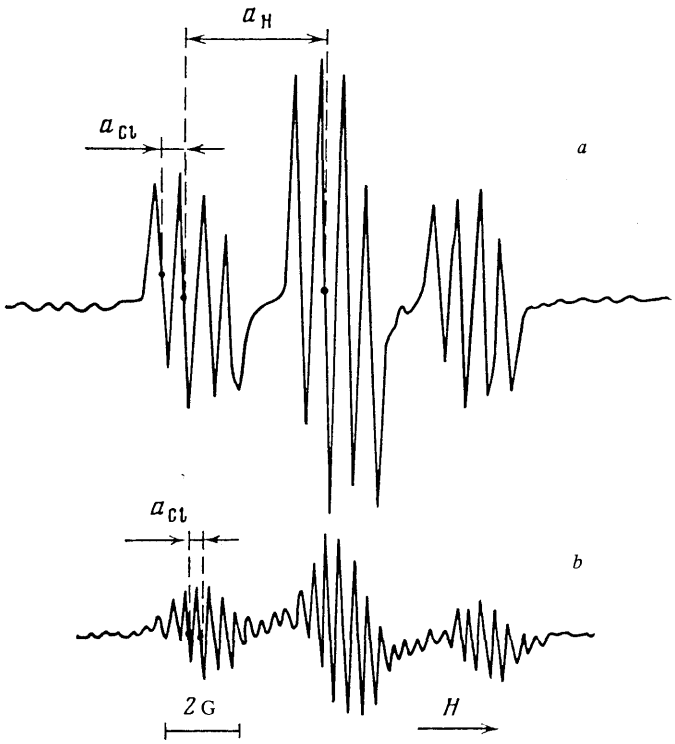


Figure 11. EPR spectrum of the complex (XXVII) in solution in toluene at 0 °C (*a*) and 100 °C (*b*).[44]

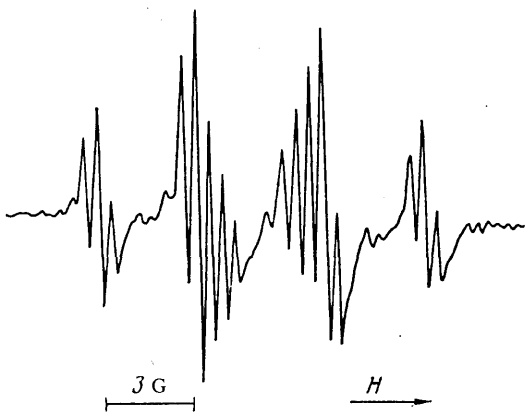

Figure 12. EPR spectrum of the complex (XXVIII) in toluene at 20 °C.[56]

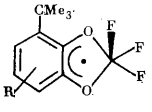
The HFC constants (3.8 G) were assigned to two protons of the *o*-semiquinone ligand on the grounds that their sum [$a_{H(4)} + a_{H(5)} = 7.6$ G] is typical for organoelemental radicals with 3,6-di-t-butyl-1,2-dihydroxybenzene ligands. The greater magnetic moment of the ^{19}F nuclei compared with the $^{35}Cl(^{37}Cl)$ nuclei as well as the small size of the central atom compared with tin are responsible for the higher constants for the hyperfine coupling with these nuclei and also for the detection of the hyperfine coupling with the fluorine nuclei located in the vicinity of the nodal plane in this case. Over the entire temperature range (from -80° to 100 °C), the spectral pattern remains unchanged, which is apparently associated with the low frequencies of rotation of the TiF_3 groups relative to the plane of the catechol ligand[56].

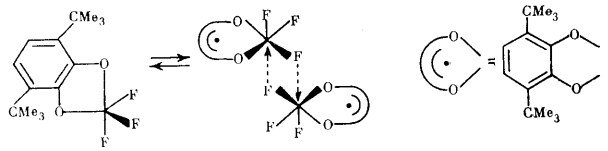


Hyperfine coupling with three nonequivalent nuclei having a spin of 1/2 (the HFC constants are 3.5, 4.2, and 4.9 G) and with the ^{117}Sn and ^{119}Sn nuclei has been recorded in toluene for the 3,6-di-t-butyl-*o*-semiquinone complex containing the SnF_3 group[55]. The HFC constants amounting to 3.5 and 4.2 G were assigned to the protons of the *o*-semiquinone ligand on the basis of their characteristic sum, which is 7.7 G.[47] Correspondingly, the HFC constant equal to 4.9 G was assigned to the ^{19}F nucleus located outside the nodal plane. Since two structures—a tetragonal pyramid and a trigonal bipyramid—are possible for the pentacoordinate tin compounds, the observed non-equivalence of the ring protons can be explained by the distortion of the former structure towards the latter structure with an apical equatorial disposition of the *o*-semiquinone ligand. On the other hand, the non-equivalence of the ring protons in the trigonal bipyramid reflects the non-equivalence of the apical and equatorial E–O bonds[48].

Table 5. The spectroscopic parameters (G) of the radicals (XXIX)–(XXXI) in toluene at 20 °C.[56]

Radical	$a_{H(4)}$	$a_{H(5)}$	a_F^a	a_F^e
(XXIX)	4.2	3.6	0.35 (2)	10.1 (1)
(XXX)	—	3.8	1.0 (2)	9.7 (1)
(XXXI)	—	3.8	—	9.9

Note: the number of fluorine atoms is indicated in brackets. $a_H = 0.4$ G for the hydrogen atoms of the t-butyl groups in the radical (XXX); a_F^a and a_F^e refer respectively to the apical and equatorial positions of the ligand.



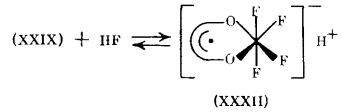
The structure of the trigonal bipyramid with an apical-equatorial disposition of the *o*-semiquinone ligand is characteristic of all the pentacoordinate silicon complexes which we investigated[49]. They were obtained by the reaction of SiF_4 with substituted *o*-quinones in weakly solvating media (toluene, ether). Table 5 presents the spectroscopic parameters for the complexes (XXIX), (XXX), and (XXXI) formed, on the basis of which it was concluded that they have a chelate trigonal-bipyramidal structure[56]:

(XXIX)–(XXXI)

where R = 6-t-butyl (XXIX), 5-t-butyl (XXX), or 5-trityl (XXXI). In this case the non-equivalence of the fluorine atoms is caused by their different steric dispositions relative to the nodal plane of the π orbitals of the unpaired electron. The non-equivalence of the ring protons of the 3,6-di-t-butyl-*o*-semiquinone ligand is caused by the non-equivalence of the apical and equatorial Si–O bonds in the trigonal bipyramid[49].

On reducing the temperature, spectroscopic changes were observed for the 3,6-di-t-butyl-*o*-semiquinone ligand, which can be explained by the association of the radical complexes (XXIX). This resulted in an alteration of the ratio of the constants for the hyperfine coupling with the ^{19}F nucleus and an additional hyperfine coupling (0.2 G), which we assumed to be due to the ^{19}F nucleus of another molecule of the complex, was recorded. The ring protons of the 3,6-di-t-butyl-*o*-semiquinone ligand then become equivalent:[50]

(XXIX)



The spectra of the frozen solutions are characterised by an effective spin–spin interaction, which also confirms our hypothesis of the formation of associated species. On the basis of the zero splitting parameters obtained ($D = 316$ G, $E = 27$ G), the distance between the radical centres ($r = 4.4$ Å) was determined. The evolution of the spectra as a function of temperature is fully reversible.

Thus the coordination sphere of the central atom expands to six during the association process and there is a corresponding transition from the trigonal bipyramid to an octahedron, which is manifested spectroscopically by the appearance of a symmetrical distribution of the spin density (equivalent ring protons of the 3,6-di-t-butyl-*o*-semiquinone ligand) and the detection of hyperfine coupling with four fluorine nuclei.

Pentacoordinate tetragonal-pyramidal and trigonal-bipyramidal complexes of silicon, titanium, and tin exhibit electron-deficient properties and can coordinate additionally various electron-donating species (anions, solvent molecules) with formation of hexacoordinate octahedral radical-anions or molecular complexes.

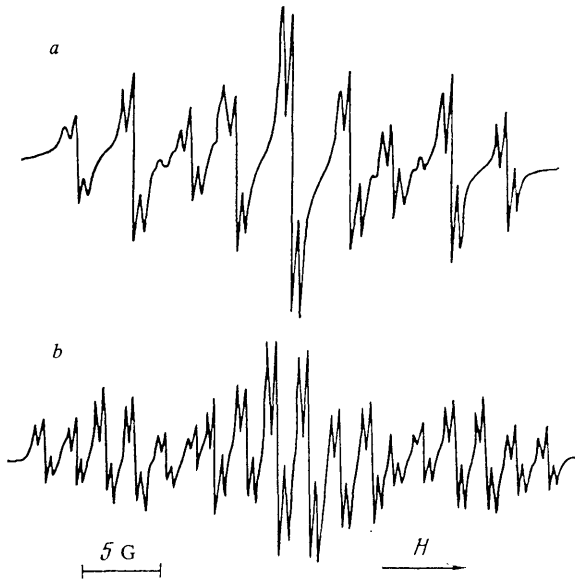
2. Octahedral Chelate Complexes

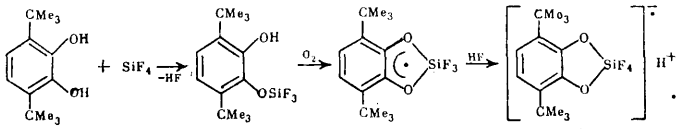
In toluene which has not been carefully freed of moisture, the evolution of the spectra of the radical (XXIX) as a function of temperature differed significantly from that in dry toluene and corresponded to equilibrium between the radical (XXIX) and the radical-anion (XXXII) having an octahedral structure (Fig.13):[48]

(XXXII)

The change in the geometry of the complex from a trigonal bipyramid to an octahedron leads to the equalisation of the constants for the hyperfine coupling with the ring protons and the constants for the hyperfine coupling with the four ^{19}F nuclei, which are equal in pairs, are determined by their disposition relative to the nodal plane of the free-radical ligand. The evolution of the spectra as a function of temperature is fully reversible. The addition of diphenylamine or triethylamine to the reaction mixture fully displaces the equilibrium towards the radical-anion and the spectrum of

(XXXII) is recorded over the entire temperature range (up to 80 °C). Evidently the radical-anion complex is stabilised by the formation of an ammonium cation.





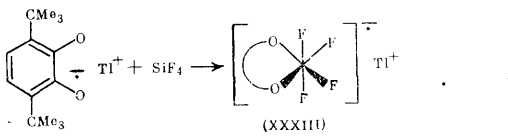


Figure 13. EPR spectra of the radical-anion (XXXII) (*a*) and its thallium salt (*b*) in toluene at 20 °C.[49]

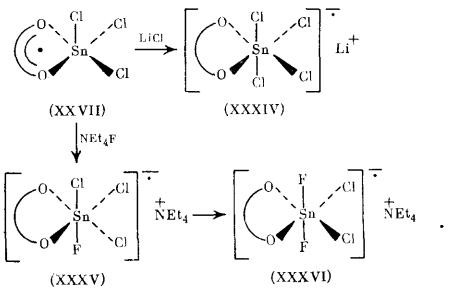
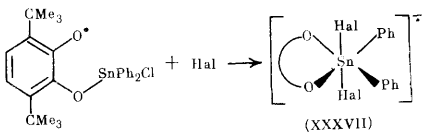
When tetrafluorosilane interacts with 3,6-di-t-butyl-1,2-dihydroxybenzene, the EPR spectrum of the radical-anion (XXXII) is also recorded. Under the conditions indicated, the formation of large amounts of HF is apparently inevitable, which displaces the above equilibrium towards (XXXII):



When thallium semiquinolate interacts with tetrafluorosilane, the corresponding thallium salt (XXXIII) is formed and the splitting due to the ^{203}Tl and ^{205}Tl nuclei (a_{Tl} = 2.1 G) is recorded (Fig. 13*b*):

(XXXIII)



The 3,6-di-t-butyltrifluorostannyl-*o*-semiquinone complex forms analogous salts in moist toluene as a result of the formation of HF during the reaction. Hyperfine coupling with the four nuclei, equivalent in pairs and having a spin of 1/2, is then recorded, two signals referring to the ring protons (a_H = 3.8 G) and the other two to the ^{19}F nuclei located outside the nodal plane of the free radical ligand (a_F = 4.2 G).

Tin-containing complexes of the radical-anion type [the complexes (XXXIV), (XXXV), and (XXXVI)] have been obtained also by the addition of lithium halides in the presence of crown-ether and tetraethylammonium to a toluene solution of the complex (XXVII):

(XXVII) (XXXIV) (XXXV) (XXXVI)

Hyperfine coupling with the two equivalent ring protons of the *o*-semiquinone ligands, the halogen nuclei located outside the nodal plane, and the ^{117}Sn and ^{119}Sn nuclei is detected in the EPR spectra of the complexes (XXXIV) to (XXXVI). Complexes of an analogous type [the complexes (XXXVII)] arise also when the 3,6-di-t-butyldiphenylchlorostannyloxyphenoxy-radical, where the coordination number is in essence four, is treated with the same salts[51]:

(XXXVII)

where Hal = Cl^- (XXXVIIa) or F^- (XXXVIIb).

Table 6 lists the spectroscopic parameters of the radical-anionic complexes obtained. In the instance indicated above, the transformation of a typical phenoxy-radical into an octahedral chelate complex can be seen. This transition as well as the equalisation of the lengths of the Sn–O bonds apparently take place as a result of the intramolecular charge transfer to the univalent oxygen atom from the central atom which is electronically saturated by the additional halide anion. After treating the 3,6-di-t-butyl-2-triphenylstannyloxyphenoxy-radical with salts, we were unable to detect the formation of radical-anionic complexes. This shows that the stability of the octahedral radical-anionic complexes is determined by the electron deficit of the central atom, which depends in its turn on the number of halogen atoms bound to it[52].

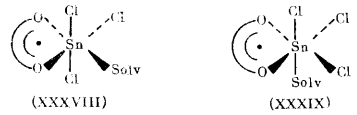


Table 6. The spectroscopic parameters (G) of the radical-anionic complexes of tin with the 3,6-di-t-butyl-1,2-dihydroxybenzene ligands in toluene at 20 °C.[51]

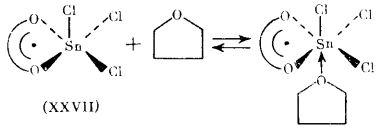
Complex	$a_{H(1)=a_{H(5)}}$	$a_{^{35,37}Cl}$	a_F
(XXXIV)	3.6	0.6 (2)	—
(XXXV)	3.7	0.6 (1)	4.1 (1)
(XXXVI)	3.7	—	4.0 (2)
(XXXVIIa)	3.7	0.6 (2)	—
(XXXVIIb)	3.7	—	4.0 (2)

Note: $a_{^{117,119}Sn}$ = 6.0 G for all the complexes indicated; the number of chlorine or fluorine atoms respectively is indicated in brackets.

Electron-donating molecules can also form complexes with pentacoordinate compounds of Group IV elements. It follows from the analysis of their EPR spectra that the coordinated molecule can be located either in the plane of

the *o*-semiquinone ligand or outside it. Thus the complex (XXVII) can give rise to one of the structures indicated below depending on the nature of the ligand entering it[44]:



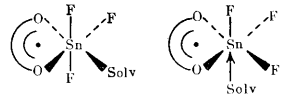
(XXXVIII) (XXXIX)

Solv = CH_3COCH_3, CH_3CN, DMF Solv = $P(O)R_3$, THF

Hyperfine coupling with two $^{35}Cl(^{37}Cl)$nuclei (apart from the hyperfine coupling with the equivalent ring protons) is detected in the spectra of the complexes (XXXVIII) and hyperfine coupling with a single $^{35}Cl(^{37}Cl)$nucleus is detected in the spectra of structure (XXXIX). For complexes where a phosphate molecule is coordinated to the central atom, additional splitting by the ^{31}P nucleus, amounting to approximately 0.2–0.4 G, is detected, which confirms the coordination of the phosphate outside the plane of the free-radical ligand. These complexes are extremely stable and the form of the spectra does not change over a wide temperature range (up to 100 °C).

A complex of type (XXXIX) with THF, which is in equilibrium with the initial complex (XXVII) and free THF, is an exception:

(XXVII)



The spectra of the free complex (XXVII) and the complex solvated by THF molecules have the same hyperfine structure, but their *g*-factors differ somewhat. Analysis of the line intensities of both species made it possible to estimate the thermodynamic parameters of the above equilibrium: K_p(20 °C) = 0.23 litre mol^{-1}, ΔH = 4.1 kcal mol^{-1}, and ΔS = −14 e.u.

Table 7. The spectroscopic parameters (G) of the 3,6-di-t-butyl-*o*-semiquinone complex containing the trifluorostannyl group in various solvents at 20 °C.[56]

Solvent	α	$a_{H(4)}$	$a_{H(5)}$	a_F	a_F	$a_{^{117}Sn}$	$a_{^{119}Sn}$
Diethyl ether	0.6	4.1	3.6	4.1	4.1	13.4	14.0
		3.9	3.9	4.4	—	11.9	12.3
THF	0.3	4.1	3.6	4.1	4.1	12.8	13.5
		3.9	3.9	4.4	—	12.5	13.2
Acetone	0.1	4.2	3.7	4.2	4.2	13.2	13.8
		3.9	3.9	4.6	—	14.2	14.8
Acetonitrile	0.03	4.1	3.6	4.1	4.1	13.0	13.4
		3.9	3.9	4.6	—	13.2	13.7
Ethanol	0.3	3.8	3.8	4.4	4.1	12.5	12.5
		3.8	3.8	4.7	—	12.8	12.8

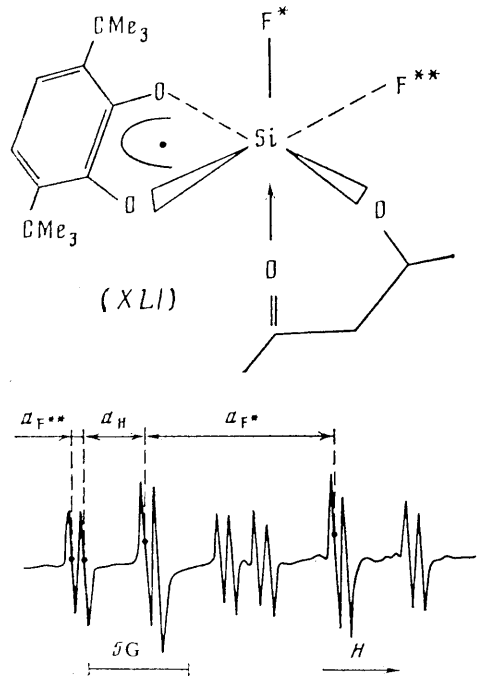
Note: the spectroscopic parameters of the complexes (XXXVIIIa) and (XXXIXa) are quoted for each solvent in the upper and lower row respectively; α is the ratio of the mole fractions of the complexes (XXXIXa) and (XXXVIIIa).

The simultaneous existence of complexes of types (XXXVIII) and (XXXIX) has been detected in the EPR spectra of trifluorostannyl complexes with the 3,6-di-t-butyl-*o*-semiquinone ligand in polar solvents. The spectroscopic parameters of these complexes are presented in Table 7, which also lists the ratios of the mole fractions of these forms: α = [(XXXVIII)]/[(XXXIX)].

(XXXVIIIa) (XXXIXa)

The non-equivalence of the ring protons in the form (XXXVIIIa) is due to the slight distortion of the octahedral structure. It is noteworthy that, for measurements in ethanol, the spectroscopic parameters of the form (XXXVIIIa) indicate the absence of distortion of the octahedral configuration. The relative line intensities of the EPR spectra assigned to these forms are independent of temperature, which is apparently associated with the similar thermodynamic stabilities of the two forms.

The molecular octahedral complex formed following the addition of acetylacetone to a toluene solution of the radical (XXIX) (acetylacetone : toluene = 1 : 1), is of interest. The fluorine is substituted in this instance by the acetylacetonate ligand which, being bidentate, occupies two coordination sites in the sphere of the central silicon atom, which leads to the formation of the complex (XL) whose EPR spectrum and structure are illustrated in Fig. 14.



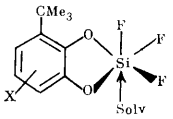


Figure 14. EPR spectrum and structure of the complex (XL) (toluene : acetylacetone = 1 : 1) at 20 °C.[56]

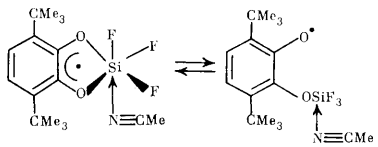
The interaction of SiF_4 with substituted *o*-quinones in solvating solvents—THF, dimethoxyethane (DME), and acetonitrile—yielded *o*-semiquinone complexes whose spectroscopic parameters (Table 8) correspond to an octahedral configuration in which one site outside the plane

of the free-radical ligand is occupied by the solvent molecule (Solv):[50]

(XLI)-(XLIII)

where X = 6-t-butyl (XLI), 5-t-butyl (XLII), or 5-trityl (XLIII). The unexpectedly high constants for hyperfine coupling with the ^{19}F nuclei located in the vicinity of the nodal plane of the free-radical ligand in the complexes (XLII) and (XLIII) are apparently caused by the distortion of the octahedral structure towards a trigonal pyramid as a result of the low symmetry of the *o*-semiquinone ligands.

Table 8. The spectroscopic parameters (G) of the radicals (XLI)–(XLIII) in tetrahydrofuran at −70 °C.[53]



Radical	$a_{H(4)}$	$a_{H(5)}$	a_F	$a_{F'}$
(XLI)	4.1	4.1	0.72 (2)	9.4 (1)
(XLII)	—	4.0	5.50 (2)	9.0 (1)
(XLIII)	—	4.0	5.40 (2)	9.4 (1)

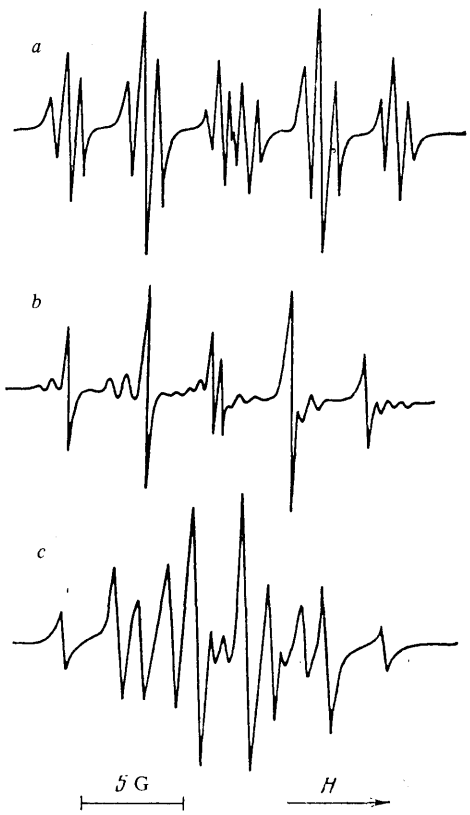
Note: a_F and $a_{F'}$ are the constants for the hyperfine coupling with the fluorine nuclei near and outside the nodal plane of the free-radical ligand. The number of fluorine atoms is indicated in brackets. The constant for the hyperfine coupling with the protons of the t-butyl group in (XLII) is $a_H = 0.5$ G.

The evolution of the EPR spectra of the complex (XLI) as a function of temperature corresponds to the hindered rotation of the trifluorosilyl group relative to the plane of the *o*-semiquinone ligand (Fig. 15): at −70 °C hyperfine coupling with three non-equivalent ^{19}F nuclei is detected, while above 30 °C all three ^{19}F nuclei become equivalent ($a_F = 3.2$ G).[53] Analysis of the line widths in the spectra corresponding to slow exchange made it possible to estimate the rotation frequencies of the SiF_3 group:

$$\nu_{rot}(s^{-1}) = 7\cdot10^{13}\exp[-(6200\pm1000)/RT];\ \nu_{rot}(20\,^{\circ}C) = 1.7\cdot10^{9}\ s^{-1}.$$

The mechanism of the hindered rotation can be intermolecular in this instance due to the decomposition of the complex (XLI) and the formation of the complex (XXIX). In the subsequent coordination, a THF molecule can add from the other side, whereupon the relative disposition of the fluorine atoms and the THF molecule can be different. One cannot rule out the possibility that the ligand exchange can be synchronous, i.e. can proceed without the formation of the complex (XXIX). An analogous spectral pattern has been recorded in DME. The spectral changes in acetonitrile at low temperatures (up to 0 °C) also correspond to the hindered rotation of the SiF_3 group. Above 0 °C, the chelate ring opens and the corresponding phenoxy-radical with the trifluorosiloxy-group in the *o*-position is formed. The ring protons then become non-equivalent [$a_{H(4)}$ = 4.0 G, $a_{H(5)}$ = 2.6 G]; on the other hand, the constants for the hyperfine coupling with the ^{19}F nuclei are equalised and greatly diminish ($a_F = 1.7$ G); furthermore, an additional splitting by the ^{14}N nucleus ($a_N = 4.0$ G) of the solvent molecule is detected:

(XLIV) (XLV)



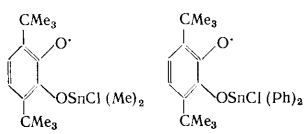


Figure 15. EPR spectra of the complex (XLI) in THF at different temperatures (°C): *a*) −70; *b*) −30; *c*) 30.[53]

The chelate complex (XLIV) can be converted into the phenoxy-radical (XLV) also when the electronegativity of the substituents at the central atom is reduced. Thus, after the replacement of two chlorine atoms in the complex (XXVII) by methyl or phenyl substituents, the chelate complex is converted into the phenoxy-radicals (XLVI) and (XLVII) respectively:

(XLVI) (XLVII)

* *

*

The examples presented show that the application of the EPR and electronic absorption spectroscopic methods to the study of variable-valence metal complexes of *o*-quinones makes it possible to establish the electronic structure of the complexes and to elucidate the wide variety of electronic configurations permitted by the nature of the *o*-benzoquinone ligands.

Analysis of a large number of experimental constants for hyperfine coupling with the magnetic nuclei forming part of the composition of the ligands in the paramagnetic *o*-quinone complexes of Group IV elements permits a conclusion concerning the geometrical structures of the complexes and about the alteration of the latter following the coordination of new ligands, which is of general interest for the chemistry of coordination compounds.

Oligomers and Polymers with Reactive Acetylenic Groups

V.A.Sergeev, Yu.A.Chernomordik, and A.S.Kurapov

The problem of the synthesis and study of the properties of thermoreactive oligomers and polymers containing reactive acetylenic groups, leading to the formation of compounds with a three-dimensional structure, are examined. Pathways leading to the formation of oligomers and polymers from acetylenic monomers during their polycyclotrimerisation with retention of the residual acetylenic groups as well as the methods of synthesis of various oligomers and polymers with subsequent introduction of acetylenic groups into the latter are indicated. The possible structural transformations of the acetylenic groups during the hardening process with formation of rigid and cross-linked polymers without the evolution of volatile products are discussed. The bibliography includes 126 references.

I. INTRODUCTION

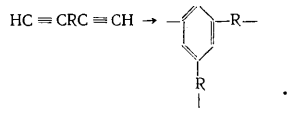
The problems of the synthesis of oligomers and polymers with acetylenic bonds and of the preparation of materials based on them has recently been attracting increasing attention. This can be explained by the likely usefulness of acetylenic compounds for the preparation of reactive oligomers and polymers and heat resistant and thermostable materials based on them. The acetylenic group is being successfully used nowadays in various classes of thermostable polymers: polyphenylenes and carbochain polymers, polyethers and polyesters, polyamides, polyurethanes and other heterochain compounds, and polymers with a heterocyclic structure: polyimides, polyphenylquinoxalines, polydibenzoxazoles, etc.

The use of the acetylenic group in the synthesis of polymers has led to considerable progress in the chemistry and technology of materials based on the polymers enumerated above. In the first place mention should be made of the decreased processing temperature, the improved solubility and fluidity of the starting materials, the possiblity of obtaining large components, and an improvement in the quality of the articles. One of the first polymers of acetylene has been "cuprene" obtained at the end of the last century by passing acetylene through a copper tube heated to 240–250 °C.[1] It did not find practical applications.

At the end of the 1960s Korshak and co-workers[2,3] achieved the polymerisation of a number of acetylenic compounds under pressure. Phenylacetylene and propargyl alcohol were polymerised and polymers with a system of conjugated double bonds were obtained. In a number of other studies[4,5], various monomers were subjected to catalytic and radiation-induced polymerisation. These investigations indicated ways of employing the acetylenic group in polymer synthesis and revealed the possibility of stabilising many polymers by binding the free radicals formed on decomposition of the polymer.

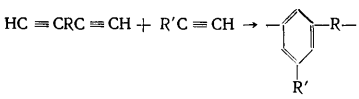
Oligomers and polymers containing acetylenic groups were first obtained by Korshak and co-workers[6,7] and also by Kotlyarevskii et al.[8] by the oxidative dehydropolycondensation of acetylenic monomers. Thus, "carbyne"—a polymer with triple carbon–carbon bonds in the chain which constitutes a new linear modification of carbon—was obtained from acetylene by this reaction; it is a black powder capable of being converted into graphite at 2300 °C.[7] The carbyne formation reaction can be represented schematically in a general form as follows:

$$n\,HC{\equiv}CH \xrightarrow{[O]} (-C{\equiv}C-)_n- \quad .$$



Polyacetylene having the structure

has been obtained from *p*-diethynylbenzene. The study of polyacetylenes showed that they possess semiconducting properties and exhibit photoconductivity.

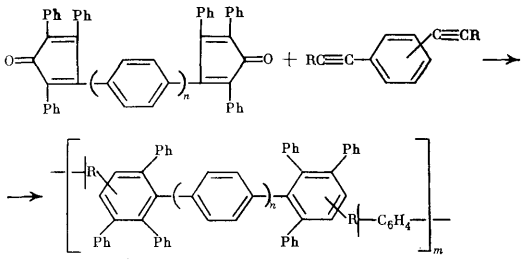


The specific synthesis of carbyne has been achieved[9] by the dehydrochlorination of poly(vinylidene chloride).

The polymerisation and oxidative dehydropolycondensation reactions of acetylenic monomers lead to the formation of linear polymers. At the end of the 1960s and the beginning of the 1970s Korshak and co-workers[10,11] developed a funamentally new method of synthesis of polymers with acetylenic groups by the polycyclotrimerisation of acetylenic compounds in which aromatic carbocycles are formed as a consequence of the interaction of three acetylenic groups and their closure to form a six-membered ring in accordance with the scheme

However, certain difficulties arise in carrying out this process with a high degree of selectivity, because all the monomers used for the polycyclotrimerisation can just as readily polymerise with the parallel formation of other unity in the chain, which is undesirable from the standpoint of the polycyclotrimerisation process. In order to carry out the polycyclotrimerisation reaction, it is necessary that at least one of the monomers involved in the process should contain two acetylenic groups. The polycyclotrimerisation reaction is usually performed in the presence of a catalyst[12–15] whose efficienty largely determines the selectivity of the process.

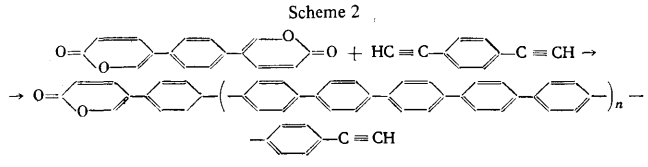
The joint polycyclotrimerisation in accordance with the scheme



is of greatest practical interest. This reaction is based on the use of acetylenes and their derivatives and does not lead solely to the formation of polyphenylenes having various structures and containing reactive groups. The most interesting are the oligophenylenes containing residual triple bonds as functional groups, because this facilitates the subsequent, chemical modification and hardening of the polymers. The polycyclotrimerisation process makes it possible to regulate the content of the triple bonds in the polymer[15-18].

The above possibilities of the polycyclotrimerisation reaction have attracted in recent years much attention by investigators working in the field of the synthesis of polymers both in our country and abroad. A review was published in 1980 [19] which attempted to extend the fundamental approach to the introduction of the acetylenic linkage into an oligophenylene, developed by Soviet workers[20], to other classes of polymers. The studies initiated by Korshak and co-workers[10] on the polycyclotrimerisation of acetylenic compounds were subsequently extended by the same investigators to the polycyclotrimerisation of dinitriles and dicyanoesters; on this basis, a general method was developed for the synthesis of polymers[21,22], their modification, and the formation of three-dimensional networks.

Before the publication of the studies by Korshak and co-workers, isolated communications on the problems of the synthesis of acetylene-containing polyphenylenes could be found in the literature. Thus the Diels–Alder reaction of bistriphenylcyclopentadienones with diacetylenes in accordance with the scheme



Scheme 1

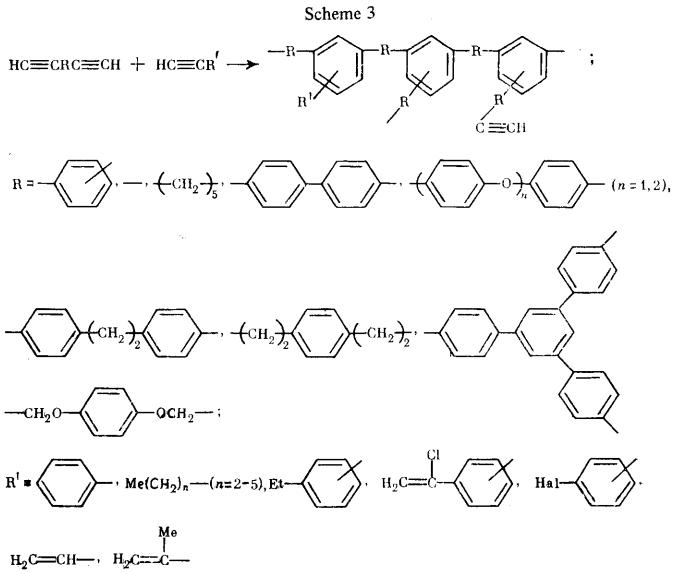
has been described[23,24]. In the presence of more than a twofold excess of acetylene, the resulting polymer could contain acetylenic groups at the ends of the macromolecule.

The reaction of bispyrones with diacetylenes[24] via the scheme

Scheme 2

proceeds analogously.

At attempt has been made to obtain aromatic polymers from non-conjugated diacetylenes[26]. However, the oligomers synthesised consisted mainly of polymers having a polyene structure with small amounts of admixtures of dimers and trimers having indan, cyclophane, and arylacetylene structures.



Extensive data have now accumulated on the problem of the synthesis and study of the structures and properties of oligomers and polymers containing reactive acetylenic groups; examination and survey of these data is the aim of the present review.

II. CARBOCHAIN OLIGOMERS AND POLYMERS

1. Polyphenylenes

One of the most common methods of synthesis of oligophenylenes with acetylenic groups is the polycyclotrimerisation of diethynylcompounds or their mixtures with monoethynyl compounds. The possibility of carrying a selective process under relatively mild conditions has been noted[10,27,28]. A series of syntheses in accordance with the scheme

Scheme 3

were carried out.

p-Diethynylbenzene and phenylacetylene have acquired the greatest importance as the diethynyl and monoethynyl compounds respectively. The polycyclotrimerisation reaction is usually accompanied by the conversion of the acetylenic compounds into polyenes. The catalysts of such a mixed process may be $[(EtO)_3P]_4CoBr$, $NiCl_2.2PPh_3.2NaBH_4$, and also Ziegler catalysts[20]; it has been shown that the last are the most effective and that in their presence (for specific ratios of AlR_3 and $TiCl_4$) the polycyclotrimerisation reaction becomes dominant. The oligophenylenes obtained with molecular weights in the range 1000–5000 readily dissolve in benzene, toluene, and chlorinated organic solvents.

The study of the thermal properties of the products showed that they are readily hardened[10] at temperatures in the range 150–250 °C and that the hardening process is completed at 300–350 °C. Oligophenylenes containing residual ethynyl groups are therefore capable of producing polyphenylenes with a high deformation thermal stability, the latter increasing with the number of ethynyl groups in the initial oligophenylene. The properties of the oligophenylene depend on the structure of the initial monomers, on the reaction conditions, on the type and composition of the catalyst, and the ratio of the initial monoethynyl and diethynyl monomers, etc. Certain methods of synthesis and properties of the oligophenylenes were described previously in reviews[29,30] and here we shall deal with the main new investigations.

The mechanism of the polycyclotrimerisation reaction of acetylenic compounds was investigated by statistical and thermodynamic methods and also a number of other procedures[15,16,29–36] and it was concluded that the reaction involves stepwise coordination polyaddition which differs from both polymerisation and polycondensation and is a new reaction leading to the synthesis of polymers. As a consequence of the coordination character of the process, the structure and properties of the oligomers obtained depend on the structure of the initial monomers and in the first place on the flexibility or rigidity of the interethynyl diacetylene fragment[37–40] and on steric factors[17,18,36,41], because they determine the nature of the preliminary orientation of the acetylenic molecules in the formation of the aromatic ring on the catalytic complex. The stepwise, discrete character of the process is responsible for the additivity of the influence of the ratio of the diethynyl and monoethynyl monomers, of the order of the introduction of the monomers, and of other reaction conditions on the structure and properties of the polyphenylenes[18,42–44].

The reaction mechanism was inferred with the aid of the statistical theory of branching processes based on the cascade theory[15,16,39,40,45,46]. The structure of the oligophenylenes was investigated by the method of ozonolysis[47]; it was shown that the polycyclotrimerisation of acetylenic compounds in the presence of the $Al(iso\text{-}C_4H_9)_3$–$TiCl_4$ catalytic system is a highly selective process and the influence of the polyene sections has almost no effect as a consequence of their small amount.

Taking into account the characteristics of the polycyclotrimerisation reaction, polymers with properties useful in practice, namely thermostable and mechanically strong polymers, were synthesised specifically from phenoxyacetylenes[38,48,49]. Thus, as a consequence of the presence of oxygen "hinge" atoms between the benzene rings, the polymers based on di(4-ethylphenyl) ether and 1,4-di(4-ethynylphenoxy)benzene produced specimens which are more easily worked than oligophenylenes based on *p*-diethynylbenzene and have high moduli of elasticity and high compressive strengths (reaching 1000–1400 kg cm^{-2} compared with 350 kg cm^{-2} for oligophenylenes based on *p*-diethylbenzene); the limiting deformation of these polymers without rupture and their thermal stability and heat resistance were also higher. According to thermogravimetric data, intense weight losses are observed in an inert atmosphere in the temperature range 450–600 °C.[48]

In order to modify the properties of the oligomers, oligophenylenes based on various diethynyl, triethynyl, and monoethynyl monomers were synthesised: diphenyl butadiyne[50], 4,4′-diethynylbiphenyl[48], di(4-ethynylphenyl)ethane[37], diethynyltetraphenyldisiloxane[51], vinyl- and isopropenyl-acetylenes[52,53], chlorovinylphenylacetylene[42], ethylphenylacetylene[54], tri(ethynylphenyl)benzene[41] and other triethynyl compounds.

In order to increase the thermal stability of the polymer by increasing the number of unsaturated groups in the oligophenylene and in order to be able to employ the latter as a cross-linking agent, branched oligophenylenes with double bonds were synthesised[52,53] by the partial or complete replacement of phenylacetylene (in its copolycyclotrimerisation reaction with *p*-diethynylbenzene) by alkenylacetylenes: binylacetylene or isopropenylacetylene. The reaction was carried out at −10 °C in the presence of $Al(iso\text{-}C_4H_9)_3$–$TiCl_4$, which is the most effective catalyst of the trimerisation of alkenylacetylenes[55,56]. In view of the ready structure formation in oligophenylenes with vinyl groups, a product fully soluble in organic solvents was obtained only on the basis of the ternary copolymer of *p*-diethynylbenzene, phenylacetylene, and vinylacetylene. The possibility of regulating the number of unsaturated groups in the ternary copolymers by varying the ratio of the initial components was demonstrated.

Oligophenylenes containing vinyl chloride groups have been synthesised[42]. During the preparation of *p*-diethynylbenzene from technical divinylbenzene, ethynyl(chlorovinyl)benzene remains in the reaction products as a consequence of the incomplete dehydrochlorination; it is difficult to remove completely. In order to elucidate the influence of this group on the polycyclotrimerisation product and to determine the possibility of achieving the synthesis from unpurified *p*-diethynylbenzene, the study mentioned above[42] was undertaken.

It was established that, when *p*-diethynylbenzene, phenylacetylene, and ethynyl(chlorovinyl)benzene interact, an oligomer with an increased degree of saturation of the bonds is formed as a result of the retention of the vinyl chloride group during the reaction. It was shown that phenylacetylene is more reactive towards *p*-diethynylbenzene than ethynyl(chlorovinyl)benzene. The chlorine atom in ethynyl(chlorovinyl)benzene apparently reduces (as a consequence of the inductive effect) the electron density in the triple bond of the acetylenic group relative to the electron density of the triple bond of phenylacetylene. The use of triethynyl monomers greatly improves the thermal stability of the polymers formed, whose softening temperature is in the region of intense thermal decomposition, i.e. above 500 °C.[41]

A polyphenylene and an oligophenylene have been synthesised from diacetylene and substituted acetylenes have been obtained by the polycyclotrimerisation reaction in solution in toluene at −10 °C in the presence of $Al(iso\text{-}C_4H_9)_3$–$TiCl_4$.[17,43,57]. Both synthetic diacetylene, obtained by chlorinating butynediol with thionyl chloride and subsequent dehydrochlorination by alcoholic alkali, and pyrolytic diacetylene, which is a side product in the synthesis of acetylene from natural gas, were employed in the reaction. It was shown that an aromatic polymer is formed from initial monomers without benzene rings. In the polymer obtained from diacetylene alone, each aromatic ring is formed as a result of the interaction of three diacetylene molecules. The polymer is an amorphous yellow powder containing aromatic and ethynyl groups; it softens at 150–200 °C and hardens (owing to the presence of residual ethynyl end groups) on heating; in the cross-linked state, it exhibits a high thermal stability. According to thermogravimetric data, intense weight losses are observed in air at 400–600 °C.[43]

The high chemical stability of polyphenylenes and graphite-filled plastics based on them has been demonstrated[58]. Chemically stable polymeric materials used as binders and impregnating substances in industry include furan and phenol-formaldehyde resins and compositions based on them; however, they are stable only in relation to a 70% solution of sulphuric acid. Polyphenylenes and graphite-filled plastics exhibited an effective chemical stability in relation to an 80% solution of sulphuric acid at its boiling point (120–125 °C) for 850 h and also in relation to a 93% solution of sulphuric acid. The high thermal and corrosion stabilities of polyphenylene, which can be explained by its aromatic structure, make it a promising material as a binder in the preparation of graphite-polymeric materials.

The use of the products of the copolycyclotrimerisation of *p*-diethynylbenzene and a halogenophenylacetylene showed[44] that the reactivity of *p*-diethynylbenzene is somewhat higher than that of the halogeneophenylacetylene; the oligomers are therefore enriched in *p*-diethynylbenzene fragments compared with the initial mixture.

The capacity of oligophenylenes for structure formation under the influence of ultraviolet irradiation has been studied[48,60]. It has been suggested that, in the absence of oxygen, the photoinitiated cross-linking takes place via the

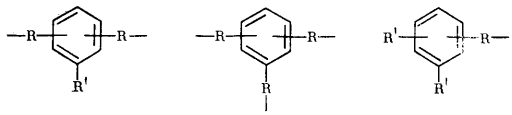
residual ethynyl end-groups, as in thermal cross-linking in an inert atmosphere. In the presence of oxygen, the rate of cross-linking increases as a consequence of the oxidation of the ethynyl groups to peroxy-groups and the decomposition of the latter with subsequent recombination of the radicals. The mechanism of the photochemical cross-linking of polyphenylenes by diazides has also been described[60].

The oligophenylenes obtained by the polycyclotrimerisation reaction are characterised by the presence of residual ethynyl groups which can enter into various reactions: they can be oxidised to carboxy-groups[12], can combine with decaborane[61] to form oligophenylenecarbaboranes, and can interact with diazo-compounds[62] to form oligophenylenepyrazoles. The oligomers obtained have acquired new functional groups, which expands the synthetic possibilities in polymer chemistry.

An oligophenylenecarbaborane has been synthesised by the chemical modification of an oligophenylene containing acetylenic end-groups under the influence of decaborane[61]. It was established that, under the chosen conditions, the replacement of the ethynyl groups of the oligophenylene by carbaborane groups takes place almost quantitatively via the scheme

$$B_{10}H_{14} + PhNMe_2 \rightarrow B_{10}H_{12}(PhNMe_2)_2 \xrightarrow{HC\equiv C-} HC(B_{10}H_{10})C- + PhNMe_2 + H_2 .$$

This demonstrated that the polycyclotrimerisation of ethynyl compounds in the presence of $Al(iso\text{-}C_4H_9)_3$–$TiCl_4$ leads to the formation of oligphenylenes containing only aromatic units and residual triple bonds, which are responsible for the acquisition of a three-dimensional structure by the oligophenylene.



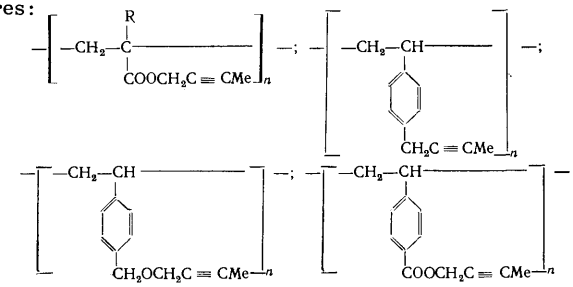
Oligophenylenepyrazoles have been obtained as a result of the modification of an oligophenylene having terminal ethynyl groups on treatment with diazomethane and bisdiazohexane and some of their properties, particularly their resistance to thermo-oxidation, have been estimated[62]. The ethynyl groups of oligophenylenes have been hydrosilyated by dihydrosilanes in order to improve their mechanical characteristics[63].

Oligophenylenes based on the dipropargyl ethers of hydroquinone and dian have been obtained recently together with phenylacetylene in the presence of cobaltocene as the catalyst[64]. The polymers exhibit an enhanced fluidity and fusibility and possess effective mechanical characteristics.

A wide range of acetylenic compounds capable of undergoing polycyclotrimerisation and copolycyclotrimerisation have been enumerated[65,66] and the importance of using effective catalytic systems has been discussed. The authors of these studies point out that many transition metal compounds used as the catalysts of the polymerisation of monoacetylenes cannot be used for polycyclotrimerisation. For example, nickel chloride in the presence of sodium tetrahydroborate leads to the formation of thermally unstable polyolefins and not aromatic structures in the polymerisation of phenylacetylene. The catalyst $Ni(CO)_2(PPh_3)_2$, which has been widely used for the polymerisation of acetylenes, leads to the formation of unsaturated linear trimers as well as trisubstituted benzenes. The reaction of phenylacetylenes and diethynylbenzene in the presence of this catalyst leads to the formation of polymers in the infrared spectra of which a band appears at 965 cm^{-1}, characteristic of a *trans*-substituted terminal double bond, which indicates the occurrence of linear polymerisation. The copolymerisation of phenylacetylene and *p*-diethynylbenzene in the presence of the carbonylphosphinenickel complex leads to the formation mainly of polyolefins instead of the required thermostable polyphenylenes.

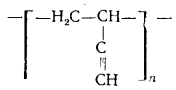
When the $AlEt_2Cl$–$TiCl_4$ Ziegler catalyst is used under the conditions of its effective operation, only triphenylbenzene is formed from phenylacetylene, while high-molecular-weight polyphenylene polymers can be obtained by copolymerisation. The authors[65,66] believe that the main cause of the formation of polyphenylenes rather than polyolefins is the molar ratio Al/Ti = 1.5–5.0. They believe that the catalyst concentration can vary within wide limits but the molar ratio of the catalyst to the acetylene-containing monomers must be at least 1 : 300–1500. Chemical study of the reaction products demonstrated the absence of unsaturated double and triple bonds from the polymer. Taking these findings into account, it was established on the basis of infrared, ^1H NMR and, ^{13}C NMR spectroscopic data that the polymer contains only aromatic structures.

However, the absence of terminal acetylenic groups from the reaction products (polyphenylenes) precludes their modification; such polymers are hardened thermally at high temperatures via secondary processes involving the degradation of the oligophenylenes and the recombination of radicals. The authors[65,66] introduced the monoacetylene monomer (phenylacetylene or tolylacetylene) into the reaction with diethynylbenzene in portions, which they believe to ensure a high solubility of the resulting polymer. They suggest that the reaction proceeds via three different pathways: chain propagation, chain branching, and chain termination, to which correspond three different types of fragments.



The synthesis of a polyphenylene containing residual ethynyl groups has been described[67]. Only one component, namely *p*-diethynylbenzene, was used for its synthesis; the reaction was carried out in the presence of two different catalytic systems: diethylaluminium chloride and titanium tetrachloride and nickel acetylacetonate. The authors[67] point out that the polyphenylenes which they obtained were soluble in organic solvents up to high degrees of conversion of the monomer into the polymer. For the Ziegler type catalyst, this claim conflicts with data[66] according to which a soluble polyphenylene cannot be obtained from diethynylbenzene alone.

2. Carbochain Polymers



Carbochain polymers with a linear structure have been obtained, as already stated, by the oxidative dehydropolycondensation reaction[7]. By treating the polymers obtained with bistetraphenylcyclopentadienone, it is possible to increase their thermal stability and to employ them as binders, films, and coatings.

Carbochain polymers containing acetylenic groups in the side chain have been synthesised by the polymerisation of vinyl monomers[68–70] and were found to have the following structures:

Polymers of this type, soluble in organic solvents at elevated temperatures (120 °C and above), were cross-linked. It was established that the non-cross-linked polymers can combine with bromine and decaborane at the triple bonds.

Polymers with an unsubstituted acetylenic group in the side chain have also been synthesised[71]. A polymer with a triple bond linked directly to the main chain could not be obtained from a polyolefin. A polyconjugated polymer containing vinyl, allene, and acetylenic groups is formed in this case. In order to obtain a polymer containing an ethynyl side group of the type

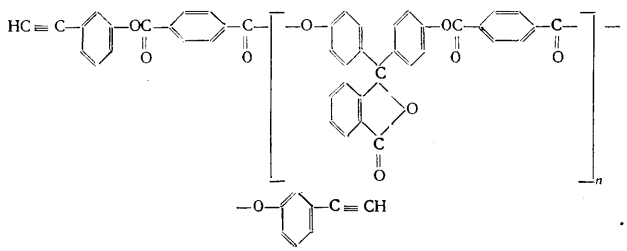
trimethylsilylvinylacetylene is usually polymerised with subsequent removal of the trimethylsilyl group.

III. HETEROCHAIN OLIGOMERS AND POLYMERS

1. Polyethers and Polyesters

Polyethers have been obtained by the thermal polymerisation of di(4-ethynylphenyl) ether on heating to 150 °C.[72] The polymer obtained was used as a binder for composite materials. The kinetics of the thermal polymerisation of 3-ethynylphenyl phenyl ether have been investigated[73]. By treating bisphenols having the general formula

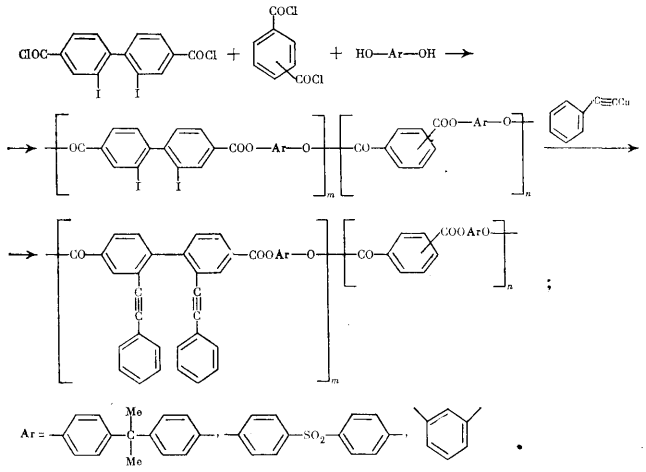
X=O, S, SO_2, CMe



and also hydroquinone and a novolac resin with propargyl bromide in an alkaline medium, oligomers having acetylenic end-groups and capable of thermal polymerisation at 200 °C without the evolution of volatile products were obtained[74].

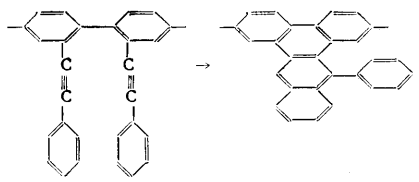
Oligoesters containing propargyl groups of the following type have been synthesised[75,76]: oligoesterpropargylates

and $(HC{\equiv}CCH_2OCOCH_2CH_2OCO)_2R$, oligocarbonatepropargylates $(HC{\equiv}CCH_2OCO)_2R$, and oligoesterpropiolates $(HC{\equiv}CCOOROCO)_2C_6H_4$ and $(HC{\equiv}CCOOROCO)_2C_2H_4$, where R is a diol residue. It has been shown that they harden at 200–300 °C with formation of cross-linked products and that their thermal stabilities are much higher than those of the analogous polymers with saturated bonds in the chain.



Thermostable thermoreactive aromatic polyesters containing acetylenic groups have been obtained by the polycondensation of aromatic bisphenols (phenolphthalein, phenolphthalimidine, phenolsulphonephthalein, and fluorescein) with the chlorides of isophthalic or terephthalic acid with subsequent addition of ethynylphenol[77]. When phenolphthalein is used together with terephthalic acid chloride and 3-ethynylphenol for the synthesis, the polymer has the following structure:

Glass plastics based on this polyester have a high strength and exhibit low weight losses on thermal ageing (0.4% at 250 °C for 1000 h).



Aromatic polyesters containing phenylethynyl groups have been obtained[78] by the interfacial condensation of the dichloride of 2,2'-di-iodobiphenyl-4,4'-dicarboxylic acid and isophthaloyl or terephthaloyl chloride with bisphenols and subsequent substitution of the iodine by phenylethynyl groups in accordance with the scheme

Scheme 4

The resulting polyesters are soluble in pyridine and tetrachloroethane and harden at 200 °C in argon in the course of 30 h via an intramolecular cyclisation mechanism (Scheme 5):

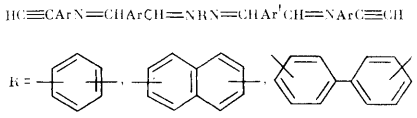
Scheme 5

Polyesters containing conjugated diacetylenic groups in the chain have been synthesised by the polycondensation of the chlorides of dicarboxylic acids (succinic, azelaic, adipic, sebacic, isophthalic, and terephthalic) with 3,5-hexadiyne-1,6-diol and their photochemical and thermal behaviour has been investigated. The synthesis of epoxide resins containing ethynyl end-groups by the interaction of epoxide oligomers with aminophenylacetylene has been described[80]. The resins were hardened at 250 °C with formation of impact-resistant thermostable polymers.

2. Polyamides

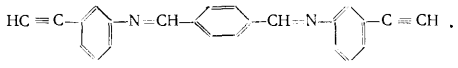
Analogously to aromatic polyesters, aromatic polyamides with phenylethynyl side groups have been obtained by the low-temperature polycondensation of diamines with the dichloride of 2,2'-di-iodobiphenyl-4,4'-dicarboxylic acid or its mixture with the dichloride of biphenyl-4,4'-dicarboxylic acid in dimethylformamide (DMF) followed by the treatment of the iodine-containing polyamides with an excess of copper phenylacetylide[81]. Most of these polyamides were soluble in DMF, had softening temperatures in the range 177–247 °C, and showed weight losses amounting to 1.1–3.9% after three

days at 300 °C. It was established that the solubility of polyamides with an identical structure of the acid component of the molecule decreases in the following sequence of aromatic diamino-fragments:



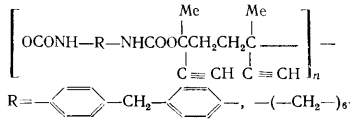
Like polyesters, these polyamides are capable of being hardened via an intramolecular cyclisation mechanism with formation of 9-phenylbenzanthracene units.

Polyamides containing tolane fragments have been obtained by the condensation of the dichlorides of isophthalic and terephthalic acids with 4,4′-diaminotolane in DMF containing LiCl.[82] Polyisophthalamides are soluble in DMF and *N*-methylpyrrolidinone with added LiCl and polyterephthalamides are soluble in sulphuric and methylsulphuric acids. According to thermogravimetric analysis, the temperature of the onset of the thermal decomposition of these polymers is 445–470 °C in air and 490–530 °C in an inert atmosphere.



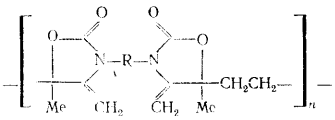
3. Polymeric Schiff Bases

Oligoimines containing acetylenic end-groups and having the following structures can be obtained by the reaction of aromatic aldehydes with aromatic diamines and subsequent treatment of the reaction product with aminoarylacetylene[83]:



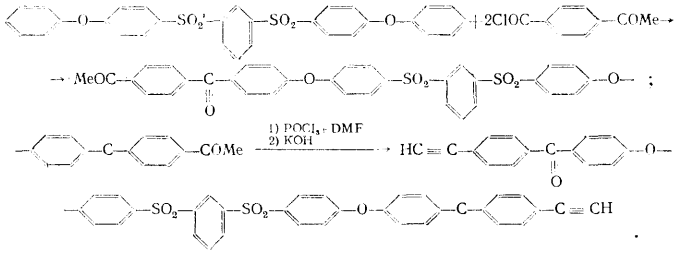
The resulting oligomers are soluble in halogenated solvents. They are capable of hardening on heating. Thus the oligoimine obtained from isophthalic dialdehyde, 1,3-di(3-aminophenoxy)benzene, and 3-aminophenylacetylene has a softening temperature of 40–45 °C and on heating to 150 °C in the absence of air for 16 h it gives rise to a hard material with a glass point T_g = 230–260 °C and remains thermally stable up to 350 °C.

Analogous oligomers have been obtained by the reaction of 3-aminophenylacetylene with terephthalic dialdehyde[84]. In particular, a product having the following structure and a melting point of 136–139 °C has been isolated:



4. Polyurethanes

Acetylene-containing polyurethanes have been obtained by the polycondensation of di(4-isocyanatophenyl)methane and hexamethylene di-isocyanate with 3,6-dimethylocta-1,7-diyne-3,6-diol:[85]

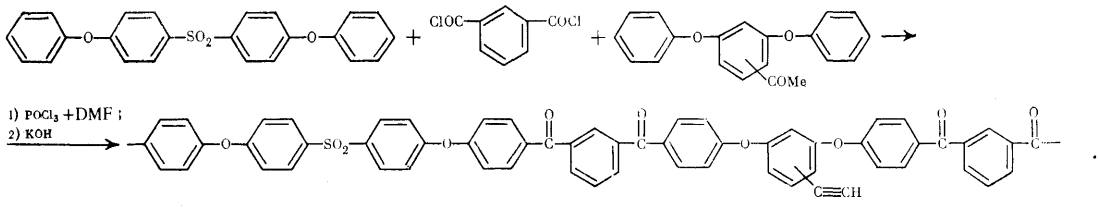


They are soluble in organic solvents and form transparent films. They have a viscosity η_{log} = 0.4–0.54 (30 °C, DMF), T_g = 135° and 54 °C, and temperatures corresponding to a 10% weight loss of 260° and 175 °C respectively. When solutions of the polyurethanes in DMF are heated, intramolecular cyclisation with formation of the corresponding polyoxazolidinones takes place:

The polymers obtained have high glass points T_g = 170–175 °C and a high temperature corresponding to a 10% weight loss (390–410 °C).

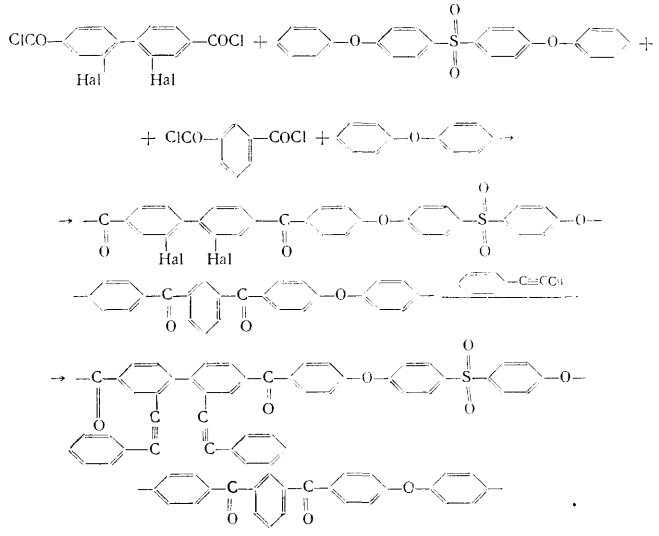
5. Polysulphones

Polysulphones with acetylenic end-groups have been obtained by the reaction of 1,3-di(4-phenoxybenzenesulphonyl)benzene with 4-acetylbenzoyl chloride via the following scheme[86]:



This bisacetylenic oligomer is a relatively low-melting solid soluble in the usual organic solvents: chloroform, dioxane, and tetrahyrofuran (THF). It was hardened in nitrogen at 300 °C. The authors[86] suggest that the hardening proceeds via a polycyclotrimerism with formation of polymers of the type of polyphenylenes. The hardened products have high glass points and a high thermo-oxidative stability. The weight losses at 300 °C in circulating air amounted to 4–6 wt.% after five days.

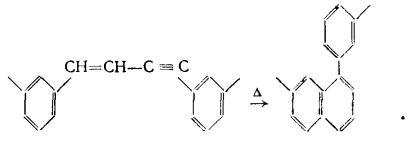
The question of the synthesis and properties of polysulphones with acetylenic groups has been examined in detail in a review[19]. Here we may mention that the synthesis of a polysulphone with an acetylenic side group via Scheme 6 is possible[87].



The polymers are soluble in DMF and have η_{log} = 0.23–0.43 and T_{soft} = 185–225 °C. After hardening in the presence of palladium chloride in nitrogen at 210° and 285 °C, they lost their solubility and did not soften up to 300 °C. According to thermogravimetric data, they are thermally stable in an inert atmosphere up to 550 °C and retain their thermo-oxidative stability up to 250 °C.

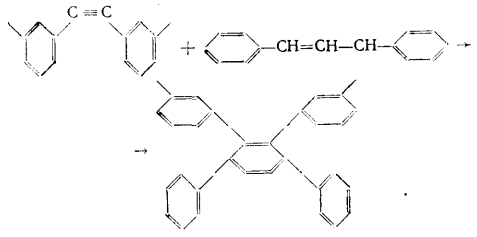
The sulphone oligomers have also been hardened by the intramolecular cyclisation of derivatives of 2,2′-di(phenylethynyl)biphenyl[88–92]. The oligomers were obtained via Scheme 7:

Scheme 6



Scheme 7

After the polymers have been hardened in an inert atmosphere at 280 °C for 24 h, their thermo-oxidative stability increases and the weight losses at 300 °C in air amount to 1–2 wt.% (compared with 6–7 wt.% for the unhardened polymer).



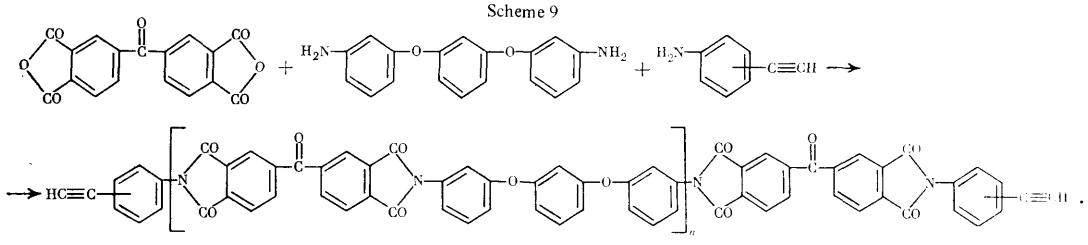
In order to achieve intramolecular cyclisation, polysulphones containing the enyne group in the polymer chain have been synthesised[93–95]:

On heat treatment, the enyne group was converted into the phenylnaphthalene group and the polysulphone was hardened. Such polymers are photosensitive but after hardening they become very brittle.

The Diels–Alder reaction has also been used to harden polysulphones[96]. Polysulphones containing tolane groups were treated with 1,4-diphenylbutadiene in accordance with Scheme 8:

Scheme 8

Among other classes of polymers, mention may be made of acetylene-containing phosphazene copolymers[97] obtained by treating polydichlorophosphazene with propargyl alcohol.



IV. HETEROCYCLIC OLIGOMERS AND POLYMERS

Polyimides, polybenzoxazoles, polyphenyltriazines, and polyphenylquinoxalines have been obtained in the series of heterocyclic polymers containing acetylenic groups.

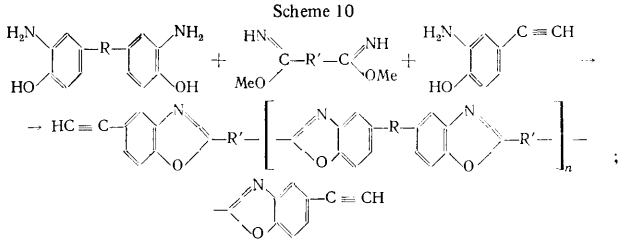
1. Polyimides

Polyimides with ethynyl end-groups have been described in a number of communications[19,82,98–103]. They are obtained by the condensation of aromatic diamines, for example, 1,3-bis-3-aminophenoxybenzene, with aromatic tetracarboxylic acid dianhydrides, for example, benzophenonetetracarboxylic acid, and of aminophenylacetylenes with the ethynyl-substituted anhydride of an aromatic dicarboxylic acid using a two-stage method in accordance with Scheme 9:

Scheme 9

The thermal and mechanical characteristics of the polyimides have been described[19]. It is noteworthy that the glass points of the hardened polyimides are fairly high (up to 340 °C) and depend on the conditions in the subsequent (final) hardening. Graphite filled plastics with the polyimide binder retain their strength effectively at high temperatures.

Differential scanning calorimetric data[98] have demonstrated the two-stage character of the hardening of the acetylene-containing polyimides. It is believed that the $-C\equiv C-\overset{\overset{\|}{CH_2}}{C}-$ groups are formed initially (at 200 °C), while in the second stage (at 240–260 °C) a third group adds on, which is accompanied by the formation of a benzene ring.



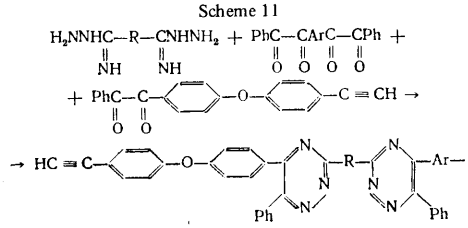
The dialkyl esters of tetracarboxylic acids can be used instead of the dianhydrides for the synthesis of polyimides with acetylenic end-groups[99], while the propargyl ester of aminobenzoic acid can be employed as the ethynyl component[102].

Branched oligoimides containing ethynyl end-groups have been obtained by the reaction of the dianhydride of benzophenonetetracarboxylic acid with aromatic triamines for the introduction of the ethynyl group into the polyimide chain by the reaction of diaminotolane with the dianhydride of pyromellitic acid has been described[82].

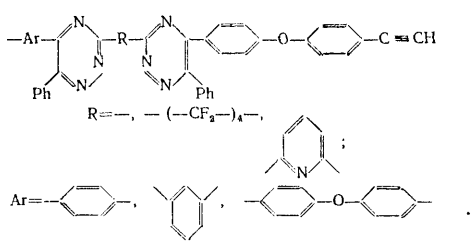
2. Polybenzoxazoles

Dibenzoxazole oligomers with fluorocarbon ether linkages and acetylenic end-groups have been synthesised via the Scheme[104]

Scheme 10



$n = 0, 1, 2$; R=—$CF_2CF_2O(CF_2)_5OCF_2CF_2$—;
R′=—$CF_2(OCF_2CF_2)_xO(CF_2)_3O(CF_2CF_2O)_yCF_2$—; $x + y = 5, 6$.

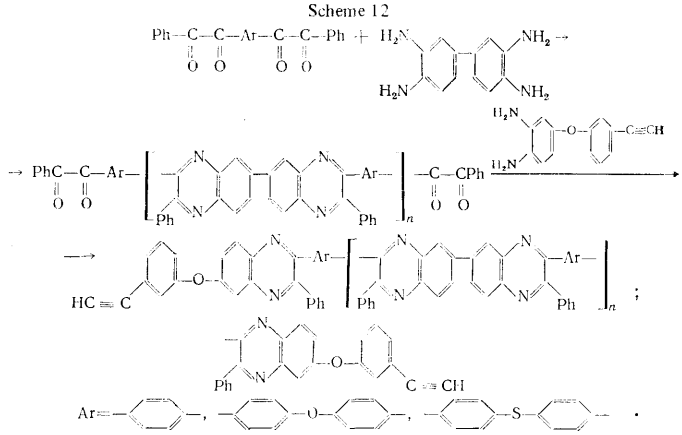


The polymers obtained had glass points ranging from −61° to −56 °C, were hardened via the acetylenic end groups at 180–200 °C, and in the hardened state began to be degraded in air at 375–400 °C.

3. Polyphenyltriazines

Oligophenyl-1,2,4-triazines containing acetylenic end-groups have been obtained by the reactions of bisamidrazones, dibenzils, and 4-(4-ethynylphenoxy)benzil via the scheme[105]

Scheme 11



These polymers have a high thermo-oxidative stability and proved promising as binders.

4. Polyphenylquinoxalines

Polyphenylquinoxalines containing ethynyl end-groups have been obtained by a two-stage method in accordance with the scheme

Scheme 12

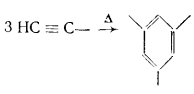
The scheme shows that oligomers with benzil end-groups were synthesised initially by the reaction of diaminobenzidine with an excess of an aromatic dibenzil and then a solution of 3-(3,4-diaminophenoxy)phenylacetylene was added to the reaction mixture. The polymer dissolves in THF, chloroform, dioxane, and methylene chloride; its cross-linking via the acetylenic end-groups takes place in the temperature range 200–275 °C according to differential scanning calorimetric data; the weight loss begins at 300 °C in air and at 465 °C *in vacuo*.

This and other reactions involving the formation of polyphenylquinoxalines and their properties have been described in detail in a review[9] and here we shall only note some of them. It is possible to synthesise polyphenylquinoxalines containing the 2,2′-(phenylethynyl)biphenylyl groups, which are capable of forming (via intramolecular cyclisation) 9-phenyldibenzanthracene fragments on heat treatment or exposure to radiation[108]. The viscosities of 5% solutions of the polymers obtained in chloroform at 30 °C were $\eta_{log} = 0.18–0.3$, their molecular weights ranged from 15000 to 17200, and their glass points were $T_g = 215–330$ °C. After hardening (at 245–320 °C in nitrogen), the polymers lost their solubility in sulphuric acid, which indicates the occurrence of intermolecular cross-linking.

In order to reduce the T_g of the oligomeric polyphenylquinoxalines with ethynyl end-groups, to increase the fluidity of their melts, and to decrease their hardening time, low-molecular-weight reactive plasticisers were employed:

6-(3-ethynylphenoxy)-3-[4-(3-ethynylphenoxy)phenyl]-2-phenylquinoxaline[109], 1-phenoxy-3-(3-ethynylphenoxy)-benzene, and 1,3-di(3-ethynylphenoxy)benzene[110]. The polyphenylquinoxalines with added plasticiser had T_g = 100 °C, the viscosities of their melts were reduced, and their hardening times and temperatures were lower.

V. THE HARDENING OF THE OLIGOMERS AND PRACTICAL APPLICATIONS OF THE POLYMERS



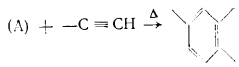
The authors of the present review believe that further progress in the field of the chemistry of polymers with acetylenic linkages will be determined not only by the synthesis of new polymers and the development and expansion of the raw materials resources but also by the development of methods which will ensure a high degree of the reaction involving the triple bond and which will increase the selectivity of the reaction with respect to the formation of aromatic rings in the three-dimensional network on hardening the polymers.

However, at the present time only a low degree of formation of aromatic rings is attained in the hardening of polymers, particularly those with rigid chains which have a high glass point, which is bound to affect their thermo-oxidative stability. Thus it has been established[111] by NMR that the ethynyl groups in polyimides with acetylenic end-groups are converted into aromatic rings to the extent of only 30%, while the remaining groups apparently give rise to olefinic fragments. The mechanisms of the hardening reactions are at present insufficiently clear and Baise[111] has pointed out the possibility of the occurrence of several different reactions of the acetylenic groups during hardening at elevated temperatures. Certain free-radical polymerisation reactions have been described. The pyrolytic cyclotrimerisation of acetylene to benzene or higher aromatic compounds may also proceed with participation of free radicals. There is also a possibility of aromatisation with conversion of acetylene-containing groups into condensed aromatic fragments.

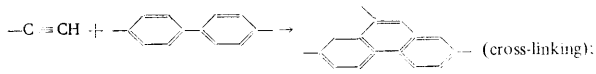
Thus the possibility of the manifestiation of a hetero-unit structure, which is in general characteristic of high-molecular-weight compounds, must be taken into account in processes involving the formation of various fragments during the hardening of compounds with acetylenic linkages[112]. The hetero-unit principle was considered previously in assessing the structures of polyphenylenes in which the main chain structures consisted of mono-, di-, and tri-substituted benzene rings (in different proportions) and also are of residual ethynyl end-groups and possibly defective polyene fragments. By altering the conditions of the synthesis, it was possible to influence within certain limits the structure of the polymer formed. The hardening conditions can also effect the character of the fragments produced.

The problems involved in the hardening of polymers with acetylenic end-groups have been considered[113]. Polymers containing acetylenic end-groups are hardened as a result of the following reactions:

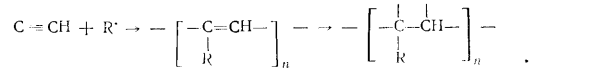
(1) trimerisation[114,115]:



(2) Glaser coupling[116]:

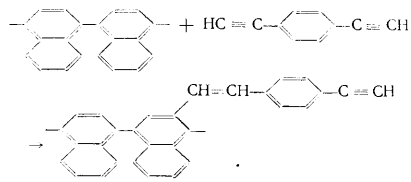


(3) Strauss coupling[117]:



(4) Diels–Alder reaction with participation of the products (A) formed as a result of the Strauss and Glaser coupling[118]:

(5) Diels–Alder reaction in the polymer chain[118]:



(6) free-radical polymerisation with formation of linear or branched products[118]:

The degree of reaction depends on the hardening of the polymer and on its character (thermal or catalytic)[111], but thermal hardening via the triple bonds is the most convenient method for the conversion of the oligomer into a three-dimensional polymer. Such hardening is usually carried out at 180–250 °C, where the main polymer chain is not degraded; however, it is then necessary to carry out the final hardening at 300–350 °C, since the thermal transformation of the acetylenic groups into aromatic rings takes place at 250–300 °C. This applies to the formation of a thermoreactive binder on the basis of oligophenylenes, developed in the USSR under the brand name "Reaktofen" and in the USA under the brand name "H-Resin".[119]

The oligophenylenes obtained on the basis of diethynylbenzenes are used to prepared articles by sintering, pressing, casting under pressure, and extrusion methods. These plastics can be used for a long time at 315 °C and briefly at 350 °C.[67,104,120] In order to increase the fluidity of the melt and to improve its adhesion to fillers, low-molecular-weight acetylenes are introduced into the resins[105]. Antifriction materials consisting of oligophenylenes, *p*-diethynylbenzene, and antifriction fillers, which are heat-resistant up to 380 °C, have been obtained[121].

The modification of the oligomers by the addition of low-molecular-weight oligomers has found extensive applications. There are patents for ternary and quaternary copolymers containing 25–75% of polyacetylene, obtained by the oxidative dehydropolycondensation of *p*- and *m*-diethynylbenzenes and dipropargyl ethers of phenols, together with 75–25% of low-molecular-weight acetylenes which consist of 1,4-diphenylbutadiyne, 1,3-di(phenylbutadiynyl)benzene, and others[122,123]; the copolymers are used to prepare graphite fibres. Phenol-formaldehyde resins are modified in the same way[124]. Polymers without ethynyl and other reactive groups are hardened using aromatic acetylenes. Thus the oligophenylenes obtained by the oxidative dehydropolycondensation of benzene, naphthalene, and anthracene are hardened with the aid of *p*-diethynylbenzene at 100–280 °C;[125,126] this entails the formation of insoluble and infusible products in almost quantitative yields. The study of the products of the hardening reaction for low degrees of conversion by NMR and infrared spectroscopy and also the investigation of the molecular weight distribution led to the following hardening mechanism:

Polyphenylenes can be used in the form of compositions for the construction of rocket nozzles, as ablation materials, and in composite materials together with carbon fibres for the construction of turbine blades and other devices which can operate for a long time at high temperatures and possess high resistance to wear. As a consequence of the satisfactory electrical, physical, and chemical characteristics, these polymers are promising for the preparation of electrical insulators, protective coatings, lining materials and filters in the form of compositions with metals, asbestos, and glass and carbon fibres, all components capable of being used at high temperatures[65].

The likely usefulness of polyimides with acetylenic groups as binders for carbon and glass plastics has been demonstrated[98,99]. Polyphenylquinoxalines are suitable for the preparation of adhesion materials[127] and polysulphones are capable of forming films which retain strength and flexibility after hardening[92]. Polymeric Schiff bases[83] serve as effective varnish coatings and impregnating materials and can be used to prepare semiconducting and conducting materials.

---o0o---

The problems containing the employment of acetylenic compounds in the synthesis and chemical modification of polymers examined in this review are at present extremely urgent and offer much promise from the standpoint of both the preparation on their basis of traditional polymers with more effective operating characteristics and for the preparation of materials with fundamentally new properties.

A Microheterogeneous Medium for Chemical (Enzymic) Reactions Based on a Colloidal Solution of Water in an Organic Solvent

Yu.L.Khmel'nitskii, A.V.Levashov, N.L.Klyachko, and K.Martinek

The structure and properties of inverted surfactant micelles in non-polar solvents are examined. The methods for the solubilisation of proteins (enzymes) in such systems and the molecular mechanisms of solubilisation are characterised. The kinetics of chemical enzymic reactions in inverted micelle systems are discussed. The factors influencing the catalytic activity and substrate specificity of the solubilised enzymes are analysed. The characteristic features of the shift of the chemical equilibrium in inverted micelle systems are considered and the prospects for the employment of such systems in fundamental research (particularly in the modelling of the structure and functions of biological membranes) and for the solution of applied problems in chemistry are discussed.
The bibliography includes 132 references.

I. INTRODUCTION

The most important elements in a chemical process are the selection of the reaction medium and the catalyst. Enzymes are the best catalysts of chemical reactions available at present. Their exceptionally high catalytic activity under mild conditions and the unsurpassed selectivity of their action[1] lead to extensive prospects for the employment of biocatalysis in technological processes[2]. The use of enzymes as catalysts in fine organic synthesis and in the preparation of medicinal drugs and valuable biologically active compounds is particularly promising. However, the wide scale employment of enzymes in practice is hindered by the fact they retain their unique catalytic properties usually only in

aqueous solution. On the other hand, it is known that many chemical reactions are driven by thermodynamic factors towards the required product only in specific organic solvents. This is associated both with specific solvation effects and with the solubilities of the individual reaction components or, in other cases, with the fact that water is formed together with the required product and the equilibrium is therefore displaced towards the starting materials when the reaction is carried out in aqueous solutions. Unfortunately the transition from water as the reaction medium to an organic solvent entails as a rule either complete denaturation of the enzyme or a sharp decrease of its catalytic activity and the disappearance of its substrate specificity[3].

One of the possible ways out of this situation is the creation of model catalytic systems, soluble in organic solvents, which make it possible to approach to some extent the efficiency of catalysis by enzymes in aqueous solutions. In particular, systems of inverted surfactant micelles in organic solvents can be used as such model systems. The inverted micelles consist of closed aggregates of associated surfactant molecules whose outer layer is made up of their hydrocarbon fragments and whose nucleus consists of their polar (ionic) groups. Such associated species are capable of solubilising in organic solvents considerable amounts of polar compounds, which are located within the inner cavity (nucleus) of the micelle.

The unique properties of the micromedium in the inner cavity of inverted micelles, namely a reduced polarity, a high microviscosity, and a high concentration of functional groups, justify the consideration of the inner cavity of inverted micelles as an extremely realistic model of the micromedium in the active centres of enzymes[4,5]. Indeed many reactions are greatly accelerated when they are carried out in systems of inverted micelles and the acceleration effects sometimes approach in order of magnitude those observed in enzyme catalysis[6]. The acceleration of reactions in inverted micelle systems is caused, apart from the trivial effect arising because the reactants are concentrated as a result of being bound to the micelles and the effects of the micromedium in the inner cavity, by the rigid fixation of the reactant molecules to the inner cavity of the micelles[6,7] as happens in enzyme catalysis[1]. Effects associated with specificity in relation to the size[8] and configuration[9] of the reactant molecules, characteristic of enzyme catalysis, can also be observed in catalysis by inverted micelles.

It is noteworthy that the acceleration and specificity effects, comparable in magnitude to those observed in enzyme catalysis, are manifested in an inverted micelle system only in individual instances and are not general. A procedure, which would permit a direct combination of the advantages of an enzyme as a catalyst with the advantages of an organic solvent as the reaction medium is therefore more promising. Its fundamental idea is to "force" enzymes to operate in an organic solvent with a low water content. Evidently, in employing this approach, it is necessary to solve the problem of the stabilisation of the enzyme in relation to the denaturing effect of the organic solvent[3].

This problem can be solved in principle by employing as the reaction medium a "water–water-immiscible organic solvent" system or an organic solvent which ensures the integrity of the native structure of the enzyme globule and hence its catalytic activity[10]. Another solution of the problem has been found recently. Namely we have shown[11], and this was subsequently confirmed in studies by other investigators (which are discussed below), that water-soluble enzymes can be solubilised in organic solvents with the aid of surfactants and that their catalytic activity can be simultaneously preserved. As a result of the solubilisation, the enzyme is incorporated in the inner cavity of an inverted surfactant micelle, as shown in Fig.1, and is thereby protected from the denaturing action of the organic solvent.

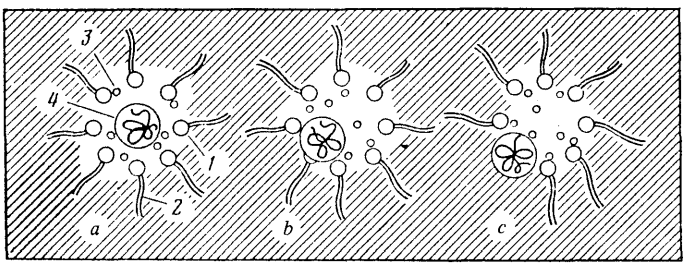

Figure 1. Schematic representation of an inverted micelle containing hydrophilic (*a*), surface-active (*b*), and hydrophobic (*c*) proteins: *1*) ionic (polar) group in the surfactant molecule; *2*) hydrocarbon group in the surfactant molecule; *3*) counterions and/or solubilised water molecules; *4*) enzyme molecule; the organic solvent is shown shaded.

We shall consider the principal aspects and achievements in this new field—micellar enzymology, which permits the employment of biocatalysts for the acceleration of chemical reactions in an organic solvent.

II. PHYSICOCHEMICAL PROPERTIES OF INVERTED MICELLES

The Structure of Inverted Micelles

In non-polar organic solvents inverted micelles consist of associated surfactant species whose inner component is made up of the polar "heads" and whose outer layer consists of the hydrocarbon "tails" of these molecules. The micelle-formation process in a non-polar medium can be described[12] in some cases within the framework of the mass action model, which presupposes an equilibrium between the monomeric surfactant molecules and the micelles of the "all or nothing" type and in other cases by a stepwise model, according to which a set of associated species with different aggregation numbers, which are in equilibrium with one another, exist in solution.

The size and form of the inverted micelles are closely related to the micelle formation mechanism: in the case of the mass action mechanism the micelles are nearly spherical, while in the case of the stepwise mechanism they assume extended, rod-like and lamellar structures[13]. The linear dimensions of the micelles do not usually exceed several tens of Angstroms. The micelles formed via the mass action mechanism are usually characterised by a narrow distribution with respect to size and shape, which is independent of the surfactant concentration[14–16]; this feature applies mainly to systems with anionic surfactants. In the case of surfactants undergoing association via the stepwise mechanism (these are as a rule cationic surfactants) the micelles are polydisperse and the distribution shifts towards larger associated species as the surfactant concentration rises[13,17,18].

On solubilisation of water in surfactant solutions in non-polar solvents, hydrated micelles are formed and differ significantly in their size and shape from the micelles which

exist in anhydrous systems. The hydration of the micelles reduces the degree of their asymmetry, since they acquire an almost spherical shape[19,20], and leads to a sharp increase of their size and molecular weight owing to the formation of a water-filled microcavity within the inverted micelle[16,19-23]. For example, in the system of inverted micelles formed by the sodium salt of the di-iso-octyl ester of sulphosuccinic acid (OT or AOT aerosol) in iso-octane, an increase of the degree of hydration, i.e. of the molar ratio $[H_2O]/[AOT]$, from 0 to 50 entails an increase of the hydrodynamic radius of the micelle from 17 to 120 Å.[22]

The Micromedium in the Inner Cavities of Inverted Micelles

The water filling the inner cavities of the hydrated inverted micelles differs in its physicochemical properties from the usual (bulk phase) water. The scale of the differences is determined by the degree of hydration by the inverted micelles, which is usually expressed as the ratio of the molar concentrations $[H_2O]/[\text{surfactant}] = w_0$. For low values of w_0 (of the order of several units), the properties of the micellar and bulk-phase water differ greatly but, as w_0 increases, the differences are gradually smoothed out. The cause of this is that the first portions of the water added to the system are bound firmly to the surfactant molecules as a result of the hydration of their polar components. The amount of strongly bound water is 4–10 molecules per surfactant molecule depending on the nature of the latter. The so-called "free" water, constituting an independent microphase and approaching in its properties the bulk-phase water, appears within the inverted micelles only after the completion of the hydration of the surfactant[20,24,25]. For example, for low values of w_0, the viscosity of the water solubilised by the inverted AOT micelles in an aliphatic hydrocarbon exceeds that of the bulk-phase water by a factor greater than 200 and its polarity corresponds to that of chloroform; with increase of w_0, these differences between the properties of the micellar and bulk-phase water decrease monotonically and disappear[25,26].

The aqueous cavities of the hydrated inverted micelles are inhomogeneous in their physicochemical properties and are characterised by different local polarities, viscosities, etc. at different points[20,26,27]. For example, the local viscosities and polarities of water within the cavities of the hydrated inverted AOT micelles in iso-octane respectively decrease and increase on moving away from the boundary of the aqueous cavity to its centre[26]. The existence of the inhomogeneity can be explained by the presence within the micelle of layers of water of hydration bound to different extents[20,26,27].

The pH Values in the Inner Cavities of the Inverted Micelles

The inner cavity of a hydrated inverted micelle is characterised by a high concentration of electric charges arising on ionisation of the polar groups in the surfactant molecules. As a result of this, the local pH of the aqueous cavity can differ significantly from the pH of the solubilised aqueous solution[28-32]. The question of the pH assumes a particular importance in the study of chemical (and particularly enzymic) reactions in the inner cavities of the inverted micelles.

In order to estimate the acid–base properties of the micromedium in the inner cavities of the inverted micelles, the method based on comparing the pK_a of different indicators dissolved in pure water and solubilised by the inverted micelles is most widely employed[29-32]. Analysis of the data obtained with the aid of the indicator method permits the conclusion that the micromedium in the inner cavity is in general more acidic than the initial aqueous solution in the case of an anionic surfactant[29,30] and more alkaline in the case of a cationic surfactant[32]. The pH shift is ~1–2 units. When a non-ionic surfactant is employed, the acidity in the inner cavity of the micelles hardly differs from that in the initial aqueous solution[31].

A new approach to the determination of the pH in the inner cavities of the inverted micelles, in which the dependence of the chemical shift of the ^{31}P NMR signal due to the ^{31}P nucleus, forming part of the composition of the phosphate ion, on the pH of the surrounding medium employed is used, has been proposed recently[28,33]. A relation between the pH of the aqueous cavity in an inverted AOT micelle in iso-octane and the initial aqueous solution (the "acidity scale") has been obtained with the aid of this method[28]. The pH shifts determined in this way agree with the values obtained by the indicator method[29,30].

Both approaches described suffer, however, from significant disadvantages. In particular the pK_a of the solubilised "reporter" molecule (indicator or phosphate anion) cannot be determined independently, which necessitates appropriate assumptions and hence leads to an uncertainty in the pH value obtained.

The Reactivity of the Water Solubilised by Inverted Micelles

The rates of chemical reactions involving water as a rule increase sharply on passing from an aqueous solution to a system of hydrated inverted micelles and the acceleration effect can reach a factor of 10^6 and more[5,34,35]. The acceleration effect is largely due to the high reactivity of the water solubilised in the inner cavities of the inverted micelles where the reaction takes place. For example, the nucleophilic activity of the water solubilised by inverted AOT micelles is at least 10^3 times higher than that of the bulk-phase water[5,35]. The water which is either involved in the hydration of the polar groups in the surfactant molecule[5,36] or appears directly after the completion of the hydration[35] shows the highest reactivity. Further addition of water leads to the formation of hydrogen bonds between the water molecules themselves which results in a decrease of their reactivity[36]. The high reactivity of the water molecules involved in the initial hydration of the surfactant can be caused by the high mobility and/or the change in their acid–base characteristics[5].

III. METHODS FOR THE INCORPORATION OF THE PROTEIN (ENZYMES) IN INVERTED MICELLES

Homogeneous (optically transparent) solutions of proteins (enzymes) in organic solvents can be obtained by employing one of the following three procedures.

The first procedure was proposed by ourselves[11] and is nowadays most widely used[37-44]. A small amount (of the order of several volume per cent) of the aqueous protein solution was introduced into a surfactant solution in an organic solvent (the actual ratio of the volumes of the aqueous and organic solutions is determined by the object of the experiment, the required degree of hydration of the surfactant, etc.). The resulting mixture is vigorously shaken (for several tens of seconds) until the formation of an optically transparent solution. Exposure of the

mixture to ultrasound is also used instead of mechanical shaking[45,46]. It must be emphasised that the choice of the method of stirring is important in the study of enzymes and particularly enzyme kinetics in inverted micelle systems, because the time taken to attain equilibrium in the colloidal system depends on its efficiency: in some cases the equilibration time in inverted micelle systems (in the absence of a solubilised protein) can be measured in hours and tens of hours (see, for example, Becher and Clifton[47] and Corkill et al.[48]).

The equilibration time in surfactant solutions apparently depends to a considerable extent on the nature of the surfactant and/or solvent. For solutions of one of the most widely used surfactants—the OT (OAT) aerosol—in aliphatic hydrocarbons, it has been shown[22,49] that equilibrium (the attainment of constant dimensions of the micelles) is established rapidly and there is no need for ultrasonic treatment. We arrived at an analogous conclusion using the same surfactant for the solubilisation of enzymes[50]. The question of the necessity for the ultrasonic treatment can, however, arise when other surfactants are used. One must then bear in mind that the action of ultrasound can inactivate the enzyme[51]. In the solubilisation of aqueous enzyme solutions without the application of ultrasound, there is virtually no inactivation of the enzyme[11,41,52,53].

The second procedure, proposed in Menger's laboratory[54], consists in the initial introduction of the required amount of water into the surfactant solution in an organic solvent (in order to attain the required degree of hydration of the surfactant), after which a dry (lyophilised) protein is dissolved in the resulting transparent solution with vigorous shaking. The time required for the dissolution of the dry protein is usually greater than in the procedure employing aqueous solutions but it diminishes with increase of the degree of hydration of the surfactant[50]. The complete dissolution of the dry protein sample takes place only at moderate protein concentrations, comparable to those obtained by the first method[50].

In order to obtain highly concentrated protein solutions, an excess of the dry protein is introduced into the surfactant solution in an organic solvent and its undissolved part (after several hours) is separated by centrifugation[50]. The repetition of the procedure for the dissolution of the protein in the resulting supernatant increases the protein content in the micellar solution. When this method is used to obtain concentrated protein solutions, it is necessary to monitor the surfactant and water contents in the supernatant after separating the soluble component, because the latter can entrain both the surfactant and water.

The third solubilisation method, proposed by Luisi and co-workers[55,56], involves the spontaneous transfer of the protein in a two-phase system consisting of approximately equal volumes of the aqueous protein solution and the organic solvent containing the surfactant. After the completion of the solubilisation, carried out with slight stirring or altogether without stirring, the organic phase containing the dissolved protein is separated. A disadvantage of this method is the long time required for the solubilisation process. In addition, the problem of determining the amount of water solubilised by the micelles (the degree of hydration of the surfactant) arises.

We draw attention to the fact that, for very low values of $w_0 < 1-2$, proteins are almost insoluble in inverted micelle systems. The solubilisation of the protein begins only for a certain value of w_0, beyond which an increase of the degree of hydration of the surfactant is accompanied by an almost linear increase of the solubility of the protein up to concentrations comparable to those attainable in an aqueous solution[50]. The specific solubilisation limits depend on the temperature, the pH of the aqueous solution, the nature of the surfactant, the concentrations of water and the surfactant in the system, and also the nature of the protein[41,50].

Molecular Mechanisms of the Incorporation of the Protein in Inverted Micelles

In organic solvents inverted micelles provide a methodologically unique possibility for the dissolution of proteins of different kinds under standard conditions where the dissolved protein molecule can itself "select" the microenvironment corresponding to its nature (optimal from the thermodynamic standpoint). In fact, as can be seen from the schematic illustration in Fig. 1*a*, the molecule of a hydrophilic protein can avoid direct contact both with the organic solvent and with the surface of the inner cavity of the inverted micelle formed by the polar "heads" of surfactants molecules, being localised in the aqueous nucleus of the hydrated inverted micelle. Surface-active enzymes, for example lipases, are able to interact with the surface layer of the inverted micelle or can be even partly immersed in the latter (Fig. 1*b*). Finally, typical membrane enzymes, can, in principle, come into contact even with an organic solvent, provided that this is favoured by thermodynamic factors (Fig. 1*c*).

Examples of the solubilisation by inverted micelles of enzymes of different kinds, corresponding to type *a*,[11,37-45,52-59] *b*,[60,61] and *c*,[46,62] have been described in the literature (Fig. 1). In all cases the solubilisation results in the formation of an optically transparent solution and the solubilised enzymes retain their catalytic activity. Only the molecular mechanism of the solubilisation of proteins (enzymes) of type *a* (Fig. 1), i.e. the water-soluble proteins, has been investigated quantitatively[38,63,64]. In particular, it has been shown by sedimentation analysis[63,64] that the molecules of typical water-soluble proteins (lysozyme, trypsin, α-chymotrypsin, ovalbumin, alcohol dehydrogenase, and γ-globulin) are capable of being incorporated into inverted AOT micelles in octane over a wide range of experimental conditions without a significant change in the initial dimensions of the micelle. This result agrees with the scheme in Fig. 1*a* and indicates the absence of a significant interaction of the protein with the surfactant.

IV. KINETIC THEORY OF CHEMICAL REACTIONS IN INVERTED MICELLE SYSTEMS

The rates of many chemical reactions increase sharply when they are transferred from an aqueous medium or an organic solvent to organic solvent–surfactant or organic solvent–surfactant–water systems (see the relevant reviews[6,24,65]). In discussing the reaction acceleration effects, the term "micellar catalysis" (which has come to be generally accepted for aqueous systems) must, however, be used with caution because the increase of the rates of reactions in the presence of surfactants in organic solvents is by no means always caused by micellar effects[66]. In certain cases inverted micelles are not formed at all and the acceleration can be achieved as a result of the homogeneous-catalytic effect of monomeric surfactant molecules[66].

Analysis of the numerous experimental data available at present permits the conclusion that in those cases where the acceleration is indeed micellar in nature, it can be caused by

the operation of factors analogous to those which ensure[67,68] the increase of the rates of reactions in aqueous micellar systems. Namely the acceleration can be due to the reactants becoming concentrated as a result of their binding to the micelles, the catalytic action of the polar groups in the surfactant molecules, the rigid fixation and/or orientation of the reactant molecules in the inner cavity of the micelles, and also the characteristic features of the micromedium in the inner cavity where the reaction takes place (reduced dielectric constant, increased reactivity of water, and a shift of the pK_a of the ionic groups of the interacting molecules).

In the kinetic analysis of chemical reactions in an inverted micelle system, it is necessary in the first place to take into account the distribution of the reactants in this microheterogeneous medium. The analogous problem in micellar catalysis in aqueous solutions has already been adequately solved[67,68] within the framework of the pseudophase model. The pseudophase approach can also be employed in the study of the kinetics of chemical reactions in inverted micelle systems.

According to the pseudophase model[69], a surfactant solution consists of the bulk phase of the organic solvent and the micellar "phase" and there is an equilibrium distribution of the reactants between these phases, for example:

$$A_{bulk} \overset{P_A}{\rightleftharpoons} A_{mic}, \qquad (1)$$

where P_A is the partition coefficient of the reactant A:

$$P_A = [A]_{mic}/[A]_{bulk}. \qquad (2)$$

Here and henceforth the subscripts "mic" and "bulk" refer respectively to the micellar and bulk phases. The concept of the set of micelles as an independent "continuous" phase agrees with experimental data, which indicate the free character of the intermicellar exchange of the solubilised molecules[45,70-74]. The applicability of the pseudophase model is limited by the assumption that the equilibrium distribution of the reactants between the phases [formula (1)] does not shift as a consequence of the chemical reaction, i.e. the exchange of matter between the phases is fairly rapid (takes place at diffusional rates). This assumption, which is valid for normal surfactant micelles in aqueous solutions[68], remains in force also on passing to inverted micelle systems[75-78]. We shall consider the application of the pseudophase approach to the analysis of chemical reactions of various types occurring in inverted micelle systems.

First-Order Reactions

Within the framework of the pseudophase model, first-order reactions can be described by the following scheme:

$$\begin{array}{ccc} A_{bulk} & \overset{P_A}{\rightleftharpoons} & A_{mic} \\ \downarrow k_{bulk} & & \downarrow k_{mic} \\ \text{products} & & \text{products} \end{array} \qquad (3)$$

where k_{bulk} and k_{mic} are the true rate constants for the transformation of A in the bulk phase and micellar phase respectively and the partition coefficient P_A is specified by Eqn.(2). Under conditions where [surfactant] $\gg$ [A], the expression for the effective rate constant is[67,68]

$$k_{obs} = (k_{bulk} + k_{mic}P_A cV)/(1 + P_A c) \qquad (4)$$

where c is the concentration obtained after subtracting the critical concentration for micelle formation (CCM), V the molar volume of the surfactant, and $cV \ll 1$ the volume fraction of the micellar phase. It follows from Eqn.(4) that the dependence of k_{obs} on c has the form of a curve with a plateau, which is indeed observed experimentally[4,5,79-81]. The limiting value of k_{obs} is equal to k_{mic} and characterises the true reactivity of the reactant A in the micellar medium.

Second-Order Reactions

Kinetic analysis of a second-order reaction $A + B \xrightarrow{k_{obs}}$ products, occurring in a micellar system under the conditions of strong binding of the reactants to the micelles, leads to the following expression for the dependence of the observed reaction rate constant on the surfactant concentration[67,68]:

$$k_{obs} = \frac{(k_{mic}/V)\,K_A K_B c + k_{bulk}}{(1 + K_A c)\,(1 + K_B c)} \qquad (5)$$

where $K_A = P_A - 1$, $K_B = P_B - 1$, and $P_A \gg 1$ and $P_B \gg 1$ are the partition coefficients of the reactants A and B between the phases determined in accordance with Eqn.(2). According to Eqn.(5), the dependence of k_{obs} on c should be represented by a curve with a maximum, which agrees with experimental data[82,83]. The proposed methods for the linearisation of the experimental k_{obs}–c curves[67,68] make it possible to find both the true rate constants k_{mic} in the micellar medium and the binding constants.

As a general comment on Eqns.(4) and (5), one must emphasise that, in the study of the dependence of k_{obs} on c within the framework of the model discussed, the surfactant concentration should be varied in such a way that the ratio $[H_2O]/[\text{surfactant}]$ is kept constant. In other words, the change in the surfactant concentration should be always accompanied by the corresponding change in the water concentration and conversely. Otherwise a change in c leads to an alteration of the properties of the micromedium within the inner cavities of the inverted micelles where the reaction proceeds (see Section II) and hence to a change in k_{mic} and a distortion of the type of dependence of k_{obs} on c predicted by Eqns.(4) and (5).

Enzymic Reactions in Inverted Micelle Systems

We shall consider the kinetics of the reaction between the enzyme E and the substrate S proceeding in accordance with the Michaelis mechanism

$$E + S \rightleftharpoons ES \rightarrow E + \text{products} \qquad (6)$$

in an organic solvent–water–surfactant system. We shall assume that an equilibrium distribution of the substrate between the phases has been established:

$$S_{bulk} \overset{P_S}{\rightleftharpoons} S_{mic}, \qquad (7)$$

where P_S is the partition coefficient of the substrate:

$$P_S = [S]_{mic}/[S]_{bulk}. \qquad (8)$$

The distribution of the enzyme need not be considered because proteins are almost insoluble in hydrophobic solvents[84]; in addition, enzymes are as a rule denatured in non-aqueous media (see the review of Martinek and Berezin[85]). We shall therefore assume that the catalytic activity is concentrated only in the micellar phase.

The rate of reaction (6) in the micelles, referred to the bulk phase of the entire system, can be expressed (in the initial instant when the concentration of the products is low compared with the initial concentration of the substrate,

in the presence of an excess of the substrate relative to the enzyme, and under stationary conditions) in the form of the Michaelis–Menten equation:

$$v = \frac{k_{cat,mic}[E]_{0,mic}[S]_{0,mic}}{K_{M,mic} + [S]_{0,mic}} \cdot \theta \qquad (9)$$

where θ is the volume fraction of the micellar phase and the subscript 0 indicates initial concentrations.

We shall assume that the exchange of substrate molecules between the phases is fairly rapid, i.e. the occurrence of the enzyme reaction (6) does not impair equilibrium (7). The concentrations of the reactants can then be found from Eqn.(8) and the material balance equations:

$$[S]_{0,mic} = [S]_{0,mic}\theta + [S]_{0,bulk}(1-\theta)$$
$$[E]_{0,tot} = [E]_{0,mic}\theta \,. \qquad (10)$$

However, one should remember that Eqn.(8) is valid only for fairly dilute solutions and the reactant concentrations must therefore be much lower than the surfactant concentration.

After substituting Eqns.(8) and (10) in Eqn.(9), we have

$$v = \frac{k_{cat,app}[E]_{0,tot}[S]_{0,tot}}{K_{M,app} + [S]_{0,tot}} \qquad (11)$$

where

$$k_{cat,app} = k_{cat,mic} \qquad (12)$$

$$K_{M,app} = K_{M,mic}[1+\theta(P_S-1)]/P_S \,. \qquad (13)$$

In the case of a reaction involving a charged substrate, Eqn.(13) can be simplified by assuming that the substrate molecules exist only in the aqueous micellar phase and hence not only $P_S \gg 1$ but also $P_S\theta \gg 1$. Then

$$K_{M,app} = K_{M,mic}\theta \qquad (14)$$

Here we have considered only the simplest pseudophase model[52,86,87], which presupposes a uniform distribution of the reactants throughout the bulk of the hydrated micelles. In the general case the model must naturally be more complex and must take into account the microheterogeneity of the inner cavities of the inverted micelles; in particular, one could take into account the distribution of the substrate between the inner surface layer and the aqueous nucleus of the inverted micelle. Nevertheless, even the simplest model and the equations obtained within its framework permit a successful kinetic analysis of enzymic reactions in inverted micelle systems.

In order to determine the "true" parameters of the Michaelis equation, characterising the enzymic reaction in the aqueous micellar phase, it is necessary to investigate the dependence of the observed rate of the enzymic reaction on the ratio of the bulk phase (organic solvent) and the aqueous micellar phase. The volume fraction of the aqueous micellar phase θ should then be varied in such a way that the ratio w_0 is kept constant, i.e. the properties of the aqueous micellar phase itself are not altered (see Section II).

The validity of Eqns.(11)–(14) has been confirmed[52,86,87] in relation to the trypsin-catalysed hydrolysis of the *p*-nitroanilide of *N*-benzoyl-D,L-arginine in the system of the inverted micelles of cetyltrimethylammonium bromide in a 1:1 chloroform–octane mixture. The dependence of the observed kinetic parameters of this reaction ($K_{M,app}$ and $k_{cat,app}$) on the volume fraction of water in the system is illustrated in Fig.2. Evidently conditions can be achieved (for low values of θ) where, according to Eqn.(14), the observed $K_{M,app}$ is superior to (smaller than) K_M in an aqueous solution (indicated by the dashed line in Fig.2). In principle, by virtue of this factor, it is possible to achieve higher observed reaction rates in an inverted micelle system than in an aqueous solution.

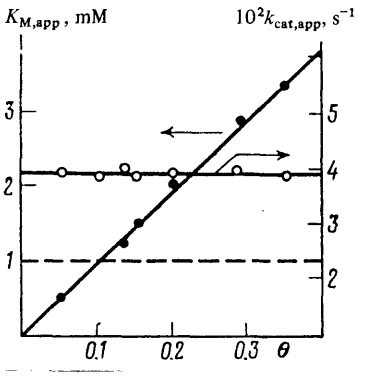

Figure 2. Hydrolysis of the *p*-nitroanilide of *N*-benzoyl-D,L-arginine catalysed by trypsin solubilised in the system cetyltrimethylammonium bromide–aqueous buffer (0.02 M phosphate–borate–acetate, pH 8.0)–1:1 chloroform–octane mixture[86]. The Michaelis parameters $K_{M,app}$ and $k_{cat,app}$ are plotted as a function of the volume fraction of water θ in the system with $[H_2O]/[surfactant] = 25$ and [surfactant] = 0.1–0.8 M. Experimental conditions: 26 °C, $[E]_{0,tot} = 5 \times 10^{-6}$ M. $K_{M,app}$ for the reaction in water is indicated by a dashed line.

This phenomenon, which has long been known for organic (non-enzymic) reactions in micellar solutions[67,68], is associated with the fact that the reactants become concentrated in the micelle. In principle, the concentration effect influences all the kinetic parameters whose dimensions include concentration. On the other hand, Fig.2 shows that the quantity K_{cat}, which has the dimensions [time^{-1}], is independent of θ and hence the observed value of k_{cat} is equal to the true value of this constant for the reaction in the aqueous micellar phase [see Eqn.(12)]. This is precisely why the *true* reactivity of the enzyme and hence its state in the micelle can be inferred from the observed value of $k_{cat,app}$.

V. CATALYTIC ACTIVITY OF SOLUBILISED ENZYMES

The Influence of the Degree of Hydration of the Inverted Micelles

One of the most striking effects observed in the study of enzymes in inverted micelle systems is the dependence of the catalytic activity of the solubilised enzymes on the degree of hydration of the inverted micelle w_0, i.e. on the parameter which determines the size and properties of the micromedium within the inner cavities of the micelles. The dependence of the catalytic activity on w_0 has been observed for enzymes such as α-chymotrypsin[40,52,58,87], trypsin[88], lysozyme[41], phospholipase A_2,[60] alcohol dehydrogenase[52], pyrophosphatase[52,57,87], and pancreatic lipase[61]. As a rule, this dependence is bell-shaped, i.e. there is an optimum value of w_0 for which the catalytic

activity of the solubilised enzyme is a maximum. The optimum values of w_0 differ for different enzymes.

As an example, we shall consider the dependence of the rate constant k_{cat} for the deacylation of *N*-trans-cinnamoyl-α-chymotrypsin, solubilised by inverted AOT micelles in octane, on the degree of hydration, which is illustrated in Fig.3. The possible causes of the appearance of the maximum in the relation between k_{cat} and w_0 have been analysed in detail[58]. Here we shall draw attention to the fact that, under the conditions of the maximum, k_{cat} exceeds the value observed in an aqueous solution (shown by a dashed line in Fig.3). This phenomenon of the "superactivity" of the α-chymotrypsin solubilised by inverted AOT micelles has also been observed by other workers[40,54]. The phenomenon of superactivity is apparently partly due to the effects of the microenvironment of the enzyme molecule in the inverted micelle.

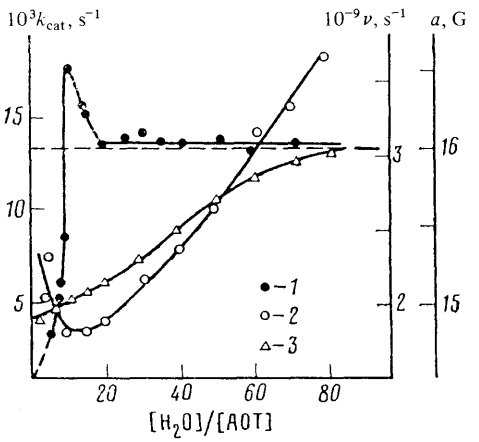

Figure 3. Dependence of the first-order rate constant k_{cat} for the deacylation of *N-trans*-cinnamoyl-α-chymotrypsin (curve *1*), the rotational frequency ν (curve *2*), and the hyperfine splitting constant *a* (curve *3*) for the spin-labelled α-chymotrypsin on the ratio $[H_2O]/[AOT]$ in the AOT (0.1 M)–octane–water (0.05 M tris buffer, pH 8.0) system at 25 °C.[89] The 4-iodoacetamido-2,2,5,5-tetramethylpyrrolidin-1-ylo y-radical was used as the spin label. The values of k_{cat} and *a* in aqueous solution are indicated by the dashed line.

Indeed, Fig.3 shows that the enzyme exhibits the maximum activity for moderate degrees of hydration of the surfactant, i.e. under conditions where the microenvironment of the enzyme molecule within the micelle differs significantly from that in aqueous solution. In particular, it follows from Fig.3 that the hyperfine splitting constant *a* of the EPR signal of a spin label introduced into the active centre of α-chymotrypsin is smaller under the conditions of the catalytic activity optimum than in an aqueous solution[89]. This implies that the polarity of the medium in which the active centre of the solubilised enzyme is located is significantly lower than the polarity of the aqueous solution[90].

On the other hand, the appearance of "superactivity" can also be caused by conformational changes in the enzyme molecule when it is incorporated in the inverted micelle. Thus, under the conditions of the catalytic activity optimum, a minimum is observed in the curve representing the dependence of the frequency of rotation ν of the spin label in the α-chymotrypsin active centre on w_0 (Fig.3), i.e. there is a minimum in the conformational mobility of the label. The circular dichroism spectra have led to the conclusion[40] that there is an increase of the rigidity (degree of helical configuration) of the α-chymotrypsin molecule solubilised by inverted AOT micelles in iso-octane (the region where $w_0 \cong 10$). The increased conformational rigidity of the enzyme molecule for $w_0 \cong 10$ can apparently be explained by the fact that under these conditions the diameter of the inner cavity of an empty inverted AOT micelle[21] is close to the dimensions of the α-chymotrypsin molecule (40 × 40 × 50 Å).[91]

Another example is provided by horse radish peroxidase solubilised by inverted AOT micelles in octane. Fig.4 shows that the optimum value of k_{cat} greatly exceeds the activity manifested by the enzyme in aqueous solution (dashed line). Furthermore, Fig.4 shows that the optimum value of k_{cat} increases with decrease of the surfactant concentration (with decrease of the area of the interface) and in the limit reaches values hundreds of times greater than the catalytic activity of the peroxidase in aqueous solution[59].

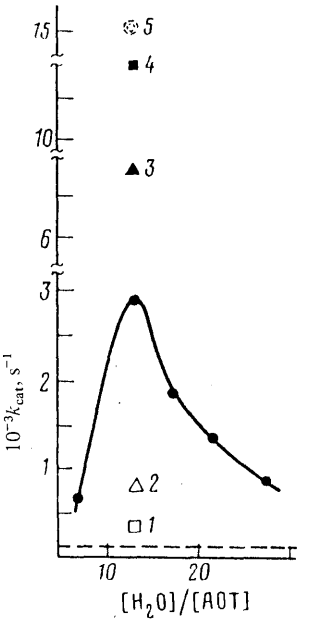

Figure 4. Dependence of the first-order rate constant k_{cat} for the peroxidase-catalysed oxidation of pyrogallol by hydrogen peroxide on the degree of hydration of the surfactant in the AOT (0.1 M)–octane–water (0.025 M phosphate buffer, pH 7.0) system at 26 °C.[59] The rate constants k_{cat} were measured for a fixed degree of hydration $[H_2O]/[AOT] = 13$ at different surfactant concentrations: *1*) 0.5 M AOT; *2*) 0.3 M AOT; *3*) 0.03 M AOT; *4*) 0.03 M AOT + 0.1 M imidazole; *5*) k_{cat} found by extrapolation to zero surfactant concentration. Dashed line—the value of k_{cat} in aqueous solution.

The "superactivity" of the enzyme solubilised by inverted micelles is so far a fairly rare phenomenon. In most cases the catalytic activity of enzymes under normal conditions is close to that observed in aqueous solution (for example in the

case of horse liver alcohol dehydrogenase[39,53], trypsin[45], and pyrophosphatase[57,87]). This fact is consistent with the results of spectroscopic studies[37,39,44–46,54–56,88], according to which the conformation of the protein molecules solubilised by inverted micelles is usually in the main identical with that observed in aqueous solution.

However, it must be emphasised that the relation between the conformational (according to spectroscopic data) and catalytic characteristics of enzymes is not always unambiguous. For example, the catalytic activity of lysozyme solubilised by inverted AOT micelles in iso-octane approaches under optimum conditions that observed in aqueous solution, although the conformation of this enzyme undergoes significant changes after its incorporation into the inverted micelle according to circular dichroism data[41]. On the other hand, spectroscopic characteristics of another enzyme, horse radish peroxidase, hardly change on solubilisation by inverted AOT micelles[46,59], while the optimum catalytic activity of the solubilised peroxidase greatly exceeds that manifested by the same enzyme in aqueous solution (Fig.4). The interpretation of spectroscopic data for solubilised enzymes must therefore be treated with caution.

The Influence of the pH

The rates of enzymic reactions and the kinetic parameters describing them in most cases depend on the pH (see, for example, Berezin and Martinek[1]). When an enzymic reaction was transferred from an aqueous solution to a system of inverted surfactant micelles, significant shifts of the pH profiles were observed[37,40,41,45,52,54,87]. This phenomenon is due to different causes. Firstly, the use of ionogenic surfactants, forming a charged layer (electrical double layer) around the enzyme molecule, can lead to a local shift of the pH (as a function of the sign of the charge of the ionic groups and the degree of hydration of the surfactant molecule). The apparent shift of the pH (and correspondingly of the effective pK) is in this case usually 1–2 units (see the section above dealing with the micromedium in the inner cavities of inverted micelles). Secondly, the acid–base properties of the ionogenic groups of the enzymes solubilised in the inverted micelles can vary with their microenvironment (for example, on partial dehydration). It is well known that the dehydration of ionic groups, which occurs when an aqueous solution is replaced by an aqueous organic solution or a purely organic solution, leads to changes in the pK of the ionic compounds by an amount up to several units[92]. Finally, it is necessary to take into account the possibility of a conformational change in the enzyme on solubilisation, which can also alter the observed pK of its ionogenic groups, including the functional groups involved in the enzymic reaction.

VI. SUBSTRATE SPECIFICITY OF SOLUBILISED ENZYMES

The change in the specificity of the enzyme as a result of its solubilisation can be both true, i.e. associated with a change in the catalytic properties of the enzyme itself, and apparent, i.e. caused by a change in the observed Michaelis constant, which depends, as can be seen from Eqn.(13), on the distribution of the substrate in the inverted micelle system (i.e. on the local concentration of the substrate around the solubilised enzyme molecule.

A change in the true substrate specificity has been established for pancreatic lipase, which catalyses the hydrolysis of the glycerol esters of aliphatic acids[61]. Namely, whereas in aqueous solution k_{cat} for the hydrolysis of tributyrin is greater by a factor of ~2 than for triolein[93], in the AOT inverted micelle system in octane k_{cat} for triolein actually exceeds k_{cat} for tributyrin by a factor greater than 15.[61] This means that the transition from an aqueous solution to the inverted micelle system is accompanied by a significant shift of the true substrate specificity of the lipase in favour of high-molecular-weight substrates.

A striking example of a change in the substrate specificity of an enzyme due to the substrate distribution effects is provided by the oxidation of aliphatic alcohols catalysed by horse liver alcohol dehydrogenase in the AOT inverted micelle system in octane[53]. Fig.5 shows that the transition from an aqueous solution to the inverted micelle system is accompanied by a shift of the maximum on the curve describing the dependence of the second-order rate constant for this reaction $k_{cat}/K_{M,app}$ on the length of the hydrocarbon chain in the molecule of the alcohol substrate n; it is seen that octanol ($n = 8$) is the optimum substrate in water, while butanol ($n = 4$) is the optimum substrate in a colloidal solution of water in octane. In other words, the substrate specificity of alcohol dehydrogenase, whose measure is in fact the quantity $k_{cat}/K_{M,app}$,[94] changes sharply on passing from an aqueous to a micellar solution.

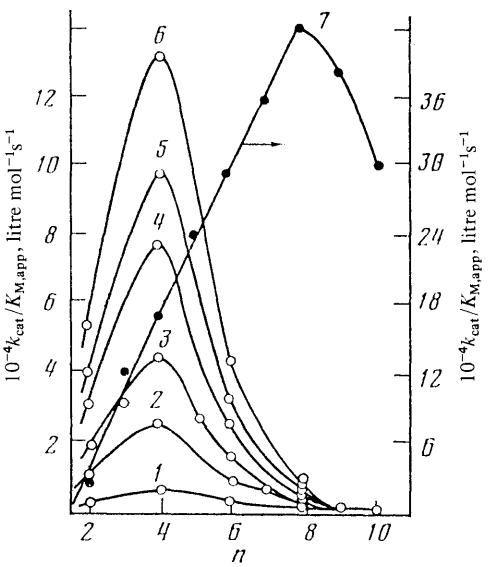

Figure 5. Dependence of the second-order rate constant $k_{cat}/K_{M,app}$ for the oxidation of aliphatic alcohols, catalysed by horse liver alcohol dehydrogenase, on the length of the hydrocarbon chain n in the alcohol substrate molecule[53]. *1*)–*6*) AOT (0.1 M)–octane–water (0.02 M phosphate buffer, pH 8.8) inverted micelle system; $[H_2O]/[AOT]$: *1*) 12.2; *2*) 23.0; *3*) 29.0; *4*) 37.7; *5*) 42.3; *6*) 48.9; aqueous solution (0.02 M phosphate buffer, pH 8.8); temperature 25 °C.

On the other hand, the conformation of the active centre of alcohol dehydrogenase hardly changes in such a transition, which is indicated by spectroscopic data[39] and the fact that the character of the dependence of k_{cat} on n is the same in aqueous solution and in the inverted micelle system[53]. The observed change in substrate specificity is caused[53] by the change in the character of the dependence of $K_{M,app}$ on n

associated with the effects due to the distribution of the alcohol substrate between the micellar and organic phases.

VII. REGULATION OF THE CHEMICAL EQUILIBRIUM IN INVERTED MICELLE SYSTEMS

The system of hydrated inverted surfactant micelles in an organic solvent in the presence of a not unduly high water content constitutes in essence a two-phase water–organic solvent phase, in which, however, the aqueous phase is "uniformly" distributed (by virtue of the presence of the surfactant) in the bulk of the organic solvent. The characteristics of the shifts in the equilibria of the chemical reactions (including enzymic reactions) in two-phase water–organic solvent systems in the absence of surfactants (i.e. in systems where there is a macroscopic interface between the phases) have been investigated in fair detail[95–102]. The approach[95–100] taking into account the distribution of the reactants between the organic and aqueous phases proved fruitful in the analysis of such systems. In particular, for the simplest reaction A ⇌ B in a two-phase system, the kinetic scheme assumes the following form:

$$\begin{array}{ccc} & \overset{K_W}{} & \\ (A \rightleftharpoons B)_W & & \\ {\scriptstyle P_A}\downarrow\uparrow & & \downarrow\uparrow{\scriptstyle P_B} \\ & \overset{K_{org}}{} & \\ (A \rightleftharpoons B)_{org} & & \end{array} \qquad (15)$$

where K_W and K_{org} are the equilibrium constants of reaction (15) in water and in the organic solvent respectively and $P_A = [A]_{org}/[A]_W$ and $P_B = [B]_{org}/[B]_W$ are the partition coefficients of the reactants between the phases, while the subscripts "w" and "org" refer to the aqueous and organic phases respectively. The expression for the effective equilibrium constant of reaction (15), which is equal to the ratio of the concentrations of the reactants A and B relative to the overall volume of the system, i.e. $K_{eff} = [B]_{tot}/[A]_{tot}$, can be formulated[95–98] as follows:

$$K_{eff} = K_W(1+\alpha P_B)/(1+\alpha P_A) \qquad (16)$$

where $\alpha = V_{org}/V_W$ is the ratio of the volumes of the organic and aqueous phases. In conformity with Eqn.(16), the quantity K_{eff} varies monotonically with increase of α—from $K_{eff} = K_W$ for $\alpha = 0$ to $K_{eff} = K_W P_B/P_A = K_{org}$ for $\alpha \to \infty$ (see, for example, curve *1* in Fig.6).

In the more complex case of a bimolecular reaction A + B ⇌ C + D in a two-phase system, the dependence of K_{eff} on α can have the non-trivial form of a curve with an extremum[96–98]. In other words, in a system of two immiscible solvents the effective equilibrium constant can be higher (or correspondingly lower) than the limiting values characterising the equilibrium in each of the phases.

On passing from a truly two-phase water–organic solvent system to a pseudo-two-phase system of hydrated inverted surfactant micelles in an organic solvent, one may expect, in principle, the appearance of effects associated with the specific influence of the surfactant on the equilibrium position. Effects of this kind have been observed[103] in the oxidation of isobutyl alcohol to isobutyraldehyde catalysed by horse liver alcohol dehydrogenase in a system of inverted AOT micelles in octane:

$$RCH_2OH + NAD^+ \overset{K}{\rightleftharpoons} RCHO + NADH + H^+ . \qquad (17)$$

The pH-dependent equilibrium constant of reaction (17) was investigated:

$$K = \frac{[RCHO]_{eq}\,[NADH]_{eq}}{[RCH_2OH]_{eq}\,[NAD^+]_{eq}} . \qquad (18)$$

The results are presented in Fig.6 in the form of plots of $\lg(K/K_W)$, where $K_W = 2.2 \times 10^{-3}$, against the ratio of the volumes of the organic and aqueous phases V_{org}/V_W.

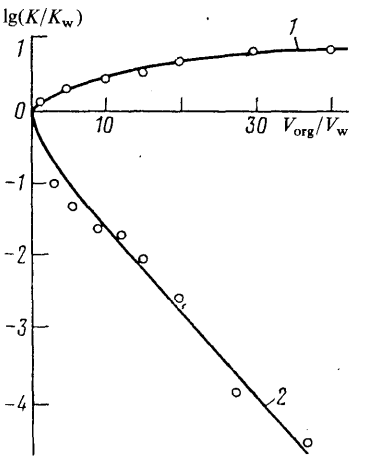

Figure 6. Dependence of the equilibrium constant of reaction (17) on the ratio of the volumes of the organic and aqueous phases[103]; *1*) water (0.02 M phosphate buffer, pH 8.8)–octane two-phase system; *2*) inverted AOT micelle–octane–water (0.02 M phosphate buffer, pH 8.8) system; initial AOT concentration in octane 0.7 M; temperature 20 °C.

In the truly two-phase water–octane system (in the absence of a surfactant), the equilibrium position of reaction (17) can be described by an equation analogous to Eqn.(16), because the coenzymes NAD^+ and NADH are insoluble in octane (their partition coefficients are zero).[96,97] Indeed in this case the dependence of $\lg(K/K_W)$ on the phase volume ratio V_{org}/V_W has the form of a curve with a plateau in conformity with Eqn.(16) (curve *1* in Fig.6). In other words, as the water content in the system diminishes, the equilibrium constant of reaction (17) increases, i.e. the equilibrium shifts to the right (in the direction of the aldehyde). On passing from the two-phase water–octane system to a homogeneous (micellar) solution of water solubilised in octane with the aid of AOT, the character of the dependence of the equilibrium constant on V_{org}/V_W changes sharply (cf. curves *1* and *2* in Fig.6 respectively). Namely an increase of the content of the organic component (octane) in the system leads to a more significant shift of the equilibrium in the presence of the surfactant than in its absence and in addition the shift is in the opposite direction (towards the formation of the alcohol).

The specific influence of AOT on equilibrium (17) is due to the differences between the capacities of the starting materials and reaction products for binding onto the inner surfaces of the inverted micelles formed by the ionic groups of the AOT molecules[103].

It is important to emphasise that the degree of the alcohol–aldehyde conversion in the micellar system can be regulated reversibly by varying the composition of the reaction medium, for example, the water content[103]. Even a slight change in the water content in the system (several tenths vol.%) can then lead to a significant (by an order of magnitude and more) shift of the equilibrium constant (see curve *2* in Fig.6).

VIII. MODELLING OF THE STRUCTURE AND FUNCTION OF BIOLOGICAL MEMBRANES

The idea that inverted micelles constitute an extremely realistic model of biological membrane structures has been frequently stated in the literature[5,104–106]. This hypothesis has been recently confirmed experimentally by Dutch[107–117] and English[118,119] investigators. It was observed that the bilayer membranes frequently contain nonbilayer structures, the so-called lipid particles, which can be clearly distinguished in electron photomicrographs. Investigations showed that these particles consist of associated lipid molecules constructed in the form of inverted micelles and incorporated between the monolayers of the bilayer membrane (Fig.7*a*).

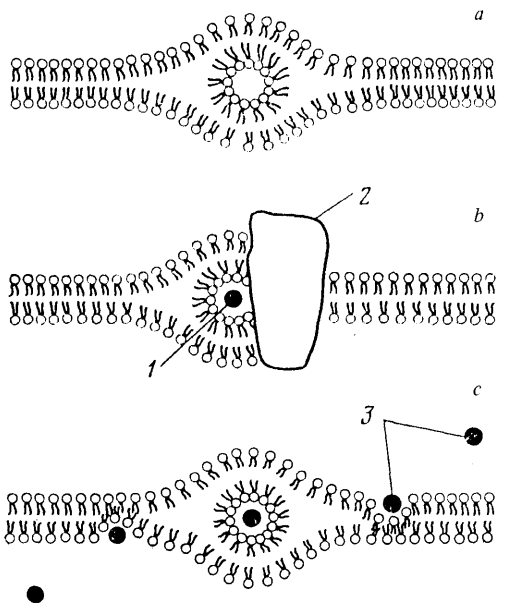

Figure 7. Some of the possible functions of the intramembrane lipid particles (*a*) in a biological membrane[107–122]; *b*) interaction of cytochrome *c* (*1*) with cytochrome oxidase (*2*); *c*) transmembrane transfer of a protein molecule (*3*).

The intramembrane lipid particles together with the intramembrane particles of another kind (for example, protein particles) apparently play an important role in the functioning of biological membranes. This conclusion is based on the fact that membranes characterised by a high metabollic activity (for example, the membranes of mitochrondria and chloroplasts) contain a large number of intramembrane particles, while the relatively inert membranes contain none at all[117]. The most important cell processes such as the coalescence and compartmentalisation of the membranes[110–112, 120,121], exocytosis[111], the transport of lipids through membranes via the "flip–flop" mechanism[113,114], and the transmembrane transport of ions[107,111] proceed via a mechanism similar to that illustrated in Fig.7*c* for protein molecules.

Data[115,116,122] showing that certain proteins, for example, cytochrome *c*, are capable of inducing the formation of inverted micelles in a bilayer membrane, being incorporated at the same time in the inner cavity of such a micelle, are of fundamental importance. It may be that this mechanism plays a significant role in the interaction of cytochrome *c* with the membrane enzyme cytochrome oxidase[116] (Fig.7*b*) and in the transmembrane transport of proteins[115,116,122] (Fig.7*c*).

The functions of the lipid particles and related structures enumerated above have served as a basis of a recently proposed new metamorphic mosaic model of biological membranes[111].

Studies designed to elucidate the role of the nonbilayer lipid particles in membrane processes have only just begun. Nevertheless their first results already show how fruitful can be the employment of inverted micelles as a model of biological membrane structures. We believe[123] that micellar enzymology is fully capable of reflecting the true picture of the functioning of enzymes *in vivo* (particularly when natural lipids are used for the formation of inverted micelles in an organic solvent).

Thus the enzyme "superactivity" [58,59] in inverted micelles compared with the enzyme activity in aqueous solution (see Figs.3 and 4) shows that the catalytic potential of enzymes cannot always be fully elucidated in classical *in vitro* experiments. The most significant differences between catalytic activities will probably be found for the membrane enzymes.

The results obtained in the study of the substrate specificity of pancreatic lipase and alcohol dehydrogenase in the inverted AOT micelle system in octane (Fig.5) justify the expectation of significant differences between the substrate specificities which the enzyme exhibits in a living cell and in aqueous solution in experiments carried out *in vitro*. Furthermore it is possible that the regulating effects observed in the study of the characteristic features of the equilibrium of an enzymic reaction in a micellar system (Fig.6) occur also in a living cell where the content of metabolites might be regulated (with participation of enzymes) by varying the degree of hydration of biological membranes.

IX. APPLIED ASPECTS OF MICELLAR ENZYMOLOGY

The science of chemical reactions and their catalysis by enzymes in inverted micelles is at present in its initial stage and a wide range of problems in this field still awaits solution. However, the experimental data already accumulated indicate the exceptional fruitfulness of this field, which extends and deepens the fundamental knowledge about enzymes and biological membranes.

Micellar enzymology leads to new prospects for the employment of biocatalysis in chemical practice. Thus micellar systems find extensive applications in **organic synthesis**, in the first place for the enzymic transformation of water-insoluble compounds, such as fats, steroids, petroleum products, etc. The possibility of the enzymic hydrolysis of fats has been demonstrated for the action of pancreatic lipase on triglycerides in the "AOT–water–octane" system[61] and a higher catalytic activity of the solubilised enzyme relative to a long-chain less water-soluble substrate was noted. A striking example of the employment of enzymes in inverted micelles for organic synthesis is provided by the work of Dutch investigators[124], who proposed a relatively simple and effective system for the stereospecific production of steroids. This communication should apparently arouse special interest in chemists specialising in synthesis, because, by virtue of the cofactor regeneration system, ordinary molecular hydrogen was used as the reducing agent.

Studies designed to create an energy conversion system have begun to develop in recent years (Berezin and Martinek[2], Chapter XII). A process for the photochemical

formation of hydrogen with participation of an enzyme (a hydrogenase) solubilised by inverted micelles in an organic solvent has been proposed[125].

Enzymes are already used in **analytical chemistry**[2]. Inverted micelle systems lead to new possibilities for the employment of enzymes in the detection of water-insoluble compounds. This is particularly important for the monitoring of the contamination of the environment, which is frequently due to hydrophobic substances such as pesticides and other chemical poisons, the products of incomplete fuel combustion, the waste from chemical industry, etc. The use of enzymes as analytical reagents can lead to the solution also of a more general problem—the creation of reliable test systems for the biological activities of various compounds both water-soluble and water-insoluble. Examples of such analytical systems for the investigation of water-insoluble derivatives of vitamin B_2 have already been successfully realised on the basis of micellar solutions of D-aminoacid oxidase and lipoxygenase[126].

Inverted surfactant micelle systems in organic solvents supplement and extend the methodology of **protein** (enzyme) **chemistry**. They have been used successfully to determine the molecular weights and effective sizes of protein globules[127,128] and also in the thin-layer chromatography of aminoacids[129]. Inverted micelle systems can serve as a universal medium for reactions involved in the **chemical modification of proteins** (enzymes). An envelope of surfactant molecules protects the protein from uncoiling (denaturation) and the presence of the aqueous and organic phases makes it possible to introduce into the reaction both water-soluble and water-insoluble reactants.

In order to impart membranoactive properties to water-soluble proteins, it is necessary to introduce one–two hydrophobic (anchor) groups into the molecule: this procedure has been applied successfully in the treatment with the water-insoluble stearoyl chloride of α-chymotrypsin solubilised by inverted AOT micelles in octane[130]. The converse problem can probably be solved analogously—water-insoluble membrane enzymes can be made hydrophilic by chemical modification.

Although we have consistently emphasised the advantages of employing micellar systems for reactions involving water-insoluble reactants, these systems can prove useful also in many cases regardless of the nature (solubility) of the reactants. From the standpoint of **organic synthesis**, the possibility of regulating the equilibrium position in the catalysed reaction, which should make it possible to carry out reactions whose equilibria in aqueous solution are displaced towards the starting materials (see the relevant reviews[2,100–102]), must be regarded as an important property of inverted micelle systems. The concentration effect and the effects involving an increase of the catalytic activity of enzymes in inverted micelles can increase significantly the sensitivity of **analytical systems**. Indeed it has been shown[131] that, on passing from a traditional aqueous solution to the Brij 96–water–octane system, the sensitivity of the bioluminescence analysis of ATP increases by more than an order of magnitude. Furthermore, the stabilisation of the level of the detected signal is observed in the micellar system, which makes it possible to simplify significantly the entire analytical procedure[131].

The present state and prospects for the practical utilisation of biocatalysis are closely related to the development and improvement of methods for the stabilisation and immobilisation of enzymes[2]. "Molecular immobilisation" has been achieved[132] by the polymerisation of a micellar matrix and/or the components of the inner cavity of the inverted micelle made up of reactants containing a double bond. Protein preparations with an envelope having a specified thickness around each protein molecule were obtained as a result.

It is clear from the achievements and prospects in micellar enzymology that this field of science merits new efforts and investigations. There is every reason to believe that in the course of such investigations new possibilities for the application of micellar enzymology in other fields, not considered in this review, will be discovered and developed.

The Reactivity of Addends in the 1,3-Dipolar Cycloaddition Reaction

Ya.D.Samuilov and A.I.Konovalov

The influence of donor-acceptor interactions and localisation energies on the reactivity of addends in the 1,3-dipolar cycloaddition reaction is examined. It is shown that the interactions between the symmetric frontier orbitals and between the antisymmetric frontier orbitals are qualitatively different in $(4\pi + 2\pi)$-cycloaddition reactions. The effects arising as a result of the interaction of the symmetric frontier orbitals lead to an alteration of the position of the transition state on the potential energy surface for the reaction and increase the sensitivity of the 1,3-dipolar cycloaddition reactions to localisation effects.
The bibliography includes 113 references.

I. INTRODUCTION

The 1,3-dipolar cycloaddition reaction has been vigorously investigated in the last few decades. Interest in this field of study can be accounted for primarily by the fact that a wide variety of heterocyclic compounds, many of which have found extensive application, can be synthesised in a single stage under mild conditions with the aid of the 1,3-dipolar cycloaddition reaction. The theoretical ideas developed in the course of the investigation of this reaction not only promote the understanding of its mechanism and a number of fine details of intermolecular interactions but can also be used successfully in the study of other reactions. The enormous amount of experimental data on the 1,3-dipolar cycloaddition reaction, including the results of kinetic and preparative experiments, have now been surveyed in a series of reviews[1-9].

Both single-stage and two-stage mechanisms have been proposed for the 1,3-dipolar cycloaddition reaction. There is controversy in the literature concerning the type of mechanism which actually operates[10-13]. However, characteristic features of the 1,3-dipolar cycloaddition reactions such as the low sensitivity of the reaction rates to a change in the nature of the solvent[14-16], the weak influence of the substituents in the addends on the reactivity[17-20], the high negative activation entropies, low activation enthalpies, and large negative activation volumes[21], the exceptionally rigorous observation of the *cis*-principle,[22] and the kinetic isotope effects[23-25] agree to a large extent with a synchronous mechanism.

Quantum-chemical calculations of the potential energy surfaces for 1,3-dipolar cycloaddition reactions also indicate a synchronous mechanism of this process[26-34].

There have been reports that the reactions of diazomethanes with dipolarophiles having pronounced electron-accepting properties result in the formation of radical-ions[35-38] but so far it is impossible to solve unambiguously the problem of the role of these species in the reaction.

One of the most important tasks in the study of the 1,3-dipolar cycloaddition reaction is the discovery of factors which determine the reactivity of the addends. These data are essential for the prediction of the reactivity of systems, periselectivity, and stereoselectivity.

The present review is devoted to the consideration of the most important factors responsible for the reactivity of various 1,3-dipole–dipolarophile pairs. Analysis of kinetic data leads to the conclusion that a fairly complete description of the reactivities of such systems is possible only when account is taken simultaneously of the donor–acceptor interactions and the localisation effects. The existence of qualitative differences in the character of the interaction of the symmetric and antisymmetric frontier orbitals of the reactants in the 1,3-dipolar cycloaddition reaction has been established.

II. THE INFLUENCE OF DONOR–ACCEPTOR INTERACTIONS ON THE REACTIVITY OF THE ADDENDS IN THE 1,3-DIPOLAR CYCLOADDITION REACTION

It is nowadays believed that the reactivity of the addends in the 1,3-dipolar cycloaddition reaction depends mainly on the character of the intermolecular donor–acceptor interactions. Stabilisation energies are used for the comparative assessment of the donor–acceptor interactions[39-46]. They are calculated by methods of perturbation theory from the following formula:

$$\Delta E = 2\sum_{t}^{\text{occ}}\sum_{l}^{\text{unocc}} \frac{(C_t^{(l)}C_u^{(l)}\gamma_{tu} + C_{t'}^{(l)}C_{u'}^{(l)}\gamma_{t'u'})^2}{\varepsilon_{a_t} - \varepsilon_{b_l}} + 2\sum_{k}^{\text{occ}}\sum_{j}^{\text{unocc}} \frac{(C_t^{(j)}C_u^{(k)}\gamma_{tu} + C_{t'}^{(j)}C_{u'}^{(k)}\gamma_{t'u'})^2}{\varepsilon_{b_k} - \varepsilon_{a_j}}$$

where C_t are the coefficients of the atomic orbitals in the molecular orbital of the 1,3-dipole, C_u are the coefficients of the atomic orbitals in the molecular orbital of the dipolarophile, γ are interaction integrals, and ε are the energies of the molecular orbitals of the non-interacting systems. The summation is carried out over all possible combinations of the orbitals.

However, this formula is rarely used in specific calculations. In the interpretation of the experimental reactivity data in terms of stabilisation energies, it is usually sufficient to restrict the treatment to allowance for the interaction of the frontier orbitals and it is possible to neglect the differences between the coefficients of the atomic orbitals of the reaction centres[44,46,47]. As a result, the following simple expression is obtained for the stabilisation energy:

$$\Delta E = K\left(\frac{1}{\epsilon_{\text{HOO}}^{\text{1,3-dip}} - \epsilon_{\text{LUO}}^{\text{dip}}} + \frac{1}{\epsilon_{\text{HOO}}^{\text{dip}} - \epsilon_{\text{LUO}}^{\text{1,3-dip}}}\right).$$

Further simplifications in this formula may be associated with allowance for the relative disposition of the frontier orbitals of the addends. Sustmann[39] isolated three types of 1,3-dipolar cycloaddition reactions (Fig.1).

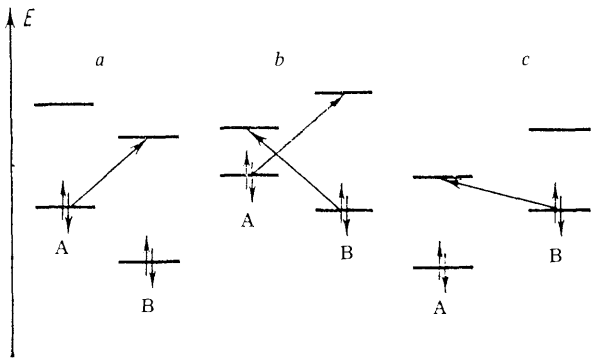

Figure 1. The relative disposition of the energy levels of the frontier orbitals of the addends in the 1,3-dipolar cycloaddition of the type where the 1,3-dipole and the dipolarophile are the donor and acceptor respectively (*a*), of the "neutral" type (*b*), and of the type where the 1,3-dipole and dipolarophile are the acceptor and donor respectively (*c*); A = 1,3-dipole; B = dipolarophile.

(1) The 1,3-dipole and the dipolarophile are the donor and acceptor respectively. In this case the interaction between the highest occupied orbital (HOO) of the 1,3-dipole and the lowest unoccupied orbital (LUO) of the dipolarophile is dominant.

(2) The "neutral" type. In this case the energy levels of the frontier orbitals of the 1,3-dipole are arranged symmetrically relative to the energy levels of the frontier orbitals of the dipolarophile.

(3) The 1,3-dipole and the dipolarophile are the acceptor and donor respectively. Reactions of this type obtain when the interaction between the lowest unoccupied orbital of the 1,3-dipole and the highest occupied orbital of the dipolarophile is dominant.

The usefulness of the above classification of the 1,3-dipolar cycloaddition reactions has been confirmed by numerous experimental data on the reactivity of the addends in the 1,3-dipolar cycloaddition reactions involving diazomethanes[48–52], nitrile imines[17], nitrile oxides[19,53,54], azides[55,56], etc. Fig.2 presents the dependence of the reactivities of a series of dipolarophiles in the 1,3-dipolar cycloaddition reactions with diazoacetic ester and dimethyl diazomalonate[50] on the ionisation potentials of alkenes. The figure shows that the type of reaction varies with the donor–acceptor characteristics of the dipolarophiles.

However, these and similar correlations may not be associated with a specific relative disposition of the energy levels of the frontier orbitals of the addends in the 1,3-dipolar cycloaddition reaction. Data on the reactivity of *C*-benzoyl-*N*-phenylnitrone in condensations with various dipolarophiles are of interest from this point of view. *C*-Benzoyl-*N*-phenylnitrone is a fairly powerful electron-accepting compound, its electron affinity is 1.0 eV, and its ionisation potential is 10.2 eV.[57] According to theoretical postulates, one might therefore expect that the type of reaction of this nitrone varies readily as the electron-donating character of the dipolarophile is altered.

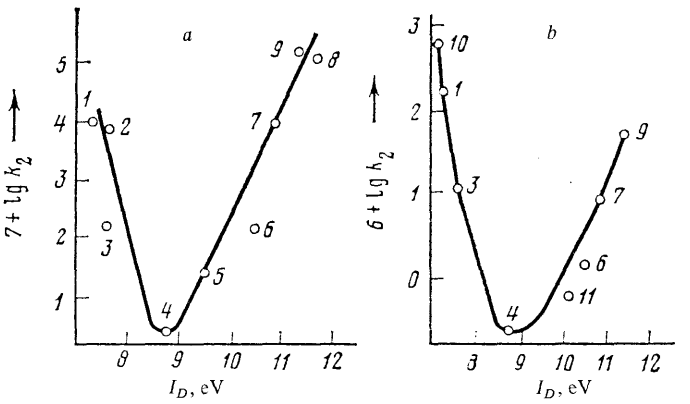

Figure 2. Dependence of the reactivities of diazoacetic ester (*a*) (toluene, 80 °C) and dimethyl diazomalonate (*b*) (mesitylene, 110 °C) in the 1,3-dipolar cycloaddition reaction on the ionisation potentials of the dipolarophiles[50]: *1*) pyrrolidinocyclohexene; *2*) 2-diethylamino-1-methylacetylene; *3*) 1,1-dimethyl-2-pyrrolidinoethylene; *4*) butyl vinyl ether; *5*) dec-1-ene; *6*) styrene; *7*) acrylonitrile; *8*) tetracyanoethylene; *9*) dimethyl acetylenedicarboxylate; *10*) pyrrolidinocyclopentene; *11*) methyl *trans*-crotonate.

In order to test this hypothesis, a kinetic study was made of the reactions of benzoylnitrone with a series of vinyl compounds (Table 1).[57,58] A symmetrical disposition of the energy levels of the frontier orbitals of the addends is attained in the reaction with acrylonitrile (Fig.3). However, the reduced reactivity of dipolarophiles with weaker electron-accepting properties than those of acrylonitrile shows that the entire reaction series belongs to the first type (where the 1,3-dipole and the dipolarophile are the electron donor and acceptor respectively).

Table 1. The reactivities of *C*-benzoyl-*N*-phenylnitrone in the 1,3-dipolar cycloaddition reactions with vinyl compounds (toluene, 20 °C).

Dipolarophile	$10^4 k_2$, litre mol^{-1} s^{-1}	lg *A*	E_A, kJ mol^{-1}	$-\Delta S^{\neq}$, J mol^{-1} K^{-1}
Acroleine	107.3	2.3	23	210
Acrylic acid	90.0	4.6	38	165
Methyl acrylate	44.6	5.4	44	150
Acrylonitrile	28.2	4.9	42	160
Allyl alcohol	14.9	3.9	39	179
Allyl methyl ether	1.4	8.3	69	94

In the reactions of *C*-benzoyl-*N*-phenylnitrone with styrene, the interaction between the lowest unoccupied orbital of the 1,3-dipole and the highest occupied orbital of the dipolarophile is much stronger than the interaction between the other two frontier orbitals (Fig.4). The reactions of styrenes with this nitrone should proceed in accordance with the third type (where the 1,3-dipole and the dipolarophile are the electron acceptor and donor respectively), but kinetic data have shown that the reactivity of arylethylenes determines the interaction between the highest occupied orbital of the nitrone and the lowest unoccupied orbital of the dipolarophile and the reactions proceed in accordance with the first type (with the 1,3-dipole and

dipolarophile as the electron donor and acceptor respectively),[58] this being confirmed by the correlation between the reactivities and the reciprocals of the differences between the ionisation potential of the nitrone and the electron affinities of the styrenes (Fig.5). Changes in the type of reaction are also not observed in the reactions of *C*-benzoyl-*N*-phenylnitrone with dipolarophiles having stronger electron-donating properties than styrenes, namely dipolarophiles such as aryl vinyl ethers[63] and aryl vinyl selenides[58]. Only in reactions with electron-donating dipolarophiles such as α-piperidinylstyrenes was it possible to observe a change in the type of reaction[63]. In this case a correlation is observed between the reactivities and the reciprocals of the differences between the ionisation potentials of the enamines and the electron affinity of *C*-benzoyl-*N*-phenylnitrone (Fig.6), which is evidence that the reaction proceeds in accordance with the third type (where the 1,3-dipole and the dipolarophile function as the electron acceptor and donor respectively).

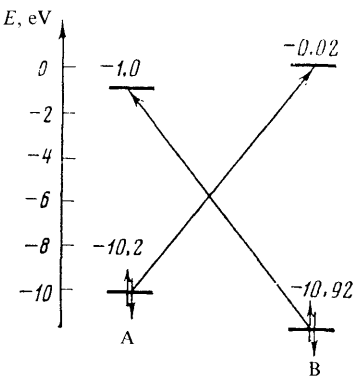

Figure 3. The relative disposition of the energy levels of the frontier orbitals of *C*-benzoyl-*N*-phenylnitrone (A) and acrylonitrile (B). The electron affinity and ionisation potential of acrylonitrile are based on the data of Houk and Munchausen[59].

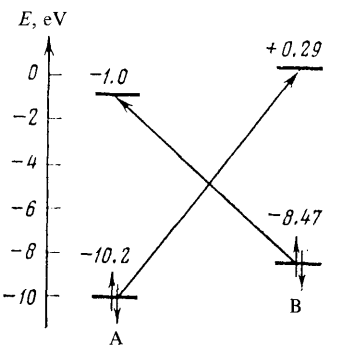

Figure 4. The relative disposition of the energy levels of the frontier orbitals of *C*-benzoyl-*N*-phenylnitrone (A) and styrene (B). The electron affinity and the ionisation potentials are based on the data of Hush and Pople[60] and Gurvich et al.[61] respectively.

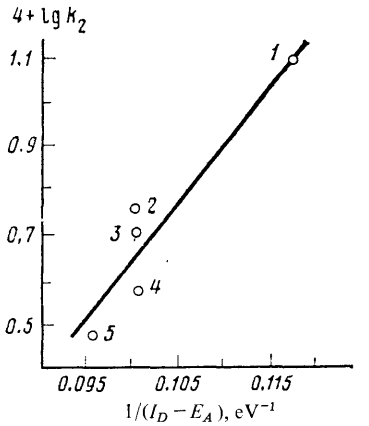

Figure 5. Dependence of the reactivity of *C*-benzoyl-*N*-phenylnitrone in the 1,3-dipolar cycloaddition reaction with styrenes of the type $R-C_6H_4-CH = CH_2$ [58] on the reciprocal of the difference between the ionisation potential of the 1,3-dipole and the electron affinity of the dipolarophile (toluene, 20 °C). The electron affinities of the styrenes were taken from Samuilov et al.[63]; R: *1*) *p*-NO_2; *2*) *p*-Br; *3*) *p*-Cl; *4*) H; *5*) *p*-CH_3O (r = 0.920).

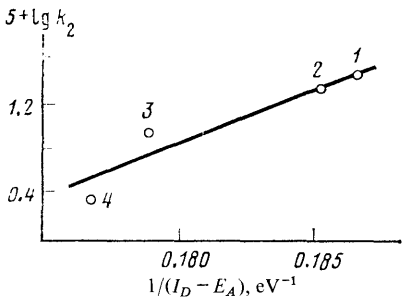

Figure 6. Dependence of the reactivity of *C*-benzoyl-*N*-phenylnitrone in the reaction with α-piperidinylstyrenes $RC_6H_4-CN(CH_2)_5 = CH_2$ on the reciprocal of the difference between the ionisation potential of the enamine and the electron affinity of the nitrone (toluene, 25 °C);[63] R: *1*) *p*-CH_3O; *2*) *p*-CH_3; *3*) H; *4*) *p*-Br.

The data presented indicate a clear preference for the interaction between the highest occupied orbital of the 1,3-dipole and the lowest unoccupied orbital of the dipolarophile compared with the interaction between the lowest unoccupied orbital of the 1,3-dipole and the highest occupied orbital of the dipolarophile. The above phenomenon is characteristic also of the Diels–Alder reaction[64–66]. It is of interest to note that even reactions of electron-accepting dienes such as tetrahalogeno-*o*-benzoquinones with styrenes proceed in accordance with the "neutral" diene synthesis[67], although there is no doubt that in such systems the interactions between the highest occupied orbitals of the styrenes and the lowest unoccupied orbitals of the quinones are much more intense than the interaction between the other two frontier orbitals.

It follows from the data presented that the character of the (4π + 2π)-cycloaddition reactions is probably determined by

the interaction between the highest occupied orbital of the four-electron π-system and the lowest unoccupied orbital of the two-electron π-system.

III. QUALITATIVE DIFFERENCES BETWEEN THE EFFECTS ARISING AS A RESULT OF THE INTERACTION OF ANTISYMMETRIC AND SYMMETRIC FRONTIER ORBITALS IN 1,3-DIPOLAR CYCLOADDITION REACTIONS

The above feature of the interaction of the frontier orbitals of the addends in the 1,3-dipolar cycloaddition reaction becomes understandable after more detailed analysis of the structure of the highest occupied orbital of the 1,3-dipole and the lowest unoccupied orbital of the dipolarophile (each of these orbitals is antisymmetric relative to the plane dividing the system in half) compared with the lowest unoccupied orbital of the 1,3-dipole or the highest occupied orbital of the dipolarophile (symmetric orbitals). The interactions of the frontier orbitals of these pairs lead to qualitatively different effects[68,69].

The formation of a chemical bond requires that the electron density be concentrated during the reaction in the space between the reaction centres. In the case of the synchronous mechanism, this condition is fulfilled for the antisymmetric frontier orbitals (Fig.7). The changes in the coordinates of the atomic nuclei of the interacting centres are in this case such that they promote the occurrence of the reaction. When symmetric frontier orbitals interact, a less favourable situation arises. Cross interactions lead to the localisation of the electron density in the inner part of the intermolecular space. Synchronous changes in the atomic coordinates of the reaction centres do not promote the occurrence of the reaction in this instance. Therefore, even in those cases where the energies of the symmetric frontier orbitals of the addends are fairly similar, nevertheless the antisymmetric orbitals are apparently responsible for the occurrence of the 1,3-dipolar cycloaddition reaction. From this standpoint, it becomes clear that the decisive influence, noted above, on the reactivity by the character of the interaction of the antisymmetric frontier orbitals rest on an entirely well-founded theoretical basis.

We may note an important consequence of the qualitative differences in the character of the interaction of the antisymmetric and symmetric frontier orbitals. When the interaction of the lowest unoccupied orbital of the 1,3-dipole and of the highest occupied orbital of the dipolarophile makes a significant contribution to the stabilisation energy, the contribution by the interaction between the other frontier orbitals can depend on the degree of localisation of the electrons in the reaction centres, which can lead to an alteration of the position of the transition state on the potential energy surface for the reaction and to its shift towards the adduct.

An approach to the interpretation of the reactivities of the addends in the 1,3-dipolar cycloaddition reaction in terms of localisation energies has been available[70,71] but has not come to be widely used. We believe that two approaches, based on the concepts of the stabilisation and localisation energies respectively, supplement one another. In estimating the stabilisation energies, no account is taken of the energy expenditure necessary for the localisation of electrons on the reaction centres. The two approaches describe different aspects of the process in which the transition state is established. An exact description of the reactivity in the 1,3-dipolar cycloaddition reaction is therefore possible only when both effects are taken into account.

In typical Diels–Alder reactions of the first type (where the diene and the dienophile are the electron donor and acceptor respectively) the symmetric frontier orbitals interact only slightly. The influence of the electron localisation effects on the reactivity is therefore insignificant in these reactions. The presence of heteroatoms more electronegative than carbon in the 1,3-dipoles leads to an appreciable enhancement of the electron-accepting properties of these systems[72]. An increased sensitivity to localisation effects should therefore be characteristic of the 1,3-dipolar cycloaddition reactions as a whole.

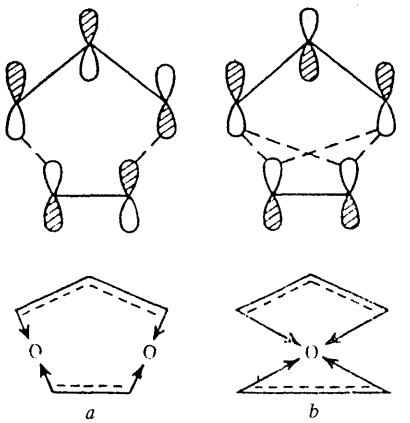

Figure 7. The frontier orbitals in the 1,3-dipolar cycloaddition reaction; *a*) the highest occupied orbital of the 1,3-dipole and the lowest unoccupied orbital of the dipolarophile (antisymmetric orbitals); *b*) the lowest unoccupied orbital of the 1,3-dipole and the highest occupied orbital of the dipolarophile (symmetric orbitals).

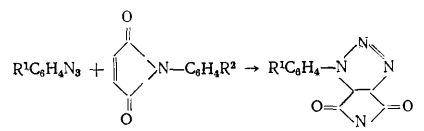
Correlations are possible in many instances between the stabilisation and localisation energies[73–75]. However, they are not general. Therefore, in interpreting reactivity, it is necessary to estimate each factor separately.

The localisation energies for the addends can be calculated by quantum-chemical methods. They can be estimated also with the aid of the enthalpies of the corresponding reactions, because the localisation energies and the enthalpies of reaction are linearly related[76].

The dependence of the position of the transition state on the potential energy surface on the character of the donor–acceptor properties of the addends has been discussed[71,77]. On the basis of simple geometrical constructions, the authors of the above studies concluded that an increase of the strength of the intermolecular donor–acceptor interactions leads to a shift of the transition state towards the adduct. We believe that this conclusion is insufficiently well-founded. In the general case donor–acceptor interactions leads to effects stabilising the transition state, which implies that the transition state can be established with a lower degree of formation of new bonds, which corresponds to a shift of the position of the transition state towards the addends.



We may note in conclusion that the shift of the position of the transition state on the potential energy surface of the reaction towards the adduct is of the kind indicated in the above studies[71,77] and is associated with the characteristics of the symmetric frontier orbitals of the addends, which do not favour the reaction.

IV. THE INFLUENCE OF LOCALISATION EFFECTS ON THE REACTIVITY OF THE ADDENDS IN 1,3-DIPOLAR CYCLOADDITION

It is clear from the above analysis that the 1,3-dipolar cycloaddition reaction should be characterised by an increased sensitivity to changes in the localisation energies of the addends. When this factor is taken into account, certain anomalies observed for this reaction become understandable. Thus, it is known that 2,4,6-trimethylbenzonitrile oxide gives the "neutral" 1,3-dipolar cycloaddition reaction with styrenes[78]. The enhancement of the electron-accepting character of the dipolarophile should intensify the interaction between the antisymmetric frontier orbitals of the reactants and these reactions should proceed in accordance with the type where the 1,3-dipole and dipolarophile are the donor and acceptor respectively. However, kinetic study of the reactivity of *N*-arylmaleimides (dipolarophiles containing two carbonyl groups at the reaction centres, which ensures pronounced electron-accepting properties of these compounds) in the reaction with 2,4,6-trimethylbenzonitrile oxide[79] has shown that the influence of the substituents is manifested only slightly and the course of the reaction is inconsistent with the expected pattern. This result is not associated with the characteristic features of the transfer of electronic effects in the imides to the reaction centre via the bridging nitrogen atom; this has been confirmed in Diels–Alder reactions with imides, which proceed in accordance with the type where the diene and dienophile function as the donor and acceptor respectively[80,81], in which the accelerating influence of the electron-accepting substituents in the imides and the inhibiting effect of the electron-donating substituents is clearly manifested. Furthermore, the study of the polarographic reduction of *N*-arylmaleimides [82,83] also failed to reveal any characteristic features in the transfer of electronic effects to the multiple bond.

The unusual behaviour of *N*-arylmaleimides in the reaction with 2,4,6-trimethylbenzonitrile oxide is in all probability associated with the fact that the localisation energy increases with enhancement of the electron-accepting character of the substituents in these dipolarophiles[76]. In the reactions with imides, which proceed, according to the classification based on allowance for the donor–acceptor properties alone, in accordance with the type where the 1,3-dipole and the dipolarophile are the donor and acceptor respectively, there is therefore a possibility of cases where the substituents do not exert an appreciable influence on the reactivity or this influence diminishes with enhancement of the electron-accepting character of the dipolarophiles.

Kinetic data for the reactivity of aryl azides in the 1,3-dipolar cycloaddition reaction with *N*-arylmaleimides are of interest in this connection[84]:

(I)–(III) (IV)–(IX)

R^1=*p*-CH_3O (I), H (II), *p*-NO_2 (III), R^2=*p*-$(CH_3)_2N$ (IV), *p*-CH_3O (V), *p*-CH_3 (VI), H (VII), *p*-Br (VIII), *p*-NO_2 (IX)

Fig. 8 illustrates the correlation between the reactivity of aryl azides in the reaction with arylmaleimides and the Hammett σ constants. It is seen that in the reactions of the azide (I) with the imides (IV)–(IX) there is a tendency towards an increase of the rate of reaction with enhancement of the electron-accepting character of the imides. In the reactions of the azide (II) with the imide (IV)–(IX), both electron-donating and electron-accepting substituents in the dipolarophile favour the reaction. In the case of the azide (III) the electron-donating substituents in the imides increase the rate of reaction, while the electron-accepting substituents reduce it.

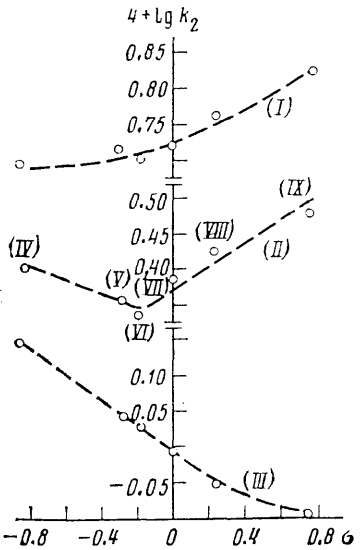


Figure 8. Dependence of the reactivities (lg *k*) of the aryl azides (I)–(III) in the reactions with the *N*-arylmaleimides (IV)–(IX) on the Hammett σ constants (chlorobenzene, 80 °C).[84]

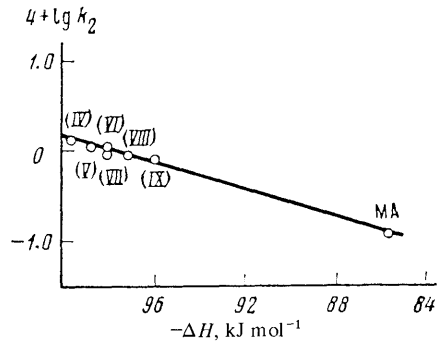
The results obtained can be explained from the standpoint of the donor–acceptor properties assuming that an increase of the electron-donating character of the azide entails a change in the type of reaction from that where the 1,3-dipole and the dipolarophile are the acceptor and donor respectively to that where the roles are reversed. This conclusion conflicts with the reactivities of a series of azides in relation to individual imides: all the reactions indicated proceed in accordance with the type where the 1,3-dipole and the dipolarophile are the donor and acceptor respectively regardless of the electronic character of the substituents in the dipolarophile.

The observed changes in reactivity can be explained by assuming that the reactivity in the systems investigated is determined not only by the donor–acceptor properties but also by the localisation energies. If the role of these factors varies within the limits of one series, the non-linear correlations described above can arise. From this standpoint, the relative reactivity in reactions with the azide (I) (the azide having the most pronounced electron-donating properties among those investigated) is largely determined by the relative disposition of the energies of the frontier orbitals of the addends.

When the above azide is replaced by phenyl azide (II), which is a weaker electron donor, the role of the antisymmetric frontier orbitals diminishes, while that of the symmetric frontier orbitals increases, which leads to a displacement of the position of the transition state on the potential energy surface towards the adduct. The energy expended on the localisation processes increases and the stabilisation energy diminishes, which results in a decrease of the reactivity of the system. In reactions with imides

containing fairly strong electron-accepting groups in the aromatic ring, the reactivity is largely determined by stabilisation energies. If, on the other hand, arylmaleimides have electron-donating substituents, then the relative reactivity is determined by localisation energies. In the 1,3-dipolar cycloaddition reactions of the azide (III) with the imides (IV)–(XI) the interaction of the symmetric frontier orbitals is most intense for the series considered. The relative reactivity is controlled in this case solely by the localisation energies of the dipolarophiles, as shown by the correlation between the reactivities of the arylmaleimides in the reaction with the azide (III) and the enthalpies of the Diels–Alder reactions of compounds (IV)–(XI) with 1,3-diphenylisobenzofuran (Fig.9). The enthalpies of the reactions considered can be used to estimate the localisation energies of the imides. Fig.9 also presents the point corresponding to maleic anhydride, which is least reactive, although, compared with the imide[86], it is a stronger acceptor[85] and hence should have been more reactive.



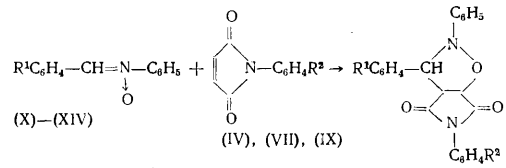


Figure 9. Dependence of the logarithms of the rate constants for the reactions of *p*-nitrophenyl azide (III) with the *N*-arylmaleimides (IV)–(IX) and maleic anhydride on the enthalpies of the reactions of these dipolarophiles with 1,3-diphenylisobenzofuran[84]; MA = maleic anhydride; $r = 0.995$.

The question arises whether the relative changes in reactivity in the above reactions with styrenes are also associated with localisation effects. The change in the electronic character of the substituents in the aromatic ring of styrenes hardly affects the localisation energies of these dipolarophiles, which has been demonstrated by quantum-chemical calculations[87] and has been confirmed by thermochemical experiments[88]. The relative reactivities of styrenes in the 1,3-dipolar cycloaddition reactions are therefore correlated with the stabilisation energies characterising the changes in the donor–acceptor properties.

All these data show that, within the limits of the same series, non-linear correlations can arise. The appearance of these correlations is associated with the change in the relative roles of the donor–acceptor interaction and the localisation effects. The non-linear correlations observed in the study of the 1,3-dipolar cycloaddition reaction have been analysed[89]. The author proposed a new modification of the Hammett equations based on the linearisation of correlations of this type. However, this approach is applicable only in those cases where the reactivity of the addends in several series is determined by at least two factors and the influence of one factor, responsible for the deviation from the Hammett equation, should be the same in all the series, while the influence of the second factor on the reactivity should be correlated with the Hammett σ constants. The applicability of this modification of the Hammett equation is extremely limited. In those cases where the relative roles of the factors determining the reactivity of the addends vary even within the limits of one series, the attempts to linearise the correlations are hardly useful.

The data on the reactivities of nitrones in 1,3-dipolar cycloaddition reactions also cannot be accounted for from the standpoint of the donor–acceptor properties alone. For example, it is known[90] that electron-accepting substituents in dipolarophiles increase their reactivity in reactions with nitrones. It would have been logical to expect that the electron-donating substituents in nitrones also accelerate the reactions. However, kinetic data have shown that both electron-donating and electron-accepting substituents reduce the reactivity in the reactions of *C*-aryl-*N*-phenylnitrones with ethyl crotonate[90]. The existence of such series is altogether incomprehensible from the standpoint of the method of stabilisation energies. In the reactions of *C*-phenyl-*N*-arylnitrones with ethyl crotonate[90], a decrease of the reactivity is observed following the introduction of electron-donating substituents. The hypothesis that these reactions proceed in accordance with the type where the 1,3-dipole and the dipolarophile are the acceptor and donor respectively is unlikely, because even in reactions of an electron-accepting nitrone, such as *C*-benzoyl-*N*-phenylnitrone, with styrenes, which have more pronounced electron-donating properties than ethyl crotonate, an accelerating effect of the electron-accepting substituents in the dipolarophile is observed. The joint kinetic and thermochemical study of the reactions of *C*,*N*-diarylnitrones with *N*-arylmaleimides made it possible to explain the existing phenomena[79,91,92].

Table 2 presents data on the reactivities of *C*-aryl-*N*-phenylnitrones in the 1,3-dipolar cycloaddition reaction with *N*-arylmaleimides and the enthalpies of reaction of these nitrones with *N*-phenylmaleimide:

R¹ = *p*-NO_2 (X), *p*-Br (XI), H (XII), *p*-CH_3O (XIII), *p*-$(CH_3)_2N$ (XIV)

Table 2. The reactivities of *C*-aryl-*N*-phenylnitrones in the 1,3-dipolar cycloaddition reactions with *N*-arylmaleimides and the enthalpies of the reactions of the nitrones with *N*-phenylmaleimide (toluene).[79,92]

The accelerating effect of the electron-donating substituents in the 1,3-dipole and the inhibiting effect of the electron-accepting substituents, which is characteristic of reactions proceeding in accordance with the type where the

1,3-dipole and the dipolarophile are the donor and acceptor respectively, is manifested in the reactions of the nitrones (X)–(XIV) with the most electrophilic imide (IX). In this case the reactivity can be described satisfactorily in terms of the donor–acceptor properties of the addends alone, which is indicated by the correlation between the reactivities of the nitrones (X)–(XIV) and the reciprocals of the differences between the ionisation potentials of the 1,3-dipoles (I_D) and the electron affinities of the dipolarophiles (E_A) (the ionisation potentials of the nitrones have been determined by Samuilov et al.[93]):

$$\lg k = 25.05\ (I_D - E_A)^{-1} - 6.25\ (r = 0.960)$$

As the electron-donating character of the imides becomes more pronounced, the reactivity of the nitrones diminishes after the introduction of both electron-donating and electron-accepting substituents into the C-aromatic ring. The enthalpies of reaction vary analogously. The inclusion of the enthalpies of reaction, which are linearly related to the localisation energies of 1,3-dipoles, in the correlation equations together with the parameter describing the donor–acceptor interactions, makes it possible to describe the reactivity correctly in this instance. The correlations are based on the following parameters:

(1) for the imide (VII):

$$\lg k = 6.512\ (I_D - E_A)^{-1} - 0.019\ \Delta H - 5.016\ (r = 0.981)$$

(2) for the imide (IV):

$$\lg k = 0.662\ (I_D - E_A)^{-1} - 0.021\ \Delta H - 4.44\ (r = 0.938)$$

In terms of the sign of the coefficient of the reciprocal of the difference between the ionisation potential of the nitrone and the electron affinity of the imide, all the series investigated belong to reactions of the type where the 1,3-dipole and the dipolarophile are the donor and acceptor respectively. As the electron-donating character of the imide becomes more marked, i.e. as the interactions between the antisymmetric frontier orbitals are weakened and the interactions between the symmetric orbitals are intensified, the role of the localisation effects becomes successively more pronounced. Thus, in the series investigated, consecutive changes in the factors determining the reactivities of the compounds are observed.

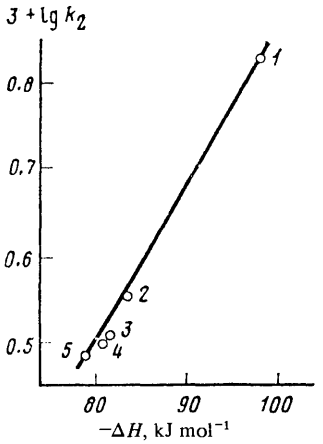

Figure 10. Dependence of the reactivities of *N*-aryl-*C*-phenylnitrones $C_6H_5CH = N(O)-C_6H_4R$ in the reactions with *N*-phenylmaleimide on the enthalpies of reaction (toluene, 20 °C);[92] R: 1) *p*-NO_2; 2) *p*-Cl; 3) H; 4) *p*-CH_3; 5) *p*-CH_3O; $r = 0.990$.

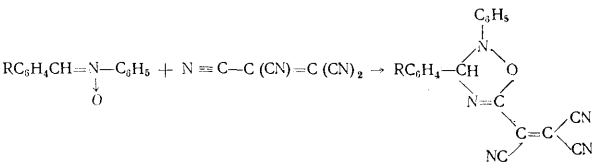
Kinetic and thermochemical study of the reactivities of *C*-phenyl-*N*-arylnitrones with *N*-phenylmaleimide[92] showed (Fig. 10) that the changes in reactivity in this case are parallel to the changes in the enthalpies of reaction, which can be regarded as an indication that the relative reactivities are in this case determined by localisation effects.



The inconsistency between the electron-donating properties of the nitrones and their reactivities in the 1,3-dipolar cycloaddition reaction with maleic anhydride has been demonstrated[63] (Table 3). In this case the reactivity also varies in parallel with the enthalpies of reaction. This permits the conclusion that in the reactions investigated the localisation effects play an important role, although the reactivity may partly depend also on polar effects[63].

Table 3. The activities of nitrones in the 1,3-dipolar cycloaddition reactions with maleic anhydride, the enthalpies of reaction with toluene, and the ionisation potentials of the nitrones[63].

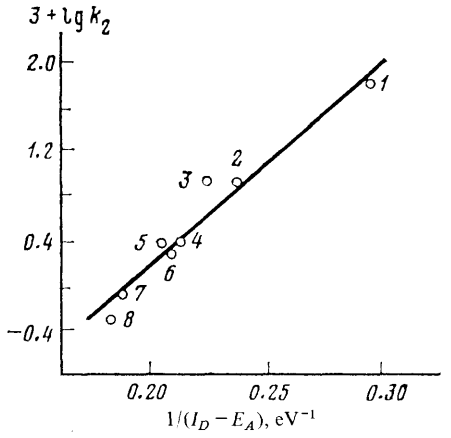
Nitrone	$10^5 * k_2$, litre mol^{-1} s^{-1}	$-\Delta H_p^{**}$, kJ mol^{-1}	I_D, eV
C-Benzoyl-N-phenylnitrone	3460	84.5	10.2
C,N-Diphenylnitrone	61.1	65.7	7.3
N-Methyl-C-phenylnitrone	8.19	55.6	7.7

*At 20 °C.
**At 50 °C.

In reactions of nitrones with ethyl acrylate[90], *N*-arylmaleimides[79,92,99], and maleic anhydride[63], the influence of the localisation effects on the relative activities is manifested. In conformity with theoretical postulates, it might have been expected that the reactions of nitrones with dipolarophiles more electrophilic than those enumerated above would be controlled solely by the changes in the donor–acceptor properties. One of the most electrophilic dipolarophiles is tetracyanoethylene, whose electron affinity is 2.3 eV.[94] Indeed, the relative reactivities of *C*-aryl-*N*-phenylnitrones in their reactions with tetracyanoethylene are determined by the character of the changes in the electron-donating properties of the 1,3-dipoles (Fig. 11).[93] However, the reactions investigated proceed via the carbon–nitrogen triple bond and not the carbon–carbon double bond[93]:

If these reactions were controlled solely by stabilisation energies, one would expect them to proceed via the carbon–carbon double bond, because the absolute coefficients of the atomic orbitals for the lowest unoccupied molecular orbitals of cyanoethylenes are highest for this bond[59] and in a typical Diels–Alder reaction of the type where the diene and the dienophile are the donor and acceptor respectively the reaction proceeds precisely via this bond[95,96]. A possible cause of the anomalous behaviour of nitrones is the greater strength of the $C_{sp^2}-C_{sp^2}$ π-bond compared with the $C_{sp}-N_{sp}$ π-bond. Thus the strength of the π-bond in ethylene estimated from the difference between the dissociation energies of ethylene and ethane is 314 kJ mol^{-1}, while the similar estimate of the bond strength in hydrocyanic acid is 293 kJ mol^{-1}.[97] The replacement of the hydrogen atoms

in ethylene by cyano-groups results in an additional increase of the strength of the carbon–carbon double bond[76]. The periselectivity of these reactions is apparently determined by the localisation energies.



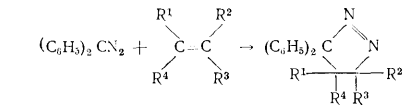


Figure 11. Dependence of the reactivities of *C*-aryl-*N*-phenylnitrones $RC_6H_4CH = N(O)-C_6H_5$ in their reactions with tetracyanoethylene on the reciprocal of the difference between the ionisation potential of the nitrone and the electron affinity of tetracyanoethylene (methylene chloride, 20 °C);[93] R: *1*) *p*-$(CH_3)_2N$; *2*) *p*-CH_3; *3*) H; *4*) *p*-Cl; *5*) *m*-Cl; *6*) *p*-Br; *7*) *m*-NO_2; *8*) *p*-NO_2; $r = 0.951$.

It is of interest to note that, whereas in the reactions of diazomethane[98] and diphenyldiazomethane[99] with tetracyanoethylene products resulting from addition to the carbon–carbon double bond are formed, diazoacetic ester[100] reacts with this dipolarophile via the carbon–nitrogen bond. In the first two instances, the attack is on the site corresponding to the most favourable interaction of the antisymmetric frontier orbitals of the addends, while in the third it is on the centres having the lowest localisation energies. It is remarkable that periselectivity changes in parallel with enhancement of the electron-accepting character of the 1,3-dipole, i.e. with increase of the contribution of the interaction of the symmetric orbitals to the stabilisation energy. The interaction via the carbon–nitrogen triple bond of tetracyanoethylene also takes place in reactions with nitrile sulphides, nitrile oxides[99], and certain other 1,3-dipoles.[101,102]

It was noted above that in a number of instances the stabilisation energy method has been used successfully to interpret the reactivities of dipolarophiles in reactions involving diazomethanes. However, the reactivity of diazo-compounds cannot always be described by taking into account only their donor–acceptor properties. For example, diazomethane is much more reactive in relation to 1,3-dipolar cycloaddition than diphenyldiazomethane[52]. Owing to the increase of the conjugation chain length on passing from diazomethane to diphenyldiazomethane, the energy levels of the frontier orbitals of the 1,3-dipoles approach one another, which can be seen from a comparison of the ultraviolet spectra ($\lambda_{max} = 395$ nm for diazomethane[103] and $\lambda_{max} = 527$ nm for diphenyldiazomethane[37]).

Polarographic data for the anodic oxidation of diazomethane and diphenyldiazomethane indicate an enhancement of the electron-donating character of the compound with increase of the conjugation chain length. Whereas the potential of the first reversible one-electron oxidation half-wave of diphenyldiazomethane at a rotating platinum disc electrode is 0.95 V relative to the saturated calomel electrode[104], for diazomethane the corresponding value is 1.7 V.[105] In view of these data, a higher reactivity of diphenyldiazomethane compared with diazomethane was to be expected. Apparently, the phenylation of diazomethane not only changes the donor–acceptor properties of the 1,3-dipoles but also increases the localisation energies. We may note that an increase of the localisation energies of dienes with increase of the degree of their phenylation had been convincingly demonstrated in earlier studies in relation to the diene synthesis reaction as a result of thermochemical studies of the reactions of butadiene and its phenylated derivative with tetracyanoethylene[106] and 4-phenyl-1,2,4-triazoline-3,5-dione[88]. Presumably a similar phenomenon obtains also in the case of diazomethane.

From the standpoint of the manifestation of qualitative differences between the effects of the interaction of the symmetric and antisymmetric frontier orbitals in 1,3-dipolar cycloaddition reactions, data on the reactivity of diphenyldiazomethane in relation to cyanoethylenes are of interest[107]:

(XV) (XVI)–(XX)

$R^1=R^2=R^3=H$, $R^4=CN$ (XVI); $R^1=R^3=H$, $R^2=R^4=CN$ (XVII); $R^1=R^4=H$, $R^2=R^3=CN$ (XVIII); $R^1=H$, $R^2=R^3=R^4=CN$ (XIX); $R^1=R^2=R^3=R^4=CN$ (XX)

The kinetic parameters of these reactions are presented in Table 4, which also includes the energies of the lowest unoccupied orbitals of the cyanoethylenes (XVI)–(XX) and the localisation energies calculated by the Hückel MO method[108]. It is seen from the data presented that the rate constants and activation energies for the reactions of compounds (XVI) to (XX) are inconsistent with their electron-accepting properties. The cyanoethylene (XVIII) shows the highest reactivity in the reaction with compound (XV), while the dipolarophile (XX), which is a much more powerful electron acceptor than compound (XVIII), reacts more slowly almost by a factor of 100. The variation in the reactivities of cyanoethylenes is also inconsistent with the localisation energy series.

Table 4. Kinetic parameters of the 1,3-dipolar cycloaddition reactions of the cyanoethylenes (XVI)–(XX) with diphenyldiazomethane in chlorobenzene[107] and the energies of the lowest unoccupied orbital (ε_{LUO}) and the localisation energies ($L_{1,2}$) of the dipolarophiles[108].

Cyanoethylene	k_2 litre mol^{-2} s^{-1}, 50 °C	lg *A*	E_A, kJ mol^{-1}	$-\Delta S^{\neq}$, J mol^{-1} K^{-1}	$-\varepsilon_{LUO}$, β	$L_{1,2}$, β
(XVI)	$4.5\cdot10^{-4}$	6.6	47	146	0.6891	2.462
(XVII)	$7.1\cdot10^{-4}$	6.1	51	130	0.6153	2.924
(XVIII)	10^{-2}	—	—	—	0.4826	2.888
(XIX)	13.8	5.2	21	155	0.4008	3.350
(XX)	0.38	4.8	28	159	0.2886	3.776

*At 5 °C.

Thus in the series investigated, the reactivity of the addends is not determined by the preferential influence of a particular factor and is in all probability determined by both factors. This is confirmed by the relation between the activation energies for the reactions of the cyanoethylenes (XVI)–(XX) with diphenyldiazomethane (XV) and the parameters (E_{LUO}, $L_{1,2}$) characterising the electron-accepting and

localisation properties of the dipolarophiles[107]:

$$E_A = -231.8\ (\varepsilon_{LUO} - 0.236\ L_{1,2}) - 250.2\ (r = 0.955).$$

(For a narrow range of compounds, in particular for cyanoethylenes, a linear correlation has been observed between the reciprocals of the differences between the ionisation potentials and the electron affinities and the ionisation potentials or electron affinities[59]. Direct correlations with I_D and E_A have therefore found extensive applications for the description of the reactivities in the series when allowance for the other reactant is unimportant[45].)

In terms of the sign of the constant preceding ε_{LUO}, the series investigated belongs to reactions of the type where the 1,3-dipole and the dipolarophile are the donor and acceptor respectively. The activation energy for the reaction of the cyanoethylene (XVIII) with diphenyldiazomethane calculated from the parameters of the equation is 20 kJ mol^{-1}. In the Diels–Alder reactions of cyanoethylenes with cyclopentadiene and 9,10-dimethylanthracene, which are typical electron-donating dienes, the reactivity of the dienophiles is consistent with their electron-accepting properties[109], while in the reactions of the same compounds with electron-accepting dienes such as substituted phenylcyclones[110] and tetracyclones[111] an appreciable influence of the localisation effects on the reactivities is manifested, although from the standpoint of the donor–acceptor properties these reactions are also of the type where the diene and the dienophile are the donor and acceptor respectively.

Table 5. The enthalpies of activation for the reactions ($\Delta H^{\neq}_{soln}$), the enthalpies of solution of tetracyanoethylene (ΔH^{TCE}_{reactn}) and *C,N*-diphenylnitrone (ΔH^{N}_{reactn}), and the enthalpies of transolvation of the reactants (ΔH^{react}_{solv}) and the transition state (ΔH^{ts}_{solv}) relative to chlorobenzene in the 1,3-dipolar cycloaddition reaction of *C,N*-diphenylnitrone with tetracyanoethylene[112].

Solvent	$\Delta H^{\neq}_{soln}$, kJ mol^{-1}	ΔH^{TCE}_{reactn}, kJ mol^{-1}*	ΔH^{N}_{reactn}, kJ mol^{-1}	ΔH^{react}_{solv}, kJ mol^{-1}	ΔH^{ts}_{solv}, kJ mol^{-1}
Chlorobenzene	56.9	23.1	22.6	0	0
Benzene	78.6	14.9	23.0	−7.8	13.9
Toluene	84.5	9.7	22.6	−13.4	14.2
o-Xylene	109.2	1.4	24.3	−20.0	32.3

*Konovalov et al.[113]

The usual influence of solvents on the reactivity, which can be explained in terms of the qualitative differences between the effects of the interaction of the symmetric and antisymmetric frontier orbitals of the addends, has been observed in the reaction of *C,N*-diphenylnitrone with tetracyanoethylene[112]. The kinetic and thermochemical data for this reaction are presented in Table 5. Evidently, the differences between the activation barriers in different reactions are not only caused by the differences between the solvation energies of the reactants but also depend significantly on the solvation energy of the transition state, the transolvation energy of the activated complex increasing with enhancement of the electron-donating character of the solvent. The observed trends in the transolvation of the transition state become understandable when account is taken of the possibility of a change in the position of the transition state on the potential energy surface.

Enhancement of the electron-donating properties of the solvent reduces the electron-accepting properties of tetracyanoethylene owing to complex formation processes. This entails a weakening of the interaction between the antisymmetric orbitals of the addends and an increase of the contribution to the stabilisation energy by the interaction of the symmetric orbitals. As a result of this, the transition state becomes more localised, i.e. it shifts along the reaction coordinate in the direction of the products. The energy consumed on the localisation increases the energy of the transition state, which parallels the enhancement of the electron-donating properties of the solvent and the diminution of the electron-accepting character of tetracyanoethylene. It is of interest to note that, in the Diels–Alder reaction of tetracyanoethylene with anthracene, the contribution to the stabilisation energy resulting from the interaction of the symmetric orbitals is low and an appreciable influence of the nature of the solvent on the energy of the transition state is not observed[113], which confirms the above point of view.

There is no doubt that the strong influence of solvents on the character of the reaction is possible only in the presence of specific solvation in the system. In those cases where the interaction of the addends with the solvent is weak the rates of 1,3-dipolar cycloaddition reactions change only slightly when the nature of the solvent is altered[14,90].

* * *

The above discussion shows that, for the interpretation of the reactivities of the addends in 1,3-dipolar cycloaddition reactions, it is necessary to take into account not only the donor–acceptor properties of the 1,3-dipoles and dipolarophiles but also the localisation energies of the corresponding reaction centres. While concentrating attention on these two factors, we naturally do not deny the existence of other electronic and steric effects. However, allowance for these factors alone makes it possible in a number of instances to describe the reactivity satisfactorily.

We believe that the qualitative differences in the character of the interaction of the symmetric and antisymmetric frontier orbitals are important. The understanding of the role of these interactions facilitates the prediction of the reactivities of addends in the $(4\pi + 2\pi)$-cycloaddition reaction and makes it possible to carry out a specific search for systems whose reactivity is determined mainly by a particular effect.

Advances in the Synthesis of Aromatic Iodo-compounds

E.V.Merkushev

The review presents a compilation of data on the iodination of aromatic compounds published during the last 10-20 years. The synthetic advantages of various methods of preparation of aromatic iodo-derivatives are examined and data concerning the mechanism of direct iodination are presented.
The bibliography includes 127 references.

I. Introduction 343
II. Direct iodination 343
III. Indirect iodination 345
IV. The mechanism of the iodination of arenes 347

I. INTRODUCTION

The expansion of the range of methods of organic synthesis involves both the discovery of new reactions and reagents and a deepening of our knowledge of the chemical properties of compounds already known. The latter applies fully to the chemistry of aromatic iodo-derivatives. For about 100 years, aryl iodides have been used in various organometallic syntheses, mainly in the Ullmann reaction (for the latest reviews on this reaction, see Fanta[1] and Goshaev et al.[2]). A new branch of this by no means complete field of study involves the condensation of copper acetylides with compounds containing a halogen attached to an unsaturated carbon atom (usually with aryl iodides). Further progress in this field is associated with the application of transition metal complexes, particularly palladium complexes (see the relevant reviews[3-6]). Summarising the reactions of halides in the presence of palladium salts, Heck[7] noted the enhanced and frequently uniquely high reactivity of the iodo-derivatives.

One must note the elegant method of generating aryl radicals in the photolysis of aryl iodides discovered by Kharasch and co-workers[8,9]. It must be emphasised that the reaction between aryl iodides and styrenes leads to stilbenes, which are the starting materials for the synthesis (by photochemical dehydrocyclisation) of a wide variety of compounds containing the phenanthrene fragment[10].

It is to be expected that further studies will expand still more the applications of aromatic iodo-derivatives in organic synthesis. One of the causes which has retarded a more extensive involvement of aryl iodides in practical organic synthesis has been the lack of simple and reliable methods of their preparation; the main method for the synthesis of the majority of aryl iodides up to the 1950s involved a multistage synthesis based on the Sandmeyer reaction. However, the studies in the last 10–20 years have led to the discovery of new simple methods which have made aryl iodides quite easily available.

Whereas the methods of synthesis of aromatic bromo-, chloro-, and fluoro-derivatives have been widely described in monographs and have been published periodically in journal reviews, there are no similar publications devoted to aromatic iodo-derivatives with the exception of a short chapter in a monograph[11]. The main aim of this review is to draw the attention of chemists engaged in synthesis to the advances in the synthesis of aromatic iodo-derivatives.

The known methods of synthesis of aryl iodides can be divided into two large groups: direct iodination based on the direct formation of the carbon–iodine bond on substitution of aromatic compounds and indirect iodination involving the initial substitution of hydrogen in the aromatic substrate by an atom or group with its subsequent replacement by iodine. The entire experimental data are examined henceforth on the basis of this classification.

II. DIRECT IODINATION

The vast majority of aromatic compounds, with the exception of a series of amines and phenols whose reactions are not considered in this review, do not interact with molecular iodine in the absence of oxidants. The set of oxidants used in direct iodination reactions was extremely limited up to the 1950s, but studies in recent years have greatly increased their number, which has led to the development of simple and reliable methods of synthesis of iodo-derivatives of different classes.

1. Iodination by the Tronov–Novikov Method

At the beginning of the 1950s, Tronov and Novikov showed that the iodination reaction can be successfully carried out in acetic acid in the presence of nitric and sulphuric acids as oxidants[12-14]. In the course of numerous experiments, it was established that the best results are obtained when mixtures of nitric ($d = 1.4$) and sulphuric ($d = 1.84$) acids are employed. This method was subsequently extended to a wide range of aromatic substrates[15-18] including benzene and its homologues, polynuclear aromatic compounds, oxygen-containing aromatic compounds (ethers, aldehydes, ketones, and carboxylic acids) and aromatic compounds of other classes.

In iodination by the Tronov–Novikov method, the organic substrate is usually dissolved in glacial acetic acid, finely ground iodine is added, and then a mixture of nitric and sulphuric acid is added dropwise with intense stirring (at temperatures ranging from room temperature to the boiling point of glacial acetic acid). In the iodination of reactive aromatic compounds, the acid mixture is diluted with acetic acid[19]. Sometimes, when the reaction is carried out at an elevated temperature, it is useful to add several millilitres of carbon tetrachloride to the reaction mixture in order to wash off the subliming iodine. The reaction is accompanied by the evolution of nitrogen oxides; it can be followed visually from the disappearance of iodine. In order to isolate the reaction products, the reaction mixture is diluted with water in most cases, and the iodo-derivative formed is filtered off.

Iodobenzene (80%), 2-iodo-*p*-xylene (87%), 2,5-di-iodo-*p*-xylene (85%), iodomesitylene (88%), iododurene (100%), di-iododurene (88%), di-iodomesitylene (80%), tri-iodomesitylene (63%), iodopentamethylbenzene (87%), 4,4′-di-iodobiphenyl (68%), 2,7-di-iodofluorene (50%), 2,7-di-iodofluorenone (75%), 2,7-di-iodophenanthrenequinone (50%), 2-iodofluorenone-5-carboxylic acid (65%), as well as many other aromatic iodo-compounds have been obtained by this method.

Iodonitro-derivatives are formed as side products at elevated temperatures[20], which suggested a "single-stage" reaction for the introduction of iodine and nitro-groups into aromatic compounds[21]; studies of the isomeric composition of the products led to the conclusion that iodination takes place initially and is followed by nitration[22]. 4-Iodonitrobenzene (46%), 2-iodo-5-nitro-*p*-xylene (45%), 4-iodo-4′-nitrobiphenyl (50%), and 2-iodo-7-nitrofluorene (61%) have been synthesised successfully by this method[22-25].

Further studies of the oxidative side processes will probably lead to the development of new useful methods, as can be seen from the synthesis of 4,4′-di-iodobenzophenone in 40% yield on iodination of diphenylmethane[26].

2. Iodination in the Presence of Iodic and Periodic Acids

Although iodination in the presence of iodic acid has been known for more than 100 years (see, for example, Kekulé [27]), the extensive possibilities of this reagent as an oxidant in the iodination of a large number of aromatic substrates were demonstrated only in 1960.[28] Subsequently, this reagent was used in the iodination of *p*-xylene and durene[29]. The method is convenient for the iodination of fluorene whose molecule contains the readily oxidisable methylene group[30]; it proved useful also in the iodination of methylated polyphenylenes[31-33].

Periodic acid dihydrate is used in the iodination of alkylbenzenes[34-36]. In particular, satisfactory results have been obtained in the presence of this oxidant in the monoiodination of mesitylene, durene, pentamethylbenzene, 5-t-butyl-1,3-dimethylbenzene, 4-t-butyl-1,2-dimethylbenzene, and even 5-t-butyl-1,2,3-trimethylbenzene, 1,2,4,5-tetraisopropylbenzene, and *p*-di-t-butylbenzene. A critical examination of the methods of synthesis of iodo-derivatives of alkylbenzene led to the conclusion[37] that the above procedure is the most suitable for the introduction of one and two iodine atoms into the alkylbenzene molecule. The efficiency of periodic acid in the iodination of unsubstituted polyphenylenes[38,39], fluoranthene[40], and acenaphthene[41] has been demonstrated.

3. Iodination in the Presence of Peracetic Acid

It was shown in the middle 1960's [42-46] that peracetic acid is an effective oxidant in direct iodination. The method was extended to a wide range of aromatic substrates; particularly good results were obtained for atomatic compounds containing electron-donating substituents.

The study of the reaction mechanism led to the hypothesis that acetyl hypoiodite and its protonated form are the source of electrophilic iodine[44]. Autocatalysis in the iodination of benzene homologues with electron-donating substituents was noted and the authors explained it by the oxidation of the iodo-derivatives formed initially by the corresponding iodoso-derivatives or their acetates in accordance with the following scheme:

$$ArI + CH_3CO_3H \rightarrow ArIO + CH_3CO_2H ,$$
$$ArIO + 2CH_3CO_2H \rightarrow ArI(OCOCH_3)_2 + H_2O .$$

The polyvalent iodine compounds formed are effective oxidants in the oxidation of iodine to acetyl hypoiodite:

$$ArI(OCOCH_3)_2 + I_2 \rightarrow ArI + 2CH_3COO^{\oplus}I^{\oplus}$$

This hypothesis was confirmed by the successful iodination of *m*-xylene in warm acetic acid in the presence of iodosobenzene or phenyliodoso acetate+.

4. Iodination in the Presence of Variable-Valence Metal Chlorides

In 1970 a method was proposed for the direct iodination of aromatic compounds using bivalent copper chloride and an iodine donor (I_2, AlI_3, or $FeI_2.4H_2O$).[47] It was also found that the copper acetate–iodine system is effective for the iodination of azulene[48].

The effectiveness of antimony pentachloride as the oxidant in the oxidation of aromatic compounds in carbon tetrachloride was demonstrated in 1974.[49] It is of interest to note the very high yields of the *p*-isomers, which are respectively 98, 99, and 100% in the case of fluorobenzene, chlorobenzene, and bromobenzene.

5. Iodination by *N*-iodoamides

N-Iodosuccinimide is used successfully in the iodination of fluorene[50] (for the synthesis of the reagent, see Benson et al.[51]). The effectiveness of acid *N*-iodoamides in arene iodination reactions has been demonstrated[52-55]. These reactions are accelerated on catalysis by acids; particularly good results have been obtained using trifluoroacetic acid[55]. The authors believe that trifluoroacetyl hypoiodite is the source of electrophilic iodine in this process.

Trifluoroacetyl hypoiodite was probably first postulated as a source of electrophilic iodine by Henne and Zimmer[56], who demonstrated the effectiveness of the iodine/silver trifluoroacetate system in the iodination of aromatic compounds; an elegant method of synthesis of iodoveratrol was developed on the basis of this procedure[57]. In this reaction, iodine can be successfully replaced by chlorine iodide[58]. It has been shown that in the series of acetyl hypohalites, trifluoroacetyl hypohalites are the most powerful halogenating agents[59].

6. Iodination in the Presence of Phenyliodoso Trifluoroacetate#

An attempt at the coupled addition of iodine and trifluoroacetoxy-groups to the triple bond of tolane, by analogy with iodoacetoxylation by the iodine/phenyliodoso acetate system was made in 1979.[60] However, instead of the expected addition to the triple bond, tolane was oxidised to an α-diketone (benzil). It was found that the oxidation of diarylacetylenes to α-diketones is a general reaction[61]. Together with benzil, *p*-di-iodobenzene, formed as a result of the iodination of iodobenzene whose source was a molecule of phenyliodoso trifluoroacetate, was isolated from the reaction product[62]. Inorganic derivatives of polyvalent iodine (iodic and periodic acid) are widely used as oxidants in direct iodination reactions but organic derivatives of polyvalent iodine have not

---

+Bis(acetato-*O*)phenyliodine (Ed.of Translation).

#Bis(trifluoroacetato-*O*)phenyliodine (Ed.of Translation).

been used until recently in preparative organic chemistry, although the possibility, in principle, of iodinating *m*-xylene in warm acetic acid using iodosobenzene or phenyl iodosoacetate was demonstrated as early as 1963.[44] Phenyliodosoacetate has no special advantages over more readily available oxidants in direct iodination reactions; when azobenzene is iodinated in the presence of phenyl iodosoacetate, 4-iodoazobenzene is formed only in insignificant yield[63].

A detailed study of iodination in the presence of phenyliodoso trifluoroacetate showed that, in contrast to phenyliodoso acetate, this reagent is very effective as an oxidant and makes it possible to introduce from one to three iodine atoms into the aromatic ring at room temperature[64–66]. It was found that the iodine/phenyliodoso trifluoroacetate system is effective in the iodination of not only benzenoid compounds but also certain heterocycles[67]. It was discovered that the bromine/phenyliodoso trifluoroacetate system is effective in the bromination of aromatic compounds[60]. Some data on the iodination of aromatic compounds by the iodine/phenyliodoso trifluoroacetate system at room temperature are presented in Table 1.

Table 1. Iodination in the presence of phenyliodoso trifluoroacetate.[66]

Aromatic substrate	Aryl iodide	Yield, %
Benzene	Iodobenzene	72
o-Xylene	4,5-Di-iodo-*o*-xylene	55
m-Xylene	4,6-Di-iodo-*m*-xylene	77
p-Xylene	2,5-Di-iodo-*p*-xylene	65
Mesitylene	Tri-iodomesitylene	84
Durene	Di-iododurene	52
Diphenylmethane	4,4'-Di-iododiphenylmethane	52
Triphenylmethane	4,4',4''-Tri-iodotriphenylmethane	32
Biphenyl	4,4'-Di-iodobiphenyl	87
p-Terphenyl	4,4''-Di-iodo-*p*-terphenyl	93
Chlorobenzene	1-Chloro-4-iodobenzene	61
Bromobenzene	1-Bromo-4-iodobenzene	63
Iodobenzene	1,4-Di-iodobenzene	73
Diphenyl ether	Di(4-iodophenyl) ether	79
Fluorenone	2,7-Di-iodofluorenone	51
Biphenyl-4-carboxylic acid	4-Iodobiphenyl-4'-carboxylic acid	81
Fluorene-9-carboxylic acid	2,7-Di-iodofluorene-9-carboxylic acid	70
Methyl fluorene-9-carboxylate	Methyl 2,7-di-iodofluorene-9-carboxylate	52
Diphenylene oxide	3,6-Di-iododiphenylene oxide	59

On the basis of the data obtained in a ^{19}F NMR study of the iodination of arenes in carbon tetrachloride at room temperature, trifluoroacetyl hypoiodite has been proposed as the iodinating agent:

$$C_6H_5I(OCOCF_3)_2 + I_2 \rightleftarrows C_6H_5I + 2F_3CCOOI;$$
$$ArH + F_3CCOOI \rightarrow ArI + F_3CCOOH\ .$$

It was established that phenyl iodosotrifluoroacetate, prepared beforehand, must be used in the reaction. It can be generated in the reaction mixture *in situ* from phenyl iodosoacetate and trifluoroacetic acid[66].

The iodination reaction takes place at room temperature with aromatic substrates which are not oxidised under the experimental conditions and are more reactive in electrophilic substitution reactions than iodobenzene. The attempt to iodinate nitrobenzene, benzoic acid, and benzophenone led only to *p*-di-iodobenzene as a consequence of the iodination of the iodobenzene formed from phenyliodoso trifluoroacetate.

7. Iodination of Polymers

Reagents on a polymeric support have been recently introduced into practical organic synthesis. From this standpoint, iodine-containing polymers are of special interest since iodine can be readily substituted by another functional group or a reagent with polyvalent iodine can be formed. Compounds containing the iodosochloride [aryliodine dichloride] group in the benzoic acid residue, joined by an ester linkage to a steroid molecule[69], or an iodosofluoride [aryliodine difluoride] group in a polymeric molecule[70], have been used successfully in the selective halogenation of organic compounds. Polystyrene can be iodinated in the presence of iodic acid[71] or iodine pentoxide[72] as oxidants but iodination in the presence of phenyliodoso trifluoroacetate is a more convenient method[73].

8. Introduction of Polyvalent Iodine into the Aromatic Ring

The introduction of the iodo-group into the aromatic molecule on treatment with iodic and sulphuric acids can be classified as a variety of the direct iodination reaction[74]. Together with benzene, halogenobenzenes, benzoic acid, and nitrobenzene can enter into this reaction. The reduction of iodo-derivatives leads to the corresponding aryl iodides. On treatment with iodine tris(trifluoroacetate), it is possible to introduce the $(CF_3COO)_2I$ group[75]. The reduction of aryliodoso trifluoroacetates leads to aryl iodides. Many problems involving the mode of substitution in the benzene ring can be solved in this field. Whereas iodine is *ortho-para* directing, polyvalent iodine exhibits a powerful *meta*-directing effect.

III. INDIRECT IODINATION

The reaction involving the replacement of the amino-group by iodine via diazonium salts has still not lost its importance especially when the amine is commercially available or it is necessary to synthesise an iodide having a specific structure without admixtures of other isomeric iodo-derivatives. The diazotisation of aniline in the presence of iodine[76], which makes it possible to obtain *p*-di-iodobenzene, probably via an intermediate aniline iodination stage, can be classified as a reaction of this type. In this connection it is necessary to point out a publication[77] whose authors claim that the synthesis of iodo-derivatives with the aid of diazonium salts in the presence of crown-ethers has advantages over the classical version of the Sandmeyer reaction. It is of interest to note the thermal stability of aryl iodides; the thermolysis of aryl bromides in the presence of iodine can serve as a preparative method of synthesis of iodo-derivatives[78].

Since, together with primary aromatic amines, aromatic carboxylic acids are the most readily available functional derivatives, the potential possibility of replacing the carboxy-group by iodine is of undoubted interest. A number of methods for the replacement of the carboxy-group (in the form of various derivatives) by iodine have been developed in recent years and will be considered below. Striking advances in the synthesis of aryl iodides were associated with the application of organometallic compounds, particularly thallium derivatives. In addition, reactions involving the decomposition of organic compounds of polyvalent iodine, leading to aryl iodides, have been examined; a series of effective methods of synthesis of polyvalent iodine compounds, which have led to the use of these previously exotic compounds as intermediates in the preparative synthesis of aromatic iodo-derivatives, have also been developed.

1. The Replacement of the Carboxy-Group by Iodine

The catalytic decarbonylation of aromatic carboxylic acid iodides to the corresponding aryl iodides by tris(triphenylphosphine)rhodium chloride was described in 1968.[79] *o*-Diiodobenzene, *o*-chloroiodobenzene, and *m*-di-iodobenzene, which are difficult to obtain by direct iodination, have been obtained in satisfactory yields by the above method. The reaction proceeds under mild conditions and gives rise to high yields of the iodide. The discovery of a relatively simple method of synthesis of aroyl iodides from the corresponding aroyl chlorides and sodium iodide[80] undoubtedly makes the decarbonylation reaction valuable in practice.

It is known that the thermolysis of aroyl peroxides in the presence of iodine can serve as a preparative method of synthesis of aryl iodides; particularly good results have been obtained using the peroxides of nitrobenzoic acids[81].

The Borodin–Hunsdieker reaction has not found extensive applications in the synthesis of aryl iodides but it should be noted that the photolysis of naphthoic acids in the presence of lead tetra-acetate and iodine has led to the corresponding iodonaphthalenes in high yields[82].

2. The Synthesis of Iodo-derivatives Via Organothallium Compounds

As early as the 1940's, Gilman observed[83] that organothallium compounds can be obtained with the aid of thallium trichloride. However, this reaction did not find applications in organic synthesis, probably as a consequence of the insignificant yield and severe conditions. In the 1950's Glushkova and Kocheshkov discovered the reaction involving the direct introduction of thallium into aromatic compounds by thallium tri-isobutyrate at 95–115 °C with formation of arylthallium di-isobutyrates[84–87]; they also demonstrated the ease of the cleavage of the thallium–carbon bond by molecular iodine with formation of iodo-derivatives. However, this reaction has not found synthetic applications, probably because of the difficulties in the introduction of thallium into deactivated aromatic compounds owing to the low electrophilicity of thallium tri-isobutyrate.

In 1969 McKillop and co-workers[88] showed that thallium tris(trifluoroacetate) is an excellent reagent for the introduction of thallium into organic substrates. It may be noted that the method of synthesis of thallium tris(trifluoroacetate) quoted in the well-known book by Fieser and Fieser[89] cannot be reproduced. Fieser and Fieser apparently based their description on a brief communication[88] where it was not stated that a small amount of water is essential for the preparation of thallium tris(trifluoroacetate) from thallium oxide and difluoroacetic acid; this was noted in a subsequent more detailed publication[91]. It has been established[90,91] that treatment of arylthallium bis(trifluoroacetate) with an aqueous solution of potassium iodide constitutes a very simple method of synthesis of aryl iodides:

$$ArH \xrightarrow{Tl(OCOCF_3)_3} ArTl(OCOCF_3)_2 \xrightarrow{KI} ArI$$

Substitution by thallium is usually carried out in trifluoroacetic acid; in the case of substrates sensitive to the action of acids, it is possible to employ acetonitrile. Aromatic compounds are usually substituted by thallium in the course of several minutes at room temperature but deactivated substrates require heating with thallium tris(trifluoroacetate) in boiling trifluoroacetic acid. Some data on the synthesis of aryl iodides via organothallium compounds are listed in Table 2.

Table 2. Synthesis of aromatic iodo-derivatives via organothallium compounds.
