where E_{SC} is the value of the potential in the volume zone of the oxide, and E_H and E_{el} the decrease in the potential in the Helmholtz layer and in the electrolyte respectively.[32] Regions of volume charge are produced on both sides of the boundary.[32] The equivalent scheme of the boundary is represented by three condensers connected in series.[33] The production of the volume charge in the oxide when it is brought into contact with the electrolyte is due to the insertion of protons (hydroxide groups) into the solid phase.[34] The charge density in this oxide is much lower than that in the metal.[33,35] Thus the potential jump between the phases[33] is concentrated almost entirely in the solid phase, and the contribution made to it by the Helmholtz layer is usually negligible.[35,36]

The magnitude and distribution of the charges and potentials are calculated using two fundamental relationships:

1) the Poisson equation

$$d^2E/dr^2=-\rho/\varepsilon\varepsilon_0 \qquad (5)$$

where ρ is the charge density (made up of both mobile charges, that is electrons $n(r)$ and holes $p(r)$, and stationary charges, that is ionised donors (N_D) and acceptors (N_A), that is $\rho(r) = e[-n(r) + p(r) - N_D + N_A]$); and ε and ε_0 are the dielectric constants of the specimen and a vacuum respectively;

2) the Gauss equation

$$dE/dr=-Q/\varepsilon\varepsilon_0 \qquad (6)$$

where Q is the density of the surface charges. It follows from Eqns.(5) and (6) that the value of the potential in the three regions will be given by the expression (see Fig.4)

$$E=\varepsilon_{sc}r_{sc}+\varepsilon_H r_H+\varepsilon_{el}\varkappa^{-1}$$

where ε_{SC}, ε_H, and ε_{el} are the electric field intensities in the region of the volume charge, the Helmholtz layer, and the electrolyte respectively; and r_{SC}, r_H, and $\varkappa^{-1}$ are the Debye length (characterising the extent of the layer occupied by the volume charge), the extent of the Helmholtz layer, and the thickness of the Gouy layer respectively. The analytical[37] and graphical[38] solution of Eqns.(5) and (6) makes it possible to calculate quantitatively a large number of parameters characterising the distribution of the potential jump. It should be noted that the calculated value $r_{SC} = (\varepsilon_{SC}kT/4\pi e^2 n_0)^{1/2}$ depends on the concentration of free charges (n_0) in the oxide. If $n_0 = 1 \times 10^{13}$ cm^{-3}, and the concentration of ions in a 0.01 M solution of the electrolyte

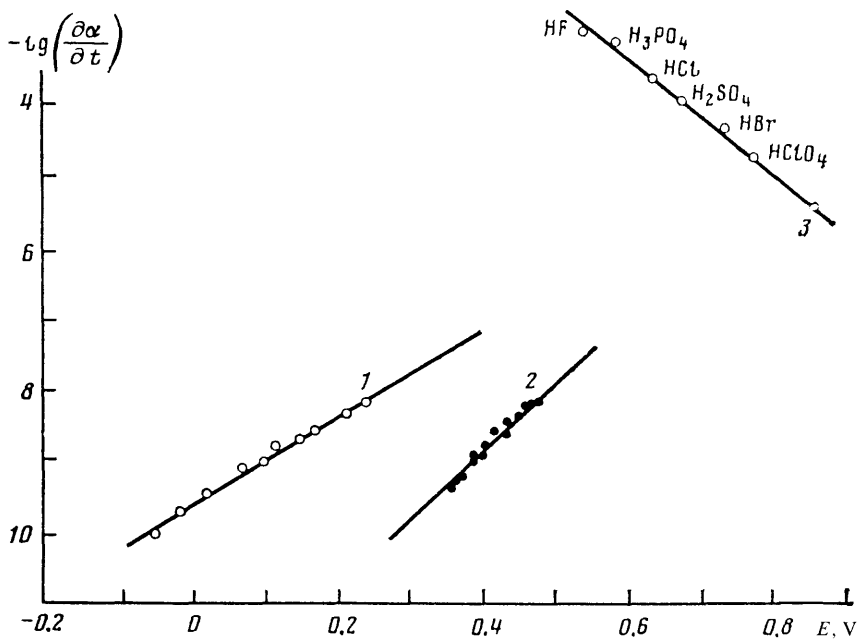

Figure 3. Dependence of the rate of dissolution on the potential for the following oxides: *1*) UO_2 (0.2 M Na_2CO_3 + 0.2 M $NaHCO_3$, 25 °C; $\partial E/\partial \lg \partial\alpha/\partial t$ = 150 mV); 2) UO_2 (1 M $HClO_4$, 25 °C; $\partial E/\partial \lg \partial\alpha/\partial t$ = 120 mV);[30] 3) Fe_2O_3 (1 M acid solutions, 50 °C; $\partial E/\partial \lg \partial\alpha/\partial t$ = 120 mV.[153]

is 10^{19} cm^{-3}, then the extent of the region occupied by the space charge ($r_{sc} \cong 10^{-4}$ cm) is 100 times the thickness of the diffuse layer. With increase in the concentration of free carriers (for example in the reduction of oxides showing *n*-conductivity), the quantity $r_{sc} \to 0$ as $n_0 \to \infty$. In this case all the space charge is "concentrated" on the electrode surface.

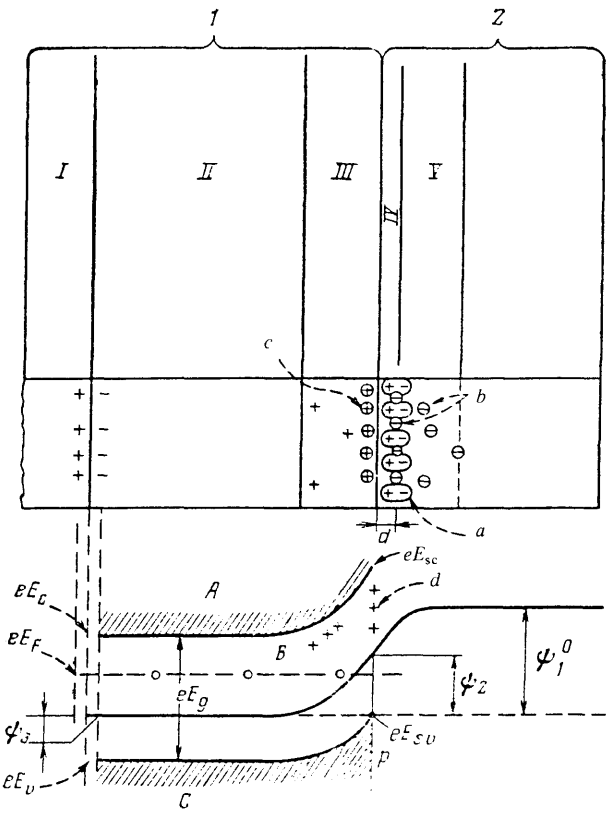

Figure 4. Structure of the electrical double layer at the oxide/electrolyte interface: *1*) solid phases: *I*) metal, *II*) oxide, *III*) region of space charge in the oxide; *2*) electrolyte: *IV*) Helmholtz layer, *V*) Gouy layer. Species creating the electrical double layer: *a*) oriented dipoles of water; *b*) excess ions of the solutions; *c*) adsorbed ions on the oxide, creating surface states; *d*) ionic states. Energy characteristics of the semiconductor (oxide): *A*) conductivity zone, *B*) non-compensated ions of the donors, *C*) valence zone; ψ_1, ψ_2, ψ_3 are the galvanic potentials of the solution, the surface states of the oxide phase, and the metal respectively.[73]

The rate of the dissolution of oxides is controlled chiefly by the magnitude of the potential in the Helmholtz layer. The magnitude of the potential in this case cannot be found experimentally. The values of the other components can be determined. For example, the magnitude of the potential E_{sc} is calculated from the dependence of the photopotential, the differential capacity, and the surface conductivity on the polarisation potential of an oxide electrode.[39-41] Usually, the value of the potential of the planar zones (E_{fb}), when $E_{sc} = 0$ and $E_{el} = 0$, was found. The values of E_{fb} are given in Table 1.

Table 1. Width of the band gap of metal oxides (eE_g) and the potentials of the planar zones of the electrodes [E_{fb}, V (normal electrode)] for different pH values.

Oxide	eE_g, eV	pH 2.0	pH 4.0	pH 6.0	pH 8.0	pH 10.0	pH 12.0	pH 14.0	Refs.

*p-Type conductivity; n-type conductivity in the other cases.

**Studied in an acetate buffer containing $Fe(EDTA)^{2-}/Fe.(EDTA)^{-}$.

In the study of the kinetics of the dissolution of oxides, it has been assumed that the rate of the process is limited by the potential jump in the Helmholtz layer.[29,48] The factors influencing its magnitude can therefore be considered.

a) Factors influencing the magnitude of the potential in the Helmholtz layer. At $E_{sc} = 0$ (that is in the absence of a potential jump in the region of the space charge), the magnitude of the total E is determined by the potential jump in the Helmholtz layer. The study of the influence of various factors[32] on the potential of the planar zones is now not only a stimulus to study but also one of the methods for studying this layer. On oxides (ZnO, TiO_2, SnO_2, Fe_2O_3), the magnitude of E_H is a linear function of pH

$$E_H = E^0 - \left(\frac{2.3\,kT}{e}\right)(\mathrm{pH})$$

since the potential E_H is related to the concentration of adsorbed protons H^+ (the potential-determining ion). If it is assumed that the capacity C_H per unit surface area of the oxide electrode is independent of E_H, it follows that

$$e[H_s^+] = C_H E_H \qquad (7)$$

Here, the pH dependence is due to the reactions: $H_3O^+(aq) \to H^+(solid) + H_2O(aq)$

$$MO_{x_1} + (x_1 - x_2)e + (x_1 - x_2)H^+ \to MO_{x_2} + (x_1 - x_2)H_2O$$
$$\Delta G^0 = \Delta G^0(MO_{x_2}) - \Delta G^0(MO_{x_1}) + \Delta G^0(H_2O)$$
$$\frac{[H^+(solid)]}{[H_3O^+(aq)]} = \exp\left(-\frac{\Delta G^0}{kT}\right) = A\exp\left(-\frac{eE_H}{kT}\right) \qquad (8)$$

Comparison of Eqns.(7) and (8) shows that $eE_H = B - 2.3\,kT$ (pH). If adsorption of other ions of the electrolyte takes place, it leads to a change in the magnitude of E_H.

This potential jump is practically independent of the polarising potential, and its magnitude is not influenced by ions which have not been adsorbed on the electrode. The reason is that the extent of the Helmholtz layer is smaller than the thickness of the layer of the space charge. When charge is transferred from the volume to the surface of the semiconductor, only a small fraction of the consequent change in

the potential difference corresponds to E_H. The decrease in potential takes place chiefly in the region of the space charge, and not in the Helmholtz layer. The potential jump in the Helmholtz layer at the oxide/electrolyte boundary depends on the surface properties of the semiconductor, the ionic strength of the electrolyte, the pH of the solution, and the specific adsorption. The change in potential in the Helmholtz layer is due to the establishment of equlibrium between the solution and the oxide electrode.[49] When the oxides come into contact with the electrolyte solutions, a surface charge is produced as a result of the dissociation of acidic and basic groups; this process can be represented by the equations

$$HOMO^- + H^+ \overset{K_+}{\leftarrow} MO(solid) + H_2O \overset{K_-}{\rightarrow} MOH^+ + OH^-$$

where K_+ and K_- are the dissociation constants of the acidic and basic groups respectively.

Table 2. Electrocapillary zero at 25 °C and the isoelectric point of metal oxides.

Oxide	Coordination	Structure	$pH_{e.z.}$	$pH_{i.p.}$ (Ref.51)	
				hydrate	anhydrous
Cu_2O	2—4	oct.	>11.5	—	9.5±0.4
MgO	6—6	cub.	12.4	—	12.4±0.3
CdO	6—6	cub.	10.4	>10.5	10.4±0.2
NiO	6—6	cub.	9.85*	—	10.3±0.4
CuO	6—6	cub.	9.5	—	9.5±0.4
ZnO	4—4	hex.	9—10	10.3	9.3
α-Al_2O_3	6—4	hex.	6.5—9.5	9.2	6.7
α-Fe_2O_3	6—4	rhomb.	8.5	8.0±0.2	6.5
α-Cr_2O_3	6—4	rhomb.	7.0	7.29	6.49
UO_2	8—4	cub.	3.5—6.5	—	5.8±0.2
TiO_2	6—3	tetr.	4.7	6.0±0.3	3.5±0.2
SnO_2	6—3	tetr.	5.5	5.5	4.7
β-MnO_2	6—3	tetr.	7.0	—	4.0—4.5
WO_3	6—2	rhomb.	0.5	<0.3	—
Co_3O_4	—	cub.	10.35*	—	—
Fe_3O_4	—	cub.	6.4**	—	6.5±0.2

Note: oct. = octahedral, cub. = cubic, hex. = hexagonal, rhomb. = rhombohedral, tetr. = tetragonal symmetry. The pH values at the electrocapillary zero at 40, 60, and 80 °C for NiO are 9.58, 9.25, and 9.06 respectively, and those for Co_3O_4 are 10.04, 9.82, and 9.62.[52]

*Data from Ref.52; **data from Ref.2; for the other oxides—data from Ref.4.

For oxides, the potential-determining ions are usually hydrogen cations or hydroxide anions.[50] In the case of oxides, a change in pH has a significant influence on the sign of the surface charge. There exists a state of the solution (pH value) corresponding to the electrocapillary maxima, when the oxide surface has equal numbers of positive and negative groups. This point (the electrocapillary zero) is the most important parameter of the interface. The electrocapillary zero (e.z.) of an oxide (Table 2) is related to the change in the surface charge. Thus the surface charge (σ_0) is usually described using the specific adsorption of the potential-determining ions (H^+ or OH^-): $\sigma_0 = eF(\Gamma_{H^+} - \Gamma_{OH^-})$, where F is the Faraday number, and Γ_{H^+} and Γ_{OH^-} the quantities of adsorbed protons and hydroxide ions respectively. This charge leads to the production of a potential which changes with increase in the distance from the surface. The state of the solution corresponding to zero potential is called the isoelectric point (i.p.). In the absence of specific adsorption, that is in a solution of an indifferent electrolyte, the electrocapillary zero and the isoelectric point coincide (zero zeta-potential).

The value of the $pH_{i.p.}$ for oxides changes systematically with change in the properties of the cation. A study of 18 oxides[51] showed that the change is described by the equation

$$pH_{i.p.} = 18.6 - 11.5\ (z/r)$$

where z is the charge of the cation, and r the distance between the adsorbed proton and the cation (equal to the diameter of the oxygen ion plus the radius of the cation). It has been proved experimentally[53,54] that the position of the electrocapillary zero is related to the average electrostatic field in the oxide lattice.

It is of interest to try to find a correlation between the potential jump in the Helmholtz layer (E_H) and the magnitude of the surface charge. According to the ion–dipole model,[55,56] E is separated into the internal potential E_H and the psi-potential (ψ_1):

$$d\psi_1 = -59.2\, d\ (pH).$$

In the case of an oxide, the surface potential is given by more complicated equations.[57,58] Determination of the values of the electrocapillary zero and the isoelectric point on oxides has shown that their values depend on the structure of the surface and on the orientation of the atoms in the crystal (deviation from an ideal crystal usually displaces the isoelectric point towards the more acidic range), on the degree of surface hydration (with increase in the degree of hydration, the isoelectric point corresponds to a higher pH value[59]), and on the magnitude of the charge of the cation in the oxide,[59] the nature of the semiconducting properties of the oxide,[59] the presence of impurities, etc. The pH corresponding to the electrocapillary zero is also influenced by various factors,[59,60] some of which are indicated in Table 2.

A correlation exists between the position of the electrocapillary zero and the rate of dissolution of oxides. The lower the pH corresponding to the electrocapillary zero, the more difficult the dissolution of the oxide. Thus under identical conditions, ZnO and Cu_2O dissolve in acids much more rapidly than TiO_2, α-Cr_2O_3, and α-Fe_2O_3,[59] and the values of the pH at the electrocapillary zero are correspondingly much higher for zinc and copper(I) oxides. With increase in temperature, the electrocapillary zero for a number of specimens (oxides) studied is displaced into the acidic range.[52] The isoelectric point is displaced to higher pH values for hydrated specimens, compared with non-hydrated specimens, so that the former usually dissolves more readily.[51,59] At pH values above the electrocapillary zero, the oxide surface is negatively charged as a result of the strong adsorption of OH^- groups. The magnitude of the surface charge (q_-) decreases with decrease in pH. The magnitude of the positive charge (for example for haematite) depends chiefly on the activity a_{H^+}, and depends little on the anionic composition of the electrolyte.[59]

The surface charge is determined chiefly by the desorption of H^+ on the neutral surface. In some electrolytes (of the KCl type), q_+ depends not only on a_{H^+} but also on a_{Cl^-}. Under these conditions, the surface OH^- groups are displaced by Cl^- ions:

$$\left[\begin{array}{l}\diagdown\\ \text{—FeOH}(OH)_2\\ \diagup\end{array}\right]^- \underset{OH^-}{\overset{2H^+,Cl^-}{\rightleftharpoons}} \left[\begin{array}{l}\diagdown\\ \text{—Fe}(H_2O)_2^{2+}Cl^-\\ \diagup\end{array}\right]^+ + OH^-$$

There are two approaches to the solution of the problem of the nature of the potential jump. Quasi-equilibrium[34,35] and non-equilibrium (compromise)[49,61,62] potential jumps are distinguished. The reactions taking place at the oxide/electrolyte interface determine the magnitude of the potential jump and the rate of dissolution of the oxide in the acid.

b) Principal types of quasi-equilibrium reaction determining the magnitude of the potential jump in the Helmholtz layer. According to the theories of electrochemical kinetics, the magnitude of the potential jump at a phase boundary may be determined both by the exchange of hydrogen cations and metal ions between the oxide phase and the electrolyte solution and also by reactions of other types.[29,34,49,62,63] It is suggested that the potential-determining reactions in a multi-stage process of oxide dissolution are close to equilibrium (quasi-equilibrium), since the current due to the exchange of the potential-determining ions of the oxide phase[64] is greater than the current due to the dissolution of the oxides.[2]

Analysis of experimental data on the potential (E) for FeO_x and MnO_x electrodes shows that E is a complex function of pH, x, and $\ln a_{M^{2+}}$. In strongly acidic media, the magnitude of E is determined by the reaction

$$M^{3+}+e=M^{2+} \qquad (9)$$

and obeys the Nernst equation

$$E = E^0 + \frac{RT}{F} \ln \frac{[M^{3+}]}{[M^{2+}]}$$

In media close to neutral, the dependence of the potential on various factors (in the absence of M^{2+} ions) is determined by the parameters[49]

$$\partial E/\partial \ln[M^{2+}] \sim 0;\ \partial E/\partial(\mathrm{pH}) = 0.059;\ E^0 = f(x) \qquad (10)$$

and the value of E is determined by a reaction of the form:

$$MO_{x_1} + 2(x_1 - x_2)H^+ + 2(x_1 - x_2)e \rightarrow MO_{x_2} + (x_1 - x_2)H_2O$$

The potential may be linearly dependent on the stoichiometry of the oxide: $E^0 = a + bx$, or be determined by the expression:

$$E = E^0 + \frac{RT}{F} \ln \frac{[M^{z+}]}{[M^{(z-1)+}]} \qquad (11)$$

In the presence of M^{2+} ions (at the same pH values):[49]

$$\partial E/\partial \lg[M^{+2}] = -\frac{1}{x-1}0.029;\ \partial E/\partial(\mathrm{pH}) = -\frac{x}{x-1}0.059;\ E^0 = f(x) \qquad (12)$$

The change from Eqn.(10) to Eqns.(11) and (12) is determined by the magnitude of the pH and the ratio $[M^{3+}]/[M^{2+}]$.

To explain the dependence of the magnitude of the potential of the manganese oxide electrode on various factors, it has been suggested that use be made of reaction (9), which in weakly acidic media is complicated by the disproportionation of Mn^{3+}:

$$Mn^{3+} + \frac{x}{2(x-1)}H_2O \rightarrow \frac{2x-3}{2(x-1)}Mn^{2+} + \frac{1}{2(x-1)}MnO_x + \frac{x}{x-1}H^+ \qquad (13)$$

In this case the magnitude of the potential (11) is determined by the overall reaction

$$MnO_x + 2(x-1)e + 2xH^+ \rightarrow Mn^{2+} + xH_2O \qquad (14)$$

and obeys the equation:[95]

$$E = -1.196 + 0.687\frac{x^2 - 0.155x}{x-1} - \frac{0.059x}{x-1}\mathrm{pH} - \frac{0.029}{x-1}\lg[Mn^{2+}] \qquad (15)$$

Eqn.(15) corresponds to the theoretical relationship (14), which can be calculated using the expression:

$$E = -\frac{\Delta G^0}{2(x-1)F} = -\frac{x\Delta G^0(H_2O) + \Delta G^0(Mn^{2+}) - \Delta G^0(MnO_x)}{2(x-1)F} \qquad (16)$$

The relationship between the free energies of formation of the oxides of 3d elements $[\Delta G^0(MnO_x)]$ and x is given by the equation

$$\frac{\Delta G^0_x}{x} = \frac{\Delta G^0_i}{i} - \frac{\Delta G^0_i/i - \Delta G^0_j/j}{i-j}(i-x) \qquad (17)$$

where ΔG^0_i and ΔG^0_j are the free energies of formation of the oxides MO_i and MO_j from the elements.[65,66]

Substituting Eqn.(17) in Eqn.(16) gives†

$$E = E^0_{M/M^{2+}} + \frac{\Delta G^0_i/i - \Delta G^0_j/j}{2(i-j)F}\cdot\frac{x^2 - [\Delta G^0_i(i-j)/(\Delta G^0_i/i - \Delta G^0_j/j) + 1]x}{x-1} - \frac{xRT\cdot 2.303}{F(x-1)}(\mathrm{pH}) - \frac{RT\cdot 2.303}{2(x-1)F}\lg[M^{2+}] \qquad (18)$$

which corresponds to the empirical equation (15) found experimentally. It is also possible to verify the dependence of $\Delta G^0(MnO_x)$ on x:

$$\Delta G^0(MnO_x)/x,\ \mathrm{kJ\ mole^{-1}\ (g\text{-}atom\ O)^{-1}} = -496.733 + 132.773\,x \qquad (19)$$

The published[67] and calculated values of $\Delta G^0(MnO_x)/x$ are compared below:

x	1.00	1.33	1.50	2.00	2.50	3.00
Calculated from Eqn. (19)	363.96	320.15	297.57	231.19	164.80	98.41
Published data (Ref.67)	363.86	321.16	293.72	233.68	—	98.38

The data given confirm the results of the determination of the magnitude of the potential at the manganese oxide/electrolyte interface.

Other reactions may determine the magnitude of the potential in the Helmholtz layer, when E depends on the stoichiometric composition of the oxide phase:

$$MO_{x_1} + 2(x_1 - x_2)H^+ + 2(x_1 - x_2)e \rightarrow MO_{x_2} + (x_1 - x_2)H_2O$$
$$E = E^0_{O_x} + a + b(x_1 + x_2) + RT/F\ln[H^+]$$
$$x_2MO_{x_1} + 2(x_1 - x_2)e + (x_1 - x_2)M^{2+} \rightarrow x_2MO_{x_2}$$
$$E = E^0_{M/M^{2+}} + bx_1x_2 + \frac{RT}{F}\ln[M^{2+}]$$

$$MO_x(\mathrm{solid}) + H^+(\mathrm{aq}) + e \rightarrow MO_xH(\mathrm{solid});\ E = E^0 + RT/F\ln[H^+]$$

where $a = [\Delta G_j^0/j)i - (\Delta G_i^0/i)j]/(i-j)F,\ b = (\Delta G_i^0/i - \Delta G_j^0/j)/2(i-j)F.$

The nature of the observed dependence of the potential of the oxide electrode on pH and $\lg a_{M^{2+}}$ is used to establish the form of the equilibrium, and Eqn.(18) is used to determine the phase composition of the oxide being studied, to refine the value of E, and to find the thermodynamic characteristics of the phase MO_x.[61,65,66]

c) The theory of stationary (compromise) potentials. A compromise potential jump is produced if the oxide is not in equilibrium with the electrolyte solution. A theory of stationary potentials has been developed.[68] According to this theory, at the stationary potential the sum of the cathodic currents is equal to the sum of the anodic currents

$$\sum k_+[\mathrm{Ox}]\exp\left(\frac{\beta_i z_i FE}{RT}\right) = \sum k_-[\mathrm{Red}]\exp\left(\frac{\beta_i z_i FE}{RT}\right) \qquad (20)$$

† Here,

$$\Delta G_i^0 = \Delta G^0(M^{2+}) + \Delta G^0(H_2O) - \Delta G^0(MO).$$

where k_+ and k_- are the rate constants of the anodic and cathodic reactions; β_j and β_i the transfer coefficients; and E the electrode potential. In the general form, this equation cannot be solved for E.

The kinetic equations of stationary potentials have been studied in detail.[69-71] The case of the production of a compromise potential jump at an oxide/electrolyte phase boundary has been examined.[72] According to the ideas developed, in the dissolution of an oxide the magnitude of E is determined by the parallel transfer of OH^-(solid) and M^{z+}(solid) to the electrolyte:

$$OH^-(solid) + H^+(aq) \rightarrow H_2O(aq);\ M^{z+}(solid) \rightarrow M^{z+}(aq)$$

The rates of these reactions depend on the potential. The driving force of the dissolution process is the magnitude of the potential drop in the Helmholtz layer. For $E_{sc}^0 = \text{const}$ and $E_{el} = 0$, the rates of the transfer of the M^{z+} ions (i_M) and OH^- ions (i_{OH}) to the solution can be written in the form:

$$i_M = {}_+k_M \exp(\beta_+ z_+ FE/RT) \quad (21)$$

$$i_{OH} = {}_-k_A a_{H^+} \exp(\beta_- z_- FE/RT) \quad (22)$$

The magnitude of the stationary potential is calculated by solving the simultaneous equations (21) and (22):

$$E = \frac{RT}{(\beta_+ z_+ - \beta_- z_-)F} \ln\left(\frac{k_-}{k_+} a_{H^+}\right) = E^0 - \frac{RT \cdot 2{,}303}{F(\beta_+ z_+ - \beta_- z_-)}(\text{pH}) \ . \quad (23)$$

The value of E obtained can be used to calculate the orders of the reaction with respect to H^+ and other ions.

Since there are two theories of the production of the potential jump (quasi-equilibrium and compromise), there are two approaches to the explanation of the reasons for the influence of E on the rate of the dissolution of oxides. A linear correlation is observed between E_{fb} and the value of E_{max} corresponding to the rate maximum.

2. Relationship Between the Semiconducting Properties of an Oxide and the Electrochemical Properties of the Electrolyte

A relationship exists between the semiconducting properties of an oxide and the electrochemical characteristics of the electrolyte solution–oxide system. The solution is characterised by the following electrochemical parameters: the standard oxidation (redox) potential for the redox couple (E^0), the average energy of the energy level of the molecule of the oxidising agent (unoccupied energy level) in the solution eE_{ox}, the average energy of the energy level of the molecule of the reducing agent (occupied energy level) in the solution eE_{red}, and the energy parameter of the solution eE_F, whose significance is analogous to that of the Fermi energy, since it is given by the relationship $eE_F = \frac{1}{2}(eE_{ox} + eE_{red}) = -E$.[36]

The properties of oxides as semiconductors are characterised by the following parameters: eE_v and eE_{vs} represent the energy of the top of the valence zone in the volume of the specimen and on the surface respectively, eE_F the Fermi energy, and eE_c and eE_{cs} the energies of the bottom of the conductivity zone in the volume and on the surface. The required relationship is established in explicit form by calculating and measuring the values of the potential of the planar zones (E_{fb}).

The comparison of the energy levels of the ions and the zone boundaries of an oxide on the same energy scale represents the most valuable contribution of the electrochemistry of semiconductors to the kinetics of the dissolution of oxides (see Fig.4). This comparison of the energy characteristics and electrochemical parameters is carried out as follows. The experimental relationship between the differential capacity of the oxide electrode (C_{SC}) and the polarisation potential of the oxide E (as $1/C_{SC}^2 \rightarrow 0$) is used to determine the value of E_{fb} from the Mott-Schottky equation:

$$\frac{1}{C_{sc}^2} = \frac{2}{\varepsilon\varepsilon_0 e N_D}\left(eE_{sc} - \frac{kT}{e}\right) \quad (24)$$

According to Eqn.(24), when oxides are polarised, a linear relationship is usually observed between C_{SC}^{-2} and the polarisation potential of the oxide electrode. In this case, if $E_{el} \rightarrow 0$ (concentrated solution), the potential of the planar zones is measured:

$$E_{fb} \approx E_H + E^0 \quad (25)$$

In other words, the main potential jump corresponds to the Helmholtz layer. The linear relationships between C_{SC}^{-2} and E, obtained for oxides, indicate that the potential in the Helmholtz layer remains constant when the electrode is polarised; only the magnitude of the potential in the volume of the oxide phase is changed.[32] When E_{fb} has been determined, the electrochemical potential of the Fermi level of the oxide on the energy scale is found:

$$eE_{fb} = eE_F = -eE^0$$

For example, for ZnO, $eE_{fb} = -0.231$ eV (normal hydrogen electrode).[73] This result and Eqn.(25) give: $eE_F = -eE + eE^0 = +0.231 + (-4.5) = -4.269$ eV, where $eE^0 = 4.5$ eV[32] (see Fig.5). The values of eE_F and n and the known concentration N_c can then be used to determine the position of the bottom of the conductivity zone eE_c:

$$eE_F = eE_c - 2{,}3\ kT \lg(N_c/n) \ .$$

The width of the forbidden zone $eE_g = eE_c - eE_v$ can be used to find the positions of the zone boundaries.

The energy diagrams of the boundary of separation between the phases, constructed in this way, can be used to provide qualitative and semi-quantitative explanations for all the regular features of the dissolution of metal oxides in different media.

For example, the energy level diagram given in Fig.6 can be used to try to find which oxides can reduce hexacyanoferrate(III) ions by conductivity electrons, and which semiconductors by the injection of holes, that is by giving up electrons from the valence zone (see Fig.6, GaP and GaAs). These diagrams can be used only as the starting point for an analysis of the possible reactions between oxides and the ions of the liquid phase (solutions). To bring about the injection of electrons into an oxide, the energy of the levels eE_{red} should be equal to or greater than the energy of the unoccupied levels of the oxide, and for the capture of an electron by the ions, the energy of the level eE_{ox} should take values equal to or lower than the energy of the occupied levels. It has been found empirically[74] that injection of electrons is observed when the energy of the bottom of the conductivity zone of a semiconductor is higher than the energy $eE_{redox}^0 = -eE^0$ by not more than 0.8 eV. Thus the ions Cr^{2+}, Eu^{2+}, V^{2+}, and Co^{2+} inject electrons into ZnO ($eE^0 \gg 0.1$ eV).[75]

Surface reactions (such as dissolution) involving the oxides, together with reactions involving the ions which complicate the picture (hydrolysis, complex formation, dimerisation, the production of unstable states), make the situation much more complex.

Positions of the energy zones of the oxide (*a*—ZnO, *b*—TiO_2) and the Fermi levels (potentials E_1–E_8) for various electrode reactions taking place at an oxide electrode in aqueous solution at pH 7: *1*) ZnO + $2H^+(aq)$ + $2e \rightarrow Zn + H_2O$ (E_1); *2*) $2H^+(aq) + 2e \rightleftharpoons H_2$ (E_2); *3*) ZnO + $2Cl^-(aq) + 2p \rightarrow ZnCl_2(aq) + \frac{1}{2}O_2$ (E_3); *4*) $H_2O + 2p \rightleftharpoons 2H^+(aq) + \frac{1}{2}O_2$ (E_4); *5*) $TiO_2 + 4H^+(aq) + 4e \rightarrow Ti + 2H_2O$ (E_5); *6*) $2H^+(aq) + 2e \rightleftharpoons H_2$ (E_6); *7*) $H_2O + 2p \rightleftharpoons 2H^+(aq) + \frac{1}{2}O_2$ (E_7); *8*) $TiO_2 + 4Cl^-(aq) + 4p \rightarrow TiCl_4(aq) + O_2$ (E_8).[85]

IV. FORMAL ELECTROCHEMICAL THEORIES OF THE DISSOLUTION OF METAL OXIDES

There are different versions of the theory of the influence of oxidising agents and reducing agents in an electrolyte on an oxide phase during its dissolution. The present-day physical theories of the reduction and oxidation of oxides as semiconductors, and classical electrochemical theories, explaining the mechanism of the influence of the potential on the dissolution of oxide materials, can be distinguished.

The dissolution of oxides is possible if the concentration of the ions in the electrolyte is lower than the saturation concentration. For a given deviation of the concentration from the limiting value, the rate of dissolution is related to the transfer reaction:

$$M^{z+}(solid) \rightarrow M^{z+}(aq);\ A^{z-}(solid) \rightarrow A^{z-}(aq)$$

For the dissolution of crystals in the absence of an external current, the densities of the transfer currents i_M and i_A are equal in magnitude, have different signs, and are conjugated. Volmer's equation[49] is used to describe the regular electrochemical features of the transfer of ions. The dependence of the rates of the transfer of the ions M^{z+} and A^{z-} to the solution on the potentials can be expressed by equations analogous to Eqns.(16) and (17):

$$i_M = {}_+k_M[M]\exp\left(\frac{\beta_+ z_+ F}{RT}E\right) - {}_-k_M a_{M^{z+}}\cdot\exp\left[-\frac{(1-\beta_+)z_+F}{RT}E\right] \quad (26)$$

$$i_A = {}_+k_A a_{A^{z-}}\exp\left(\frac{\beta_- z_- F}{RT}E\right) - {}_-k[A]\cdot\exp\left[-\frac{(1-\beta_-)z_-F}{RT}E\right] \quad (27)$$

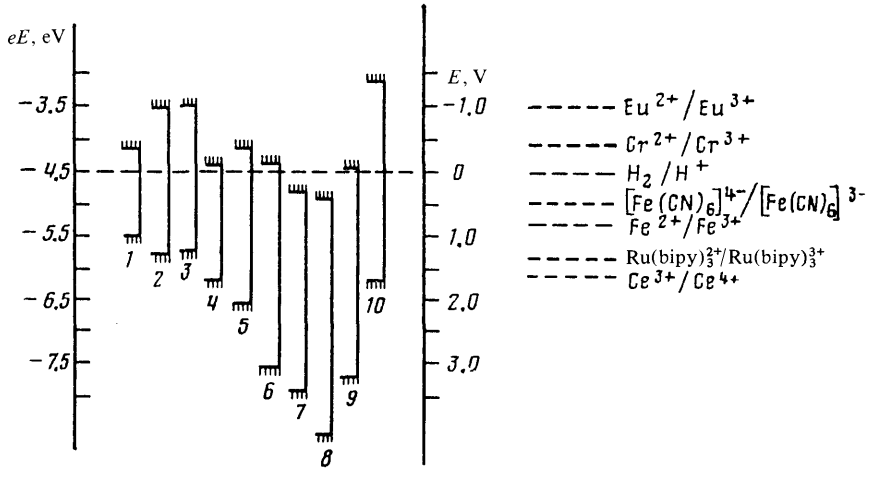

Figure 6. Relative positions of the energy levels of semiconductors and the Fermi levels for various redox reactions taking place at an electrode in aqueous solution: *1*) GaAs, pH 14; *2*) GaAsP, pH 14; *3*) GaP, pH 1; *4*) CdSe, pH 6; *5*) CdS, pH 6; *6*) ZnO, pH 2; *7*) SnO_2, pH 14; *8*) SnO_2, pH 1; *9*) TiO_2, pH 1; *10*) SiC, pH 1.[32]

1. Theory of the Conjugated Transfer of the Cations and Anions of an Oxide to an Electrolyte Solution

a) Jaenicke's theory of the dissolution of ionic crystals.[62,63] The transfer of cations is expressed by the anodic current (i_M), and the transfer of anions by the cathodic (i_A) current. The dissolution is associated with diffusion (through the electrical double layer of thickness δ) according to the equation:

$$i_d = i_M = -i_A = zFDc_M/\delta = zFDc_A/\delta$$

Jaenicke and Haase,[63] by combining Eqns.(26) and (27), and also taking account of the electrical neutrality condition ($a_{M^{z+}} = a_{A^{z-}}$), derived equations of the form:

$$i_d = \frac{\exp\left(\frac{zF\eta}{RT}\right) - \exp(-zF\eta/RT)}{\exp[(1-\beta_+)z_+F\eta/RT]/i_{e,M} - \exp[(-\beta_-z_-F\eta)/RT]/i_{e,A}} \quad (28)$$

where η is the overvoltage and $i_{e,M}$ and $i_{e,A}$ the exchange currents of the metal ions and the anions respectively;

$$c/c_{sat} = \exp\left(-\frac{zF\eta}{RT}\right)\left\{1 - \frac{i_{e,M}}{i_{e,A}}\exp\left[\frac{(1-\beta_-)+\beta_+}{RT}zF\eta\right]\right\} \Big/ \left\{1 - \frac{i_{e,M}}{i_{e,A}}\exp \times \right.$$
$$\left. \times\left[-\frac{1-\beta_+ + \beta_-}{RT}zF\eta\right]\right\} \quad (29)$$

It follows from Eqn.(29) that as $c/c_{sat} \to 0$, the maximum overvoltage ($\eta = \eta_{max}$) is observed

$$\eta_{max} = \eta = \frac{RT}{(1-\beta_- + \beta_+)zF}\ln\frac{i_{e,A}}{i_{e,M}}$$

which corresponds to the maximum rate of dissolution:

$$i_{d,max} = i_{e,A}^{\beta_+/(1-\beta_-+\beta_+)} \cdot i_{e,M}^{\beta_+/(1-\beta_-+\beta_+)}$$

For $\beta_+ = \beta_- = 0.5$:

$$i_{d,max} = (i_{e,A} \cdot i_{e,M})^{1/2} \quad (30)$$

Analysis of Eqn.(30) shows that the rate of dissolution depends on the magnitude of the exchange currents ($i_{e,A}$ and $i_{e,M}$). At low values of the overvoltage ($\eta \ll RT/zF$):

$$(\partial\eta/\partial i_d)_{\eta=0} = \frac{RT}{2zF}\left(\frac{1}{i_{e,M}} - \frac{1}{i_{e,A}}\right) \quad (31)$$

The applicability of relationships (30) and (31) has not yet been confirmed experimentally.

b) Engell's theory of the dissolution of oxide phases.[29] In the derivation of the $E(i)$ relationship, Engell made the following assumptions: 1) the processes involved in the transfer of the ions [M^{z+}(solid) → M^{z+}(aq); A^{z-}(solid) → A^{z-}(aq)] are independent; 2) the total value of the chemical potential for the anions (μ_A) and cations (μ_M) is constant, that is $\mu_M + \mu_A = \mu_\pm$; 3) the dissolution is a non-equilibrium process, since the reverse reaction is suppressed; 4) the fact that the composition is constant is explained by the fact that the fluxes of the ions (the cations i_M and the anions i_A) through the electrical double layer are the same ($|i_M| = |i_A|$); 5) the rate of dissolution depends on the potential in the Helmholtz layer, in accordance with the Volmer equation; and 6) the surface concentrations of the cations and anions are given by the Boltzmann equation:

$$[A] = \exp[(\mu_A - \mu_A^0)/RT];\ [M] = \exp[(\mu_M - \mu_M^0)/RT]$$

where μ_M^0 and μ_A^0 are the chemical potentials of the ions at the surface at an ion concentration $c = 1$.

Allowance for the above assumptions, Eqns.(26) and (27), and

$$k_+\exp(-\mu_A^0/RT) = k_A^0;\ k_-\exp\left(-\frac{\mu_M^0}{RT}\right) = k_M^0;$$

$$\mu_M = \frac{1}{2}\{\mu_\pm RT\ln(k_A^0/k_M^0) + (\beta_Az_A - \beta_Mz_M)FE\};$$

$$\mu_A = \frac{1}{2}\{\mu_\pm + RT\ln(k_M^0/k_A^0) + (\beta_Az_A - \beta_Mz_M)FE\}$$

gives for $z_A = -z_A$

$$i_M = i_A = (k_A^0k_M^0)^{1/2}\exp(\mu_\pm/2RT)\exp[\{\beta_M|z_M| - \beta_A|z_A|\}FE/2RT] \quad (32)$$

It follows from Eqn.(32) that the slope of the Tafel section is

$$\partial E/\partial\ln i = 2RT/F(\beta_M|z_M| - \beta_A|z_A|)$$

If $\beta_Az_A > \beta_Mz_M$, an increase in the rate is observed with decrease in the potential. The values of the slope have been given[29] for cases where the dissolution is limited by the transfer of the anions

$$\partial E/\partial\ln i = (z_M - \beta_A|z_A|)F/RT$$

or the cations

$$\partial E/\partial\ln i = [\beta_Mz_M - |z_M|]F/RT$$

Thus for FeO,[29] $\partial E/\partial\ln i = 0.080$ V. Since

$$z_{Fe^{2+}} = 2,\ z_{O^{2-}} = -2, \text{ it follows that } (\beta_{O^{2-}} - \beta_{Fe^{2+}}) = 0.32$$

Some aspects of Engell's theory have led to a number of comments:[2,48] 1) Engell regards oxides as purely ionic compounds, completely ignoring the influence of the important semiconducting properties of oxides (volume charge, electron and hole conductivity, energy of the levels); 2) according to Engell, the polarisation potential corresponds only to the region of the volume charge (the potential jump in the Helmholtz layer is not taken into account); and 3) some of the assumptions made by Engell exclude even slight deviation from stoichiometry.

c) Vermilyea's theory of the dissolution of oxide phases[72] makes it possible to explain the formal orders of the reaction with respect to hydrogen ions, the dependence of the rate of dissolution on the potential, and the influence of the anion composition of the electrolyte. According to Vermilyea,[72] the dissolution is an electrochemical process, and consists of two conjugated reactions, involving the transfer to the solution of the metal ions and oxygen ions.

Vermilyea established the dependence of the rate of dissolution on the potential by making use of the following assumptions: a) the dissolution process is irreversible; b) the concentration of ions on the surface is equal to $2n^0$:

$$[M] + [A] = 2n^0$$

where it follows from the last expression that deviations from stoichiometry are possible; and c) the rate of removal of the anions and cations are equal, that is $i_M = i_A$. From Eqns. (26) and (27) and assumptions (a)–(c), taking account of the fact that

$$_+k_M^0[M]\exp(\beta_+z_+FE/RT) = {}_+k_A[A]\exp(\beta_-z_-FE/RT)$$

it can be shown that the rate of dissolution is equal to

$$i_A = 2i_0[\exp(-\beta_-z_-F\eta/RT) + \exp(-\beta_+z_+F\eta/RT) \quad (33)$$

where the rate of free dissolution of the oxide (the magnitude of the potential is E_f) is:

$$i_0 = k_A^0\exp(\beta_-z_-FE_f/RT);\ \eta = E - E_f$$

If η is very small, it follows that

$$i_A = 2i_0[2 - (\beta_+z_+ + \beta_-z_-)\eta F/RT]^{-1} \quad (34)$$

The result obtained agrees with Engell's conclusion.[29] Eqn.(33) provides a fairly realistic explanation of the nature and existence of the maximum of the dependence of the rate of the dissolution of oxide phases on the potential.

In the case of cathodic polarisation, when the magnitude of the anodic current (i_A) can be neglected, Eqn.(33) becomes

$$i_A = kc^m_{H^+} \exp(\beta_- z_- F\eta/RT)$$

where $\eta \gg 0$. For $\beta_- = 0.5$ and $z_- = 1$, the calculation gives the value $\partial E/\partial \ln i = 120$ mV, which agrees with the experimental data.[76-78]

The above theories start from the assumption that the currents of the metal and oxygen ions are equal, that is that these transfer reactions are conjugated. Usually, the rate of removal of the ions is such that $i_M \gg i_A$ or $i_A \gg i_M$, so that the rate of dissolution is determined by the transfer of one particular ion. In this case the dissolution current is much smaller than the current of the exchange with respect to the metal ions and with respect to the anions.

2. Electron–Proton Theory of the Influence of the Potential

According to the electron–proton theory, the influence of the potential on the boundary of separation is revealed in the fact that the proton brings about mass transfer. Its first stage includes the electrochemical process of the transfer of protons through the oxide/solution interface and their adsorption on the surface of the oxide:

$$M^{z+}(solid) + O^{2-}(solid) + H^+(aq) + e \rightarrow OH^-(solid) + M^{(z-1)+}(solid)$$

where $M^{z+}(solid)$, $M^{(z-1)+}(solid)$, $O^{2-}(solid)$, and $OH^-(solid)$ are the species of the oxide phase. As a result of this reaction, the surface layer of the oxide is converted into a compound with variable (non-stoichiometric) composition. The concentration of protons present as OH groups, the electrical conductivity, and the stoichiometry of oxide are related to one another and depend on E. The second stage involves the "diffusion" of the atoms into the depth of the oxide phase with the simultaneous transfer of an electron from one metal ion to another, or dissociative diffusion. When the value of the potential is displaced into the cathodic range, the rate of the introduction of protons into the oxide increases. Their concentration in the oxide depends on the mobility of H^+ and on the magnitude of E.

The electron–proton theory is confirmed by a number of facts. Data obtained using hydrogen and oxygen isotopes indicate that hydrogen, and not oxygen, is transferred from the electrolyte solution into the oxide and in the opposite direction.[79,80] The fact that the cathodic and anodic charging curves show hysteresis, and also the slow changes in the current after the polarisation current is switched off, indicate that there is retarded diffusion of the protons.[34] The high rate of the electrochemical processes indicates that they involve fairly mobile species (the proton).

The participation of the protons in the electrochemical processes explains the differences in activity observed for hydrated and non-hydrated oxides. The introduction of protons into an oxide does not lead to a significant change in the crystal lattice parameters of the oxide.[34,81] It has been established that the rate of dissolution and the magnitude of the potential are directly proportional to the quantity of adsorbed protons [H^+(ads) ions[82]]:

$$i_d = (\partial\alpha/\partial t)_{sp} = K'[H^+(solid)] = K\theta_{H^+}$$

where θ_{H^+} is the degree of covering of the oxide surface by protons. It is known that the dependence of the degree of covering of a surface by adsorbed protons on the equilibrium concentration of the acid corresponds to the Freundlich equation[59,83]

$$\theta_{H^+} = Ba^n_{H^+}$$

where $n = 0.5$–0.6.

The above arguments have been used to derive# the dependence of the specific rate of dissolution of an oxide on the adsorption of H^+ ions on the oxide, the pH of the electrolyte, and E:

$$(\partial\alpha/\partial t)_{sp} = k \cdot a^m_{H^+} \exp[-(1-\beta_+)z_+FE/RT] \quad (35)$$

This expression makes it possible to explain all the regular kinetic features of the influence of H^+, E, and T on the specific rate of dissolution of oxide phases.

The order of the rate of dissolution of oxides with respect to hydrogen ions, $n_{H^+} = m$, should be 0.5. When E is displaced into the cathodic range, the rate of dissolution of the oxide should increase. The species taking part in the dissolution process is the proton.

For $\beta_+ = 0.5$ and $z_+ = 1$, the value of $\partial E/\partial \lg[(\partial\alpha/\partial t)_{sp}]$ should be 120 mV, which agrees with the experimental data.

V. THE SEMICONDUCTOR THEORY OF THE OXIDATION AND REDUCTION OF OXIDE PHASES

A different approach has been developed[35,36,84,86] for describing the regular kinetic features of the dissolution of oxides, which are semiconductors, in electrolytes containing added oxidising agents and reducing agents. According to this theory, when oxides are brought into contact with electrolyte solutions, transfer of electrons to the semiconductor from the ions of the solution, or in the opposite direction, this is due to the fact that the Fermi level (eE_F) in the oxide does not correspond to the Fermi level ($eE_{F,el}$) of the ions of the electrolyte.

When there is electrochemical polarisation of oxides in solutions of electrolytes having an oxidation potential E^0, an increase in their rate of dissolution in acidic media is possible. The thermodynamic conditions for the processes involved in the dissolution of oxide phases have been examined.[84] The thermodynamic data can be used to determine the standard potentials of the reactions involved in the cathodic and anodic decomposition of oxide materials. If $E < E^{decomp}$ or $eE_F > eE^{decomp}$, cathodic dissolution of the oxides, taking place with the participation of the electrons of the conductivity zone, is possible (see Fig.5). When $E > E^{decomp}_d$ or $eE < eE^{decomp}_d$, anodic dissolution of the oxides with the participation of the electrons of the conductivity zone is possible. For example, for the dissolution of zinc oxides with anodic polarisation of the electrode, these reactions can be represented in the form:

$$ZnO + p + H^+ \rightarrow Zn^{2+} + {}^1/_2H_2O_2$$

$$\Delta G^0_d = \Delta G^0(Zn^{2+}) + {}^1/_2\Delta G^0(H_2O_2) - \Delta G^0(ZnO) = -87.8 \text{ kJ mole}^{-1},$$

and the decomposition potential will be equal to:

$$E = -\Delta G^0_d/F = 0.91 \text{ V}.$$

The mechanism of the oxidation or reduction of oxides during dissolution with potentiostatic polarisation can also be explained with allowance for the semiconducting properties of the oxide phases. The transfer of electrons with polarisation, and the corresponding current, can be calculated

For a discussion of this topic see Refs.153, 166, and 209.

qualitatively using the diagram giving the distribution of the energy levels at the boundary of separation between the phases. The electrochemical reactions of oxide electrodes involve both electrons and holes. For an exchange reaction to take place on the surface of oxides, transfer must take place to levels situated close to the bottom of the conductivity zone or close to the top of the valence zone.[75] The positions of the characteristic energy levels in oxides (for example the bottom of the conductivity zone in a semiconductor) can be determined unambiguously, but in electrolyte solutions it is necessary to consider only the average values of the characteristic energies of the ions in the liquid (that is to take account of the fluctuation of the energy levels). These levels can be described by a Gaussian distribution function[32,88,89] (see Fig.7):

$$D(E) = W(E) = (4\pi kT\lambda_i)^{-1/2} \exp[-(eE - eE_{redox})^2/4kT\lambda_i]$$

where λ_i is the energy of the reorganisation of the environment which takes place as a result of the transfer of electrons from the electrode to the reagents in the solution as a result of the change in the charge of the particles. If it is necessary to determine, for example, the rate of transfer of an electron from the donor to the electrode, it can be expressed in terms of the rate of electron exchange between two isoenergetic levels in the electrode and in the solution, where the first of these levels is occupied, and the second is unoccupied. The rate of the redox reaction at the oxide surface is determined by the surface concentration of current carriers at the boundary of separation between the phases.[36] The expression for the exchange current of redox reactions at the boundary of separation should include the values of the standard redox potential E^0_{redox} and the concentrations of the reagents c_{red} and c_{ox}. It is possible to distinguish two cases (for *n*- and *p*-type semiconductors). The current of the electron transfer (i) from the valence zone of the semiconductor into the solution and on to the species being reduced, the acceptor (Ox), can be calculated. This reaction can be regarded as the transfer of a hole (p) from the acceptor into the valence zone:

$$Ox \rightarrow Ox^- + p$$

The rate of the process in this case will be directly proportional to the concentration of carriers in the valence zone and the density of acceptors (oxidising agent), which can capture an electron. Account must be taken of the fact that this exchange reaction can take place when the levels are situated close to the bottom of the conductivity zone or near the top of the valence zone. The transfer of an electron from the electrode to the acceptor is equivalent to the passage of an anodic current

$$i = c_{ox} \int_{-\infty}^{\infty} D(E)\, k(E)\, n(E)\, dE$$

where $D(E)$ is the probability of the distribution of the reagent particles with respect to energy, which can be described by a Gaussian distribution function; $n(E)$ the partial concentration of electrons (close to the surface of the semiconductor), whose energy is equal to eE; and $k(E)$ is the rate of the transfer of an electron with energy eE from the semiconductor to an ion in the solution having an energy eE'. Since the values of the functions $n(E)$ in the valence zone and $k(E)$ are practically constant for $eE \cong eE_S$, and the energy of the top of the valence zone close to the surface differs by an amount $-eE_{SC}$ from the energy of the top of the valence zone in the volume of the semiconductor (eE_V), it follows that the final expression for the current has the form:

$$i = kc_A \exp\{(eE^0 - eE_A)^2/4kT\lambda_i\} \qquad (36)$$

According to Eqn.(36), the rate of the process will be a maximum when the magnitude of the energy of the energy level of the acceptor eE_A is equal to the energy of the surface state. Eqn.(36) has been verified experimentally.[87] For ZnO, it was found that the value of the potential E^0 corresponding to the maximum of the exchange current is 0.8 V. Since $eE^0_{redox} = -eE^0$, it follows that $eE_{CS} = eE^0_{ox} = eE^0_{redox} + \lambda_i = -0.8 + \lambda_i$.

The current of the electron transfer from the species being oxidised, the donor (D_{red}), in the solution to an energy level of the surface states of the oxide can be found analogously. The corresponding reaction can be written in the form:

$$D = D^+ + e$$

For the calculation of the current it is possible to obtain a

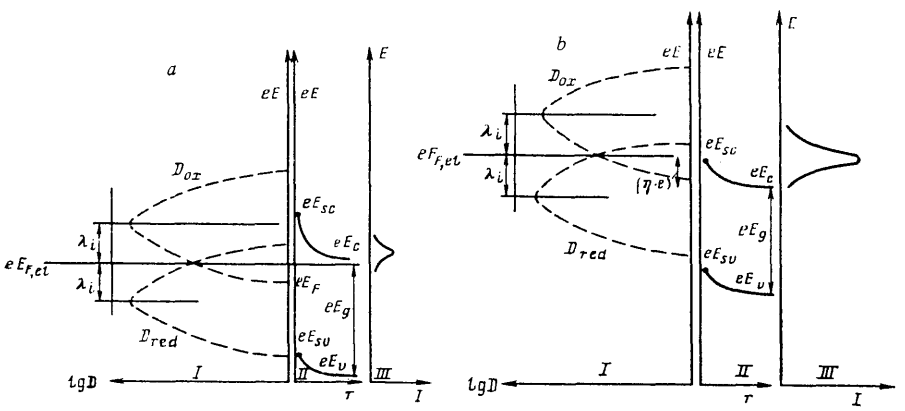

Figure 7. Positions of the energies at the semiconductor–solution interface for equilibrium (*a*) and for anodic polarisation of the semiconducting electrode (*b*): *I*) plot of the logarithm of the probability of the electrolyte redox species distribution against the magnitude of the energy, *II*) dependence of the position of the energy zones of the oxide on the distance from the interface, *III*) dependence of the current of the dissolution of the oxide phase on the magnitude of the applied voltage.[88]

relationship analogous to that proposed above:

$$i=kc_d\exp[(-eE-eE_d)^2/4kT\lambda_i] \quad (37)$$

Comparison of Eqns.(36) and (37) shows that the dependence of the current of the transfer of electrons on the potential passes through a maximum.[32] These regular features make it possible to explain the dependence of the rate of dissolution on the potential of the redox couples for oxides which are *p*- or *n*-type semiconductors.

Since the above theories are formal, it is of interest to examine the mechanism of the cathodic reduction or anodic oxidation of oxide phases and to discuss the question of why polarisation influences the rate of their dissolution.

VI. MECHANISM OF THE DISSOLUTION OF METAL OXIDES WITH CATHODIC AND ANODIC POLARISATION

The rates of these processes are limited by the magnitude of the potential of the redox reactions taking place on the surface of the oxide phase.[2] When the value of the stationary potential is displaced into the cathodic region, the rates of the dissolution of iron and manganese oxides increase.[2,90,91] The polarisation curves obtained for the polarisation of MnO_2 show two reduction waves, whose potentials depend on the concentration of metal ions and on pH. The peaks correspond to two processes:

$$MnO_2+H^++e\rightarrow MnOOH \quad (I)$$

$$MnOOH+H^++e\rightarrow Mn(OH)_2\rightarrow Mn^{2+} \quad (II)$$

The form of the polarisation curves ($E-i$) corresponds to the dependence of the rate of dissolution of the oxides Mn_2O_3, Fe_3O_4, and Fe_2O_3 on the potential.[90,91] There are two theories of the reduction of metal oxides. According to the first theory,[92–94] the reduction of an oxide phase is limited by the rate of removal of metal ions from it (Mn^{2+} for MnO_2 or Fe^{2+} for Fe_3O_4 and Fe_2O_3):

$$MO_x+2xH^++2(x-1)e\rightarrow M^{2+}+xH_2O$$

It is considered that MnO_2 (or Fe_3O_4) reacts as a reversible electrode, whose potential is determined by the concentration of metal ions M^{2+} and by the pH,[95,96] and $\partial E/\partial(pH) = 120$ mV/pH in the presence of both Mn^{2+} ions[95] and Fe^{2+} ions.[96] The quantity of electricity used up in this process[77] is twice that required for the reaction.[97] According to the theory being considered, the MnOOH formed is not the primary product, but is produced as a result of the reaction:[92,93,97–99]

$$MnO_2+Mn^{2+}+2H_2O\rightarrow\rightarrow 2MnOOH+2H^+$$

According to the second theory, the reduction of metal oxides is limited by the introduction of protons into the oxide phase. The reduction of the oxides takes place as a result of the transfer of protons through the electrolyte/oxide interface,[34,98–100] and is described by the equation:

$$MO_x(solid)+mH^+(aq)+me\rightarrow MO_{x-m}OH_m(solid)$$

There is no doubt that the last reaction takes place in alkaline media. The proton mechanism is confirmed by the ($E-i$, $i-t$) curves, which show the phenomena of concentration polarisation in the solid phase.[34] In the reduction of the oxides, the initial process is the adsorption of protons (to give OH groups); in the subsequent reduction, the hydrogen atoms diffuse into the oxide phase, leading to the reduction of deeper layers. The slow diffusion of hydrogen atoms brings about concentration polarisation in the solid phase.[34] X-Ray diffraction study of the products of the oxidation or disproportionation of magnetite has confirmed that under these conditions, a continuous series of solid solutions of Fe_3O_4 in γ-Fe_2O_3 is formed.[101] The yield of the cathodic process for the reaction for the most part never exceeds 100%; a solid solution of M_2O_3 in MO_2 or a solution of MOOH in MO_2 is formed.[102] The mechanism of the diffusion of protons has been examined quantitatively.[103,104] The presence of combined water in the oxides leads to an increase in the rate of diffusion of H^+.[34] The theory of the limiting stage of the diffusion of protons into the oxide does not explain the appearance in the electrolyte (in appreciable quantities) of Fe^{2+} and Mn^{2+} ions (at pH < 6) for the cathodic polarisation of Fe_2O_3 and MnO_2 respectively.

The theories can be combined by assuming that the chemical stage is complicated by a subsequent process. Using the last of the above equations for the reactions and taking account of the possible disproportionation of manganese(III) oxide gives:[76,105,106]

$$\begin{array}{l} 2(MnO_2+H^++e\rightarrow MnOOH) \\ 2\,MnOOH+2\,H^+\rightarrow MnO_2+Mn^{2+}+2\,H_2O \\ \hline MnO_2+4\,H^++2e\rightarrow Mn^{2+}+2\,H_2O \end{array}$$

Studies of the kinetics of the dissolution of the oxides NiO,[107] Cu_2O, CuO,[108,109] and UO_2[30] have shown that the rate of the process increases on anodic polarisation and when oxidising agents are introduced into the electrolyte solution.[30,109,110] The question of the stability of oxides on anodic polarisation is important not only in the study of their dissolution but also in practice, for the transformation of light energy into chemical energy. The question of the stability of oxides in acidic media has been studied.[36,84] It has been established experimentally that when holes are generated by anodic polarisation, illumination, or the addition of oxidising agents, there is an increase in the rate of dissolution, which (for example for ZnO) can be respresented in the form:

$$ZnO+2p\rightarrow Zn^{2+}+{}^1/_2O_2$$

In the dissolution of ZnO, oxygen is liberated, and Zn^{2+} ions are formed.[36,85,111–114] Similar results were obtained in the dissolution of copper oxides (Cu_2O, CuO),[85] which have hole conductivity and which decompose in acidic solutions with anodic polarisation to give Cu^{2+} and O_2. On the basis of potentiostatic measurements of the reduction and oxidation of a passivated nickel surface, a proton mechanism was proposed for the anodic polarisation of the oxides.[115–123]

1. Nature of the Active Centres and the Role of the Hydration of the Surface of Oxides in the Kinetics of Dissolution§

The dissolution of oxides begins on the active regions of their surface, as confirmed by etch figures. The introduction of the oxide TiO_2 into Fe_2O_3 (*n*-type semiconductor),[127] and also the addition of reducing agents to the acid solution, increases the rate of dissolution of iron(III) oxide, since there is an increase in the quantity of Fe^{2+} ions in the volume of the oxide phase.[2,128–130] The active centre for the dissolution in this case is Fe^{2+}. The rate of the dissolution of the oxides NiO and Cu_2O, which show *p*-type conductivity, increases when they are heated in an atmosphere with an increased oxygen pressure, and also when the value of the potential is displaced in the anodic direction. This is related to the fact that the active centres for the dissolution of NiO are Ni^{3+}.

§ For the bibliography on this topic, see Refs.53, 58, and 124–126.

The rate of the dissolution of oxides, and also their physical and chemical properties, are related to the degree of hydration of the surface.[4] A number of reviews[131–134] have been devoted to the study of the hydration and dehydration of oxide surfaces. Up to five types of isolated hydroxide group are usually distinguished on oxide surfaces. For example, the centre consisting of an OH group surrounded by four O^{2-} ions is the most basic, and a centre which has no neighbours (O^{2-} ions) is regarded as the most acidic. Acids react primarily with basic centres. The rate of the dissolution of ionic oxides is influenced considerably by change in the concentration of water in the acidic electrolyte. The rate of the dissolution of ZnO in alcoholic solutions of H_2SO_4 and HCl is slower by factors of 10^2–10^3 than that in aqueous solutions of the acids at the same concentrations.[135] A similar effect has been detected in the study of the kinetics of the dissolution of GeO_2 [10] and Al_2O_3 [136] in acids. The increase in the rate of dissolution of the oxides is directly proportional to the degree of hydration of the oxide phase.[10]

Another relationship was detected in studies of the influence of the concentration of acetone or ethylene glycol on the kinetics of the dissolution of Fe_3O_4 in HCl.[137,138] The rate of dissolution increases with increase in the concentrations of the acid, the iron(II) ions, and the non-aqueous solvents. The dependence of the time taken for 50% dissolution of Fe_3O_4 (0.5 g specimen) in 6 *N* HCl on the concentration (vol.%) of acetone and ethylene glycol is given below.

Acetone, vol. %	0	5	10	15	50	
$t_{0.5}$, min	47	41	23	15	1	
Ethylene glycol, vol.%	0	10	20	30	40	50
$t_{0.5}$, min	87	70	55	42	27	12

The rate of the dissolution is limited not by the reaction of magnetite with water molecules but by the process of proton transfer for the solution to the oxide phase. The increase in the rate of dissolution with increase in the concentration of non-aqueous solvents is related to the increase in the activity of the hydrogen ion (a_{H^+}) and the displacement of the potential (E_H) into the cathodic region.

2. Diffusion of Protons in the Oxide Phase During Its Dissolution

The study of the exchange equilibrium of ^2H and ^{18}O between a hydroxide and an electrolyte[34,139] has shown that the rate of the transfer of the hydrogen atoms is greater than that of the oxygen atoms. Linear scanning during the reduction of NiOOH gave the value of the proton diffusion coefficient ($D_{H^+} = 2 \times 10^{-9}$ cm^2 s^{-1}).[140] Higher values of the proton diffusion coefficient were observed during anodic polarisation, compared with the cathodic process. Other workers[141] have proposed a proton-diffusion process ($D_{H^+} = 2 \times 10^{-10}$ cm^2 s^{-1}) for the electrochemical formation of an NiOOH oxide film. Wyttenbach[142] gives the value $D_{H^+} = 4 \times 10^{-23}$ cm^2 s^{-1} (for the diffusion of H^+ at 25 °C) and $E_a = 96$ kJ mole^{-1}. The values of D_{H^+} for the other compounds are given below.

Compound	α-FeOOH	γ-AlOOH	NiOOH	δ-MnO_2
D_{H^+}, cm^{2}s^{-1}	$5.8 \cdot 10^{-17}$ [143, 144]	$5 \cdot 10^{-19}$ [145]	10^{-10}—10^{-11} [34]	10^{-18}—10^{-17} [139]

These values of the diffusion coefficients lie in a range between their values in electrolyte solutions and in the solid phase.

In electrochemical methods for determining the value of D_{H^+}, it is assumed that the rate of the redox processes is limited only by the diffusion of protons. The use of a potentiostatic method to study the formation of NiOOH during the anodic oxidation of Ni^{2+} ions[146,147] established, however, that the formation of $Ni(OH)_3$ is controlled by the change in the nature of the surface during the three-dimensional growth of the crystal. A noteworthy feature is the observed relationship between the diffusion of the protons and the semiconducting properties of the electrodes. In the opinion of Takehara and co-workers,[148] the surface concentration of the protonated regions and vacancies in oxides changes as a result of the reaction of charge transfer. The proton concentration gradient produced determines the rate of diffusion of H^+ between the surface and the volume of the oxide.

a) The specific features of the diffusion of protons.[12] Electrons move much more rapidly than protons, and lead to the appearance of a space charge, creating an electric field ($\partial E/\partial r$), which increases the velocity of the hydrogen ion flux (j_{H^+}).[149] The H^+ ion diffusion current will be:[150]

$$j_{H^+} = D_{H^+}\frac{\partial [H^+]}{\partial r} - \frac{D_{H^+}}{kT}[H^+]\frac{\partial E}{\partial r}. \qquad (38)$$

where $\partial[H^+]/\partial r$ is the proton concentration gradient in the oxide phase, j_{H^+} the velocity of the H^+ ion flux in the metal oxide, and D_{H^+} the proton diffusion coefficient in the oxide.

Eqn.(38) gave:

$$j_{H^+} = D_{H^+}\frac{\partial N_{H^+}}{\partial r}\{1 + N_{H^+}[N_D \exp(E_D - E_F)/kT + N_0 \exp(E_F - E_0)/kT]^{-1}\} \qquad (38a)$$

where N_D and N_{H^+} are the concentration densities of the donors and the protons respectively in the oxide.

Analysis of Eqn.(38a) shows that the effective proton diffusion coefficient (D_{eff}) in this case passed through a maximum as N_{H^+} increases with time and approaches N_D:

$$j_{H^+} = D_{H^+}\frac{\partial N_{H^+}}{\partial r}\left[1 + \frac{N_D}{N_{H^+} - N_D}\right] = \frac{\partial N_{H^+}}{\partial r} D_{eff} \qquad (39)$$

This result indicates that the rate of penetration of the protons into the oxide phase increases with time and passes through a maximum.

3. Dependence of the Specific Rate of Dissolution of Oxides on the Concentration of H^+ and Acids and on the Nature of the Electrolyte

The influence of the concentration of acids on the rate of dissolution of oxides has been the subject of a large number of studies.[2,4,12,13,17–20,151–166] The formal order of the reaction with respect to hydrogen ions (n_{H^+}) for the dissolution of oxide phases is ~0.5 (Table 3). When the dissolution is complicated by hydration, redox reactions, complex formation, and other factors, the formal order of the reaction with respect to acid takes different values. For the dissolution of iron(III) oxide in hydrochloric and hydrobromic acids, $n_{HA} \cong 2$,[18] and for the reaction of Fe_2O_3 with $HClO_4$, $n_{HA} = 0.9$.[18] The dependence of α on $t/t_{0.5}$ is invariant with respect to the acid concentration.[22] In most cases, the formal order of the reaction with respect to acids remains unchanged in the range of values of α 0.1–0.8.[22] This indicates that the morphology of the oxide phase/electrolyte interface remains unchanged for different values of α, and that the nature of the limiting stage of the process is independent of the acid concentration.

a) Interpretation of the order of the reaction according to Vermilyea's theory. According to Vermilyea's theory,[72] the mechanism of the dissolution of oxides is electrochemical, and

consists of two parallel reactions involving the transfer of H^+ and M^{z+} ions from the oxide to the solution. Substituting Eqn.(23) into Eqn.(21) shows that the rate of removal of the cations (M) will be:

$$i_M = a_{H^+}^{\beta_+ z_+/(\beta_+ z_+ - \beta_- z_-)} \cdot k_-^{\beta_+ z_+/(\beta_+ z_+ - \beta_- z_-)} / k_+^{\beta_- z_-/(\beta_+ z_+ - \beta_- z_-)} \qquad (40)$$

Table 3. Formal order of the reaction for the dissolution of metal oxides with respect to hydrogen ions (n_{H^+}) and acid (n_{HA}).

Oxide	Electrolyte	n_{H^+}	Oxide	HA	n_{HA}
MgO	HCl	0.47 [167]	Fe_2O_3	HCl	1.94 [18]
Fe_2O_3	HCl	0.5÷0.6 [48]	Fe_2O_3	H_2SO_4	0.56 [18]
Fe_2O_3	H_2SO_4	0.5÷0.6 [48]	Fe_2O_3	HF	1.06 [18]
Fe_2O_3	HNO_3	0.5÷0.6 [48]	Fe_2O_3	H_3PO_4	0.59 [18]
Fe_2O_3	$HClO_4$	0.5÷0.6 [48]	Fe_3O_4	HCl	2 [18]
Fe_3O_4	HCl	0.5 [31]	BeO	HCl, H_2SO_4, $H_2C_2O_4$	1 [154]
BeO	HCl	0.47÷0.53 [154]	MnO	H_2SO_4	2 [160]
BeO	H_2SO_4	0.68÷0.70 [154]	Fe_2O_3	HCl	2 [161]
V_2O_5	$HClO_4$	0.5 [155]	Fe_3O_4	HCl	3 [161]
Cr_2O_3	$HClO_4$	0.46 [156]	Fe_2O_3	HCl	2.4 [162]
Mn_2O_3	H_2SO_4	−0.5 [157]	NiO	H_2SO_4, HNO_3	1.0±0.1 [163]
α-Fe_2O_3	HNO_3	0.65 [158]	Ni_2O_3	H_2SO_4, HNO_3	1.0±0.1 [163]
Ni_2O_3	H_2SO_4	0.5±0.2 [159]	NiO, Ni_2O_3	HCl	0.6±0.1 [163]
MnO	H_2SO_4	0.5 [160]	CuO	H_2SO_4	1.0±0.1 [163]

Note. Numbers in square brackets denote references (Ed. of Translation).

Table 4. Dependence of the formal orders of the reaction with respect to H^+ ions (n_{H^+}) on the nature of the stage limiting the dissolution of the metal oxide*.

Limiting stage	n	ν	z_-	$z_+=1$	$z_+=2$	$z_+=3$	$z_+=4$
$OH^- + H^+ \rightarrow HOH$	1	1	−1	1/2	2/3	3/4	4/5
$O^{2-} + H^+ \rightarrow OH^-$	1	1	−2	1/3	1/2	3/5	2/3
$O^{2-} + 2H^+ \rightarrow HOH$	2	1	−2	2/3	1	6/5	4/3

*The orders were calculated using the equations:[2]

$$i_{M^{z+}} = k_{M^{z+}}^{n/\nu} \left(\frac{\beta_+ z_+}{\beta_+ z_+ - \beta_- z_-}\right) = i_{OH^-} = k_{H^+}^{n/\nu} \left(\frac{\beta_- z_-}{\beta_+ z_+ - \beta_- z_-}\right)$$

Table 4 gives the values of the formal orders of the reactions with respect to H^+ for different limiting stages. Eqn. (40) does not make it possible to explain the formal order of the reaction with respect to other ions (Fe^{2+}, Ni^{3+}, Cu^+, Mn^{2+}) influencing the rate of dissolution of the corresponding oxides. In the derivation of Eqn.(40) it was assumed that the quantity E is a compromise potential, and that reactions (21) and (22) are far from equilibrium. According to the experimental data, however, the potential jump should be regarded as quasi-equilibrium.

b) Determination of the formal order of a reaction with respect to the ions for the dissolution of metal oxides, on the basis of the proton theory. It is possible to find how the formal orders with respect to the ions change with change in the nature of the potential-determining reaction. If the magnitude of the potential

$$E = E^0 + \frac{RT}{F} \ln \frac{[Fe^{3+}]}{[Fe^{2+}]} = \frac{RT}{F} \ln \left\{ \frac{[Fe^{3+}]}{[Fe^{2+}]} \exp\left(\frac{E^0 F}{RT}\right) \right\} \qquad (41)$$

of iron oxides is determined by the reaction $Fe^{3+} + e \rightarrow Fe^{2+}$, the rate of dissolution can be found by substituting Eqn.(41) in Eqn.(35) for $\beta_+ = 0.5$, $z_+ = 1$, $m = 0.5$:

$$\left(\frac{\partial \alpha}{\partial t}\right)_{sp} = k a_{H^+}^m a_{Fe^{2+}}^{(1-\beta_+)z_+} a_{Fe^{3+}}^{-(1-\beta_+)z_+} = k a_{H^+}^{0.5} a_{Fe^{2+}}^{0.5} a_{Fe^{3+}}^{-0.5} \qquad (42)$$

It follows from Eqn.(42) that the rate of dissolution of iron oxides increases with increase in the concentration of H^+ and Fe^{2+} ions (the formal order of the reaction with respect to Fe^{2+} is 0.5 ± 0.1, and that with respect to Fe^{3+} is −0.5 ± 0.1.[153] If the potential

$$E = E_x^0 + \frac{RT}{F} \ln (a_{H^+}^{x/(x-1)} / a_{Mn^{2+}}^{[2(x-1)]^{-1}})$$

is determined by the reaction

$$MnO_x + 2(x-1)e + 2xH^+ \rightarrow Mn^{2+} + xH_2O \qquad (43)$$

reversible with respect to metal and hydrogen ions, it follows from Eqns.(25) and (43) that¶

$$k_i = k a_{H^+}^{n - x(1-\beta_+)z_+/(x-1)} \cdot a_{Mn^{2+}}^{(1-\beta_+)z_+/2(x-1)}$$

The formal order of the reaction with respect to H^+ and Mn^{2+} ions depends on the stoichiometric composition of the oxide. For $x = 1.5$ in MnO_x, the formal order of the reaction with respect to H^+ is −0.5, and that with respect to Mn^{2+} is +0.5. For $x = 2.0$, the formal orders of the reaction with respect to these ions are +0.1 and +0.25 respectively. The rate of dissolution of the oxide depends on x, and the reaction rate constant has a minimum value for $x \cong 2$. Expressions for determining the formal order with respect to the ions H^+ and M^{z+} for other versions of the potential-determining reactions are given below:

$$\frac{x_2}{x_1 - x_2} MO_{x_1} + M^{z+} + ze \rightarrow \frac{x_1}{x_1 - x_2} MO_{x_2} \qquad (III)$$

$$MO_x + 2xH^+ + 2(x - z/2)e \rightarrow M^{z+} + xH_2O \qquad (IV)$$

Reaction	n_{H^+}	$n_{M^{z+}}$
(III)	m	$-\frac{(1-\beta_+)z_+}{z}$
(IV)	$m - \frac{(1-\beta_+)z_+ x}{(x - z/2)}$	$\frac{(1-\beta_+)z_+}{2(x-z/2)}$

c) The influence of the anionic composition of the electrolyte and complex formation on the specific rate of dissolution of oxides in acidic media and complexones. The addition of anions to an electrolyte and the formation of stable complexes increases the rate of the dissolution of metal oxides. The extraction of cuprite into H_2SO_4 is more rapid than that into $HClO_4$,[168] since the sulphate complex of copper(II) is more stable than the perchlorate complex. A study of the dissolution of α-iron(III) oxide in mineral acids[19,48] showed that the formal orders with respect to the anions are 0.72 for Cl^-, 0.35 for SO_4^{2-}, 0.30 for NO_3^-, and 0.02 for ClO_4^-. The rate of dissolution can be represented in the form:[19]

$$d[Fe^{3+}]/dt = k[H^+]^{0.5}[A^{z-}]^m$$

A study of the influence of EDTA and hydroxyethylidenediphosphonic acid (HEDP) on the rate of dissolution of iron and manganese oxides established that complex formation leads to an increase in the intensity of the process. The logarithm of the rate constant for the dissolution of Fe_3O_4 or Fe_2O_3 increases linearly with increase in the logarithm of the

¶ At a constant potential, $n_{H^+} = m$, and the order of the reaction with respect to Mn^{2+} is equal to zero. 0.

stability constant of the complex of iron(III) with the anion of the electrolyte.[19] This agrees with data obtained by other workers.[153,154,168]

The more rapid extraction of BeO [154] and dissolution of titanium minerals[169] in H_2SO_4, compared with hydrochloric acid, indicates that the anions influence the kinetics of these processes, and is due to the ability of the SO_4^{2-} anions to form more stable complexes with beryllium and titanium ions. The influence of anions on the potential and the rate of the dissolution of UO_2 has been discussed.[30] The rate of dissolution of the oxides NiO, Ni_2O_3, and CuO in complexones, which form stable complexes with metal ions, however, decreases with increase in the ligand concentration.

There are two approaches to the explanation of the influence of anions on the dissolution of metal oxides.

The mechanism of the conjugated influence of cations and anions. According to the theory proposed by Vermilyea,[12,72] the increase in the rate of the dissolution of oxides under the influence of anions and complex formation is due to an increase in the ease of removal of cations from the crystal lattice of the oxide, in accordance with equations reflecting both the adsorption and reaction of ligands with the metal ion:

$$[M(OH)_n]^{(z_+-n)+}(\text{solid}) + p\,A^{q-}(\text{ads}) \rightleftarrows [M(OH)_n(A^{q-})_p]^{(z_+-n-qp)+}(\text{solid})$$

and to the subsequent transfer of the resulting complex to the solution

$$[M(OH)_n(A^{q-})_p]^{(z_+-n-qp)+}(\text{solid}) \rightarrow [M(OH)_n(A^{q-})_p]^{(z_+-n-qp)+}(\text{aq})$$

where A^{q-} is an anion with charge $q-$, A^{q-}(ads) represents anions adsorbed on the oxide phase, p is the coordination number of the metal ion, and n the number of OH^- ions coordinated to the M^{z+} ion.

The dependence of the rate of dissolution of the oxide on the concentration of protons and anions for the complex

$$[M(OH)_n(A^{q-})_p]^{(z_+-n-qp)+}$$

according to Vermilyea[72] will be:

$$i = k a_{H^+}^{\frac{\beta_+(z_+-n-qp)}{\beta_+(z_+-n-qp)-\beta_-z_-}} \cdot a_{A^{q-}}^{-\frac{\beta_-z_-qp}{\beta_+(z_+-n-qp)-\beta_-z_-}} \qquad (44)$$

Eqn.(44) gives the theoretical order of the reaction with respect to H^+ and A^{q-} ions. The available published data are given in Table 5.

Vermilyea's theory has made it possible only to establish the relationship between the stability constant of the complex formed by the metal cation with the ligand and the rate of dissolution of the oxide. This theory requires further development, since there are experimental data which it does not explain.

1) According to Vermilyea's ideas,[19,48] the limiting stage of the process reduces to the removal of a cation from the lattice (that is when the values of E are displaced into the positive range, the rate of the dissolution of the oxide should increase), whereas it has been established experimentally† that the rate of the process is limited by the removal of oxygen (OH group) or by the introduction of a proton into the oxide phase (since a displacement of the potential into the cathodic range increases the rate of dissolution of most oxides).

2. For the oxides Fe_2O_3, Fe_3O_4, MnO_2, MnO, and Mn_2O_3, the addition of the corresponding cations (strong reducing agents, Fe^{2+}, Mn^{2+}) to the acid increases the rate of dissolution of the oxide phase,[31,160,166] which is not consistent with the theory being discussed, since the species adsorbed is not the anion (in accordance with Vermilyea's ideas), but the cation.[48]

3. The theory does not explain the decrease in the rate of the dissolution of manganese and iron oxides in acidic media when MnO_4^-, $Cr_2O_7^{2-}$, and other anions which are oxidising agents with respect to Fe^{2+} and Mn^{2+} ions respectively are added to the electrolyte.

4. The theory does not explain the decrease in the rate of the dissolution of various oxides (CuO, Cu_2O, NiO, Ni_2O_3) with increase in the concentration of Complexones (EDTA, HEDP).

5. In Vermilyea's opinion, a strong complex-forming reagent such as 1,10-phenanthroline should increase the rate of the dissolution of the oxide phase, whereas experimentally, a decrease in the rate of the dissolution of iron oxide (Fe_3O_4, Fe_2O_3) is observed when this reagent is added to the solution.

The electron–proton mechanism of the influence of anions and complex formation. According to this mechanism, the influence of anions and complex formation reduces to a change in the value of E for the oxide electrode. Since at the surface of separation between the phases the value of the potential is determined by the reaction

$$M^{z+}A + e \rightarrow M^{(z-1)+}A$$

it follows that displacements of the potential into the cathodic region and into the anodic region are observed, depending on the nature of the ligand A.

Table 5. Theoretical values of the orders of the reaction with respect to hydrogen ions (n_{H^+}), anions (n_{Aq^-}), and the species whose transfer limits the rate of dissolution of metal oxides.[12]

Oxide	n_{H^+}	n_{Aq^-}			
		ClO_4^-	Cl^-	SO_4^{2-}	NO_3^-
$Fe_2O_3 \cdot nH_2O$	0.50	0.02; $Fe(OH)_2^+$	0.72; $FeCl_2^+$	0.35; $FeSO_4^+$	0.30; $Fe(OH)NO_3^+$, $Fe(NO_3)_2^+$
$Cr_2O \cdot 3.6H_2O$	0.46	~0; $Cr(OH)_2^+$	0.27; $Cr(OH)Cl^+$, $CrCl_2^+$	0.29; $CrSO_4^+$	—
$NiO \cdot nH_2O$	0.56	~0; $NiOH^+$	—	—	—

† There is other evidence that the limiting stage reduces to the transfer of a proton to the oxide phase (see p.1048).

In aqueous EDTA solutions, the magnitude of the standard redox potential of the reaction $Fe^{III}(EDTA) + e \rightarrow Fe^{II}(EDTA)$ is +0.14 V,[170] whereas for the systems containing 1,10-phenanthroline, the value of E is +1.2 V (at pH 0).[171] These ligands form stable complexes with iron ions. It is assumed that $pK_{Fe^{II}L} = 14.26$, $pK_{Fe^{III}L} = 25.1$, and $pK_{Fe(phen)_3^{2+}} = 21.3$.

Experimentally, different effects are observed (with increase in the ligand concentration, an increase in the rate of the dissolution of the oxide is observed for EDTA, and a decrease is observed for 1,10-phenanthroline), proving that the potential of the medium plays a decisive role in the kinetics of the dissolution of the oxide phase.

The increase in the rate of the dissolution of iron oxide with change in the anion composition of the electrolyte in the order: $HClO_4 < HNO_3 < HBr < H_2SO_4 < HCl < H_3PO_4 < HF$ [19,53] is due to the change in the magnitude of the potential[153]

$$E = E^0 + \frac{RT}{F}\ln\frac{[Fe^{III}]_{total}}{[Fe^{II}]_{total}} + \frac{RT}{F}\left(\ln\frac{1}{\gamma_{ox}} - \ln\frac{1}{\gamma_{red}}\right)$$

of the reaction $Fe^{III}A + e = Fe^{II}A$, which limits the transfer of protons from the acid solution to the oxide (Fe_2O_3).[174] Substituting Eqn.(44) in Eqn.(35) shows that the rate of the dissolution of iron(III) oxide is given by an expression of the form

$$k_i = k a_{H^+}^{n_i} a_{Fe(II)}^{(1-\beta_+)z_+} a_{Fe(III)}^{-(1-\beta_+)z_+}\left[\sum_{n=0}^{q}(K_{red})_n[A]^n \Big/ \sum_{i=0}^{q}(K_{ox})_i[A]^i\right]^{-(1-\beta_+)z_+} \quad (45)$$

$$\frac{1}{\gamma_{ox}} = \sum_{i=0}^{q}(K_{ox})_i[A]^i;\ (K_{ox})_0 = 1;\ \frac{1}{\gamma_{red}} = \sum_{n=0}^{q}(K_{red})_n[A]^n;\ (K_{red})_0 = 1$$

where γ_{ox} and γ_{red} are the fractions of the iron(II) and iron(III) ions not combined in the complex, and K_{ox} and K_{red} are the stability constants of the complexes formed by the Fe^{3+} and Fe^{2+} ions respectively.

It follows from Eqn.(45) that for $z_+ = 1$ and $\beta_+ = 0.5$, the rate constant (k_i) is linearly dependent on the difference between the stability constants of the complexes of Fe^{III} and Fe^{II} with the anion of the electrolyte. The calculated values of the orders of the reaction with respect to the ions Fe^{2+}, Fe^{3+}, and H^+ agree with the experimental values. The experimental data obtained are given in Table 6.[153]

Complexones, which displace the stationary value of E into the cathodic range, facilitate the dissolution of oxides (Mn_2O_3, MnO_2, Fe_3O_4, Fe_2O_3, etc.). The greater the difference $(pK_{Fe^{III}(EDTA)} - pK_{Fe^{II}(EDTA)} = 10.74$ [175]), the greater the rate of the dissolution of iron oxide. The reason for the decrease in the rate of the dissolution of copper and nickel oxides with increase in the concentration of Complexones in the solution is that these ligands displace the potentials of the oxide electrodes into the cathodic range. To increase the rate of the dissolution of these oxides, it is necessary to displace the potential into the anodic range. The electron–proton mechanism makes it possible to explain all the experimentally observed regular kinetic features of the dissolution of metal oxides.

4. The Influence of the Preparation of the Specimen and the Experimental Conditions

The kinetics of the dissolution of oxides are influenced by the method used to prepare the specimens,[176] the nature of the defects,[107] the state of the surface,[177] and the adsorption of ions from the solutions.[107] The dissolution of NiO in sulphuric acid shows an induction period,[107] the duration of which increases with increase in the time for which the specimen is kept in air, and this can be related to a change in both the quantity of defects and the electrical conductivity of the specimen. With increase in the oxygen pressure, the induction period for the dissolution of nickel(II) oxide decreases, due to an increase in the number of Ni^{3+} vacancies. In the dissolution of the oxides of copper, iron, and nickel, the addition of oxidising agents (MnO_4^-, $Cr_2O_7^{2-}$) and reducing agents (Fe^{2+}, I^-) to the electrolyte solution changes the duration of the induction period.[31,109,176] In the presence of these ions, which show oxidising properties in an acidic medium, the concentration of the defects (Ni^{3+}) in NiO decreases. The sites corresponding to the intersection of dislocations on the surface of the crystals represent the centres at which the dissolution process begins. The rate of the dissolution of NiO and Fe_2O_3 decreases with increase in the temperatures at which the specimens are heated from 700 °C to 1000 °C, since thermal treatment decreases the number of defects and leads to a decrease in the effective surface area of dissolution.[107,178,179]

The anisotropy of the dissolution of metal oxides. Polycrystalline specimens are characterised by orientational non-uniformity of the properties, so that a change in the nature of the kinetic curve with time is sometimes related to the non-uniformity of the dissolution of the surface of the specimen. This situation is observed in the dissolution in acid of TiO_2,[180] FeOOH,[181] Fe_2O_3,[182,183] and Al_2O_3.[184] Each plane of α-Al_2O_3 crystals is characterised by a definite form and orientation of the etch pits.[185]

The basal plane (0001) of α-Al_2O_3 and α-Fe_2O_3 is extracted into acids much more rapidly than the other planes.[4] The etch figures are determined by the crystal defects, depend on the anion composition of the solution and on the nature of

Table 6. Dependence of the kinetic parameters of the dissolution of iron(III) oxide on the nature of the acid (at 50 °C).

Acid	$t_{0.5}$, min	α_{max}	$E_{Fe(III)A/Fe(II)A}$, V (Ref.174)	Eqn. (46)	Eqn. (48)			
				$10^7 k_i$, cm min^{-1}	$10^7 k_i$, cm min^{-1}	$10^{-2} k_g$, cm^{-2}min^{-1}	$10^{-3} A$	$\tau_{0.5}$
HF	246	0.25	0.55	126	103.7	122.30	5.0	0.17
H_3PO_4	360	0.12	0.59	86	33.3	49.49	63.0	0.08
HCl	522	0.15	0.64	59.3	28.7	21.67	32.0	0.10
H_2SO_4	1 860	0.21	0.68	16.6	11.3	2.67	10.0	0.14
HBr	4 200	0.30	0.75	7.4	7.9	0.37	2.0	0.22
$HClO_4$	30 000	0.15	0.78	1.03	0.5	0.38	32.0	0.10

Note. $t_{0.5}$ is the time required for the dissolution of half of the oxide specimen; the rate constant (k_i) according to Eqn.(42) was calculated for 1 M acid solutions; $\tau_{0.5}$ is a quantity proportional to the time taken for the reaction to proceed to the extent $\alpha = 0.5$ ($\tau_{0.5} = k_i t_{0.5}$).

the acid, and show different geometries, depending on the orientation of the face.[4] The rate of the dissolution of a polycrystalline specimen depends on the relationship between its dimensions and the magnitude of the granules of which it is made up.[186] The chemical etching of crystals has established[187,188] that there is an increased reactivity at the dislocation sites. Studies carried out in this direction have been reviewed.[126]

5. Dependence of the Nature of the Dissolution on the Character of the Chemical Bond in Oxides and on the Presence of Additives

The processes associated with the dissolution of oxides (see Fig. 3) can be divided into three classes:[2]

1) non-oxidative dissolution (BeO, CdO, Al_2O_3);

2) the dissolution of oxides (CuO, NiO, UO_2) accelerated by oxidation processes[30,107–110] and anodic polarisation;[30, 107,110]

3) the dissolution of oxides (Fe_2O_3, MnO_2) accelerated by reduction processes[31] and cathodic polarisation.[152]

The dissolution of metal oxides in acids is a multi-stage process. The limiting stage may be a solid-phase process[189,190] or a reaction in the electrolyte solution (as shown for zinc oxide[191]). In an oxide with ionic bonds, the dissolution takes place by a solid-phase mechanism. The transfer of ions to the electrolyte solution in this case takes place without a change in the oxidation state of the cations and anions. The presence of additives and impurities in these oxides has little influence on the rate of their dissolution. The addition of the oxides Li_2O or Al_2O_3 to ZnO does not change the rate of their dissolution in HCl.[192]

In oxides with more covalent bonding, the presence of additives influences the rate of dissolution. The addition of Li^+ ions to NiO leads to an increase in the rate of the dissolution of the specimen, due to an increase in the electrical conductivity of this oxide.[107,149,193] The increase in electrical conductivity[193,194] leads to an increase in the exchange current of the potential-determining reaction and an increase in the rate of the diffusion of H^+ into the oxide. A similar effect is observed when Ti^{4+} ions are added to Fe_2O_3.[193]

For the dissolution of ionic crystals (BeO, ZnO) in H_2SO_4, the properties of the solution play a more important role than the properties of the solid phase. In the dissolution of covalent oxides, the structure of the solid phase (volume charge, different surface states, and also specific adsorption) determines the chemistry of the dissolution.

6. Influence of the Temperature of the Electrolyte on the Rate of the Dissolution of Oxides

The study of the influence of temperature on the dissolution of oxides in acids has established that the rate of the dissolution increases considerably with increase in the temperature of the electrolyte. The activation energy of the process reaches ~80–90 kJ mole^{-1} (see Table 7), which coincides with that obtained for the solid-phase reduction of iron oxides using H_2, CO, and other reagents as reducing agents.[206,207] The order of magnitude of these quantities is close to that of the activation energy of the diffusion of a proton into the oxide phase.[208] The high activation energy of the dissolution is due to heterogeneous processes whose limiting stage lies in the kinetic range.[20,31,153,209] The nature of the limiting stage remains unchanged with increase in the temperature of the electrolyte.

VII. MODELS DESCRIBING THE CHANGE IN THE SURFACE AREA OF THE DISSOLVING PARTICLE

The increase in the rate of the dissolution of oxides with time is attributed to a change in the magnitude of the surface area of the specimen as a result of etching. For the interpretation of the change in the kinetics of the process with time, it is possible to put forward a number of models which

Table 7. Effective activation energies (E_a, kJ mole^{-1}) of the dissolution of metal oxides in acid solutions.

Oxide	Acid	E_a	Oxide	Acid	E_a	Oxide	Acid	E_a	Oxide	Acid	E_a

describe the development of the reaction front during the reaction of the specimen with the electrolyte and which make it possible to determine the explicit form of the function $f(\alpha)$ (1). It is of interest to discuss the general regular features of the dissolution of oxide particles when they are present continuously in the suspended state in the reaction vessel and are subjected to the action of the electrolyte. The change in the surface area during the dissolution of oxides is described by different relationships, depending on the original geometry of the specimens. If the original oxide can be represented in the form of a flat plate (electrode), and its dissolution takes place uniformly, the fraction of dissolved substance will change linearly with time: $\alpha = k_i t / r_0$.

The explicit form of this function has not yet been established for the case where the magnitude of the surface changes non-uniformly during the dissolution.

If the particle has a spherical shape, the time dependence of the fraction of the dissolved oxide will be described by the following equations:

$$1-(1-\alpha)^{1/3}=\frac{k_i t}{r_0};\ \frac{\partial\alpha}{\partial t}=(k_i/r_0)(1-\alpha)^{2/3} \qquad (46)$$

These equations were derived with the assumption that uniform dissolution of the particle takes place; usually, however, the dissolution of the particles of the oxide specimen is non-uniform. One of the formal heterogeneous models which shows the development of a non-uniform reaction front during the reaction of a particle with an acid is described below.

Kinetic theories of the dissolution of oxides taking account of the formation of active centres on the surface of spherical oxide phases are based on the applicability of the mathematical apparatus proposed by Delmon and Mampel.[210] According to this theory, the rate of dissolution is determined by two parameters: the rate constant for the production of nuclei, that is the active centres of the dissolution (k_g), and the rate constant for their dissolution (k_i). A relationship between α and t has been proposed.[210] The volume of a spherical particle with radius r_0 is equal to the sum of the volumes of layers which have a thickness dx and which are situated at a distance x from the surface. The volume of one dissolving layer is $\beta(x, t)$ and represents the sum of the dissolved volumes of each sphere, divided by the original volume $\frac{4}{3}\pi r_0^3$:

$$\alpha=\int_0^{r_0}\frac{3(r_0-x)^2}{r_0^3}\beta(x,t)\,dx=\frac{3}{r_0}\int_0^{r_0}\left(1-\frac{x}{r_0}\right)^2\beta(x,t)\,dx \qquad (47)$$

From the theory of heterogeneous kinetics, the value of $\beta(x, t)$ will be determined by the Poisson relationship[211]

$$\beta(x,t)=1-\exp(-S\gamma)$$

where $\gamma = r_0^2 k_g/(r_0 - x)^2 = N(\theta, x)$ is the number of dissolution centres produced on the surface of spheres with radius $(r_0 - x)$ at moment of time θ; and

$$S=\pi\left(\frac{r_0-x}{r_0}\right)[k_i^2(t-\theta)^2-x^2]$$

is the surface area of a dissolved segment with radius $(r_0 - x)$. Using the new parameters

$$A=4\pi r_0^3 k_g/k_i;\ \tau=k_i/r_0 t;\ \xi=x/r_0$$

Eqn.(47) can be reduced to the form:

$$\alpha=1-(1-\tau)^3-3\int_0^{\tau}(1-\xi)^2\exp\left(-\frac{A}{12}\,\frac{\tau^3-3\xi^2\tau+2\xi^3}{1-\xi}\,d\xi\right) \qquad (48)$$

Eqn.(48) does not have an analytical solution. The kinetic parameters are calculated using the tabulated values of this function for different values of τ and A.[210] The calculation of the quantities k_i and k_g reduces to the determination of $\tau_{0.5}$, A, and $t_{0.5}$. The determination of A reduces to the superposition of the graph of the experimental data, constructed on coordinates $\alpha - (t - t_l)/(t_{0.5} - t_l)$, on the network of theoretical curves (on the same coordinates) for different values of A. The value of A (tabulated values[210]) is used to find $\tau_{0.5}$ for $\alpha = 0.5$.[210] The values of k_i and k_g are determined using the equations

$$k_i=r_0\frac{\tau_{0.5}}{t_{0.5}-t_l};\ k_g=Ak_i/4\pi r_0^3$$

Usually, k_i is much smaller than k_g, that is the process is limited by the rate of the dissolution of each active centre. As $A \to \infty$, the dependence of α on t is described by the expression used to analyse the kinetics of the dissolution of oxides:

$$1-(1-\alpha)^{1/3}=k_i t/r_0$$

The proton theory of dissolution, taking account of the formation of active nuclei in the volume of spherical oxide particles. To explain the anomalously rapid dissolution of oxides, there is another theory, according to which an increase in the number of active centres (nuclei) in the volume of an oxide takes place as a result of diffusion of H atoms.[166] During dissolution, filamentary branching of the nuclei is observed in a direction perpendicular to the surface of the specimen. Two stages of the process are distinguished: the production of the nuclei and their dissolution.[166,212] In front of the moving surface of the oxide/electrolyte interface there are nuclei (N_0) whose activation requires that they react with the adsorbed hydrogen diffusing from the surface of the oxide phase. The active centres are usually formed at dislocation sites. The hydrogen atoms can diffuse along the dislocations into neighbouring centres, forming new active centres (N).[212] These assumptions agree with data on the adsorption of protons and their subsequent diffusion into the volume of an oxide phase, and with the ideas developed by Lukovtsev and co-workers.[120]

The relationship between α and t was found from the following considerations:

a) the rate of formation of the nuclei $(\partial N/\partial t)_\theta$ is directly proportional to the product of the number of potential centres $(N_0 - N)$ existing at a given moment of time θ and the apparent degree of transformation, with allowance for their overlap and absorption (αf):[213]

$$\partial N/\partial t=k(N_0-N)\alpha_f=-k(N_0-N)\ln(1-\alpha) \qquad (49)$$

where αf is related to the actual degree of transformation α (in accordance with the Poisson equation) by the relationship

$$\alpha_f=-\ln(1-\alpha)=\int_0^t S(\theta,x)N(0,x)\,d\theta$$

where $N(\theta, x)$ is the number of active centres on unit surface area of the sphere (at moment of time θ), observed at a depth x from the surface of the oxide; and $S(\theta, x)$ is the size of the segment cut out by the active centre in the sphere situated on the oxide surface;

b) the rate of dissolution of oxides is directly proportional to the product of the number of active centres and the unreacted fraction of the oxide $(1 - \alpha)$ (and not simply $\partial\alpha/\partial t = kN$, as given by Prout and Tomkins):[214]

$$\partial\alpha/\partial t = kN(1-\alpha) \quad \text{or} \quad \partial\alpha_f/\partial t = k_1 N \tag{50}$$

Assuming that the potential centres are in a large excess, Eqns.(49) and (50) can be used to find α_f:

$$\partial\alpha_f/\partial t = kN$$
$$\partial N/\partial t = k_1 N_0 \alpha_f \quad \text{or} \quad \partial^2\alpha_f/\partial t^2 - k_1 k N_0 \alpha_f = 0 \tag{51}$$

The solution of the differential equation (51) is the function

$$\alpha_f = A \operatorname{sh} k_i t$$

This gives an equation of the form:

$$-\ln(1-\alpha) = A \operatorname{sh}(k_i t); \; \partial\alpha/\partial t = A k_i (1-\alpha)[A^2 + \ln^2(1-\alpha)]^{1/2} \tag{52}$$

where $k_i = (k_1 k N_0)^{1/2}$.

---o0o---

The quantitative comparison, carried out in the present review, of the factors influencing the rate of the dissolution of metal oxides in acids has revealed the decisive role of the proton and electron concentration gradients (potential) on the kinetics of this process. The knowledge of the kinetics and mechanism of the dissolution of oxide phases has now reached a state in which future progress will depend on obtaining further details of the description of electrochemical processes at the oxide/solution interfaces.

The mechanism of the dissolution of a metal oxide and the nature of the limiting stage have still been insufficiently studied. The classical theories of the dissolution of ionic crystals require further development, since they do not yet make it possible to explain the influence of complexones on the kinetics of the dissolution of semiconducting oxides (CuO, NiO, Ni_2O_3, and other oxide specimens); moreover, for the great majority of metal oxides, the nature of the potential-determining reactions at the surface of separation between the solid and liquid phases has not yet been explained.

Phase Equilibria and Mutual Diffusion in Polymer—Polymer Systems with Chlorine-containing Components

A.E.Chalykh and I.N.Sapozhnikova

The experimental studies of the phase equilibria and mutual diffusion in polymer mixtures are examined. A thermodynamic analysis of the phase equilibria in the poly(vinyl chloride)-poly(methyl methacrylate) and chloropolyethylene-poly(methyl methacrylate) systems is presented within the framework of classical and new theories; the influence of the previous history of the specimens and of the chemical structure and stereoregularity of the polymer chains on the phase composition of the mixtures is demonstrated. The translational mobility of the macromolecules in the highly elastic and highly fluid states and its role in the formation of the phase structure of the mixtures and also the irreversible changes in the phase structure on thermal decomposition of chlorine-containing polymers are considered.
The bibliography includes 95 references.

I. INTRODUCTION

The interest in the problem of the compatibility of polymers is due to the need to create new polymeric materials and procedures including the blending of polymeric components. There exist nowadays extensive data whose analysis makes it possible to determine the principal trends in the research into polymer blends: the empirical search for materials with specified properties, the study of the thermodynamics of the blending of polymers, analysis of the colloidal-chemical properties of disperse systems, the study of the compatibility of various polymer pairs, and the search for new research techniques and new criteria of compatibility.

A single physicochemical approach to the analysis of polymer blends, which requires information about the equilibrium phase structure and kinetic characteristics of the systems, namely the diffusion coefficients, the decomposition constants of the components, etc., which would make it possible to predict the changes in the properties of polymer blends during their preparation, use, and storage, is particularly important. The neglect of this approach and methodological difficulties lead to the accumulation of contradictory information concerning the compatibility of polymers, which is frequently useless from the standpoint of practical employment. The difficulty of determining diffusion coefficients for polymer blends is associated with the low translational mobility of the macromolecules in a medium comprising similar molecules and the scope of the integral methods used nowadays for the determination of the compositions of the coexisting phases is extremely limited, because these methods require prolonged isothermal annealing in order to attain equilibrium throughout the bulk of the blend, which is not always attainable owing to the thermal decomposition of the components.

The present level of the development of local analytical methods with high resolution makes it possible to revise the methodology of the approach to studies of this kind, because in local contact regions the times required for the attainment of equilibrium have a significantly different scale. During the last five years, a local X-ray microanalytical method combined with scanning electron microscopy has been developed and used in the combined study of the parameters of mutual diffusion, thermal stability, and phase equilibria in polymer—polymer (P—P) systems. The pronounced "localisation" of the method ensures that the equilibrium isothermal annealing is carried out during sufficiently short periods and makes it possible to investigate any P—P systems before the onset of intense thermal decomposition and also to trace its influence on the phase structure of the blend. Such studies have been carried out in relation to systems with chlorine-containing components: poly(vinyl chloride) (PVC)—poly(methyl methacrylate) (PMMA), chloropolyethylene (CPE)—PMMA, and certain others; the phase diagrams and the diffusion constants have been obtained and the influence of the thermal decomposition of the components and the previous history of the blends on these parameters has been examined.

The aim of the present review is the analysis of the characteristic features of the phase equilibria and the mutual diffusion in polymer blends based on experimental results obtained with the aid of the local analytical methods for systems with chlorine-containing components and also the examination of the prospects which arise as a consequence of the application of these methods to the experimental solution of the problem of the compatibility of polymers.

II. THE STATE OF RESEARCH INTO PHASE EQUILIBRIA IN POLYMER—POLYMER SYSTEMS

A characteristic feature of polymer solutions is the slow attainment of equilibrium in phase separations. Even for polymer—low-molecular-weight solvent (P—S) systems, complete phase separation with formation of a single interface is not always attained;[1] this applies even more to P—P systems. Polymer blends are therefore frequently obtained

and used under conditions far from equilibrium. Nevertheless phase diagrams actually determine the structural-morphological characteristics of the structure of the materials and the trends in the variation of the properties during prolonged use. The analysis of the phase equilibrium is therefore a task of primary importance for the practical selection of the specified materials, for the determination of the conditions of their processing and storage, etc.

Until recently phase equilibria in P–P systems have been discussed solely in theoretical terms. Within the framework of the classical theories (the Hildebrand, Flory–Huggins, Tompa, and Scott theories), the miscibility is limited from above as regards molecular weight. Indeed the positive combinatorial entropy ($\Delta S_{comb} > 0$), which is related to the number of species per unit volume and which determines the entropy of mixing (ΔS_{mix}) in the Flory–Huggins–Scott lattice model, diminishes with increasing molecular weight (MW) of the components. Consequently the positive enthalpy of mixing (ΔH_{mix}), for which phase separation takes place, also diminishes with increasing MW. The incompatibility of polymeric components has been for a long time thought to be a general phenomenon precisely from these standpoints.[2,3] However, the Flory–Huggins–Scott theory is not universal; it does not take into account the concentration and temperature dependences of the interaction parameter χ_{12} and the non-combinatorial entropy contribution to ΔS_{mix} and accounts for the phase equilibrium only in those systems which are characterised by an upper critical solution temperature. This theory has received a number of improvement designed to take into account the volume changes occurring on mixing of the components and responsible for the discrepancy between the theory and the behaviour of solutions. Thus Flory divided χ_{12} into the enthalpy (χ_H) and entropy (χ_S) components. The determination of these quantities for polymer–solvent systems made it possible to explain many phenomena occurring in polymer solutions.[4] Evidently, the determination of these parameters also for P–P systems should be very important for the understanding of the thermodynamics of phase equilibria in polymer blends.

In modern theories constructed on the basis of Prigogine's general theory of corresponding states, the properties of mixtures are expressed in terms of the characteristic parameters of state of the pure components: pressure, volume, and temperature. This applies primarily to Flory's new theory, Patterson's theory, and the lattice theory of Sanchez and Lacombe. These theories take into account the influence of the structure and properties of the components on the properties of the mixture and make it possible to explain the phenomenon of both the upper and lower critical solution temperatures of polymers. Fig.1 illustrates the possible types of phase diagrams of P–P mixtures which obtain in calculations over narrow limits of variation of the parameters of the equation of state.[5]

On the basis of the new theory, Flory calculated the changes ΔH_{mix} and ΔS_{mix} on blending polyisobutylene and polymethylene in the liquid state and found that the free energy of mixing is positive ($\Delta G_{mix} > 0$) over the entire range of compositions, which indicates the incompatibility of the above polymers.[6] However, calculations of this kind involve certain difficulties owing to the large amount of labour involved in the experimental determination of the parameters of the equation of state. Only individual attempts at a general theoretical analysis of the phase equilibria of polymer mixtures on the basis of the theory have therefore been made so far. Thus McMaster[7] used modified equations of Flory's new theory to calculate the phase diagrams of P–P blends. We carried out calculations for two types of hypothetical systems. The first was selected with the maximum possible difference between the parameters of the equations of state of the components and the second was selected with identical parameters with the exception of the coefficient of thermal expansion α. The chain length, the degree of polydispersity, the pressure, and the coefficient of thermal expansion were varied alternately. For $X_{12} = Q_{12} = 0$, the phase equilibria are characterised by a lower critical solution temperature (LCST) (the values of X_{12} and Q_{12} characterise the difference between the interaction energies between identical and non-identical pairs of segments and the change in the entropy of interaction of neighbouring segments respectively). It has been shown that LCST decreases with increasing molecular weight and increases with increasing pressure; similar values of α for components 1 and 2 improve their compatibility. Whereas the presence of the LCST is characteristic in cases where $X_{12} \leqslant 0$, when $X_{12} > 0$ an upper critical solution temperature (UCST) appears together with the LCST. For high positive values of X_{12}, the diagrams assume an hour-glass form. The fulfilment of the condition $Q_{12} \neq 0$ also leads to the presence of the UCST. It is striking that the UCST has been observed over a very narrow range of values of X_{12} (from 0.005 to 0.001). The conclusion, which had a major influence on the course of further studies, namely that an equilibrium with a LCST is typical for P–P systems, was in fact reached on this basis.

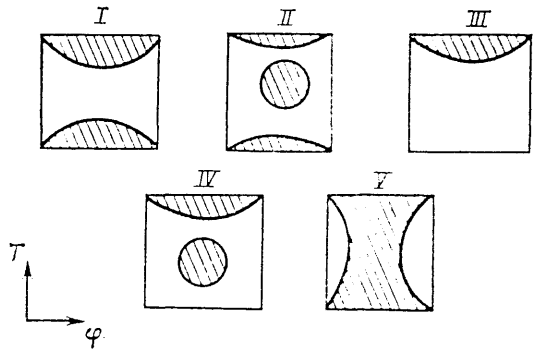

Figure 1. Schematic representation of "temperature–composition" (T–ϕ) phase diagrams predicted by the theory of the equation of state for P–P systems.[5]

However, it is noteworthy that the task is at present experimental rather than theoretical: the aim is to discover which values of the thermodynamic parameters are characteristic of P–P systems and which type of phase equilibrium is most typical for such systems. In calculations on hypothetical systems, the universality of the theory makes it possible to obtain any of the diagrams illustrated in Fig.1 subject to certain assumptions. Thus the hypothesis that $X_{12} \leqslant 0$ and $Q_{12} = 0$ (McMaster[7]) rules out the UCST version and leads to diagrams of type III (Fig.1).

The temperature dependence of X_{12} has been analysed[8] within the framework of the above theory. The following expression has been obtained:

$$\frac{\chi_{12}}{M_1 V_1^*} = \frac{P_1^*}{RT}\left[\underbrace{\frac{\tilde{V}^{1/3}}{(\tilde{V}^{1/3}-1)}\left(\frac{X_{12}}{P_1^*}\right)}_{A} + \underbrace{\frac{\tilde{V}^{1/3}}{2(4/_3-\tilde{V}_1^{1/3})}\cdot\tau^2}_{B}\right], \qquad (1)$$

where the quantities marked by an asterisk are characteristic parameters and those marked by a bar are reduced parameters; $\bar{V} = V/V^*$, $\bar{T} = T/T^*$, $\bar{P} = P/P^*$, $\tau = 1 - T^*/T_2^*$, and M_1 is the molecular weight of the segment. The reduced volume can be expressed in terms of the coefficient of thermal expansion:

$$\bar{V}_1^{1/3} = 1 + \frac{\alpha T}{3(1+\alpha T)}. \qquad (2)$$

Eqn.(1) shows that the χ_{12} comprise two contributions: the contribution of the term describing the interaction of a pair of segments (the first term A) and the contribution of the term describing the change in free volume on mixing the segments (the second term B). It follows from Eqns.(1) and (2) that, when $\alpha \to 0$, then $\bar{V}_1^{1/3} \to 1$ and $A \to \infty$; on the other hand, when $\alpha \to \infty$, then $\bar{V}_1^{1/3} \to 4/3$ and $B \to \infty$. The values of $\bar{V}_1^{1/3}$ quoted[8] for polymers and low-molecular-weight liquids and the results of the calculations show that the role of the free volume in the miscibility of polymers is significantly smaller than in P–S systems and smaller than the values obtained in McMaster's calculations. It has been shown that the appearance of a LCST higher than the UCST in P–P systems is theoretically impossible owing to the free volume effects, since τ should then increase to values unacceptable for the thermal stability of P–P systems.

Flory's new theory and its modifications provide criteria for the search for and the determination of compatible polymer–polymer systems. It is assumed that the conditions under which we have simultaneously $T_1^* > T_2^*$ and $P_1^* > P_2^*$ are the most favourable for the compatibility of polymers and the values of T_1^* and T_2^* themselves should not differ by more than 200 K. (Subscripts 1 and 2 correspond to the individual components.) One of the most evident criteria of Flory's new theory is the parameter X_{12}. A negative value of X_{12} implies that the polymeric components are characterised by the so-called specific interaction and the phase equilibrium has a LCST. However, it has been noted[8,9] that the case where $X_{12} < 0$ (i.e. $\Delta H_{mix} < 0$) can be abolished when $Q_{12} < 0$ ($\Delta S_{mix} < 0$), as has been shown for certain polymer–solvent systems;[4] this creates difficulties in the prediction of the types of equilibrium for P–P systems.

Thus, despite the fact that the theories mentioned are universal and provide criteria for the prediction of the compatibility of the components of the blend, they have still not been adequately analysed and so far have been interpreted in different ways. In addition, a much wider comparison between the conclusions reached in terms of different theories and experiment is necessary in order to reach a conclusion concerning the superiority of a particular theory in describing the behaviour of polymer blends and to ensure the possibility of predicting the phase equilibria by means of analytical methods.

Topological analysis based on comparison of the positions of the phase transition regions has been recently applied to P–P blends with alternating molecular weights of the components (block-copolymers).[10] This analysis provides an estimate of the general type of phase diagrams but does not determine the quantitative miscibilities of the components, which can only be obtained experimentally.

Any properties characterising the homogeneity of the system for different compositions (the intensity of the low-angle, optical, X-ray, electronic, or neutron scattering and the glass point) or the thermodynamic characteristics (free energy of mixing, enthalpy of mixing, the solubility parameter, the interaction parameter, and the specific heat) are used as experimental criteria of compatibility. As a rule, there is no agreement between the limits of compatibility found from these criteria within a single system; this is illustrated by Table 1.

A similar discrepancy can be observed also on comparing the experimental data for the compatibilities of many other pairs of polymers.[2,16] Attention has been frequently drawn to be discrepancies between the experimental results and specific causes of incompatibility have been discussed in the literature.[12,15,17] From our point of view, this situation can be accounted for by the limited nature of the criteria employed and also of the methods of their determination. Thus the compatibility data obtained by direct measurements of any parameter characterising the homogeneity of the system are limited and uncertain as regards temperature. In all probability, the information obtained refers to the temperature of the mixing of the components. The thermodynamic characteristics measured in binary systems using a third component, namely the solvent (for example, ΔG_{mix} determined by the method of Hess's cycle or χ_{12} obtained by the method of reverse gas chromatography or neutron scattering[18–20]), are also functions of the initial state of the system and cannot serve as criteria of the existence of a true equilibrium.

Table 1. The compatibility of PVC and PMMA.

Methods: I) electron microscopy; II) thermodynamic method (method based on Hess's cycle); III) determination of the glass point T_g by differential scanning calorimetry; IV) determination of the phase separation from turbidity points; ω_1'' and ω_2'—weight fractions of PVC in PMMA and of PMMA in PVC respectively determined as compatibility limits.

*Incompatible.

**Fully compatible.

An experimental criterion characterising the miscibility of the components may be the phase composition of the system determined over a wide temperature range under conditions close to equilibrium. The determination of the true phase diagrams for P–P systems is a complex task. Classical methods,[21] involving homogenisation and prolonged thermal annealing, are not always suitable for this purpose owing to the high viscosity and low thermal stability of polymers. In order to obviate these difficulties, the mixtures are prepared as a rule in an effective solvent with its subsequent removal. However, it has been shown[22] that in this case the limits of the miscibility depend on the "quality" of the solvent. They characterise the phase equilibrium in a three-component P–P–solvent system established during the formation of the mixture and corresponds to a non-equilibrium state of the binary system in the absence of a solvent. Fig.2 illustrates the variation of ω_1'' for the PVC–PMMA system obtained in "good" (dichloroethane, $\chi_{PVC} = 0.428$) and "poor" (benzene, $\chi_{PVC} = 0.77$) solvents with isothermal annealing. Evidently the equilibrium values of ω_1'' attained during annealing are higher than for the system obtained from the "poor" solvent and lower than the values found using the "good" solvent.

The accumulation of a large amount of contradictory information concerning the miscibility of polymers is probably in fact to a large extent associated with the previous history of the specimens. Unfortunately, the accumulation of contradictory information has not ceased even when the method of turbidity points, traditionally used to study P–S and polymer–oligomer (P–O) systems, was used to construct phase diagrams.[1]

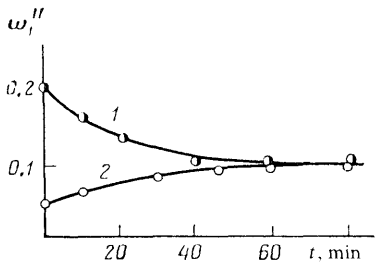

Figure 2. Variation of the limit of the compatibility of PVC and PMMA during annealing at 413 K for blends prepared from solution in DCE (curve *1*) and in benzene (curve *2*).[44]

Analysis of the data obtained by the method of turbidity points in thin films (Table 2) shows that all the phase diagrams have a LCST and that it is as a rule in the region of temperatures traditionally considered as "non-working" temperatures for the corresponding polymer compositions. It is also noteworthy that almost always [with the exception of the polystyrene–poly(methyl vinyl ether) (PS–PMVE) system] no thermodynamic analysis of the phase diagrams and their comparison with known theoretical and experimental data can be found in the literature. For example, the polyisobutylene–polyethylene system (PIB–PE) has a LCST above the liquidus curve according to Tyukova et al.,[34] while according to Flory et al.[6] the system is fully incompatible over the entire range of compositions at temperatures above the melting point T_m. Furthermore, the character of the phase equilibria and the range of critical solution temperatures T_c frequently conflict with the available experimental facts.

As an example, we may quote the PS–PMVE system, since it has been studied most thoroughly: the variation of the LCST with the molecular weight has been demonstrated,[35] a study has been made of the mechanism of the phase separation, and the diffusion coefficient has been found.[24] The values of χ_{12} have been measured at two temperatures; the values obtained suggest a U-shape relation between χ_{12} and T. On this basis, it has been suggested[24] that two critical solution temperatures, namely LCST and UCST, exist in the system. Later two critical solution temperatures T_c were found experimentally for this system:[25] the UCST at 303 K and the LCST at 353 K [sic.]. The intensity of the scattering of a laser beam on passing through the PS–PMVE–benzene system has been measured for constant compositions of the mixture and a variable content of the solvent with subsequent extrapolation to zero content of the solvent.

However, it is noteworthy that extrapolation of the miscibilities of a P–P–S system to the values for the P–P system is impossible not only owing to the error associated with the low concentration limits of the dissolution of high-molecular-weight components in low-molecular-weight solvents but also because of fundamental considerations, since such extrapolation presupposes an additive relation between the miscibilities of the binary and ternary systems, which conflicts with the theories of polymer solutions. Furthermore, additional limitations as regards temperature (apart from the glass points T_g and decomposition temperatures T_{decomp} of the polymers), associated with the crystallisation temperature T_{cryst} and boiling point T_b of the solvent, apply to this method. The identity of the LCST and the T_b of benzene is striking in this connection.[25]

We may note that other investigators[36] showed by the method involving the determination of the velocity of sound and by electron microscopy that the PS–PMVE system, also obtained from solution in toluene, is microheterogeneous when the PMVE content is between 5 and 70% in the range from the normal temperature to 413 K. Evidently these results conflict with the full compatibility of the components, which should obtain in the temperature range investigated in conformity with the phase diagram obtained in previous studies.[23-25] Thus, the final elucidation of the phase equilibrium in this system requires allowance for all the known experimental data.

Such discrepancies throw doubt on the validity of the application of the method of turbidity points particularly when the authors failed to observe reversible turbidity (in the PSAN–PMMA system)[27] or when T_c is very close to T_{decomp} of the components.[29,31-33] The authors of a review[17] draw attention to the necessity to take into account the influence of various chemical processes between the components of mixtures on their compatibility. However, the same investigators failed to attempt in their own study[27] a serious analysis of the system investigated precisely from these standpoints assuming that the weight loss up to 22% in the PVF–PEMA system which they observed does not affect the character of the phase equilibria.

Mixtures with chlorine-containing components, such as PVC and CPE, capable of undergoing dehydrochlorination even at $T = T_g$,[90] which significantly alters the chemical structure and hence also their miscibility with other polymers, merit especial attention from this standpoint. Thus, according to some data,[31] the PVC–CPE (42% Cl) mixtures

are characterised by an equilibrium with a LCST at 393 K, while according to other data[37] these mixtures are compatible to only a limited extent at temperatures below 393 K and the degree of chlorination of CPE must not be less than 48%. For a 30% chlorine content in CPE, the polymer is incompatible with PVC, PMMA, and certain other polymers even on mixing in a common solvent.[38] A phase diagram having both a UCST and a LCST has been published[32] for the CPE (27% Cl)–PMMA system, while an "hour glass" diagram has been obtained for the CPE (47.8% Cl)–PMMA system. In another study[33] the same workers obtained a phase diagram with a LCST for the CPE (49.8% Cl)–PMMA system (Table 2). Such a wide variety of types of phase equilibria within the limits of virtually a single system cannot be explained from a purely thermodynamic point of view if one disregards the chemical reactions occurring during the annealing of the system and also other kinetic factors which include mass-exchange processes and the thermal stability of the polymers. All these factors make the problem of the simultaneous study of phase equilibria and the translational mobility and thermal stability of the components one of the most urgent and general in the study of the compatibility of P–P systems.

Definite advances have been achieved in this field with the aid of a qualitatively different approach to the methodology of the study of P–P systems, namely in the investigation of the local contact regions of polymer components using highly resolving diffusion methods. The principle of these methods is based on the study of the distribution of the concentrations ω in the direction of the diffusion flux x in a local region after diffusional annealing of the specimens in contact over a period t. Such methods include, for example, the method of scanning infrared spectroscopy with a spatial resolution of 100 μm,[39] an interference micromethod with a resolution of ~10 μm,[40] and the electron probe (X-ray spectroscopic) microanalysis whose spatial resolution is ~1 μm.[40–42] There exists a definite correspondence between the form of the concentration profiles and the phase diagrams (Fig.3), which makes it possible to obtain, simultaneously with the diffusion constants, quantitative information about the compositions of the coexisting phases over a wide temperature range.[43] The application of the method of X-ray microanalysis, based on the recording of the characteristic X-ray emission of the element analysed, makes it possible to follow quantitatively, apart from the determination of the above information, the variation of the chemical structure of the components of the systems investigated directly on the basis of the change of the intensity of the analytical line after isothermal annealing.[44]

Various oligomeric and polymer–oligomer systems have now been investigated with the aid of the interference micromethod. Phase diagrams and mutual diffusion coefficients for mixtures have been obtained: elastomers–oligoester acrylates and oligomethylenes,[45,46] PVC–oligoester acrylates,[47] elastomers–epoxy-ologiomers, etc.[48] The influence of the end group, the chain length, and the nature of the components on the phase equilibria and mutual diffusion in mixtures has been studied. The advantages of the local methods, whereby one can determine equilibria which are not established throughout the bulk of the specimen but only at the contact boundary, are particularly evident and it is necessary to investigate more complex P–P systems or rapid processes. Thus in the study of epoxide–rubber hardening systems[49] only the application of the interference micromethod made it possible to follow the evolution of the phase states determined by the varying degree of departure of the system from the critical solution temperatures during the continuous variation of the chemical nature of the epoxide component during the hardening process, to identify the diffusion-controlled stages in the formation of heterogeneous polymer compositions, and to determine the process conditions ensuring a specific regulation of the physicomechanical properties of the material.

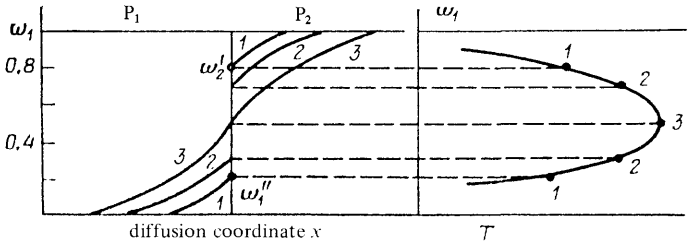

Figure 3. Schematic illustration of the transition from diffusion profiles in terms of ω–x plots to the ω–T phase diagram for the P_1–P_2 system. The numerals opposite the curves (*1* → *3*) correspond to an increase in the annealing temperature (case with a UCST).[43]

The X-ray microanalytical method, whose spatial resolution makes it possible to retain the time scale of the diffusional annealing in the region of minutes, is used in the study of blends of polymers with high molecular weights. This method, the apparatus for which is combined with that for scanning electron microscopy, has been developed in greatest detail and has been used in the study of mutual diffusion and phase equilibria in polymer mixtures with chlorine- and fluorine-containing components, such as PVC–PMMA, PVF–PMMA, CPE–PMMA, PVC–P-ε-CL, etc.[22,44,50–53] The mutual diffusion coefficients and phase diagrams have been obtained for the PVC–PMMA system and the influence of the molecular weight, the chemical stability, and the structure of one of the components as well as the previous history of the system on the phase composition of the mixture has been investigated.[22,44,50,54–56] These experimental data provide the necessary and sufficient information for the consideration of the processes occurring in the system from the instant of the formation of the real mixtures up to the establishment in the latter of the phase structure corresponding in terms of composition to the equilibrium phase diagram, which can be responsible for the discrepancies between the existing experimental results mentioned above. Certain characteristic features of the phase equilibria and of the diffusion and other properties characterising P–P mixtures will be considered below on the basis of the system indicated.

III. PHASE EQUILIBRIA IN THE POLY(VINYL CHLORIDE)–POLY(METHYL METHACRYLATE) SYSTEM

The phase diagrams for mixtures of PVC and PMMA with different molecular weights have been obtained in the temperature range 400–470 K (Fig.4a).[56] The low-temperature branches of the binodals cannot be obtained by this and other methods owing to the loss of translational mobility by the macromolecules in the region of the T_g, while the high-temperature branches (at $T \geq 470$ K) cannot be obtained owing to the intense thermal decomposition of PVC. Fig.4 shows that the regions of the homogeneous mixing expand with increase of temperature, which is characteristic of systems with a UCST; this effect is greater the lower the molecular weight of PMMA.

The critical concentrations (Table 3) of mixtures of PVC and PMMA, corresponding to the mixing of components at the critical points, are close to 0.5 over the entire range of experimental molecular weight ratios M_{PMMA}/M_{PVC}, from 0.45 to 5.12, in contrast to a solution of PVC in the PMMA monomer whose phase diagram is appreciably asymmetric (Fig. 4*b*) and the critical composition corresponds to a comparatively low PVC concentration ($\phi_c = 0.12$). The experimental values of ϕ_c in the PVC–PMMA system, found from the point of intersection of the rectilinear diameter and the composition axes, are compared in Table 3 with the values calculated on the basis of the Flory–Huggins–Scott theory from the equation $\phi_c = n_2^{1/2}/(n_1^{1/2} + n_2^{1/2})$, where n_1 and n_2 are the degrees of polymerisation of the components. Only a qualitative agreement is observed between the experimental and calculated quantities, particularly for molecular weight ratios differing appreciably from unity.

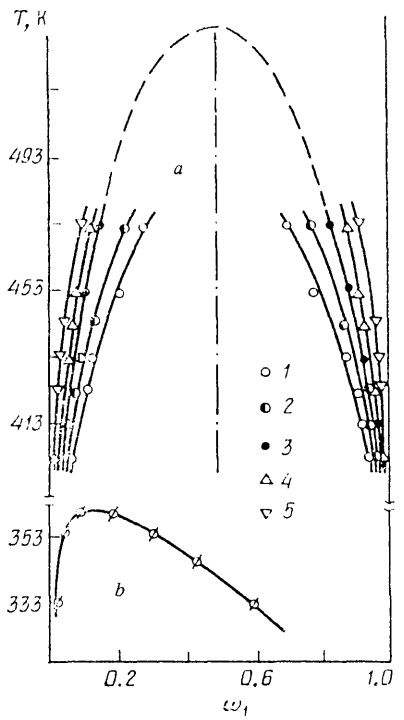

Figure 4. Phase diagrams for the PVC–PMMA (*a*) and PVC–MMA (*b*) systems; $M_{PVC} = 1.4 \times 10^5$; $10^{-5}M_{PMMA}$: 1) 0.64; 2) 1.12; 3) 1.87; 4) 3.02; 5) 7.26.[56]

Table 3. The critical parameters of the PVC–PMMA system.[56–58]

M_{PMMA}/M_{PVC}	φ_c (expt)	φ_c (calc.)	UCST, K
0.45	0.49	0.34	538
0.80	0.50	0.45	522
1.33	0.50	0.51	533
2.15	0.51	0.58	545
5.18	0.51	0.64	556

The influence of the molecular weight on the magnitude and position of T_c has been studied also in the PS–PMVE system.[35] However, it is difficult to reach a conclusion concerning the form of the binodal on the basis of these data, because the temperature range in which they were obtained did not exceed 20 K with the exception of one instance where it amounted to 70 K and it was evident that the binodals are disposed symmetrically; this corresponded to the ratio $M_1/M_2 \approx 1$.

On plotting $\omega_1'(\omega_1'')$–M or $\omega_1'(\omega_1'')$–$1/M$ phase diagrams for isothermal conditions, it is possible to find quantitative relations between the molecular weight and the phase composition of the solution.[45,57] Linear relations have been observed for the PVC–PMMA system: $\omega_1' = \omega_{1,\infty}' + K'M^{-1}$ and $\omega_1'' = \omega_{1,\infty}'' - K''M^{-1}$ (here K' and K'' are empirical constants and $\omega_{1,\infty}'$ and $\omega_{1,\infty}''$ are the solubilities of the components when $M_{PMMA} \to \infty$). Approximate estimates obtained by extrapolating the ω_1'–$1/M$ straight lines to regions of high and low molecular weights showed that an increase of temperature from 433 to 473 K is accompanied by a change of $\omega_{1,\infty}$ from 0.01 to 0.06 in terms of weight fractions of PVC; under these conditions, $(M_{PMMA})_c = 16\,000$ at 433 K, 26 000 at 453 K, and 35 000 at 473 K. Such analysis yields preliminary quantitative information about the miscibility when the molecular weight of one of the components is varied, which is important for the practical employment of the blend.

Theoretical analysis of the experimental binodals is of special interest for the understanding of the processes occurring on blending polymers. Such analysis for the PVC–PMMA system has been carried out within the framework of the classical Flory–Huggins–Scott theory, the improved Flory theory, and the new Flory–Patterson theory.[58] The interaction parameters χ_{12} (Table 4) were calculated from the equation of the binodal based on the Flory–Huggins–Scott theory:

$$\ln \varphi_1' + \left(1 - \frac{n_1}{n_2}\right)\varphi_2' + n_1\chi_{12}(\varphi_2')^2 = \ln \varphi_1'' + \left(1 - \frac{n_1}{n_2}\right)\varphi_2'' + n_1\chi_{12}(\varphi_2'')^2.$$

Table 4. The parameters χ_{12} and $(\chi_{12})_c$ for the PVC–PMMA system as a function of M_{PMMA}.[56,58]

$10^{-5}M_{PMMA}$	$10^3\chi_{12}$				$10^3(\chi_{12})_c$
	413 K	433 K	453 K	473 K	
0.640	2.430	2.280	2.125	2.080	1.640
1.120	1.877	1.714	1.557	1.435	1.130
1.870	1.777	1.520	1.359	1.196	0.824
3.020	1.658	1.381	1.216	1.063	0.645
7.269	1.660	1.274	1.130	0.951	0.434

Account was taken of the experimental values of ϕ_1 and ϕ_2 in the experimental temperature and molecular weight ranges; the $(\chi_{12})_c$ were obtained from the equation

$$(\chi_{12})_c = \frac{1}{2}\left(\frac{1}{n_1^{1/2}} + \frac{1}{n_2^{1/2}}\right)^2 .$$

It is striking that the χ_{12} have low positive values which vary consistently as T and the molecular weight are altered. The relations between the χ_{12} and $1/T$ are linear in the experimental temperature range. Here χ_{12} is almost equal to χ_{21}, which indicates the absence of a concentration dependence of this parameter and is reasonable for the observed symmetry of the binodals. The dependence of χ_{12} on $1/T$

has been used[46,47] for the thermodynamic analysis of P–O blends: the determination of the consolute temperatures, the enthalpy and entropy components of χ_{12}, etc. The linearity of this relation observed for the PVC–PMMA system and the deviation of the constant from the zero value permitted an analogous analysis for the P–P system. The UCST (Table 3), the high-temperature branches of the binodal (see the dashed line in Fig.4*a*), χ_H, and χ_S were determined (Table 5).

Table 5. The values of χ_H and χ_S for the PVC–PMMA system.[56,58]

$10^{-5}M_{PMMA}$	$10^3\chi_H$				10 χ_S	$10^3(\chi_H)_c^*$
	413 K	433 K	453 K	473 K		
0.640	3.35	3.20	3.05	3.00	−1.92	2.56
1.120	3.54	3.41	3.22	3.00	−1.67	2.80
1.872	3.82	3.57	3.39	3.24	−2.05	2.80
4.020	3.90	3.62	3.45	3.40	−2.24	2.89
7.269	4.11	3.72	3.58	3.40	−2.45	2.88

*$(\chi_H)_c = \chi_c - \chi_S$.

Such formal analysis permits the estimation of the contribution of each parameter to the miscibility of the polymers. It follows from Table 5 that χ_H is a decreasing function of temperature, which is the reason for the observed decrease of χ_{12} with increase of T. As the molecular weight rises, χ_H also increases and to a lesser extent at higher temperatures T. At the critical point the quantity $(\chi_H)_c$ is almost constant and independent of the molecular weight except for the system having the lowest molecular weight. Evidently this is associated with the independence of the miscibility parameters δ of the molecular weight in the experimental range of values of M_{PMMA} from 1.12×10^4 to 7.26×10^5. On the other hand, χ_S has negative values, which increase in absolute magnitude with increase of M_{PMMA}.

Comparison of the thermodynamic parameters in Tables 3–5 shows that negative values of χ_S should have a definite significance for P–P systems characterised by a UCST, because they correspond to a positive value of the non-combinatorial entropy ($\Delta S_{non\text{-}comb} > 0$) and make an additional contribution to the free energy of mixing. Their increase with increasing molecular weight probably partly compensates the characteristic decrease of ΔS_{comb} associated with the decreased number of molecules per unit volume. The competition between these two processes apparently explains also the attainment of a plateau on the relation between T_c and the molecular weight as the Θ temperature is approached. The Θ temperature for the PVC–PMMA system, found from the linear plot of $1/T_c$ against $1/M^{1/2}$, is 588 K; it is striking that it lies appreciably above T_{decomp} for the polymers.

Thus it is evident that a high negative value of χ_{12}, ensured by a high non-combinatorial contribution to the entropy of mixing, can obtain in P–P systems with a UCST only at temperatures greatly exceeding those corresponding to their chemical stability. In this connection it is essential to mention the results of Ielenic's study.[20] A negative interaction parameter ($\chi_{12} = -0.0044$) has been obtained for blends of high-molecular-weight PVC and PMMA by the method of neutron scattering. Since the PVC–PMMA system is only partly compatible (Table 1, Fig.4*a*) and is heterogeneous over a wide range of compositions,[13,59] the view, expressed above, that the thermodynamic quantities determined for the specimens using a third component characterise the equilibrium in the P–P–solvent three-component system and cannot serve as criteria of the compatibility of the P–P binary system at a normal temperature is evidently valid. The same order of magnitude (in terms of the absolute value) of the quantity χ_{12} obtained by the neutron scattering method[20] and the values quoted in Table 4 [56,58] suggest that a conformational state of the macromolecules identical with that which should obtain at a temperature above the Θ temperature and corresponding to a non-equilibrium conformation at the experimental temperature is realised on formation of the P–P system in the presence of a solvent.

Thus theoretical analysis of the experimental phase diagram showed that the phase equilibrium in the PVC–PMMA system, characterised by a UCST, depends significantly on the molecular weight of one of the components and that this dependence is qualitatively described satisfactorily within the framework of the Flory–Huggins–Scott theory and the improved Flory theory. However, this agreement obtains only for the ratios $M_1/M_2 \geq 1$ and $M_1 > 10^5$. It has been shown that the deviation of the parameters of the PVC–PMMA system for $M_{PMMA} = 6.4 \times 10^4$ from the theory (see Tables 3 and 5) is associated with the influence of the free volume effect, which is not manifested for higher values of M_1.

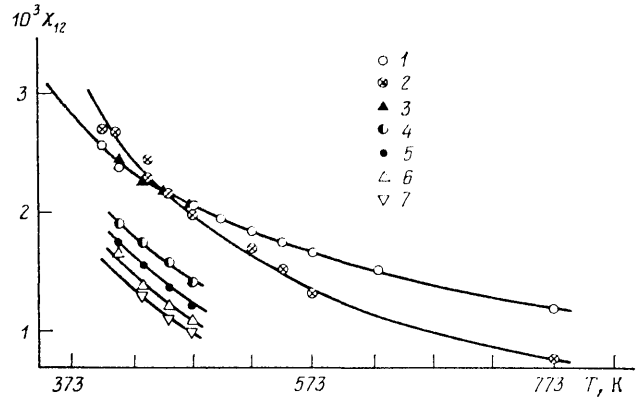

Figure 5. Temperature variation of χ_{12} (1) and the interaction term (2) calculated by Eqn.(1); 3)–7) the values of χ_{12} derived from external binodals as a function of M_{PMMA}.[58] The minima on curves *3*–*7* correspond to curves *1*–*5* in Fig.4.

The influence of these effects has been traced in the analysis of the temperature variations of χ_{12} calculated by Eqn.(1). The contribution of the free volume term B in Eqn. (1) to the overall quantity χ_{12} can be seen from Fig.5, in which the dependence of χ_{12}/Mv_1^* on T (curve *1*), the temperature variation of the interaction term in Eqn.(1) (curve *2*), and the dependence of χ_{12} on T (curves *3*–*7*) are compared. It is seen that curves *4*–*7* are parallel to curve *2*, while curve *3*, corresponding to the system with $M_{PMMA} = 6.4 \times 10^4$, is parallel to curve *1*. Consequently the miscibility of PVC and PMMA for $M_{PMMA} > 6.4 \times 10^4$ is determined solely by the interaction of the components, while under conditions where $M \leq 6.4 \times 10^4$ the difference between the free volumes exerts an appreciable influence. Evidently the latter influence will increase with decrease of M_{PMMA} and with increase of the difference between M_{PVC} and M_{PMMA}. However, calculations showed[58] that the appearance of a

LCST above the UCST in this system (U-shaped dependence of χ_{12} on T) requires necessarily the complete conversion of one of the polymers into the monomer, which would ensure an increase of τ by an order of magnitude and the predominance of the contribution by the second term of Eqn.(1) to the overall quantity $\chi_{12}/M_1 v_1^*$. Analogous calculations have been carried out for the PS–PMMA system and it has been shown that the UCST lies above the decomposition temperatures of the polymers.[60]

Although analysis of this kind is qualitative and in no way replaces the experimental study of compatibility, its employment makes it possible to account for certain features of the phase equilibria in specific systems.

Many attempts have been made recently[15,61–64] to determine the compatibility of polymers (including PVC) with stereoregular components. Fig.6[58] presents sections of the binodal for the PVC–*iso*-PMMA system; it is seen that PVC and stereoregular PMMA (as well as α-PMMA) are partly compatible and phase equilibrium is characterised by the presence of a UCST; secondary processes (associated with crystallisation or other structural transformations) are superimposed on the amorphous equilibrium and complicate its character and the form of the binodal above the melting point of *iso*-PMMA. At temperatures below the melting point, *iso*-PMMA is less compatible with PVC than *a*-PMMA, while above it the solubility of *iso*-PMMA in PVC increases appreciably. The overall tendency in the phase equilibrium and the PVC–*iso*-PMMA system, determined by sections of the binodal,[58] does not conflict overall with the data of other workers, demonstrating a particular degree of limited compatibility of the system in the range $T < T_m$ (melting point), T_{fl} (fluidity temperature) of the polymers.[15,62,64]

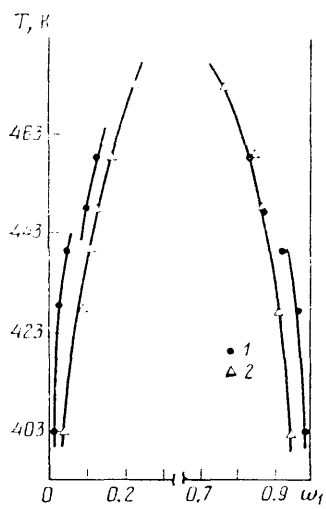

Figure 6. Temperature variation of the compositions of the coexisting phases in the PVC–*iso*-PMMA (1) and PVC–*a*-PMMA (2) systems with identical molecular weights.[58]

IV. MUTUAL DIFFUSION OF POLY(VINYL CHLORIDE) AND POLY(METHYL METHACRYLATE)

The study of the diffusion coefficients and of the characteristics of their variation is a necessary component in the investigation of P–P mixtures, because, together with phase diagrams, they constitute the theoretical basis for the determination of the conditions for the processing of blends, the formation of the phase structure of the material, and the estimation of its thermodynamic and kinetic stabilities.

The mutual diffusion coefficients D_v for PVC and PMMA, determined in the temperature range between T_g and T_{decomp} by X-ray microanalysis, vary in the range from 10^{-14} to 10^{-17} m^2 s^{-1}.[54] Table 6 presents the values of D_v measured at 453 K and the activation energies for diffusion E_D, calculated from the temperature relations $D_v(T)$. The energies E_D for blends with *a*-PMMA are independent of the molecular weight of the diffusing species and the diffusion medium and amount on average to 113 kJ mol^{-1} for the diffusion of PVC in PMMA (D_{12}) and to 134 kJ mol^{-1} for the diffusion of PMMA in PVC (D_{21}). These values are close to the activation energies for viscous flow E_η of the components and demonstrate the segmental character of the movement of macromolecules in polymer blends.

Table 6. Diffusion coefficients and activation energies for diffusion in the PVC–PMMA system.[54]

Diffusing species (*M*)	Diffusion medium	$10^{15}D_v$, m^{2}s^{-1} (453 K)	E_D, kJ mol^{-1}

»	PMMA (726 900)	1.00	115
»	*iso*-PMMA (100 000)	0.35	—

The diffusion parameters presented in Table 6 are fairly unique not only because they have determined for the first time for the PVC–PMMA system but also because nowadays the diffusion parameters of macromolecules in a medium consisting of similar macromolecules are known only for a small number of systems. Thus the self-diffusion and mutual diffusion coefficients have been determined by the radioactive label and spin-echo relaxation methods for polymers and systems: PS, styrene–n-butyl acrylate copolymer (in Bueche's work), PS_1–PS_2,[65] natural rubber (NR), synthetic isoprene rubber (SIR)–NR system,[66] polydimethylsiloxane (PDMS),[67,68] and certain others.[69–72] Certain systems in the elastic and fused states have been investigated by local methods, particularly by the interference micromethod: PIB–synthetic buta-1,4-diene rubber (SBR), PE–atactic polypropylene (*a*-PP), PE–SIR, etc.[73,74]

Analysis of the available data showed that the values of D determined by various workers at temperature above T_{fl} and T_m are 10^{-12}–10^{-14} m^2 s^{-1}, while in the highly elastic state they are lower by 3–5 orders of magnitude (10^{-15}–10^{-19} m^2 s^{-1}). The values of D_{12} and D_{21} obtained for the first time with the aid of local X-ray microanalysis agree well with the values of D determined by the traditional methods. Fig.7 illustrates the temperature variation of the coefficients D_{12} and D_{21} for the PVC–PMMA system and those of D^* and D_{12}^* for other systems in terms of the reduced variables lg D and $T-T_g$.

It is seen that the values of D for various polymers with similar molecular weights fit on a single straight line to within 40%. It is reasonable that the values of D_{12}^* for the diffusion of SIR in vulcanised natural rubber, D_{12}^* for the methylvinylpyridine synthetic rubber (SMVPR), containing a polar component in the side chain, as well as D_V for the PVC–*iso*-PMMA system are exceptions. Evidently the mechanism of the diffusion process in the PVC–PMMA system is analogous to the mechanism of the diffusion of other linear amorphous polymers: PS, NR, poly(butyl acrylate) (PBA), etc. The values of D for a further series of polymers, such as polyacrylates, polymethacrylates, α-PP, and amorphous rubbers, will probably fit on the straight lines in Fig. 7. Deviations are to be expected for systems with specific properties (polar, crystallisable, and structured systems).

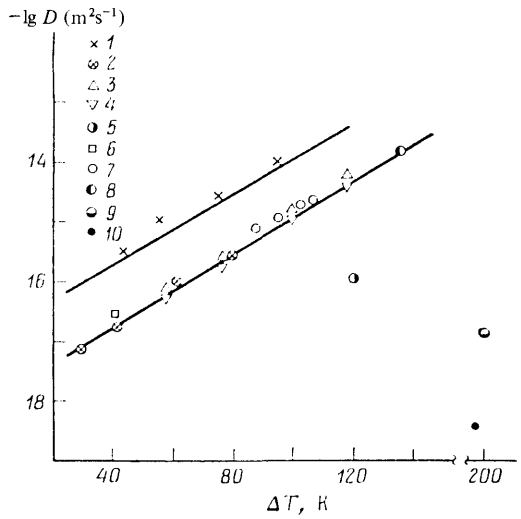

Figure 7. Dependence of the diffusion coefficient D on the difference between the experimental temperature and T_g: 1) D_{21} for PVC–PMMA ($M = 6.4 \times 10^4$); 2) D_{21} for PVC–PMMA ($M = 7.26 \times 10^5$); 3) D_{12} for PVC–PMMA ($M = 6.4 \times 10^4$); 4) D_{12} for PVC–PMMA ($M = 7.26 \times 10^5$); 5) D_{21} for PVC–*iso*-PMMA ($M = 10^5$); 6) D^* = SBR;[69] 7) D^* for PBA; 8) D_{12}^* for PS; 9) D_{12}^* for SIR–NR_{vulc};[66] 10) D_{12}^* for SMVPR.[70]

The studies of the dependence of D on the molecular weight of the diffusing species and the diffusion medium have acquired much importance for the understanding of the mechanism of the translational movement of macromolecules in P–P systems. The influence of the molecular weight of the diffusing species for a constant molecular weight of the medium on the diffusion of PMMA in PVC (D_{21}) and the influence of the varying molecular weight of the diffusion medium for a constant molecular weight of the diffusing species on the diffusion of PVC in PMMA (D_{12}) are illustrated in Fig. 8. It is seen that, with increase of the molecular weight of the diffusing species, the absolute values of D diminish. In the experimental molecular weight range and for all the experimental temperatures, the following relation holds:

$$D = AM^{-b}, \qquad (3)$$

where A and b are empirical coefficients. The coefficient b is a function of temperature and decreases with increase of temperature from 1.57 at 413 K to 1.40 at 473 K.[54]

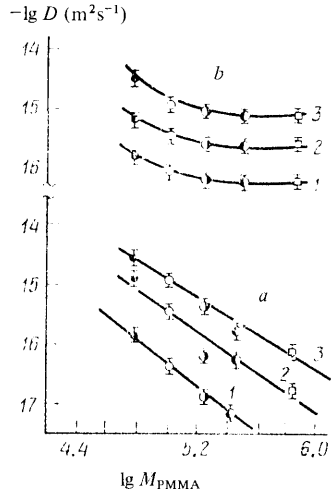

Figure 8. Dependence on the diffusion coefficients D_{21} (a) and D_{12} (b) on M_{PMMA} at different temperatures (K): 1) 413; 2) 433; 3) 453.[54]

A change in the molecular weight of the diffusion medium for a constant molecular weight of the diffusing species leads to the dependence of $\lg D$ on $\lg M$ characteristic for binary systems; the plot has the form of a concave curve described by the expression $\lg D_{12} = \lg D_{12}^{\infty} + n/M_2$, where $n = 3.5 \times 10^4$ is a constant and D_{12}^{∞} is the diffusion coefficient at $M \to \infty$. It is striking that D_{12}^{∞} is attained for the ratio $M_{diff.species}/M_{medium} = 1$ and is not related to M_c (the molecular weight between the entanglement nodes).[54]

The available theories of macromolecular movement are based on the concept of a randomly intertwined structure of the amorphous polymer with a characteristic value of M_c. Bueche's theory considers the energy lost in friction betwen sections of the chain in the course of the translational movement of the molecule and takes into account the entanglements which retard the movement, because one molecule carries behind it others intertwined with it. The theory predicts a dependence of D on M raised to the power 3.4. The "reptation" models of de Gennes[75,76] and Edwards,[77,78] which also take into account the entanglement nodes but deal with the movement of macromolecules which, in essence, bypass these nodes during movement in a closed "tube", significantly differ from Bueche's model. According to De Gennes and Edwards,[75–78] the power exponent b in Eqn. (3) should be 2.

We may note that the values of b determined for the PVC–PMMA system are significantly lower than those predicted theoretically, although the molecular weights of the components of the diffusion pair exceed the molecular weight corresponding to the formation of an entanglement network [M_c(PMMA) = 3×10^4] and are not constant, as predicted by the theory.

The fact that the entanglement network does not influence the diffusion of the macromolecules was noted in an earlier study[66] of D_{12}^* in the SIR–NR system; it was later noted by Tanner[67] and was subsequently formulated in a general

form[79] in the analysis of the experimental data. However, the controversy on this question still continues.[72,76,80,81] It is therefore of interest to analyse the available experimental data for the $D = f(M)$ relations. The studies of the self-diffusion of normal paraffins and PE oligomers yielded $b = 1.7$. According to Bresler et al.,[66] D_{12}^* is proportional to the molecular weight raised to the power of −1.3. The self-diffusion of PEO and PDMS has been investigated[67,68] over a wide range of molecular weights and the power exponent b proved to be 1.7. When the partial self-diffusion coefficients were investigated, it was found that $b = 1$. Kumagai et al.[65] investigated D^* and D_{12}^* for PS; they obtained $b = 1$ for $D_{12}^*(M)$ and $b = 2$ (2.7) for $D^*(M)$. It was also possible to calculate b from Skewis's data[69] (D_{SBR}^*) and the data of Nikiforova et al.[74] ($D_{vPP-SIR}$); $b = 1.65$ and 1.2–1.4 in the former and latter cases respectively.

Thus the experimental values of b can be divided into two groups—those determined from the self-diffusion coefficients D^* and those found from the partial self-diffusion and mutual diffusion coefficients D_{12}^* and D_v (Table 7). Since the values of D_v in infinitely dilute solutions characterise the translational mobility of the polymer in another polymer, it follows that D_v and D_{12}^* have a similar physical significance. For the first group, the parameters b vary from 1.7 to 2, which agrees fairly well with the values predicted theoretically.[76] However, for the second group, b has values ranging from 1 to ~1.6. Evidently the modern theory does not as yet yield a description of the translational movement of macromolecules in P–P systems characterised by the coefficients D_v and D_{12}^* and corresponding to the experimental results. Isolated attempts have only been made to account for such experimental observations by a mixed mechanism of the macromolecular movement.[81]

Table 7. The parameter b in Eqn.(3) for different P–P systems.[45,54,66–71,74].

System	D	b	System	D	b
SIR-NR	D_{12}^*	1.31	PE*	D^*	1.7
PS-PS	D_{12}^*	1.0	PS	D^*	2 (2.7)
PDMS-PDMS	D_{12}^*	1.0	PDMS	D^*	1.7
PP-SIR	D_v	1.2–1.4	SBR	D^*	1.65
PE-SIR	D_v	1.2			
PVC-PMMA	D_v	1.4–1.57			

*Oligomers.

Thus the experimental studies of blends of PVC and PMMA and analysis of data for other systems have shown that the thermal translational mobility of macromolecules in P–P systems is determined, in the case of amorphous linear components, by diffusion coefficients in the range ~10^{-15}–10^{-19} $m^2\ s^{-1}$ at temperatures above T_g and in the range 10^{-12}–10^{-14} $m^2\ s^{-1}$ above T_{fl} (or T_m in the case of crystallisable polymers); this mobility depends on the molecular weight of the diffusing species in accordance with Eqn.(3) and $b < 2$ and is independent of the molecular weight of the medium when $M_{diff.sp.}/M_{medium} \leq 1$. Attention should be drawn to the fact that the translational mobility of the macromolecules in the P–P system is on the whole low on the macroscopic time scale and yet is fairly high on the microscale, particularly at temperatures above T_g, i.e. at the processing temperature and at the real temperatures at which many P–P systems are actually used. This must be taken into account in considering certain features of the formation of the phase structures of polymer blends.

V. THE PHASE STRUCTURE OF HETEROGENEOUS BLENDS OF POLY(VINYL CHLORIDE) AND POLY(METHYL METHACRYLATE)

Blends based on PVC and PMMA, formed from the melt and the solution and in other ways, are heterogeneous systems with a large area of the interface in the range from room temperature to the decomposition temperatures of the components.[12,13,59,82] This agrees well with the limited miscibility of the polymers, which follows from the phase diagrams (Fig. 4*a*). However, the results of indirect measurements of the comptability of PVC and PMMA (Table 1) indicate discrepancies between the absolute compositions of the coexiting phases obtained by different workers.

In this connection it must be emphasised that the low translational mobility of the macromolecules and the high viscosity of P–P systems, which prevent their separation into phases during the finite period of the experiment and which lead to the formation of kinetically stable metastable disperse structures,[83] at the same time are responsible also for the capacity of P–P systems for supercooling. The latter factor should result in the variation of the composition of the coexisting phases as a function of temperature, time, the quality and concentration of the solvent, and other specific processing conditions. The specific features of the translational mobility on the macroscale and the microscale are such that the range of variation of the composition can extend over a large temperature and concentration range: according to the data in Table 1 and the paper of Walsh and McKeown,[84] the composition varies within the limits from incompatibility to complete miscibility. The question arises whether most of the information available today on the compatibility of various P–P systems,[16] including the PVC–PMMA system (Table 1), does not in fact refer to real materials obtained under specific processing conditions and not to equilibrium P–P systems. Examination of this question appears to be extremely important for the understanding of the entire problem of phase equilibria in polymer–polymer systems—from the critical assessment of the methods for the determination of phase diagrams and the type of phase equilibria in P–P systems to the stability of composite materials.

The influence of the conditions in the preparation of blends of PVC and PMMA on the limits of their miscibility has been investigated[13,59] by electron microscopy (Table 1). It has been shown that the character of the disperse structure and also the limits of its manifestation depend on the concentration and rate of evaporation of the solvent; the influence of the quality of the solvent on the miscibility is illustrated in Fig. 2.[22]

The present level of development of analytical electron microscopy combined with methods for the calculation of the dimensions of the disperse phases and X-ray microanalysis for the identification of the phase composition, on the one hand, and also the familiar theories of mass transfer in disperse systems, on the other, make it possible nowadays to proceed tc the analysis of the disperse phase structure of P–P blends from the standpoint of the kinetics of the attainment of phase equilibria.

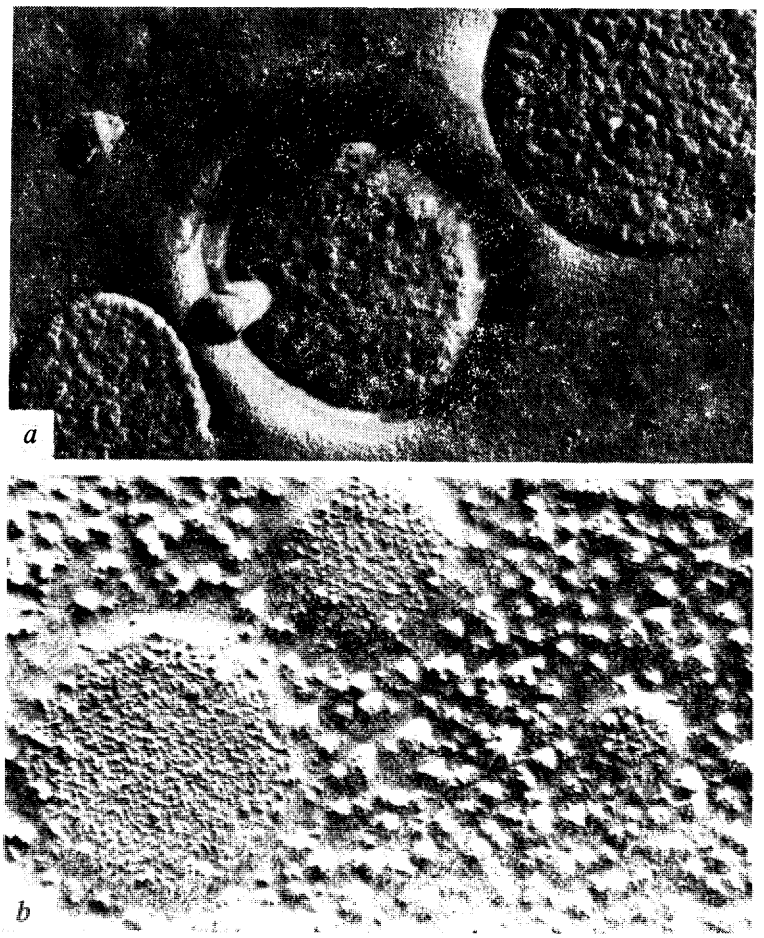

Figure 9. Photomicrographs of the PVC–PMMA system (1 : 3) obtained from solution in cyclohexanone: *a*) before annealing; *b*) after annealing for 30 min at 433 K.[82]

Thus a special study has been made[82] of the influence of the conditions of preparation and thermal annealing on the phase structure of PVC–PMMA blends in comparison with the phase diagrams obtained by Chalykh and Sapozhnikova.[56] The blends prepared from solutions in cyclohexane or THF are initially in a state far from phase equilibrium. X-Ray microanalysis has shown that the compositions of the dispersion medium (PMMA) and the disperse phase (PVC) are supersaturated relative to the corresponding solubility curve on the diagram in Fig. 4*a*. The higher the rate of evaporation of the solvent and the lower the film formation temperature, the greater the deviations from the phase diagram. Thermal annealing of such specimens at a temperature higher by 30 to 40 K than T_g for the components leads to additional phase separation (Fig. 9). The composition of the disperse phases then tends to that of the coexisting phases which follows from the phase diagram at the given temperature. It is striking that an increase of the duration of annealing does not alter the composition of the coexisting phases but does affect the character of the distribution of species with respect to size. A decrease of the concentration of the finely disperse phase and an increase of the size and number of large particles in the PVC–PMMA system take place in conformity with the redistribution of the substance in the direction from the surfaces of the small particles towards the large particles observed for low-molecular-weight systems. The kinetics of this process are described by the Lifshits–Slezov theory, according to which the change in the number of species during prolonged annealing is defined by the equation

$$\partial N/\partial t = (2\sigma D c_p V_m/r^*)\,(RT\partial/\partial r\,[(r-r^*)N(r,\ t)/r^2]), \qquad (4)$$

where σ is the interfacial tension, D the diffusion coefficient, c_p the solubility at $r \to \infty$, V_m the molar volume, r the radius of the particle, and r^* the equilibrium radius of species in the dispersion medium.

The solution of this differential equation for the Gaussian distribution of particles with respect to dimensions is given by the equation

$$N(0)/N(t) = 1 + t/\tau \qquad (5)$$

where

$$\tau = 9RT/8D\sigma V_m^2 c_p r^3(0)\,. \qquad (6)$$

The applicability of the Lifshits–Slezov theory to P–P systems has also been demonstrated to another study[85] in relation to the polybutadiene ($M = 1.5 \times 10^4$)–poly(propylene oxide) ($M = 1.5 \times 10^3$) system. On the basis of electron microscopic

observations on the kinetics of the transformation of the disperse phase structure and on the basis of Eqns.(4)–(6), the phase diagram has been obtained for this system, characterised by a UCST.

Thus it is evident that, by following the kinetics of the changes in the phase structures of polymer blends, it is possible to determine the miscibility of the components; and, conversely, knowing the miscibility and diffusion parameters, it is possible to predict with the aid of Eqn.(4)–(6) the changes which will occur in the disperse system during use.

Fig.10 presents the phase diagram for the PVC–PMMA system and illustrates the position of the spinodal calculated on the basis of the Flory–Huggins–Scott theory from the equation

$$(\chi_{12})_{sp} = \frac{1}{2}\left[\frac{1}{n_1(\varphi_1)_{sp}} + \frac{1}{n_2(\varphi_2)_{sp}}\right].$$

Lines corresponding (according to different authors' data) to the limits of the miscibility in the system, obtained at normal temperatures but using a solvent, are drawn on the diagram parallel to the ordinate axis. Comparison of the positions of these straight lines relative to the binodal and the spinodal in different temperature ranges demonstrates the changes which should occur in the specimens during thermal annealing and also the causes of the quantitative discrepancies between the results of different workers.

It can be seen that, with the aid of solvents, disperse systems corresponding to a metastable state are formed (shaded region between the binodal and the spinodal) over a wide temperature range. This is naturally the reason why the annealing of such systems at temperature above T_g alters the compositions of the coexisting phases in the direction determined by their positions relative to the binodal. Thus the system obtained from a solution in cyclohexanone (straight line 4 in Fig.10) was initially supersaturated relative to the equilibrium compositions of the coexisting phases, which was demonstrated by X-ray microanalysis and electron microscopy. Annealing of such a system at 433–443 K leads to a thermally induced phase separation (Fig.9) and to a decrease of the miscibility limits ω_1'' and ω_2'), while at 473 K it leads to their increase and the dissipation of the particles of the disperse phase.[82] The displacement of ω_1'' and ω_2' along the composition line during annealing is indicated in Fig.10 by arrows.

An analogous displacement of the composition points on the phase diagram has been observed during the annealing of a system prepared from solutions in THF, DCE, and benzene or from the melt after rapid cooling.[22,50,56,82] It is noteworthy that the observed nucleation decomposition and growth of the particles of the disperse phase confirm that the system formed initially was located in the metastable region of the phase diagram.

Thus the phase diagram determines the general trend in the variation of the disperse phase structure of the blend during thermal annealing. Thermally induced phase separation is not then always a sign of a LCST; it can be also a consequence of kinetic processes involving the establishment in the system of the equilibrium compositions of the coexisting phases. It is striking that in this case irreversible changes take place in the phase structure of the polymeric material obtained initially.

At the present time the kinetics of the phase separation of P–P systems via both spinodal and nucleation mechanism have been investigated very little indeed. It follows from a review[86] or another communication[87] that the efforts of investigators have been directed towards the search for and elucidation of the conditions for the spinodal or nucleation mechanisms of the decomposition of P–P systems. However, the question arising from the study of the kinetics of the attainment of phase equilibria in the experimental determination of binodal and spinodal curves remains open. The large number of unexplained contradictory data on the compatibility of polymers, so frequently discussed in the literature[15,16,59,94] (and other communications), is probably in fact associated with this factor.

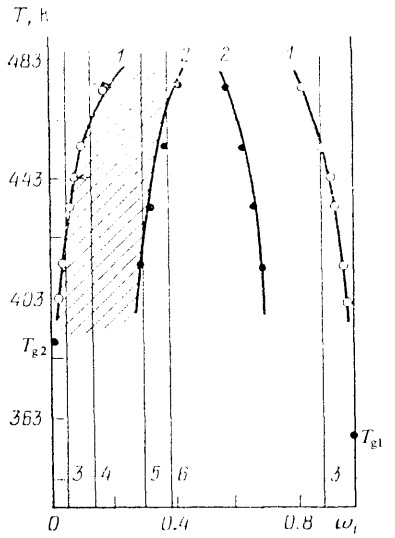

Figure 10. Phase diagram for the PVC–PMMA system: 1) sections of the binodal; 2) sections of the spinodal. The vertical lines correspond to the limits of compatibility of the system obtained using a solvent according to different data: 3) Razinskaya et al.;[13] 4) Matveev et al.;[82] 5) Tager et al.;[14] 6) Shrer et al.[15]

VI. THE INFLUENCE OF IRREVERSIBLE THERMAL DEGRADATION PROCESSES INVOLVING THE CHLORINE-CONTAINING COMPONENTS ON THE MISCIBILITY IN POLYMER BLENDS

The kinetic thermal decomposition processes influencing irreversibly the compatibility of polymers have been examined for at least two reasons. The first is associated with the stability of the phase structure of the blends during their preparation and use and the second with the very problem of the construction of phase diagrams, because the low thermal stability combined with the high viscosity of the polymers actually creates the problem of the attainment of equilibrium under the conditions of isothermal annealing without appreciable chemical transformations. This applies particularly to blends whose composition includes chlorine-containing components (PVC, CPE, etc.), which are capable of intense dehydrochlorination even at $T > T_g$. Numerous data, to a large extent contradictory (see Section II), have now been obtained on the compatibility of polymers with participation of PVC and CPE,[31–33,37,38], but special studies of the influence of their thermal decomposition on compatibility with other polymers have not been made. The application of local X-ray microanalysis made it possible to obtain simultaneously information about the phase diagrams, the diffusion constants, and the thermal stability parameters of chlorine-containing components, which made it possible to demonstrate

quantitatively the influence of thermal decomposition on the character of the phase diagrams of the PVC–PMMA and CPE–PMMA systems.[44,48]

The kinetic curves for the thermal decomposition of PVC at early stages are presented in Fig. 11*a*. The range of times investigated was chosen in accordance with those necessary to obtain equilibrium values of ω_1'' and ω_2'. These data on the kinetics of the decomposition of PVC, obtained with the aid of X-ray microanalysis, are consistent with the familiar data of different workers.[89–91]

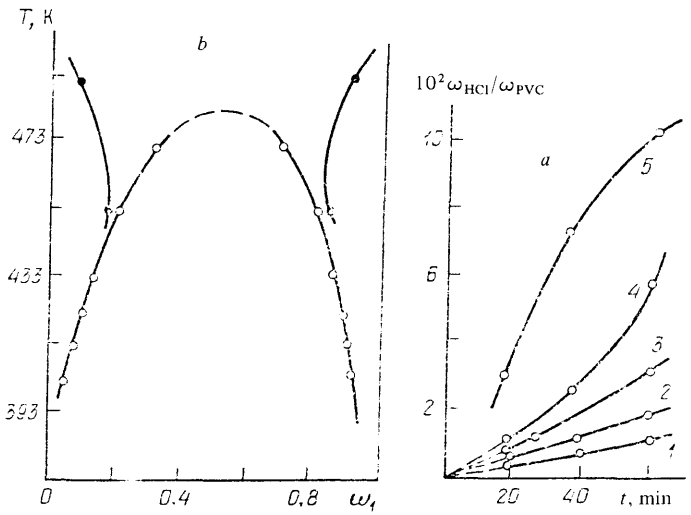

Figure 11. *a*) Kinetic curves for the dehydrochlorination of PVC at different temperatures [*T* (K): 1) 433; 2) 443; 3) 453; 4) 473; 5) 493]; *b*) variation of the phase structure of the PVC–PMMA system after annealing under the conditions of intense thermal decomposition (filled circles).[88]

Fig. 11 shows that annealing at 423–433 K for 60 min and at 443–453 K for 30 min leads to a loss of chlorine equivalent to a weight fraction of only 0.01. Such a change in the chemical structure does not influence the overall form of the binodal characteristic of systems with a UCST. In this case, when the temperature or duration of the annealing exceed the temperature of the chemical decomposition or the induction period of the decomposition reaction (for example, the system has been annealed at 493 K for 20 min or at 453 K for 60 min), the miscibility of the polymers diminishes. The values of ω_1'' and ω_2' obtained under these conditions impart to the phase diagram the "hour glass" character (Fig. 11*b*). However, such a change in the temperature variation of ω_1'' and ω_2' should be explained by the decrease of the miscibility of the components on formation of unsaturated conjugated bonds and partial structure formation in PVC [89] and not by the thermodynamic characteristics, as has been done in a number of studies[32,33,92,94] on blends with chlorine-containing components. Vigorous thermodynamic decomposition processes occurring for certain values of *T* and *t*, limited the possibility of obtaining the complete binodal for the PVC–PMMA system in two investigations.[42,56]

Whereas the PVC dehydrochlorination processes have been studied in fair detail and the variation of the compositions of the coexisting phases illustrated in Fig. 11*b* may prove to be self-evident, in the case of other chlorine-containing polymers, in particular CPE, the relation between the phase equilibrium and the thermal decomposition is significantly more complex.

The miscibility curves for the CPE (62% Cl)–PMMA system and the kinetic CPE thermal degradation curves are illustrated in Fig. 12.[44,88] The phase diagram is complex and resembles the type of diagrams with a "latent maximum", familiar in metallography, which is characteristic of systems undergoing chemical transformations during thermal annealing.

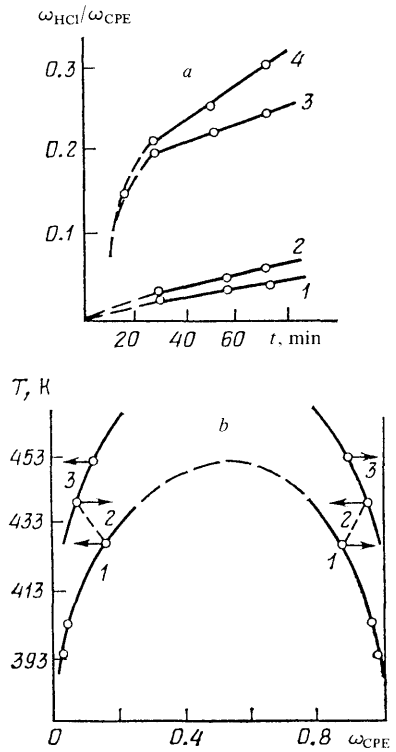

Figure 12. *a*) Kinetic curves for the dehydrochlorination of CPE at different temperatures [*T* (K): 1) 403; 2) 428; 3) 439; 4) 458]; *b*) "composition–temperature" curves for the CPE–PMMA system (for explanation, see text).[95]

We shall consider the dehydrochlorination process occurring during the annealing of the system. It follows from the kinetic curves (Fig. 12*a*) that up to 428 K dehydrochlorination proceeds at a constant rate up to an annealing time of 80 min and the loss of HCl from the CPE specimen amounts to a weight fraction not exceeding 0.03. At 439 K a sharp increase of the rate of elimination of HCl is observed already for short thermal exposures and the loss of HCl is in this case equivalent to a weight fraction of 0.23. An increase of temperature to 453 K hardly alters the degree of dehydrochlorination compared with 439 K. Thus initially a sharp increase of the rate of evolution of HCl is observed (at temperatures above 428 K) and this is followed by retardation, probably owing to the decreased overall chlorine content in the specimens and the appearance of CPE having a higher stability.[93]

We shall now examine Fig.12*b* and compare it with Fig.12*a*. Sections *1* on the "composition–temperature" curve indicate an increase of the miscibility of CPE and PMMA with increase of temperature to 428 K. The chlorine content in CPE is in this case 61%. The jump along sections *2* at 439 K corresponds to a change in the chlorine content in CPE up to 39% (sections *2* are designated in Fig.12*b* by dashed lines because the process is reversible). An increase of temperature to 453 K for an annealing time of 25 min does not alter the chlorine content in the specimen and the values of ω_1'' and ω_2' increase (section *3*). It is seen from the above comparison that this system represents a combination of two systems: CPE (61% Cl)–PMMA and CPE (39% Cl)–PMMA. Like the PVC–PMMA system, the two systems are characterised by phase diagrams with a UCST, but the CPE containing 39% Cl is less compatible with PMMA than the CPE containing 61% Cl. This fact can be satisfactorily accounted for by the extremum in the variation of $(\delta_1-\delta_2)^2$, where δ_1 and δ_2 are the miscibility parameters of PMMA and the CPE decomposition products respectively, with the chlorine content in CPE (Fig.13).

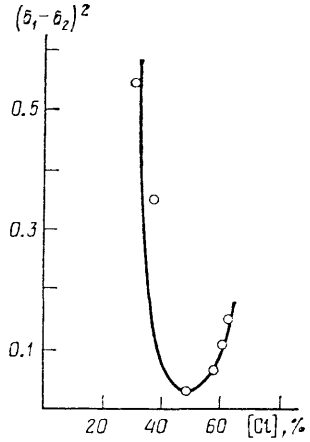

Figure 13. Dependence of $(\delta_1-\delta_2)^2$ on the chlorine content in CPE for the CPE–PMMA system; the values of δ were calculated from the additive contributions by different atomic groups.[95]

Thus it has been shown that the stability of chlorine-containing polymers and their decomposition kinetics have a decisive influence on their compatibility with other polymers and on the character of the phase diagrams for the blends. The extremum in the variation of the miscibility with the chlorine content in the specimen suggests that both trends in the variation of the miscibility operate—both towards its decrease and towards its increase as a function of the thermal decomposition conditions. Thus the slower decomposition of CPE, which depends on the initial PE, the conditions and degree of chlorination, etc., shifts the positions of ω_1'' and ω_2' along section *2* in Fig.13 towards higher values, while longer annealing (for $t > 25$ min), which leads to structure formation in CPE, entails a decrease of ω_1'' and ω_2'. The possible movements of the composition points are indicated by arrows in Fig.13. The combination of the characteristic features of the kinetics of the thermal decomposition of CPE with the complex dependence of the miscibility on the chlorine content in the polymer have in fact enabled the authors[32,33] to obtain a wide variety of types of "phase equilibria" within the limits of the single CPE–PMMA system; diagrams I, III, and V (Fig.1). The results of Chalykh and co-workers[44,88] have shown that the complete description of systems containing unstable components requires a more complex model taking into account the time variation of not only the temperature and composition but also of the chemical structure of the system.

---o0o---

Thus the review has considered many specific phenomena and properties characteristic of P–P systems and determined mainly by the non-equilibrium nature of their phase structure. The non-equilibrium structure, associated with the low translational mobility and thermal stability of the polymers, arises under the real conditions for the formation of the blends and is manifested by a deviation of the compositions of the disperse phase and the dispersion medium from the equilibrium compositions of the coexisting phases. It reflects the previous history of the blends and influences the mode of variation of the properties during further use. This is observed in experimental studies of the miscibility of polymers and constitutes the basis of numerous contradictions in results obtained by different workers. The data on the translational mobilities of the components of polymer blends examined in this review show that, the attainment of real advances in the study of the equilibrium states in condensed P–P systems requires the abandonment of the traditional integrated methods in favour of local methods employed at a microlevel. In this connection it appears useful to develop and apply the methods of analytical electron microscopy in the study of P–P systems. Highly resolving analytical methods make it possible to carry out a combined study of the phase equilibria, translational mobilities, and thermal decomposition processes, which is essential both from the standpoint of the reliability of the phase diagrams and for their practical employment.

General Characteristics of the Changes in the Thermal Stability of Proteins and Enzymes After the Chemical Modification of Their Functional Groups

G.D.Kutuzova, N.N.Ugarova, and I.V.Berezin

The principal structural and physicochemical factors determining the stability of protein macromolecules in solution and the characteristics of the structure of the proteins from thermophilic microorganisms are examined. The mechanism of the changes in the thermal stability of proteins and enzymes after the chemical modification of their functional side groups and the experimental data concerning the influence of chemical modification on the thermal stability of proteins are analysed. The dependence of the stabilisation effect and of the changes in the structure of protein macromolecules on the degree of modification and on the nature of the modified groups and the groups introduced into proteins in the course of modification (their charge and hydrophobic properties) is demonstrated.
The great practical value of the method of chemical modification for the preparation of stabilised forms of biocatalysts is shown in relation to specific examples.
The bibliography includes 178 references.

I. INTRODUCTION

The problem of the stability of globular proteins (and enzymes), i.e. the problem of the determination of the relation between the structure and stability of biomacromolecules, has been and remains one of the most important and complex problems of the modern physical chemistry of biopolymers which have still not been solved. The problem of increasing the stability of enzymes in relation to various denaturing influences is closely related to the first problem as regards practical needs, because, without knowing the fundamental structural factors determining the stability of the protein globule, it is impossible to alter it in a specific manner. The importance and the necessity for the solution of these problems arose as a consequence of the development of modern biotechnology, which involves the carrying out of many enzymic processes under extreme conditions (in particular, at elevated temperatures).

Numerous data show that there is apparently no single general principle governing the formation of a stable protein conformation and hence there is no single universal method for the stabilisation of proteins. The correlations established in recent years between the primary structure and stability of biomacromolecules are valid only for a limited number of proteins within a specific class.[1] Comparison of the primary, secondary, and tertiary structures of enzymes isolated from thermophilic sources and distinguished by a higher stability with their labile analogues reveals a wide variety of structural characteristics of thermophilic proteins and enzymes responsible for their increased stability as well as a few common features. Nevertheless the knowledge of the main structural factors determining the stability of the native conformation of the protein in solution makes it possible to formulate the fundamental principles of its stabilisation.

One of the most widely used methods for the alteration of the properties (in particular, their stability) of proteins and enzymes in solution is the chemical modification of their functional groups not involved in the active centre. The chemical modification is frequently the first stage of the procedure for obtaining stabilised insoluble enzyme preparations. In many cases the change in the stability of the enzyme as a result of covalent immobilisation is caused not only and not so much by its binding (covalent and non-covalent) to the carrier as by the chemical modification of its functional groups. Chemically modified stabilised soluble enzymes have a number of advantages over insoluble enzymes, in particular, they exhibit a high catalytic activity and have a weaker antigenic activity, which is important for medical applications.

The stabilisation of enzymes in nature is achieved as a result of mutations, i.e. the replacement of a small number of some aminoacid residues by "suitable" other aminoacid residues both within and on the surface of the protein globule. Such stabilisation is apparently a consequence of "natural selection" occurring as a result of changes in the conditions of the existence of the given class of microorganisms (for example, following an increase of temperature), whereupon among the multiplicity of isoenzymes modified by mutations, only those which exhibit a sufficiently stable conformation under extreme conditions "survive". On the other hand, the artificial stabilisation of enzymes by chemical modification can be achieved only by modifying the side residues accessible to the modifying agents under the given conditions, whose number in each protein is not quite so large. The set of chemical modification methods suitable for proteins is so far small compared with the scope of natural mutations.

In the reviews[2-5] devoted to the stabilisation of proteins and enzymes in solution which have been published in recent years, the influence of chemical modification on their stability is considered exclusively in phenomenological terms. Some workers assume that it is impossible to predict the effects of the modification.[5] The literature data on this question are not numerous, are incomplete, and are characterised by differences between the criteria used to define the stability of proteins, which hinders their comparison. In the present review the literature and the authors own results concerning the influence of chemical modification on the stability of proteins and enzymes is analysed, which made it possible to formulate certain general rules and the mechanism governing the variation of the stability of biomacromolecules as a result

of the chemical modification of their functional groups. The knowledge of these rules can help investigators to achieve success in the formation of enzyme preparations with a specified stability, having correctly selected the method of modification. From the theoretical standpoint, this is one of the important approaches to the elucidation of the interrelation between the structure and stability of biomacromolecules.

The analysis of studies of the influence of chemical modification on the stability of proteins and enzymes is preceded by the consideration of the main factors which determine the stability of the macromolecules in solution and the possible interrelation between the stability and structural parameters of macromolecules.[6,7]

II. THE STABILITY OF BIOMACROMOLECULES AS A FUNCTION OF THEIR STRUCTURE

1. The Principal Structural and Physicochemical Factors Determining the Stability of Protein Macromolecules in Solution

The native conformation of a protein having the minimum Gibbs free energy G_n under the given physical conditions consists of a three-dimensional structure, determined by the aminoacid sequence and the given microenvironment,[8] which exhibits the flexibility and internal dynamics essential for the manifestation of the functional activity of the protein.[9] Analysis of the three-dimensional structutes of a set of globular proteins have shown that all the aminoacid residues can be divided into three types in terms of their location in the globule: (1) hydrophobic, located preferentially within the molecule (Cys, Ile, Leu, Met, Val, Trp, and Phe); (2) hydrophilic, located preferentially in the surface layer (Asp, Glu, Lys, Asn, Gln, Pro, Arg, Ser, Thr); (3) neutral and ambivalent, indifferent as regards location on the surface or within the inner region of the molecule (Ala, His, Gly, Tyr).[10,11] A tendency towards the preferential cooperation of some aminoacid residues with others is characteristic of proteins,[12,13] which leads to the formation of structural domains in the macromolecule: clusters of hydrophobic or hydrophilic aminoacids.[14,15] Thus a high degree of mutual cooperation has been discovered between the following pairs of residues: Glu–Lys, Met–Arg, Asn–Trp, Gln–Pro.[12]

The transition of the biopolymer, without rupture of covalent bonds, from the native state (N) in which it exhibits its functional activity *in vivo* or *in vitro*, to the denatured (D) state, in which the activity has been lost either reversibly or irreversibly is the denaturation transition.[16,17] The principal feature of a cooperative system is the interaction between individual units whose energy is greater than the energy of thermal movement (kT).[18] The energy of the cooperative interaction is decisive for the operation of a particular kinetic mechanism of the cooperative transition from a disordered to a random state. Three types of interactions are possible in the system: (1) weak; (2) strong; (3) intermediate. In the first case the kinetics of the transition of the system from the ordered to the random state do not differ from those of the rearrangement of an individual unit. In the case of a strong interaction of the units, the system can rearrange as a whole only after an energy sufficient for the disruption of all the bonds of the system has accumulated simultaneously via a fluctuation process. Such transitions (in particular, the fusion of solids) are distinguished by high activation energies. The third, intermediate type of interactions occurs in proteins and the denaturation transition in a protein proceeds via a cooperative mechanism. Nevertheless, proteins resemble solids more closely than liquids and the enthalpy of fusion of the protein structure is a significant factor governing the stability of proteins.[19]

In order to describe the denaturation transition between the N and D states, the "all or nothing" mechanism, put forward *a priori*, is most frequently employed.[20] For the transition to be correctly analysed from the standpoint of the theory of two states and to obtain the true thermodynamic parameters of the transition, the transition must satisfy a number of tests, formulated by Brandts.[20] According to a large number of experimental data, the theory of two states can be used to a first approximation for virtually all globular proteins of small size.[7]

The change in the Gibbs free energy ΔG_{den} on complete and reversible uncoiling of the protein can serve as a measure of the stability of the latter:[6,7]

$$\Delta G_{den} = G_d - G_n,$$

where G_n and G_d are the free energies of the native and denatured forms, ΔG_{den} is the free energy of the stabilisation of the protein, and $a - \Delta G_{den}$ the free energy of its destabilisation. The numerical value of ΔG_{den} for the protein macromolecule is measured as a rule under the conditions involving the disruption of its native structure under the influence of heating, a change of pH, the addition of organic solvents, etc. This quantity is therefore significant only in relation to a specific type of denaturation.[7]

If the denaturation process is reversible, then ΔG_{den} is determined by measuring the constants for the equilibrium between the native and denatured forms of the protein, or by measuring the heat of denaturation with the aid of a scanning microcalorimeter. In the literature, the stability of the proteins is frequently characterised by the average temperature of the transition to the denatured state T_{den} (or T_m), at which 50% of the protein has been denatured and $\Delta G_{den} = 0$, by the temperature of the maximum stability of the protein T_{max} at which ΔG_{den} is a maximum (Fig.1), or by the average concentration of the denaturing agent, etc. In the case of irreversible denaturation (as a consequence of secondary processes) the kinetic stability of proteins is frequently characterised by the rate constants k_{in} for the change in any one property of the protein (the circular dichroism and ultraviolet spectra, fluorescence, and in the case of enzymes also their activity). In the general case the retention of the enzymic activity may not be identical with the stability of the entire protein globule.

The stability of a protein in solution is determined by a number of factors associated with the structural characteristics of the molecule.[20,21] An increase of the conformational entropy (~2–6 e.u. per uncoiled residue) decreases ΔG_{den}. The hydrogen bonds between the peptide groups in the biomolecule (the energy of a single bond is ~1.4 kcal mol^{-1})[17] increase ΔG_{den}.

Depending on the pH of the medium, the long-range electrostatic interactions of the charged groups on the surface of the protein can either stabilise (at pH close to the isoelectric point) or destabilise (at extreme pH values) the native conformation of the macromolecule. The hydrophobic interaction of the non-polar side residues stabilises the native conformation of proteins in aqueous solutions (the ΔG for the system decreases by ~2.8 kcal mol^{-1} when the aliphatic side residue is transferred from water to a non-polar solvent[22]). The intramolecular salt bonds (the energy of a single bond is ~1–3 kcal mol^{-1}), which can be formed either in the form of single electrostatic "fastenings" or within the composition of a spatially limited cluster consisting of several groups of charges of different sign, stabilise the native conformation of the protein. In the clusters a single ionogenic group can be involved in two, three, or four ionic interactions.[23–29]

Specific covalent cross-links in a polypeptide chain (in particular the S–S bonds) stabilise proteins not only as a result of a decrease of the entropy of the uncoiling of the globule[6] but also as a result of the enthalpy contribution (~1.8 kcal mol^{-1} per S–S bond[30]). Prosthetic groups form covalent, ionic, or coordinate bonds with the protein and stabilise the macromolecule as a whole.[31,32] Coordinate bonds involving Ca^{2+}, Mg^{2+} and Zn^{2+} metal ions are very important for the stabilisation of the native conformation of many protein molecules.[33,34]

Thus the total free energy of the denaturation of the protein ΔG_{den} includes the sum of the energies of all the types of interactions indicated above. The stability of the native conformation of a protein is achieved as a result of the displacement of the enthalpy and entropy functions along the temperature scale (Fig.1)[6] and reflects the fine balance between the stabilising and destabilising contributions of interactions of different types. At physiological temperatures, the ΔG_{den} of different globular proteins differ insignificantly and vary from 5 to 15 kcal mol^{-1}.[7] However, even a slight change in the balance between different interactions in the protein can greatly alter its stability, as will be seen below when the experimental data for stabilised proteins and enzymes are considered.

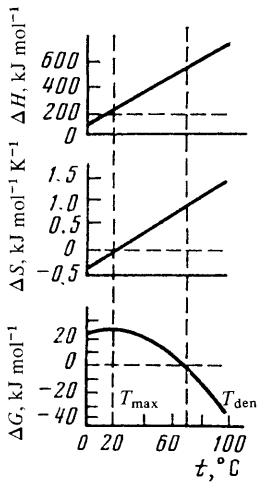

Figure 1. Temperature variation of the enthalpy, entropy, and free energy (ΔG_{den}) of denaturation of cytochrome b_5 (pH 7.4).[6]

Analysis of the principal energy characteristics of the protein structure shows[6] that (1) the protein should be stable under specific external conditions in order to retain its specific structural and functional properties; the energy reserves ensuring the stability of the protein should therefore greatly exceed RT—the minimum necessary value; (2) the protein should not be unduly "rigid", i.e. the structural changes in the course of the functioning of the protein should occur without much energy expenditure and at the same time the protein–water system should be capable of energy exchange in the course of its functioning without its breakdown; (3) since the stability of the protein is not correlated with its molecular weight, the size of the macromolecule should be the smallest possible to ensure its coiling up, transport, and functioning. This principle is realised by the formation of intramolecular domains or a subunit structure.[7] In contrast to the view that the protein structure is "rigid", which was held previously on the basis of X-ray diffraction data, thermodynamic data confirm the existence of fluctuations in the protein structure.[35] The amplitudes of the fluctuations of the atoms about their mean values are greater for less stable proteins and smaller for more stable proteins.[36] In conformity with the proposed mechanism of the dynamic stabilisation of the protein structure,[37] the internal mobility of the clusters of hydrophobic aminoacid residues in the macromolecule is responsible for the overall stability of its native conformation.[38]

The kinetic stability of the protein ($\Delta G^{\neq}_{den}$) is characterised by the inactivation constant k_{in} and the activation parameters determined from the temperature dependence of k_{in}. The kinetic and thermodynamic parameters of the denaturation of proteins vary in parallel as the denaturation conditions are altered,[20,39] which shows that the intramolecular interactions responsible for the thermodynamic stability (ΔG_{den}) determine also the kinetic stability ($\Delta G^{\neq}_{den}$) of proteins.

One of the commonest types of denaturation is thermal denaturation, on which attention has been concentrated in this review. An increase of temperature has different effects on the intramolecular interactions in proteins (Fig.2): (1) the degree of structure formation in water diminishes and up to about 60 °C the strength of the hydrophobic interactions increases; (2) the conformational entropy increases, which makes it possible to attain protein conformations with a higher free energy, i.e. more uncoiled forms of the macromolecule; (3) other intramolecular interactions stabilising the protein (salt, coordination, etc.) are weakened.[40]

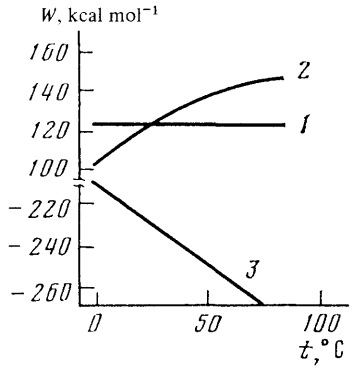

Figure 2. The influence of temperature on the overall contribution W of various factors to ΔG_{den} for native chymotrypsinogen: 1) hydrogen bonds; 2) hydrophobic binding; 3) conformational entropy.[40]

For the majority of globular proteins, the temperature dependence of ΔG_{den} is described by curves (Figs.1 and 3) which pass through a maximum (ΔG^{max}_{den}) at the temperature of the maximum stability of the protein T_{max} and which have upper (T_{den}) and lower temperature limits of the stability of the protein (at $\Delta G_{den} = 0$). T_{max} is usually appreciably lower than physiological temperatures[7] and for many globular proteins is in the range from −3° to +10 °C, which is important for practical purposes and makes it possible to store proteins for a long time at these temperatures.[2] With increase of temperature up to 55 °C, the exposure of the internal aminoacid residues to the solution and the increase of the mobility of the individual sections of the polypeptide chain lead to the reversible local expansion of the native protein macromolecule.[20,41] Above 55 °C, these changes

become irreversible and the protein assumes a fully uncoiled structure.

Water has a destabilising effect on the protein macromolecule. Practical experience has shown that lyophilised proteins keep much longer than in solution. When the water content is more than 0.75 g per gram of protein, the degree of hydration does not affect T_{den} and ΔH_{den} for the protein.[42-44] For a water content below 0.75 g per gram of protein, ΔH_{den} gradually diminishes and T_{den} increases slightly. When the water content is below 0.4 g per gram of protein, T_{den} rises sharply by 30–40 °C. These facts reflect the existence in proteins of various types of bound water. A small number of water molecules are strongly bound to the protein and the system can be regarded as a single whole. The less strongly bound water is distributed over the entire surface of the globule, interacting with its hydrophilic residues. The next layer is transitional in relation to water in bulk.[43] The largest contribution to ΔH_{den} for the protein comes from the ΔH for the disruption of the hydrophobic contacts when the protein is uncoiled, i.e. the ΔH for the ordering of the water molecules around the exposed non-polar groups of the protein. With decrease of the water content, the degree of hydration of the non-polar residues in the denatured state of the protein diminishes, which entails a decrease of ΔH_{den} for the protein.[44] Since the uncoiling of the protein molecules during denaturation is due to the competition between water molecules and protein residues for hydrogen bonds, in the presence of a very low water content the protein molecule is not fully uncoiled.

Although a correlation between the physicochemical properties of proteins and their stability has not been discovered, analysis of data for a large number of proteins suggested the following:[7] (1) in the course of their functioning, proteins forming complexes with other biomacromolecules have as a rule low values of ΔG_{den} (α-lactalbumin, cytochromes *c* and b_5); (2) proteins reacting with low-molecular-weight compounds or with individual sections of other macromolecules have high values of ΔG_{den} (myoglobin, various hydrolytic enzymes).

On the basis of numerous data, a satisfactory correlation has been observed between the stabilities of proteins *in vivo* and *in vitro*.[45-48] This is due to the fact that one of the causes of protein and enzyme inactivation in the cell is the proteolysis of their denatured (uncoiled) conformers, the rate of which is limited by the rate of uncoiling of the native conformation.[47] The turnover rate of the protein *in vivo* is correlated with its T_{den} and with its stability in relation to acid and mechanical denaturation.[46,48] The stability of certain proteins is satisfactorily correlated with the metabolic rate.[49]

However, overall, the thermal stability of the protein is not correlated either with ΔG_{den}, measured under standard conditions, or with T_{den}, i.e. these quantities cannot by themselves serve as objective measures of thermal stability when different proteins are compared.[1,7] For example, cytochrome *c* and lysozyme have the same T_{den} but their maximum values of ΔG_{den} differ approximately by a factor of two. At certain temperatures α-chymotrypsin and lysozyme have almost identical ΔG_{den}, but their T_{den} differ by 20 °C (Fig.3). The thermal stability of the protein is correctly described only by the complete temperature dependence of ΔG_{den} over a fairly wide temperature range. It is particularly important to bear this in mind on comparing the stability of the modified or immobilised enzyme with that of the native enzyme, because the ratio of the ΔG_{den} at a single fixed temperature cannot be extrapolated to other temperatures.

Thus the knowledge of the principal factors responsible for the stability of the native conformation of the protein in solution makes self-evident the general principles by which one should be guided in obtaining protein and enzyme preparations with increased stability over a specific temperature range: (1) the introduction of additional intramolecular bonds (salt and hydrogen bonds) and the enhancement of hydrophobic interactions will increase ΔG_{den} for the protein (one additional bond with an energy of 1–3 kcal mol^{-1} can significantly increase the stability of the protein); (2) a decrease of the conformational mobility of fragments of the polypeptide chain as a consequence of the formation of additional intramolecular (covalent or non-covalent) "cross-links" in the globule (additional S–S bonds, coordinate bonds with metal ions, etc.) will diminish the conformational entropy[6] and hence will increase ΔG_{den}.

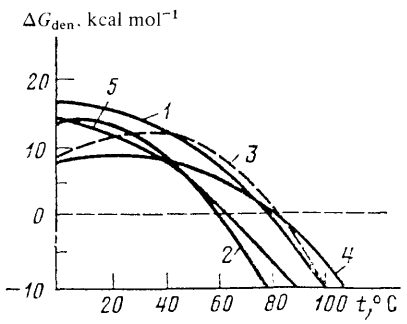

Figure 3. Temperature variation of the free energies ΔG_{den} for globular proteins measured microcalorimetrically: 1) lysozyme; 2) α-chymotrypsin; 3) metmyoglobin; 4) cytochrome c; 5) ribonuclease.[21]

As will be shown below, these principles hold in nature in the formation of proteins and enzymes with increased stability (enzymes from thermophilic microorganisms) and under practical conditions in the preparation of stabilised enzymes by their chemical modification or immobilisation.

2. Relation between the Stability of Biomacromolecules and Their Primary, Secondary, and Tertiary Structures

In order to discover the principal structural factors related quantitatively to the stability of biomacromolecules, a number of attempts have been made in recent years to find a correlation between the stability and the primary, secondary, and tertiary structures of proteins. For this purpose, the aminoacid compositions of proteins with different stabilities were compared and studies were made of the physicochemical causes of the increased stabilities of proteins and enzymes isolated from thermophilic sources and also of the influence of point mutations on the stability of proteins and enzymes.

(a) Correlation between the primary structure and the stability of proteins. An empirical relation between T_{den} and the hydrophobic index X_1 and the average volume of aminoacid residues in the protein X_2 has been discovered for 14 proteins:

$$T_{den} = 226.81 - 0.01270X_1 + 3.847X_2 .$$

It is seen that the main contribution to T_{den} comes from the average volume of the aminoacid residues X_2 and not from their hydrophobic properties. The Glu residues stabilise proteins to the maximum extent, while the Ser residues

destabilise them.[50] However, for a large number of proteins a correlation between T_{den} and X_2 has not been found.[51]

The correlation between the hydrophobic properties and thermal stability of proteins proposed by Bigelow[52] was not subsequently confirmed.[53]

A clear relation has been observed between T_{den} and the ratio S_n/S_d, where S_n and S_d are the surface areas of the protein accessible to the solvent in the native and denatured states respectively: $S_n = 11.116\,M^{2/3}$, while $S_d = 1.44\,M$ (M is the molecular weight of the protein). For 20 of the proteins investigated, T_{den} increases linearly with increase of S_n/S_d, i.e. with decrease of M. The ratio S_n/S_d diminishes with increasing M and there is a decrease of the thermal stability of the protein. For the same ratio S_n/S_d, the quantity T_{den} is greater for subunit proteins than for monomeric proteins. The thermal stability of a long polypeptide chain can be increases in the following way: (1) by the association of the globular subunits to form an oligomer; (2) by coiling up with formation of a multiplicity of globular domains. In such cases S_n/S_d (and T_{den}) increases for an unchanged molecular weight M. The deviations from linearity for certain proteins can be accounted for by the influence on their stability of intramolecular interactions such as those involved in S–S bonds in the binding of metal ions, cofactors, etc.[53]

The microstability of the protein globule differs from its macrostability G_{den} by the fact that the former characterises the local uncoiling of the protein and is determined from the rate of exchange of the protons in the inner part of the macromolecule with water.[54] The microstability, i.e. the "rigidity" of the protein globule, does not characterise the macromolecule as a whole. It depends on the degree of saturation of the protein by non-polar contacts and increases as the hydrophobic nucleus of the macromolecule grows. On the other hand, ΔG_{den} is independent of the hydrophobic properties of the protein globule and is directly related to the number of intramolecular cross-links, which diminish the conformational entropy of ΔS_{conf} of the uncoiling of the polypeptide chain (the binding of M^{n+} ions and cofactors has an analogous influence).[54]

The specific preferential cooperation of various aminoacid residues in proteins with one another, which has been found on the basis of their three-dimensional structure,[12,13] apparently determines the increased or reduced stability of a particular protein with increase of temperature.[55] Comparison of the T_{den} and the aminoacid compositions for a large number of proteins made it possible to establish a relation between the content of each aminoacid residue and T_{den} for the protein. All the aminoacid residues are divided into stabilising (positive correlation with T_{den}) and destabilising (negative correlation with T_{den}). A combination of charged and non-polar helical residues (I), namely Asp, Cys, Lys, GlU, Leu, Arg, Trp, and Tyr has the greatest stabilising effect, while a combination of neutral and short non-polar residues (II), namely Ala, Asn, Gly, Gln, Ser, Thr, Val, and Tyr has a destabilising effect. The overall correlation can be formulated by the equation

$$T_{den} = 64.46202 + 0.89432Y_1 - 0.59065Y_2,$$

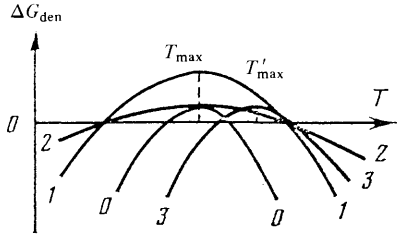
where Y_1 and Y_2 are the percentage contents in the protein of the stabilising (I) and destabilising (II) aminoacid residues. Phe, Ile, Met, His, Asn, and Pro do not influence the stability of the protein.[55] The upper limit of the stability of the protein, corresponding to a 100% content of group I residues, is $T_{den} = 164.3$ °C, while the lower limit of the stability, corresponding to a 100% content of group (II) residues, is $T_{den} = 5.4$ °C. However, the proposed correlation between T_{den} and the aminoacid composition of the proteins is valid only for small compact monomeric proteins. Under these conditions, haem or S–S bonds have a lesser influence on the stability of the protein than its aminoacid composition.[55]

A disadvantage of all the correlations discussed above is that, firstly, they are valid only for a limited group of proteins and enzymes, which is as a rule the group for which the given correlation had been derived. Secondly, T_{den} has been used as a general criterion of thermal stability, but, as already mentioned above, it cannot serve as an objective measure of the stability of the protein over a wide temperature range (Fig.3). The determination of a simple thermal stability–temperature correlation is apparently impossible owing to the complex relation between ΔG_{den} for the protein and temperature:[7]

$$\Delta G_{den}(T) = \Delta H_{den}(T_{den} - T)/T_{den} - \int_T^{T_{den}} \Delta C_p \, d\,T + T \int_T^{T_{den}} \Delta C_p \, d \ln T.$$

In the future, it will probably be necessary to establish a relation between $\Delta G_{den}(T)$, and not T_{den} for proteins, and the structure of the macromolecules. In addition, by virtue of the multiplicity of the structural factors responsible for the stability of the native conformation of the protein, the existence of such a correlation is possible only for a limited number of isotypical globular proteins.

(b) Physicochemical causes of the increased stability of the enzymes derived from thermophilic sources. From the standpoint of the determination of the stability–structure function, comparison of the structures of proteins and enzymes isolated from thermophilic micro-organisms (t-enzymes) and exhibiting an increased thermal stability with their mesophilic analogues (m-enzymes), having structures similar to those of the t-enzymes, is more promising. Such a comparison makes it possible to discover the principal structural characteristics of t-enzymes responsible for their increased thermal stability.



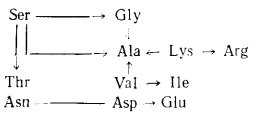


Figure 4. Hypothetical curves for the temperature variation of ΔG_{den} for globular proteins from thermophilic sources: *0*) mesophilic protein; 1) thermophilic protein with a higher value of ΔG_{den} (rise of curve *0*); 2) thermophilic protein with a higher temperature range of stability (the levelling off of curve *0*); 3) thermophilic protein with a displaced stability maximum (shift of curve *0* from T_{max} to T'_{max}).[60]

The thermal stability of microbial enzymes is correlated with the temperatures corresponding to the existence of the micro-organisms.[56] At low culture temperatures (<50 °C) m-enzymes are synthesised, while at high culture temperatures (>50 °C(t-enzymes are synthesised.[57,58] t-Enzymes are also stable in relation to other types of denaturation, namely denaturation by urea, guanidine hydrochloride, and organic solvents and under the influence of pH.[59]

The increased thermal stability of a t-protein compared with an m-protein can result from the operation of the following factors (Fig.4): (1) the increase of the activation energy for the denaturation process; (2) the increase of the free energy of denaturation ΔG_{den}; (3) the equalisation of the free energy of denaturation profiles; (4) a shift of the ΔG_{den} profile.[60] The stability of the majority of t-enzymes increases as a result of the higher position of the curve describing the temperature dependence of ΔG_{den} (from curve *0* to curve *1* in Fig.4). Additional hydrophobic, hydrogen, salt, and S–S linkages, which are present in t-enzymes but not m-enzymes, lead to such alteration of ΔG_{den}. On the other hand, ΔG_{den} for t-enzymes can vary in accordance with curve *2* (Fig.4) as for *t*-phosphoglycerate kinase.[60]

Thermophilic proteins and enzymes have high thermodynamic and kinetic stabilities. Since in terms of the absolute temperature scale, the difference between 35 °C (T_{den} for m-enzymes) and 80 °C (T_{den} for t-enzymes) is relatively small (~15%), even small differences between the activation energies and ΔG_{den} for t- and m-enzymes can lead to appreciable differences between their thermal stabilities for a small difference between their structures. Calculation shows that a decrease of k_{in} by a factor of ten at 70 °C requires an increase of ΔG_{den} by only 1.56 kcal mol^{-1}. In order to increase T_{den} from 35° to 45 °C for a polypeptide chain with $M = 35\,000$, it is necessary to increase the number of hydrogen bonds by only 3%. The differences between ΔG_{den} and $\Delta G^{\neq}_{den}$ for proteins amounting up to 10 kcal mol^{-1} can be obtained following the replacement of one or two aminoacid residues in the molecule.[53]

(c) The fundamental differences between the structures of enzymes from thermophilic and mesophilic sources. The fundamental differences between the aminoacid compositions of t- and m-enzymes have been discovered following a comparison of the aminoacid compositions of a large number of t- and m-enzymes. In relation to ferredoxins, glyceraldehyde-3-phosphate dehydrogenases, and lactate dehydrogenases, the following directions of the preferential exchange of aminoacid residues on transition from m- to t-enzymes have been discovered:[61]

The above changes enhance the hydrophobic properties of the residues and their capacities for helix formation and folding. Under these conditions, the volume of the internal residues increases somewhat and a more compact packing is achieved in the structure of the protein globule. The principal role of the stabilising additional ion pairs in these t-enzymes has been demonstrated on the basis of structural investigations.[62] A higher content of Ala and Gly and charged residues is characteristic of t-lactate dehydrogenase (LDH), while m-LDH contains more Ser, Thr, Gln, Asn, and polar residues. Although the content of hydrophobic residues is the same in the two enzymes, in the t-enzyme they exist only within the globule, while in the m-enzyme they are also present on the surface. The spatial dispositions of the charged and polar residues are also different in t- and m-LDH:[62] in t-LDH the charged residues are located only on the surface of the molecule, while in m-LDH they are also present inside it. Thus the distribution of the aminoacid residues in the t-LDH molecule is thermodynamically more favourable.

Analysis of the aminoacid compositions of 14 t-enzymes and 207 m-enzymes showed that the thermophilic enzymes contain more Gly, Arg, Glx but less Asx and Ser.[63] A positive correlation between the thermal stability and the ratio of Arg and Lys in the protein has also been noted.[64] Arginine is the most hydrophilic aminoacid and its location on the surface is more favourable compared with Lys. The resonance structure of the guanidinium ion enables it to form more than one bond with anionic residues. t-Enzymes are also characterised by a higher content of α-helices and of the β-structure than m-enzymes. The increased Glu content in t-enzymes increases their capacity to bind metal ions. It may be that this is one of the principal causes of the increased stability of t-enzymes.[63]

A positive correlation between the thermal stability and the aliphatic index of the protein A, determined from the formula

$$A = \chi_{Ala} + a\chi_{Val} + b(\chi_{Ile} + \chi_{Leu}),$$

where $a = 2.9 \pm 0.1$, $b = 3.9 \pm 0.1$, and χ represents the content of Ala, Val, Ile, and Leu residues in the protein (in molar percentages), has been established for 34 t-enzymes and 208 m-enzymes. Since the content of the above residues in t-enzymes is much higher than in m-enzymes, each t-enzyme has a greater aliphatic index than its mesophilic analogue.[65]

Comparison of the tertiary structures of t- and m-enzymes revealed two additional salt and hydrogen bonds in t-ferredoxin.[53,66] The increased stability of t-triose phosphate isomerase is due to additional salt and hydrophobic linkages between the subunits.[66] Two additional intersubunit and intrasubunit salt linkages stabilise t-glyceraldehyde-3-phosphate dehydrogenase,[21,67–69] while additional salt linkages, hydrophobic interactions, and bonds with additional Ca^{2+} ions are responsible for the stabilisation of thermolysin.[70–72] The additional salt linkage between Asp (201) [Asn(201) in the m-enzyme] and the His residue increases the activation energy for the thermal denaturation of t-tyrosinase.[73] Among the ten ion pairs in t-LDH, eight are formed by Arg residues, while in different m-LDH only 2, 4, or six ion pairs, containing Lys instead of Arg, have been found.[62] The principal role in the stabilisation of t-LDH has been attributed to additional surface salt linkages formed by Arg residues and also to an enhancement of the intramolecular hydrophobic interactions as a consequence of the decrease of the number of hydrophobic residues on the surface of the globule and of its increase within the globule.[62] The greater thermal stability of other thermophilic enzymes, whose tertiary structures have not been studied in detail, compared with m-enzymes has been explained by the greater number of hydrogen bonds and the stronger intersubunit interaction in the case of enolase,[74,75] the greater number of intramolecular cross-links (S–S bonds) in the case of the iron–sulphur protein[76] and glutamine synthetase,[77] the protective effect of the surface carbohydrates in β-glucosidase,[78] or the change of conformation in the case of dehydrogenase.[79]

Thus the high thermal stability of the enzymes from thermophilic microorganisms is due to the exceptionally small number of additional (compared with m-enzymes) bond both within the macromolecule and on its surface. For the majority of t-proteins, these are mainly salt linkages, which follows from a comparison of the tertiary structures of t- and m-enzymes.

(d) Point mutations and the stability of the protein. The study of the influence of point mutations (which alter only 1–2 aminoacid residues in the polypeptide chain) on the stability of the protein can also yield valuable information about the relation between structure and stability. In contrast to t-enzymes, where the natural selection of the most

stable form from the multiplicity of mutant forms takes place, the artificial mutations are random in their influence on the stability of the protein, which relates them to chemical modification.

The replacement of a single Trp (138) residue by Tyr in the lysozyme of the T4 phage (a polypeptide without S–S bonds) diminishes ΔG_{den} (and T_{den}) over the entire temperature range from 0° to 60 °C by 2–3 kcal mol^{-1} (Fig.5).[80] Here ΔH_{den} diminishes by 20 kcal mol^{-1}. The replacement of a further two Trp residues by Tyr diminishes ΔG_{den} to a still greater extent at all the temperatures studied (Fig.5). Although the overall conformation of the lysozyme hardly changes after the mutations, one of the possible explanations of the marked decrease of ΔH_{den} after the mutation and of its compensation by the simultaneous decrease also of ΔS_{den} might be the local uncoiling of the molecule.[80]

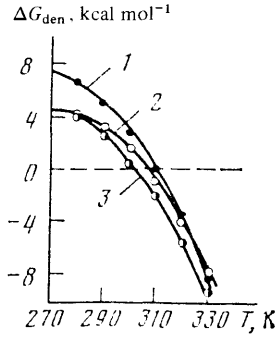

Figure 5. Temperature variation of ΔG_{den} for the native (curve *1*) and mutant (curves *2* and *3*) forms of lysozyme at pH 2.0: 2) Trp (138) replaced by Tyr; 3) Trp (138), (126), and (158) replaced by Tyr.[80]

The single-point replacements of Glu (128) by Lys, of Arg (96) by His, and of Ala (146) by Thr in the T4 phage lysozyme do not alter its tertiary structure but diminish T_{den} by 5°, 14°, and 9° respectively.[81,82] The first mutation increases ΔH_{den}, while the second and third diminish it. The greatest destabilising effect (T_{den} diminishes by 14°) is shown by the replacement of Arg (96) by His. According to the authors, this can be explained by a weakening of the hydrophobic interactions in the molecule and the possible rupture of the α-helix between the aminoacid residues in the 82–90 position.[81]

The replacement of Glu (49) by Met in the α-subunit of tryptophan synthetase from *E.coli* yields a mutant which is twice as stable (at 58 °C) in relation to thermal denaturation and the denaturation by urea.[82] The spatial structure of the enzyme does not then change. According to the authors, the enhancement of the hydrophobic interactions in the mutant following the replacement of the hydrophilic Glu in the hydrophobic nucleus by Met is responsible for the observed stabilisation effect. The nature of the aminoacid residue in the 49-position revealed an interesting relation: the replacement of the charged Glu (49) by the uncharged polar residues Tyr, Ser, and Gln increases the stability of the α-subunit of tryptophan synthetase in relation to guianidine hydrochloride at pH 9.0, while at pH 7.0 and 5.5 it destabilises the enzyme, which is shown most strikingly in the case of Gln.[84] On the other hand, the replacement of Glu (49) by the hydrophobic aminoacid residues Met and Val greatly increases (by 5 kcal mol^{-1}) the stability of tryptophen synthetase relative to guanidine hydrochloride at all pH (particularly at pH 7.0 and 9.0). According to the authors,[83] Glu (49) is in a hydrophobic environment and any diminution of the hydrophilic properties of the residue in the 49-position will therefore naturally induce an increase of the stability of the enzyme. The replacement of Gly (211) in the α-subunit of tryptophan synthetase by Arg or Glu increases somewhat the thermal stability of the enzyme (at 57.8 °C ΔH_{den} increases by 0.1 and 0.6 kcal mole^{-1}, while T_{den} increases by 0.2° and 1.8 °C respectively).[85] On the other hand, ΔH_{den} increases by 17 and 15 kcal mol^{-1} as a result of these mutations. It has been shown that the conformations of the native enzyme and the two mutants are similar. The segment of the chain containing Gly (211) is apparently located on the surface of the molecule and does not participate in any appreciable interactions, so that the replacement of Gly by the more bulky charged Glu and Arg residues induces only small changes in the non-covalent interactions on the surface of the protein.[85]

Studies on point mutations have shown that even the replacement of one aminoacid residue induces an appreciable change in the stability of the protein. Depending on the location of the replaced residue, its immediate environment, and the nature of the substituting residue, the stability either increases or decreases after the mutation as in the case of chemical modification (this will be demonstrated in the next Section). Mutations increasing the polarity within the protein globule (the hydrophobic nucleus) diminish its stability, while those which enhance its hydrophobic properties stabilise it. The mutations of the surface aminoacid residues have only a weak influence on the stability of the macromolecule.

In conclusion it must be emphasised that the stability of the protein is very sensitive not only to changes in its conformation but also to slight variations in the primary structure (as can be seen in relation to point mutations). Therefore a change in the stability of the protein (in particular, its thermal stability) constitutes a sensitive test for the changes in the structure of the protein, which may be below the limits of the resolution of both structural analysis and other physicochemical methods.[7,86]

III. THE MECHANISM OF THE CHANGES IN THE THERMAL STABILITY OF PROTEINS AND ENZYMES AFTER THE CHEMICAL MODIFICATION OF THEIR FUNCTIONAL GROUPS

The chemical modification method is used widely for the identification of the groups in the active centres of enzymes and for the investigation of the topography and conformations of biomacromolecules.[87] In connection with the problem of the stabilisation of biocatalysts, increasing attention has been devoted in recent years to the chemical modification of the functional groups of the protein which do not enter into the active centre.[2–4] Only the surface groups of the protein or those near the surface under the given conditions are as a rule accessible to chemical modification. Depending on the conditions (pH, temperature, etc.), the number of surface groups, i.e. groups accessible to the solvent, can vary.

The reactive groups of the protein can be divided into three components: (1) acid groups (the COOH groups at the C-ends and in the Asp and Glu residues); (2) basic groups (the α-NH_2 groups at the N-ends, the Lys and Arg residues, and the OH groups in the Tyr, Ser, and Thr residues and in the carbohydrates in glycoproteins); (3) neutral groups (the imidazole group in His).[88] The reagents most frequently used for the chemical modification of proteins and enzymes in order to stabilise them or alter their structure are listed in Table 1.

Table 1. The changes in the structure and stability of proteins and enzymes as a result of the chemical modification of their functional groups.

Protein	Modifying agent	Modified residue[a]	Derivatives obtained	Degrees of modification: not influencing structure and thermal stability	Degrees of modification: increasing thermal stability[b]	Degrees of modification: uncoiling and destabilizing the molecule[b]	Refs.
Bovine serum albumin	Succinic anhydride[c]	Lys (59)	$E-NH_3^{\oplus} \rightarrow E-NHCOCH_2CH_2COO^{\ominus}$	Up to 60% (up to 30–34 residues)	—	more than 80%	[90—92]
	Methyl acetimidate[c]	»	$E-NH_3^{\oplus} \rightarrow E-NHC(NH_2^{\oplus})CH_3\ Cl^{\ominus}$	up to 100%	—	—	[92]
	Butyric anhydride	»	$E-NH_3^{\oplus} \rightarrow E-NHCOCH_2CH_2CH_3$	up to 90%	—	more than 90%	[93]
Human immunoglobin G	Succinic anhydride[c]	Lys[?] (90)	$E-NH_3^{\oplus} \rightarrow E-NHCOCH_2CH_2COO^{\ominus}$	up to 87% (up to 78 residues)	—	more than 87% (expansion of molecule, decrease of β-folds owing to electrostatic repulsion)	[90]
	Citraconic anhydride[c]	»	$E-NH_3^{\oplus} \rightarrow E-NHCOCH=C(CH_3)-COO^{\ominus}$	Low degrees of modification	—		[94]
	Potassium iso-cyanate[c]	»	$E-NH_3^{\oplus} \rightarrow E-NHCONH_2$	up to 100%	—	—	[94]
	Acetylacetone[c]	Lys (29)	$E-NH_3 \rightarrow E-N=C(CH_3)CH_2COCH_3$	—	—	from 1 to 6 Lys	[95]
Leucine-binding protein	»	Arg (7)	$E-NHC(NH_2^{\oplus})NH_2 \rightarrow E-NH-C(N-C(CH_3)=CH-C(CH_3)=N)$	up to 3 Arg	—	—	[95]
11S globulin	Acetic anhydride[c]	Lys[e]	$E-NH_3^{\oplus} \rightarrow E-NHCOCH_3$	up to 21%	—	more than 21%	[96]
Ovalbumin	Succinic anhydride[c]	Lys[e] (19)	$E-NH_3^{\oplus} \rightarrow E-NHCOCH_2CH_2COO^{\ominus}$	Up to 66%	—	More than 66% (uncoiling of protein globule)	[97]
Cytochrome *c*	Tetranitromethane	Tyr (4)	$E-C_6H_4-OH \rightarrow E-C_6H_3(NO_2)-OH$	—	1 residue (increase of T_{den})	2 residues (extensive uncoiling	[98]
Cytochrome *c*-552	Acetic anhydride[c]	Lys[e] (4)	$E-NH_3^{\oplus} \rightarrow E-NHCOCH_3$	Up to 100%	—	—	[99]
Horse cytochrome *c*	4-Chloro-3,5-dinitrobenzoic acid	Lys (19)	$E-NH_3^{\oplus} \rightarrow E-NH-C_6H_2(NO_2)_2-COO^{\ominus}$	2 residues (7 and 60) remote from top and bottom of of haem crevice	2 residues (27 and 72) on frontal surface near exposed portion of haem moiety (formation of new surface salt bonds)	Lys (13) on top of haem crevice [rupture of Lys (13)–Glu (90) salt bond greatly widens haem crevice); lysines 8, 86, and 87 on top of crevice (destabilisation as a consequence of decrease of electrostatic potential in this region)	[29, 100, 101]
	Succinic anhydride	Lys	$E-NH_3^{\oplus} \rightarrow E-NHCOCH_2CH_2COO^{\ominus}$	Up to 95% (up to 18 residues), stability does not change relative to denaturation by urea	—	100%	[102]
	Maleic anhydride[c]	Lys	$E-NH_3^{\oplus} \rightarrow E-NHCOCH=CHCOO^{\ominus}$	—	—	Modification of all 19 residues	[103]
Myoglobin	Bromoacetate	His (12)	$E-C_3H_3N_2^{\oplus} \rightarrow E-C_3H_3N_2-N-CH_2-CO-OCH_3$	Up to 50–58% (6–7 residues)	—	—	[104]
	Iodoacetamide		$E-C_3H_3N_2^{\oplus} \rightarrow E-C_3H_3N_2-N-CH_2-CO-NH_2$	Up to 50–58% (6–7 residues)	—	—	[104]
β-Lactoglobulin	Succinic anhydride	Lys[e] (16)	$E-NH_3^{\oplus} \rightarrow E-NHCOCH_2CH_2COO^{\ominus}$	—	1–3 residues (small increase of stability relative to denaturation by urea)	From 4 to 10 residues (lower stability); more than 10 residues (uncoiling of protein also in absence of urea)	[102]
Ribonuclease	Succinic anhydride	Lys[e] (11)	$E-NH_3^{\oplus} \rightarrow E-NHCOCH_2CH_2COO^{\ominus}$	Up to 100% (relative to denaturation by urea)	—	—	[102]

Table 1 (contd.)

Protein	Modifying agent	Modified residue[a]	Derivatives obtained	Degrees of modification: not influencing structure and thermal stability	Degrees of modification: increasing thermal stability[b]	Degrees of modification: uncoiling and destabilizing the molecule[b]	Refs.
	Acetic anhydride	Lys	$E-NH_3^{\oplus} \rightarrow E-NHCCH_3$ (O)	—	Low degree of modification: some stabilisation	All 11 residues	[105]
	N-Acetylhomocysteine thiolactone	Lys	$E-NH_3^{\oplus} \rightarrow E-NHCCHCH_2CH_2SH$ (O; NHCOCH$_3$)	—	8 residues: increase of stability	—	[106]
Glucoamylase	Acryloyl chloride	Lys	$E-NH_3^{\oplus} \rightarrow E-NHCCH=CH_2$ (O)	Up to 66 residues	—	More than 66% of residues: stability falls sharply; 100% of residues: stability diminishes by a factor of 2.5 at 65 °C	[107]
Horseradish peroxidase	Acetic and oenanthic anhydrides	Lys (6), OH groups of Tyr(5), Ser (25), Thr (25), and carbohydrate residues	$E-NH_3^{\oplus} \rightarrow E-NHCOCH_2 \cdot R$; $E-OH \rightarrow E-OCOR$	Up to 2 Lys residues, up to 30 surface OH groups	3–4 Lys residues (below 75 °C, k_{in} falls with increase of degree of modification); stabilisation as a result of increase of strength of haem–protein bond	6 Lys residues, more than 30 OH groups (when internal OH groups are also involved)	[34, 108, 109]
	Trinitrobenzenesulphonic acid	Lys (6)	$E-NH_3^{\oplus} \rightarrow E-NH-SO_2-C_6H_2(NO_2)_2$	—	3 residues, same effects as in previous case	6 residues: decrease of stability (weakening of haem-protein bond)	[108]
α-Amylase	*p*-Nitrophenyl acetate	Lys	$E-NH_3^{\oplus} \rightarrow ENHCOCH_3$	—	—	With increase of degree of modification from 1.5 to 11.5 residues, the protein conformation approaches that of denatured form, k_{in} increases below 67 °C, and $\Delta H^{\neq}$ and $\Delta S^{\neq}$ diminish	[110, 111]
Myosin	β-Naphthoquinone-4-sulphonic acid	Lys			Thermal stability increases with increase of degree of modification from 1 to 15 residues	—	[112]
Lactate dehydrogenase	*O*-Methylisourea	Lys	$E-NH_3^{\oplus} \rightarrow E-NH-C(=NH_2^{\oplus})-NH_2$	—	4–5 residues per subunit: sharp increase of stability (formation of stronger salt bonds between COO^- and guanidine groups introduced; from 5 to 15 residues slight increase of stability	—	[113]
Lactate dehydrogenase	Methyl 4-hydroxy-3-nitrobenzimidate	Lys	$E-NH_3^{\oplus} \rightarrow E-NH-C(=NH_2^{\oplus})-C_6H_3(OH)(NO_2)$		With increase of degree of modification from 5 to 30 residues, stability increases by a factor of 2–6 at 60 °C		[114]
α-Chymotrypsin	Succinic anhydride	Lys[c] (17)	$E-NH_3^{\oplus} \rightarrow E-NHCCH_2CH_2CO^{\ominus}$ (O; O)	Up to 50% modification; for 100% modification the structure is close to native structure, slight increase of stability	From 60 to 95%: sharp increase of thermal stability (~20 times)	More than 95%: sharp fall of stability (approximately down to that of native protein)	[115, 116]
	Acrolein (with subsequent reduction by $NaBH_4$)	Lys	$E-NH_3^{\oplus} \rightarrow E-NH_2^{\oplus}-CH_2CH=CH_2$	Up to 50%: slight increase of stability	From 50 to 95%: sharp increase of thermal stability (~120 times for 95% modification); cause: change in conformation after modification	More than 95%: sharp fall of stability (down to that of native protein)	[116]

[a] The total number of given residues in the protein is indicated in brackets.

[b] The physicochemical causes responsible for the given change in the structure and stability of the protein are indicated in brackets.

[c] The thermal stability was not investigated in these studies.

[d] Alkylation entails the modification, apart from the NH_2 groups of Lys, of the SH groups of Cys and OH groups of Tyr, Ser, and Thr,[117,118] which was not taken into account by the authors of the given investigations.

[e] E = enzyme or protein.

Carboxylic acid anhydrides and chlorides, iminoesters, aldehydes, and chloro- and sulpho-derivatives of tri- or di-nitrobenzenes are employed for the modification of the amino-groups. The Arg residues are modified by various diketones. The nitration or iodination of proteins lead to the modification of the Tyr and Trp residues. The Ser and Thr residues and the OH groups of the carbohydrate residues in glycoproteins are acylated by acid anhydrides and chlorides. Bromoacetate and iodoacetamide modify the His residues. The carboxy-groups in the Leu and Asp residues are modified by means of carbodiimides or the Woodward reagent.[119,120] The above groups of proteins are also used in covalent immobilisation and the alteration of the stability of the biocatalyst can be to a large extent associated with the modification of its primary structure.

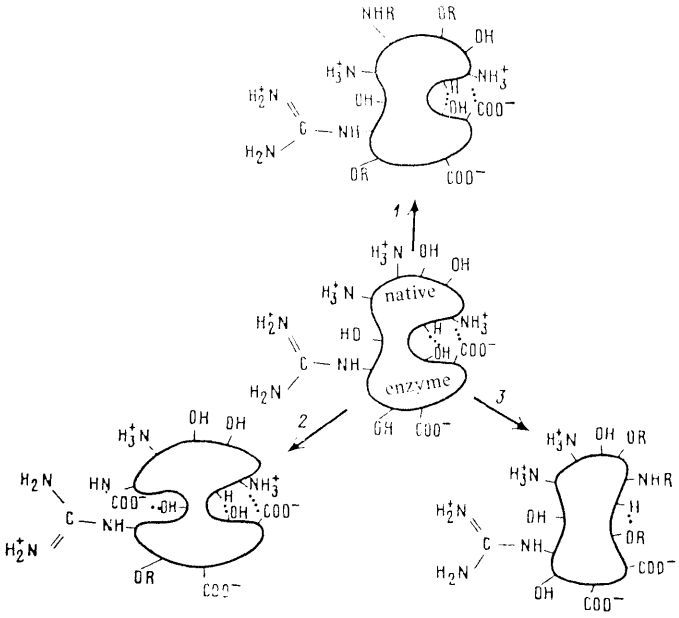

Figure 6. Schematic representation of various types of functional groups of enzymes; types of groups modified: 1) type I; 2) type II; 3) type III.[121]

The same functional groups of proteins and enzymes play different roles in the stabilisation of their native structures depending on their location in the globule and on whether or not they are involved in intramolecular interactions stabilising or destabilising the macromolecule. It is possible to isolate three types of functional groups accessible to modification (Fig.6). *Functional groups of type I* are located on the surface of the globule. These are effectively hydrated polar or charged groups, which do not interact with one another under the given conditions and interact only with the solvent or with ions from the solution. *Functional groups of type II* are located on or near the surface of the protein. In the native enzyme they have an unfavourable environment (charged groups in a hydrophobic environment or in an environment of groups bearing like charges) and destabilise the protein globule. The number of groups of this type in the protein is usually small. *Functional groups of type III* are remote from the surface of the globule and form intramolecular salt or hydrogen bonds stabilising the enzyme. These groups are inaccessible to modification under the usual conditions and are modified only for a loosened conformation of the protein (at an elevated temperature, at extreme pH values, or in the presence of organic solvents).

Chemical modification of functional groups of different types has different effects on the structure and stability of the enzyme. The observed effect also depends on the nature of the residues introduced into the enzyme on modification. Modification of groups of type I in the general case causes little alteration in the conformation and stability of the enzyme regardless of the dependence on the nature of the modifying agent and the degree of modification. If a large number of bulky hydrophobic residues or residues bearing a like charge are introduced into the enzyme at the same time, partial uncoiling of the molecule and its destabilisation can take place. In the same case, when the residues introduced form additional non-covalent bonds (salt and hydrogen bonds) with the neighbouring groups of the protein, the stability of the enzyme can actually increase. A large stabilisation effect is to be expected on modification of groups of type II when the interactions destabilising the native conformation are eliminated. On modification of groups of type II, the degree of modification, the charge, and the hydrophobic properties of the residues introduced actually exert a great influence on the thermal stability. Modification of groups of type *III* should diminish the thermal stability of the enzyme as a result of the breakdown of the intramolecular bonds stabilising its native conformation. The structure of the enzyme approaches the denatured structure after such modification.

Consequently, depending on which role particular functional groups play in maintaining the native structure of the enzyme, their modification either does not influence the thermal stability (groups of type I) or stabilises (groups of type II) or destabilises (groups of type III) the enzyme. It is to be expected that for each specific enzyme the ratios of the groups of each type are different. A low degree of modification of particular groups of the enzyme is most likely to involve groups of type I, a moderate degree of modification involves groups of types I and II, while exhaustive modification can result also in the modification of groups of type III in the enzyme. After the modification of groups of type III in the protein, the entire system of intramolecular stabilising interactions breaks down and the destabilising effect arising as a consequence of the modification of these groups can therefore overlap the stabilising influence of the modification of groups of type II.

Analysis of the data in Table 1 shows that in the general case there is a possibility of three types of modification of the functional groups of the protein: (1) modification with a change in the charge in the aminoacid residues which alters the electrostatic interactions of the groups on or near the surface of the protein and its isoelectric point and can therefore change the conformation of the globule;[89] (2) modification with introduction of hydrophobic groups into the protein, which can have different effects on the properties of the latter depending on the location and nature of the hydrophobic group introduced, exerting the greatest influence on the conformation, the solubility, and the surface characteristics of the protein; (3) the introduction of hydrophilic groups into the protein molecule, which has little influence on its properties, since the surface of the protein globule is hydrophilic.

The above analysis of the problem of the stability of globular proteins and of the characteristics of the structure of t-proteins permits certain hypotheses concening the possibility of the stabilisation of enzymes as a result of their chemical modification: (1) the stability can increase on formation in the protein after modification of even a small

number of additional non-covalent linkages; (2) modification with introduction of charged groups can exert a great stabilising influence provided that the formation of additional salt bonds is possible; (3) the replacement of the amino-groups of Lys by arginine-like groups following the introduction of amide or guanidine groups should increase the stability of the protein; (4) other conditions being equal, imparting of hydrophobic properties to the protein molecule can hardly appreciably increase its stability. These features have been confirmed in practice, as will be shown below.

The main difficulty in the analysis of literature data is that of comparing the results obtained by different workers on different objects, because almost no systematic and comprehensive investigations of the influence of modification on the structure and stability of proteins are described in the literature. The authors have used different stability criteria, although, as already mentioned, only ΔG_{den} and, in the case of irreversible thermal inactivation, $\Delta G^{\neq}_{den}$, can serve as objective measures of stability. The equilibrium constant K_{den}, related to ΔG_{den}, can be conveniently used as a quantitative characteristic of the thermal denaturation process:

$$\ln K_{den} = -\frac{\Delta G_{den}}{RT},$$

while the rate constant k_{in}, related to $\Delta G^{\neq}_{den}$, can be used for irreversible thermal inactivation:[3]

$$\ln k_{in} = \ln \frac{k_B T}{h} - \frac{\Delta G^{\neq}_{den}}{RT},$$

where k_B is the Boltzmann constant.

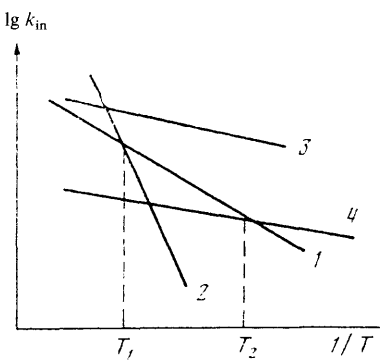

Figure 7. Hypothetical Arrhenius lg k_{in} relations for the native (line *1*) and modified or immobilised (lines *2–4*) enzymes; T_1 and T_2—isokinetic temperatures for the low-temperature (T_1) and high-temperature (T_2) stabilisation.[3]

When the thermal stabilities of the native and modified enzymes are compared, it is essential to compare the temperature variations of $\Delta G_{den}(K_{den})$ or $\Delta G^{\neq}_{den}(k_{in})$. The stabilisation effect θ^t at a given temperature is defined as the ratio of k_{in} for the native enzyme to k_{in} for the modified enzyme, i.e. $\theta^t = k_{in,nat}/k_{in,mod}$. If this ratio is greater than unity, then the modification stabilises the enzyme at a given temperature, while in the case where it is less than unity modification has a destabilising effect. The greater $\Delta G^{\neq}_{den}$, the more stable the enzyme (the smaller the value of k_{in}). The change of $\Delta G^{\neq}_{den}$ after the modification of the enzyme can be caused by the dominant alteration of the enthalpy term ($\Delta H^{\neq}$) or the entropy tern ($\Delta S^{\neq}$) in accordance with the equation

$$\Delta G^{\neq}_{den} = \Delta H^{\neq} - T\Delta S^{\neq}.$$

The quantity $\Delta H^{\neq}$ is determined from the experimental activation energy for the thermal inactivation process E_a: $\Delta H^{\neq} = E_a - RT$. When E_a for the thermal inactivation process is altered following the modification of the enzyme, one can observe two possible cases (Fig.7):[3,86]

(1) An increase of E_a (and $\Delta H^{\neq}$) for the modified enzyme. Depending on the scale in the change of $\Delta S^{\neq}$, the Arrhenius relations for K_{in} for the native and modified enzymes intersect outside or within the limits of the experimental temperature range (Fig.7, curves *1* and *2*). The modified enzyme is more stable than the native enzyme below the isokinetic temperature. The stabilisation effect increases with decrease of temperature. This is the case of the "low-temperature stabilisation" of the enzyme.

(2) A decrease of E_a (and $\Delta H^{\neq}$) after modification (Fig.7, curves *1* and *3*). The stabilisation effect can be observed only above the isokinetic temperature and is greater the higher the temperature at which it is considered. This is the case of the "high-temperature stabilisation".[3]

If $\Delta H^{\neq}$ changes little after modification, then the stabilisation (destabilisation) effect is due solely to the decrease or increase of $\Delta S^{\neq}$. Consequently, the study of the temperature variation of k_{in} makes it possible to discover the conditions under which the modified enzyme is more stable than the native enzyme and the extent to which this happens (and conversely). The knowledge of the temperature variation of k_{in} makes it possible to estimate objectively the enzyme stabilisation (or destabilisation) effects after the enzyme has been modified. The inadequate amount of information derivable from many literature stability data can be explained by the fact that they have been obtained at a single temperature.

1. Analysis of Experimental Data for the Influence of Chemical Modification on the Structure and Thermal Stability of Proteins and Enzymes

Studies of the influence of chemical modification by monofunctional agents are considered in this Section. We shall not deal with the results obtained on modification by bifunctional agents, because the effects of covalent intermolecular or intersubunit binding as well as the effect of the formation of intramolecular cross-links are superimposed on the single-point modification effects, which hinders an unambiguous interpretation of the results.

(a) The influence of the degree of modification on the structure and stability of proteins and enzymes. The modification of ~50% of the side residues frequently does not alter the conformation, the hydrodynamic properties, and the sedimentation constant of the protein (Table 1). The most accessible surface groups of type I are apparently modified in this case. For a number of proteins and enzymes (cytochrome *c*, horseradish peroxidase, and chymotrypsin), local changes in conformation are observed for a specific degree of modification indicating an increase of the number and energy of the intramolecular bonds.[29,108,109,116] At the same time, an increase of the stability of the macromolecules has been noted: the dominant increase of $\Delta H^{\neq}_{den}$ compared with $\Delta S^{\neq}_{den}$. In this case groups of type II were apparently modified. Table 1 shows that proteins and enzymes contain few groups of type II (from one to five). For high degrees of modification, involving internal groups which are masked

in the native conformation and which are involved in the main protein stabilising interactions, the conformation of the macromolecule changes sharply approaching that of the denatured macromolecule. The stability of the protein diminishes as a result of the dominant decrease of $\Delta H^{\neq}_{den}$ compared with that of $\Delta S^{\neq}_{den}$ (Table 1). Consequently, functional groups of type III are modified in this case.

Various acylating agents are used most frequently for modification (Table 1). Many workers assume *a priori* that only the NH_2 groups of Lys are modified and yet the SH groups of Cys and the OH of Tyr, Ser, Thr, and carbohydrate residues are also readily acylated[34,117,118] and a change in the properties of the acylated proteins can be caused by the modification of all the groups indicated and not only the amino-groups. When account is taken of this factor, the literature data might be interpreted somewhat differently. The influence of the degree of modification on their stability has been studied only for a small number of proteins and enzymes (Table 1). Some of these studies must be considered in greater detail.

Interesting results for the influence of the degree of modification on the structure and stability have been obtained for cytochrome *c*—a protein with a known tertiary structure. The stability of cytochrome *c* is determined by the stability of its conformation with a closed structure of the haem crevice[29,101] and is determined by two bonds: the salt bond between Lys (13) and Glu (90) "on top" of the crevice and the hydrogen bond between Lys (79) and the carbonyl residue (47) at the "bottom" of the crevice. The modification of Lys (13) results in a sharp broadening of the crevice and the destabilisation of the protein (k_{in} increases in the temperature range 25–60 °C). The modification of two Lys residues remote from the "bottom" and the "top" of the haem crevice does not influence the conformation and stability of the protein. The two NH_3^+ groups of Lys on the frontal surface of the molecule destabilise the latter as a consequence of electrostatic repulsion and the reversal of their charge therefore stabilises cytochrome *c* as a consequence of the diminution of the repulsion or the formation of new surface salt bonds. The modification of the three Lys residues located "on top" of the crevice in the region of the protein stabilising the Lys (13)–Glu (90) salt bond somewhat diminishes its stability as a consequence of the competition between the negatively charged carboxydinitrophenyl residues introduced and Glu (90) for Lys (13).[29]

With increase of the degree of modification of the amino-groups in bacterial α-amylase by *p*-nitrophenyl acetate to 10.5 groups at 75 °C, the thermal stability improves.[110] The temperature variations of k_{in} for α-amylases with different degrees of modification intersect in one point at 67 °C and have $E_a(\Delta H^{\neq})$ smaller than the native enzyme and to a greater extent the greater the degree of modification.[111] This means that, at temperatures below 67 °C, the thermal stability of the acetylated α-amylase is lower than that of the native enzyme and to a greater extent the higher the degree of modification. Above 67 °C the opposite relation between the thermal stability and the degree of modification is observed.[110] This is an example of the "high-temperature stabilisation". According to the authors,[111] the decrease of $\Delta H^{\neq}(\Delta S^{\neq})$ for the thermal inactivation process from 83 to 46 kcal mol^{-1} on modification of 11.5 Lys residues is due to a change in the conformation of the enzyme to give a partly uncoiled activated state.

We have shown that the "low-temperature stabilisation" of horseradish peroxidase is observed after the modification of Lys residues by trinitrobenzenesulphonic acid (TNBSA) or by oenanthic anhydride.[108] The Arrhenius plots for the $\lg k_{in}$ for the native enzyme and peroxidases with different numbers of modified Lys residues intersect, as for α-amylase, at the isokinetic point (75 °C). The modification of two amino-groups hardly alters $\Delta H^{\neq}$ and $\Delta S^{\neq}$ for the thermal inactivation of the enzyme. For peroxidase with 3–4 modified groups, $\Delta H^{\neq}$ and $\Delta S^{\neq}$ are much greater than for the native enzyme and increase with increasing degree of modification (Fig.8). The stability of peroxidase modified in this way is many times greater than that of the native enzyme at all temperatures below 75 °C and the difference between their stabilities is greater the lower the denaturation temperature. For example, at 50 °C, the modified enzyme is ~100 times more stable than the native enzyme. The modification of all six Lys residues present in peroxidase diminishes $\Delta H^{\neq}$ and $\Delta S^{\neq}$ for thermal inactivation and hence the thermal stability of the enzyme (Fig.8). Thus, we have been able to isolate three types of Lys residues in peroxidase in terms of their accessibility and role in the stabilisation of the globule: two residues on the surface of the enzyme, whose modification does not alter the thermal stability regardless of the nature of the modifying agent (groups of type I); two residues whose modification stabilises the enzyme and the stabilisation effect depends on the nature of the residues introduced (groups of type II); two residues located within the globule whose modification destabilises peroxidase (groups of type III). The increase of thermal stability after the modification of 3–4 Lys residues is correlated with the changes in the circular dichroism spectra of peroxidase indicating an increase of the strength of the haem-protein bond after modification.[108,109] This relation can be understood because the rate-limiting stage in the peroxidase thermal inactivation process is the dissociation of the haem–protein complex with subsequent denaturation and aggregation of the apoprotein.

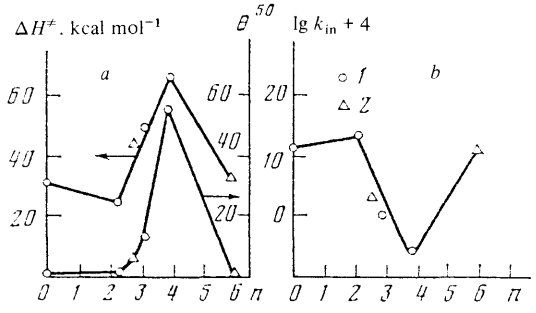

Figure 8. The influence of the number *n* of modified ε-NH_2 Lys groups in peroxidase on $\Delta H^{\neq}$ for irreversible thermal inactivation and on the stabilisation effect ($\theta = k_{in,nat}/k_{in,mod}$) at 50 °C (*a*) and on $\lg k_{in}$ at 50 °C (*b*) (pH 7.0); the peroxidase was modified with oenanthic anhydride (*1*) and TNBS (line *2*).[121]

We have shown[34] that the acetylation of peroxidase entails the modification at 0–22 °C, together with that of the Lys residues, also of the surface OH groups (up to 30 groups) of Tyr, Ser, Thr, and the carbohydrate component of the enzyme, which belong to type I: regardless of its extent, their modification does not influence the thermal stability of the enzyme over the entire experimental temperature range (60–80 °C).[34] With increase of temperature (40 °C), the internal groups are acylated in addition to the three surface NH_2 and OH groups (groups of type I and II): one OH group of Tyr and the OH groups of other residues (groups of

type III). The stability of peroxidase then diminishes by a factor of ~8 at 50 °C compared with the native protein and by a factor of 100 compared with the peroxidase having three acylated amino-groups. The observed destabilisation effect is due exclusively to the modification of the internal OH groups of the enzyme.[34] After the removal of the modification of these groups with the aid of hydroxylamine, the thermal stability of the enzyme again rises sharply (by a factor of 100), i.e. becomes the same as that of the peroxidase with three modified amino-groups (Fig.8). The one internal OH group of Tyr is particularly important for the stability of native peroxidase.

The virtually complete modification of the amino-groups of α-chymotrypsin by succinic anhydride causes little alteration to the structure of the molecule (as can be seen from absorption and circular dichroism spectra) and to its kinetic properties.[115] Following the alkylation of 60% of its amino-group by acrolein and succinylation, the thermal stability of chymotrypsin increases insignificantly. For a degree of modification of 60–95%, the thermal stability of the enzyme increases sharply (by factors of 20 and 100 respectively) and after the complete substitution of the amino-groups it falls to the level for the main enzyme.[116] The authors introduced the concept that the enzyme contains several "key" groups whose modification sharply increases its thermal stability.

Thus the structure and stability of proteins and enzymes depend significantly on the degree of modification of their functional groups. For a large number of other proteins, the dependence of the thermal stability on the degree of modification also passes through a maximum (Table 1): for ribonuclease,[102,105,106] glucoamylase[107] and guanidinated lactate dehydrogenase.[113,114] Groups of types I, II, and III can be detected in virtually every protein.

Local chemical modification. Like point mutations, such modification makes it possible to discover the role of individual aminoacid residues in the stabilisation of the native conformation of the protein. On transamination, the N-terminal amino-group of the main pancreatic inhibitor of trypsin is replaced by the keto-group, which entails the removal of one salt or hydrogen bond. In the presence of 6 M guanidine hydrochloride, T_{den} diminishes after modification from 75° to 68 °C, while at pH 1.0 neither the native nor the modified protein are denatured up to 82 °C. Consequently, the $NH_3^+ \ldots COO^-$ salt bond stabilises the inhibitor at neutral pH but not at acid pH, where the COOH group is protonated. The authors believe that one salt bond with an energy of ~1 kcal mol^{-1} can play an important role in the stabilisation of the native conformation of the inhibitor.[122]

Three other local modifications have also been carried out in the pancreatic inhibitor: (1) one S–S bond was reduced; (2) one Lys–Ala peptide bond was cleaved; (3) the Ala (16) and Arg (17) residues were removed from the active centre. Only local changes were then observed in the conformation near the region of the modifications, while the overall conformations of the modified molecules corresponded to the structure of the native inhibitor. On the other hand, the stability of the globular conformation of the modified protein diminished appreciably and the exchange of the internal amide protons of the protein with the solvent became faster.[123]

After the reduction of the S(14)–S(38) bond [compound (I)], the SH groups formed in the inhibitor were modified by means of charged residues: with iodo acetamide [a neutral group was introduced—compound (II)], with iodoacetic acid [a negatively charged group was introduced—compound (III)]; with ethyleneimine [a positively charged group was introduced—compound (IV)]. The three-dimensional structures of the reduced compound (I) and the three modified proteins proved to be almost identical, but T_{den} was altered: T_{den} = 76 °C for compounds (I) and (II), T_{den} = 79 °C for compound (III), and T_{den} = 70 °C for compound (IV). Thus the maximum stability of the reduced inhibitor was attained when the SH groups were modified with negatively charged groups, because the S–S bond cleaved is located in the positively charged cluster made up of Lys and Arg residues and the groups introduced form with the latter new ion pairs which stabilise the protein. At the same time, the introduction of a positively charged group destabilised the inhibitor for the same reason.[124]

The local chemical modification clearly demonstrates the fact that the modification of the groups involved in protein stabilising interactions diminishes the stability of the protein. An increase of the stability of the protein after modification is observed only on formation of new additional bonds, particularly salt bonds.

(b) The influence of the nature of the residues introduced on modification. The nature of the modifying agent has an appreciable influence on the stability of the macromolecules, particularly in the modification of groups of type II. The possible instances of modification can be divided into several groups: (1) modification with retention of the charge of the modified groups; (2) modification of uncharged residues by uncharged agents; (3) modification involving a change in the charge of the modified groups; (4) modification with change in the hydrophobic properties of the residues introduced.

Modification with retention of the charge of the modified groups. Mainly three modification reactions are used to modify the Lys residues with retention of their positive charge. Amidination with the aid of iminoesters:

$$E\text{—}NH_3^+ + R'\text{—}O\text{—}C(=NH_2^+)R \rightarrow E\text{—}NH\text{—}C(=NH_2^+)R \quad (1)$$

Guanidination with *O*-methylisourea:

$$E\text{—}NH_3^+ + CH_3O\text{—}C(=NH)NH_2 \rightarrow E\text{—}NH\text{—}C(=NH_2^+)NH_2 \quad (2)$$

Modification with aldehydes followed by reduction of the Schiff bases formed:

$$E\text{—}NH_3^+ + RCHO \rightarrow E\text{—}N{=}CH\text{—}R \xrightarrow{NaBH_4} E\text{—}NH_2^+\text{—}CH_2\text{—}R \quad (3)$$

In the first two cases arginine-like groups are introduced into the protein and the p*K* of the Lys residues increases from 10.5 to 12.5 after modification.[125] In the third case the primary amino-group is replaced by a secondary amino-group whose p*K* is somewhat reduced.

We may recall that an increased content of Arg residues compared with Lys residues is characteristic of many t-enzymes (Section II). For example, for less stable proteinases (pig chymotrypsin and trypsin), the Arg : Lys ratios are 4 : 14 and 2 : 14 respectively, while for the more stable enzyme elastase the ratio is 12 : 3.[126] It is therefore logical to expect an increase of the stability of the proteins and enzymes after the guanidination of the Lys residues. Indeed, after the modification of the Lys residues in seven proteins of six different classes with *O*-methylisourea, their stability increases (ΔG for the internal and external tritium exchange increases). This is due to the decrease of the conformational mobility of the local segments of the protein structure.[126]

The guanidination of 15 Lys residues in lactate dehydrogenase does not alter appreciably the protein conformation but greatly increases the thermal stability of the enzyme, which the authors believe to be caused by the formation of the $COO^- \ldots NH_2{=}C(NH_2)E$ salt linkages both within the subunits and between them.[113] A somewhat smaller stabilisation

effect has been observed on acetamidination of the same enzyme.[127] On the other hand, the modification of lactate dehydrogenase with formaldehyde followed by the reduction of the azomethine bonds decreased its thermal stability and even induced partial dissociation of the tetramer.[128] Thus the important role of salt bonds in the stabilisation of the protein has been demonstrated in relation to lactate dehydrogenase: the greater the charge on the modified Lys residues, the stronger the electrostatic interactions stabilising the macromolecule.

The acetamidination of a number of other enzymes (thermophilic glutamine synthetase[129] and peroxidase[34]) also increased their thermal stability and only local changes in the protein conformation were then observed. The increase of the stability of trypsin after the acetamidination of Lys was explained, in particular, by the decrease of its autolysis.[130]

On the other hand, the excess guanidination of proteins by converting their COOH groups into amino-groups with subsequent modification using *O*-methylisourea should apparently lead to their destabilisation as a consequence of the electrostatic repulsion of a large number of positively charged groups, as has been shown for chymotrypsinogen.[131]

Thus the amidination and guanidination of proteins, in which their physicochemical properties are fully retained, can serve as a simple and convenient general method for their stabilisation. The stabilisation mechanism apparently consists in the fact that the arginine-like residues are more hydrophilic than Lys, which reduces the possibility of finding them within the hydrophobic nucleus of the molecule compared with Lys. The arginine-like residues increase the rigidity of the protein globule and, having a higher p*K* than Lys, form stronger salt bonds in the protein.[126]

Less unambiguous results have been obtained in the study of the stability of proteins in which the Lys residues were subjected to the reductive alkylation [reaction (3)].

Thus modification of aminogroups with propionaldehyde or glutaraldehyde decreased the thermal stability of chymotrypsin at 60 °C by a factor of 1.5–3 depending on the pH, while modification with acrolein increased its thermal stability by a factor of 100 under the same conditions.[116,132] Modification with glutaraldehyde decreased the thermal stability of trypsin[133] but increased that of glycogen phosphorylase b [134] and β-glucosidase.[135] Unfortunately, the data for the stability of proteins modified by glutaraldehyde are difficult to interpret owing to the complexity and ambiguity of the processes occurring during modification.[88]

In the general case one should note that the positive charge on the amino-groups of proteins is retained during their alkylation, but hydrophobic residues are introduced whose presence on the surface of the macromolecule is frequently inconvenient. After modification, the capacity of the amino-group for the formation of salt bonds also diminishes. These are apparently in fact the main causes of the decrease of the thermal stability of the majority of proteins and enzymes after reductive alkylation.

Modification of the uncharged residues with uncharged agents. In this case one is dealing primarily with the modification of polar OH groups in the Ser, Thr, and Try residues, as well as the residues of aromatic aminoacids and the carbohydrate groups in glycoproteins. The main reactions used for this purpose were (1) acylation with monocarboxylic acid anhydrides, (2) oxidation of carbohydrate residues, and (3) nitration or iodination of Tyr or Trp residues.

The acylation of up to 30 surface OH groups by monocarboxylic acid anhydrides in horseradish peroxidase does not influence its thermal stability.[34]

Many plant proteins and enzymes contain covalently bound carbohydrate residues which form a polar "coat" round the macromolecules protecting them from proteolysis and stabilising their tertiary structure.[136] The oxidation of carbohydrate residues by sodium periodate or their removal with the aid of enzymes therefore as a rule diminishes the thermal stability of glycoproteins: invertase,[136] cellulase from thermophilic fungi,[77] t-glucosidase from *Mucor miehei* UN-10,[137] and catalase.[138] As was to be expected, the destabilisation effect depends on the degree of modification of the carbohydrate residues. For example, the deglycosylation of 20% of the carbohydrate residues in the catalase of *A.niger* does not influence the stability of the enzyme while after the oxidation of 40% of the carbohydrate residues, $T_{1/2}$† diminishes after 10 min from 75° to 72 °C.[138] The destabilisation effect for glucose oxidase, 50% of the carbohydrate residues of which are oxidised by periodate, is observed only in the presence of denaturing agents: sodium dodecylsulphate or urea. In this case $\Delta H^{\neq}$ for the enzyme diminishes by a factor of 1.3.[139,140] In certain cases, for example, for horseradish peroxidase, the oxidation of carbohydrate residues does not alter the thermal stability of the enzyme.[141]

On the other hand, the covalent addition of polysaccharides to proteins and enzymes as a rule increases their thermal and pH stability as well as their resistance to proteolysis.[2,7] The cause of the universal stabilising action of polyols bound covalently to the protein has become clear in the study of the influence of added sucrose and other polyols on the stability of proteins in solution. It has been established that sugar solutions are a less favourable solvent than water for aromatic and aliphatic aminoacids.[142] Sugars increase the surface tension of water and the degree of structure formation in it near the surface of aminoacid residues of the protein to a greater extent the larger the number of equatorial OH groups in their molecule. This makes the uncoiled (denatured) conformation of the macromolecule thermodynamically less favourable and shifts the equilibrium between the native and denatured protein towards the former, which increases ΔG_{den}.[143] Thus the stabilisation of proteins in sugar solutions or after the covalent binding of sugars is due to the enhancement of the intraglobular hydrophobic interactions. The stabilising action of added glycerol involves a different mechanism: glycerol reduces the surface tension of water and interacts mainly with the polar groups on the surface of the protein molecule.[143] An increase of the glycerol concentration in the protein solution diminishes $\Delta H^{\neq}_{den}$ (and $\Delta S^{\neq}_{den}$) for cytochrome P-450.[144,145]

The nitration of thermolysin with tetranitromethane decreases by a factor of two its activity and thermal stability, while the percentage content of the α-helix remains unaltered. It has been shown that the Tyr and Trp residues are modified in the enzyme, being probably present in the hydrophobic region of the molecule. For this reason, their modification following the introduction of the nitro-group destabilises the enzyme.[146]

Modification with alteration of the charge on the modified groups. The change in the charge (its removal or reversal) of the functional groups of the protein takes pldce on modification of the charged Lys, Arg, Glu, and Asp residues and on acylation of the polar Ser, Tyr, and Thr residues with dicarboxylic acid anhydrides. The modification which alters the sign of the modified group makes it possible to discover the influence of both the overall charge of the molecule and of the local electrostatic interaction on the structure and stability of the protein. The charged and polar residues are located as a rule on the surface of the protein globule and can be involved in local interactions, stabilising or

† $T_{1/2}$ is the temperature at which 50% of the enzyme is inactivated during a specific selected time interval.

destabilising the native conformation of the molecule. Since salt bonds both within the globule and near the surface of the macromolecule play a significant role in its stabilisation, their formation or rupture as a result of modification should be markedly reflected in the stability. The majority of studies of the influence of modification on the stability of proteins and enzymes have been devoted to the acylation of their amino-groups, whose positive charge is removed or reversed. Such modification can also involve the SH and OH groups.[118]

One of the first studies dealt with the stability of acylated trypsin.[147–149] Admittedly, the data obtained are not easy to interpret unambiguously since the blocking of the Lys amino-groups in trypsin diminishes autolysis apart from anything else, which increases the stability of the enzyme.[147] For example, acetyltrypsin is more stable than the native enzyme in an alkaline medium at 25 °C, but is less stable in an acid medium. Its thermal stability is also lower than that of the native enzyme. Modification of trypsin by various monocarboxylic and dicarboxylic anhydrides showed that, for the same degree of modification of the amino-groups at 100 °C and pH 5.5, the monocarboxylic acid derivatives are the least stable. Their stability increases in the sequence acetyltrypsin, propionyltrypsin, butyryltrypsin, diethylacetyltrypsin, phthalyltrypsin << β-sulphopropionyltrypsin < itaconyltrypsin < native trypsin < succinyltrypsin < citraconyltrypsin.[148,150] Succinyltrypsin is more stable than the native enzyme also at pH > 5. According to the authors, the electrostatic repulsion of the equally charged COO^- groups introduced is a factor stabilising the enzyme. On the other hand, acylation has little influence on the denaturation of trypsin by urea.[149] Thus, the removal of the charge from the amino-group diminishes the thermal stability of the protein, while its replacement by a negative charge increases somewhat the thermal stability.

The acetylation of alkaline phosphatase increases its thermal stability at 30 °C and at pH from 4.0 to 11.0. The authors believe that the protecting effect of acetylation and alkaline pH is common to many proteins, which is surprising in view of the fact that acetylation greatly increases the overall negative charge of the enzyme molecule, which is in any case high at alkaline pH.[151] Acylation increases the stability of thermolysin,[152] but diminishes the thermal stability of subtilisin and ferredoxin.[153,154]

Invertase from baker's yeast has been modified by citraconic anhydride, acetaminoester, and carbodiimide in the presence of ethylenediamine. The reversal of the sign of the charge on the NH_3^+ and COO^- groups significantly destabilised the enzyme (65 °C), while modification with retention of the positive charge on the amino-groups did not affect the stability. The authors conclude that the native structure of invertase is stabilised by the $NH_3^+ \ldots COO^-$ salt bonds whose rupture on modification of either amino- or carboxy-groups destabilises the enzyme.[155]

For the same degree of modification of the NH_2 groups of α-chymotrypsin, the greatest stabilising effect was shown by the modification of the enzyme with acrolein (the positive charge is retained).[116,153] The weakest stabilisation was observed on acylation with acetic, succinic, and citraconic anhydrides, possibly because, in contrast to the first modification, functional groups other than the NH_2 group were acylated in the enzyme and their modification might have destabilised the latter.

The thermal stability of pepsin increases at 30 °C by a factor of 10–20 (depending on the excess of the nucleophile employed) when its COOH groups are modified with the aid of carbodiimide and methyl glycinate. The stabilisation of the enzyme is due to the decrease of the overall negative charge after modification, because native pepsin is rapidly denatured at pH 7.0 as a consequence of the electrostatic repulsion of the large number of negatively charged COOH groups.[156]

The removal of the charge, as a result of the modification, from the lysine (13) residue, which forms the main salt bond maintaining the closed structure of the haem crevice in cytochrome *c*, fully destabilises the protein. On the other hand, modification involving the removal of the charge from Lys residues destabilising the native protein results in a further closure of the haem crevice.[29]

For each degree of modification of the amino-groups of pig heart lactate dehydrogenase, the neutralisation of the positive charge after their modification with methyl 4-hydroxy-3-nitrobenzimidate (the aminophenoxide form) (Table 1) as well as acetylation greatly destabilise the enzyme. On the other hand, the aminophenol form of the modified amino-groups (the positive charge is retained) increases the stability of the enzyme like its acetamidination and guanidination.[114]

The removal of the positive charge from virtually all the amino-groups of malate dehydrogenase after acetylation or modification with methyl 4-hydroxy-3-nitrobenzimidate diminishes $T_{1/2}$ for the enzyme (after 20 min) by 16–17° and 7 °C respectively. The decrease of stability is apparently caused by the breakdown of intersubunit interactions in which the Lys residues are involved.[157]

The influence of the charge on the amino-group on the thermal stability of horseradish peroxidase has been determined by comparing the stabilities of the enzyme whose four amino-groups have been modified with acetimidate and butyric, succinic, and maleic anhydrides.[34,158] Whilst retaining the positive charge on the amino-group, acetamidination adds the small methyl residue and increases the length of the "foot" at the positive charge by ~1.5 Å. After modification with butyric anhydride, the positive charge of the amino-group disappears, while modification with succinic and maleic anhydrides results in the introduction of a negative charge. All three types of residues introduced have a similar structure. After acetamidination, $\Delta H^{\neq}$ for the thermal inactivation of peroxidase increases and hence the thermal stability at temperatures below 75 °C increases somewhat; it increases by a factor of 2.5 after modification with butyric anhydride and by a factor of 3 after modification with succinic and maleic anhydrides. This can be explained by the decrease of the local and not the total positive charge of the macromolecule. It may be that the two amino-groups of the peroxidase are located in the hydrophobic cavity or in a positively charged cluster of groups and destabilise the native structure of the enzyme. Their modification with removal of the positive charge or the introduction of a negative charge promotes the formation of additional salt bonds in the molecule, which increase the strength of the haem–protein bond, i.e. the thermal stability of the enzyme. Even a slight increase of the length of the "foot" at the positive charge of the amino-group after acetamidination increases somewhat the thermal stability of peroxidase. On the other hand, the appearance of a negative charge on a large number of surface OH groups of peroxidase on succinylation does not affect the thermal stability of the enzyme.[34]

Thus data for the modification of the functional groups involving a change in the charge demonstrate the different roles of the charged aminoacid residues in the stabilisation of the native structure of enzymes. In trypsin, subtilisin, invertase, and lactate and malate dehydrogenases, the amino-groups of the Lys residues are involved in the formation of intramolecular salt bonds or in maintaining the three-dimensional structure of the native enzyme. The removal of the charge from these groups destabilises the enzymes. On the other hand, in a number of enzymes (peroxidase,

cytochrome *c*, chymotrypsin, pepsin, etc., amino- or carboxy-groups destabilising the native protein as a consequence of unfavourable electrostatic interactions have been discovered. Their modification, involving a change in the charge, makes it possible to achieve large stabilisation effects (by factors up to 100 for peroxidase and chymotrypsin).

The influence of the hydrophobic nature of the residues introduced. For the same degree of modification and using modifying agents with similar chemical structures, the influence of the hydrophobic properties of the residues introduced on the stability of proteins and enzymes has been analysed in a number of investigations. In order to elucidate this influence in a "pure" form, it is more correct to compare with one another the properties of members of a series of modified enzymes which differ only by the length of the hydrocarbon residues incorporated in them and not the properties of the native and modified enzymes. Although the number of studies devoted to this question is small, they make it possible to elucidate the overall dependence of the thermal stability of enzymes on the hydrophobic properties of the groups introduced, which is represented by a curve with a maximum (Fig.9). Such relations have been obtained for phosphorylase *b*,[159] α-amylase,[110] horseradish peroxidase,[86, 108] and thermolysin,[152] the accessible amino-groups of which were alkylated or acylated by a series of agents with different hydrophobic properties. In all cases an increase of the thermal stability of the enzymes was observed after their modification [derivatives of the type $E(NHR)_n$ or $E(NHCOR)_n$, where n is constant for each enzyme and R varies].

In phosphorylase *b* ~10% of the Lys residues were modified by aldehydes derived from monocarboxylic acids (from C_2 to C_7) and the azomethine bonds were reduced with $NaBH_4$ (the positive charge on the amino-group is retained under these conditions). Thermal stability at 0° and 50 °C increased with increase of the length of the hydrocarbon residue R in a series of derivatives $E(NHR)_n$ from C_2 to C_5 and then diminished (Fig.9). When the polar glyceraldehyde was used, the stabilising effect was hardly observed.[159]

For bacterial α-amylase, whose amino-groups were modified by the *p*-nitrophenyl esters of monocarboxylic acids (C_1, C_7, and C_{15}), the greatest stabilisation effect was observed after the introduction of the CH_3 group, while for the C_7 and C_{15} derivatives the stability diminished with increase of the length of the hydrocarbon residue.[110] Since data for other derivatives in this series are lacking, it is not known what should be the length of the hydrocarbon residue to give the optimum stabilisation. Possibly it is in the range from C_1 to C_7.

In a series of preparations of peroxidase acylated by monocarboxylic acid anhydrides [the $E(NHCOR)_4$ derivatives, where $R = C_nH_{2n+1}$] the thermal stability $\Delta H^{\neq}_{den}$ increases with increase of the size of the hydrocarbon residue R introduced from C_1 to C_3, while on further increase of R from C_3 to C_6 $\Delta H^{\neq}_{den}$ diminishes (Fig.9). Each succeeding member of the series differs from the preceding one only by the addition of four CH_2 groups. The increment $\Delta(\Delta H^{\neq}_{den})$ per methylene group is 1.5–2 kcal mol^{-1}.[86,108]

The hydrophobic properties of the residues introduced can be varied not only by altering their size but also be replacing the hydrophilic groups in R by hydrophobic groups. For example, the seven accessible amino-groups of thermolysin have been modified by a series of derivatives of normal carboxylic acids, the $[E(NHCOR)_7$ derivatives, where $R = C_{n+8}H_{2n+17}.O_{5-n}]$. The enhancement of the hydrophobic properties in this series was achieved by replacing the ester group by the methylene group. The methylene group enhances the hydrophobic properties of the aminoacid side residue by ~0.7 kcal mol^{-1}, while the ester group diminishes it by ~0.7 kcal mol^{-1}. Thus the replacement of one ester group by the methylene group enhances the hydrophobic properties of the residue by ~1.4 kcal mol^{-1}. The hydrophobic properties of the residues become more pronounced when n is varied from 1 to 5. For n = 4 and 5, insoluble and relatively inactive derivatives are obtained and these were not investigated further. The thermal stability of other derivatives with n = 1–3 varied at 80° and 90 °C as shown in Fig.9, i.e. it passed through a maximum at n = 1.[152]

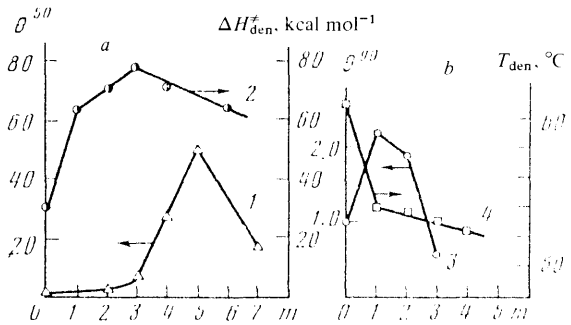

Figure 9. Dependence of the stability of enzymes on the hydrophobic properties of the residues introduced on modification; n is the number of C atoms in the residue for modified derivatives of type $ENHC_nH_{2n+1}$ for phosphorylase *b* (line *1a*),[159] $E(NHCOC_nH_{2n+1})_4$ for horseradish peroxidase (line *2a*),[86,108] $E(NHCOC_{n+8}H_{2n+17}O_{5-n})_7$ for thermolysin (line *3b*)[152] and $E(NHCOC_nH_{2n+1})_{12}$ for ribonuclease (line *4b*);[162] the stabilisation effect ($\theta = k_{in,nat}/k_{in,mod}$) at 50 °C (line *1a*) and 90 °C (line *3b*), the enthalpy of the denaturation process $\Delta H^{\neq}_{den}$ (line *2a*), and the average denaturation temperature T_{den} (line *4b*) have been used as measures of stability.

There is no doubt that the hydrophilic nature of the surface of enzymes is important for their solubility and for the manifestation of their catalytic activity in aqueous solutions. In all the cases considered, the greatest stabilisation of proteins is attained for a definite and comparatively small length of the hydrocarbon residue R: at C_3 for peroxidase and at C_5 for phosphorylase (Fig.9). The interaction of the hydrocarbon residues introduced, having the optimum length for each enzyme, with the nearest hydrophobic groups of the enzyme leads to the greatest stabilisation of the tertiary structure of the protein. On the other hand, when the size of R begins to exceed the size of the hydrophobic cavity in the enzyme molecule, the partial exposure of the R residue to the solution is thermodynamically unfavourable and results in a diminuation of stabilisation effects ($\Delta H^{\neq}_{den}$ decreases) and in certain cases leads to destabilisation. Analogous stabilisation effects for different proteins have been noted when the latter solubilised small amounts of hydrocarbons.[160,161] The dependence of ΔH for thermal denaturation of proteins in the presence of hydrocarbons also passes through a maximum and the increment $\Delta(\Delta H)$ per CH_2 group of the solubilised hydrocarbon is ~2 kcal mol^{-1}.

The dependence of the thermal stability on the hydrophobic properties of the residues introduced passes through a maximum i.e. the introduction of hydrophobic residues of specific dimensions into the protein can stabilise the latter only when the modification does not by itself diminish the stability of the

enzyme (or increases it). In those cases where the modification destabilises the enzyme, an increase in the length of the hydrophobic residues leads to a progressive albeit not very great diminution of the stability of the macromolecule. For example, the thermal stability of ribonuclease modified with different succinimides [the $E(NHCOR)_{11}$ derivatives, where $R = C_nH_{2n+1}$] decreases sharply when the C_1 derivative is used. The increase in the size of the residue R from C_1 to C_4 entails only a slight further decrease of the thermal stability of the enzyme (Fig.9). According to the authors, the destabilisation of the enzyme after modification is similar to the denaturation of ribonuclease by alcohols.[162]

The introduction of very bulky hydrophobic residues decreases sharply the stability of the enzyme in all cases regardless of whether the given modification itself stabilises or destabilises the enzyme. Despite the fact that acetamidination of lactate dehydrogenase stabilises the enzyme,[127] when a very bulky hydrophobic agent is employed, namely methyl *N*-(2,4-dinitrophenyl)-ε-aminocaproimidate, the thermal stability of the modified enzyme becomes smaller than that of the native enzyme. This is due to the marked enhancement of the hydrophobic properties of the enzyme globule and the rupture of the bonds between the Lys residues and other residues, which have a favourable effect on the stability, as a consequence of the introduction of large and bulky substituents despite their positive charge.[163] Thus the introduction of large hydrophobic residues can abolish the stabilising effect of the modification.

The observed change in the thermal stability of enzymes after modification is not always associated with the influence of the hydrophobic properties of the residues introduced. For example, the acylation of α-amylase by various *N*-hydroxysuccinimides and 1-hydroxybenzotriazole increases the thermal stability of the enzyme at 60 °C in the sequence native < α-amylase ($E - NH_2$) ≤ dimethylcarbamoylated α-amylase [$E - NHCON(CH_3)_2$], ethoxyformylated α-amylase ($E - NHCOOC_2H_5$) < formylated α-amylase ($E - NHCHO$) < acetylated α-amylase ($E - NHCOCH_3$) < dimethylpropanoylated α-amylase [$E - NHCOC(CH_3)_3$]. The increase of thermal stability in this sequence is correlated with the weakening of the electron-donating capacity of the amide nitrogen and not with the change in the hydrophobic properties of the residue introduced.[164]

In conclusion one should note that the "pure" contribution of the hydrophobic properties of the residues introduced to the observed stabilisation–destabilisation effect for the modified enzyme is extremely small compared with the effects of the local or overall changes in the charge of the molecule. For example, the acetylation of the four amino-groups of peroxidase increases $\Delta H^{\neq}$ for thermal inactivation by a factor of two (from 30 to 65 kcal mol^{-1}), while the additional contribution to the stability (to the increase of $\Delta H^{\neq}$) by the four CH_2 groups introduced does not exceed 6–8 kcal mol^{-1}.

2. Physicochemical Characteristics of the Change in the Stability of Enzymes after Their Chemical Modification and Immobilisation

The results in the previous Section clearly demonstrate that the chemical modification of the functional groups of enzymes not involved directly in the active centre by monofunctional agents can exert a strong influence on their structure and stability. The studies considered confirm the hypothesis of the existence in proteins and enzymes of three types of functional groups whose modification has different effects on their structure and stability.

The change in the thermal stability of enzymes as a result of their chemical modification is a consequence of local or overall changes in the three-dimensional structure of the protein—in the conformational mobility of individual fragments of the polypeptide chain. Despite the considerable alteration of the stability of the protein, the variations in its structure can frequently be so small that they cannot always be detected by analysing the absorption, fluorescence, or circular dichroism spectra.[127,129,165,166] The stability of proteins is therefore the most sensitive test for any change in their structure.[7,86]

The relation between the changes in the structure and thermal stability after chemical modification and the contributions of different types of groups in the protein have been clearly traced only for several enzymes, for example, for horseradish peroxidase.[34,86,108,109] Modification of groups of type I (up to 30 surface OH groups and two ε-NH_2 Lys groups) does not affect the structure and stability of the peroxidase regardless of the degree of modification. The modification of the other two ε-NH_2 Lys groups (groups of type II) with removal of the positive charge diminishes the conformational mobility of the protein in the haem-binding region, which is reflected in the circular dichroism spectra of the peroxidase. As a consequence of this, there is an appreciable increase of the stability of the enzyme. Finally, the modification of the internal OH and ε-NH_2 groups (groups of type III) reduces the intensity of the haem and aromatic aminoacid bands in the circular dichroism spectra, which indicates a weakening of the heam–protein bond and the approach of the structure of the enzyme to that which obtains after thermal denaturation. The thermal stability of such an enzyme is lower than that of the native enzyme.[108]

Analysis of the literature data shows that, as in the case of the proteins and enzymes from thermophilic sources (Section II), the main cause of the increase of the stability of the modified enzyme is the formation of additional bonds (salt and hydrogen bonds) within and on the surface of the molecule, the enhancement of the hydrophobic interactions in the protein, and also the strengthening of the bonds between the protein and the prosthetic groups, metal ions, etc.

Analysis of the temperature variations of k_{in} for the native and modified (including immobilised) enzymes shows that the stabilisation effect varies with temperature. The term "stabilisation" is significant only for a specific temperature range. "Absolute stabilisation", i.e. the case where the ratio of the constants k_{in} for the native and immobilised enzymes is the same over a fairly long temperature range, is hardly possible. It will be possible only when the $\Delta H^{\neq}_{den}$ for the native and modified enzymes are the same and $\Delta S^{\neq}_{den}$ for the modified enzyme is lower than for the native enzyme by an appreciable amount. However, in all cases known from the literature ΔH_{den} and ΔS_{den} (or $\Delta H^{\neq}_{den}$ and ΔS_{den}) for the enzyme thermal denaturation process vary in parallel after the chemical modification or immobilisation of the enzymes. This is apparently to be explained by the existence of a compensation effect for protein systems in solution, which is most likely to be determined by the properties of water.[167] This effect consists in the fact that, despite the large changes in ΔH_{den} (or $\Delta H^{\neq}_{den}$), the values of ΔG_{den} (or $\Delta G^{\neq}_{den}$) change little in most cases after the chemical modification or immobilisation of enzymes owing to the compensating effect of the entropy term $T\Delta S_{den}$. ΔG_{den} increases either because ΔH_{den} increases more than ΔS_{den} or because ΔS_{den} decreases more than does ΔH_{den}.

Fig.10 presents the experimental compensation relation between $\Delta H^{\neq}_{den}$ and $\Delta S^{\neq}_{den}$ for the thermal inactivation of a series of native and modified enzymes. The relation between $\Delta H^{\neq}_{den}$ and $\Delta S^{\neq}_{den}$ indicates the existing limits of variation of

these parameters as the nature of the modifying agent (or the carrier for immobilised enzymes) is altered or for different degrees of modification. All the points on the compensation relation lying to the left of those corresponding to the native enzymes correspond to preparations of the modified or immobilised enzymes for which $\Delta H^{\neq}_{den}$ and $\Delta S^{\neq}_{den}$ are smaller than for the native enzyme. Such preparations are more stable than the native enzyme above the isokinetic temperature ("high-temperature stabilisation"). All the preparations the points for which lie to the right of the point corresponding to the native enzyme have higher values of $\Delta H^{\neq}_{den}$ and $\Delta S^{\neq}_{den}$ than the native enzyme. These compounds are more stable than the native enzyme below the isokinetic temperature ("low-temperature stabilisation"). If the isokinetic temperatures are similar for different derivatives of the enzyme, then the modified enzymes are more stable below the isokinetic temperature the higher their values of $\Delta H^{\neq}_{den}$.

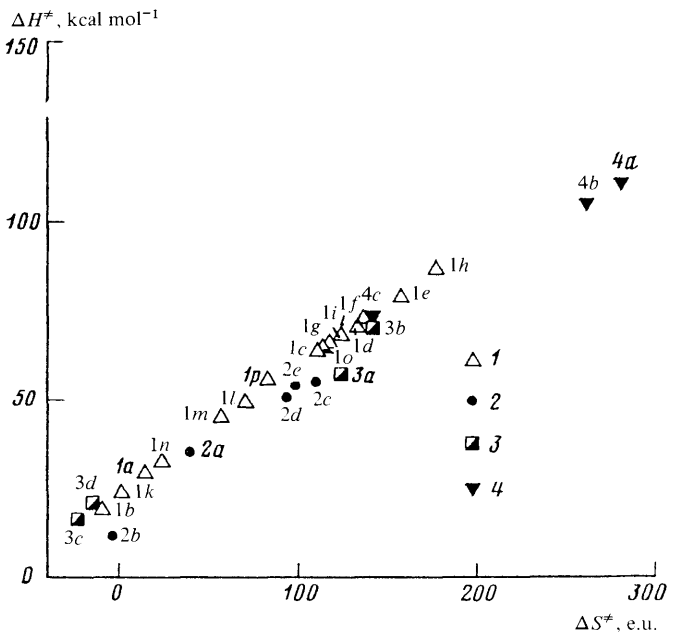

Figure 10. Compensation relation between $\Delta H^{\neq}$ and $\Delta S^{\neq}$ for the thermal inactivation of soluble (native and modified) and immobilised enzymes: 1) horseradish peroxidase: native (*a*), immobilised in polyacrylamide gel (*b*), modified (four NH_2 groups) with acetic (*c*), propionic (*d*), butyric (*e*), valeric (*f*), oenanthic (*g*), succinic (*h*), and maleic (*i*) anhydrides, modified with oenanthic anhydride [*k*) two NH_2 groups; *l*) three NH_2 groups] and trinitrobenzenesulphonic acid [*m*) three NH_2 groups; *n*) six NH_2 groups] and peroxidase–albumin conjugates [*o*) fraction I; *p*) fraction II]; 2) glow-worm luciferase: native (*a*), immobilised on ultragel (*b*), ultradex (*c*), cellophane (*d*), and Sepharose (*e*) and activated with bromocyanogen; 3) α-chymotrypsin: native (*a*), soluble conjugates with dextran (*b*), and sodium alginate (*c*), and immobilised on KM-cellulose (*d*); 4) β-galactosidase: native (*a*), and modified with a dye (*b*) and then sorbed on DEAE-Sephadex (*c*) according to different literature data.[39, 86,108,158,168,169,172,175,178]

Since the native and modified (immobilised) enzymes have different temperature variations of k_{in} (K_{den}), in the general case there is always a temperature range where the native enzyme is more stable and a range where the modified or immobilised enzyme is more stable (Fig.7). As the isokinetic point is approached, the difference between the stabilities of the native and modified enzyme diminishes, while under conditions remote from this point it increases.

Studies involving the comparison of the kinetic and thermodynamic parameters of the thermal inactivation of native and modified proteins and enzymes have shown that in many cases these parameters vary in parallel.[20,39,168] The increase or decrease of $\Delta H^{\neq}_{den}$ and $\Delta S^{\neq}_{den}$ for the thermal inactivation of enzymes after their chemical modification or immobilisation can be accounted for by a change in their thermodynamic stability and hence by a change in the relative contributions of various factors which determine the thermodynamic stability of the protein globule of the enzyme in solution.

Stabilisation of enzymes in solution after the chemical modification of their functional groups. Such stabilisation is caused as a rule by the increase of $\Delta H^{\neq}_{den}$ and $\Delta S^{\neq}_{den}$ for thermal inactivation. This is "low-temperature stabilisation" of enzymes below the isokinetic temperature (Fig.7, curves *1* and *2*), which is as a rule above 50 °C. Chemical modification of enzymes leading to an enhancement of the intramolecular interactions in the globule increases ΔG_{den} for the modified enzyme compared with the native enzyme, whereupon we have $\Delta G_{den,mod} - \Delta G_{den,nat} < 0$. The formation of additional intramolecular bonds on modification increases ΔH_{den}, while the introduction of additional residues increases ΔS_{den} (mainly as a result of an increase in conformational entropy). The greater the amount by which the increase of ΔH_{den} predominates over that of ΔS_{den}, i.e. the greater the number of additional bonds formed following the introduction of a given number of residues, the higher the isokinetic temperature for the native and modified enzymes and the wider the range of experimental temperatures where $\Delta G_{den,mod} < \Delta G_{den,nat}$, i.e. the modified enzyme is more stable than the native enzyme. The activation parameters for the thermal denaturation of the enzyme vary analogously after chemical modification. If chemical modification results in an intensification of the intramolecular interactions in the enzyme globule as a result of the formation of additional bonds, then $\Delta H^{\neq}_{den}$ and $\Delta S^{\neq}_{den}$ for the modified enzyme are greater than for the native enzyme. "Low-temperature stabilisation" obtains in this case (Fig.7, curves *1* and *2*). With increase of inactivation temperature, the intramolecular stabilising interactions are weakened and the conformational entropy $\Delta S^{\neq}_{conf}$ increases in both the native and modified enzymes (see above). As a result of this, the difference $\Delta G^{\neq}_{den,mod} - \Delta G^{\neq}_{den,nat}$ become smaller the higher the inactivation temperature and is zero at the isokinetic temperature. Above the isokinetic temperature, the native enzyme becomes more stable than the modified enzyme.

If modification resulted in the cessation of the enzyme-stabilising interactions (in particular, on modification of groups of type III), then the structure of the enzyme becomes close to that of the denatured enzyme. $\Delta H^{\neq}_{den}$ and $\Delta S^{\neq}_{den}$ diminish after modification (Fig.7, curves *1* and *3*), but, by virtue of the predominance of the decrease of $\Delta H^{\neq}_{den}$ over that of $\Delta S^{\neq}_{den}$, the isokinetic temperature is in this case high and the stability of the modified enzyme is lower than that of the native enzyme virtually over the entire experimental temperature range.

Stabilisation of enzymes after immobilisation. After multipoint interaction with the carrier (covalent and non-covalent), such stabilisation is caused as a rule by the decrease of $\Delta S^{\neq}_{den}$, which predominates over the decrease of $\Delta H^{\neq}_{den}$ for thermal inactivation. This is the "high-temperature stabilisation" of enzymes[39,169–178] (Table 2). The decrease of $\Delta H^{\neq}_{den}$ and $\Delta S^{\neq}_{den}$ (ΔH_{den} and ΔS_{den}) after the immobilisation of

enzymes can be accounted for as follows. When the enzyme interacts with the matrix (the formation of external bonds), the bonds within its molecule are affected, which is accompanied by a decrease of ΔH_{den}. By virtue of the covalent and non-covalent fixation of the polypeptide chain at several points, this is accompanied by the simultaneous decrease of ΔS_{conf}. The greater the decrease of $\Delta S(\Delta S^{\neq})$ (the greater the number of points at which the enzyme is bound to the carrier) compared with ΔH, the lower the isokinetic temperature of the native and immobilised enzymes and the greater the temperature range in which the immobilised enzyme is more stable than the native enzyme and the greater the stabilisation effect ($\Delta G_{den,imm} - \Delta G_{den,nat}$) above the isokinetic temperature (Fig.7, curves *1* and *4*). In multipoint immobilisation the protein is probably fixed in a conformation close to that of the denatured enzyme.[168,176] This may be one of the main reasons for the low activity of enzymes after their multipoint immobilisation. In the absence of external bonds between the enzyme and the carrier (when the enzyme is incorporated in a polymer gel), the thermodynamic parameters of denaturation may not change.[174]

Enzymes functioning in membrane structures in aqueous solutions can have a conformation different from the native conformation. After a successful choice of the carrier, the structure of such protein macromolecules after immobilisation may be closer to the native structure than in solution. It is to be expected that $\Delta H^{\neq}_{den}$ and $\Delta S^{\neq}_{den}$ for such an immobilised enzyme will increase. We observed this type of experimental fact, for example, for the glow-worm luciferase immobilised on polysaccharide carriers.[175] $\Delta H^{\neq}_{den}$ was 35 kcal mol^{-1} for the enzyme in solution and 54 kcal mol^{-1} for the enzyme immobilised on Sepharose.[175] Similar effects are to be expected also for other enzymes functioning in nature in an immobilised state.

---o0o---

In many cases the modification of enzymes by monofunctional agents appreciably increases their resistance to temperature, extreme pH, and organic solvents. In most cases the stabilisation effect does not exceed a factor of 10–20, but in some cases it reaches a factor of 100 and more.[108,116] In

[a] The temperature at which the stabilisation effect has been measured is indicated in brackets (in °C).

[b] The values of $\Delta H^{\neq}$ and $\Delta S^{\neq}$ as well as the stabilisation effect θ were calculated by ourselves from the temperature variations of $\lg k_{in}$ quoted in different communications.

[c] Values calculated from our own extrapolations.

[d] T_i is the isokinetic temperature.

order to attain the maximum stabilisation effect, account must be taken of those features which have been discovered by the analysis carried out in the present review. The modification of enzymes involving the introduction of carbohydrate residues, amidination, and guanidination as a rule increases the stability of enzymes (at worst it does not diminish it). The greatest influence on stability is shown by the modification involving a change in the charge of the functional groups. In addition, one must avoid the modification of internal groups (type III) of the enzyme by employing for modification the mildest possible conditions (low temperatures and minimum concentrations of organic additives), a high degree of modification, and the introduction into the enzyme of unduly bulky hydrophobic residues.

In the development of methods for stabilisation by chemical modification, it is necessary to obtain data for the thermal stability of enzymes over a wide temperature range as a function of the degree of modification and the nature of the modified groups and the modifying agent. Such analysis makes it possible to optimise not only the conditions in the preparation of the biocatalyst but also its applications. As shown above, chemically modified soluble enzymes are usually more stable at temperatures below 50–60 °C. For experiments at higher temperatures (60–70 °C), it is more desirable to employ enzymes, immobilised on polymer matrices, which are characterised by the high-temperature stabilisation, although immobilisation is frequently accompanied by a decrease of catalytic activity, in particular owing to the approach of the structure of the enzyme to that of the denatured enzyme.

The use of several additive stabilising influences, which makes it possible to achieve the greatest stabilisation effects, is extremely promising.[34]

Fundamentals of the Theory of Capillary Gas-Liquid-Solid Chromatography

V.G.Berezkin and P.P.Zolotarev

It is shown that the known instances of the separation of volatile compounds actually refer to gas-liquid-solid chromatography and not gas-liquid chromatography, the walls of the capillary column fulfilling the function of the solid. The theories of the retention and spreading of the chromatographic bands in elution gas-liquid-solid chromatography are examined. The results of theoretical and experimental studies indicate the need to take into account the role of adsorption in capillary gas-liquid chromatography.
The bibliography includes 140 references.

I. INTRODUCTION

Gas–liquid chromatography is the commonest version of capillary chromatography. The retention of the chromatographed compounds in capillary gas–liquid chromatography is characterised by the same fundamental features as in gas–liquid chromatography on packed columns. It is therefore useful to examine the general theory of the retention of chromatographed compounds together with the main results of the application of this theory to capillary chromatography.

The discovery by Martin and Synge in 1941 of partition chromatography, based on the different partitions (adsorptions) of the substances to be separated between two phases, namely the mobile (gas, liquid) and stationary (liquid) phases, was an important stage in the development of chromatography.[1] In the conclusion of their communication, Martin and Synge noted that they proposed a new type of chromatography based on the partition of the solutes between two liquid phases and not on adsorption on a solid phase.[1] We may note that they also proposed[1] a new type of partition chromatography, namely gas–liquid chromatography (GLC). The first experimental study on GLC was published by James and Martin in 1952,[2] who found that the separation of the lower aliphatic acids (formic and acetic) exhibited asymmetric peaks (diffuse tails and steep fronts). This phenomenon was explained by the adsorption of the acids being separated on the surface of kieselguhr. It was shown that the adsorption can be weakened by introducing phosphoric acid into the stationary liquid phase (SLP) or by depositing it on the surface of kieselguhr (a solid carrier). Thus in the first study on GLC James and Martin should already have taken into account the phenomenon of the adsorption of the substance being separated on the solid carrier and should have taken special measures to reduce it.

Subsequently, as a result of the efforts of many investigators,[3-20] the qualitative idea concerning the role of adsorption in GLC was formulated perhaps most clearly by Dal Nogare and Juvet in a monograph.[18] In their view, adsorption on the active surface of the solid carrier is the factor responsible for the formation of tails behind the peaks. Although diatomaceous carriers are weak adsorbents compared with alumina, silica get, etc., their activity is usually sufficient for the above adsorption effect to be fully evident in the case of polar substances, for example, alcohols, water, ketones, and ethers. Adsorption on refractory brick is stronger than on celite. It is less evident in the case of non-polar substances and large relative amounts of the liquid phase and in cases where polar liquid phases, saturating the active sections of the adsorbent surface, are used.[18] An analogous view has also been expressed in the monographs of Zhukhovitskii and Turkel'taub[20] and Moshier and Sievers.[19]

We may note that capillary gas chromatography is a version of gas–liquid chromatography in which the internal walls of the capillary tube play the role of the solid carrier.

The experimental data for the adsorption of the substances separated in GLC conflicted with the view, current at the time, that GLC is a purely partition version of chromatography, and also with the theory adopted for the retention of the compounds separated in GLC, which related the retention of such compounds solely to their dissolution in the stationary liquid phase (SLP). This contradiction stimulated studies of the role of adsorption in GLC. Theoretical and experimental investigation of adsorption phenomena in GLC led to significant progress in understanding the processes occurring in chromatographic columns.

II. FUNDAMENTALS OF RETENTION THEORY

In analysing the chromatographic process in GLC, it is useful to examine primarily the model of the sorbent which can be regarded solely as an SLP. The real sorbent is a multiphase material and its simplest model is illustrated in Fig.1. The surface of the solid carrier (internal walls of the capillary column) is coated by a continuous film of the SLP of non-uniform thickness. This model of the sorbent is consistent with porometric data, mass transfer kinetic data (see, for example, Berezkin and co-workers[21,22]), data for the filling

of the pores of the solid carrier with SLP,[23] and the results of special studies based on the use of a version of the "labelled" surface method.[24] It also agrees with the results obtained in the investigation of the partition of the stationary liquid phase on the surface of the solid carrier by scanning electron microscopy.[25]

Despite its simplicity, systematic analysis of this model makes it possible to elucidate the main features of the retention of volatile compounds on a real sorbent. Indeed, it is necessary to isolate in the sorbent not one (SLP) but three phases which absorb and adsorb the substances to be separated, namely the SLP, the gas–SLP interface, and the SLP–solid carrier interface.

The equilibrium retention theory, taking into account the adsorption of the compounds to be separated, is based on a logical allowance for the contribution of the retention on individual bulk and surface phases of the real sorbent to the overall retention volume and also on the experimental test of the equations obtained (including their test by independent methods).

If the SLP layer covers fully the surface of the solid carrier, then the retention volume is determined by the equilibrium characteristics of three processes: (1) dissolution of the compound chromatographed in SLP, (2) its adsorption at the gas–SLP interface, and (3) the adsorption at the SLP–solid carrier interface. The equilibrium theory of the retention of the compounds chromatographed must take into account the contributions of all three processes indicated to the overall retention.

The need to take into account, in addition to dissolution, the adsorption of chromatographic compounds at the gas–SLP interface when an allowance is made for the contributions of these processes to retention in GLC was first pointed out by Martin,[26,27] who confirmed experimentally his postulate. An equation has been proposed[28,29] for the retention volume, which took into account both the dissolution and also the adsorption of the substance chromatographed on the surface of the solid carrier.

For the model of the sorbent with a thick SLP layer which we are considering and which usually obtains on sorbents containing more than 3% of SLP on the solid carrier, the system of equations relating to the development chromatography of one component subject to the operation of longitudinal spreading factors with allowance for absorption in the SLP and adsorption at the interfaces differs from the equation adopted previously in chromatography (see, for example, the relevant monograph[30]) by the presence of terms which take into account the adsorption at the interfaces between the SLP and the carrier gas and the solid carrier.

We shall consider the equations for the retention volume relating to the model in which the SLP covers in a continuous film the surface of the solid carrier under conditions of ideal non-linear chromatography. The system of equations for the ideal (non-equilibrium) non-linear development chromatography of one substance taking into account the adsorption of the latter on the SLP and at the interfaces can be described as follows:

$$u\frac{\partial c_g}{\partial x}+\chi_g\frac{\partial c_g}{\partial t}+\chi_{gl}\frac{\partial a_{gl}}{\partial t}+\chi_l\frac{\partial a_l}{\partial t}+\chi_{ls}\frac{\partial a_{ls}}{\partial t}=0, \quad (1)$$

$$a_{gl}=f_{gl}(c_g), \quad (2)$$

$$a_l=f_l(c_g), \quad (3)$$

$$a_{ls}=f_{ls}(a), \quad (4)$$

where u is the linear flow rate of the carrier gas, x the coordinate, t the time, c_g the volume concentration of the chromatographed substance in the gas phase, a_l the volume concentration of the substance in the SLP, a_{ls} the surface concentration of the substance at the SLP–solid carrier interface, χ_g the fraction of the gas phase along the column cross-section, χ_l the fraction of the liquid phase along the column cross-section, χ_{gl} the ratio of the area of the SLP–solid carrier interface to the volume of the sorbent, and a_{gl} the surface concentration of the test substance at the gas–SLP interface.

Eqns.(2) and (4) are the equations of the adsorption isotherms of the chromatographed compound at the SLP–solid carrier and gas–SLP interfaces and Eqn.(3) is that of the isotherm of absorption (dissolution) in the SLP. Eqn.(1) differs from that usually considered (see, for example, Rachinskii[30]) by the presence of two additional terms – the third and the fifth. The introduction of these terms made it possible to take into account the adsorption at the interface between the SLP and the carrier gas and the solid carrier.

The solution of the above system of equations on the assumption of the carrier gas pressure drop along the length of the chromatographic column is small so that the correction for the compressibility of the carrier gas can be disregarded, yields the following equation for the pure retention volume:

$$V_N=V_R^0-V_M=f'_{gl}S_l+f'_lH_l+f'_lf'_{ls}S_s, \quad (5)$$

where $f'_{gl}=da_{gl}/dc_g$, $f'_l=da_l/dc_g$, $f'_{ls}=da_{ls}/da_l$, S_l is the area of the gas–SLP interface for the sorbent in the column, H_l the volume of the SLP in the column, S_{ls} the area of the SLP–solid carrier interface, V_N the pure retention volume,

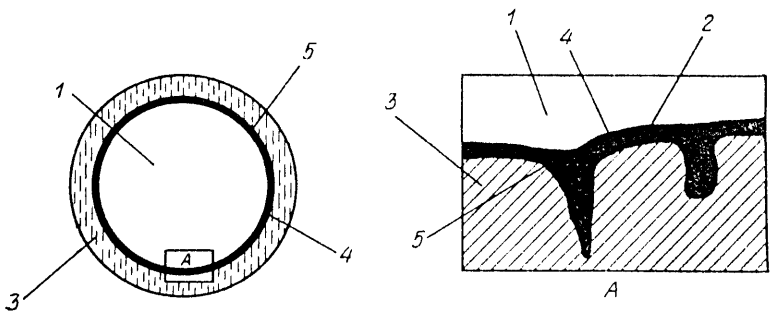

Figure 1. A simplified model of the real sorbent in capillary GLC: 1) gas phase; 2) SLP; 3) solid carrier (wall of capillary column); 4) gas–SLP interface; 5) SLP–solid carrier interface.

V_R the retention volume, and V_M the dead volume of the column. If the adsorption and absorption isotherms are linear, the derivatives f'_{gl}, f'_l, and f'_{ls} are constant.

Eqn.(5) establishes the relation between the retention volume and the characteristics of the sorbent employed taking into account the dissolution in the SLP and the adsorption at its interfaces. It follows from this equation that the retention volume in equilibrium chromatography is an additive function of the retention volumes in the separate phases of the real sorbent. We may note that previously Giddings[31] proposed an additive equation for the second quantity (the lag factor) characterising the relative retention (R_f), which is used widely in thin-layer chromatography.

There is also a possibility of another derivation of the additivity equation for the ideal non-linear chromatography based on Wicke's Law using the adsorption isotherms for a real complex sorbent in its equation. In this case the sorption also consists of the adsorption at the SLP interfaces and the dissolution in the SLP film.

Since in the general case the real sorbent may contain not three but a significantly greater number of phases, each of which is capable of retaining the chromatographed compounds, the relations obtained above can be usefully extended to the case of a large number of phases. Within the framework of ideal non-linear chromatography (i.e. on the assumption of the instantaneous establishment of equilibrium and of the absence of diffusional spreading effects), it has been shown[32,33] that the pure retention volume V_N in a real multiphase sorbent consists of the sum of the partial retention volumes V_{li} and V_{sj} due respectively to the adsorption and absorption of the chromatographed substance on the individual phases of the sorbent:

$$V_N = \sum_{i=1}^{m} V_{li} + \sum_{j=1}^{n} V_{sj} \qquad (6)$$

or

$$V_N = \sum_{i=1}^{m} K_{li} H_{li} + \sum_{j=1}^{n} K_{sj} S_{sj}, \qquad (7)$$

where K_{li} is the constant for equilibrium of the test substance between the mobile phase and the SLP of the ith type, H_{li} the volume of the SLP of the ith type in the chromatographic column (for example, the volume of the macrolayer or microlayer in the liquid phase on the surface of the solid carrier, the volume of the liquid phase in the micropores, etc), K_{sj} the constant for equilibrium of the test substance between the stationary phase and the jth type interface, and S_{sj} the area of the jth type interface in the column (for example, the gas–solid carrier, SLP–solid carrier, gas–SLP, etc. interfaces).

Eqns.(6) and (7) are fairly general. It can be shown that the known equations for the retention volume are special cases of these equations. For specific values of the parameters i and j, it is possible to obtain directly from Eqn.(7) the familiar equations for the retention volume: the equation of the traditional GLC (see, for example Dal Nogare and Juvet[18]); the equation taking into account the dissolution and the adsorption at the gas–SLP interface,[26] the equation taking into account the dissolution and adsorption at the SLP–solid carrier interface;[28] the equation taking into account the dissolution and adsorption of the sorbate on the SLP–solid carrier and SLP–carrier gas interfaces;[32] the equation reflecting the interaction between the sorbate and the solid alone;[34] the equation taking into account only the adsorption at the gas–SLP interface;[35] the equation for the retention volume on complex sorbents (for example, a solid carrier combined with an adsorbent modified by the SLP).[36]

If the adsorption isotherm is described by a non-linear equation, then in this case Eqns. (6) and (7) are valid only within the framework of ideal non-linear chromatography, which naturally limits their applicability. However, one should note that development gas-chromatographic methods for the determination of non-linear adsorption isotherms, developed on the basis of ideal non-linear chromatography, have been used successfully in chromatographic practice and the results obtained are independent of the carrier gas flow rate, the sample size, etc. In gas–solid chromatography the adsorption isotherms measured by the gas-chromatographic and static methods mentioned above are in good agreement with one another (see, for example, Kiselev and Yashin[34] and Roginskii et al.[37]). The region of the applicability of Eqns. (6) and (7) is therefore fairly broad also for non-linear isotherms.

When the general Eqns.(6) and (7) are used, it is necessary in the general case to resort to data for the phase characteristics of the sorbent employed and for the distribution of the SLP on the surface of the solid carrier. In the case occurring commonly in chromatographic practice, where the surface of the solid carrier is fully coated by a macrofilm of the liquid, Eqn.(8), which is a corollary of Eqn.(5), is therefore used most frequently:

$$V_{Ns} = K_l H_{ls} + K_{gl} S_{ls} + K_{ls} S_{ss}, \qquad (8)$$

where V_{Ns} is the retention volume referred to 1 g of the solid carrier, K_l, K_{gl}, and K_{ls} are the constants for equilibrium of the chromatographed substance between the SLP and the gas phase, between the SLP–gas interfacial phase and the gas phase, and between the SLP–solid carrier interfacial phase and the SLP respectively, H_{ls} is the volume of the SLP in the column referred to 1 g of the solid carrier, S_{ls} and S_{ss} are the areas of the SLP–gas and solid carrier SLP interfaces referred to 1 g of the solid carrier respectively, $K_l = a_l/c_g$, $K_{gl} = a_{gl}/c_g$, and $K_{ls} = a_{ls}/a_l$.

Eqn.(8) establishes the relation between the retention volume and the characteristics of the sorbent used. The retention volume in equilibrium linear chromatography with operation of longitudinal spreading factors is an additive function of the retention in the individual phases of the real sorbent. The first term of this equation reflects the contribution of the adsorption of the chromatographed substance on the SLP, the second term the contribution of the adsorption on the gas–SLP interface, and the third term the contribution of the absorption of the SLP–solid carrier interface.

Table 1 presents the main stages in the development of ideas about adsorption in GLC along three main pathways: theory, chromatographic experiment undertaken to test the theory, and independent experimental tests of the theory by non-chromatographic methods. Naturally, the isolation of specific stages in the development of ideas about the role of adsorption in GLC is fairly subjective. Like any important trend in science, it arose and developed by virtue of the investigations of many workers from different countries. The work of Nikolov,[52,53] Suprinowicz, Waksmundski, Rudzinski, and co-workers,[54–56] Hüber and Gerritse,[57] Eon and Guiochon, [58,59] Kovats and co-workers,[60] and many other investigators[61–86] has also made an important contribution to the study of the role of adsorption in GLC. Thus, revolutionary changes involving the study of adsorption phenomena have occurred in the last two decades in the ideas concerning the mechanism of the retention of chromatographed compounds in GLC as a result of the work of many investigators from different countries.

The view that adsorption on the surface of the solid carrier (walls) in capillary chromatography is negligible and can be neglected has been expressed fairly frequently. Investigators sharing this view usually adduce the following arguments in its defence. Firstly, the surface of the capillary column (glass, quartz, stainless steel) is more inert than the surfaces of solid carriers used in packed columns and the chromatographic bands in capillary chromatography are as a consequence usually more symmetrical than in packed columns.

Table 1. The principal stages in the development of ideas concerning the role of adsorption in GLC.

Stage	Characteristic	Refs.
Adsorption at gas–SLP interface	Theory	[26]
	Experiment	[26]
	Independent test	[27]
Adsorption at SLP–solid carrier interface	Theory: linear isotherm	[28, 31]
	Theory: non-linear isotherm	[32, 39]
	Experiment: determination of isotherm	[40, 41]
	Experiment: determination of heat of adsorption	[42]
	Independent test	[43, 45]
Joint determination of the contribution of adsorption at gas–SLP and SLP–solid carrier interfaces	Theory and experiment	[32]
The influence of adsorption on the relative retention parameters (relative retention time and Kovats retention index)	Theory and experiment	[33, 46]
Retention on sorbents with thin SLP films (less than 3% on solid carrier)	Theory and experiment	[47, 48]
Adsorption in open capillary columns	Theory and experiment	[49, 51]

Secondly, the ratio of the volume of the SLP to the surface area of the solid carrier is usually greater in capillary chromatography than in packed columns, which should decrease the contribution of adsorption to the overall retention volume. As regards the first argument, glass and quartz surfaces cannot be regarded as inert with respect to adsorption. Experimental data have shown that even the most inert quartz columns exhibit distinct adsorption properties in relation to polar compounds (see, for example, Jennings[87]). One should also note that the symmetry of the chromatographic band is only a necessary but not a sufficient condition for the adsorption inertness of the given surface in relation to a given compound under the given conditions. Furthermore, glass (and other) surfaces are frequently subjected to a preliminary treatment whose purpose is to roughen the surface, which increases its adsorption capacity. The second argument does not appear to be convincing for the following reason. On average, the separation temperature in capillary chromatography is lower by ~50–100 °C than the separation temperature in packed columns. Since the heat of adsorption of polar chromatographed compounds when non-polar SLP are used is several times higher than the heat of solution, a significant decrease of the separation temperature causes a relative increase of the contribution of adsorption to the retention compensating at least partially the increase of the thickness of the SLP layer. We may note that the retention volume varies exponentially with the heat of the decisive chromatographic processes and linearly with the thickness of the SLP film, i.e. the heat of the process has a more significant influence on the retention.

Yet another factor enhancing the degree of adsorption in capillary chromatography is noteworthy: the resolving capacity of the capillary column is ~5–10 times higher than that of a packed column. Indeed it is known (seen, for example, Dal Nogare and Juvet[18]) that the separation factor for two compounds R is a function of the following characteristics of the chromatographic column employed:

$$R = \frac{N^{1/2}}{4}\left(\frac{\alpha-1}{\alpha}\right)\frac{k}{k+1}\ , \qquad (9)$$

where N is the number of theoretical plates of the column, α the column selectivity (the relative retention of the compounds separated), and k the capacity coefficient. The ratio of the separation factors in capillary (R_{cc}) and packed (R_{pc}) columns can be represented by the following relation:

$$\frac{R_{cc}}{R_{pc}} = \frac{(\alpha_{cc}-1)}{(\alpha_{pc}-1)}\cdot\frac{\alpha_{cc}}{\alpha_{pc}}\cdot\frac{k_{cc}}{k_{pc}}\cdot\frac{k_{pc}+1}{k_{cc}+1}\cdot\left(\frac{N_{cc}}{N_{pc}}\right)^{1/2}\ , \qquad (10)$$

where the subscripts cc and pc refer respectively to quantities characterising the capillary and packed columns.

Since the first terms of Eqn.(10) are close to unity and $N_{cc} \cong 60 \times 10^3$ and $N_{pc} \cong 10^3$, we obtain in accordance with Eqn.(10).

$$\frac{R_{cc}}{R_{pc}} \simeq \left(\frac{60\cdot 10^3}{10^3}\right)^{1/2} \simeq 8\ . \qquad (11)$$

Thus, under the conditions examined above, the width of the chromatographic band in a capillary column is 10 times smaller than in a packed column. This means that the real accuracy of the measurements of the retention using capillary columns is 10 times greater than for packed columns; even small contributions of adsorption to the retention have a greater importance in capillary chromatography owing to the greater resolving capacity of the latter.

We shall consider certain most important consequences arising from allowance for adsorption phenomena in GLC.

III. THE INTERACTION OF THE SOLUTE WITH THE STATIONARY LIQUID PHASE UNDER THE CONDITIONS OF THE ADSORPTION OF THE CHROMATOGRAPHED SUBSTANCES AT THE STATIONARY LIQUID PHASE INTERFACES

In his Nobel Lecture in 1952 Martin noted that the application of the chromatographic method and apparatus makes it possible to measure fairly simply the free energies of solution of volatile compounds in the SLP and thus to investigate successfully the molecular forces in solutions.[88] The development of GLC fully confirmed the validity of this prediction, but the correct employment of the methods for the investigation of the interaction of the solute and the involatile SLP, which have been thoroughly developed in gas chromatography is possible only when the contribution determined solely by the dissolution of the chromatographed substance in the SLP is isolated from the overall retention volume. For example, in order to determine V_{gtl}, which is the initial quantity needed to determine the specific retention volume due solely to the dissolution of the test substance in the SLP, it is useful to employ Eqn.(12):

$$V_{gt} = \frac{V_N}{W_l}\ , \qquad (12a)$$

$$V_{gt} = \frac{V_{NL}}{W_l} + \frac{1}{W_l}\sum_{i=2}^{n} V_{Ni}\ , \qquad (12b)$$

$$V_{gtl} = \frac{V_{Nl}}{W_l}\ , \qquad (12c)$$

where $V_{gtl} = V_{gl}\ (273/T)$, V_{gl} is the specific retention volume due solely to the dissolution of the volatile substance in the SLP, V_{Nl} the part of the pure retention volume due solely to the dissolution of the chromatographed substance in the SLP macrolayer, W_l the mass of the SLP in the column, and V_{Ni} the part of the pure retention volume due to the retention of the volatile substance by the ith phase of the sorbent (with exclusion of the SLP macrolayer).

Fig. 2 presents the ratios $\psi = V_g$ (refractory brick)$/V_{gt}$ (Chromosorb W) and $\psi_l = V_{gil}$ (refractory brick)$/V_{gt}$ (Chromosorb W) which we calculated[21] from the experimental data of Pecsok et al.;[14] the type of the solid carrier used to prepare the sorbent is indicated in brackets. The calculation was performed by Eqn. (12c) and also by the traditional method, i.e. by Eqn. (12a). The data presented in Fig. 2 were obtained for sorbents containing ~8.8% of the SLP.

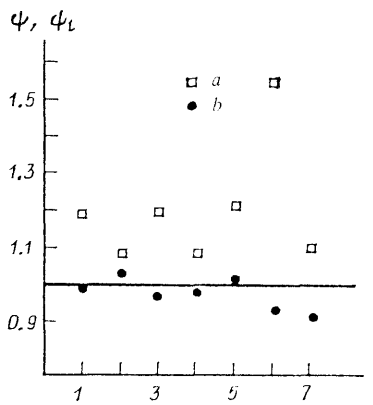

Figure 2. Dependence of ψ (points *a*) and ψ_l (points *b*) on the nature of the chromatographed compounds; the numerals along the abscissa axis denote the chromatographed compounds: 1) propionaldehyde; 2) benzene; 3) ethyl acetate; 4) acetone; 5) ethyl methyl ketone; 6) hex-1-ene; 7) cyclohexene. The $\psi_l = 1.0$ straight line, corresponding to the complete compensation of adsorption and other effects, is shown.

It follows from the results presented that the extrapolation method, taking into account adsorption, yields stable constant values of ψ_l, which are independent of the type of solid carrier, while the values of ψ obtained by the traditional method do depend on the type of solid carrier and higher values for the sorbent are obtained using refractory brick, which has a higher adsorption activity, as the solid carrier.

We may note that the contribution of adsorption to the overall retention volume is appreciable for the series of systems (solid carrier–SLP–sorbate) usually employed in GLC (Table 2).[21,22,24,36] Thus, in a quantitative study of the interaction of the solute with the SLP, it is essential either to take into account adsorption or to show that it can be neglected compared with dissolution.

We shall consider the main results obtained using the additive theory of retention in capillary chromatography. In the first quantitative study[49] of the contribution of adsorption to retention in capillary chromatography, the experimental data of Brunner and Cartoni[79] were used to test the applicability of the theory.[32] It was shown that the retention theory developed previously can be applied successfully also to capillary chromatography. Fig. 3 illustrates the dependence of V_N^0/W_l on $1/W_l$, which is described satisfactorily by the equation:

$$\frac{V_N^0}{W_l} = V_g + A\frac{1}{W_l}, \qquad (13)$$

where A is a coefficient characterising the contribution of adsorption to retention and V_N^0 the pure retention volume adjusted to 0 °C and a pressure of 1 atm. Eqn. (13) is a corollary of the general Eqn. (8) when the contribution of adsorption can be regarded as constant. Eqn. (13) can be usefully employed to determine the specific retention volume V_g, which is normally used in various physicochemical calculations (see, for example, Dal Nogare and Juvet[18] and Conder and Young[89]).

Table 2. Estimation of various contributions to the overall retention volume.

Chromatographic system	*a*	*b*	*c*	*d*	*e*
Refractory brick (INZ-600)–Apiezon K–benzene	60	150	57	—	43
Chromosorb P–stearic acid–n-hexane	72	63	75	5.0	20
Chromosorb W–stearic acid–n-hexane	72	65	81	—	19
Polychrom-1–diethylene glycol succinate–diethylene glycol	138	3509	80	20	—
Graphitised black–squalane–cyclohexa-1,4-diene	28	980	72	—	28
Bentone-245–di-iso-octyl sebacate–benzene	50	380	15	—	85
Refractory brick–ββ-thiodipropionitrile–heptane	25	18	25	67	8.0
Chromosorb W–ββ-thiodipropionitrile–heptane	25	19.9	54	42	4

Notation: *a*) temperature (degrees C); *b*) distribution constant of the sorbate in the gas–SLP system; *c*) contribution of dissolution to the retention volume (%); *d*) contribution of adsorption at the gas–SLP interface (%); *e*) contribution of adsorption at the SLP–solid carrier interface.

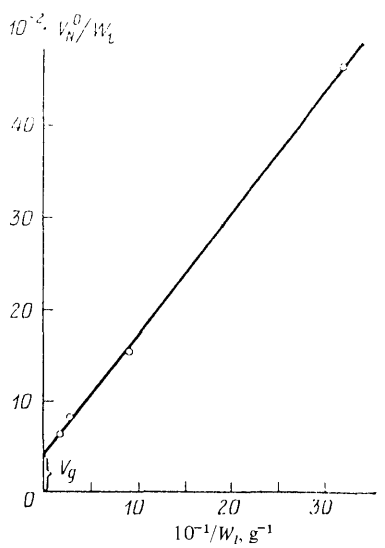

Figure 3. Dependence of V_N^0/W_l on $1/W_l$ (according to the experimental data of Brunner and Cartoni[79]).

It is noteworthy that the glass capillary columns used by Berezkin et al.[49] had a high internal surface area; the pure retention volume of heptane at 40 °C on a 38 m column (0.22 mm in diameter) was 14.7 ml. Furthermore, the absolute retention volumes are quoted by Brunner and Cartoni[79] only for one hydrocarbon (n-heptane). It therefore appeared essential, firstly, to investigate the role of adsorption in capillary columns which do not exhibit such a high adsorption activity and, secondly, it was necessary to develop rational forms of the equations of the additive theory to calculate retentions specifically in capillary chromatography. The latter task was undertaken because the use of the absolute mass or volume of the SLP in capillary chromatography presents certain difficulties.

The following study of the role of adsorption in capillary columns was therefore carried out for aromatic hydrocarbons and paraffins in the perdeuteriosqualane–stainless steel system.[50]

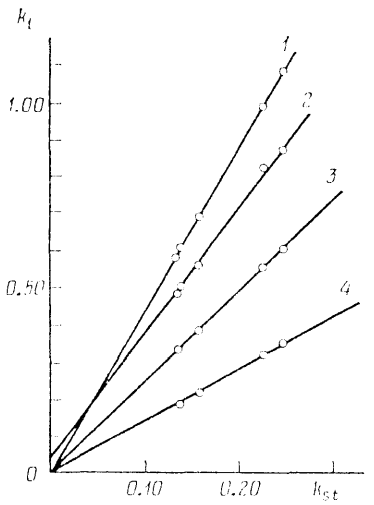

Figure 4. Dependence of k_i on k_{st} for hydrocarbons on a stainless steel column (standard–n-heptane): chromatographed substance: 1) cyclohexane; 2) benzene; 3) n-hexane; 4) 2,2-dimethylbutane.

Using the general Eqn.(8) obtained previously and assuming that the retention volume is independent of the sample size, that the properties of the thick SLP layer do not differ from those of the corresponding bulk phase, that the area of the gas–SLP interface hardly changes with increase of the thickness of the SLP film on the inner wall of the column, and that the SLP film covers the entire internal surface of the column, it is possible to obtain by means of simple transformations, the following equations, which can be usefully employed for the quantitative estimation of the role of adsorption in capillary chromatography:

$$V_{ri} = \frac{V_{Ni}}{V_{N,st}} = \frac{K_{li}}{K_{l,st}} + \frac{A_i}{V_M} \cdot \frac{1}{K_{st}} , \qquad (14)$$

where V_{ri} is the relative retention volume of the ith substance, A_i a coefficient reflecting the contribution of adsorption to the relative retention volume, and k_{st} the extraction coefficient or the capacity coefficient of the compound adopted as the standard. The standard compound is chosen in such a way that its retention is determined virtually only by the dissolution in the SLP and adsorption can be neglected, i.e. so that the relation $V_{N,st} = K_{l,st}\ H_l$ (H_l is the volume of the SLP in the column) holds. The capacity coefficient and not the relative retention volume can be usefully employed in many instances as the determining quantity. Eqn.(14) can then be expressed in the following form:

$$k_i = \frac{A_i}{V_M} + \frac{K_{li}}{K_{l,st}} \cdot k_{st} . \qquad (15)$$

The parameters of Eqns.(14) and (15) can be determined graphically, for example. The limiting retention is then of greatest interest:

$$V_{rli} = \frac{K_{li}}{K_{l,st}} . \qquad (16)$$

The limiting retention V_{rli} can be used as the initial retention for various calculations characterising the sorbate–SLP interaction and, by resorting to the absolute thermodynamic parameters for one compound (the standard), it is possible to obtain the absolute values of the physicochemical characteristics of all the compounds used in the chromatographic experiment.

Eqns.(14)–(16) have been used to interpret experimental data obtained in Keulemans' laboratory.[50] A stainless steel capillary column 100 mm long and with an internal diameter of 0.25 mm was used; the SLP was perdeuteriosqualane; the column temperature was 70 °C. Fig.4[50] presents the experimental results obtained on this column; it is seen that Eqn.(15) describes the experimental data satisfactorily. Calculation by Eqn.(15) makes it possible to determine the limiting relative retention V_{rli} and to estimate the contribution of adsorption to the retention.

Table 3[50] presents the parameters of Eqn.(15) evaluated by the method of least squares (on a computer). For the saturated hydrocarbons investigated, including cyclic hydrocarbons, adsorption can be neglected. However, adsorption exerts a significant influence on the retention of aromatic compounds, for example, benzene. For example, $V_{rli} = 3.42$ for benzene, while the limiting retention index is 636.0; the experimental retention indices of benzene determined on this column amounted to 639.8–643.8.[50]

Table 3. The ratio of the distribution constants and the adsorption characteristic of the sorbate for a stainless steel capillary column [parameters of Eqn.(15)].[50]

Compound	$K_{li}/K_{l,st}$	A_i/V_M
n-Pentane	1.000	0.000
2,2-Dimethylbutane	1.438	−0.004
2,3-Dimethylbutane	1.888	−0.004
3-Methylbutane	2.184	−0.004
n-Hexane	2.469	+0.002
Methylcyclopentane	3.250	−0.003
Benzene	3.418	−0.033
Cyclohexane	4.480	−0.008
3-Methylhexane	4.939	−0.008
n-Heptane	5.968	+0.010

Thus the additive theory of retention is fully applicable also in capillary chromatography. Exact measurements of the ratio of the partition constants of the chromatographed compounds in gas–liquid capillary chromatography are possible only when account is taken of the contribution of adsorption.

IV. THE ADSORPTION OF VOLATILE COMPOUNDS

Gas chromatography has been used traditionally as a physicochemical method for the investigation of adsorption on solid adsorbents from the gas phase.[34] Since the adsorption of chromatographed compounds at the interfaces between the SLP and the carrier gas and the solid carrier influences their retention volumes [see Eqns.(7) and (8)], the above relations can be used for the quantitative study of the adsorption of volatile compounds at the gas–SLP and SLP–solid carrier interfaces.

Many investigators have studied the influence of adsorption on the retention indices. As an example, Table 4 presents data for the relative retention of methyl oleate, methyl linoleate, and methyl linolenate on Rheoplex 400 using different solid carriers, including a stainless steel capillary column.[70] It follows from the data presented in Table 4 that the solid carrier (in the first place the area and type of its surface) exerts a significant influence on retention.

Table 4. The influence of the solid carrier (SLP–Rheoplex 400) on the retention of the methyl esters of unsaturated C_{18} acids (standard–methyl stearate).[70]

Solid carrier	Relative retention time		
	methyl oleate	methyl linoleate	methyl linolenate
Gas-chrom P, silanised	1.10	1.33	1.71
Chromaton N AW HMDS	1.10	1.32	1.70
Gas-chrom Q	1.09	1.31	1.70
Chromosorb W, silanised	1.09	1.32	1.69
Chromosorb P, silanised	1.10	1.32	1.70
Chezasorb AW HMDS	1.09	1.31	1.68
Chromosorb G AW	1.09	1.31	1.64
Celite 545	1.08	1.29	1.60
Chromosorb W	1.06	1.28	1.62
Chromosorb P	1.05	1.23	1.54
Kieselguhr	1.07	1.27	1.62
Capillary column*	1.10	1.32	1.69

*Stainless steel.

The development of methods for the quantitative assessment of adsorption phenomena in GLC has led to fundamental new possibilities in the investigation and quantitative measurement of the degrees of adsorption of volatile substances, in the first place at the gas–liquid interface and in the second place at the SLP–solid carrier (solid) interface.

After the determination of the dependence of the partial retention volumes on concentration, which is in its turn determined by the adsorption at the interfaces between the SLP and the gas and the solid, it is possible to calculate the adsorption isotherms at the gas–SLP and the SLP–solid interfaces using the following equation:[90]

$$a_{sj} = \frac{1}{S_{sj}} \int_0^c V_{sj}(c)\,\mathrm{d}c \ , \qquad (17)$$

where a_{sj} is the concentration of the test substance in the stationary surface phase of the jth type, S_{sj} the surface area of the surface phase of the jth type, and $V_{sj}(c)$ the partial retention volume of the test substance when its concentration in the mobile phase is c.

The methods for the "isolation" of the pure partial retention volumes from the overall retention volume and the methods for the determination of the isotherms have been described in detail.[24,36,43,90–92] As an example, Fig.5[43] presents the isotherm for the adsorption of *p*-xylene on the dimethyldioctadecylammonium derivative of vermiculite impregnated with di-iso-octyl sebacate, which has been obtained gas-chromatographically at 65 °C, as well as the experimental points for the same system obtained from static experiments. The results of the gas-chromatographic and static experiments agree satisfactorily. Other examples of analogous experiments for solid carriers have been published elsewhere.[44,45]

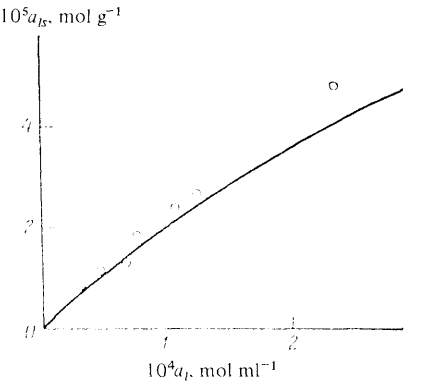

Figure 5. Isotherm for the adsorption of *p*-xylene on methyldioctadecylammonium vermiculite from solutions in di-iso-octyl sebacate; continuous line–adsorption isotherm according to gas-chromatographic data; circles–data obtained by a static method.

For linear dissolution and adsorption isotherms, the retention volume depends on the characteristics of the adsorption in accordance with Eqn.(8). Having determined experimentally the dependence of the retention volume on the content of the SLP on the solid carrier V_{Ns} on H_{ls} and the dependence of the area of the gas–SLP interface S_{ls} on H_{sl} as well as the surface area of the solid carrier S_s, it is possible to determine the adsorption coefficients K_{gl} and K_{ls}; the methods of calculation have been described.[24,32,91]

Table 5. Heats of solution (ΔH_s) in Apiezon K and adsorption (ΔH_a) at the Apiezon K–INZ-600 (solid carrier) interface measured by the gas-chromatographic method.[42]

Compound	ΔH_s, kcal mol^{-1}	ΔH_a, kcal mol^{-1}
n-Hexane	5.8	4.6
Hex-1-yne	5.2	10.9
n-Heptane	6.6	7.6
Hept-1-yne	8.6	17.8

The procedures proposed[42] for the measurement of the dissolution coefficients of volatile compounds in the SLP and of the adsorption coefficients on the SLP–solid carrier interface made it possible to determine the heats of solution and adsorption from the temperature variation of these coefficients. Table 5[42] presents the results of the determination of the

heats of solution and adsorption for a sorbate–refractory brick (INZ-600)–Apiezon K system. It follows from the results that the heats of adsorption of alkynes are much higher than the heats of solution, which can be accounted for by their specific interactions with the silanol surface groups.

In order to test the ideas developed, measurements have been made[32] by gas–liquid and liquid chromatography of the adsorption coefficients K_S at the SLP–solid interface for the hexadecane–Chromosorb P and hexadecane–Chromosorb W systems at 26 °C. The adsorption coefficients measured by these two independent methods are close to one another. For example, the K_S obtained by the GLC and liquid chromatographic methods for benzaldehyde in the hexadecane–Chromosorb P system are 0.091 and 0.090 $cm^3\ g^{-1}$; the values for ethyl methyl ketone in the hexadecane–Chromosorb W system are respectively 0.109 and 0.09 $cm^3\ g^{-1}$, and those for pyridine in the hexadecane–Chromosorb W system are respectively 0.165 and 0.164 $cm^3\ g^{-1}$. Hence an independent test of the proposed methods confirmed their validity.[45] Thus, using the methods developed, it is possible to calculate not only the partition (absorption) isotherms but also the (adsorption) isotherms at the SLP isotherms. which is a fundamentally new physicochemical application of chromatography.

It has been found that the influence of adsorption on the separation has not only a physicochemical but also an analytical application. The influence of adsorption on the separation in capillary gas–liquid chromatography has been investigated by Sojak and Berezkin.[93] Since the resolution in capillary columns is greater than in packed columns by a factor of 5–10, even relatively small changes in the contribution of adsorption can induce an appreciable change in the separation up to an alteration of the order in which the components emerge. Therefore allowance for and employment of the adsorption factor is particularly justified, in our view, for the improvement of the separation in gas–liquid capillary chromatography. The sorbate-adsorbent adsorption interactions are of a type fundamentally different from that of the sorbate–SLP interaction and are particularly sensitive to the structure of the compounds separated (see, for example, Kiselev and Yashin[34]). The change in the separation can be a result of the ageing of the columns, a change in the content of the SLP in the capillary column, an increase in the adsorption activity of the internal surface of the column, or a change in the adsorbent present in the SLP layer.

Since the separation depends significantly on the selectivity of the sorbent employed, whose measure is the relative retention, it is useful to examine the dependence of the selectivity α on the degree of adsorption in the capillary column:

$$\alpha = \frac{V_{N1}}{V_{N2}} = \frac{K_{l1}}{K_{l2}} \cdot \frac{1 + a_1/H_l}{1 + a_2/H_l}\ , \qquad (18)$$

where

$$a_1 = \frac{K_{gl1}S_l + K_{l1}K_{ls1}S_s}{K_{l1}}\ ;$$

$$a_2 = \frac{K_{gl2}S_l + K_{l2}K_{ls2}S_s}{K_{l2}}\ .$$

The subscripts 1 and 2 in Eqn.(18) refer to the compounds separated (the first and second respectively). Having expanded this expression in a Maclaurin's series in terms of the variable $1/H_l$, we obtain

$$\alpha = \frac{K_{l1}}{K_{l2}} + \frac{K_{l1}}{K_{l2}}(a_1 - a_2) \cdot \frac{1}{H_l}\ . \qquad (19)$$

Depending on the relative values of the degrees of adsorption ($a_1 > a_2$ or $a_1 < a_2$), the quantity α can increase or decrease with increase of H_l. For components with similar properties, whose separation is of interest, one can assume that $K_{l1}/K_{l2} \cong 1$; we then obtain

$$\alpha - 1 \simeq \frac{K_{l1}}{K_{l2}}(a_1 - a_2) \cdot \frac{1}{H_l} \simeq (a_1 - a_2) \cdot \frac{1}{H_l}\ . \qquad (20)$$

On substituting this expression in Eqn.(9), we obtain

$$R \simeq \frac{1}{4} N^{1/2} \cdot \frac{k}{1+k} \cdot \frac{a_1 - a_2}{H_l}\ . \qquad (21)$$

Thus in the case which we have considered the separation factor depends significantly on the ratio of the difference between the adsorption terms of the retention to the amount of SLP in the capillary column.

Fig. 6[93] presents chromatograms illustrating the influence of the adsorption factor on the separation. A change in the thickness of the SLP layer alters the ratio of the adsorption and absorption factors, which alters the separation. A mixture of pentadecene isomers has been separated on two glass columns *A* and *B*. Comparison of the chromatograms shows that the order of the emergence of *trans*-pentadec-6-ene and *cis*-pentadec-5-ene separated in the two columns is different.[93] The capacity coefficient, which reflects the thickness of the SLP film is 2.1 in column *A* and 1.3 in column *B* for *cis*-pentadec-5-ene, i.e. the difference is not very great. The difference between the retention indices for these isomers is 1.2 in column *A* and 0.9 in column *B*.

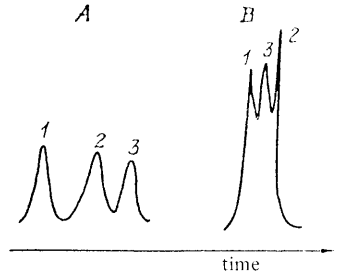

Figure 6. The influence of the thickness of the SLP layer on separation in capillary gas–liquid chromatography.[93] Separation conditions: 300 m × 0.25 mm glass columns *A* and *B*; SLP–Carbowax 20M; temperature 95 °C; the thickness of the SLP layer is greater in column *A*; compounds: 1) *trans*-pentadec-7-ene; 2) *trans*-pentadec-6-ene; 3) *cis*-pentadec-5-ene.

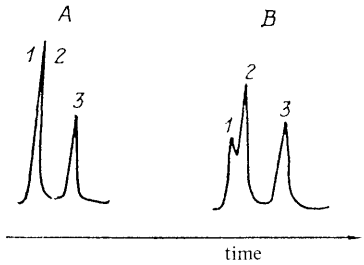

Figure 7. The influence of the adsorption activity of the column on separation.[93] Separation conditions: 100 m × 0.2 mm glass capillary columns; SLP–Apiezon L; temperature 164 °C; compounds: 1) n-heptadecane; 2) *trans*-heptadec-2-ene; 3) *cis*-heptadec-2-ene.

Fig. 7 illustrates the separation of *cis*-heptadec-2-ene and *trans*-heptadec-2-ene and n-heptadecane on two glass capillary columns *A* and *B*.[93] The adsorption activity of the internal surface of column *B* is appreciably higher than that

of column *A*, which accounts for the successful separation of *trans*-heptadec-2-ene and n-heptadecane on column *B*.

The examples presented show that adsorption can exert a significant influence (both positive and negative) on the separation of the compounds analysed, including compounds with similar properties, for example, isomers, in capillary chromatography.

V. METHODS FOR THE IDENTIFICATION OF CHROMATOGRAPHIC BANDS TAKING INTO ACCOUNT THE ADSORPTION PHENOMENA IN GAS–LIQUID–SOLID CHROMATOGRAPHY

The qualitative interpretation of the chromatograms of complex organic mixtures is an important stage in gas-chromatographic analysis. The identification methods, based on a comparison of the experimental retentions of the unknown compounds chromatographed with the available literature data, are widely used in gas-chromatographic analytical practice. However, the application of this simple and effective method is restricted owing to the inadequate reproducibility of the retention parameters in different laboratories.

The retention theory developed above makes it possible to explain a number of causes of the non-reproducibility of the retentions and suggests new effective chromatographic methods for the identification of compounds.

In the general case the relative retention can be expressed by the equation

$$\frac{V_N}{V_{N,st}} = \frac{K_l}{K_{l,st}} \cdot \frac{1 + \left(\sum_{i=2}^{m} K_{li} H_{li} + \sum_{j=1}^{n} K_{sj} S_{sj} \right) (1/K_l H_l)}{1 + \left(\sum_{i=2}^{m} K_{li,st} H_{li} + \sum_{j=1}^{n} K_{sj,st} S_{sj} \right) (1/K_{l,st} H_l)} , \qquad (22)$$

where $V_{N,st}$ is the true retention volume of the substance adopted as the standard $K_{l,st}$ the constant of the equilibrium involving the standard substance between the SLP and the gas phase, $K_{sj,st}$ the constant for the equilibrium involving the standard substance between the SLP and the *j*th type interface, and $K_{li,st}$ the constant of the equilibrium involving the standard substance between the *i*th type SLP and the mobile phase.

Apart from dissolution processes, Eqn.(22) takes into account the adsorption interactions associated with the properties of the solid carrier and the phase characteristics of the sorbent. It follows from Eqn.(22) that the relative retention is not a constant for a given chromatographed compound and cannot be used for qualitative analysis on the basis of literature data. The modification of solid diatomaceous carriers or the employment of polymeric solid carriers lead in many instances solely to a decrease of the role of adsorption phenomena, but the contribution of adsorption to the retention frequently remains appreciable.

If the retention volume is determined solely by the dissolution of the chromatographed substance in the SLP and by the adsorption at the interfaces between the SLP and the mobile phase in the solid carrier [see Eqn.(8)], then the relative retention volume can be expressed by the equation

$$\frac{V_N}{V_{N,st}} = \frac{K_l}{K_{l,st}} + \lambda_1 \frac{1}{H_l} , \qquad (23)$$

where

$$\lambda_1 = \frac{(K_{gl} K_{l,st} - K_{gl,st} K_l) S_{ls} + (K_s - K_{s,st}) K_l K_{l,st} S_s}{K_{l,st}^2} . \qquad (24)$$

It is desirable to select as the standard a substance for which the retention is determined solely by dissolution, i.e. $V_{N,st} = K_{l,st} V_l$; in this case we obtain

$$\lambda_{10} = \frac{K_{gl} S_{ls} + K_l K_s S_s}{K_{l,st}} . \qquad (25)$$

Eqn.(23) is linear in $1/H_l$ and makes it possible to determine the relative distribution constants. In many instances, when the determination of H_l presents certain difficulties, it is convenient to employ the percentage content *P* of the SLP in the column as a characteristic:

$$\frac{V_N}{V_{N,st}} = \frac{K_l}{K_{l,st}} + \lambda_2 \frac{1}{P} , \qquad (26)$$

where λ_2 is a constant.

The proposed methods can be used to determine the ratio of the distribution constant to the thermodynamic characteristic of the substance which can be used to identify it. The relative distribution constant is independent of the content of the SLP and of the type of solid carrier.

Together with relative retentions, the system of Kovats indices[34] is used in gas chromatography for the identification of compounds:

$$I = 100z + 100 \cdot \frac{\lg (V_N / V_{Nz})}{\lg (V_{N(z+1)} / V_{Nz})} , \qquad (27)$$

where V_{nz} and $V_{N(z+1)}$ are the corrected retention volumes of n-alkanes whose molecules contain *z* and *z*+1 carbon atoms. This equation can be reduced to equations of the type

$$I = I_0 + \lambda_3 \cdot \frac{1}{H_l} , \qquad (28)$$

$$I = I_0 + \lambda_4 \cdot \frac{1}{P} , \qquad (29)$$

where λ_3 and λ_4 are constants, which are determined by the adsorption interactions of the sorbate in the chromatographic system and by the dimensions of the argument employed; I_0 is an invariant quantity for the determination of which one employs the corresponding relative distribution constants instead of the relative retention volumes, i.e. it is a universal constant:

$$I_0 = 100z + 100 \cdot \frac{\lg (K_l / K_{lz})}{\lg (K_{l(z+1)} / K_{lz})} . \qquad (30)$$

It is desirable to select as standard a substance whose retention is determined solely by dissolution. For non-polar phases and phases of medium polarity, n-alkanes meet the requirements for standard compounds, while in the case of polar SLP it is convenient to select polar compounds (for example, alcohols) as standards. Consequently, in order to identify the compounds analysed, it is essential in the general case to separate from the overall retention volume the contribution due solely to the dissolution of the chromatographed substance in the SLP.

Thus general methods have been proposed for the identification of chromatographed compounds in gas–liquid chromatography,[90] based on the use of invariant characteristics of the retention, independent of adsorption.

We used the methods[46,90] based on the employment of the relation between the relative retentions and the reciprocal of the content of the SLP on the solid carrier to interpret both literature data and our own experimental data. A completely satisfactory agreement between experiment and theory was obtained in all cases.

As an example, Fig.8 presents the relations between the relative retention volume and the reciprocal of the content of the SLP on the solid carrier; experimental data obtained by Pecsok et al.[14] were used to derive these relations. It is seen from Fig.8 that, in conformity with the theory, the graphs for all the substances chromatographed are linear and make the same intercept on the ordinate axis for different solid carriers, which corresponds to the ratio of the distribution constants of the given substance and the standard. The methods

proposed can therefore be used successfully to determine the ratio of the distribution constants – a thermodynamic characteristic of the substance on the basis of which it can in fact be identified. The ratios $K_l/K_{l,st}$ obtained are independent of the content of SLP and of the type of solid carrier. As already mentioned above, the application of the additive theory of retention in capillary chromatography has a number of specific features associated with the need to use the capacity coefficient k_{st} as the characteristic of the content of SLP in the capillary column. Since the Kovats retention indices are at present the most widely used system of retention units in gas chromatography, it appeared essential to test the validity of the following expression for the retention indices in capillary chromatography:[51]

$$I_i = I_{0i} + a_{Ii} \cdot \frac{1}{k_{st}} . \qquad (31)$$

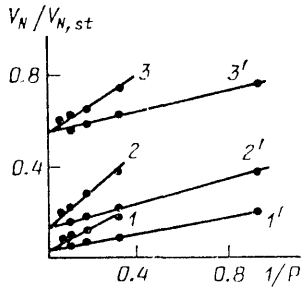

Figure 8. Dependence of the relative retention volume (standard–ethyl methyl ketone) on the reciprocal of the SLP content on the solid carrier (according to the data of Pecsok et al.[14]). Experimental conditions: SLP–ββ'-oxydipropionitrile, temperature 25 °C, solid carrier–Chromosorb W (lines *1'–3'*) and refractory brick (lines *1–3*); compounds: 1) and 1') n-heptane; 2) and 2') butyl ethyl ether; 3) and 3') ethyl acetate.

Using this equation, it is possible to determine the limiting value of the retention index I_{0i}, which depends solely on the solubility of the chromatographed substance in the SLP, and the quantity a_{Ii}, which depends on the adsorption of the chromatographed substance on the interfaces between the SLP and the carrier gas and the solid carrier. Experiments on a capillary column were carried out using different chromatographic systems: gas–polar phase [1,2,3-tris(cyanoethoxy)-propane]–stainless steel, gas–polar phase (Carbowax 20M)–alkaline glass, and gas–non-polar phase (Apiezon L)–alkaline glass. For all the systems indicated and compounds investigated (benzene, *o*-xylene, and *cis*- and *trans*-isomers of pentadecene), it has been shown[95] that Eqn.(31) describes satisfactorily the experimental data (Fig.9).

An important condition for the successful employment of an equation of type (31) is the selection of a system of standards for the retention indices. For the homologous series of compounds employed as standards as well as the compound whose capacity coefficient was used in Eqn.(31), it is useful to choose substances whose properties approach ideality, i.e. whose retention is determined mainly by dissolution and the contribution of adsorption to retention is minimal. The importance of this factor had been demonstrated earlier for packed columns and it has been studied systematically for capillary columns.[95] In the case of a stainless steel column (50 m × 0.25 mm) with 1,2,3-tris(cyanoethoxy) propane as the SLP at 50 °C, $I_{0i} = 1405 \pm 38$ and $a_{Ii} = 245 \pm 54$ (with n-alkanes as standards) or $I_{0i} = 908.3 \pm 2.0$ and $a_{Ii} = -10.4 \pm 4.0$ (with n-alkenes as standards) have been obtained for *o*-xylene. Table 6[95] presents the values of I_{0i} and a_{Ii} obtained for n-pentadecene isomers on Carbowax 20M at 110° on a 50 m × 0.25 mm stainless steel column. Evidently the use of the homologous series of alk-1-enes made it possible to improve the reproducibility of the quantities I_{0i} by a factor of 2–50 and that of the quantities a_{Ii} by a factor of 3–70. 2-Alkyl-1-ethylbenzenes have also been used[95] as standards. However, a better reproducibility of I_{0i} and a_{Ii} was achieved using as standards alk-1-enes, i.e. compounds whose chemical properties are closest to those of the compounds investigated.[33]

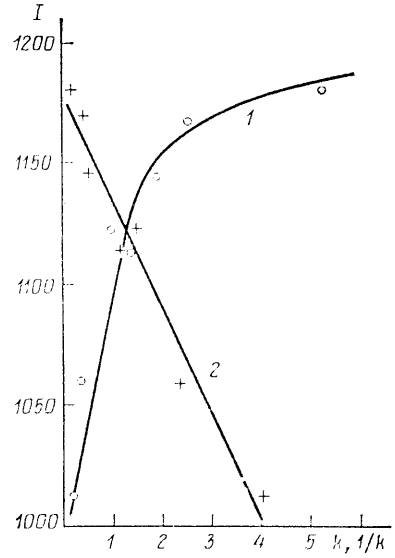

Figure 9. Dependence of the retention index of benzene (standards–n-alkanes) on the capacity coefficient (curve *1*) and on its reciprocal (curve *2*).[95] Experimental conditions: 50 m × 0.25 mm stainless steel columns, SLP–tris(cyanoethoxy) propane, temperature 50 °C.

The analysis of n-alkenes (for example, pentadec-1-ene) on a non-polar phase (Apiezon L) at 164 °C using compounds in the homologous series of n-alkanes as standards yielded $I_{0i} = 1489.6 \pm 1.0$ and $a_{Ii} = -0.38$.

A rational choice of the homologous series of compounds to be used as standards for the system of Kovats indices significantly improves the reproducibility of the latter for the compounds chromatographed and the reproducibility of the limiting value of I_{0i}. Thus, instead of the usually employed retention index I, the quantity I_{0i} can be usefully employed for the identification of compounds on the basis of chromatographic data; this quantity should in fact be used in tables bearing in mind its better reproducibility in experiments in different laboratories.

The differences between the retention characteristics of hydrocarbons as a function of their type (for example, the *cis*- or *trans*-isomers of alkenes) on columns with different SLP contents can be employed in gas–liquid–solid chromatography for the identification of the compounds analysed. This assumption was first made in a study[51] where it was shown that the relative retentions of n-paraffins and aromatic hydrocarbons vary unequally as the column ages, which can

be employed for the identification of these classes of compounds.

Indeed, if the retention of compounds analysed is determined by two groups of phenomena—the dissolution in the SLP and adsorption at the SLP interfaces, then, following a change in the SLP content, one in fact obtains a new column with new chromatographic properties, which is equivalent to the employment of a new phase. In analysing this phenomenon, one should note that, in conformity with the available data (see, for example, Berezkin et al.[92]), the contribution of adsorption to retention is unique as regards the chromatographic separation effects attained and can be particularly usefully employed in the separation of isomeric compounds. Therefore, using jointly dissolution and adsorption, it is possible in many instances to improve the separation and, when two and more columns are employed, it is possible to achieve the group identification of compounds.

Table 6. The invariant values of the retention index I_{0i} and the adsorption parameter a_{Ii} and the corresponding standard deviations s for n-pentadecene isomers [calculation by Eqn. (31)].[95]

n-Pentadecene isomers	Standards—n-alkanes				Standards—alk-1-enes			
	I_{0i}	s	a_{Ii}	s	I_{0i}	s	a_{Ii}	s
cis-Pentadec-7-ene	1525.4	3.0	−41.7	1.3	1476.8	1.7	1.9	0.74
cis-Pentadec-6-ene	1528.5	2.9	−42.1	1.3	1480.4	1.6	1.2	0.72
cis-Pentadec-5-ene	1533.7	4.8	−43.5	2.2	1485.9	0.2	−0.2	0.1
cis-Pentadec-4-ene	1539.9	5.4	−44.5	2.4	1491.9	0.5	−0.7	0.2
cis-Pentadec-3-ene	1548.4	5.9	−46.0	2.4	1500.5	0.1	−1.1	0.2
cis-Pentadec-2-ene	1576.4	7.2	−23.6	4.9	1529.6	2.2	−7.4	1.2
trans-Pentadec-7-ene	1526.2	3.6	−9.6	1.6	1477.9	1.1	3.8	0.5
trans-Pentadec-6-ene	1528.2	3.5	−9.7	1.6	1479.6	1.0	3.0	0.5
trans-Pentadec-5-ene	1531.1	3.5	−10.4	1.6	1482.8	1.1	3.0	0.5
trans-Pantadec-4-ene	1533.0	3.8	−11.1	1.7	1484.6	0.9	3.0	0.4
trans-Pentadec-3-ene	1542.6	4.9	−13.6	2.4	1494.1	0.1	1.8	0.1
trans-Pentadec-2-ene	1562.2	6.4	−25.4	3.4	1514.7	1.7	−2.7	0.8
Pentadec-1-ene	1547.9	5.0	−14.7	2.5	—	—	—	—

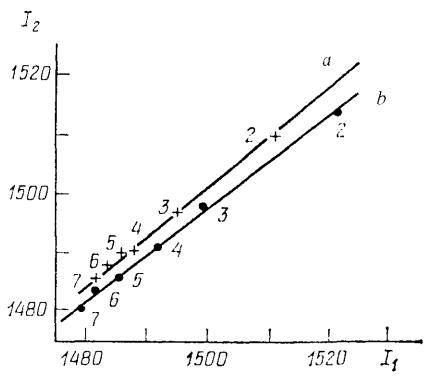

Figure 10. Relation between the retention indices for the *cis*- and *trans*-isomers of pentadecene on Carbowax 20M at 110 °C on two glass columns differing in the effective thickness of the SLP film;[51] I_1 and I_2 are the retention indices of the compound on columns *1* and *2* respectively; the thickness of the SLP layer on column *2* is twice as great as on column *1*: *a*) relation for the *trans*-isomers of pentadecene; *b*) relation for the *cis*-isomers of pentadecene; the numerals opposite the points denote the position of the double bond in the pentadecene isomer.

Fig. 10 presents data obtained on glass columns[51] differing only in the SLP content (the thickness of the SLP film on the second column was approximately twice as great as on the first). The use of data obtained on these two columns makes it possible to trace clearly two linear relations for the *cis*- and *trans*-isomers of pentadecene, which can be used for identification. We may note that relations of this type had been employed earlier solely for columns with different SLP.[96] In order to enhance the role of the adsorption factor, it may be that in the future it will prove desirable to employ one of the following procedures: (1) to increase the surface area of the walls of capillary columns and to subject them to extensive special treatment (for example, etching, deposition of a porous layer, etc); (2) to introduce specially into the SLP a small amount of a finely dispersed solid adsorbent. New possibilities for identification can be particularly usefully employed in capillary chromatography bearing in mind the selectivity and accuracy of the measurements of the retention characteristics.

VI. THE ROLE OF ADSORPTION PHENOMENA IN THE AGEING OF CAPILLARY COLUMNS

An important problem in capillary chromatography is the time variation of the properties of capillary columns (ageing), which has a negative influence on almost all the chromatographic properties of the columns (efficiency, separation, symmetry of chromatographic bands, reproducibility, retention characteristics, etc.). The ageing of packed columns was investigated long ago (see, for example, Dal Nogare and Juvet[16]): different investigators put forward the following main causes of the time variation of the properties of packed columns during their use: (1) the volatilisation of the stationary liquid phase from the columns;[16,97] (2) the redistribution of the SLP on the sorbent;[98,99] (3) the variation of the properties of the SLP as a result of its decomposition or oxidation by admixtures of oxygen in the carrier gas.[100]

The ageing of columns in capillary chromatography has not been studied in detail, although a number of hypotheses have been put forward concerning its nature.[87] Thus, according to Schomburg et al.,[101] one of the main causes of ageing is the transition from a continuous homogeneous film of SLP to a coating on the internal walls of the columns made up of isolated droplets. In a study specially devoted to the problem of ageing of capillary columns,[51] the hypothesis was put forward that the ageing process is associated mainly with the volatilisation of part of the SLP from the column. Jennings pointed out in a monograph[87] the great importance of the problem of the ageing of capillary columns in connection with the increase of their useful life.

Ageing has been studied on stainless steel columns (50 m × 0.25 mm) with 1,2,3-tris(cyanoethoxy)propane (TCEP) as the SLP. The changes in the properties of the columns were investigated at 130 °C in a stream of nitrogen (the pressure at the inlet to the column was 2.0 atm). The ageing of the columns was assessed from the change in the retention index I and the capacity coefficient k for benzene; I and k were measured at 50 °C and a nitrogen pressure at the inlet to the column of 0.6 atm. The maximum permissible working temperature for TCEP is 150–160 °C.[87,103]

In the first place it is essential to note that ageing influences not only the retention characteristics but also the separating capacity of the capillary column. Fig. 11[102] presents two chromatograms obtained on an ageing column over a period of two weeks. As a result of ageing for two weeks, two pairs of hydrocarbons, which were satisfactorily separated on a freshly prepared column, virtually ceased to

separate. The above example demonstrates the significant influence of ageing and the importance of studying its causes.

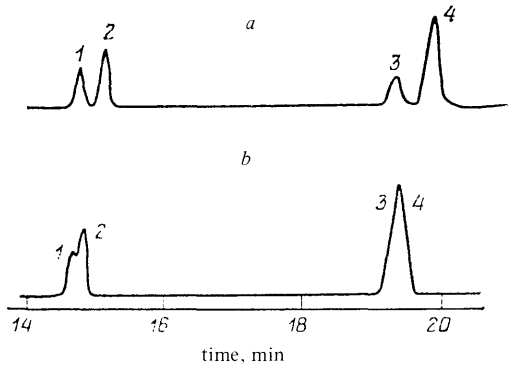

Figure 11. Variation of the separation during the ageing of the capillary column:[102] *a*) separation on a freshly prepared column; *b*) separation on the same column after ageing for 2 weeks. Experimental conditions: column length 50 m; SLP–tris(cyanoethoxy)propane; ageing temperature 130 °C; temperature of the measurement of the chromatographic characteristics 94 °C; compounds: 1) n-tetradecane (C_{14}); 2) 1-ethyl-4-methylbenzene; 3) n-pentadecane (C_{15}); 4) 1-methyl-2-propylbenzene.

The results of the variation of the quantities I and k for benzene as a function of the duration of ageing on capillary columns at 130 °C are presented in Fig.12.[102] The retention index and the capacity coefficient were measured at 50 °C.

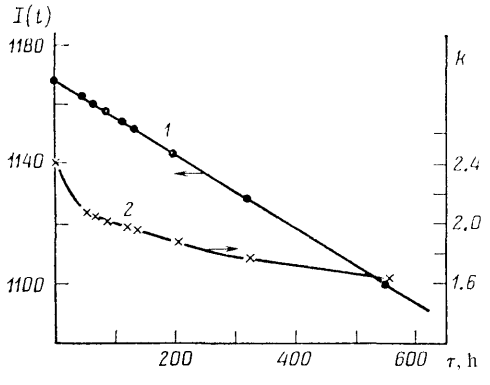

Figure 12. Variation of the retention index I (line *1*) and the capacity coefficient k (line *2*) for benzene as a function of the duration of ageing τ of a capillary column with tris(cyanoethoxy)propane at 130 °C.[102]

Independent experiments have shown that the variation of the chromatographic properties of open capillary columns for small carrier gas pressure drops in the column is associated mainly with the volatilisation of the SLP in the initial sections of the column. Thus, a small initial section consists of a column with a very thin layer of SLP. The separation in the initial (first) column is due mainly to adsorption processes. Therefore an ageing capillary column can be regarded to a first approximation as a compound column. Using the theory of retention on compound columns,[104] the following equation has been obtained:[102]

$$I(t) = I(0) - dt, \qquad (32)$$

where $I(t)$ is the retention index of the test substance at time t, t the ageing time, d a constant, and $I(0)$ the retention index in the initial instant. This equation describes experimental data satisfactorily (Fig.12).

In order to increase stability, it is useful to employ the SLP in capillary columns at a temperature 50 °C below that recommended for packed columns. It is recommended that a carrier gas fully or partly saturated by the vapour of the SLP employed be used at elevated temperatures in order to increase the lifetime of capillary columns. A device proposed recently is useful for the realisation of this recommendation.[105]

VII. THE INFLUENCE OF ADSORPTION PHENOMENA ON THE SPREADING OF CHROMATOGRAPHIC BANDS IN GAS–LIQUID CAPILLARY CHROMATOGRAPHY

The first studies on the theory of the efficiency of capillary chromatographic columns were the familiar investigations by Golay,[107,108] which have still not lost their importance even at the present time. A straight capillary column with a circular or slit-like cross-section and smooth walls coated by a thin layer of SLP was considered in these studies. Golay obtained an expression for the HETP in the cases indicated. The influence of the finite rate of diffusion within the SLP film was taken into account approximately with the aid of an equivalent electrical circuit for the retaining layer.[109,110] In subsequent studies by Golay[111–114] the above theory was developed in several directions. Following the introduction of capillary columns with a porous layer, Golay modified his equation and extended it to such columns.[111] A detailed investigation of this equation was described subsequently.[115] Golay[112] considered a flow of the Poiseuille type in a bent column and showed that, under the conditions of the Poiseuille type in such a column, the operation of centrifugal forces creates a "secondary flow", which decreases the HETP. An expression has been obtained[113] for the dynamic diffusion coefficient, which plays a significant role in the spreading of the chromatographic band in capillary chromatography in columns (tubes) with an elliptical cross-section. Golay[114] considered the question of the magnitude of this coefficient for tubes with an extended rectangular cross-section.

In a series of communications, Giddings[116–120] considered in general terms the processes occurring in chromatographic capillary columns; using the approximate principle of additivity, the author estimated the contributions of different mechanisms leading to the spreading of the chromatographic band.

The influence of various types of mass transfer in gas–liquid capillary chromatography was estimated approximately in the book of Zhukhovitskii and Turkel'taub.[20]

A mathematically more rigorous study of the chromatographic band in a capillary column, compared with the work of Golay and Giddings, has been carried out by Khan[121] using the method of moments; it took into account the effect of the finite rate of mass transfer through the gas phase–liquid phase interface (see also another communication by the same author[122]).

The expression obtained by Golay for the height equivalent to a theoretical plate H in the case of a capillary column having a circular cross-section with a radius r_0 is

$$H = \frac{2D_g}{u} + \left[\frac{(1+6k+11k^2)}{24(1+k)^2}\frac{r_0^2}{D_g} + \frac{2}{3}\frac{k}{(1+k)^2}\cdot\frac{\delta^2}{D_l}\right]u \cdot \qquad (33)$$

For a column having a slit-like cross-section with a slit width $2h$, this expression is somewhat modified:

$$H = \frac{2D_g}{u} + \left[\frac{4}{105}\cdot\frac{(1+9k+25.5k^2)}{(1+k)^2}\frac{h^2}{D_g} + \frac{2}{3}\cdot\frac{k}{(1+k)^2}\frac{\delta^2}{D_l}\right]u \quad (34)$$

where D_g and D_l are the diffusion coefficients of the chromatographed substance in the gas and liquid phases and δ is the thickness of the SLP film.

The first (identical) terms in Eqns.(33) and (34) describe the effect of longitudinal diffusion in the gas phase, while the second terms are due to the phenomenon of dynamic diffusion arising from the fact that in the capillary column there is a distribution of the flow rate with respect to the radius. The last term, which is also identical for the columns of the forms considered, is associated with the effect of diffusion within the SLP film.

A more general expression for the HETP, obtained by Khan,[121,122] includes an additional term:

$$H_M = \frac{2k}{(1+k)^2}\cdot\frac{\delta}{k_d}, \quad (35)$$

where k_d is the rate constant for the desorption of the test substance from the gas phase–liquid phase interface. This term reflects the effect of the additional resistance to mass transfer at the gas–liquid boundary associated with the finite rate of attainment of equilibrium at this boundary. However, it has been shown[123] that the above term does not usually make an appreciable contribution to the spreading of the chromatographic peak in gas–liquid capillary chromatography.

As in gas–liquid chromatography on packed columns,[32,124,125] allowance for the influence of adsorption phenomena on such a spreading process appears much more significant in this instance. In this connection mention should be made of a study[126] in which the theory of the spreading of peaks in a capillary column proposed by Golay was tested and the occurrence of peak spreading not taken into account by Golay's theory was demonstrated. This spreading is associated with the mass transfer in the stationary phase but is independent of the thickness of the liquid film. The authors[126] believe that it is caused by the adsorption of the substances analysed from the stationary liquid phase on the walls of the nylon capillary.

It therefore appears useful to discuss briefly a theoretical model of the chromatographic process in a capillary column taking into account the adsorption at the gas–SLP and SLP–solid wall interfaces. In order to obtain the principal characteristics of the chromatographic elution curve, we shall employ the method of static moments which is nowadays widely used in the theory of chromatography [see, for example, Zolotarev's review[127]]. The approach described below has been proposed by Zolotarev et al.[128]

We shall consider initially a straight cylindrical column with a circular cross-section. Suppose that $c_g^*(x,r,t)$ is the local concentration of the chromatographed substance in the gas phase. Then, if the distribution of the local velocity $v(r)$ in the gas along the tube cross-section is parabolic, the local differential equation of mass transfer in the capillary column can be formulated as follows:

$$D_g\left(\frac{\partial^2 c_g^*}{\partial r^2} + \frac{1}{r}\frac{\partial c_g^*}{\partial r} + \frac{\partial^2 c_g^*}{\partial x^2}\right) - v(r)\frac{\partial c_g^*}{\partial x} - \frac{\partial c_g^*}{\partial t} = 0,$$
$$v(r) = 2u\left(1 - \frac{r^2}{r_0^2}\right), \quad (36)$$

where x is the coordinate along the column axis, r the radial coordinate reckoned from the centre of the column, t the time, u the carrier gas flow rate averaged with respect to the cross-section, and r_0 the radial coordinate of the boundary of the free part of the column (Fig.1). Eqn.(36) represents the mass balance of the chromatographic impurity in a small volume element at a distance r ($r<r_0$) from the column axis. The mass balance condition should hold at the gas–SLP ($r = r_0$) interface: the diffusion flux of the impurity across this interface should be equal to the sum of the rates of change of the masses of the impurity in the liquid phase and in the adsorbed states at the interfaces:

$$\gamma_l\frac{\partial a_l}{\partial t} + \gamma_{gl}\frac{\partial a_{gl}}{\partial t} + \gamma_{ls}\frac{\partial a_{ls}}{\partial t} = -\frac{2\gamma_g D_g}{r_0}\cdot\left.\frac{\partial c_g^*}{\partial r}\right|_{r=r_0}. \quad (37)$$

We shall average Eqn.(36) with respect to the free volume of the column. For this purpose, we shall apply to each term of Eqn.(36) the averaging operator with respect to the cross-section and we shall take into account Eqn.(37). We then obtain

$$\gamma_l\frac{\partial a_l}{\partial t} + \gamma_g\frac{\partial c_g}{\partial t} + \gamma_{gl}\frac{\partial a_{gl}}{\partial t} + \gamma_{ls}\frac{\partial a_{ls}}{\partial t} =$$
$$= \gamma_g D_g\frac{\partial^2 c_g}{\partial x^2} - 4\gamma_g\frac{u}{r_0^2}\int_0^{r_0}\frac{\partial c_g^*}{\partial x}\left(1 - \frac{r^2}{r_0^2}\right)r\,dr, \quad (38)$$

where $c_g(x,t)$ and $a_l(x,t)$ are the average concentrations of the chromatographed impurity in the mobile phase and in the SLP. The local concentration of the impurity in the SLP will be designated by $a_l^*(x,y,t)$.

We shall assume as usual that the SLP is thin ($\delta \ll r_0$). For such a thin film, we have

$$\gamma_l + \gamma_g = 1;\ \gamma_g = \frac{r_0^2}{(r_0+\delta)^2} \simeq 1 - \frac{2\delta}{r_0};\ \gamma_l \simeq \frac{2\delta}{r_0^2};\ \gamma_{gl} \simeq \gamma_{ls} \simeq \frac{\gamma_l}{\delta}. \quad (39)$$

We shall assume that the equilibrium at the interfaces is established at an infinitely high rate. The following equilibrium relation between the local concentrations of the impurity in the gas and liquid phases will then hold at the gas–SLP interface:

$$(a_l^*)_i = K_l(c_g^*)_i, \quad (40)$$

where K_l is the partition coefficient between the gas and liquid phases and the subscript i refers to this interface. In addition, assuming that the gas adsorption isotherm is linear with a Henry coefficient K_{gl}, we have at the above interface

$$a_{gl} = K_{gl}(c_g^*)_i. \quad (41)$$

The diffusion of the impurity in the thin SLP film ($\delta \ll r_0$) can be described by the one-dimensional equation for diffusion along the coordinate y at right angles to the film boundaries (Fig.1):

$$\frac{\partial a_l^*}{\partial t} = D_l\frac{\partial^2 a_l^*}{\partial y^2};\ a_l(x,t) = \frac{1}{\delta}\int_0^{\delta} a_l^*(x,y,t)\,dy;\ 0 \leqslant y \leqslant \delta. \quad (42)$$

At the $y = 0$ (solid wall) boundary and at $y = \delta$ we also obtain the following relations in the case under consideration:

$$a_{ls} = K_{ls}a_l^*|_{y=0};\ \frac{\partial a_{ls}}{\partial t} = D_l\left.\frac{\partial a_l^*}{\partial y}\right|_{y=0};\ a_l^*|_{y=\delta} = (a_l^*)_i. \quad (43)$$

The first of these relations takes into account the adsorption at the SLP–solid interface in terms of the linear isotherm approximation, while the second represents the local mass balance equation at this interface with allowance for adsorption. On solving Eqn.(42) with the aid of the Laplace transformation with respect to time,[129] we obtain the following expression for the representation $\tilde{a}_l = \int_0^{\infty} e^{-st}a_l^* dt$:

$$\tilde{a}_l^* = \frac{(\tilde{a}_l^*)_i[\sinh(\varkappa y) + (D_l\varkappa/K_{ls}s)\cosh(\varkappa y)]}{\sinh(\varkappa\delta) + (D_l\varkappa/K_{ls}s)\cosh(\varkappa\delta)};\ \varkappa = \left(\frac{s}{D_l}\right)^{1/2}. \quad (44)$$

Application of the Laplace transformation to Eqn.(43) and substitution of Eqn.(44) for $\tilde{a}_l^*$ yields after simple rearrangements

$$(\tilde{a}_l^*)_i = P_1(s)\,\tilde{a}_l$$

$$P_1(s) = \frac{(\varkappa\delta)\{\sinh(\varkappa\delta) + [1/(\varkappa K_{ls})]\cosh(\varkappa\delta)\}}{\{\cosh(\varkappa\delta) + [1/(\varkappa K_{ls})]\sinh(\varkappa\delta) - 1\}} \quad . \tag{45}$$

Using Eqns.(43)–(45), we find the following formula for a_{ls}:

$$\tilde{a}_{ls} = P_2(s)\cdot\tilde{a}_l$$

$$P_2(s) = \frac{\delta}{\cosh(\varkappa\delta) + [1/(\varkappa K_{ls})]\sinh(\varkappa\delta) - 1} \quad . \tag{46}$$

Taking into account the boundary conditions (40) and (41) and also Eqn.(45), we obtain

$$\tilde{a}_{gl} = (K_{gl}/K_l)\,P_1(s)\,\tilde{a}_l \quad . \tag{47}$$

For subsequent treatment, we express[107,108,121] the local concentration of the test substance in the gas phase c_g^* by the equation

$$c_g^* = c_g + \Delta c_g;\ \int_0^{r_0} \Delta c r\,\mathrm{d}\,r = 0 \quad . \tag{48}$$

In addition we assume that the relation

$$\Delta c \ll c_g \tag{49}$$

holds.

Then, substituting Eqn.(48) in Eqns.(36) and (38), and taking into account formula (49), we obtain the following equation for Δc after a few steps which we omit here:

$$\frac{\partial^2\Delta c}{\partial r^2} + \frac{1}{r}\frac{\partial\Delta c}{\partial r} = \frac{u}{D_g}\left(1 - 2\frac{r^2}{r_0^2}\right)\frac{\partial c}{\partial x} - \\ - \frac{\chi_l}{D_g\chi_g}\frac{\partial a_l}{\partial t} - \frac{\chi_{gl}}{\chi_g D_g}\cdot\frac{\partial a_{gl}}{\partial t} - \frac{\chi_{ls}}{\chi_g D_g}\cdot\frac{\partial a_{ls}}{\partial t} \quad . \tag{50}$$

On solving this equation taking into account condition (45) and the requirement that Δc be finite at $r \to 0$, we find

$$c_g^* = c_g + \frac{u}{D_g}\left(\frac{r^2}{4} - \frac{r^4}{8r_0^2} - \frac{r_0^2}{12}\right)\frac{\partial c_g}{\partial x} - \\ - \frac{\chi_l}{D_g\chi_g}\left(\frac{r^2}{4} - \frac{r_0^2}{8}\right)\left(\frac{\partial a_l}{\partial t} + \frac{\chi_{gl}}{\chi_l}\frac{\partial a_{gl}}{\partial t} + \frac{\chi_{ls}}{\chi_l}\frac{\partial a_{ls}}{\partial t}\right) \quad . \tag{51}$$

Application of the Laplace transformation to Eqn.(51) at the gas–SLP interface taking into account Eqns.(40) and (41) yields

$$(\tilde{c}_g^*)_i = \frac{(\tilde{a}_l^*)_i}{K_l} = \frac{P_1(s)}{K_l}\,\tilde{a}_l = \tilde{c}_g + \frac{ur_0^2}{24D_g}\frac{\mathrm{d}\,\tilde{c}_g}{\mathrm{d}\,x} - \frac{r_0^2 s}{8D_g}\frac{\chi_l}{\chi_g} \times \\ \times\left(\tilde{a}_l + \frac{\chi_{gl}}{\chi_l}a_{gl} + \frac{\chi_{ls}}{\chi_l}a_{ls}\right) \quad . \tag{52}$$

On substituting Eqns.(44)–(46) in Eqn.(52) and on solving the resulting expression for $\tilde{a}_l$, we find

$$\tilde{a}_l = K_l\left[P_1(s) + \frac{r_0^2 s}{8D_g}k\left(1 + \frac{\chi_{gl}K_{gl}}{\chi_l K_l}P_1(s) + \frac{\chi_{ls}P_2(s)}{\chi_l}\right)\right]^{-1} \times \\ \times\left(\tilde{c}_g + \frac{ur_0^2}{24D_g}\cdot\frac{\mathrm{d}\,c_g}{\mathrm{d}\,x}\right), \\ k = \chi_l K_l/\chi_g. \tag{53}$$

We now differentiate Eqn.(53) with respect to x and substitute the resulting expression in Eqn.(47). After integration and subsequent application of the Laplace transformation taking into account Eqns.(44)–(46) and (53), we obtain the following expression for $\tilde{c}_g$:

$$B\frac{\mathrm{d}^2\tilde{c}}{d\,x^2} - \frac{\mathrm{d}\tilde{c}_g}{\mathrm{d}\,x} - E\tilde{c}_g = 0 \ , \\ B = \frac{1}{u\theta}\left\{\left(D_g + \frac{u^2r_0^2}{48D_g}\right)\left[P_1(s) + \frac{r_0^2 s}{8D_g}kQ(s) - ksQ(s)\left(\frac{ur_0^2}{24D_g}\right)^2\right]\right\}, \\ E = \frac{1}{u\theta}\left\{s\left[P_1(s) + \frac{r_0^2}{8D_g}skQ(s) + ksQ(s)\right]\right\} \ , \tag{54}$$

$$\theta = P_1(s) + \frac{sr_0^2}{24D_g}ksQ(s) \ ,$$

$$Q(s) = 1 + \frac{\chi_{gl}K_{gl}P_1(s)}{K_l\chi_l} + \frac{\chi_{ls}P_2(s)}{\chi_l} \quad .$$

We shall assume that the impurities are introduced into the column in the form of a rectangular pulse of duration ε:

$$x = 0 \quad \begin{cases} c_g = c_0, & 0 < t \leqslant \varepsilon \\ c_g = 0, & t > \varepsilon \end{cases} \tag{55}$$

Accordingly, we have the following boundary conditions for Eqn.(54):

$$\tilde{c}_g = \frac{c_0}{s}(1 - \mathrm{e}^{-\varepsilon s}),\ x = 0 \ , \tag{56}$$

where $\tilde{c}_g$ is finite at $x \to \infty$.

The solution of Eqn.(52) subject to conditions (54) is

$$\frac{\tilde{c}_g(L, s)}{\varepsilon c_0} = \left(1 - \frac{\varepsilon s}{2!} + \frac{\varepsilon^2 s^2}{3!} - \cdots\right)\exp\left\{\frac{L}{2B}[1 - (1 + 4BE)^{1/2}]\right\}, \tag{57}$$

where $x = L$ is the distance from the beginning of the column at which the chromatographic elution curve is measured.

We apply the familiar methods for the calculation of the moments of the elution curve from its representation[129,130] and then, using Eqns.(57) and (54), we obtain

$$m_1(L) = \int_0^\infty \frac{c_g(L, t)}{\varepsilon c_0}\,t\,\mathrm{d}\,t = -\lim_{s\to 0}\frac{\mathrm{d}}{\mathrm{d}\,s}\left[\frac{\tilde{c}_g(L, s)}{\varepsilon c_0}\right] = \frac{\varepsilon}{2} + \frac{L}{u}(1 + k_*), \tag{58}$$

$$m_2(L) = \int_0^\infty \frac{c_g(L, t)}{\varepsilon c_0}\,t^2\,\mathrm{d}\,t = \lim_{s\to 0}\frac{\mathrm{d}^2}{\mathrm{d}\,s^2}\left[\frac{\tilde{c}_g(L, s)}{\varepsilon c_0}\right] = \frac{\varepsilon^2}{12} + \left[\frac{\varepsilon}{2} + \frac{L}{u}(1 + k_*)\right]^2 + \\ + \frac{L}{u^2}(1 + k_*)^2\left[\frac{2D_g}{u} + \frac{ur_0^2}{D_g}\frac{(1 + 6k_* + 11k_*^2)}{24(1 + k_*)^2} + \frac{2}{3}\frac{uk_*}{(1 + k_*)^2}\frac{\delta^2}{D_l}f_1(K_{gl}, K_{ls})\right], \tag{59}$$

$$f_1 = \frac{\delta^2 + 3K_{ls}\delta + 2K_{ls}^2}{\delta^2 + K_{gl}\delta/K_l + K_{ls}\delta};\quad k_* = \frac{\chi_l}{\chi_g}K_l\left(1 + \frac{K_{gl}/K_l + K_{ls}}{\delta}\right). \tag{60}$$

Here

$$m_k(x) = \int_0^\infty t^k c_g(x, t)\,\mathrm{d}\,t \Big/ \int_0^\infty c_g(x, t)\,\mathrm{d}\,t$$

is the initial moment of the kth order chromatographic elution curve.

In order to obtain, in particular, the HETP, we make use of the relation

$$H = L\mu_2^{(0)}/(m_1^{(0)})^2,\ \mu_2^{(0)} = m_2^{(0)} - [m_1^{(0)}]^2 \ , \tag{61}$$

where $m_1^{(0)}(x)$, $m_2^{(0)}(x)$, and $\mu_2^{(0)}(x)$ are the first and second initial moments and the second central moment of the chromatographic curve for a sample volume tending to zero ($\varepsilon \to 0$).

Taking into account Eqns.(54)–(57), we obtain the following formula for the HETP:

$$H = \frac{2D_g}{u} + \frac{1 + 6k_* + 11k_*^2}{24(1 + k_*)^2}\frac{ur_0^2}{D_g} + \frac{2}{3}\frac{uk_*}{(1 + k_*)^2}\frac{\delta^2}{D_l}f_1(\delta, K_{gl}, K_{ls}). \tag{62}$$

The expression for the HETP in a column with a slit-like cross-section can be readily obtained with the aid of the method used above for the evaluation of the moments and the HETP for a cylindrical column. Here the term describing the internal diffusion for the thin SLP films considered ($\delta \ll r_0$, $\delta \ll h$) will be the same as for a cylindrical column. For a column with a rectangular cross-section, the expression for the HETP is

$$H = \frac{2D_g}{u} + \frac{4}{105}\cdot\frac{(1 + 9k_* + 25.5k_*^2)}{(1 + k_*)^2}\cdot\frac{uh^2}{D_g} + \frac{2}{3}\frac{uk_*}{(1 + k_*)^2}\cdot\frac{\delta}{D_l}f_1(\delta, K_{gl}, K_{ls}) \tag{63}$$

It is evident from the expressions obtained that adsorption at the gas–SLP and SLP–solid interfaces influences H in two ways. Firstly, the capacity coefficient k changes (increases):

$$k_* = k\left(1 + \frac{K_{gl}/K_l + K_{ls}}{\delta}\right), \quad (64)$$

as already stated in previous Sections. Secondly, an additional multiplier appears in the component of H taking into account the contribution of the internal diffusion resistance to mass transfer:

$$f_1(\delta, K_{gl}, K_{ls}) = \frac{\delta^2 + 3K_{ls}\delta + 3K_{ls}^2}{\delta^2 + (K_{gl}/K_l)\delta + K_{ls}\delta}, \quad (65)$$

whose magnitude is greater than unity and which takes into account the adsorption phenomena.

The contribution of adsorption phenomena at the interfaces to the spreading, i.e. to the HETP, can be taken into account also within the framework of the approximate approach developed by Giddings[118] (see also Garbuzov et al.[131]). However, the above approximate approach does not permit the estimation of the contribution of adsorption phenomena to the moments of the chromatographic elution curve of an order higher than the second; the higher order moments characterise the degree of asymmetry of this curve, its steepness, etc. The above treatment allows this. As an example, we shall write the formula for the asymmetry coefficient

$$\gamma = \mu_3^{(0)}/[\mu_2^{(0)}]^{3/2}$$

($\mu_3^{(0)}$ is the third central moment of the elution curve) for the chromatographic elution curve:

$$\gamma = \left[\frac{2D_g L(1+k_*)^2}{u^3} + \frac{r_0 L}{D_g u}(1 + 6k_* + 11k_*^2) + \frac{2}{3}\frac{k_*}{u}\frac{\delta^2}{D_l} f_1\right]^{-3/2} \times$$

$$\times \left[\frac{12D_g^2 L(1+k_*)^2}{u^5} + 4k_*(1+k_*)\frac{D_g L}{D_l u^3}\cdot\delta^2 f_1 + \frac{r_0^2 L}{2u^3}(1 + 6k_* + 12k_*^2 + 7k_*^3) + \right.$$

$$\left. + 2k_*\frac{\delta^2 L}{D_l^2 u} f_2 + \frac{r_0^2 L}{12 D_g u}\frac{\delta^2}{D_l} k_*(3 + 11k_*) f_1 + \frac{3}{(24)^2}\frac{r_0^4 L}{u D_g^2}(1 + 11k_* + 45k_*^2 + 65k_*^3)\right], \quad (66)$$

where

$$f_2(\delta, K_{gl}, K_{ls}) = f_1(\delta, K_{gl}, K_{ls})\left(\delta K_{ls} + \frac{\delta^3}{3}\right) + \frac{\delta^4}{15\left(\delta^2 + \frac{K_{gl}\delta}{K_l} + K_{ls}\delta\right)}. \quad (67)$$

Golay's Eqns.(33) and (34) and their extended forms taking into account adsorption phenomena [Eqns.(62) and (63)] are valid only for short sections of the column, because the absence of a pressure drop and the constancy of the carrier gas flow rate along the column length were assumed in their derivation. Furthermore, in these equations no account is taken of the additional contribution of the spreading outside the column to H, which is[132] a quadratic function of the gas flow rate:

$$H_0 = [\sigma_0^2/L(1+k)^2]u^2, \quad (68)$$

where σ_0 is the variance of the peak associated with the spreading outside the column. For real long gas–chromatographic capillary columns, it is necessary to take into account the effect of the compressibility of the gas, which leads to the appearance of corrections for the pressure drop[108,133] (see also Garbuzov et al.[131]).

The terms of Eqns.(33) and (34) and (62) and (63) referring to the gas phase which remain unchanged along the length of the column must be multiplied by the correction factor ψ_g given by

$$\psi_g = \frac{9}{8}\frac{[(p_i/p_0)^4 - 1][(p_i/p_0)^2 - 1]}{[(p_i/p_0)^3 - 1]^2}, \quad (69)$$

where p_i and p_0 are the pressures of the carrier gas at the inlet to and outlet from the column.

For the term taking into account the resistance to mass transfer in the SLP, the correction coefficient has the same form as the factor of James and Martin:

$$j = \frac{3}{2}\frac{(p_i/p_0)^2 - 1}{(p_i/p_0)^3 - 1} \quad (70)$$

For the term describing the spreading outside the column, the correction for the compressibility of the carrier gas can be shown to be equal to j^2. The procedure involved in the introduction of these corrections, presupposes that the diffusion coefficient in the carrier gas and its linear flow rate correspond to the conditions at the outlet from the column, i.e. that $D_g = D_0$ and $u = u_0$. Introducing the average quantities $\bar{D}_g = D_0 p_0/\bar{p}$ and $\bar{u} = u_0 p_0/\bar{p}$ and bearing in mind that $D_0 = D_g^* p_0$, $\bar{u} = j u_0$, and $\bar{p} = p_0/j$ (D_g^* is the diffusion coefficient of the substance analysed in the carrier gas at a pressure of 1.00 atm), it is possible to obtain the following general equation for the HETP of long cylindrical columns with a circular cross-section taking into account the spreading outside the column:

$$H = \frac{2D_g^* \psi_g}{\bar{p}\bar{u}} + \frac{1 + 6k_* + 11k_*^2}{24(1+k_*)^2}\frac{r_0^2 \psi_l \bar{p}\bar{u}}{D_l} + \frac{2}{3}\frac{k_* f_1(K_{gl}, K_{ls})}{(1+k_*)^2}\frac{\delta^2 u}{D_l} + \frac{r_0^2 u^2}{D_l(1+k_*)^2}. \quad (71)$$

An expression analogous to Eqn.(71) can be obtained also for long columns with a rectangular cross-section.[81] The equation for the HETP for long columns without taking into account the contribution of adsorption phenomena to the internal diffusion resistance can be obtained from Eqn.(71) if one puts $f_1 = 1$ (the modified Golay equation):

$$H = \frac{2D_g^* \psi_g}{\bar{p}\bar{u}} + \frac{1 + 6k_* + 11k_*^2}{24(1+k_*)^2}\frac{r_0^2 \psi_l \bar{p}\bar{u}}{D_l} + \frac{2}{3}\frac{k_* \delta^2 u}{(1+k_*)^2 D_l} + \frac{r_0^2 u^2}{D_l(1+k_*)^2}. \quad (72)$$

It is seen from Eqns.(71) and (72) that the $H(u)$ relation is not hyperbolic in the general case [the last term of Eqn.(71) is a quadratic function of the flow rate]. In addition, in practice the average pressure in the column frequently varies simultaneously with the average flow rate, since the flow rate is regulated by altering either the inlet or outlet pressure (this factor has been noted by Garbuzov and co-workers[131,134]). In connection with the foregoing, the test of Golay's theory undertaken by Hazeldean and Scott and Desta and Goldup[125, 135,136] appears to us to be insufficiently rigorous. This test was based on the statistical analysis of the dependence of the HETP on the average carrier gas flow rate. The coefficients of Golay's equation, found on the assumption that the latter is hyperbolic, were compared[126,135,136] (see also Giddings[147]) with the calculated values.

Another method of testing the theory has been proposed by Garbuzov and co-workers.[131,134] It is based on the analysis of the dependence of the widening of the chromatographic bands (characterised by the square of the width of the peak at the half height level in units of time–b_t^2) for C_{13}–C_{24} n-alkanes on their mass-transfer (capacity) coefficients k. The capillary tubes were made from borosilicate glass. The methylsilicone OU-101 was used as the SLP.

The HETP is related (see, for example Giddings[31] and Rudenko[138]) to the quantity b_t^2 by the expression

$$\bar{H} = b_t^2 \bar{u}^2/[(1+k)^2 L \times 8 \ln 2]. \quad (73)$$

Fig.13[131] presents the dependence of the experimental (curve *1*) and calculated (curve *2*) values of b_t^2 on the coefficient k for C_{13}–C_{20} n-alkanes (column with OU-101; the average linear flow rate of the helium carrier gas was $\bar{u} = 37.14$ cm s^{-1}). The calculation was based on Eqn.(72) without taking into account the last term (the spreading outside the column) and with allowance for Eqn.(73). It is readily seen that the effect of the spreading outside the column is reflected in the graph by the section *FE*, which can be found by extrapolating the extent of the spreading on plots of b_t^2 against k, obtained experimentally and calculated, to $k = 0$. On average, the effect of the spreading outside the column for three flow rates $\bar{u}$ amounted to $b_t^2(0) \approx 0.5c^2$.

A contribution to the spreading of the peak not taken into account by the theory has been discovered[131,134] with the aid of this procedure. In order to elucidate the causes of the band spreading which had not been accounted for, Garbuzov et al.[131] investigated the influence of the nature of the carrier gas on the behaviour of the n-tetracosane chromatographic band in a glass column with the SE-30 SLP (the carrier gases were hydrogen, helium, nitrogen, and argon). The maintenance of an identical average linear flow rate would have required the establishment of different pressure drops in the column and for this reason the average pressure in the column was different for each gas. The discrepancy between the experimental [determined with the aid of Eqn.(73)] and calculated [Eqn.(72) without the last term] values of HETP increases with increase of the molecular weight of the carrier gas. The difference $\Delta H = H_{exp} - H_{calc}$ (Fig.14) is a linear function of the reciprocal of the diffusion coefficient of n-tetracosane in the gases employed at the corresponding average pressures in the column. The discrepancy between the contribution of dynamic diffusion and the observed arrest of the mass transfer in the gas phase can be estimated from the slope of the straight line; it amounts to ~24% of the calculated value [the second term of Eqn.(72)]. According to Garbuzov et al.,[131] the discrepancy is caused by the non-ideality of the geometry of the column, which exerts a fairly powerful influence on the contribution of dynamic diffusion.[109,110,112-114] When the capillary is extended and at the same time twisted into a spiral, the column may acquire an elliptical cross-section. In addition, the different curvatures of the inner surface of the tube should produce inhomogeneity of the thickness of the liquid film along the perimeter of the column cross-section.[139] The mass rate of movement of the test substance in the gas near a wall with a greater sorption capacity is lower than the corresponding rate at a wall with a lower capacity, which should lead to additional band spreading as a result of an increase of the contribution of dynamic diffusion.

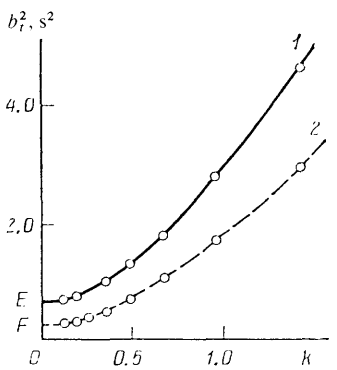

Figure 13. Dependence of the experimental (curve *1*) and calculated (curve *2*) values of b_t^2 on the mass-transfer coefficient k for C_{13}–C_{20} n-alkanes.

The intercept on the ordinate axis made by the straight line in Fig.14 characterises the band spreading which is independent of the nature of the carrier gas. It consists of the contribution to the HETP outside the column, namely $\bar{H}_0 \cong 4.3 \times 10^{-3}$ mm [this contribution is estimated from the quantity $b_t^2(0) \cong 0.5c^2$, which had been found previously by Eqn.(73)], and the contribution of the resistance to the mass transfer in the SLP.

Estimation of the internal diffusion resistance to mass transfer in the SLP film from the third term of Golay's Eqn.(72) using the experimental value $D_l(n\text{-}C_{24}H_{50}$, SE-30, 200 °C) = 2.49×10^{-6} cm²s^{-1} [139] yields a value which is smaller by a factor of 6.5 than that determined from the plot in Fig.(14).

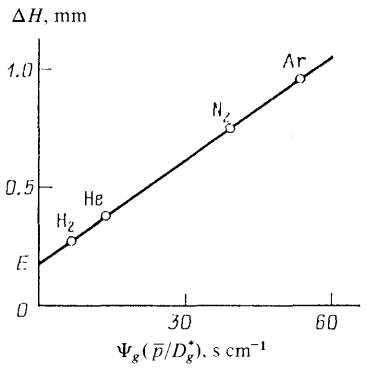

Figure 14. Dependence of the unexplained contribution to the HETP on the reciprocal of the diffusion coefficient of n-tetracosane in various carrier gases at the corresponding average pressures in a column with SE-30.

Garbuzov et al.[131] draw from this finding the entirely justified conclusion that the most probable cause of the above discrepancy is the contribution to the spreading by the adsorption phenomena at the interfaces. They attempted to estimate this contribution using an expression for H_{ads} analogous to the third term in Eqns.(62) and (71); the adsorption of n-tetracosane at the gas–SE-30 interface is then neglected. It is also assumed that the adsorption of n-tetracosane from the SE-30 liquid phase on the solid wall is 200 times less intense than the adsorption of the same substance from the gas on the same wall (the gas–solid distribution constant is known: $K_{gs} \cong 1.242 \times 10^{-4}$ m). Under these conditions, we have $f_1(\delta, K_{gl}, K_{ls}) \cong 6.6$. In other words, it has been shown that even insignificant adsorption of the substance analysed from the liquid phase on the surface of the walls of the capillary column can lead to an appreciable increase of the resistance to mass transfer in the SLP, which also follows from a qualitative model examination of the process.

We may note that we are unaware of studies in capillary chromatography in which the contributions of the adsorption at the SLP interfaces to the column efficiency have been determined rigorously and by a direct experimental method. We believe that such an estimate could be achieved by carrying out two series of experiments on the same column: (1) measurement of the efficiency of a column with adsorption-active walls on which a layer of the SLP has been deposited; (2) measurement of the efficiency of columns with suppressed adsorption activity of the walls. Suppression of adsorption at the SLP–solid interface by modifying the sorbent with small amounts of added polar substances has a positive effect on the efficiency of the preparation of the sorbent. For example, ethyl methyl ketone is eluted in the form of a diffuse band at 50 °C from unmodified Sterchamol impregnated with squalane and the HETP is 11 mm; after modification with 1% triethylene glycol, the HETP falls to 1.6 mm.[140] In the second series of experiments the substances employed to suppress adsorption may be, for example, silanising agents which modify the surface or substances which are not detected by

the flame-ionisation detector and which suppress the adsorption on the active surface centres (for example, ammonia, formamide, formic acid, etc.).

---oOo---

The development of ideas concerning the role of adsorption has led to the necessity for the refinement of the classification of the types of chromatography based on the state of aggregation of the phases involved in the chromatographic process. The traditional classification considers four main types of chromatography: gas–solid, liquid–solid, gas–liquid, and liquid–liquid.[18] However, the last two types of chromatography are strictly speaking unknown in a pure form, since they cannot be realised without the involvement of a third phase – the solid phase (solid carrier). It is therefore correct to refer to these versions as follows: gas–[liquid–solid] chromatography and liquid–[liquid–solid] chromatography.[32,106]

A rational classification of the types of chromatography which we propose is presented in Table 7. In connection with this classification, it must be emphasised that the gas–liquid chromatography which we have been considering has not so far been realised in the strict sense of its definition and that only gas–[liquid–solid] chromatography has been described. The theoretical ideas concerning the role of adsorption described systematically in this review agree also with the experimental facts obtained in the study of adsorption in capillary columns.

Table 7. Classification of certain common types of chromatography in terms of the state of aggregation of the mobile and stationary phases.

Mobile phase	Stationary phase: solid	Stationary phase: liquid–solid	
		proposed terminology	traditional terminology
Gas	gas[solid]-phase chromatography	gas[liquid–solid]-phase chromatography	gas–liquid chromatography
Liquid	liquid[solid]-phase chromatography	liquid[liquid–solid]-phase chromatography	liquid–liquid chromatography

In conclusion we may note that the new ideas about the role of adsorption in GLC have led to a significant development of the familiar trends in chromatography and the appearance of new ones. A considerable expansion of the applications and an increase of the accuracy of the chromatographic methods for the investigation of the interactions of dissolved compounds with the SLP have been achieved as a result of allowance for the adsorption of the chromatographic substances at the interfaces. The gas-chromatographic study of the adsorption of volatile compounds at the interfaces between the SLP and the solid carrier and the carrier gas has begun to develop (a new physicochemical application of gas chromatography). New ideas and new universal methods for the identification of the chromatographic bands, taking into account the adsorption phenomena in GLC, have been developed. A new classification of the types of chromatography, taking into account the role of the solid carrier (the solid) is proposed.

We may note that the development of capillary gas–[liquid–solid] chromatography is being vigorously continued also at the present time. There is no doubt that in the immediate future the efforts of many investigators will lead to a more complete understanding of the role of adsorption processes in capillary chromatography and to the development of new effective methods for chromatographic separation and physicochemical measurements.

Free-radical Mechanisms in the Cytotoxic Action of Antitumour Antibiotics

N.M.Emanuel', G.N.Bogdanov, and V.S.Orlov

The results of studies of the free-radical mechanisms of the action of various antitumour antibiotics are surveyed. The data obtained in the investigation by physicochemical methods (EPR, polarographic, and spectrophotometric) as well as quantum-chemical calculations of the biotransformation processes of antitumour antibiotics, namely the formation of chemically and biologically active free-radical forms of antibiotics, are presented. The ways in which they can be transformed, including the transfer of the electron to oxygen molecules with formation of superoxide radicals, as well as covalent binding to biomacromolecules are discussed. The important role of the acid-base properties of the antibiotics in their free-radical reactions and the characteristics of the biological action of the spin-labelled analogues of anthracycline antibiotics are examined.
The bibliography includes 76 references.

I. INTRODUCTION

The present stage of the development of the experimental chemotherapy of malignant neoplasms, including various aspects of the biochemistry of the cancer cell and the chemical pharmacology of anticancer preparations, is characterised by the wide-scale employment of the ideas and methods of the exact sciences. A combined approach to the solution of the problem of the inter-relation between the structure and biological properties of carcinolytic substances makes it possible to develop the fundamental principles which are essential for the creation of new effective anticancer preparations. An important step in the development of these principles is a new classification of antitumour preparations in terms of the types of their reactivity.[1] This classification is general and, having created the preconditions for a rational planning of the synthesis of anticancer preparations, also permits a more detailed analysis and explanation of the chemical and biological mechanisms of their action. Polyfunctional compounds with hybrid structures and reactivities fit within the framework of this classification. In particular, the majority of antibiotics are preparations of this type.

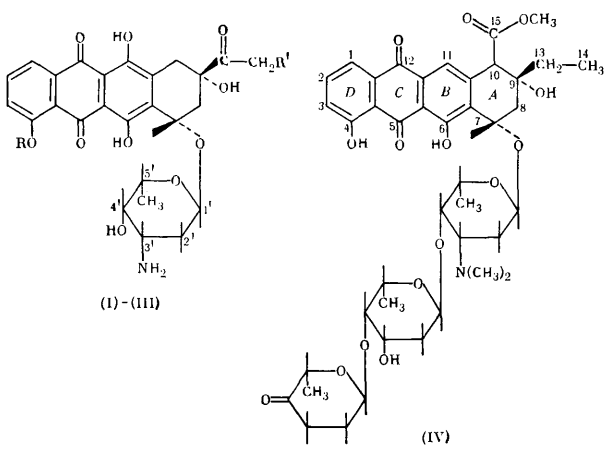
Antibiotics have been finding in recent years increasingly wide-scale applications in the chemotherapy of malignant diseases. The studies by chemists in this field have been directed towards the synthesis of derivatives of already known antibiotics by their chemical modification and also towards the total synthesis of structural analogues.

The antitumour antibiotics known at present consist of organic compounds of several types from the chemical standpoint, the cytotoxic properties of the majority of which have already been known for a long time. For example, the study of the structure of mitomycin C has demonstrated the presence in its structure of well known cytotoxic groups—benzoquinone, urethane, and aziridine. A whole series of anthracycline antibiotics are characterised by the presence as the aglycone of derivatives of hydroxyanthraquinone, while the carbohydrate fragment consists of aminosugars whose antitumour properties have also been known for a long time. Streptozotocin (a carbohydrate derivative of nitrosomethylurea) was discovered after nitrosocarbamides had been found to possess antitumour properties.

As a consequence of the polyfunctional nature of the antibiotics, studies of the role of various chemical mechanisms

(electrophilic substitution, complex formation, and free-radical reactions) in the manifestation of the biological effect are extremely important.

The oxidation-reduction biotransformation processes involving the majority of antitumour antibiotics, accompanied by the intermediate formation of free radicals, have become the subject of numerous investigations during the last decade. To a large extent, this is associated with the important biological role of the endogenic (including metabolically active) and exogenic free radicals and also with the possibility of their detection in various biological media by electron paramagnetic resonance.



It is noteworthy that ideas concerning the free-radical mechanisms in relation to *in vivo* conditions embrace a wide range of biochemical one-electron transfer processes with participation of paramagnetic species of various types, including free radicals. It is known that, under the influence of many xenobiotics, the content of the radical-ion forms of organic coenzymes and paramagnetic states of metalloprotein molecules increases in organs and tissues and the peroxide oxidation reactions of lipids are activated. Different radical states of xenobiotics, capable of resulting in the formation of active forms of reduced oxygen, are sometimes detected. The action of stable free radicals and other chemical compounds with a paramagnetic centre on living organisms constitues a special case.

Various chemobiological aspects of free-radical mechanisms have also been investigated in connection with the action of antitumour antibiotics. Attention has been concentrated on three types of free-radical species: (1) the radical-ions arising from the antibiotics during their redox reaction; (2) the nitroxy-derivatives of anthracyclines; (3) superoxides. The elucidation of the possible involvement of these radical species in the manifestation of the toxic and antitumour properties of antibiotics is of greatest interest.

II. FREE RADICALS DERIVED FROM ANTITUMOUR ANTIBIOTICS

1. Anthracycline Antibiotics

Antibiotics of the anthracycline series have found wide-scale applications in recent years in the chemotherapy of malignant tumours. The best known representatives of this class of antitumour preparations are adriamycin (I), rubomycin (daunomycin) (II), carminomycin (III), and aclacinomycin A (IV).[2] Despite the large differences in their biological activites, these antiobiotics are close chemical analogues:

(I)-(III)

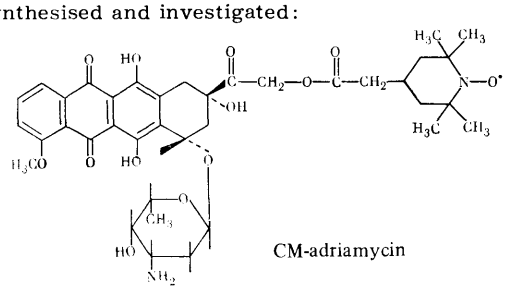
(IV)

R = CH_3, R' = OH (I); R = CH_3, R' = H (II); R = R' = H (III)

The mechanism of the biological action of antitumour anthracycline antibiotics (AAA) is associated with the suppression of the biosynthesis of nucleic acids and (to a much smaller extent) the biosynthesis of protein. Defects in the structure of chromosomes are then observed in dividing cells (fragmentation of chromosomes and mitotic aberrations, mainly the formation of anaphase bridges). Accordingly, the main morphological changes in the cells are associated with changes in the size and shape of the nucleoli and with the appearance of fine-grain chromatin.[3]

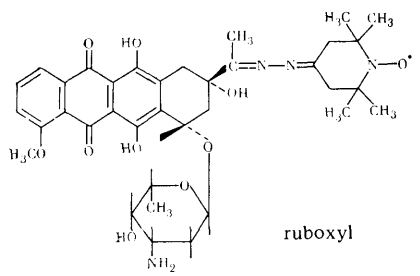
The cytotoxic effect of the AAA depends on their concentration, the duration of their action, and the method by which they are introduced into the organism. Thus it has been shown that their action on tumour cells *in vitro* depends on their extracellular concentration and the time of exposure to these substances[4] and the surviving fraction of tumour cells N is described by the relation

$$N = N_0 e^{-ktc},$$



where t is the duration of exposure (min) and c the extracellular concentration of the AAA (μg mol^{-1}). The constant k (mol μg^{-1} min^{-1}) characterises the sensitivity of particular tumour cells to the given preparation. k = 0.045 mol μg^{-1} min^{-1} for the fibroblasts of the Chinese hamster and k = 0.050 mol μg^{-1} min^{-1} for *HeLa* cells. There is a direct correlation between the extracellular and intracellular AAA concentrations. However, there is no proportionality between the duration of exposure and the intracellular concentrations of the preparations.[4]

The differences in the sensitivities to the action of the AAA are also associated with the processes involving their accumulation in the cells. Thus the preparation penetrates readily into L-1210/R leukaemia cells, which are resistant to the action of rubomycin, but it is rapidly metabolised within them; on the other hand, in the L-1210 and P-388 cells, which are sensitive to the preparation, rubomycin persists in the course of 24 h. In chemotherapy the method of introduction and the pharmacokinetic behaviour of the AAA play an important role. The maximum chemotherapeutic effect is attained when the AAA is introduced by methods which ensure direct contact between the preparation and the tumour cells. This fact, which is fairly self-evident from general considerations, has been demonstrated[5] in relation to the B-16 melanoma, which had been grafted intra-abdominally or subcutaneously. A much greater amount of adriamycin penetrates tumour cells and is contained within them for the intra-abdominal growth of the tumour and the intra-abdominal introduction of the preparation.



Many AAA derivatives and complexes based on them, differing in their pharmacokinetic behaviour in the organism, have been synthesised in order to increase the efficiency of the chemotherapeutic action. The following complexes have been obtained and investigated: AAA–DNA,[6] AAA–dextran,[7] AAA–aminoacids,[8] AAA-3 × Fe^{3+},[9] AAA incorporated in liposomes,[10] as well as complexes of adriamycin with antibodies,[11] which were distinguished by excellent antitumour properties and a reduced cardiotoxicity.

Among the numerous studies of the chemical modification of the AAA, it is possible to isolate researches[12–14] into the synthesis of nitroxy-derivatives of the AAA which have priority. Such modification of the structure of anthracyclines imparts to them the properties of organic paramagnetic materials where the presence of the free-radical centre alters significantly the oxidation-reduction properties of the preparations and their capacity for involvement in reactions with transfer of one electron. Spin-labelled derivatives of adriamycin (the nitroxy-fragment is linked to the aglycone by an ester bond) and rubomycin (the nitroxy-

fragment is linked to the aglycone via an azine bridge) have been synthesised and investigated:

CM-adriamycin

ruboxyl

The introduction into the antibiotic molecule of fragments containing a free-radical centre entails an appreciable decrease of acute toxicity and an increase of the antitumour activity of the preparations (Table 1). The characteristics of the reduction of nitroxy-fragments and the pharmacokinetic features of the modified AAA have been studied by EPR. The possible chemical causes of the differences in the pharmacokinetic behaviour of nitroxy-derivatives of the AAA can be associated with the differences in the rates and mode of enzymic reduction. Among several possible reduction centres (quinonoid, ketone, and nitroxy-groups), the free-radical fragment undergoes preferential reduction.

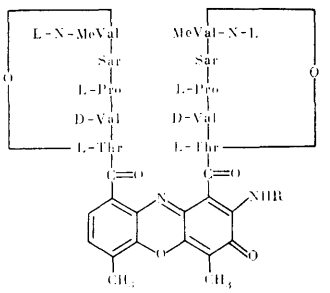


Table 1. Comparative data for the acute toxicities and antileukaemic activities of ruboxyl and rubomycin.[14]

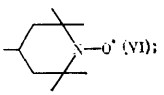
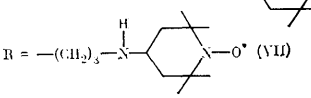
Preparation	LD_{50}, mg kg^{-1}	ILS, %	
		P-388 leukaemia	La leukaemia
Ruboxyl	44.0	155	243
Rubomycin	5.6	68	63



Notation: LD_{50} is a single dose of the preparation inducing the death of 50% of the experimental animals (mice) and ILS is the increase of the average lifespan compared with the control.



The interaction of a spin-labelled analogue of adriamycin (CM-adriamycin) with DNA has been studied by EPR.[13] In the first place one should note the resistance of the ester linkage in CM-adriamycin to hydrolysis when it interacts with DNA. At neutral pH the EPR spectra of the complex of CM-adriamycin with DNA remain unchanged in the course of several days, which indicates the absence of the hydrolytic scission of the nitroxy-fragment. The form of the EPR spectra of CM-adriamycin does not depend on its relative concentration under conditions where there are between one and four antibiotic molecules for 20 pairs of DNA bases. The subsequent increase of the CM-adriamycin concentration results in the appearance in the high-field region of the EPR spectrum of a narrow line characteristic of CM-adriamycin in solution (Fig.1). Analysis of the EPR spectra established that under these conditions CM-adriamycin forms a complex with DNA as a result of intercalation between the nitrogen-containing bases.[13]

An analogous mechanism of the interaction with DNA is characteristic also of certain other polycyclic compounds, for example, the antibiotics of the actinomycin series. The spin-labelled analogues of actinomycin D have been studied:[15]

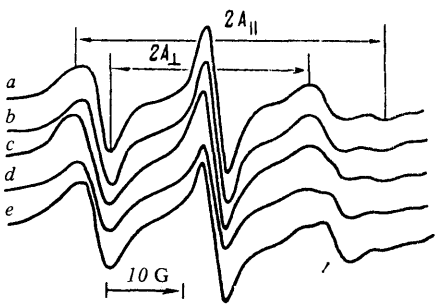
(V)-(VII)

R = H (V), actinomycin D; R =  (VI);

R =  (VII)

It is of interest that the nitroxy-derivatives of actinomycin D were bound to DNA to a lesser extent than the initial antibiotic and caused a lower degree of inhibition of the DNA-dependent RNA-polymerase. On the other hand, in experiments on P-388 leukaemia the spin-labelled analogue of actinomycin D showed an antitumour effect which was better by a factor of 1.5.[15] This example indicates the absence of a relation between the degree of intercalation and the antitumour activity of antibiotic derivatives containing a free-radical fragment.

A comparative study of adriamycin, carminomycin, and the 11-methyl ether of carminomycin on the Novikov ascites hepatoma *in vitro* showed that their cytotoxic effects could not be accounted for by their capacity to inhibit the biosynthesis of nucleic acids or to bind on to DNA molecules.[16] Nevertheless the different types of the biological action of anthracyclines (cytotoxic mutagenic, and carcinogenic effects) are explained mainly by the capacity of AAA for intercalation between the DNA bases.



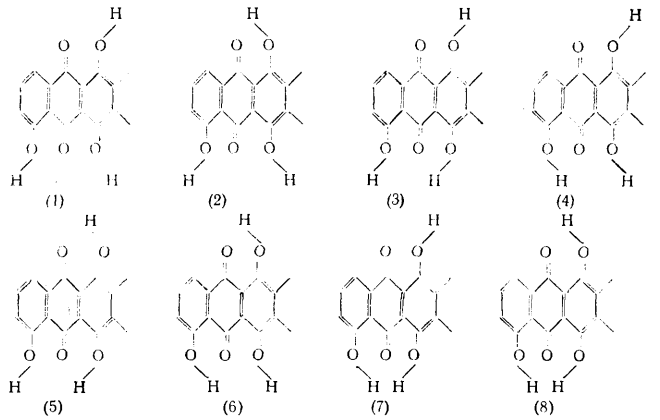


Figure 1. Variation of the EPR spectra of spin-labelled adriamycin in the presence of DNA with its concentration (0.01 M NaCl and 1.2 mg ml^{-1} DNA). Ratio of the antibiotic and DNA (base pairs): *a*) 1:20; *b*) 2:20; *c*) 4:20; *d*) 7:20; *e*) 10:20.[13]

An alternative point of view on the molecular mechanisms of the biological action of AAA, involving the formation of free-radical intermediates, attracts attention in this connection. The characteristics of the chemotherapeutic properties of anthracyclines can be accounted for by the different capacities for donor–acceptor interactions, different permeabilities, and different oxidation-reduction properties of the preparations. The attempts at a rigorous quantitative description of the individual properties of AAA and to establish correlations between the structure and the biological activity of the test substances have now acquired fundamental importance.

Quantum-chemical calculations for the model analogues of the AAA aglycones and the corresponding radical-anions for isolated molecules and their hydrate complexes have demonstrated the necessity to take into account the influence of the solvent on their electronic and conformational properties, since solvation effects can lead to significant conformational rearrangements. The semi-empirical INDO and CNDO/2 methods provide a fairly satisfactory qualitative description of the state of the system, although they yield less realistic solvation energies and hydrogen bond strengths than *ab initio* methods. Calculations of the structures of hydrate complexes incorporating four water molecules have been carried out taking into account the formation of hydrogen bonds involving the oxygen atoms of the anthraquinone fragment.[17]

It has been found that, in terms of the isolated molecule approximation, the formation of intramolecular hydrogen bonds is favoured by energy factors and the appearance of each succeeding bond causes a proportional reduction in the total energy of the system. It has been demonstrated in relation to hydrate complexes that the formation of intermolecular hydrogen bonds is easier than that of the intramolecular hydrogen bonds of hydroxyanthraquinone (Table 2).[17]

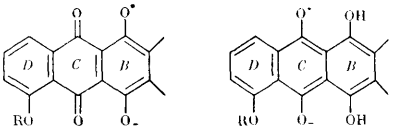
Table 2. Calculated formation energies of the intramolecular hydrogen bonds ($\Delta E_b = E_i - E_1$) in isolated molecules and the solvation energies of the tetrahydrate complexes of carminomycin for different conformations of the hydroxy-groups of the anthraquinone ring (ΔE_h).[17]

Structure	ΔE_b, kcal mole^{-1}	ΔE_h, kcal mol^{-1}	Structure	ΔE_b, kcal mole^{-1}	ΔE_h, kcal mol^{-1}
(1)	0	59.8	(5)	15.5	36.2
(2)	7.6	47.2	(6)	17.1	33.2
(3)	8.1	49.0	(7)	17.3	42.5
(4)	9.5	46.4	(8)	24.9	28.2

The distribution of charges and spin densities in the corresponding radical-anions has been investigated taking into account the structure of the isolated neutral molecules and the hydration effects of aglycones. The formation of radical-anions entails the rearrangement of the atomic structure in the chromophoric part of the AAA. The main electronic charge is localised under these conditions at the oxygen atoms of the carbonyl groups: $\Delta q_5 = q_5^a - q_5^n = 8.25 \times 10^{-2}$e and $\Delta q_{12} = 7.41 \times 10^{-2}$e. The unpaired electron is in the lowest unoccupied π_z orbital of the anthraquinone ring, while the spin densities have the maximum value at the oxygen atoms of the carbonyl groups ($\rho^5_{\pi z} = 0.489$; $\rho^{12}_{\pi z} = 0.443$) and at the carbon atoms of the carbonyl groups ($\rho^5_{\pi z} = 0.107$; $\rho^{12}_{\pi z} = 0.128$).

The theoretical spin densities at the hydrogen atoms of the carminomycin aglycone (with and without allowance for hydration) are presented in Table 3. Analysis of these data shows that the experimental splittings in the EPR spectrum ($a_H = 4.1$ G and $a_H = 2.1$ G) can be explained by the interaction of the unpaired electron with the protons of the *A* ring. The HFS constants can be determined from the formula $a(G) = K\rho^S$, where ρ^S is the spin density in the *s* orbital of the proton and *K* a constant equal to 539.86 for hydrogen atoms.[18] The theoretical spin density distributions for the aglycones of other AAA differ little from the data for carminomycin. The splittings by the protons of the *A* ring differ somewhat for the two possible conformations, namely chair and half-chair, but a choice in favour of the existence of a particular conformation in solution cannot be made on the basis of the calculated values.

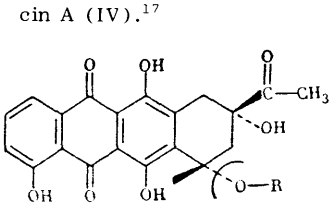
Table 3. The spin densities in the *s* orbitals of the hydrogen atoms ($10^2\rho^S$) in the radical-anions of carminomycin aglycones calculated for the conformation of the hydroxy-group corresponding to structure (1) for different conformations of the *A* ring [*a*) without allowance for the hydration of anthraquinone; *b*) with allowance for the hydration of anthraquinone[17]].



H atom	Chair		Half-chair	
	a	*b*	*a*	*b*
H(1)	0.01	−0.03	0.02	−0.03
H(2)	−0.01	−0.01	−0.02	−0.02
H(3)	−0.10	−0.11	−0.10	−0.11
H(4)	0.01	0.01	0.00	0.01
H(6)	0.01	0.01	0.00	0.00
$H(7)^{OH}$	0.53	0.50	0.47	0.38
H(7)	−0.09	−0.09	−0.46	−0.44
H(8)	−0.03	−0.03	−0.02	−0.02
H(8)	−0.05	−0.04	−0.01	−0.01
H(10)	0.46	0.41	0.52	0.27
$H(10)^a$	0.91	0.80	0.74	0.77

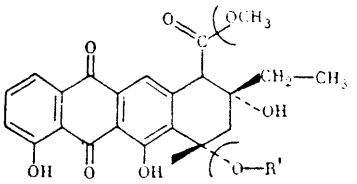
Notation: $H(7)^{OH}$ is the hydrogen atom of the hydroxy-group in the 7-position in the aglycone and $H(10)^a$ is the axial hydrogen atom in the 10-position.

An important result of the calculations is the conclusion that the C(7)–O(7) bond is weakened on formation of the radical-anions, which follows from the analysis of Wiberg's indices. Such weakening of the bond, deduced from theoretical calculations for model compounds, shows that the reduction of the AAA can entail the scission of a hydrocarbon fragment (Table 4).[17] Indeed this has been confirmed experimentally. For example, it has been shown[19] that, in the enzymic reduction of rubomycin under the conditions of hypoxia, the consumption of the antibiotic is



accompanied by an increase of the content of the free aglycone in the system (Fig.2). Anthracycline antibiotics are gradually converted in the cell into deoxyaglycones, which are more lipophilic and possibly more strongly bound to the membranes of microsomes. According to a quantum-chemical calculation, the reduction of aclacinomycin A can be accompanied by the elimination of the 15-methoxy-group as well as the hydrocarbon fragment (Table 6).

These results indicate the potentially important role of the oxidation-reduction reactions with the intermediate formation of free-radical states. One might have expected the formation of free radicals from AAA both as a result of the oxidation of the hydroquinone group (the *B* ring) and as a result of the reduction of anthraquinone (the *C* ring).



The free-radical intermediates formed under these conditions are characterised by different reactivities, which may be the reason for the selectivity of the biological action of AAA, in particular it may determine the ratio of the degree of toxicity to the antitumour effect.

Table 4. The Wiberg bond orders in the neutral molecules and radical-anions of carminomycin (III) and aclacinomycin A (IV).[17]

(III)

(IV)

State	(III)		(IV)				
	C(7)–O(7)	O(7)–R	C(7)–O(7)	O(7)–R′	C(10)–C(15)	C(15)=O	C(15)–O
Neutral molecule	0.4620	0.4890	0.4790	0.4790	0.4866	0.9274	0.4849
Radical-anion	0.4522	0.4950	0.4631	0.4793	0.4891	0.9319	0.4740

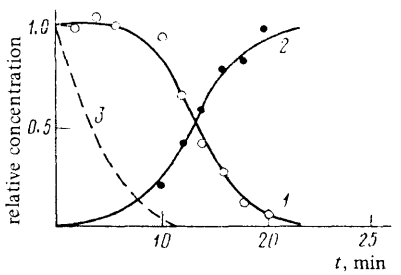


Figure 2. Kinetic curves for the variation of the contents of rubomycin (curve *1*) and its aglycone (curve *2*) and of the partial pressure of oxygen (curve *3*) in the microsomal system in the presence of NADPH (according to the data of Bachur et al.[29]

The capacity of the AAA aglycones for reduction and oxidation has been estimated on the basis of the calculation of the energies of the lowest unoccupied molecular orbital (E_{LUMO}) and the highest occupied molecular orbital (E_{HOMO}).[20] The values of E_{LUMO} and E_{HOMO} for carminomycin, rubomycin, adriamycin, and aclacinomycin A and their O_6^- anions are presented in Table 5. Evidently in the neutral state all the aglycones have similar values of both E_{LUMO} and E_{HOMO}. Consequently the anthracycline antibiotics examined above have approximately the same electron-accepting properties. The extremely high absolute values of E_{HOMO} show that in the neutral state all the aglycones are fairly resistant to oxidation. On the other hand, the AAA anions, characterised by much lower values of E_{HOMO}, exhibit an increased capacity for oxidation. It follows from Table 7 that the aclacinomycin A anion showed the lowest capacity for oxidation, which was in fact to be expected in view of the absence of the hydroquinone fragment from its structure. The most pronounced electron-donating properties are characteristic of the carminomycin aglycone anion.

Table 5. The energies of the HOMO and the LUMO for the neutral molecules and anions in the series of anthracycline antibiotics and their toxicity on intra-abdominal administration.[20,21]

Parameter	Carminomycin	Rubomycin	Adriamycin	Aclacinomycin A
E^n_{HOMO}, eV	−10.306	−10.288	−10.217	−10.342
E^a_{HOMO}, eV	−3.203	−3.209	−3.288	−3.670
E^n_{LUMO}, eV	0.690	0.690	0.719	0.633
E^a_{LUMO}, eV	4.680	4.678	4.810	3.695
LD_{50}, mg kg^{-1}	1.3	5.5	8.5	25.0
pK_a	8.4	9.6	9.6	9.0

Notation: E^n_{HOMO} and E^n_{LUMO} are the energies of the HOMO and the LUMO of the neutral molecules of the AAA aglycones and E^a_{HOMO} and E^a_{LUMO} are the energies of the HOMO and LUMO of the anions of the AAA aglycones.

Table 6. Covalent binding of [^{14}C]adriamycin labelled in the 14-position to microsomal proteins.[13]

Experimental conditions	α, %
Denatured microsomes + adriamycin + NADPH	1.1
Microsomes + adriamycin	0.8
Microsomes + adriamycin + NADPH	4.4
Microsomes + adriamycin + SOD	1.0
Microsomes + adriamycin + NADPH + SOD	4.5

Notation: SOD is superoxide dismutase and α is the fraction of the bound radioactive label.

The oxidation-reduction properties of the AAA at physiological pH can be influenced by the acid–base characteristics of the aglycones. The study of the electronic absorption spectra of the antibiotics in the visible region at different pH of the medium demonstrated the presence of isosbestic points (Fig.3), which indicates the existence of equilibrium

in alkaline solutions between the neutral and ionised forms of the antibiotics. It follows from the data presented in Table 5 that at physiological pH the molecules of the anthracycline antibiotics are in a partly ionised state.

The formation of the ionised form of the AAA is a fairly complex process owing to their polyfunctional character. Apart from the aglycone hydroxy-groups, capable of dissociation, the nucleophilic centres of the molecules, responsible for the possibility of association, also participate in the process. For example, the formation of dimers in aqueous rubomycin solutions (5×10^{-8} M) has been demonstrated spectrophotometrically and by the NMR and circular dichroism methods.[22] At a constant pH a decrease of the degree of dissociation is therefore observed with increase of the AAA concentration.

Table 7. The rate (w) of the microsomal oxidation of NADPH stimulated by various antitumour preparations.[26]

Preparation	w, nmol/mg protein per min	
	air	CO
Control	0	0
Adriamycin	73	84
Mitomycin C	84	81
Bruneomycin	249	209
Lapachol	15	11
Cyclophosphane	0	0
Methotrexate	0	0
N,N'-Di(chloroethyl)-N-nitrosourea	0	0

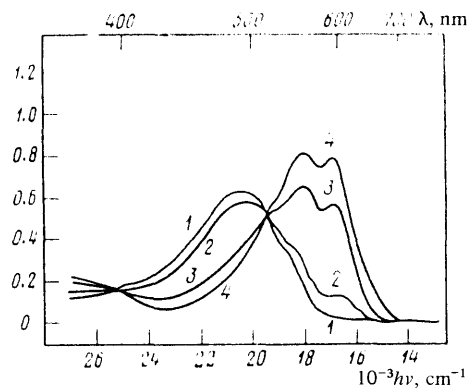

Figure 3. Optical absorption spectra of rubomycin at different pH of the medium: 1) 6.8; 2) 9.2; 3) 10.5; 4) 13.[20]

For a comparative study of the electron-donating properties of the AAA, the reaction involving the oxidation by potassium hexacyanoferrate(III) has been investigated.[20] The dependence of the effective rate constants k_{eff} for their oxidation reaction on the oxidant concentration and the pH of the medium was studied. Fig.4 illustrates the variation of k_{eff} with the oxidation of carminomycin, rubomycin, and adriamycin as a function of the hexacyanoferrate(III) concentration at pH 7.6. Evidently the replacement of the hydrogen atom in the 14-position by the hydroxy-group does not influence the electron-donating properties of the antibiotics. On the other hand, the replacement of the 4-methoxy-fragment by the hydroxy-group decreases sharply the pK_a of the aglycone and enhances its electron-donating properties. The oxidation rate constant depends markedly on the pH of the medium. Thus, in the oxidation of rubomycin and carminomycin (5×10^{-5} M) with potassium hexacyanoferrate (III) (5×10^{-3} M), it was found that k_{eff} is 0.3×10^{-2} s^{-1} and 0.7×10^{-2} s^{-1} respectively at pH 7.0, while 1.3×10^{-2} s^{-1} at pH 8.0 was obtained. The oxidation of the relatively non-toxic aclacinomycin A by the hexacyanoferrate(III) was not observed even at pH 9.5.

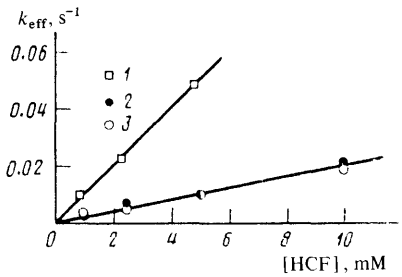

Figure 4. Dependence of the rate constants for the oxidation of different antibiotics on the concentration of hexacyanoferrate(III) (HCF) (pH 7.6, T = 25 °C):[20] 1) carminomycin; 2) rubomycin; 3) adriamycin.

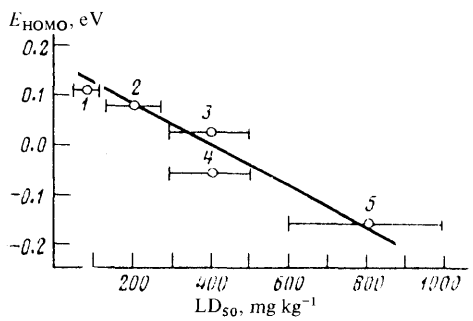

Figure 5. Correlation between the energies of the highest occupied molecular orbitals of the reduced forms (R^-) of derivatives of 2,2,6,6-tetramethyl-4-X-piperidine N-oxides [X: 1) $-(CH_2)_2NH_2$); 2) $-OC(O)NHPh$; 3) $-OH$; 4) $-NHC(O)-NCH_2CH_2$; 5) $=O$] and acute toxicity (LD_{50}).[24]

Thus the electron-donating properties of the AAA are enhanced in the sequence aclacinomycin A < adriamycin ≅ rubomycin < carminomycin; their acute toxicity increases at the same time (LD_{50}) diminishes. When account is taken of these results, the diminution of the cytotoxic properties of the 11-methyl ether of carminomycin can be accounted for by the modification of the structure accompanied by a decrease of the capacity for oxidation (there is no hydroquinone fragment in the structure).

A statistically reliable correlation between the LD_{50} for a series of 4-substituted derivatives of the 2,2,6,6-tetramethylpiperidin-1-yloxy-radical and the E_{HOMO} of the corresponding anions is noteworthy in this connection (Fig.5).[24] The linear regression equation has the following form with a reliability of 95%:

$$LD_{50} = aE_{HOMO} + b,$$

where $a = -2352 \pm 1208$ and $b = 371 \pm 119$. This result shows that the processes involving the oxidation of the reduced forms of the nitroxy-radicals are responsible for their toxicity and not reactions involving the endogenic reduction.

The above correlation between the capacity for oxidation and the toxic properties of antitumour preparations must be taken into account in their chemical modification and in the development of combined polychemotherapy. However, at the present time the formation of free radicals from anthracycline antibiotics has been studied mainly under the conditions of their reduction.

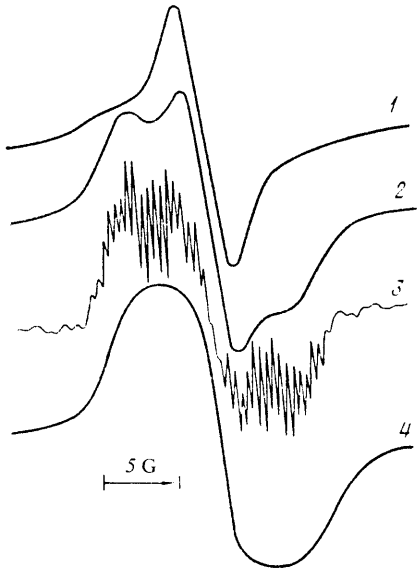

Figure 6. Changes in the EPR spectrum of the rubomycin semiquinone radicals obtained on reduction with KBH_4 after different periods (min): 1) 2; 2) 5; 3) 6; 4) 30.[17]

On reduction of rubomycin in water with potassium tetrahydroborate, an intense signal ($g = 2.004$ and $\Delta H = 4$ G) due to the primary semiquinone radical appears in the EPR spectrum during the first two minutes. After only three minutes, another signal ($g = 2.004$, $\Delta H = 12$ G) with a characteristic hyperfine structure appears against the background of the first. After a further few minutes, both signals become broadened and are recorded as one singlet with a width of 9 G (Fig.6). At the same time a precipitate is formed in the reaction mixture, which may be associated with the elimination of the carbohydrate fragment and the formation of the radical forms of the aglycones, which are sparingly soluble in water. On reduction of the AAA in methanol, stable radicals with a well resolved hyperfine structure are detected.[17]

The spontaneous formation of semiquinone AAA radicals has also been observed at physiological pH values. In this case the rate of formation of the radicals is independent of the oxygen content, but the semiquinone radicals produced are destroyed by oxygen atoms. The rate of formation of the adriamycin semiquinone radicals (20 mg ml^{-1}) varied from 7.0 nmol min^{-1} at pH 7.65 to 48.0 nmol min^{-1} at pH 8.85.[25]

The formation of free radicals has also been demonstrated on enzymic reduction of AAA.[26-30] Semiquinone radicals are detected by EPR when AAA are incubated with cells of the Ehrlich ascites carcinoma[26,27] and also with the microsomal or nuclear fraction of rat liver cells under the conditions of hypoxia in the presence of NADPH.[25,28-30] Electron transfer from the AAA to NADPH is catalysed by one-electron transfer flavoproteins such as NADPH-cytochrome P-450 reductase, nitrate reductase, and NADPH-cytochrome *c* reductase, which indicates the absence of specificity in the reduction of the quinonoid group in the AAA. Reductases of various types are capable of reducing the oxo-group of rubomycin in the 13-position with formation of 13-dihydrorubomycin (daunomycinol). Adriamycin and carminomycin undergo analogous reactions, but are transformed much more slowly. The reduction of the oxo-group can be catalysed by the aldoketoreductase from rat kidneys and liver in the presence of NADPH.[31] On treatment with reductases, the sugar fragment can be split off with formation of free aglycones, but the reduced aglycones are 100 times less active than the initial AAA.[5] This is apparently associated with the lower solubility of the AAA aglycones and the consequent pharmacokinetic characteristics.

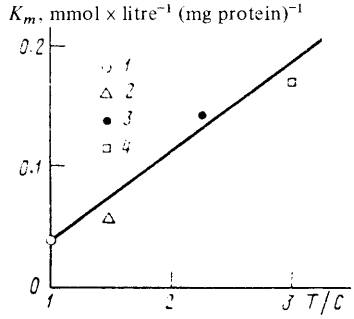

Figure 7. Relation between the antitumour effectiveness (T/C) and the Michaelis constants K_m in the enzymic reduction of rubomycin: 1) L-1210/R; 2) L-1210; 3) P-388; 4) B-16 (T is the lifespan of the animals in the experimental group following the administration of the rubomycin and C the lifespan of control animals) (according to the data of Yesaik et al[5]).

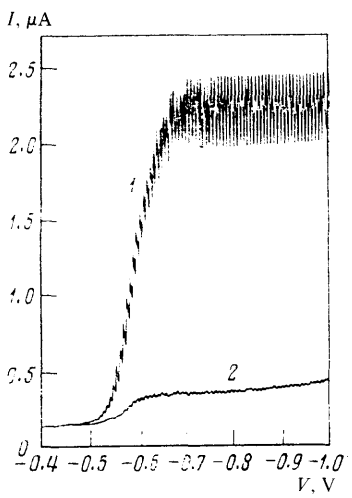
The sensitivity of tumour cells to the AAA depends on the presence in the former of enzyme systems capable of activating and metabolising the AAA. Thus rubomycin is reduced to daunomycinol most vigorously in the cells of the B-16 melanoma—the tumour which is most sensitive to the action of the AAA. This indicates the importance of the enzyme activity of rubomycin in tumours and the possible role of daunomycinol in the manifestation of the antitumour effect (Fig.7). In this connection one can also note that the local

hyperthermia of the tumours increases the effectiveness of adriamycin against the background of the increased intensity of its metabolism.[32]

Two-electron transfer enzymes such as glutathione reductase and lactate dehydrogenase are not involved in the formation of radicals.[30] The kinetics of the reduction of quinones by flavoproteins depend both on the redox potentials of the quinones and on the enzymes catalysing their reduction. Thus the lower limit of the redox potential for the reduction of quinones by the NADPH-cytochrome P-450 reductase is -240 mV, while for NADPH-cytochrome P_5 reductase and NADH-ubiquinone oxidoreductase the limit is -170 mV. Lipophilic properties apparently play a small role in the reduction of these preparations by enzymes.[33]

The EPR spectrum of the semiquinone metabolites of anthracyclines in microsomes does not appear immediately, arising after the consumption of the oxygen dissolved in them and is then observed over a period of several hours.[27] During the incubation of the antibiotics with microsomes, the partial pressure of oxygen diminishes owing to electron transfer from the semiquinone species to oxygen.[26,29,30,34,35] So long as oxygen is present in the microsomes, the signal of the semiquinone radicals is not observed in the EPR spectrum of the antibiotic. As the partial pressure of oxygen diminishes, the EPR signal referring to the semiquinone radical of the anthracycline begins to be detected. The initially symmetrical signal with $g = 2.0036$ then becomes asymmetric and after several hours the spectrum assumes the character of a strongly delayed axially symmetrical signal with $g = 2.0046$ and $g = 2.0021$.[27]



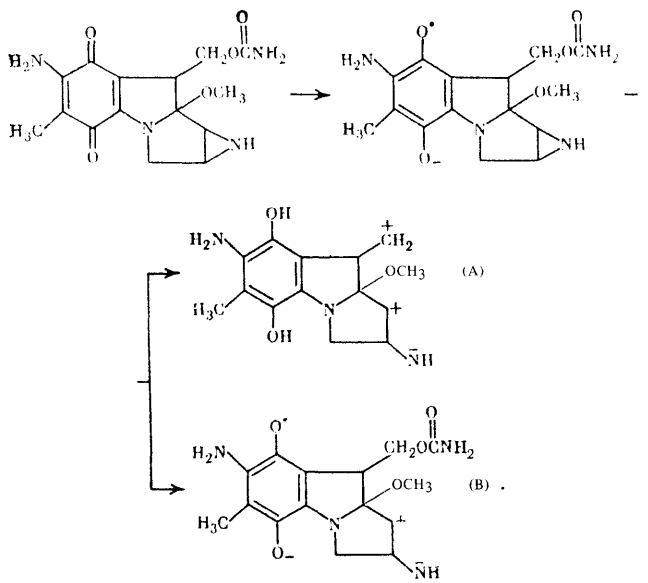


Figure 8. Polarographic reduction wave: 1) rubomycin; 2) rubomycin + DNA (molar ratio DNA : rubomycin = 8.7 : 1).[3]

The anthracycline antibiotics intercalated between the DNA bases are poorly reduced to semiquinone radicals, which agrees with the absence of a polarographic reduction wave of rubomycin after the latter has been incubated with DNA[3] (Fig.8). Antitumour anthracycline antibiotics linked to DNA are poorly reduced by microsomes following the addition of NADPH, so that only a weak signal due to semiquinone radicals is then detected by EPR.[27] All this shows that the AAA intercalated in DNA are "poor" substrates for enzymic reduction.

On chemical and biological activation, AAA molecules are capable of binding covalently to biomacromolecules, which is due to the intermediate formation of semiquinone radicals.[36] The degree of covalent binding of rubomycin to DNA under ultraviolet irradiation increases by a factor of 3 in the presence of oxygen.[36] Covalent binding of adriamycin to microsomal proteins takes place only in the presence of NADPH, which ensures the enzymic reduction of the preparation to a semiquinone. The addition of superoxide dismutase did not affect the binding of adriamycin to microsomal proteins, which rules out the involvement of the superoxide radicals in the process (Table 6).[37]

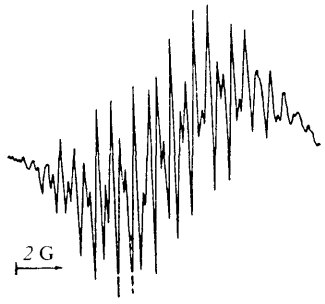
The generation of semiquinone radicals investigated in relation to anthracyclines can probably be important also for other antibiotics containing quinonoid (or analogous) fragments in their structure. Preparations, in the mechanism of the biological action of which processes involving the intermediate formation of free radicals, can play an important role, are considered below.

Mitomycin C. In 1956 an involved set of substances with antibiotic properties which effectively inhibited the growth of the Ehrlich ascites tumour were isolated from the culture medium of *Streptomyces caspitosus*. Later an individual compound, called mitomycin C, was isolated from this mixture. A rapidly acting bactericidal and cytotoxic antibiotic, mitomycin C is used in the treatment of the cancer of the stomach, the mammary gland, and the pancreas.[38] The possible pathways leading to the chemical activation of mitomycin C, including the formation of carbonium ions and semiquinone radicals, indicate a polyfunctional character of this antibiotic:

The cytotoxic activity of mitomycin C can be accounted for by its capacity both to alkylate monofunctionally the DNA bases (probably as a result of the opening of the aziridine ring) and its capacity to form cross-links between the complementary DNA chains[39-41] in consequence of the bifunctional nature of the mitomycin C intermediates. It has been shown that the DNA incubated with the antibiotic for 1 min

is characterised by the presence of covalent bonds (cross-links) between the complementary chains, which can be readily observed on the basis of the reversibility of its denaturation process.

One of the possible mechanisms of this process involves the formation of intermediates of type (A) with two electrophilic centres arising from the urethane and aziridine groups of mitomycin C. Another pathway involves the formation of the free-radical intermediate (B), which can take place in several stages. The most probable (by a factor of 10–20) monoalkylation process occurs initially and is followed by the generation of semiquinone radicals. This is indicated by the finding that the mitomycin C bound covalently to DNA is also capable of being reduced to a semiquinone radical, whose interaction with oxygen leads to the formation of superoxide radicals.[39] On chemical or enzymic reduction, mitomycin C is converted into a highly reactive bifunctional agent forming covalent bonds with nucleic acids, proteins, and other molecules in the damaged cells. The bifunctionality can therefore be a consequence of the formation from the preparation of semiquinone radicals containing an electrophilic centre consisting of the opened aziridine ring (B). The reduced mitomycin also exhibits a high reactivity and is readily bound to DNA *in vitro*, forming cross-links in the latter. The active form (B) of mitomycin C is apparently extremely unstable since the cross-links arise in DNA only if DNA is added a few seconds after the reduction of the antibiotic. Reduced mitomycin is bound initially to the guanine residues in DNA but can also readily interact with RNA and cell proteins.



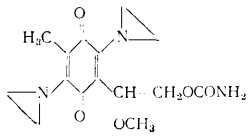


Figure 9. EPR spectrum of the semiquinone radical of mitomycin C reduced with $NaBH_4$ in phosphate buffer at pH 7.0.[39]

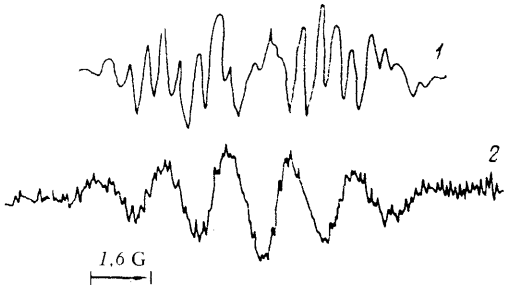
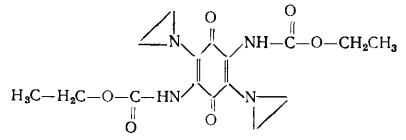
The reduction of a solution of mitomycin C in dimethyl sulphoxide (DMSO) by sodium tetrahydroborate leads to the formation of a stable semiquinone radical, whose EPR spectrum contains 36 lines with the splittings $a_{NH_2} = 2.3$ G, $a^N_{ring} = 1.7$ G, $a^H_{CH_3} = 1.0$ G, and $a^H_{CH_2} = 0.65$ G with $g = 2.0046$ (Fig.9).[39] The observation and detection of the semiquinone radicals of mitomycin C in an aqueous medium is complicated by their comparatively short life. When the preparation was incubated with microsomes in the absence of oxygen, the EPR signal of the semiquinone radical of mitomycin C with $g = 2.0035$ and $\Delta H = 9$ g, vanishing in the course of 4 min, was recorded. The signal appears only in the joint presence of mitomycin C, microsomes, and the NADPH-generating system (0.39×10^{-3} M NADH, 5.5×10^{-3} M glucose-6-phosphate, and 0.67 unit ml^{-1} of glucose-6-phosphate dehydrogenase). In terms of its spectroscopic characteristics ($g = 2.0034$), it is identical with the signal recorded on chemical reduction of mitomycin C in an aqueous medium.[27]

It must be emphasised that mitomycin C bound covalently to poly G, poly C also gave rise to a spectrum characteristic of the semiquinone radical following its reduction with $NaBH_4$.[39]

Carboquone, used in the treatment of leukaemia, is a close structural analogue of mitomycin C.

Carboquone has two polarographic reduction waves at −0.23 and −1.6 V relative to the saturated calomel electrode. In liver microsomes in the presence of NADPH carboquone is reduced to a semiquinone radical; its EPR spectrum is characterised by well-resolved hyperfine structures (Fig.10), which can be accounted for by the interaction of the unpaired electron with the three equivalent protons of the methyl group in the 6-position ($a^H_{CH_3} = 0.55$ G) and with the two nuclei of the nitrogen in the aziridine groups in the 2- and 5-positions ($a^N_{N(2)} = 2.78$ G; $a^N_{N(5)} = 3.03$ G). After the incubation of carboquone with Ehrlich ascites tumour cells, the formation of carboquone radicals is also detected. The addition of DNA or glucose under these conditions does not influence the radical formation process.[28]





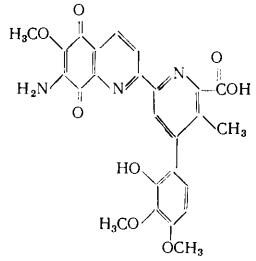


Figure 10. EPR spectra for the semiquinone radicals of carboquone (curve *1*)[28] and AZQ (curve *2*)[42] obtained on microsomal reduction in the presence of NADPH.

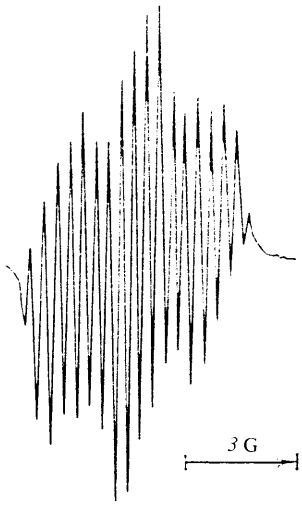
Another structural analogue of mitomycin C is the quinone-containing alkylating agent AZQ, which can also be reduced in microsomes to semiquinone radicals:[42]

Bruneomycin. Bruneomycin has been obtained in the USSR from a culture of *Streptomyces albus var bruneomicini* and is identical with the foreign compounds streptonigrin

and rubochromomycin. It is used in the treatment of lymphogranulomatosis, chronic lympholeukaemia, reticulosis and certain other systemic diseases of the blood as well as the kidney adenosarcoma (Wilm's tumour) and neuroblastoma, which are resistant to other antitumour preparations.[43] Bruneomycin suppresses the synthesis of DNA in animal and bacterial cell cultures. It remains bound to DNA isolated from ascites tumour cells of mice.



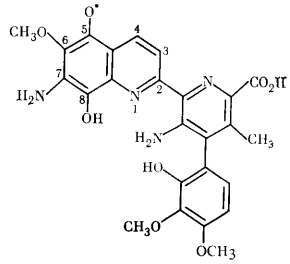


Figure 11. EPR spectrum of the bruneomycin radical (4×10^{-4} M) obtained on reduction with $NaBH_4$ (8×10^{-4} M) in phosphate buffer at pH 7.0.[39]

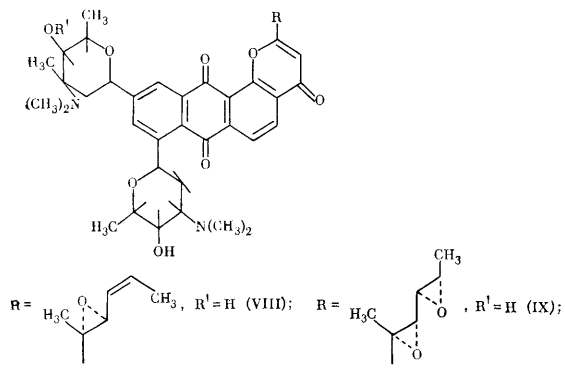
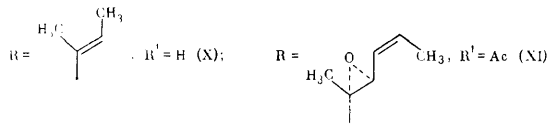


As in the case of mitomycin C, the batericidal action of bruneomycin is accompanied by the degradation of DNA molecules but it does not induce the formation of DNA cross-links.[3] The simultaneous presence of a source of electrons and oxygen is essential for the manifestation of the maximum bactericidal activity.[43] The reduction of bruneomycin by KBH_4 in DMSO in the absence of oxygen led to the formation of a semiquinone radical whose spectrum is characterised by the constants for splitting by the nitrogen atoms in 7- and 1-positions ($a^N_{N(7)} = 0.9$ G and $a^N_{N(1)} = 0.3$ G) and also by the proton in the 4-position (2.1 G) and by the two-equivalent protons of the amino-group (0.3 G).[39]

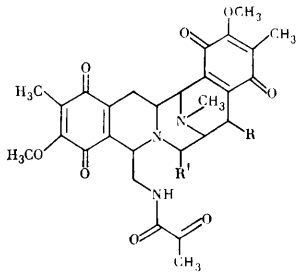


An analogous EPR spectrum has been recorded also on biological reduction of bruneomycin in a suspension of *E.coli* cells, which suggests an important role of free-radical intermediate states in the molecular mechanisms for the biological action of bruneomycin[44] (Fig.11).

The binding of bruneomycin to nucleic acids in the presence of reducing agents and metal ions has been investigated.[45] Incubation of chemically reduced bruneomycin with DNA *in vitro* was accompanied by irreversible binding and led to the formation of a complex containing one mole of bruneomycin for 250 nucleotides. The presence of Zn^{2+} ions greatly increased the degree of binding and the resulting complex contained one molecule of bruneomycin for 80 nucleotides. On the other hand, the presence of Mg^{2+} diminished such binding. A greater amount of the antibiotic was bound to the denatured DNA than to the native DNA. The maximum degree of binding is attained when bruneomycin is reduced in the presence of DNA. A much greater amount of bruneomycin is bound to DNA following its enzymic activation. Studies with synthetic polynucleotides confirmed that in the presence of Zn^{2+}, bruneomycin is capable of binding to both purine and pyrimidine bases.[45]

Rubiflavin and its analogues. The antitumour bactericidal antibiotic rubiflavin (VIII) has been obtained from *Streptomyces* (SC 3728). Rubiflavin analogues such as hedamycin (IX), kidamycin (X), and pluramycin (XI) also possess antitumour properties.[46] Rubiflavin and hedamycin selectively suppress the synthesis of DNA in the cells and affect the synthesis of RNA to a lesser extent. These antibiotics bind strongly (in actual fact irreversibly) to DNA. Both rubiflavin and hedamycin can be reduced by cultures of *E.coli* with formation of free radicals,[44,47] which indicates the importance of the free-radical states of these antibiotics in the manifestation of their biological activity. Fig.12 presents the EPR spectra of the rubiflavin radical-anions obtained on reduction of the preparation in the cells of *E.coli* and on treatment with KBH_4.[44]

Saframycins A and C. The quinone-containing antitumour antibiotics saframycins A and C have been isolated from *Streptomyces lavendulae*[48] (R = H and R′ = CN for saframycin A and R = OCH_3 and R′ = H for saframycin C):



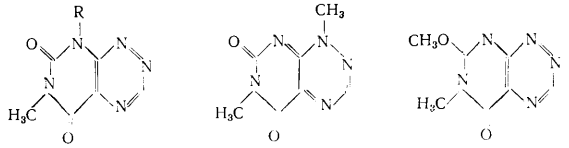


Figure 12. EPR spectra of the rubiflavin radical obtained under different conditions: *a*) on chemical reduction with KBH_4;[44] *b*) on biological reduction in a cell suspension.

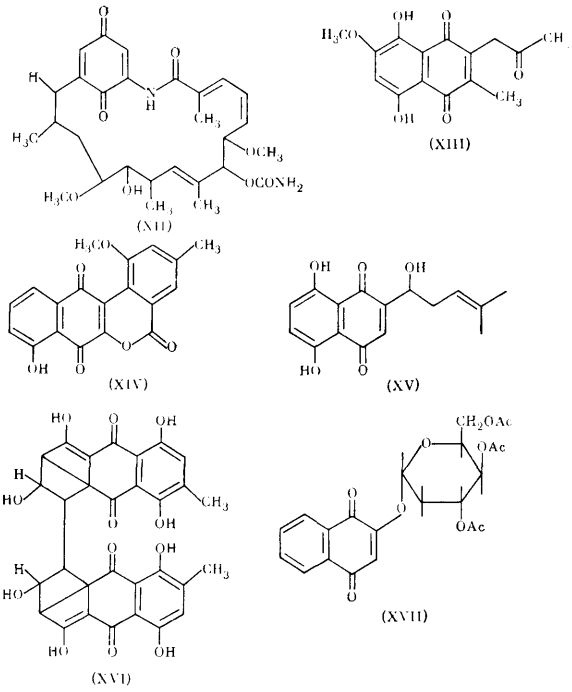
Saframycins A and C fully inhibit the growth of L-1210 cells in culture at concentrations of 0.02 and 1.0 μg ml^{-1} respectively. For mice of the C3H/He strain, the LD_{50} of saframycins A and C are 10.5 and 9.7 mg kg^{-1} respectively. The antitumour activity of saframycin A is 50–100 times greater than that of saframycin C. Saframycin A proved to be highly active against P-388 leukaemia and the Ehrlich ascites carcinoma and moderately active against L-1210 leukaemia and B-16 melanoma.[48]

In addition many other natural physiologically active substances contain quinone structures whose action can be associated with the formation of free-radical intermediates. Herbimycin B (XII),[49] javanicin (XIII),[50] the antibiotic WS-5995 A obtained from *Streptomyces auranticolor* (XIV),[51] alkannin (XV),[52] luteoskyrin (XVI),[53] and lapachol (XVII)[54] can be included among preparations of this type.

2. Antibiotics of the Pyrimido [5,6-*e*] -1,2,4-triazine Group

Antibiotics of this series include reumycin, fervenulin, xanthothricin, and 7-methoxyreumycin.

R = H, reumycin
R = CH_3, fervenulin



xanthothricin

7-methoxyreumycin

One of the representatives of this group of antibiotics, namely reumycin, has been shown experimentally to exhibit a broad spectrum of antitumour activity.

The molecular mechanisms of the biological action and biotransformations of these compounds can be related to the intermediate formation of active free-radical states. Indeed, the formation of stable radical-anions from pyrimidotriazines during their electrochemical reduction has been demonstrated by EPR.[55] Microsomes, in which the reaction and detoxication systems of the xenobiotics are localised, can be used for the enzymic activation of pyrimidotriazines *in vitro*. It has been shown that the antibiotics of this series are capable of accepting an electron from the NADPH-cytochrome b_5 reductase chain.[56]

The reduction of reumycin in microsomes has been investigated in the presence of NADPH at different pH. When reumycin was reduced in an alkaline medium (the chemical reduction was carried out with potassium tetrahydroborate at pH 9.0, while the microsomal reduction was carried out at pH 8.0), the EPR spectrum consisted of an octet of lines with the constants $a^H = a^N = 5.7$ G for splitting due to the interaction with the three equivalent nitrogen atoms and the hydrogen atom of the triazine ring (Figs.13*a* and 13*b*).

Following the microsomal reduction of the methylated reumycin derivative, an analogous eight-component spectrum was recorded, whence it follows that the electronic structure and the distribution of spin density in the reumycin and 7-methoxyreumycin radical-anions are similar. Since reumycin ($pK_a \approx 6.5$) exists mainly in the anionic form at pH 8, presumably the anion undergoes one-electron reduction in the microsomes to a radical-dianion, which is capable of being rapidly protonated at the O(7) or the N(1) atom. However, one should note that the EPR spectrum of this radical differs from that of the radical-anion obtained on electrochemical reduction of 7-methoxyreumycin in dimethylformamide, which can be attributed to the conditions of its preparation in the aprotic medium.

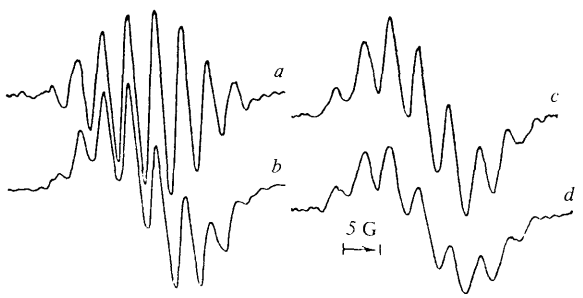


Figure 13. EPR spectra of reumycin radicals obtained under different conditions: *a*) on chemical reduction with KBH_4 at pH 9.0;[35] *b*) on microsomal reduction in the presence of NADPH at pH 8.0; *c*) on chemical reduction with KBH_4 at pH 4.0; *d*) on microsomal reduction in the presence of NADPH at pH 6.0.

In an acid medium, where unionised forms of reumycin are reduced (the chemical reduction is carried out at pH 4.0 and the enzymic reaction at pH 6.0), the character of the measured EPR spectra changes. Thus a seven-component EPR signal with constants for splitting (a = 5.6 G) by the three approximately equivalent nuclei of the nitrogen atoms in the triazine ring was obtained for the radical-anion (Figs.13*c* and 13*d*). On recording the spectra at a lower modulation amplitude, a finer structure due to the further splitting of the above seven lines was observed.

An analogous spectrum was recorded on microsomal reduction of fervenulin. The replacement of the hydrogen atom by the methyl fragment in the 8-position probably does not influence the character of the distribution of spin density in the radical-anions. Following the microsomal reduction of xanthothricin, a ten-component spectrum was obtained: this is also due to the splitting of the signal of the unpaired electron as a result of the interaction with the three equivalent nitrogen atoms and the three hydrogen atoms of the methyl group in the triazine fragment. The spin density in the pyrimidotriazine radical-anion is apparently localised mainly in the triazine ring. Thus in biological systems there is a possibility of the reduction of both reumycin and of its anion depending on the pH of the medium.[35]

In the general case the equation of the oxidation-reduction reactions in protic media can be written in the form

$$A + n e^- + m H^+ \rightleftarrows AH_m^{(n-m)-}.$$

For reversible processes, the potential of this system is described by the following expression according to the Nernst equation:

$$E = E_0^0 + \frac{RT}{nF} \ln \frac{[A]\,[H^+]^m}{[AH_m^{n-m}]}.$$

At a reduction half-wave potential $E_{1/2}$ such that the concentrations of the oxidised and reduced forms on the electrode surface are equal, the above equation can be put in the form

$$E_{1/2} \cong E^0 + \frac{RT}{nF} \ln [H^+]^m \cong E^0 - \frac{2.3mRT}{nF} \text{pH}$$

or

$$\Delta E_{1/2}/\Delta \text{pH} = -2.3 \frac{mRT}{nF}.$$

The overall dependence of $E_{1/2}$ on pH is represented by several straight lines having different slopes and the pH values at the break points correspond to the ionisation constants (pK_a) of the oxidised or reduced form. If the absolute value of $\Delta E_{1/2}/\Delta$pH, i.e. the slope of the straight line, beyond the break point decreases with increasing pH, then the break itself is due to the dissociation of the reduced form and the corresponding pK_a refers to the latter.[57]

Thus a comparative study of the rules governing the variation of the half-wave potential $E_{1/2}$ with the pH of the medium for two pyrimidotriazine antibiotics showed (Fig.14) that in the pH range 4–10 the dependence of $E_{1/2}$ on the pH for fervenulin, which is incapable of ionisation, consists of a straight line whose slope is −0.06. For reumycin, which is an acid (pK_a = 6.5), this relation has a more complex form with a characteristic break in the region where the pH approximately equals pK_a. As a result of this, reumycin is reduced less effectively in alkaline media and more effectively in acid media than fervenulin.

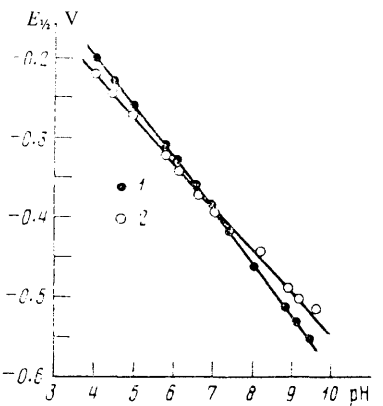

Figure 14. Dependence of $E_{1/2}$ for reumycin (line *1*) and fervenulin (line *2*) on pH.

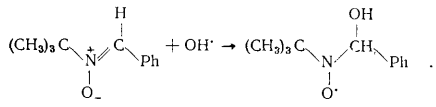
The overall tendency towards an enhancement of the electron-accepting properties of the antitumour antibiotics with decrease of pH can be one of the causes of their selective action on tumour cells whose pH is lower than the normal value.



III. THE INTERACTION OF THE SEMIQUINONE RADICALS OF THE ANTIBIOTICS WITH INTRACELLULAR OXYGEN

The semiquinone radicals of antibiotics, formed during enzymic reduction, are destroyed under aerobic conditions on interaction with oxygen, forming the superoxide radical:

$$A^{\cdot-} + O_2 \overset{k}{\rightleftarrows} A + O_2^{\cdot-}$$

The rate constant for the generation of superoxide at pH 7 is higher than 10^8 litre mol^{-1}. This reaction is reversible, the rate of the reverse reaction being lower by two orders of magnitude.[29,58,59] According to the results of Chance et al,[60] the partial oxygen pressure is 7 mmHg (10 μM) in normally functioning cells *in vivo*. Assuming that the oxygen concentration is 10 μM and that $[O_2] \gg [O_2^{\cdot-}]$ (i.e. the reaction is of pseudofirst order), we find that the lifetime of the semiquinone radical *in vivo* is $\ln 2/k[O_2] = 6$ μs. Consequently the semiquinone radicals of antibiotics are unstable in normal cells and their chemical reactions (including the possible reactions with macromolecules) are very rapid. Naturally, in the presence of a reduced oxygen content (for example, in the cells of malignant tumours) the lifetime of semiquinone radicals can increase significantly, which entails an increase of the probability of free-radical reactions in the biotransformation of the antibiotic.

The detection of the formation of the $O_2^{\cdot-}$ and $OH^{\cdot}$ radical-ions is difficult owing to their high reactivity. One of the most convenient ways of detecting the formation of superoxide and hydroxy-radicals is the spin trapping method. N-t-Butyl-α-phenylnitrone (BPN) and 5,5'-dimethyl-1-pyrroline 1-oxide (DMPO) are most often used for this purpose. For example, when an aqueous solution of BPN in a phosphate buffer at pH 7 is added to a solution of the semiquinone radical in DMSO, obtained by the reduction of the AAA with KBH_4, a radical, which is a spin-adduct of BPN and the OH group of the semiquinone radical, is formed:

Its EPR spectrum consists of a doublet (a = 16.0 G) of triplets (a = 3.4 G) with g = 2.0061. When a solution of the semiquinone radicals of antibiotics was mixed with an aqueous solution of BPN containing catalase or superoxide dismutase (SOD), the formation of nitroxy-radicals was not observed.[39] On the other hand, the denatured forms of these enzymes no longer inhibited the formation of the BPN–OH nitroxy-radical spin-adducts. It has been shown for bruneomycin that in the presence of EDTA the spin-adducts are not formed, which indicates an important role of heavy metal ions in the generation of the $OH^{\cdot}$ radical-anions.[39]

Naturally the above spin-adducts are formed only in the presence of oxygen. For example, when adriamycin is incubated with microsomes, the formation of the DMPO–superoxide adduct is observed only when oxygen is present in the microsomes.[27] After the complete consumption of the oxygen dissolved in the incubation medium, the EPR signals of the spin-adducts of $OH^{\cdot}$ and $O_2^{\cdot-}$ disappear and the EPR signal of the semiquinone radical of adriamycin appears. At least two factors influence this phenomenon: firstly, the DMPO–superoxide adduct has a lifetime of 45 s at pH 7.4[27,61] and, since molecular oxygen is consumed, the formation of nitroxy-radicals can cease; secondly the spin-adduct is enzymically reduced, like other nitroxy-radicals.[27,62] On the basis of these features, the following sequence of reactions has been proposed:[33]

$$A + e^- \rightarrow A^{\cdot-},$$

$$A^{\cdot-} + O_2 \rightarrow A + O_2^{\cdot-}$$

$$2H^+ + 2O_2^{\cdot-} \xrightarrow{SOD} H_2O_2 + O_2,$$

$$2H_2O_2 \xrightarrow{catalase} 2H_2O + O_2,$$

$$M(II) + H_2O_2 \rightarrow M(III) + OH^{\cdot} + OH^-,$$

$$M(III) + O_2^{\cdot-} \rightarrow M(II) + O_2,$$

$$H_2O_2 + O_2^{\cdot-} \rightarrow OH^- + OH^{\cdot} + O_2,$$

Another way of detecting $O_2^{\cdot-}$ radical-ions in solution may be to determine the adrenochrome formed from adrenalin.[15] The rate of formation of superoxide radicals is estimated from the rate of oxidation of adrenalin and the formation of adrenochrome, which is determined spectrophotometrically from the absorption at a wavelength of 480 nm. The addition of superoxide dismutase (10 μg ml^{-1}) inhibits the formation of adrenochrome.

The generation of superoxide radicals by pyrimidotriazine antibiotics in rat liver microsomes has been investigated.[35] In the absence of NADPH, the rate of formation of $O_2^{\cdot-}$ in the microsomes is very low (w = 0.3 nmol per mg of protein per minute) and does not increase after the addition of reumycin, which is not reduced under these conditions to a radical-anion. In the presence of NADPH, the electron transfer from NADPH to oxygen with formation of superoxide radicals is observed (w = 1.8 nmol per mg of protein per minute). The addition of reumycin to the system increases sharply the rate of formation (w = 6.5 nmol per mg of protein per minute) of superoxide radicals (the formation of adrenochrome) owing to the transfer of an electron from the radical-anions of the antibiotic to oxygen. Under these conditions, the EPR spectra of the reumycin radical-anions were detected only after the complete consumption of oxygen. Xanthothricin, which has the lowest reduction potential,[55] is capable of being reduced in microsomes without the addition of NADPH. The radical-anions formed under these conditions generate superoxide radicals at the highest rate (w = 11.1 nmol per mg of protein per minute). This can probably explain the high toxicity of xanthothricin and its low chemotherapeutic index. This confirms the earlier hypothesis of the role of the stability of the intermediate active free-radical forms of the antitumour preparations in the selectivity of their action.[63]

Comparison of the properties of reumycin with those of other antibiotics of this series makes it possible to explain the higher selectivity of its antitumour action. In tumour cells, where the pH is reduced (6.5), the reumycin–reumycin anion equilibrium is displaced towards the unionised form. Owing to its low reduction potential, the neutral form of reumycin can oxidise a large number of enzyme systems with formation of highly reactive radical-anions and, by virtue of the causes stated above, this can lead to a pronounced cytotoxic activity. In normal cells, whose pH is 7.5, reumycin exists to the extent of 90% in the ionised form, whose capacity for reduction to radical-ions is much lower. This is in fact apparently the cause of the selectivity of the action of reumycin in relation to tumour cells.

The formation of superoxide and hydroxy-radicals as a result of electron transfer from the semiquinone radicals of antibiotics to oxygen has been established also for bruneomycin,[39] actinomycin D,[15] anthracycline antibiotics,[27] and mitomycin C.[27]

The formation of radicals from quinone-containing antibiotics and their subsequent destruction on interaction with oxygen can also be characterised by the degree of microsomal oxidation of NADPH and the consumption of oxygen.

Substances of the benzoanthraquinone class, *N*-heterocyclic quinones, and naphthcquinones stimulate the oxidation of NADPH but at different rates. Cytotoxic preparations (cyclophosphane, methotrexate, etc.) are inactive, which has been established by the quantitative analysis of the microsomal oxidation of NADPH (Table 7).[26]

Another index of the intensity of electron transfer from the antibiotic semiquinone to oxygen is the increase of the rate of consumption of oxygen. It has been observed that the rate of consumption of oxygen is proportional to the concentration of both the quinone-containing antibiotic and that of the enzymes. Antitumour preparations not containing quinone groups and not increasing the rate of microsomal oxidation of NADPH do not influence the consumption of oxygen by microsomes.[26,29] The highest rates of formation of superoxide radicals, estimated from the rate of consumption of oxygen in the presence of rubomycin, was reached at pH 7.8–8.4, although in phosphate buffer a higher rate was noted than in tris buffer. The consumption of oxygen stimulated by AAA was also sensitive to the concentration of the buffer; the maximum rate was attained in 0.2 M buffer.[29]

Table 8. Rates of consumption of oxygen by various subcellular extracts in the presence of rubomycin.[29]

Object	w_1, nmol/mg protein per min	w_2, nmol/mg protein per min
Cytoplasmic liver extract	0.3	1.6
Liver mitochrondria	2.1	4.3
Liver microsomes	25.2	93.0

Notation: w_1 and w_2 are the rates of the intrinsic and rubomycin-catalysed consumption of oxygen.

Various subcellular extracts stimulate the consumption of oxygen to different extents, which is due to the differences between the amounts of enzymes capable of catalysing the electron transfer from NADPH to the quinone-containing antibiotic (Table 8).[29] This process proceeds most vigorously in microsomes. At the same time the difference between the activities of microsomes from different organs is noteworthy. The microsomes of different organs (liver, lungs, and heart) of mice and rats have been investigated and their capacity to increase the consumption of O_2 has been determined using adriamycin as the substrate (Table 9).

It has been found that the microsomes from L-1210 and P-388 tumour cells also catalyse the increase of the consumption of oxygen but to a much lesser extent than the microsomes from the normal organs, which is due to the disturbance of the functional activity of tumour cells and cell organelles (Table 9).[26]

Table 9. Kinetic constants* for the consumption of oxygen stimulated by adriamycin.[26]

Microsomes	$10^4 K_m$, mol litre^{-1}	$10^7 V_{max}$, mol min^{-1}
Rat liver	3.6	0.92
Rat lungs	3.1	0.39
Rat heart	186.0	0.89
Mouse liver	8.0	2.6
Mouse lungs	2.4	0.44
Mouse heart	3.1	0.06
Mouse spleen	28.0	0.14
L-1210 cells	4.4	0.2
P-388 cells	0.6	0.04

*K_m and V_{max} are the parameters of the Michaelis equation.

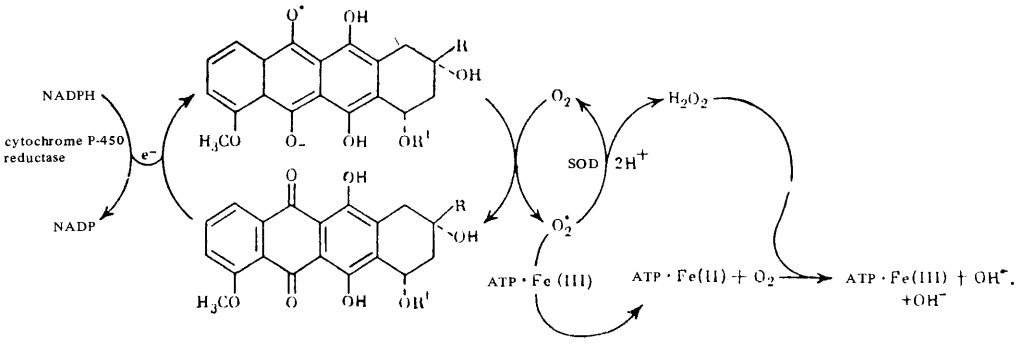


Table 10. Kinetic constants* for the consumption of oxygen stimulated by AAA in microsomes.[29]

Antibiotic	K_m, μmol litre^{-1}	V_{max}, nmol min^{-1}
Rubomycin	390	35
Adriamycin	260	240
Daunorubicinol	250	230
Carminomycin	110	770
Adriamycin Fe^{3+}	250	620

*K_m and V_{max} are the parameters of the Michaelis equation.

All the anthracycline antibiotics are capable of transferring an electron from NADPH to oxygen. Carminomycin is outstanding in this series, catalysing the electron transfer to oxygen at the highest rate; this property is correlated with its high toxicity (Table 10).[29]

In the general case the AAA and their structural analogues with an *N*-quinonoid fragment form semiquinone free radicals on reduction *in vivo*, their autoxidation resulting in the generation of superoxides.

According to the experimentally justified scheme presented above, antibiotics of this series act as competing agents for electron transfer to oxygen in the biological oxidation chain.[64] Naturally, chemical modification of the antibiotics, involving a decrease of their capacity to generate superoxides, should be accompanied by a decrease of toxicity. Indeed the monoxime of bruneomycin, which cannot function as an agent transferring electrons to oxygen, proved to be less toxic in relation to *E. coli* and the magnitude of the toxic dose was independent of the level of the superoxide dismutase activity of the cells.[65]

Various additives to microsomes can alter the consumption of oxygen. Thus coenzyme Q appreciably increases both the intrinsic and the rubomycin-stimulated consumption of oxygen. On the other hand, α-tocopherol, which is a familar natural antioxidant, inhibits the intrinsic consumption of oxygen by 60% and the antibiotic-stimulated consumption by 80%. On the other hand, glutathione and cysteine activate the consumption of oxygen (Table 11).[29]

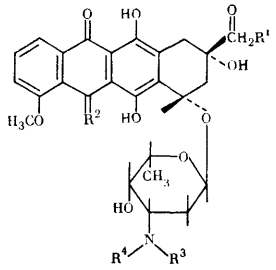

Table 11. The influence of various additives on the rate of consumption of oxygen by microsomes.[29]

additive	w_1, nmol O_2 min^{-1}	w_2, nmol O_2 min^{-1}
Without additive	35	296
Hexobarbital	88	309
Aspirin	54	302
Coenzyme Q	53	447
GSH	53	389
Cysteine	49	388
α-Tocopherol	13	68
EDTA	18	252
Fe^{3+}	49	315

Notation: w_1 and w_2 are the rates of the intrinsic and adriamycin-catalysed consumption of oxygen and GSH is reduced glutathione.

The main secondary effect of the AAA is cardiotoxicity. The relation between the cardiotoxicity in the series of AAA and the inhibition by the latter of the synthesis of cardiac guanylate cyclase has been investigated[66] and it has been observed that synthetic AAA containing hydrazone derivatives in the C(9)-position do not inhibit but actually stimulate the guanylate cyclase activity.

The cardiotoxocity has been explained recently by the formation of the O_2^- and $OH^\cdot$ radical species in the cardiac muscle. There is a correlation between the capacity to form superoxide radicals and the cardiotoxicity of certain anthracyclines[64] (Fig.15).

$R^1 = H$, $R^2 = NH$, $R^3 = H$, $R^4 = CH_2Ph$ (XVIII); $R^1 = H$, $R^2 = O$, $R^3 = R^4 = CH_2Ph$ (XIX); $R^1 = OH$, $R^2 = O$, $R^3 = R^4 = CH_3$ (XX).

The toxic activity of the radicals on cardiac muscle is associated with the reduced content of superoxide dismutase and catalase in the cell (Table 12).[34] It has been demonstrated *in vivo* that the introduction of the natural antioxidant α-tocopherol leads to a decrease of cardiotoxicity and an increase of the lifespan of animals.[67] It has been shown that ascorbate can also decrease the overall toxicity and cardiotoxicity of the preparations due to the AAA. Electron microscope and histological studies have demonstrated that ascorbate prevents the early changes in cardiac muscle under the influence of AAA.[68]

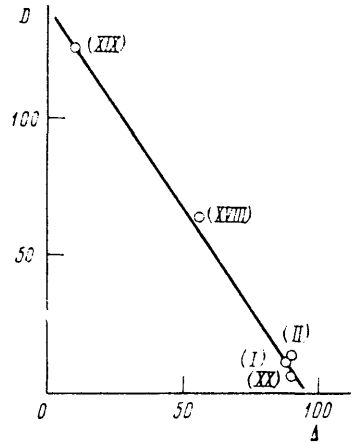

Figure 15. Relation between the dose of anthracyclines giving rise to the same Zbinden cardiotoxic effect (D) and the relative rate of generation of superoxide radicals by various anthracyclines (Δ) (according to the data of Lown et al.[64]

Table 12. The relative activities of catalase (in relative units) in various organs of the rat and rabbit.[34]

Organ	Rabbit	Rat
Blood	20	16.2
Liver	23	45.3
Kidneys	26	19.0
Lungs	2.9	1.9
Heart	1.0	1.0

It has been observed that AAA stimulate the peroxide oxidation of lipids. Incubation of rat liver microsomes with the NADPH-generating system produces approximately 10 nanoequivalents of malonaldehyde per mg of protein in 60 min. The peroxide oxidation was 6 times faster after the addition of 100 μM adriamycin. The AAA-stimulated peroxide oxidation of lipids influences the activity of certain enzyme systems of microsomes.[69] An 85% decrease of the content of cytochrome P-450 reductase and 70% inhibition of the activity of aminopyrine *N*-demethylase have been observed. The peroxide oxidation of lipids did not influence the NADPH-cytochrome *c* reductase activity; the UDP-glucuronyl transferase activity increases by a factor

of 5, while the glucose-6-phosphatase activity decreases by a factor of 6 under these conditions. In the absence of the peroxide oxidation of lipids, adriamycin also influences these enzymes[69] but to a lesser extent (Fig.16).

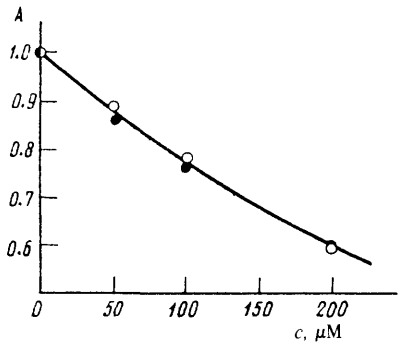

Figure 16. The influence of the concentration of adriamycin (c) on the content of cytochrome P-450 and the activity of aminopurine *N*-demethylase in the absence of the peroxide oxidation of lipids (according to the data of Mimnaugh et al).[69]

From the above, one can reach the following conclusions: both the anions and the radical-anions of the AAA can be oxidised in the organism, the toxic activity of the preparations is due to their capacity for oxidation, and the introduction of special antioxidants competing with the preparations is essential for the reduction of their toxicity.

In order to improve the antitumour index and reduce cardiotoxicity, various analogues of natural AAA have been synthesised. The introduction of the imino-group in the 5-position of the chromophore reduces the capacity for reduction and subsequent oxidation. This leads to a considerable decrease of the rate of generation of superoxide radicals compared with adriamycin.[55]

Changes in the carbohydrate ring can also influence the capacity of AAA for enzymic reduction. Thus *N*-methylation of the sugar group increases the capacity of AAA for reduction, the degree of consumption of oxygen, and the rate of formation of superoxide radicals. The cardiotoxicity of these preparations increases under these conditions.[64] If two *N*-benzyl groups are introduced into the carbohydrate fragment, then the consumption of oxygen and the formation of superoxide radicals diminish sharply. This can be associated with the steric inhibition of the action of the microsomal cytochrome P-450 on the antibiotic.

The activation of medicinal preparations and their subsequent metabolism depend on the functional state of the cells and the degree of their differentiation. The differences in the effectiveness of the action of particular antitumour antibiotics as a function of the degree of aeration of the tumour cells may be associated with this particular factor. In terms of this factor, the series of known carcinolytic substances can be divided into three groups, which are presented in Table 13.[70]

The group of preparations whose cytotoxic effect increases with increase of the concentration of oxygen includes three antibiotics: bleomycin, bruneomycin, and actinomycin D. It is known that bleomycin is characterised by high pulmonary toxicity, which increases significantly with increasing partial pressure of O_2.[71] Bleomycin causes ruptures in DNA molecules and its reactivity depends on the presence of iron ions and molecular oxygen. The highly reactive radical forms of oxygen can be responsible for the breaks in DNA under these conditions. It has been shown that the reaction of bleomycin with [^{3}H]DNA in the presence of iron ions is inhibited when the reaction mixture is bubbled with argon. On aeration, the reaction proceeds via the ternary complex O_2–Fe(II)–bleomycin [O_2–Fe(II)–B], whose properties are analogous to those of haem-containing oxygenases.[72] This complex is formed on direct oxidation with molecular oxygen of Fe(II)–bleomycin [Fe(II)–B], the second-order reaction rate constant amounting to $k = 6.1 \times 10^3$ mol^{-1} s^{-1}:

$$\left.\begin{matrix} O_2 \\ Fe(II)—B \end{matrix}\right\rangle \rightarrow O_2—Fe(II)—B \leftrightarrow O_2^{\cdot-}—Fe(III)—B \left\langle\begin{matrix} \rightarrow O_2^- \\ \rightarrow Fe(II)—B \end{matrix}\right.$$

The subsequent stage involving the generation of a superoxide radical with formation of the complex Fe(II)–B is characterised by the first-order rate constant $k = 0.12$ s^{-1}. At pH 7 the oxidation of the complex Fe(II)–B with oxygen leads to the formation of three different paramagnetic forms of Fe(III)–B: one high-spin form ($s = 5/2$) and two low-spin forms ($s = 1/2$). The low-spin form having the spectroscopic parameters $g_{xx} = 2.25$, $g_{yy} = 2.17$, and $g_{zz} = 1.94$ is unstable and disappears rapidly (after 60 s at room temperature). The other two forms, namely the high-spin form ($g = 4.3$) and the other low-spin form ($g_{xx} = 2.40$, $g_{yy} = 2.18$, and $g_{zz} = 1.90$), are stable.[73]

Table 13. Classification of the antitumour agents in terms of the effectiveness of their action as a function of the degree of aeration of the cells.[70]

Agents whose action depends on the degree of aeration		Preparations whose action is independent of the degree of aeration
active under aerobic conditions	active in hypoxia	
Bleomycin	Mitomycin C	5-Fluorouracil
Bruneomycin	Adriamycin	Methotrexate
Actinomycin D	Misonidazole	*cis*-Dichlorodiaminoplatinum
Procarbazine	Metronidazole	*N,N'*-Di(chloroethyl)-*N*-nitrosourea
Vincristine	5-Thio-D-glucose	
Ionising radiation	2-Deoxy-D-glucose	*N*-Chloroethyl-*N'*-cyclohexyl-*N*-nitrosourea

Under aerobic conditions, the reduction of bruneomycin with tetrahydroborate in the presence of DNA is accompanied by a decrease of viscosity and of the average molecular weight of DNA[44] owing to the appearance of single breaks in the DNA molecule.[74] Since superoxide dismutase inhibits this process,[75] presumably active radical forms of oxygen are responsible for the degradation of the DNA. These results make it possible to explain the enhancement of the toxic activity of bruneomycin on *E.coli* in the presence of oxygen or in the presence of a reduced SOD content.

Whereas the action of mitomycin C is determined by the alkylation of biomacromolecules and the formation of cross-links between them, the cytotoxic activity of bruneomycin is due to the active oxygen radicals. The selective action on tumour cells by preparations generating these radicals can be accounted for by the reduction of the SOD content in

tumour cells.[76] The selective increase of the O_2 concentration in tumour cells can apparently be used for the specific chemotherapy of tumours.

Yet another antibiotic of this type is actinomycin D. The mechanism of its action can be accounted for by its capacity for intercalation between the DNA bases.[38] At a concentration less than 0.01 μM, the difference between the cytotoxicities of this antibiotic under aerobic conditions and in hypoxia is small. However, at a concentration of approximately 1 μM, oxygen-rich cells are approximately 100 times more sensitive to the lethal action of actinomycin D than under the conditions of hypoxia.[70] There exists apparently an alternative oxygen-dependent mechanism of the cytotoxic action of actinomycin D where a part of it remains non-intercalated between the DNA bases at fairly high concentrations of the preparation. On incubation with microsomal proteins, actinomycin D forms a semiquinone free radical which stimulates the consumption of oxygen and the electron transfer to oxygen. When actinomycin D and its spin-labelled analogues are incubated with liver microsomes in the presence of NADPH, the rates of consumption of oxygen, of formation of superoxide, and of oxidation of adrenalin increase (Table 14).[15] Evidently the spin-labelled antibiotics stimulate the formation of superoxide radicals to a greater extent than does actinomycin D.

Table 14. The rates of consumption of oxygen (w_1) and formation of andrenochrome (w_2) from adrenalin in microsomes in the presence of actinomycin D and its spin-labelled analogues.[15]

Preparation	w_1, nmol/mg protein per min	w_2, nmol/mg protein per min
(V)	8.17	2.45
(VI)	18.37	4.66
(VII)	99.28	13.96
Control	7.23	1.29

The influence of the binding of the preparations to DNA on the generation of O_2^- has also been studied. After actinomycin D had been incubated with DNA, it lost entirely its capacity to generate superoxide. The incubation of the spin-labelled analogues (VI) and (VII) with DNA reduced the rate of consumption of oxygen by 71 and 50% respectively and also decreased the rate of oxidation of adrenalin. These results indicate yet again that the antibiotics intercalated between DNA bases are "poor" substrates for enzymic reduction. Thus the formation of superoxide, hydrogen peroxide, and hydroxy-radicals can play an important role in the antitumour activity of preparations of the type considered.[15]

---o0o---

The set of data obtained permit a number of conclusions concerning the molecular mechanisms of the toxic and antitumour activities of the active free-radical forms of antibiotics. The demonstration of the formation of the chemically reactive forms of reduced oxygen and of the covalent binding of the free-radical forms of the antibiotics to biomacromolecules must be regarded as the most important of these.

The Vibrational Spectra of Neutral Free Radicals and the Corresponding Ions

L.A.Kotorlenko and V.S.Aleksandrova

The results of studies on the vibrational spectra of simple and polyatomic neutral free radicals and the corresponding ions—the products of the one-electron reduction or oxidation of these radicals—are analysed.
The bibliography includes 157 references.

I. INTRODUCTION

Many chemical reactions proceed via a free-radical mechanism. The kinetics of such reactions are usually studied by EPR, which makes it possible to follow the time course of the reaction. However, in many instances the radicals can react without the involvement of the unpaired electron, which makes it difficult to follow the reactions of the radicals using EPR spectra. In such cases a detailed study and interpretation of the vibrational spectra of the intermediate radicals are necessary. The results of such studies for neutral and charged radicals have been surveyed.[1]

The extensive published experimental data show that, depending on the nature of the reacting substances, the free radicals can manifest a dual reactivity: on interaction with reductants and oxidants, they can respectively accept and give up an electron to form an anion or cation. Ionic reactions are known to play a significant role in organic processes and the investigation of the structures of ionic species is therefore extremely important. In the present review the vibrational spectra of free radicals and the corresponding ions are compared and certain considerations are put forward concerning the changes in the structure of the species as a consequence of the loss or addition of an electron. The influence of the protonation of molecules related to the radicals on their structure and vibrational spectra is also analysed.

II. THE VIBRATIONAL SPECTRA OF SIMPLE FREE RADICALS AND THEIR IONS

Simple free radicals and ions are extremely unstable and their detection by vibrational spectroscopy therefore involves considerable difficulties. Most studies employ the method of matrix isolation, whereby it is possible to detect free radicals and ions. There exists also another possibility for the investigation of the vibrations of short-lived molecular systems—the high speed recording of spectra; however, in view of its technical complexity it has been much less used.

Non-empirical calculations of the potential curves for the ground and excited electronic states of the $OH^{\cdot}$ radical and the ground state of the OH^{+} cation have been carried out[2] by the method of configuration interaction using pseudo-natural orbitals in terms of the approximation of bound electron pairs. The results agree with the experimental values listed in Table 1.

Table 1. The vibrational spectra and geometrical parameters of a series of simple molecules, radicals, and ions.

Notation: ν is the vibration frequency, r is the equilibrium distance, α the angle between the bonds, F_r the force constant, ω_e the normal vibration frequency for infinitesimal amplitudes, and $\omega_e\chi_e$ the anharmonicity constant. The asterisk denotes excited states.

[a] Obtained from $\omega_e = 3740\ cm^{-1}$, $\omega_e\chi_e = 86.4\ cm^{-1}$ and $\omega_e = 3181\ cm^{-1}$, $\omega_e\chi_e = 95.9\ cm^{-1}$ for $OH^{\cdot}$ and $(OH^{\cdot})^*$ respectively.[2]

[b] Calculated from $\omega_e = 1904\ cm^{-1}$, $\omega_e\chi_e = 14\ cm^{-1}$ and $\omega_e = 1371\ cm^{-1}$, $2\omega_e\chi_e = 16\ cm^{-1}$ for $NO^{\cdot}$ and NO^- respectively.[27,32]

From the analysis of the literature data on the infrared and Raman spectra of the hydroxides MOH (M = Li, Na, Rb, or Cs) and $M(OH)_2$ (M = Mg, Ca, Sr, or Ba) as well as their hydrates at 95 and 295 K, Lutz et al.[3] concluded that the frequency of the stretching vibration of the unperturbed OH^- ion is 3570 ± 10 cm^{-1}. This value differs appreciably from that usually adopted (3700 cm^{-1}). The formation of the cation decreases the vibration frequency of the O–H bond, while the latter hardly changes on formation of the anion. Since the OH^+ cation has a triplet ground state,[2] i.e. its formation involves the abstraction of an electron from the unshared pair, the observed weakening of the bond is due to the displacement of electron density from the bond to the oxygen atom. At the same time the vibration frequencies of the OH^- anion and the OH· radical are identical, which suggests that the electron which reduces the radical to the anion occupies a non-bonding orbital.

The infrared and Raman spectra of the oxonium ion H_3O^+ have been studied in a number of investigations.[4–8] The following assignment of the frequencies in the spectrum of the H_3O^+ ion has been adopted assuming a symmetrical pyrimidal structure: the symmetrical deformation (ν_2) at 1100 cm^{-1}, the antisymmetric deformation (ν_4) at 1700 cm^{-1}, the antisymmetric stretch (ν_3) at 2400 cm^{-1}, and the symmetrical stretch (ν_1) at 3200 cm^{-1}. The constants calculated using the valence bond approximation[9] describe satisfactorily the experimental data. The significantly lower force constant of the O–H bond in H_3O^+ compared with the value obtained in terms of the same approximation for H_2O (Table 1) is associated with the increase of the interatomic distance by 0.054 Å as a consequence of the shift of electron density to the O–H bond newly formed on protonation of the water molecule. On the basis of the analogous change in the equilibrium distance by 0.055 Å in OH^+ relative to OH·, a similar change in the force constant may be expected also on formation of the OH^+ cation from the OH· radical.

Milligan and Jacox[11] were able to obtain the most complete vibrational spectrum of the $NH_2^·$ radical. The band at 1499 cm^{-1} was assigned to the ν_2 deformation, while that at 3220 cm^{-1} was assigned to the ν_3 antisymmetric stretch. In the study of the fluorescence excitation spectrum of the $NH_2^·$ radical the band at 3219 cm^{-1} was assigned[12] to the ν_1 symmetrical stretch. The experimental value of ν_2 for the deuterio-analogue is 1110 cm^{-1}. According to the authors,[11] the 16 cm^{-1} hypsochromic shift of the experimental deformation vibration frequency of $ND_2^·$ relative to the calculated value is caused by the difference between the contributions of the anharmonicity to the potential energies of the $NH_2^·$ and $ND_2^·$ radicals.

The excitation of the $NH_2^·$ radical is accompanied by a considerable increase of the angle α and a decrease of the bond length (Table 1). These changes are caused by the *sp* hybridisation of the N–H bond in the excited state, while in the ground state the N–H bond has a predominantly *p* character with a small contribution of the *s* orbital.[11] On ionisation of the $NH_2^·$ radical, the valence angle increases[15] as on its excitation, according to Milligan and Jacox,[11] this should be accompanied by a decrease of the bond length. However, the presence of the positive charge localised at the nitrogen atom apparently shifts the electron density from the bond to the N atom and lengthens the bond. There are no experimental literature data for the geometry of NH_2^+, but the results of a calculation[15] (Table 1) confirm the view that these competing effects exist. On protonation of the NH_3 molecule, the valence force constant of the N–H bond diminishes compared with the initial molecule (Table 1), while the deformation force constant hardly changes.[17] A significant difference between the frequencies of the deformation vibrations of ammonia (ν_2 = 930–970 cm^{-1} and ν_4 = 1628 cm^{-1})[19] and its protonated form (ν_2 = 1680 cm^{-1} and ν_4 = 1400 cm^{-1})[19] is then observed. A characteristic feature is that the homolytic rupture of the bond in both NH_3 and in H_2O (with formation of the radical) is accompanied by a lengthening of the corresponding bond and hence by its weakening compared with the initial molecule.

The deformation vibration frequency in the ground electronic state $^2B_1$ of the $PH_2^·$ radical is 1102 cm^{-1},[20] which agrees with the values quoted by Dixon et al.[21] and Berthou et al.[22] The stretching vibration frequency of $PH_2^·$ [20,23] and the equilibrium distances, angles, and force constants of the radical and the corresponding ions, calculated[24] by the non-empirical SCF LCAO MO method, are listed in Table 1. Analysis[23] of photoelectron spectroscopic data led to the conclusion that the geometry changes insignificantly following the abstraction of an electron from the PH_2^- anion, which agrees with other results.[24] The decrease of the force constant of the P–H bond in the sequence cation > radical > anion is apparently caused by the antibonding character of the successively added electrons.

Taking into account configuration interaction, calculations have been carried out by the SCF LCAO MO method for the three ($^2\Pi$) states of the NO· radical and the 19 ($^{1,3}\Sigma$, $^{1,3}\Pi$, and $^{1,3}\Delta$) states of the NO^+ ion.[25] The calculated vibration frequencies in the ground state are 1731 cm^{-1} for the radical ($^2\Pi$) and 1515 cm^{-1} for the cation ($^1\Sigma^+$). The experimental frequencies and equilibrium distances for the NO· radical and its ions are listed in Table 1. Evidently the calculated value for the radical is too low by 10% and that for the cation is too low by 30–35%. On the basis of the experimental data (despite the fact that a fairly considerable scatter of the vibration frequencies has been observed for the cation), one can conclude that the formation of NO^+ and NO· entails the abstraction of an electron occupying an antibonding orbital; in contrast to calculated data,[25] this should be accompanied by a significant increase of the frequency. The character and magnitude of the change in frequency on reduction of the radical show that the added electron is also in an antibonding orbital but a different one, because NO^- has a triplet ground electronic state.[32]

Table 1 lists the stretching vibration frequencies of the nitrite anion NO_2^- and the corresponding radical and cation. The antisymmetric stretching vibration band of the anion[33] is a doublet due to the Fermi resonance of the ν_1 vibration with the combination $\nu_3 + \nu_C(B_1)$, where $\nu_C(B_1)$ represents the libration of the anion. We may also note that the vibration frequencies of the $NO_2^·$ radical in the gaseous state[36] and in an argon matrix[37] are virtually identical and are satisfactorily described by the calculated data.[38] The significant decrease of the symmetrical stretching vibration frequencies in the cation–radical–anion series is associated, as in the previous case, with the antibonding character of the added electrons. Consequently the reduction and oxidation of the radical are apparently accompanied by a change in geometry. Indeed, the O–N–O angles have been determined[34] on the basis of the isotope shifts with respect to oxygen and nitrogen for $NO_2^·$ and with respect to oxygen for NO_2^- (Table 1). Evidently the formation of the anion entails a change in the hybridisation of the N–O bond from sp^2 to sp^3. Whereas both the anion and the radical have a bent conformation, the cation has a linear geometry,[19] which indicates *sp* hybridisation of the N–O bond, the existence of the cumulated bond system $O{-}\overset{+}{N}{-}O$, and the localisation of the positive charge at the nitrogen atom.

Using a gas cell with multiple reflection, ensuring a beam path length of 80 m, an infrared band at 1360 cm^{-1} has been obtained[39] and interpreted as due to the antisymmetric stretching vibration of the $NO_3^·$ radical. Having measured

the Raman spectra of the substances obtained on condensation of the NO_2–N_2O_4–Ne gas mixture onto a copper support at 9 K, Griffiths et al.[30] assigned the 1042, 1324, and 714 cm^{-1} bands respectively to the ν_1, ν_3, and ν_4 vibrations of the NO_2^- anion isolated in a neon matrix. These frequencies are close to the corresponding vibration frequencies of the nitrate anion in HNO_3 [39] and $M^+NO_3^-$.[40] Comparison of the above data suggests that the antisymmetric stretching vibrations of $NO_3^{\cdot}$ and NO_3^-, like those of $NO_2^{\cdot}$ and NO_2^- (Table 1), are insensitive to changes induced by the one-electron reduction of the radicals.

The results of non-empirical calculations of the geometry and force constants of $NS^{\cdot}$ and NS^+ in the ground state by the restricted SCF method are also presented in Table 1. For the radical, they agree well with the experimental data.[42] In the case of the cation the calculated equilibrium distance differs significantly from the value of 1.25 Å found[43] from the emission spectra. It has been suggested[41] that the experimental estimate of r_e(N–S) for the cation is too low. The observed higher vibration frequency of the bond in $NS^{\cdot}$ [44] compared with the radical,[45,46] as in the case of $NO^{\cdot}$ and NO^+, indicates the removal of the electron from an antibonding orbital.

The changes in the vibration frequency and equilibrium distance on one-electron reduction of the $PO^{\cdot}$ radical[47,48] are listed in Table 1. The similarity of the vibration frequency of the $PO^{\cdot}$ radical to that of the stretch of the P–O bond in HPO (1188 cm^{-1}) indicates the localisation of the unpaired electron mainly at the phosphorus atom. The addition of an electron to the radical leads to a considerable decrease of the bond vibration frequency, caused, as in the case of $NO^{\cdot}$, by the concentration of the negative charge on the oxygen atom. The observed change in the vibrational spectrum is due to the increase of the equilibrium distance in PO^- compared with the radical.

The fluorescence and excitation spectra of the $NCO^{\cdot-}$ radical-ion isolated in an argon matrix have been obtained with the aid of a dye-based laser[48] (Table 2). The vibration frequencies ν_1 and ν_3 obtained agree well with infrared spectroscopic data,[49] while the frequency ν_2 proved to be higher by 42 cm^{-1}. The authors[48] indicated the presence of Fermi resonance between the ν_1 and $2\nu_2$ levels in the excited electronic state of $N\dot{C}O$. The reduction of the radical to the anion weakens the C–O bond (the ν_1 vibration) and strengthens the N–C bond (the ν_3 vibration) owing to the localisation of the negative charge on the oxygen atom. There are no experimental literature data for the vibrational spectra of the NCO^+ ion, while according to data calculated[53] by the SCF method for the NCO^+ linear system, the formation of the cation entails a decrease of the C–O internuclear distance and an increase of the N–C distance (Table 2). Since the cation has a triplet ground state,[53] its formation apparently involves the abstraction of an electron from the unshared electron pair of the nitrogen atom. The consequent presence of a positive charge on the nitrogen atom shifts the electron density from the bond to the nitrogen atom and lengthens the bond.

Table 2 presents the equilibrium distances and the frequencies and force constants for the $CN^{\cdot}$ radical and its ions. Analysis of the changes in the σ- and π-overlap energies[55] shows that the abstraction of an electron from the anion leads to the stabilisation of the σ-binding ($\Delta\Omega^{\sigma} = -0.40$) and to destabilisation of the π-binding ($\Delta\Omega^{\pi} = 0.57$), the influence of the latter effect being greater. According to the results of non-empirical calculations,[58] the CN^+ ion also has a triplet ground electronic state, which is indicated likewise by the character of the change in the equilibrium distance when the radical is converted into the cation. Presumably the vibration frequency of the cation is somewhat lower than that of the radical in the excited state.

The vibrational spectra of hydrogen dihalide free radicals (with $D_{\infty h}$ symmetry) and the corresponding anions have been investigated[59–65] (Table 3). In their study of the infrared spectra of the products, isolated in an argon matrix, of the interaction of Hal_2 and HHal (where Hal = Cl, Br, or I) in a discharge, Noble and co-workers[59–61] observed bands which were assigned to the ν_{sym} and ν_{asym} vibrations of the radicals $HHal_2^{\cdot}$ and $DHal_2^{\cdot}$. The presence in the spectrum of combined stretching vibration frequencies justifies the assumption that the anharmonicity of the bond vibrations is significant for the systems investigated. Indeed, the expressions for the potential energy of radicals of the type $HHal_2^{\cdot}$ include a large quartic term, which is responsible for the anharmonicity of the H–Hal bond vibrations, the contribution of the term diminishing sharply with increase of the size of the halogen atom.

Table 2. The spectroscopic characteristics and equilibrium distances of cyanate and cyanide ions and radicals.

NC^+	—	—	—	—	1.27	—	[58]

[a] Obtained from $\omega_e = 2068$ cm^{-1}, $\omega_e\chi_e = 13$ cm^{-1} and $\omega_e = 1813$ cm^{-1}, $\omega_e\chi_e = 13$ cm^{-1} for $NC^{\cdot}$ and $(NC^{\cdot})^*$ respectively.

Analysis of the infrared and Raman spectra of HCl_2^- [62] and HBr_2^- [63] indicates a linear and centrosymmetric structure of the anions. The force constants obtained from the experimental data indicate insignificant changes in the force field following the abstraction of an electron from the non-bonding molecular orbital of the ions investigated. Comparison of the force constants for the $HHal_2^{\cdot}$–$HHal_2^-$ pairs leads to the conclusion that the contribution of the anharmonic term to the expression for potential energy is greater for the radical. The dependence of the contribution of this term on the size of the halogen atom for the ions is the same as for the radicals, but it is smoother. Thus the one-electron reduction of radicals of the type $HHal_2^{\cdot}$ has little influence on the strength of the hydrogen bond, but leads to an increase of the anharmonic character of the potential function. On the grounds that the HF_2^- spectrum is characterised by the vibration frequencies $\nu_{asym} = 600\,cm^{-1}$ and $\nu_{sym} = 1450\,cm^{-1}$ [64] or $\nu_{sym} = 1377$ cm^{-1},[65] Noble and co-workers[60] therefore suggest, in contrast to the calculated data,[66] that the radical $HF_2^{\cdot}$ should be stable.

The interaction of atomic fluorine with CF_2 in an argon matrix at 14 K made it possible[67] to obtain a concentration of the $CF_3^{\cdot}$ radicals sufficient (in contrast to another study[68]) for the detection of all four vibrations. This radical has the C_{3v} symmetry; its stretching vibration frequencies are listed in Table 3. On the basis of the results of the calculation, the authors[67] concluded that there is a Fermi resonance between the $\nu_2 + \nu_4$ and ν_3 vibrations in the $^{13}CF_3^{\cdot}$ spectrum and the force field parameters obtained indicate a pyramidal form for this radical. The angle of deviation from the plane is 13°, which has been confirmed by EPR data.[69]

Among the products of the photoionisation of CF_3X (where X = Cl, Br, I, or H), stabilised cations, previously detected (from the mass spectra) only in the gas phase, have been found in solid argon (Table 3).[70] The formation of these ions is accompanied by an increase in the frequencies of both the symmetrical and asymmetrical stretching vibrations. Particular mention should be made of the high antisymmetric stretching vibration frequency of the CF_3^+ cation due to the intense $(p-p)\pi$ interaction. On this basis, it has been concluded[70] that the difficulty of the stabilisation of the cation is caused by its high reactivity and not its "physical" instability. The low frequency of the experimental ν_{asym} band for the $^{13}CF_3^+$ cation compared with the calculated value (1612 cm^{-1}) has been explained[70] by the Fermi resonance between the $\nu_1 + \nu_4$ and ν_3 vibrations.

Since only the intense antisymmetric stretching vibration band is manifested in the infrared spectrum of the radical $CCl_3^{\cdot}$ [71] (Table 4) and the symmetrical stretching vibration band is absent, it has been suggested[72] that the radical has a planar structure (D_{3h} symmetry). However, the results of a non-empirical calculation[73] and EPR data[74] indicate a pyramidal structure. Table 4 lists the force constants for both the planar and pyramidal structures. On irradiation (λ = 1216 Å) of chloroform molecules isolated in an argon matrix at 14 K, CCl_3^+ cations have been obtained at a concentration sufficient for the investigation of their infrared spectra [72] (Table 4). The decrease of the force constant on passing from the cation to the radical demonstrates, as for $CF_3^{\cdot}$, the antibonding character of the unpaired electron. It is of interest to note that in the case of the CCl_4 molecule a further decrease of the antisymmetric stretching vibration frequency (force constant) and an increase of the deformation vibration frequency take place (Table 4).

Carver and Andrews[75] carried out the simultaneous deposition of chloroform and lithium vapour onto caesium iodide windows at high dilution in argon at 15 K and obtained bands in the spectrum of the product which were assigned to $HCCl_2^{\cdot}$ vibrations (Table 4). Postulating, by analogy with radicals of the type $CHal_3^{\cdot}$, that the unpaired electron in $HCCl_2^{\cdot}$ promotes the formation of a pyramidal structure, the authors[75] assumed that the H–C–Cl and Cl–C–Cl angles are 115°. The infrared spectra of matrix-isolated ions corresponding to the $HCCl_2^{\cdot}$ radical have been investigated.[72] A planar structure (C_{2v} symmetry) in the ground electronic state has been proposed for the $HCCl_2^+$ cation, as in the case of CCl_3^+. The addition of an electron to the $HCCl_2^{\cdot}$ radical leads to the formation of the anion $HCCl_2^-$, which has a pyramidal structure with still smaller valence angles. As for the isoelectronic H_2CCl_2 molecule, the angles in the anion are therefore assumed to be tetrahedral. The valence and deformation force constants obtained from these data are listed in Table 4. Evidently the force constant of the C–Cl bond gradually diminishes as each succeeding electron is added, which corresponds to a decrease of the strength and an increase of the length of the bond (from 1.70 Å for the cation to 1.75 Å for the anion). The deformation force constant depends on the valence angle, while the interaction constant hardly changes in the cation–radical–anion series.

Table 4. Parameters of the infrared spectra and force constants of certain chloro- and bromo-methanes.

CBr_4	675	—	—	2.45	—	[76]

Notation: δ is the deformation vibration frequency and F_α the deformation vibration force constant; the remaining notation is the same as in Table 1.
*Postulated deformation vibration frequencies.

The formation of the tribromomethyl cation induces, as for CCl_3^+, an increase of the antisymmetric stretching vibration frequency (Table 4) compared with the radical. Whereas the frequency change for the trichloromethyl and tribromomethyl cations is 100–150 cm^{-1}, the corresponding value for the trifluoromethyl cation under these conditions (Table 3) is 400 cm^{-1}. The greater amount of double bond character in the $CCl_3^{\cdot}$ and $CBr_3^{\cdot}$ radicals relative to CCl_4 and CBr_4 is associated, according to the authors,[75,76] with the $(p-d)\pi$ interaction, the strength of which increases greatly for planar structures, i.e. for cations. On the other hand, following the homolytic dissociation of the C–F bond in CF_4, the asymmetric stretching vibration band (Table 3) undergoes a bathochromic shift, in contrast to $CCl_3^{\cdot}$ and $CBr_3^{\cdot}$, apparently owing to the absence of *d* orbitals.

Tevault et al.[77] investigated the infrared and Raman spectra and determined the parameters of the force field of the chlorite anion ClO_2^- and the corresponding $ClO^{\cdot}$ radical (Table 1). The calculated force constant of the Cl–O bond for the anion is much smaller than for the radical. The

results of a calculation[78] by the LCAO MO method, including the 3*d* orbitals of chlorine, predict for $ClO_2^{\cdot}$ that the π-bond order of the bond having 50% *d* character is 0.75, while that of the bond having total *d* character in ClO_2^- is 0.13. The higher π-bond order in $ClO_2^{\cdot}$ agrees with the greater bond force constant. Bearing in mind that only the *p* orbitals of the atoms are involved in the formation of molecular orbitals, one may conclude that the electron adding to the radical in the anion should occupy an antibonding molecular orbital which diminishes the $(p-p)\pi$ bond order. Both the lower valence force constant in the anion and the greater bond length agree with the antibonding character of the added electron. Tevault et al.[77] calculated the change in the O–Cl–O angle (Table 1) from the shift of the symmetrical stretching vibration frequency on isotope substitution of ^{35}Cl by ^{37}Cl, the result agreeing with the values found in other studies.[79,80]

The resonance Raman scattering (λ_{exc} = 6328 and 5145 Å) and the infrared spectra of the $ClO_3^{\cdot}$ radical formed on irradiation of $NaClO_3$ crystals by electrons having an energy of 15 MeV (T = 77 K) have been investigated[81] (Table 1). It was observed that the radical in the $NaClO_3$ lattice occupies two translationally non-equivalent positions, which leads to the splitting of the observed bands ($\Delta\nu$ = 5–7 cm^{-1}). Apart from the frequencies assigned to the vibration of the $^{35}ClO_3^{\cdot}$ radical, a band is shown in the infrared spectrum, which can be assigned to the ν_{sym} vibration of the $^{37}ClO_3^{\cdot}$ radical. However, the O–Cl–O angle obtained on this basis, which amounts to 100°, is lower than the value (112°) calculated from the EPR spectra.[82] The band at 936 cm^{-1} has been attributed to the symmetric ClO_3^- vibration, which is consistent with other data.[19] The anion under consideration has a pyramidal structure; its geometrical parameters and the valence force constants are given in Table 1. According to Wagner,[78] the ClO_3^- anion is characterised by a Cl–O bond whose π-bond order is 0.28 and which is fully of the *d* type.

In the photolysis of a Cl_2–O_2 mixture the infrared spectrum of the products showed (a multireflection gas cell with an optical length of 80 m was used) a band at 942 cm^{-1}, which was assigned[83] to the vibration of the short-lived $ClO^{\cdot}$ radical. This value is close to that (Table 1) obtained from the Raman spectra of the $ClO^{\cdot}$ radical isolated in the argon matrix. The vibrational frequency (850–1030 cm^{-1}) and force constants [$(4.8–6.9) \times 10^2$ N m^{-1}] for this radical has been calculated[78] by the method of "atoms in the molecule". The low vibrational frequency of the ClO^- anion (Table 1) indicates the localisation of the negative charge on the oxygen atom, which is confirmed by the absence of a π-component of the bond in it.[78] On the other hand, the radical has a π-bond order of 0.5 (a bond having 100% *p* character). The involvement of the *d* orbital, responsible for the electron-accepting properties, increases in the sequence[78]

$$ClO^- < ClO^{\cdot} < ClO_2^- < ClO_2^{\cdot} < ClO_3^- < ClO_4^-$$

In analysing this sequence, one can assume that the electron-accepting capacity of $ClO_3^{\cdot}$ is greater than that of ClO_3^-. However, sometimes (and the antibonding character of the outer molecular orbital of the systems of the type ClO_n considered agrees with this) the stretching vibration frequencies of the $ClO_3^{\cdot}$ radical should appear in a higher range than those of its anion. This conflicts with the results of Bates and Stidham.[81] The discrepancy with these data can be accounted for by the influence of the crystal field of $NaClO_3$, whose effect is apparently different for the radical and the anion.

The vibrational spectra of the methyl radical $CH_3^{\cdot}$ both in solid inert gas matrices and in the gaseous state have been investigated in a number of studies.[84–87] The most complete infrared spectrum has been described by Snelson[84] (Table 5). A stretching vibration frequency ν_1, not shown in the infrared spectrum, has been predicted. The force field parameters obtained for the radical agree well with the experimental data. The discrepancy between the calculated and experimental frequencies for $CD_3^{\cdot}$ is due to the influence of the anharmonicity[84] and is not a result of the interaction of the radical with the matrix. In the ground electrostatic state the methyl radical has a planar[85,86] or quasi-planar[88] structure.

The methyl anion CH_3^- has been generated in the gas phase; its photoelectron spectrum has been obtained with a well resolved vibrational structure, whereby it is possible to determine the deformation vibration (umbrella motion) frequency[88] (Table 5). It was concluded that the CH_3^- anion has a pyramidal structure, which agrees with data for anions of the type $CHal_3^-$. The methyl cation CH_3^+ has a planar structure and the equilibrium distance (Table 5) suggests that its stretching vibration frequencies should have undergone bathochromic shift compared with the radical and should appear close to the stretching vibrations of methane.

Table 5. Parameters of the infrared spectra and equilibrium distances in the molecules of methane and its derivatives.

CH_4	2916	—	3019	—	1.094	[89]

A series of studies of the structure and infrared spectra of alkyl radicals merit attention.[92–95,105,109] Pacansky and Dupuis[93] investigated the vibrations of the bonds and angles in the ethane–ethyl radical–ethylene series, which enabled them to interpret the infrared spectrum of the ethyl radical and its deuterio-analogue. The geometrical parameters calculated by the non-empirical SCF method were used in the calculation. The infrared bands of the ethyl radical $C_2H_5^{\cdot}$ can be assigned to the vibrations of the methyl and methylene groups in ethane and ethylene respectively. It has been noted that the infrared spectrum of this radical shows a number of characteristic features. Thus the low (2842 cm^{-1}) stretching vibration frequency of the β-CH bond, which shields the unpaired electron orbital, is caused[93] by the weak interaction of this bond with the radical centre (Table 6). This is the longest bond in the methyl group.[95] The appreciably lower frequency of the pyramidal deformation vibration of the CH_2 group in the ethyl radical compared with the corresponding vibrations for ethylene is induced by the absence of a π-bond in the ethyl radical and hence by the facilitation of movement of the "pyramidal" type. The broadening of the band due to this vibration is associated with the complex movement (inversion against the background of the internal rotation about the C–C bond) executed by the radical centre. The stretching vibration frequencies of the CH_2 group and the hypsochromic shift of the bands corresponding to the vibrations of the O–C bond in the radical relative to the frequency of the corresponding ethane band indicate a greater strength of all the bonds in the radical fragment; the lengths of these bonds are reduced, which has been confirmed by calculations.[95] Analogous changes have been observed in the methyl radical relative to methane

(Table 5). On the basis of results calculated by the non-empirical SCF LCAO MO method using an extended basis set of Gaussian functions, it has been shown that the formation of the $C_2H_5^+$ cation is accompanied by a further decrease of the length of the C–C bond (Table 6), which apparently entails an increase of its stretching vibration frequency. The carbon atom in the methylene group is sp^2-hybridised, that in the methyl group is sp^3-hybridised, and the HCCH angle is 90°.

Table 6. Parameters of the vibrational spectra and bond lengths of the ethyl radical, the related molecules, and the cation.

Jackels[96] calculated in terms of the harmonic approximation the vibration frequencies for the methoxy-radical $CH_3O^\cdot$ (Table 7). The values obtained agree well with the experimental data.[97–99]

It has been observed[96] that the C–O bond vibration in the ground state of $CH_3O^\cdot$ has the characteristic value, while in its deuteriated analogue there is a strong interaction of the deformation vibration of the DCO angle with the stretching vibration of the C–O bond. The stretching vibration frequencies of the C–O bond in the excited state, amounting to 678 cm^{-1} for $CH_3O^\cdot$ and 655 cm^{-1} for $CD_3O^\cdot$, have been determined from the fluorescence excitation spectra.[98] In conformity with the results of the calculations[100,101] (Table 7), the formation of the CH_3O^- anion entails an increase of the C–H bond length and the HCO angle and a decrease of the C–O bond length and the HCH angle. The decrease of the C–O bond length is somewhat unexpected, since the formation of an anion from oxygen-containing radicals, for example $NCO^\cdot$, leads to a decrease of the C–O bond vibration frequency, i.e. to an increase of the bond length compared with the radical.

In the methoxide anion the C–O bond length should apparently also increase relative to the $CH_3O^\cdot$ radical, but, since the substituents at the carbon atom are hydrogen atoms, the increase is smaller than for NCO^- and $NCO^\cdot$. Only the deformation vibration of the methyl group, whose frequency has undergone an appreciable bathochromic shift relative to the methyl radical, could be observed for CH_3O^- on the basis of photoelectron spectroscopic data.[102] A quantum-chemical analysis showed[103] that CH_3O^+ has a triplet ground state. On the other hand, according to Bouma et al.,[104] the methoxy-cation is unstable in the singlet state and undergoes the non-activated transition to the hydroxymethyl structure $HOCH_2^+$. In the triplet state the structure of CH_3O^+ is locally stable and has an energy higher by 387 kJ mol^{-1} than that of the singlet $HOCH_2^+$. Thus the formation of the CH_3O^+ cation is associated with the abstraction of an electron occupying a non-bonding orbital in the radical.

Using the second harmonic of a tunable dye laser (310–360 nm), Inoue et al.[105] obtained the excitation and fluorescence spectra of $C_2H_5O^\cdot$. The characteristics of the spectra of the ethoxy-radical are similar to those observed for $CH_3O^\cdot$. Since $C_2H_5O^\cdot$ contains the C–C–O fragment, the similarity of the force constants and the atomic weights of carbon and oxygen leads to the interaction of the C–C–C–O bond vibrations in the ground state. The vibration frequency obtained from the fluorescence spectra, amounting to 1067 cm^{-1}, is therefore associated with the stretching vibration of the C–C–O$^\cdot$ skeleton, in contrast to $CH_3O^\cdot$. According to the results of a non-empirical calculation by the same workers,[105] the 1063 cm^{-1} frequency, which virtually agrees with the experimental value (Table 7), refers to the out-of-phase skeletal stretching vibration of $C_2H_5O^\cdot$ in the ground state, while the 939 cm^{-1} frequency refers to the in-phase vibration. The fact that the frequency of the out-of-phase stretching vibration in $C_2H_5O^\cdot$ is higher than the frequency of the corresponding vibration of $CH_3O^\cdot$ in the ground state agrees with the observed difference between these frequencies for ethyl and methyl alcohols (Table 7). The stretching vibration frequency of the C–O bond in the $C_2H_5O^\cdot$ radical in the excited state is much smaller, as in the case of $CH_3O^\cdot$, than for the ground state. Pinchas[106] gives C–O$^-$ (C–C–O$^-$) bond stretching vibration frequency of the ethoxide anion $C_2H_5O^-$ a value which hardly differs from that of the corresponding vibration in the radical. This agreement may be associated with the fact that the electron which reduces the radical to the anion occupies a non-bonding orbital with the unpaired electron; the anion must then have a singlet electronic ground state.

The infrared spectrum of the isopropyl radical in an argon matrix shows[107] four groups of bands (Table 8). The out-of-plane deformation vibration frequency of the radical centre is virtually identical with the value 380 ± 18 cm^{-1} obtained from EPR data.[108] Many observed bands are doublets, which can be accounted for[107] by the existence of more than one conformation of the isopropyl radical. The manifestation of the stretching vibration of the α-CH bond of the radical in the region corresponding to the vibrations of the CH bonds of olefin molecules enabled the authors[107] to conclude that the bond length and the force constant of the radical centre are the same as in olefinic hydrocarbons. This conclusion has been confirmed by the results of a non-empirical SCF LCAO MO calculation. The low frequency of the out-of-plane deformation vibration band of the radical compared with the corresponding vibration of propene[109] shows that the p^2-hybridised carbon atom in the radical consumes less energy on the movement of the "pyramidal" type owing to the absence of the π-bond. We may note that the abstraction of an electron from iso-$C_3H_7^\cdot$ is accompanied by a decrease of the stretching vibration frequency and an

increase of the C–H bond length in the methyl groups (Table 8). The bond lengths in the methyl groups in the pairs $CH_3^{\cdot}$–CH_3^+ and $C_2H_5^{\cdot}$–$C_2H_5^+$ change similarly (Tables 5 and 6). By analogy with the variation of the C–C equilibrium distance (in the C_2H_6–$C_2H_5^{\cdot}$–$C_2H_5^+$ series) (Table 6), one may expect that the C–C bond length in the isopropyl cation is smaller than in the radical which conflicts with the data of Alah et al.[110] It may be that the cause of the 100 cm^{-1} difference between the calculated and experimental asymmetric stretching vibration frequencies of the C–C bond (Table 8) for the cation is the unduly high value of r_{CC} used in the calculation.

Table 8. The vibration frequencies and geometrical parameters of the isopropyl and t-butyl radicals and their cations.

Species	$\nu(\alpha\text{-CH})$, cm^{-1}	ν (C–H) in CH_3, cm^{-1}	r_{CH} in CH_3, Å	δ (CH_3), cm^{-1}	δ_π, cm^{-1}	ν (C–C), cm^{-1}	r_{CC}, Å	α (CCC), °	Refs.
CH_3–$\dot{C}H$–CH_3	3060	2900–2800	1.086–1.090	1500–1390	369	—	1.498	—	[107]
CH_3–$\overset{+}{C}H$–CH_3	—	2730	1.11	1499	—	1260	1.50	—	[110]
CH_3–$\dot{C}H$–CH_3	—	2870–2960	1.085	—	578	920	1.501	—	[109]
$(CH_3)_3C^{\cdot}$	—	2931; 2825	1.084; 1.091	1455; 1370	—	992; 733	1.502	118.4	[111]
$(CH_3)_3C^+$	—	2830	1.11	1455	—	1290	1.500	120	[110]

Notation: $\nu(\alpha\text{-CH})$ is the stretching vibration frequency of the C–H bond which does not shield the unpaired electron orbital in the radical and δ_π represents the out-of-plane deformation vibration.

The infrared spectrum of the t-butyl radical has been interpreted by Pacansky and Chang[111] (Table 8). As for $C_2H_5^{\cdot}$ and iso-$C_3H_7^{\cdot}$, the lengths of the C–H bond in the methyl groups of $(CH_3)_3C^{\cdot}$, which shield the unpaired electron, is greater than the C–H bond lengths in other CH_3 groups. In contrast to the radical, the central $(CH_3)_3C^+$ fragment has a planar structure. The vibrational frequencies of the cation, calculated using the geometrical parameters (Table 8), are virtually identical with the experimental data.

Thus the regularities in the variation of the stretching vibration frequencies and bond lengths for the t-butyl radical and its cation are the same as for the alkyl radicals and their cations presented above: the abstraction of an electron from the radical is accompanied by an increase of the vibration frequency of the bonds (by a decrease of bond lengths) of the fragment losing the unpaired electron and by a decrease of the stretching vibration frequencies (i.e. by an increase of the C–H bond lengths) of the methyl groups.

III. THE VIBRATIONAL SPECTRA OF POLYATOMIC FREE RADICALS AND THE CORRESPONDING IONS

The fluorescence and fluorescence excitation spectra of the cyclohexadienyl radical $C_6H_7^{\cdot}$ (at a concentration of 10^{-3} mole % relative to that of the initial molecules), obtained on irradiation of polycrystalline benzene and deuteriobenzene by fast electrons (energy 9 MeV, dose 10^7 rad) at 77 K, have been investigated[112] at 4.2 K. The source of excitation of the fluorescence was a UV-1000 nitrogen laser. Treating the radical as a benzene "molecule", the authors assigned the fluorescence lines at 5586 and 5516.5 Å to the 0–0 transition in $C_6H_7^{\cdot}$ and $C_6D_7^{\cdot}$ respectively. The shift of the absorption lines for the deuteriated specimen was 139 cm^{-1}. The vibrational frequencies of the ground and excited states of $C_6H_7^{\cdot}$ and $C_6D_7^{\cdot}$ are close to those of the corresponding benzene vibrations. On the basis of the frequency shift on deuteriation, the authors assigned the 552, 1169, and 1566 cm^{-1} bands in the spectrum of the cyclohexadienyl radical to the ν_6, ν_9, and ν_8 (C_{2g}) vibrations (Wilson's numbering).

Perkampus[113] investigated the infrared spectra of deposited films of salts having the composition ArH–HX–MX_3 (where ArH = benzene or methylbenzene and MX_3 = $AlCl_3$, $AlBr_3$, $GaCl_3$, or $GaBr_3$) at low temperatures. The nature of MX_3 does not exert a significant influence on the spectrum of the complex. The observed spectra differ appreciably from those of the aromatic hydrocarbons ArH and have been attributed to the carbonium salts $ArH_2^+MX_4^-$. The absorption bands of the anions AlX_4^- and $Al_2X_7^-$ have been detected in the infrared spectra of the complexes,[114] which serves as additional evidence for the ionic structure of the complexes: $ArH_2^+AlX_4^-$ and $ArH_2^+Al_2X_7^-$. The addition of a proton to ArH alters the symmetry of the aromatic ring (from D_{6h} for benzene to C_{2v} for the complex), as a result of which some of the bands, which are forbidden for the initial hydrocarbon, appear in the spectrum of the adduct. For example, the 1595 cm^{-1} band, observed in the spectra of substituted benzene derivatives, has been interpreted as due to the skeletal vibration of the C=C bond. On the basis of these considerations and taking into account the influence of the substitution of hydrogen by deuterium on the spectra, the vibration frequencies of the $C_6H_7^+$ ion were assigned[113] (Table 9). The new band at 640 cm^{-1}, observed in the spectrum of the benzene complex, corresponds to the 490 cm^{-1} band in the spectrum of its deuterio-analogue. The relatively large isotope shift enabled the authors to assign this band to a vibration of the C–H bond.

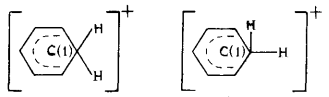

Table 9. Assignment of the bands in the infrared spectrum of $C_6H_7^+$.

Vibration (after Wilson)	Symmetry	ν, cm^{-1}		Vibration mode	ν, cm^{-1}

Notation: s. = intense (strong) absorption band, v.w. = very weak band, v.s. = very intense band, w. = weak band, and m. = moderately intense band.
Note. The numerals in square brackets denote references (Ed.of Translation).

A similar study has also been carried out for methylbenzenes.[115] The spectra were interpreted on the assumption that σ-complexes are formed in which the proton adds to one of the carbon atoms of the aromatic ring via a σ-bond

produced by two electrons from the aromatic sextet localised in a hybrid sp^3 orbital of the carbon atom. In the limiting case both hydrogen atoms at C(1) are equivalent and are disposed symmetrically relative to the plane of the ring [structure (I)]:

(I) (II)

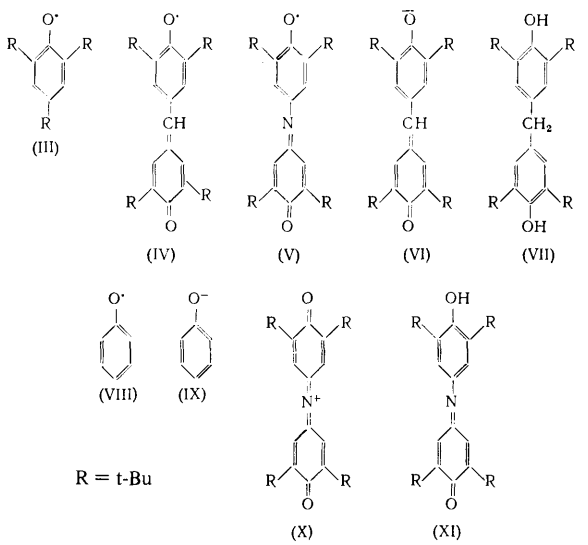
However, Bystrov[116] drew attention to the great similarity between the spectra of the σ-complex of benzene and monosubstituted benzenes; this enabled him to postulate that the π-electron system of benzene in the σ-complex is perturbed to a much lesser extent than is represented in structure (I) and that the benzene carbonium ion has the structure (II), in which the added proton is held by a σ-bond, formed by the electrons located in the *p*-orbital of the carbon atom. Such a structure can then be regarded as a "localised" π-complex differing from the usual π-complexes in which identical interactions of the proton with all the π-electrons of the aromatic sextet are assumed.

In the infrared spectra of complexes of methylbenzenes with $AlBr_3$ and HBr, an intense band has been observed[117] in the vicinity of 2800 cm^{-1}, the band being absent from the spectrum of the complex of hexamethylbenzene; it was assigned to the stretching vibrations of the CH_2 group. The absorption band corresponding to this group is broadened and displaced towards lower frequencies on passing from the anthracene complex to mesitylene, toluene, and benzene complexes, i.e. with decrease in the basicity of the hydrocarbon involved in the formation of the complex.[118] The integral intensity of the absorption bands of the quasi-aliphatic CH_2 groups of the arenium ions increases consistently with increase in their proton-donating capacity (with decrease of the basicity of the hydrocarbon). The less basic the hydrocarbon, the more marked the "acid" character of the hydrogen atoms of the quasi-aliphatic CH_2 group of the arenium ion and the greater its tendency towards involvement in the formation of hydrogen bonds. This leads to a broadening of the absorption band of the CH_2 group, to an increase in its intensity, and to its hypsochromic shift. The authors[118] regard the results as experimental confirmation of the hyperconjugation of the C–H bonds of the quasi-aliphatic CH_2 group with the positively charged carbon atoms of the pentadienyl component of the arenium ions.

This conclusion agrees with the results of a study of the Raman spectra of the mesitylene ion,[119] for which a single absorption band of moderate intensity has been observed in the range 1500–1600 cm^{-1} at 1625 cm^{-1} with a depolarisation coefficient $\rho = 0.65$. A single band of moderate intensity has also been observed in the Raman spectra of mesitylene at 1610 cm^{-1} with $\rho = 0.72$. In the spectra of unsaturated cyclic compounds containing conjugated carbon–carbon bonds of the non-aromatic type,[119] two lines are usually observed, one of which (corresponding to a symmetrical stretch) is very intense and polarised ($\rho = 0.1$–0.2). For aromatic compounds of the benzene series, the corresponding lines are depolarised ($\rho = 0.7$–0.8).[119] The position, degree of depolarisation, and relative intensity of the line of the mesitylene ion are evidence that the formation of the CH_2 group on protonation of mesitylene does not induce a complete overlap of the conjugation in the ring. This is possible only in the presence of an intense hyperconjugation of the C–H bonds in the CH_2 group with the pentadienyl component of the ion. The hypsochromic shift of certain vibration frequencies in the spectrum of the arenium cation $C_6H_7^+$ [113] (Table 9) relative to the frequencies of the analogous vibrations of the $C_6H_7^{\cdot}$ radical[112] must be attributed to an increase in the corresponding force constants.

Pellois et al.[120] investigated the quasi-line fluorescence spectrum of the triphenylmethyl radical $Ph_3C^{\cdot}$ obtained as a result of the photodissociation of triphenylmethane at 9 K in a methylcyclopentane matrix. The spectrum is due to the 0–0 transition and consists of ~50 bands in the region of 19 400 cm^{-1}. The spectrum was interpreted on the assumption that the triphenylmethyl radical should be assigned to the D_3 symmetry point group (on the basis of the data obtained with the aid of electron diffraction).

Weston et al.[121] investigated the infrared spectra and assigned the vibration frequencies of the triphenylmethyl cation $Ph_3C^+_{(1)}$ and its isotope-substituted analogues (with 1-^{13}C and Ph-d_5). It was concluded that the cation belongs to the D_3 symmetry point group, in agreement with the X-ray diffraction data, according to which the three central C–C bonds lie in a single plane. The length of each is 1.45 ± 0.018 Å, which is much less than the length of a single C–C bond (1.54 Å). The aromatic rings are slightly non-planar and are displaced from the plane of the C–C bonds by 32° in a propellar fashion. The lengths of the C–C bond within the limits of the rings [1.41, 1.36, and 1.37 Å for C(1)–C(2), C(2)–C(3), and C(3)–C(4) respectively] differ somewhat from that in benzene (1.40 Å). Comparison of the frequencies in the spectra of the triphenylmethyl radical and the triphenylmethyl cation indicates an appreciable increase of the Ph–C vibration frequency (from 1300 cm^{-1} for the radical to 1395 cm^{-1} for the cation), in agreement with the decrease of the Ph–C bond length in the case of the cation. The increase in out-of-plane deformation vibration frequencies of the C–H bonds in the ring corresponds to a decrease of the π-electronic charges on the carbon atoms. The decrease (by 15 cm^{-1}) of the stretching vibration frequency of the bonds in the ring and the increase (by 15 cm^{-1}) of the in-plane C–H deformation vibration frequencies are apparently caused by a change in the force constants of the ring bonds as a consequence of the change in their lengths.



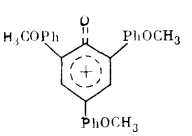
Meda et al.[122] investigated the resonance Raman spectra of the triphenylmethyl cation and anion on excitation by an argon laser. Their vibration frequencies differ very little, since the two electrons of the anions are located in a non-bonding molecular orbital. Appreciable differences are observed between the intensities and particularly between the degrees of depolarisation of the principal polarised bands. It has been suggested that the cation has the D_3 symmetry (planar propeller), while the anion has the C_3 symmetry (dome-shaped propeller).

The infrared spectrum of the allyl radical[123] consists of 16 bands; the observed frequencies agree in broad outline with the spectrum predicted for the allyl ligand (C_S symmetry) on the basis of data for π-allyl organometallic compounds.[124] However, the number and positions of the bands of the allyl radical in the range 500–1000 cm^{-1} correspond to a higher symmetry (C_{2v}) of this species, for which there are two A_2 type vibrations which are inactive in the infrared spectrum.

Saurissean et al.[125] compared the vibrational characteristics and the structures of the allyl radical $C_3H_5^{\cdot}$ and the allyl anion $C_3H_5^-$ involved in π- and anionic bonds with metals. The bands due to the skeletal stretching vibrations at 1383 and 1023 cm^{-1} in the infrared spectra of the π-allyl complexes have been interpreted as due to the asymmetric [ν_{asym}(CCC)] and symmetrical [ν_{sym}(CCC)] vibrations. The bands at 1491 and 1232 cm^{-1} have been assigned to the same vibrations on the basis of a theoretical analysis of the molecular vibrations.[124] In the case of ionic compounds, the bands at 1527 and 1022 cm^{-1} correspond to the ν_{asym}(CCC) and

ν_{sym}(CCC) vibrations. Calculations have shown that, on passing from $C_3H_5^{\cdot}$ to $C_3H_5^-$, there is a small increase of the force constants K_{C-C} and also an increase of the CCC angle from 120° to 140°. The observed decrease of the frequencies of the in-plane deformation vibrations of the CH_2 and CH groups (from 5 to 8%) reflects the change in the corresponding force constants. The intensities of the in-plane vibration bands of the CH_2 group increase on passing from the π-complexes to the ions, while the opposite behaviour has been observed for the out-of-plane deformation vibrations of the same groups. This indicates a strong anisotropic perturbation of the π orbitals in $C_3H_5^-$. The half-widths of the majority of the intense bands in the spectra of ionic compounds are much greater in the spectra of the π-complexes.[125] Thus the band half-width for the vibrations of the CH_2 group changes from 10 to 50 cm^{-1} and that for δ(CCC) changes from 15 to 75 cm^{-1}. This change is caused by the greater localisation of the electrons at the CH_2 groups in the anion as compared with the radical. The vibration frequencies of the C–H bonds in the π-complexes, which are in the range above 3000 cm^{-1}, are consistent with the aromatic character of these bonds. The ν(C–H) frequencies for the ions are observed at 2990 cm^{-1}.

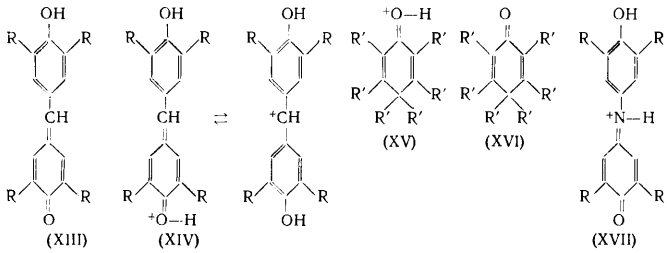
The infrared spectra of the sterically hindered phenoxy-radicals (III)–(V) have been studied systematically.[126,127] The Raman spectrum of the radical (IV) has also been investigated;[128] the frequency assignment is identical with that carried out by Samoilenko and Kotorlenko.[127]



The spontaneous Raman spectra of the phenoxy-radical $C_6H_5O^{\cdot}$ [129] have five polarised bands in the frequency range below 1700 cm^{-1}: at 1615, 1596, 1485, 1382, and 1202 cm^{-1}. The first has been assigned to the vibrations of the C–O$^{\cdot}$ bond, which agrees with other data.[126] The results of Shindo and Hiraishi[129] confirm the conclusion that there is a significant difference between the vibration frequencies of the phenoxy-radical and the corresponding phenol, which had been reached earlier[126,127] on the basis of the change in the force field parameters and not the mode of the vibrations.

The intense band at 1613 cm^{-1} in the resonance Raman spectrum of the radical (IV) has been attributed[130] to the stretching vibration on the C–O$^{\cdot}$ bond, in agreement with the earlier assignment.[127,128] The intense Raman band at 1585 cm^{-1} and the weak band at 1560 cm^{-1} were assigned[130] to the ν_{8a} and ν_{8b} vibrations respectively, while the weak bands at 1540 and 1528 cm^{-1} were assigned to the ν_{19a} and ν_{19b} vibrations.

It is impossible to agree fully with this interpretation, because, owing to the presence in the radical of two equivalent rings, each vibration is split into two. Taking into account the results of the calculation of the vibration spectrum of the radical (IV),[127] the two bands at 1585 and 1560 cm^{-1} must be attributed to the ν_{8a} vibration, which is split into A_1 and $B_1(C_2)$, while the bands at 1540 and 1528 cm^{-1} must be assigned to the ν_{19b} vibration also split into A_1 and B_1 respectively. The band at 1336 cm^{-1} should apparently be assigned to the symmetrical vibration of the bridge and that at 1292 cm^{-1} to the ν_{19a} vibration. The bands at 1226 and 1212 cm^{-1} can be interpreted as due to the ν_{18a} and ν_{18b} vibrations. This interpretation corresponds to the calculated frequencies[127] and agrees with experimental data. For the excited state, the C–O$^{\cdot}$ vibration frequency falls to 1543 cm^{-1} as a result of the interaction with the system of π-bonds. It has been concluded that the resonance Raman spectra can be recorded at concentrations of this radical less than 10^{-7} M, which makes this method promising for the investigation of radical reactions in experiments involving pulse radiolysis.



On the basis of infrared, Raman, and electronic absorption spectra, Aleksandrova and Kotorlenko[128] concluded that the rings of the anion (VI) are equivalent, as a consequence of which its symmetry (C_2) is analogous to the local symmetry of the molecule of the phenol (VII) and the radical (IV). Comparison of the vibrational spectra of the anion (VI) with those of the phenol (VII) and the radical (IV) led the authors[128] to the conclusion that the vibration frequencies of the anion have intermediate values between those of the phenol and the radical and that they are closer to the frequencies of the phenol. The hypsochromic shift of the vibration band of the C–O$^-$ bond in the phenoxide anion (VI) relative to the phenol (VII) (by 40 cm^{-1}; Table 10) is close to that obtained[131] for the unsubstituted anion (VIII) and the corresponding phenol (IX) (25 cm^{-1}). The calculated change in the force constant of the C–O$^-$ bond of the anion (VI) compared with the constant for the phenol (VII) is 0.36×10^{-6} cm^{-2}, while for the radical (IV) it amounts to 6.88×10^{-6} cm^{-2}. The slight increase of the vibration frequency of the C–O$^-$ bond and of the force constant K_{C-O} in the spectrum of the anion (VI) compared with the phenol (VII) enabled the authors to assume that the negative charge of the anion is localised predominantly on the two oxygen atoms and that this is responsible for the similarity of the spectra of the anion (VI) and the phenol (VII). The intense band at 1625 cm^{-1} was assigned to the C–O bond of the cation (X),[132] because, according to quantum-chemical calculations, it should be located between ν(C–O$^{\cdot}$) for the radical (V) (1586 cm^{-1}) and ν(C=O) for the indophenol (XI) (1642 cm^{-1}). The assignment agrees with the presence in the infrared spectrum of the cation (XII) of the ν(C...O) band at 1613 cm^{-1},[133] and is confirmed by the presence in the infrared spectrum of the cation (X) of a band at 1865 cm^{-1}, which has been interpreted[132] as being due to the asymmetric stretching vibration of the conjugated bond system C=N=C.

(XII)

The bathochromic shift of this band relative to the band of the ion NO_2^+ (2360 cm^{-1}) can be explained by the greater shift of the electron density to N^+ from the C=N bonds than from the N=O bonds. The increase of the force constant of the C=O bond in the cation (X) compared with that of the

radical (V) is 0.78×10^{-6} cm^{-2}. The formation of the cation (XIV) in the interaction of the phenol (XIII) with acids has been demonstrated.

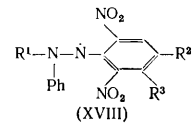
(XIII) (XIV) (XV) (XVI) (XVII)

R = t-Bu, R′ = Me

The similarity of the infrared spectrum of the latter cation to that of the anion (VI) as regards the number and positions of the bands enabled the authors[132] to conclude that these molecules belong to the same symmetry group (C_2). This means that the cation (XIV) has two equivalent rings and two OH groups, which has been confirmed by ^{1}H NMR spectra.

The absorption by the hydroxy-group is observed in the infrared spectrum of the cation (XIV) in the region of 3570 cm^{-1}. The high frequency of this band is consistent with the ^{1}H NMR data, indicating the localisation of the positive charge predominantly on the carbon atom of the bridging CH group. The intense band at 1203 cm^{-1} has been assigned to the vibration of the C–O bond. The shift of the band by 45 cm^{-1} compared with the corresponding band of the phenol (XIII) (1158 cm^{-1}) was explained by the author by the redistribution of electron density. The increase of the force constant of the C–O bond in the cation (XIV) relative to compound (XIII) owing to the increase of the amount of double bond character was 0.64×10^{-6} cm^{-2}.

The formation of the hydroxyhexamethylbenzenium cation (XV) on interaction of hexamethyldienone (XVI) with $AlCl_3$ and HCl in CH_2Cl_2 has been investigated.[134] The broad band at 3450 cm^{-1} has been assigned to the stretching vibration of the OH group involved in the hydrogen bond. The 1510 cm^{-1} band was assigned to the stretching vibration of the C–O bond and the band at 1630 cm^{-1} was assigned to the vibrations of the C–C bonds of the ring with an order of 1.5. It is noteworthy that the shift of the positive charge to the bridging carbon atom induces a rearrangement of the quinonoid ring into an aromatic form, while in the cation (XV) the quinonoid structure is largely retained.



Bands referring to the vibrations of the phenyl and quinone imine rings have been observed[132] in the infrared spectrum of the cation (XVII) obtained by the protonation of the phenol (XI) at the nitrogen atom. A bathochromic shift of the vibration band of the O–H bond at 3615 cm^{-1} relative to the spectrum of compound (XI) (3627 cm^{-1}) has been observed. The broad band at 3515 cm^{-1} was assigned to the $\overset{+}{N}$–H vibration, while the bands at 1640 and 1660 cm^{-1} were assigned respectively to the vibrations of the C=C and C=O bonds of the quinone imine ring. The bathochromic shift of the O–H and N–H bond vibrations relative to the neutral molecules led to the conclusion that the $\overset{+}{N}$–H bond is stronger than the $\overset{+}{O}$–H bond, which was confirmed by chemical experiments. Since the analysis of the vibration modes of phenol, the radical, and the quinonoid structures[126,127] indicates the predominant contribution of the same coordinate to the vibrations in question, the observed frequency shifts and the changes in the force constants permit inferences about the changes in the structures of the compounds in the series under consideration (Table 10).

It follows from the analysis of the data in Table 10 that the addition of a proton to the carbonyl group of the phenol and of an electron to the radical diminishes while the abstraction of an electron and the addition of a proton to the nitrogen atom of the bridging group increases the contribution of quinonoid structures.

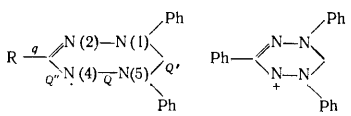
The infrared spectra of a series of free radicals of the hydrazine type (XVIII) have been investigated:[135,136]

(XVIII)



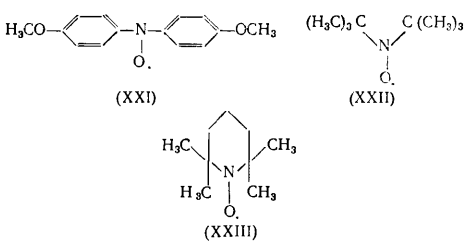
It has been noted that the intense doublet in the spectrum of the radical (XVIII) (bands at 1620 and 1600 cm^{-1}), assigned to the skeletal vibrations of the picryl and monosubstituted rings respectively, has undergone a bathochromic shift by ~20 cm^{-1} compared with the initial molecule, which is due to the increased conjugation owing to the appearance of an unpaired electron at the β-nitrogen atom. The moderately intense band in the range 1210–1250 cm^{-1} has been assigned to the stretching vibrations of the central N–N fragment. On excitation of the diphenylpicrylhydrazyl radical (DPPH) in benzene by means of a pulsed tunable dye laser (λ = 4880 Å), Wilbrandt et al.[137] observed an increase of the intensity of this band in the resonance Raman spectrum.

The spontaneous Raman spectra of the DPPH radical and of the initial diphenylpicrylhydrazine were obtained in a later study.[138] It was noted that, on passing to the radical, the analogous bands undergo a bathochromic shift, because the unpaired electron occupies as a rule antibonding molecular orbitals. New bands at 1205 and 1292 cm^{-1}, having moderate and low intensities respectively, have been observed in the spectrum of the DPPH radical. The authors[138] suggest that the bands at 1280 and 1290 cm^{-1} in the spectra of the molecule and the radical can be analogues, but noted that the increase of the frequency of this vibration on passing from the hydrazine molecule to the radical is then obscure and requires interpretation. The authors[138] proposed such an interpretation of the bands on the grounds that the vibrations of the  group in both species are quasi-characteristic. In the hydrazine molecules this

chain should be bent and a single intense fully symmetrical vibration should appear accordingly in the spontaneous Raman spectrum. In solutions of the DPPH radical the above chain straightens out, which is accompanied by a change in the hybridisation of the bonding orbitals of the N atom from sp^2 to sp. This leads to additional and significant asymmetry owing to the delocalisation of the unpaired electron. In conformity with selection rules, two fully symmetrical stretching vibrations now become active in the spontaneous Raman spectrum, to which the authors[138] assigned new bands at 1205 and 1292 cm^{-1}. Both these vibrations should be intense also in the infrared spectrum, which has indeed been observed.[136] The observed change in the geometry of the species rules out the possibility of comparing the N–N bond vibrations in the diphenylpicrylhydrazine–DPPH radical pair in solutions. According to the above data,[138] when the DPPH radical passes to a crystalline state, the hybridisation of the orbitals of the nitrogen atom again changes from *sp* (for the solution) to sp^2 and coincides with that for the initial molecule.

Mielke and Ratajczak[139] carried out a calculation for the normal vibrations of the molecule of hydrazine and its protonated derivatives $N_2H_5^+$ and $N_2H_6^{2+}$ in terms of a modified valence force field approximation. It was found that the diagonal force coefficients, ν(N–N), and δ(HNH) decrease monotonically on passing from N_2H_4 to $N_2H_6^{2+}$. The observed distribution of the potential energy indicates the absence of a significant change in the vibration modes for $N_2H_6^{2+}$. This finding suggests that the decrease of the force constant for the N–N bond on passing from hydrazine to protonated hydrazine is due to the decrease of the degree of delocalisation of the unshared electron pair from the nitrogen atoms to the N–N bond.

Studies of the infrared spectra of stable verdazyl radicals (XIX) have been considered in reviews:[1,140]



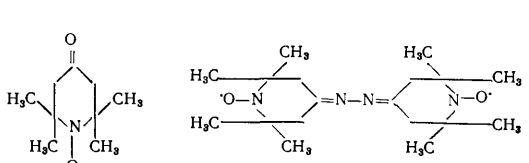
(XIX) (XX)

R = Ph (TPV), H

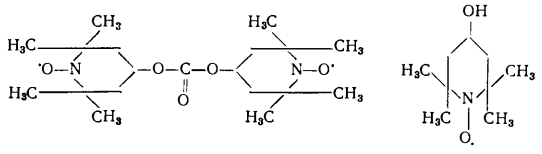
However, the assignment of the frequencies to the vibrations of individual bonds was not rigorous, since the similarity of the atomic weights of nitrogen and carbon entails an intense interaction and the normal vibrations of the heterocycle must have complex modes. For a reliable interpretation of the spectrum of the triphenylverdazyl radical (TPV) (XIX), a calculation has been made[141] of the frequencies and modes of the vibrations for two conformations—chair and boat. The correctness of the force field parameters obtained has been confirmed by the satisfactory agreement between the calculated and experimental changes in the vibration frequencies of the heterocycle with the ^{15}N atoms in the 2- and 4-positions. The calculation showed that the vibrations of the heterocycle of the TPV radical are described by complex modes. The interpretation of the complex band at 1330 cm^{-1} was revised and it was shown that it consists of two bands, the more intense of which (at 1330 cm^{-1}) is caused mainly by the deformation of the angles β(NCH), while the band at 1315 cm^{-1} is due to the vibrations of the N–Ph bonds. In addition the bands at 1400 cm^{-1} [Q''(CN), Q'(C–N)] and at 1380 cm^{-1} [q(C–C), Q(N–N), Q''(CN)] were assigned to the vibrations of the heterocycle.

The change in the infrared spectra on one-electron oxidation of the TPV radical to the corresponding cation (XX) has been investigated.[141,143] In order to obtain a quantitative characteristic of the change in the electronic structure following the abstraction of an electron from the TPV radical, the vibrational spectrum of the cation (XX) having the boat conformation was carried out. The geometrical structure of this cation was found quantum-chemically by minimising the total energy of the corresponding system with respect to the nuclear coordinates; it was shown that it differs insignificantly from the geometrical structure of the TPV radical. The experimental[141] band shift on passing from the TPV radical to the cation (XX) made it possible to find the changes in the bond force constants and the interaction constants. The increase of the force constant K_Q corresponds to a shift of electron density from the nitrogen atoms in the 1- and 5-positions to the N–N bonds, which agrees with the abstraction of an electron from the nitrogen atoms in the 2- and 4-positions on oxidation of the TPV radical to the cation (XX), which has been established on the basis of quantum-chemical calculations and X-ray electronic spectra.[144] The decrease of the force constants K_Q and K_q indicates an increase of the positive charge on the N(1) and N(5) atoms, while the decrease of the interaction constants $H_{QQ''}$, $H_{Q''Q''}$, and H_{Qq} agrees with the decrease of the degree of delocalisation of the unshared electron pair from the N(1) and N(5) atoms to the benzene rings, as a consequence of which the frequency of the out-of-plane deformation vibrations of the hydrogen atoms in the benzene rings increases and the intensity of their stretching vibrations diminishes.

The band at 1345 cm^{-1} in the spectrum of the dimethoxydiphenylnitroxy-radical (XXI) has been assigned to the vibration of the N–O· bond.[135] Comparison of the infrared spectra of the di-t-butylnitroxy-radical (XXII) [145] and the 2,2',6,6'-tetramethylpiperidin-1-yloxy-radical (XXIII) [146] with the infrared spectra of the corresponding amines established that the N–O· band is also at 1345 cm^{-1}.

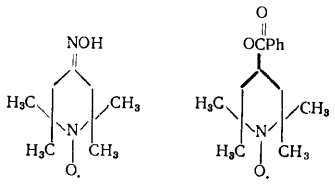


(XXI) (XXII)

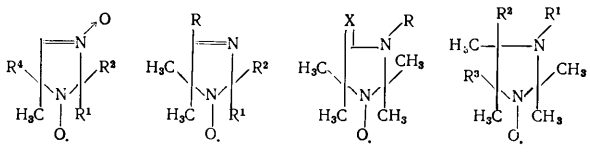


(XXIII)

The similarity of the atomic weights of carbon, nitrogen, and oxygen raises the question of the extent to which the vibrations of the N–O· bond are characteristic. A study has been made[147] of the infrared spectra of the radicals (XXII) and (XXIII) and also the frequencies and modes of their normal vibrations were calculated, which served as a basis for the interpretation of their vibration spectra, a model was proposed for the force field, and it was shown that the vibrations of the N–O· bond are characteristic as regards frequency, mode, and intensity.

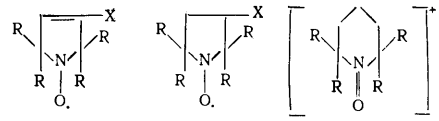


It has been shown with the aid of the ^{15}N label[148] that the N–O· band in the infrared spectra of other radicals of the piperidine series is at 1380 cm^{-1} [the radicals (XXIV) and (XXV), 1367 cm^{-1} [the radical (XXVI)], and 1371 and 1342 cm^{-1} [the radical (XXVII)].

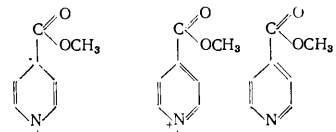


(XXIV) (XXV)

(XXVI) (XXVII)



(XXVIII) (XXIX)



(XXX) (XXXI) (XXXII) (XXXIII)

Intense bands, assigned to the vibration of the N–O bond, have been observed in the Raman spectra of the radicals (XXIV) and (XXVII) [149]—at 1370 cm^{-1} for (XXIV), at 1370 and 1359 cm^{-1} for (XXVII), and at 1362 and 1352 cm^{-1} for the radicals (XXVIII) and (XXIX) respectively. The higher N–O$^{\cdot}$ bond vibration frequency for the radical (XXIV) compared with (XXIII) can be accounted for by a difference in its steric structure. While the radical (XXIII) has the chair conformation,[150] the radical (XXIV) has the twisted boat conformation with an angle of twist at 28°.[151] The increased order of the exocyclic bond in the 4-position promotes the delocalisation of electrons in the ring,[152] which is accompanied by an increased amount of double bond character of the N–O$^{\cdot}$ bond and an increase in the corresponding frequency. The presence of two bands in the spectrum of the radical (XXVII) is apparently caused by both intramolecular and intermolecular hydrogen bonds. In dilute solutions this radical has the boat conformation with an intramolecular hydrogen bond,[151] whereas in the crystalline state the molecules are linked by hydrogen bonds into infinite chains and have a distorted chair conformation.[151] The similarity of the N–O$^{\cdot}$ bond vibration frequencies in the spectra of the radicals (XIX) and (XXIII) agrees with the conclusion of Kotorlenko et al.[147] that there is no shift of the N–O$^{\cdot}$ bond vibration frequency when the hydrogen is replaced by carbon at the C(3) atom of the radical (XXIII) and also that the vibration mode remains unaltered.

The N–O$^{\cdot}$ bond vibration frequencies for radicals of the imidazoline [the radicals (XXX) and (XXXI)] and imidazolidine [the radicals (XXXII) and (XXXIII)] series have been interpreted on the basis of their Raman spectra and also by measuring the isotope shift after the introduction of ^{15}N in the 1-position in the imidazoline ring. It has been established that the vibration band of the N–O$^{\cdot}$ bond in the infrared and Raman spectra of these radicals is at 1438 ± 5 cm^{-1} and the observed isotope shift (27 cm^{-1}) agrees with the calculated value (28 cm^{-1}). Calculation of the frequencies and modes of the normal vibrations of these radicals[149] showed that the vibration of the nitroxy-group is characteristic in terms of the frequency. The N–O$^{\cdot}$ bond vibration bands of five-membered nitroxy-radicals of the pyrroline [the radical (XXXIV)] and pyrrolidine [the radical (XXXV)] series are located in the same part of the spectrum. It has been concluded[149] that the position of the N–O$^{\cdot}$ band in the spectra of cyclic nitroxy-radicals depends on the ring size.

(XXXIV) (XXXV) (XXXVI)

(XXXVII) R=CH_3 (XXXVIII) (XXXIX)

The vibrational spectra of nitroxy-radicals and biradicals in the region of the stretching vibrations of unsaturated carbon–carbon bonds and the stretching vibrations of the CH and OH groups have been investigated by Bovina et al.[153]

The conversion of the nitroxy-radical (XXIII) into the corresponding cation (XXXVI) is accompanied by a change in the N–O$^{\cdot}$ bond vibration frequency from 1345 cm^{-1} for the radical to 1630 cm^{-1} for the cation, which is caused by the decrease of the length of this bond from 1.30 Å [154] to 1.19 Å [152] respectively and in addition by the change from the chair conformation (XXIII) [150] to the twisted boat conformation (XXXVI) with an angle of twist of 24°30′.[152] The decreased length and the strengthening of the N–O$^{\cdot}$ bond following the one-electron oxidation of the radical (XXIII) has been explained[152] by the fact that the unpaired electron in nitroxy-radicals is located in an antibonding orbital and that the conversion of these radicals into cations entails the loss of this electron. In our view, the oxidation of the radical (XXIII) to the cation (XXXVI) is accompanied by the abstraction of an electron from the unshared electron pair of the nitrogen atom with subsequent pairing of the two unpaired electrons located in the O and N atoms.

Kosover and Poziomek[155] quote the C=O bond vibration frequencies for 1-ethyl-4-methoxycarbonylpyridinium iodide (XXXVIII) (1730 cm^{-1}), 1-ethyl-4-methoxycarbonylpyridinyl (1642 cm^{-1}) (XXXVII), and methyl isonicotinate (XXXIX) (1736 cm^{-1}), which increase the decreased degree of displacement of the electron density to the ring. On the other hand, the ring stretching vibration frequencies diminish on passing from the pyridinyl radical (XXXVII) [156] to protonated pyridine[157] and further to pyridine (XXXIX).[109]

Thus the abstraction of an electron from neutral polyatomic free radicals is accompanied, as in the case of the simple radicals, by an increase of the vibration frequency and strength of the bond adjoining the atom from which the electron is abstracted, while the addition of an electron entails a decrease in the vibration frequency and order of the bond.

Comparative analysis of the vibrational spectra of neutral free radicals and the corresponding ions—the products of the one-electron reduction or oxidation of these radicals—makes it possible to infer the changes in both the geometrical and electronic structures of the species and to predict the sites of increased reactivity.

The Hydrogen Bond and CH Acidity

V.K.Pogorelyi and T.B.Vishnyakova

A systematic account is given of quantitative data on the properties of the hydrogen bonds formed by CH acids as proton donors and the influence of the nature of the substituents and of the steric and electronic structures of CH acids on the strength of these bonds is discussed. The studies in recent years devoted to the equilibrium and kinetic CH acidity are examined and the factors responsible for what is in many instances an "anomalous" behaviour of CH acids are analysed. The proton-donating capacity in hydrogen bonds and CH acidity are compared.
The bibliography includes 108 references.

I. INTRODUCTION

Protolytic reactions occupy one of the central positions in the chemistry of organic compounds. CH acids, grouped in a special class of compounds, have been arousing constant interest owing to the specific features of the factors determining their reactivity.[1,2] Hydrogen bonds involving CH acids[3] play an important role in protolytic reactions, since their properties influence the kinetics and mechanism of reactions involving proton transfer. The quantitative results of studies in this field are so far not numerous, but it is already clear that even relatively weak C–H...B hydrogen bonds can alter not only the energy profile of the process but also its probability characteristics, because the reactants involved in hydrogen-bonded complexes are close to one another and are oriented relative to the proton transfer reaction coordinate.

The question of the relation between the proton-donating capacity in C–H...B hydrogen bonds and thermodynamic and kinetic CH acidity arises naturally. For OH, SH, and NH acids, these relations have been studied on numerous examples.[4,5] On the other hand, in the case of CH acids, such comparisons have seldom been made. This review deals with the quantitative results of studies of hydrogen bonds and the acidity of CH groups polarised by electron-accepting substituents. The characteristics of the influence of the steric and electronic structures of CH acids on the strength of C–H...B hydrogen bonds are analysed. In conclusion, the proton-donating capacity of CH acids is compared with their kinetic and equilibrium acidities.

II. ASSOCIATION OF HALOGEN-SUBSTITUTED HYDROCARBONS

The CH groups polarised by electronegative halogen atoms form C–H...B hydrogen bonds with various bases. One of the first compounds for which such bonds had been observed spectroscopically was chloroform.[6] After the addition of bases, B, to chloroform, an increase of the width and intensity of the stretching vibration band is observed in its infrared spectrum, while for strong bases this band undergoes a bathochromic shift.[3] For example, in mixtures with triethylamine (TEA) the magnitude of this shift $\Delta\nu$(CH) reaches 80 cm^{-1}.[6]

Table 1. Thermodynamic characteristics of the association of $CHCl_3$ with various electron donors in cyclohexane and carbon tetrachloride.[7,13,19]

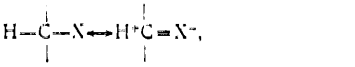
Electron donor	$-\Delta H$, kcal $mole^{-1}$	$-\Delta S$, e.u.	Electron donor	$-\Delta H$, kcal $mole^{-1}$	$-\Delta S$, e.u.
$C_2H_5NO_2$	1.5	7.1	N-Methylpyrrolidinone	4.0	10.9
$(CH_3)_2CO$	2.3	8.4	Benzene	3.2	9.0
$(C_2H_5)_5CO$	2.4	8.1	*p*-Xylene	2.5	6.7
$(C_4H_9)_2O$	2.3	5.3	Mesitylene	2.6	6.8
1,4-Dioxan	2.5	9.6	*p*-Diethylbenzene	2.7	7.8
$CH_3COOC_2H_5$	2.5	9.0	1,3,5-Triethylbenzene	2.5	7.9
$(C_2H_5O)_3PO$	3.8	9.6	*p*-Di-isopropylbenzene	3.3	10.3
$(CH_3S)_2$	0.9	6.6	1,3,5-Tri-isopropyl-benzene	2.9	9.8
$(CH_2)_4S$	2.3	10.2	18-Crown-6 ether	1.6	5.5
$(C_2H_5)_2S$	1.7	8.6	15-Crown-5 ether	4.0	7.5
$(C_2H_5)_3N$	4.1	15.2	12-Crown-4 ether	4.5	8.0

It has been established by NMR [7,8] that chloroform molecules are self-associated via C–H...Cl bonds. The self-association equilibrium constant K is low, amounting to 0.2 (mole fraction)$^{-1}$ at 25 °C, while the bond strength is $-\Delta H \cong 1$ kcal mol^{-1}. Chloroform dissolved in cyclohexane forms 1:1 complexes with the excess electron donor[7], because under these conditions the degree of its self-association is negligible. The thermodynamic characteristics of the hydrogen bonds

between chloroform and various electron donors are compared in Table 1. It is seen that the energies of the hydrogen bonds are low (2–4 kcal mol^{-1}) and that the strongest bonds are formed by amines.

The low degree of self-association of chloroform together with its tendency towards the preferential formation of 1 : 1 complexes makes it a suitable model proton donor for the study of the electron-donating properties of bases by the hydrogen bond method. The most complete data on these lines have been obtained by NMR for tertiary amines and ethers.[9] It has been shown that steric hindrance in the formation of hydrogen bonds is determined not only by the length and degree of branching of the hydrocarbon chain but also by the steric disposition of the substituents relative to the free electron pair of the heteroatom of the base. The methyl group in the β-position of the substituent hinders the approach of the proton to the electron pair. The possibility of the maximum overlap of the frontier orbitals of the proton and electron donors is then ruled out, which lengthens and weakens the hydrogen bond. For tertiary hydrogen bonds, the steric factor is most important. This is why in the series of amines there is no rigorous correlation between ΔH and Δ_C (the chemical shift due to complex formation) or $\Sigma\sigma^*$.[9]

The formation of hydrogen bonds between chloroform and phosphoryl compounds and ketones is hardly influenced by the bulk of the substituents. For this reason, a correlation is observed between ΔH and the values of $\Sigma\sigma^*$, Δ_C, or $\Delta\nu$(CH) for phosphine oxides.[10–12] Consequently the free electron pair of the donor atom, at an appreciable distance from the substituents, does not experience a steric influence by the latter.



A number of studies[13–18] have been devoted to the hydrogen bonds between chloroform and π-electron donors. In the case of alkylbenzenes it was found[13] that the intermolecular interaction parameters depend in a complex manner on the electronic and steric effects of the substituents (Table 1). Contrary to expectation, the strength of the C–H...π hydrogen bonds diminishes in many instances with increase of the number of electron-donating substituents in the aromatic ring. Steric factors influence mainly the equilibrium constants. For bases whose molecules include proton-accepting centres of the π or *n* type, studies of the relative contribution of the C–H...π and C–H...*n* hydrogen bonds to the overall complex formation process are the most important.[14–18]

The proton-accepting capacity of crown-ethers has been investigated by ^{1}H NMR as a function of the number of oxygen atoms in the macroring in relation to association with chloroform.[19] The thermodynamic characteristics of the association with chloroform have been compared with data for thio- and seleno-phenols. In terms of decreasing strength of hydrogen bonds with 18-crown-6 ether, the above proton donors can be arranged in sequence Se–H ≳ S–H > C–H. An analogous sequence based on the variation of the proton-donating capacity has been observed for hydrogen bonds with electron donors of other types.[4]

For chloroform, the strength of the bond diminishes with increase of the diameter of the macroring (Table 1). In ethers with a large cavity diameter (d = 2.6 Å) the hydrogen atom involved in the bond is probably located mainly at one of the oxygen atoms. With decrease of d, the proton-accepting capacity of crown ethers increases, since the bridging hydrogen atom occupies a central or nearly central position in the cavity on formation of the complex. The possibility of an effective collective interaction of the proton charge with the dipoles of the C–O group is then ensured, which then entails the growth of the Coulombic contribution to the overall binding energy.

The proton-donating capacity of haloforms diminishes when chlorine is replaced by other halogens. The strength of the hydrogen bonds with tetrahydrofuran (THF), determined by NMR, diminishes in the sequence $Cl_3CH > Br_3CH > F_3CH > I_3CH$ ($-\Delta H$ = 3.6, 2.6, 2.4, and 1.6 kcal mol^{-1} respectively.[20] Fluoroform has a lower proton-donating capacity than chloroform and even bromoform. On the other hand, the influence of chlorine, bromine, and iodine atoms on the C–H...O hydrogen bonds corresponds to the relative electrical conductivities [sic]. The above data agree with the results of calculations by the CNDO/2 method.[21] We may recall that the strength of the hydrogen bonds between hydrogen halides and various electron donors diminishes in conformity with the variation of electronegativity on passing from F to I.[22]

There is no unaminous view in the literature about the causes of the "anomalous" influence of fluorine atoms on the proton-donating capacity of substituted methanes. It has been suggested that the deviations are caused by the greater polarisability of C–Cl bonds compared with C–F.[23] However, the main contribution to the energy of weak hydrogen bonds comes from the polarisation component and not from the Coulombic component.[24] Furthermore, the polarisability of the H–F bond is also lower than that of the H–Cl bond but hydrogen fluoride is a stronger proton donor. We believe that the explanation put forward by Creswell and Allred[20] is acceptable. According to these workers, the decrease of ΔH on passing from chloroform to fluoroform is due to the fact that, owing to the absence of *d* orbitals in fluorine atoms, resonance of the type

as a result of which the positive charge on the hydrogen atom and the polarity of the C–H bond increase, is impossible. Furthermore, the decrease of the positive charge on the hydrogen atom in fluoroform and of the proton-donating capacity of the latter, can be induced by the +*M* effect of the free electron pairs of the halogen, which is a maximum in the case of fluorine.[25] The last two factors should play a decisive role in the variation of the strength of the C–H...B bonds whose energy is determined mainly by the electrostatic interaction. The above treatment is consistent with the results of calculations by the CNDO/2 method, according to which the charge on the hydrogen atom in the chloroform molecule is much greater than in the fluoroform molecule.[25,26]

Compared with the chlorine atom, the CF_3 substituent generates a much greater positive charge on the hydrogen atom of the C–H group.[27,28] CH acids with the trifluoromethyl substituent therefore exhibit a greater proton-donating capacity. For example, the enthalpy of formation of the hydrogen bond with methylpyrrolidinone (in kcal mol^{-1}) is 4.0 for chloroform[7] and 4.7 for $CF_3CHClBr$;[30] in the case of dimethyl sulphoxide (DMSO) the corresponding values are 1.6 for chloroform[31] and 5.6 for $(CF_3)_3CH$.[29]

III. HYDROGEN BONDS INVOLVING CH GROUPS POLARISED BY ELECTRON-ACCEPTING SUBSTITUENTS

Hydrogen bonds involving CH groups polarised by powerful electron-accepting substituents such as CN, NO_2, CO_2R, SO_2R, etc. are very common. In the first place we may note that the above substituents include atoms with proton-accepting capacity. The corresponding CH acids can therefore be self-associated. However, according to NMR data the stability of the self-associated species of monosubstituted methanes is low and amounts to 0.6–1.8 kcal mol^{-1}.[30,31]

Judging from the inductive σ constants, substituents such as the cyano-, nitro-, and sulpho-groups should increase the proton-donating capacity to a greater extent than the halogens. Indeed, the introduction of the CN group into mono- and dihalogenomethanes leads to a greater shift of the stretching vibration frequency of the C–H bond than the introduction of a second or third halogen atom.[3] The enthalpies of formation of the hydrogen bonds of CH_2Cl_2, $CHCl_3$, and $CHCl_2CN$ with dioxan are 1.3, 2.4, and 3.5 kcal mol^{-1} respectively.[3] Nitromethane and chloroform form with acetone hydrogen bonds of similar strength (2.1 and 2.3 kcal mol^{-1}),[7,32] while the strength of the hydrogen bond involving 1,1-dinitroethane varies in the range 3–7 kcal mol^{-1} depending on the strength of the electron donor.[33]

However, the available data make it possible to follow only the qualitative aspect of the influence of the nature of substituents on the properties of the C–H...B hydrogen bonds. Rigorous quantitative correlation between the association parameters and the electron-accepting properties of substituents are as a rule absent. For example, according to Slasinski et al.,[34] it is possible to set up the following series based on the influence of the substituents on the association constant of methane derivatives with hexamethyl phosphoramide (HMPA): $CN \approx NO_2 > SCN > O_2NC_6H_4 > F$, Cl, Br $> CON(CH_3)_2 > CO_2R > C_6H_5$. Overall, it resembles the sequence in the variation of the σ_I, but the correlation between $\lg K$ and σ_I is very rough. There exist several possible causes of its breakdown. The proton-donating capacity of CH groups depends significantly on steric conditions, since the electron-accepting groups are in the immediate vicinity of the reaction centre. The negative charge concentrated on them hinders the approach of the base molecule to the proton of the CH group. Furthermore, with increase of the number of substituents, there is a possibility that the saturation effect, which is a progressive decrease of the substituent influence on the polarity of the C–H bond, may be manifested.[35]

quantum-chemical calculations,[25] the CF_3 substituent increases the charge on the hydrogen atom of the CH group to a greater extent than the NO_2 substituent.

Thus it is fairly difficult to predict the proton-donating capacity of the CH group polarised by electron-accepting substituents. The use of inductive constants does not yield the desired result. In individual systems it is possible to explain reasonably the experimental behaviour by resorting to data for the charges on the reaction centre.

The dependence of the characteristics of the hydrogen bonds of di- and tri-substituted methanes with electron donors of different nature on the CH acidity has been analysed.[36,37] For the hydrogen bonds of R_2CH_2 with pyridine, a parallel variation with the proton-donating capacity and acidity is observed in the main; however, in the case of DMSO the values of ΔH are almost independent of the pK_a. Malononitrile forms the weakest bond with DMSO, while in relation to pyridine its proton-donating capacity is consistent with the acidity. The reason for the above anomaly is that, apart from the hydrogen bonds, $(NC)_2CH_2$ forms dipole–dipole associated species with DMSO (according to infrared spectroscopic data[37]) by interaction between the localised dipoles of the CN and SO groups. According to the results of calculations in terms of the CNDO/2 approximation, the electron-accepting properties of the CN substituent and the proton-donating capacity of the CH group are sharply diminished in associated species of the dipole–dipole type.[38]

On passing to trisubstituted methanes (Table 3), the increase of acidity is accompanied by the enhancement of the proton-donating capacity. However, in the series of acids $HC(Y)(SO_2CH_3)SO_2C_6H_4X$ there is no single dependence of ΔH on pK_a.

Table 2. Thermodynamic characteristics of the hydrogen bonds between trisubstituted methanes and DMSO in carbon tetrachloride.[29]

R_3CH	σ_I^*	$-\Delta H$, kcal $mole^{-1}$	Δ_C, p.p.m.
{$(CF_3)_3$}CH	0.42	5.6	2.60
$(CF_3)_2$CH{NO_2}	0.63	4.8	2.34
$(CF_3)_2$CH{CN_2}	0.58	4.7	2.23
$(CF_3)_2$CH{$COOCH_3$}	0.32	3.3	1.47
{CH_3}{$CH(NO_2)_2$}	0	2.2	0.72

*The values of σ_I are quoted for the groups shown in braces.

Table 3. Thermodynamic characteristics of the hydrogen bonds between trisubstituted methanes $HC(COY)(SO_2CH_3)$. $(SO_2C_6H_4X)$ and DMSO and acetone (at 40 °C).[37]

X	Y	pK_a (CH_3OH)	Acetone			DMSO		
			$-\Delta H$, kcal $mole^{-1}$	$-\Delta S$, e.u.	K, (mole fraction)$^{-1}$	$-\Delta H$, kcal $mole^{-1}$	$-\Delta S$, e.u.	K, (mole fraction)$^{-1}$
Cl	C_6H_5	4.77	2.5	5.0	4.6	3.3	5.5	13.6
H	C_6H_5	5.32	2.3	4.3	4.2	3.4	6.1	12.0
CH_3	C_6H_5	5.81	2.4	5.1	4.0	3.0	5.1	10.5
Cl	OC_2H_5	5.24	2.7	5.1	6.2	2.6	4.1	8.0
H	OC_2H_5	6.06	2.3	5.6	4.5	2.6	4.5	7.0
CH_3	OC_2H_5	6.36	2.5	5.3	4.7	2.6	4.6	7.0

In our view, the magnitude of the charge on the hydrogen atom of the CH group, determined by quantum-chemical calculations, should characterise the proton-donating capacity of CH acids more fully than the inductive constants of the substituents. Analysis of the results presented in Table 2 provides a definite confirmation of the above hypothesis. Evidently, the replacement of CF_3 by NO_2 weakens the hydrogen bond despite the fact that the nitro-group has a greater electron-accepting inductive effect than the trifluoromethyl group. The reason for this is that, in conformity with

The change in the nature of the substituent Y adjoining the reaction centre alters the proton-donating capacity in parallel with the equilibrium acidity. On the other hand, the effects of the substituent X remote from the reaction centre on the proton-donating capacity and on thermodynamic acidity are not correlated. The absence of a general correlation between the proton-donating capacity of R_3CH in hydrogen bonds and acidity reflects the fact that the effects of the substituents in the molecule and in the carbanion are transmitted to the reaction centre via mechanisms of different types. In the

acid, the properties of the C–H bond are mainly determined by inductive effects, while in the carbanion there is a possibility of a mesomeric interaction.

IV. THE PROTON-DONATING CAPACITY OF UNSATURATED HYDROCARBONS

The proton-donating capacity of CH groups depends not only on the number and properties of electron-accepting substituents but also on the character of the hybridisation of the valence orbitals of the carbon atom.[3] With increase of the amount of *s* character, the proton-donating capacity also increases in view of the increase of the electronegativity of carbon and the polarity of the C–H bond. An increase of the positive charge on the hydrogen atom is observed in the series of groups

$$\mathrm{H{-}\overset{|}{\underset{|}{C}}{-}} < \mathrm{H{-}\overset{|}{\underset{|}{C}}{=}} < \mathrm{H{-}C{\equiv}}$$ (Ref.26).

The introduction of electron-accepting substituents naturally increases the proton-donating capacity of unsaturated compounds. Thus the substituents R can be arranged in the following sequence in terms of their influence on the constant for the association of $R_2C{=}CHR$ with HMPA:[34] CN ≈ NO_2 > Cl > Br > C_6H_5. An analogous sequence of substituent effects was presented above for methane derivatives.

It has been shown by NMR [30] that trichloroethylene is self-associated via hydrogen bonds of the type C–H...Cl. The stability of the species produced by its association with various electron donors varies from 1.4 kcal mol^{-1} for acetone to 4.5 kcal mol^{-1} for triethylamine (TEA).[32] The CH groups of substituted benzenes with electron-accepting substituents also exhibit proton-donating properties.[34,39,40] In the aldehydes the capacity of the hydrogen atom of the CHO group to form hydrogen bonds with DMSO, phosphine oxides, and pyridine has been observed for trichloroacetaldehyde ($-\Delta H$ = 2.4–5.2 kcal mol^{-1}).[41,42]

Acetylenic compounds form hydrogen bonds involving the π electrons of the triple bond. The enthalpy of self-association is 1.5–2.0 kcal mol^{-1}. The hydrogen bonds of monoalkylacetylenes with various electron donors are characterised by the enthalpies $-\Delta H$ = 1–3 kcal mol^{-1}.[43,44] The influence of electron-accepting substituents on the proton-donating capacity of $RC{\equiv}CH$, estimated from the increase of the chemical shift on association with acetone, increases in the following sequence of substituents R: COOH < CHO < $COCH_3$ < $COOC_2H_5$ < CN,[45] while the corresponding sequence for association with pyridine is $HO(CH_2)_2$ < $CH_3OC(CH_3)_2$ < $HOC(CH_3)_2$ < C_6H_5 < $C_6H_5OCH_2$;[46] estimation of this influence from the variation of the *K* in mixtures with HMPA led to the sequence C_6H_5 (0.15) < $BrCH_2$ (0.53) < $COOC_2H_5$ (1.66) < CN (12.1).[34] The association of phenylacetylene with ethers and thioethers has been investigated by NMR and infrared spectroscopy.[47] The values of *K* obtained by different methods agree satisfactorily. A correlation is observed between lg*K* and the Δν(CH).

In concluding the discussion of the properties of the C–H...B hydrogen bonds, we may note studies[23,48–49] in which the nature of the hydrogen bonds involving CH acids was investigated by quantum-chemical methods. Analysis of the redistribution of electron density (charge shift and transfer) on formation of the C–H...B hydrogen bonds showed that the bonds do not differ from O–H...B or N–H...B. The maximum contribution to the energy of the C–H...B bonds comes, as for O–H...B bonds, from the electrostatic interaction, while the polarisation contribution and the contribution due to charge transfer play a secondary role.

V. CH ACIDITY (GENERAL POSTULATES)

The reactivity of CH acids is characterised by the kinetic (*k*) and equilibrium or thermodynamic (pK_a) acidities. These parameters are linked by the Brønsted relation:

$$\lg k_{+(-)} = \alpha(\beta)\Delta pK_a + \mathrm{const}, \qquad (1)$$

where

$$\Delta pK_a = pK_a(BH^+) - pK_a(CH)$$

and α and β are the reaction constants for the forward and reverse proton transfer reactions:

$$C{-}H + B \underset{k_-}{\overset{k_+}{\rightleftarrows}} C^- + HB^+. \qquad (2)$$

According to Eqn.(1), the rate of elimination of the proton should increase with increasing strength of the acid or base. The values of α and β are usually constant for a series of compounds of similar structure and α + β = 1.

The Brønsted correlation is a consequence of the fundamental principle of the linear relation between the free energies of activation and of the equilibrium reaction: $\Delta\Delta G^{\neq} = \alpha\Delta\Delta G$. If it is assumed that the entropy change in the reaction series can be neglected, the above expression assumes the form

$$\Delta E = \alpha\Delta Q, \qquad (3)$$

where *E* and *Q* are the activation energy for the proton transfer reaction and the heat of the latter. It is noteworthy that the constancy of α is maintained within a relatively narrow range of values of ΔQ or ΔpK_a. For highly exothermic reactions ($\Delta pK_a \gg 0$), the activation energy for the forward process is low and α → 0 and β → 1. On the other hand, for highly endothermic reactions ($\Delta pK_a \ll 0$) we have α → 1 and β → 0. In the range of intermediate values of ΔpK_a the values of α and β are between 0 and 1 and α + β = 1. The extent of the transitional region can be estimated with the aid of the Marcus semiquantitative theory,[50] according to which the relation between the free energies of activation and of the equilibrium reaction includes the so-called internal barrier to reaction, i.e. the value of $\Delta G^{\neq}$ corresponding to $\Delta G = 0$:

$$\Delta G^{\neq} = (1 + \Delta G/4\Delta G_0^{\neq})^2 \cdot \Delta G_0^{\neq} \qquad (4)$$

It follows from Eqn.(4) that

$$\alpha = d\Delta G^{\neq}/d\Delta G = \frac{1}{2}(1 + \Delta G/4\Delta G_0^{\neq}), \qquad (5)$$

$$d\alpha/d\Delta G = (8\Delta G_0^{\neq})^{-1}. \qquad (6)$$

Consequently, for symmetrical proton-exchange reactions ($\Delta G = 0$), we have α = 0.5. With increase of the internal activation barrier, the curvature of the function $\alpha = f(\Delta G)$ or $\alpha = f(\Delta pK_a)$ diminishes and the range of values of ΔG and ΔpK_a in which α varies from 0 to 1 should broaden.[51]

The Hammond–Leffler postulate,[52,53] according to which α reflects the energy symmetry of the transition state, imparts a physical significance to the reaction constant α(β). For exothermic reactions (α < 0.5), the structure of the transition state resembles that of the initial reactant, while for endothermic reactions (α > 0.5) it resembles that of the product, i.e. α reflects the degree of proton transfer in the transition state of reaction (2). However, it is not yet clear whether there is a quantitative relation between α and the length or order of the bond in the C...H...B transition state.

Definite ideas concerning the structure of the transition state have arisen from the study of the kinetic isotope effect in proton transfer reactions.[1,2] It has been established experimentally that the dependence of k_H/k_D on ΔpK_a is

represented by a bell-shaped curve and reaches a maximum in the region of $\Delta pK_a = 0$, i.e. for systems to which a symmetrical transition state corresponds according to the Hammond–Leffler postulate.

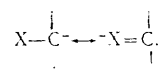
On the basis of the theoretical postulate examined above, Eigen, who carried out extensive studies on protolytic reactions, proposed a classification of acids,[53] within the framework of which the large group of OH acids is regarded as "normal". The following are the features believed to be characteristic of the normal behaviour of acids:

(1) the rate of proton transfer in the thermodynamically favourable direction is limited by diffusion and is independent of ΔpK_a, i.e. $\alpha = 0$;

(2) in the reverse, slow direction, the reaction is characterised by the maximum sensitivity of the rate to ΔpK_a, i.e. $\alpha = 1$;

(3) the values of α and β differ from 0 to 1 respectively over a narrow range of values of ΔpK_a close to zero;

(4) in the transition state the proton has been almost fully transferred to the acid or base and the observed kinetic isotope effects are therefore insignificant.



Deviations from the "normal" behaviour are characteristic of many CH acids. For example, the proton transfer even in the thermodynamically favourable direction is much slower than in the diffusion limit. Such results led to the description of CH acids as "pseudoacids". However, as will be seen below, many CH acids behave "normally", i.e. similarly to OH acids.

VI. THE ACIDITY OF HALOGEN-SUBSTITUTED HYDROCARBONS

Saturated hydrocarbons exhibit an extremely low acidity ($pK_a = 40$ for methane). In conformity with the Brønsted relation, proton transfer only to strong bases is observed and the reaction is slow.[1] The introduction of halogens sharply increases and acidity of hydrocarbons. Isotope exchange proceeds at measurable rates; alkaline but not acid catalysis is effective. The kinetics and equilibria of reactions involving proton transfer from halogen-substituted CH acids have been studied in relatively fair detail.[55–58] A general conclusion reached in the studies quoted is that a "normal" behaviour is characteristic of CH acids of this type. Thus the rate of isotope exchange involving fluoroform and chloroform in H_2O–DMSO mixtures increases, while the activation energy diminishes with increasing basicity of the medium. The kinetic results are described by the Brønsted relation ($\alpha = 0.98$). The rates of proton transfer to the carbanion are virtually the same and approach the diffusion limit. The transition state in the acid ionisation reaction probably resembles the product. The low kinetic isotope effects $k_H/k_D \leqslant 2.5$ are consistent with this hypothesis.[55]

Analogous results have been obtained for the deuterium–hydrogen exchange reactions of polyfluoro-substituted CH acids.[56] In these systems too the kinetic isotope effect was small (2.1–2.5). The transfer of the proton of the C–H bond to the methoxide ion in alcoholic solution has a high activation barrier (20–28 kcal mol^{-1}). These data indicate the antisymmetric structure of the transition state. The effect of the substituents on the equilibrium and kinetic acidities of the compounds discussed is the same, since we have $K_a \cong k_+$ when $k_- = \text{const}$.

It is noteworthy that the effect of the halogens on the equilibrium and kinetic acidities of the C–H bonds is not correlated with their electronic acitivity (Table 4) [57,58] and is probably not determined solely by the inductive effects of the substituents. According to Hine et al.,[57] the increase of acidity in the series of haloforms is due to the stabilisation of the carbanion as a consequence of the involvement of the *d* orbitals of the substituent in the delocalisation of the free electron pair:

Such resonance is impossible for fluorine owing to the absence of *d* orbitals and fluoroform is therefore least acidic. On the other hand, the increase of acidity on passing from chlorine to iodine is attributed to the greater polarisability of the orbitals of the latter.

Table 4. The rates and activation parameters of deuterium exchange involving halogenomethanes under the conditions of alkaline catalysis in aqueous solutions.[57,58]

Hal_3CD	10^4k, litre mol^{-1} s^{-1}	$\Delta H^{\neq}$, kcal mol^{-1}	$\Delta S^{\neq}$, e.u.	pK_a
F_3CD	$1.8\cdot10^{-5}$	32.0	18.0	27
Cl_2FCD	0.89	25.9	17.7	18
$BrClFCD$	21	24.3	18.3	15
Cl_3CD	47	23.5	17.0	15
Br_2FCD	180	—	—	13
Cl_2ICD	275	22.1	15.3	13
Cl_2BrCD	290	—	—	13
$ClBr_2CD$	1435	21.3	15.6	12
Br_3CD	5790	20.3	15.0	11
I_3CD	6010	20.2	14.5	11

According to ideas developed in a number of studies,[24,59,60] the destabilising +*M* effect, induced by the repulsion between the *n* electrons of the halogens and the free electron pairs of the carbanion and, evidently, to a much lesser extent also the binding electrons of the CH group in the acid, exerts the main influence on the acidity of haloforms. This effect increases on passing from iodine to fluorine, since the amount of *p* character of the *n* electrons increases in the same sequence and their energy diminishes with decrease of the atomic radius. The changes enumerated above promote the growth of the capacity of halogens for conjugation. The observed acidity series for haloforms is fully consistent with the hypothesis of the destabilising +*M* effect of the substituents.

However, the mechanism of the influence of fluorine atoms on the properties of CH acids may vary with the position of the substituent relative to the reaction centre.[56,60] For example, on passing from fluoroform to $(CF_3)_3CH$, an increase of the kinetic acidity almost by nine orders of magnitude is observed, although the inductive constants for CF_3 and F are virtually identical. Evidently, the fluorine atoms in the β-position interact with the reaction centre only via the inductive mechanism and increase the CH acidity in conformity with their high electronegativity. On the other hand, the destabilising +*M* effect remains dominant for the fluorine atoms in the α-position (see above).

Table 5 presents data[60] which make it possible to follow the dependence of the type of influence of the fluorine atoms on the acidity as a function of their position relative to the reaction centre. It is clearly seen that only F atoms remote from the CH group increase the acidity (compounds 2, 4, and 5), while the F atoms in the α-position reduce the acidity even relative to the phenyl substituent.

Thus halogen-substituted hydrocarbons belong to "normal" acids in terms of Eigen's classification. The variation of their properties as a function of the nature or position of the halogen can be accounted for satisfactorily by the competing inductive and destabilising +*M* effects.

Table 5. The relative rates of deuterium exchange involving the compounds $(CF_3)_2CHX$ in the DMSO–MeOH system catalysed by TEA (at 37 °C).[60]

No.	X	k_{rel}	pK_a

2	CF_3	4300	7
3	F	0.86	18
4	*m*-FC_6H_4	18.4	—
5	*p*-FC_6H_4	1.54	—
6	Cl	651	12.6
7	Br	2227	11.5
8	I	154	13.7

VII. THE INFLUENCE OF ELECTRON-ACCEPTING GROUPS ON THE PROPERTIES OF CH ACIDS

Electron-accepting substituents can be divided into two types. The first includes the CN, SO_2R, etc. substituents, interacting with the reaction centre of the carbanion mainly via the inductive mechanism. The second includes the COOR, COR, C_6H_5, etc. substituents, stabilising the carbanion via the conjugation mechanism. As will be seen below, the difference between the mechanisms of the influence of substituents is an important cause of the "anomalies" characteristic of many CH acids.

The CN and SO_2R ($\sigma_I = 0.58$) groups are some of the most powerful electron-accepting substituents. The acidity of the corresponding disubstituted methanes varies in the range $pK_a = 11-15$. The acid strength of the corresponding trisubstituted methanes is comparable to that of inorganic acids; for example, $pK_a = 0$ for cyanoform. Table 6 presents the results of kinetic studies of trisubstituted methanes of the type $HC(X)(SO_2R)_2$ and $HC(X)(CN)_2$.[61-63] Their analysis together with the results obtained in other studies[64,65] showed that Brønsted correlations are observed for sulpho- and cyano-methanes with X = H or alkyl and α close to unity on varying both the CH acid and the base. The rates of protonation of the carbanion are close to the rate limited by diffusion. The deprotonation of these acids is accompanied by small isotope effects: $k_H/k_D = 1.5$.[61,64,66]

Thus disulphones and dinitriles with alkyl substituents behave in deprotonation reactions as "normal" acids. Compounds with phenyl or aryl substituents are exceptions in both systems. Thus, for similar pK_a values, the kinetic acidity of the compounds with the C_6H_5 group is significantly lower (Table 6). It is noteworthy that the introduction of the phenyl group diminishes both k_+ and k_-. The above "anomalies" are not exceptional. They are characteristic also of other sulphones or nitriles containing a substituent capable of conjugation.

A significant difference between sulphones and nitriles, on the one hand, and compounds with the NO_2, COOR, COR, etc. groups, on the other, is that, while the equilibrium acidities are comparable, the latter compounds exhibit an appreciably lower kinetic acidity (Table 7) and also relatively low rates of protonation of the carbanion. Furthermore, in contrast to acids with substituents of the type Hal, CN, SO_2R, etc., the nature of the substituents in these compounds influences the rates of both the foward and reverse reactions. The coefficients α and β differ from 0 to 1 over a wide range of values of ΔpK_a. For example, the relation between $\lg k_+$ and ΔpK_a, which is common to a large number of ketones, ethers, ketoethers, and various bases, is represented by a smooth curve whose slope varies almost by a factor of 2 when pK_a changes by 25 units.[2] The kinetic isotope effect reaches a maximum in the region of $\Delta pK_a = 0$ ($k_H/k_D = 10$) and then gradually diminishes to 2 both in the region where $\Delta pK_a \cdot 0$ and the region where $\Delta pK_a \cdot 0$.

$CH_3CH(COCH_3)_2$	$1.0 \cdot 10^{-11}$	$8.3 \cdot 10^{-5}$	$8.3 \cdot 10^{6}$
$CH_2(CN)_2$	$6.5 \cdot 10^{-12}$	$1.5 \cdot 10^{-4}$	$2.3 \cdot 10^{7}$

It has been shown[68,69] that, in the proton exchange reactions of toluene, diphenylmethane, and their derivatives catalysed by bases of different strengths, the coefficient α varies in the range 0.31–0.75 and increases with decrease of the strength of the base. It is believed[68,69] that this is associated with the fact that the ionisation of CH acids of the above type entails a change in the hybridisation of the atomic orbitals of the carbon atom. On passing to the anion, the amount of *p* character of the orbital of the free electron pair increases, which stabilises the anion as a result of p–π conjugation with the electrons of the benzene rings.

Since the maximum overlap of the orbitals of the free electron pair and the substituent is possible for a planar configuration of the anion, the dissociation of CH acids of the type considered involve significant structural rearrangements promoting the delocalisation of the charge in the carbanion. Structural reorganisations require an energy expenditure and lead primarily to an increase of the internal activation barrier [see (Eqn.(4)]. This is why k_+ and k_- decrease and the range of ΔpK_a values in which α and β vary from 0 to 1 expands [see Eqn.(5)].

The conjugation effect, which increases the stability of the cation, does not influence to an equal extent the thermodynamic and kinetic acidities. The stabilisation of the carbanion leads to an increase of the strength of the acid and of the rate of its ionisation. However, the k_+ are then smaller than the expected value corresponding to an increase of the equilibrium acidity without taking into account the rehybridisation of the bonds and the delocalisation of the charge.[1]

One may expect that $\Delta G_0^{\neq}$ will increase and α will diminish in the region of positive ΔG with increase of the capacity of the substituents for delocalising the charge of the carbanion in the sequence $SO_2R < CN < COOR < COR < NO_2$ [70,71] [see Eqn.(5)]. The experimental results[72] presented in Table 8 are consistent with this hypothesis.

Table 8. The Brønsted coefficients for the ionisation of certain CH acids when the substituents X in the acid and in the base are varied.[72]

CH acid	Base	α
$C_6H_5CH_2CHCOCH_3CO_2C_2H_5$	XCO_2^-	0.44
$XC_6H_4CH_2CHCOCH_3CO_2C_2H_5$	$CH_3CO_2^-$	0.77
$C_6H_5CH_2CH(COCH_3)_2$	XCO_2^-	0.44
$XC_6H_4CH_2CH(COCH_3)_2$	$CH_3CO_2^-$	0.58
$C_6H_5CH_2CH(CN)_2$	XCO_2^-	1.00
$XC_6H_4CH_2CH(CN)_2$	$ClCH_2CO_2^-$	0.98

Thus the deviations of acids with substituents of the type C_6H_5, COOR, etc. from the "normal" behaviour are associated primarily with the fact that the conjugation effect makes a significant but not decisive contribution to the stabilisation of the carbanion.

The "normal" behaviour is characteristic of acids with substituents of the type CN, SO_2R, alkyl, and Hal, since their ionisation is not accompanied by a significant delocalisation of the charge and the carbanion is stabilised mainly via the inductive mechanism. Naturally, one cannot rule out the involvement of interactions of another type in stabilisation but for the CN and SO_2R substituents the contribution of resonance effects is small.[73]

VIII. THE "NITROALKANE ANOMALY"

Those CH acids whose behaviour can be regarded as "normal" or "anomalous" within the framework of Eigen's classification were examined above: the properties of both types of such acids are described by the Brønsted relation. Typical examples of systems whose behaviour does not obey the Brønsted equation are discussed below and the possible causes leading to the breakdown of the Brønsted relation are analysed.

Table 9 compares the acid properties of various diketones.[67,74] The fact that the replacement of the CH_3 group by CF_3 leads to an increase of the equilibrium acidity in conformity with the high electronegativity of the fluorine atom but the kinetic acidity diminishes at the same time is noteworthy. The coefficient $\alpha < 0$ for this system, i.e. has an "anomalous" value.

Anomalous values of the Brønsted coefficient ($\alpha < 0$ and $\alpha > 1$) are most characteristic of CH acids containing the nitro-group. Thus the equilibrium acidity of nitroalkanes increases in the sequence

$$CH_3NO_2\ (10.2) < C_2H_5NO_2\ (8.5) < (CH_3)_2CHNO_2\ (7.7)$$

(the pK_a are given in brackets), but the relative rates of abstraction of protons by hydroxide ions diminish (111 : 18 : 1) in the same sequence. The coefficients $\alpha = -0.7$ and $\beta = 1.7$ are anomalous.[75] The ionisation of alkyl-substituted nitromethanes of the type R_2CHNO_2 (where R = H, CH_3, C_3H_7, iso-C_3H_7, or t-C_4H_9) is also characterised by negative values of α.[71]

Table 9. The equilibrium and kinetic acidities of various diketones in aqueous solutions.[14,67]

CH Acid	pK_a	$10^5 k_+^T$, s^{-1}	$10^2 k_+^H$, s^{-1}	k_-^H, litre mol^{-1} s^{-1}
$(CH_3CO)_2CH_2$	8.99	66.5	1.6	$1.7 \cdot 10^7$
$CF_3COCH_2COCH_3$	6.78	33.3	1.5	$7.5 \cdot 10^2$
$(CF_3CO)_2CH_2$	5.3	15.1	—	—
$CH_3COCH_2COC_6H_5$	9.4	—	1.1	$2.7 \cdot 10^7$
$CF_3COCH_2COC_6H_5$	6.8	—	0.8	$5.5 \cdot 10^4$

Anomalies of another kind are also characteristic of nitrocompounds: the sensitivity of the kinetic acidity to the influence of substituents is greater than that of the equilibrium acidity, i.e. $\alpha > 1$. For example, $\alpha = 1.67$, 1.61, 1.42, and 1.56 have been found for nitroalkanes having the formulae

$R(CH_2)_3NO_2$, $ArCH_2CH(CH_3)NO_2$, $ArCH(CH_3)NO_2$ and $ArCH_2NO_2$

respectively.[71,76] The reaction constant diminishes somewhat after the introduction of the chlorine atom ($\alpha = 1.23$ for $RCHClNO_2$), but the anomaly persists.[77,78] The above systems have been investigated in water and aqueous alcoholic solution. It must also be emphasised that all systems with $\alpha > 1$ included a fixed base. If the base is varied for the same nitroalkane, then the Brønsted coefficient returns to the range within the "normal" limits, i.e. $0 < \alpha < 1$.[79,80]

The hypothesis of a relation between α and the degree of proton transfer in the transition state was discussed above. The relation implies that the influence of the substituents on the transition state is intermediate between their influence on the CH acid and the carbanion. It is quite evident that in the case of nitroalkanes and similar systems, for which $\alpha < 0$ or $\alpha > 1$, such a hypothesis lacks significance.

We shall consider the general characteristics of systems for which the Brønsted coefficient has an anomalous value. In the first place we shall note that in both cases ($\alpha < 0$ and $\alpha > 1$) the effect of the substituents on k_+ and k_- is qualitatively the same. The difference is that, when $\alpha > 1$, the substituent decreases the energy of the transition state to a greater extent than that of the anion (Fig.1, curve *b*), i.e. k_+ increases faster than k_-. When $\alpha < 0$, the substituent increases the energy of the transition state but decreases that of the anion (Fig.1, curve *c*), i.e. k_- decreases to a greater extent than k_+.

The question of the causes of the anomalies described above is controversial. The influence of substituents is manifested via various effects, which in their turn make non-equivalent contributions to the energies of the transition state and the

carbanion. Thus the conjugation effect should be fully manifested only for the carbanion and can be virtually absent in the transition state. On the basis of this hypothesis, it is possible to account for the inverse relation between the kinetic and thermodynamic acidities in the series of methylnitroalkanes. The decrease of the kinetic acidity after the introduction of the CH_3 group is induced by the electron-donating inductive effect of this group, while the increase of the equilibrium acidity is caused by the stabilisation of the anion by the hyperconjugation effect.[81]

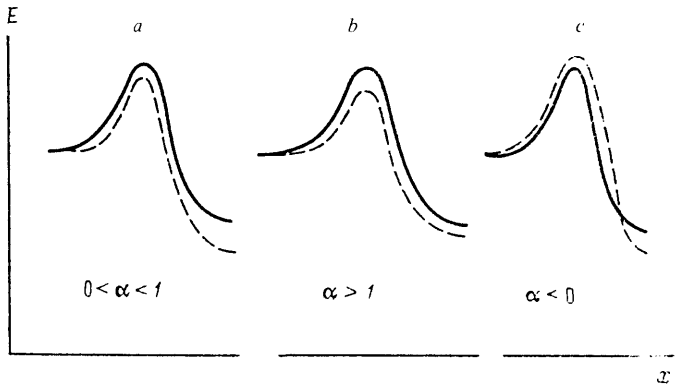

Figure 1. The effect of the introduction of a substituent on the variation of the potential energy E along the proton transfer reaction coordinate x characterised by the normal (a) and "anomalous" (b and c) values of α (continuous line—without a substituent; dashed line—with a substituent).

In aqueous alcoholic solutions specific intermolecular interactions are important apart from the intramolecular electronic effects. Solvation can stabilise the transition state and the carbanion to different extents. For example, the nitroalkane anions are stable in the ground state by virtue of solvation with which the formation of relatively stable hydrogen bonds is associated:

In this case electron-accepting substituents increase the electronic stability of the carbanion but diminish its capacity for the formation of hydrogen bonds with the solvent. Thus the influence of substituents on the anion is smoothed out. The electron-donating methyl groups promote the solvation of the anion and also increase its stability as a result of intramolecular hyperconjugation effects (see above).

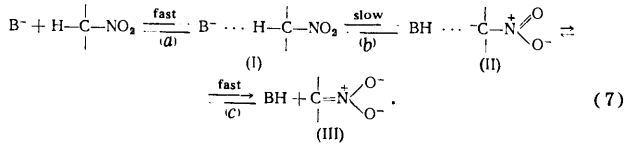
In the transition state the partial negative charge is localised on the carbon atom and the solvation effects are insignificant.[79,82] The electronic effects of the substituents in the acid and in the transition state should therefore play the major role in determining the activation energy for the abstraction of a proton.[82]

The important role of solvation effects in the manifestation of "anomalies" is indicated by the following results. On passing from $ArCH_2NO_2$ to $ArCHClNO_2$, the quantity α diminishes from 1.56 to 1.23,[77,78] while for compounds of the type $ArCH(NO_2)_2$ the normal value is attained ($\alpha = 0.75$), because polynitroalkane anions hardly form hydrogen bonds with this solvent.[83]

On passing from aqueous solutions to the aprotic solvent DMSO and in the gas phase a decrease of the "anomalous" influence of the methyl groups on the equilibrium acidity of nitro-compounds is observed (Table 10).[83,84] However, the sequence of the changes in acidity with substitution remains common to all three cases. Consequently the anomaly in the constants K_a for the acids considered is caused not only by solvation but also by hyperconjugation effects.

Table 10. The change in the thermodynamic acidity $\Delta pK_a = pK_a^H - pK_a^{CH_3}$ in water, DMSO, and the gas phase on substitution of the hydrogen in nitromethane by the methyl group.[84]

CH Acid	H_2O	DMSO	Gas phase
CH_3NO_2	0.00	0.00	0.00
$CH_3CH_2NO_2$	1.80	0.68	0.5
$(CH_3)_2CHNO_2$	2.96	0.79	1.2



For compounds having the formula $ArCH_2NO_2$, the transition from H_2O to DMSO leads to a decrease of α from 1.56 to 0.92.[82] In DMSO the rate of dissociation decreases sharply and the heat of activation falls, which is believed[24] to be associated with the fact that the basicity of the medium increases with increasing DMSO concentration. For the given fixed acid $C_7H_5CH_2NO_2$, the change in base strength in the H_2O–DMSO mixture leads to $\alpha = 0.58$. Consequently even in the aprotic solvent the values of α determined for a fixed acid (0.58) or base (0.92) are not the same. On passing from H_2O to DMSO, the anomaly does not disappear in this system, although the extent to which it is manifested diminishes.

A formal explanation of the "nitroalkane anomaly" has been proposed by Marcus.[50,85] We may recall that, when the internal activation barrier is constant within the limits of the reaction series, α is specified by Eqn.(5) and is within the normal limits ($0 < \alpha < 1$) subject to the condition that $|\Delta G| \leq |4\Delta G_0^{\neq}|$. A change in the nature of the base should not influence $\Delta G_0^{\neq}$, so that for a fixed nitroalkane the Brønsted relation holds when the base is varied. On the other hand, when the introduction of a substituent into the acid alters the internal activation barrier, then α is specified by the expression

$$\alpha = \frac{1}{2}\left(1 + \frac{\Delta G}{4\Delta G_0^{\neq}}\right) + \left[1 - \left(\frac{\Delta G}{4\Delta G_0^{\neq}}\right)^2\right]\frac{d\Delta G_0^{\neq}}{d\Delta G},$$

whose second term can influence α significantly. The change in $\Delta G_0^{\neq}$ within the limits of the reaction series is possible either as a result of a structural reorganisation of the transition state or as a consequence of solvation effects.

According to Bordwell, who investigated various series of nitroalkanes with negative coefficients α,[71,87,88] the "nitroalkane anomaly" can be accounted for by a three-stage mechanism of the dissociation of the CH acids considered:

(7)

In the rate-limiting stage (b) the proton transfer via the C–H...B$^-$ hydrogen bond leads to the formation of a carbanion having a tetrahedral structure without a significant charge delocalisation. In the next, rapid, stage (c) the tetrahedral configuration rearranges to a planar configuration, which creates conditions in the anion for delocalisation of the charge. The influence of substituents on the rate of deprotonation of the CH acid is manifested in the slow stage involving proton transfer within the complex on passing from compound (I) to (II), while the equilibrium acidity should be determined by the effect of the substituents on the planar anion (III). There is no doubt that the structural changes in the acid influence in different ways the properties of the transition state [of stage (b)] and the anion (III). If the substituents stabilise the associated species (II) to a greater extent than the anion (III), then $\alpha > 1$; however, if the substituents have the opposite effect on the stabilities of (II) and (III), then $\alpha < 0$.

The above treatment makes it possible to throw some light onto the controversial question of the structure of the transition state in the dissociation of nitroalkanes. One must suppose that the transition state does not resemble the products, because the influences of substituents on the carbanion and on the transition state are significantly different. However, for a series of fixed nitroalkanes, $\alpha = 0.50-0.65$ and varies only slightly over a wide range of ΔpK_a as the nature of the base is varied.[79] The corresponding kinetic isotope effects are fairly large and reach a maximum near $\Delta pK_a = 0$, but in the range of ΔpK_a values greater or smaller than zero the ratios k_H/k_D vary only slightly.[87,88] The hypothesis has therefore been put forward[79] that either the transition state in the proton transfer reaction is almost symmetrical or that the quantity α and k_H/k_D are in no way related to its structure.

The above discrepancies can be eliminated when account is taken of the complex mechanism of the dissociation reaction of nitroalkanes [reaction (7)]. The quantities α and k_H/k_D should probably be referred to stage (b), the structure of the transition state of which approaches a symmetrical structure. The value of ΔpK_a for this stage is significantly smaller than that adopted in the experiment, because the latter reflects the change in the free energy throughout the entire process.[87,89]

It must be emphasised that the role of the solvation effect is significant also in the multistage mechanism,[90] because the anions of types (II) and (III) differ from one another in their capacity to form hydrogen bonds. Thus the "nitroalkane anomaly" is manifested as a consequence of the different character of the influences of the substituents on the individual stages of the dissociation process and on the solvation effects stabilising the carbanion.

In order to separate the contributions of the intramolecular electronic interactions and the solvation effects, it is necessary to study the rate of dissociation and the dissociation equilibria of CH acids in aprotic weakly polar solvents. At the present time this field of study is beginning to develop.

A detailed investigation has been made[91] of the kinetics and equilibrium in proton transfer from *p*-nitrophenylnitromethane to nitrogen-containing bases in aprotic solvents of different polarity. A parallel variation of the equilibrium and rate constants is on the whole observed for this system (with the exception of the reaction with TEA in acetonitrile): both constants increase with increase of solvent polarity and the basicity of the proton acceptor. However, no irregularities can be traced in the variation of the equilibrium or activation energy and entropy parameters. The above parallel variation is caused by combinations of the quantities $\Delta H^{\neq}$ and $\Delta S^{\neq}$, which are difficult to interpret and may be random.

Studies of the kientics of proton transfer from nitroalkane to amines in various aprotic solvents have been carried out by dynamic NMR.[92–95] In these investigations the attempts by the authors to determine separately the characteristics of the stages involving complex formation and the proton transfer proper in terms of the scheme

$$C{-}H + B \overset{(a)}{\rightleftarrows} C{-}H \cdots B \overset{(b)}{\rightleftarrows} C^- \cdots HB^+ \qquad (8)$$

are particularly interesting. Table 11 compares the results obtained. Evidently, the values of E_+ are comparable in magnitude with the heats of activation for proton transfer from *p*-nitrophenylnitromethane to amines.[91] Since both reaction (8) as a whole and stage (*b*) are thermodynamically favourable, the relations $E_+ < E_-$ holds. The anomaly is that for systems (II) and (III) the values of E_+ differ significantly for virtually equal ΔpK_a and similar values of Q. We may note that analysis of the tabulated data for system (III) leads to an unexpected result. Thus simple comparison of ΔH and E_+ shows that the energy of the transition state of the proton transfer stage is lower than the energy of the reactants. In other words the overall activation energy for the forward process in reaction (8) is negative. Under this condition, the rate of reaction should diminish with increase of temperature, which conflicts with the data of Borodin et al.[95]

Table 11. The activation energies and thermodynamic characteristics of the equilibrium in reaction (8).[92–95]

No.	CH acid	pK_a	Base	Solvent	$-\Delta H$, kcal mol^{-1}	Q, kcal mol^{-1}	E_+, kcal mol^{-1}	E_-, kcal mol^{-1}
(I)	$CH_2CH(NO_2)_2$	5.13	$NH(C_8H_{17})_2$	CCl_4	--	11	10	20
(II)	$CH_2CH(NO_2)_2$	5.13	$N(C_8H_{17})_3$	$CDCl_3$	3	12	7.9	16.9*
(III)	$(CF_3)_2CHNO_2$	5.0	$N(C_8H_{17})_3$	$CDCl_3$	6.1	12.4	4.7	11*
(IV)	$(CF_3)CH_2NO_2$	7.4	$N(C_8H_{17})_3$	$CDCl_3$	0	9	6	14

Notation: ΔH is the enthalpy of formation of the hydrogen bonds, Q the heat of reaction (8), and E_+ and E_- are the activation energies for the forward and reverse reactions of stage (b) in proton transfer.

*E_- has been determined from the formula $E_- = \Delta H - Q + E_+$.

The kinetics of proton transfer from dinitromethane to trioctylamine have been studied in aprotic solvents of different types.[94] It has been found that, with increase of the dielectric constant of the solvent on passing from cyclohexane to acetonitrile, the quantities E_+ (7.4–8.0 kcal mol^{-1}) and k_+ (27–13 s^{-1}) change insignificantly. The nature of the solvent exerts a somewhat greater influence on the heats of the equilibrium reaction, because ΔH diminishes from 4.8 to 2.2 with increasing polarity, while Q increases from 11.4 to 13 kcal mol^{-1}.

Thus, on the basis of the few date examined, one can reach the preliminary conclusion that in aprotic solvents the anomalous influence of substituents on the equilibrium and kinetic acidities of nitroalkanes diminishes but does not disappear completely.

A detailed study has been made[96,97] of the state of equilibrium and the kinetics of proton transfer from trisubstituted methanes $HC(Y)(SO_2CH_3)C_6H_4X$ (X = CH_3 or Cl; Y = COC_6H_5

or $COOC_2H_5$) to γ-collidine or TEA in methylene chloride:

$$R_3CH + N \underset{k_-}{\overset{k_+}{\rightleftarrows}} R_3C^- + HN^+ \quad . \qquad (9)$$

In the case of collidine it was found that the equilibrium constant $Kp = k_+/k_-$ and the heat Q of reaction (9) vary in parallel with the acidity of R_3C-H measured in alcohol (Table 12). In other words, the change of the solvent and the base did not alter the relative acidities of the compounds R_3C-H considered.

Table 12. Thermodynamic and kinetic characteristics of proton transfer from the trisubstituted methanes HC(Y).$(SO_2CH_3)SO_2C_6H_4X$ to γ-collidine (at 20 °C).[96]

No.	Y	X	pK_a (CH_3OH)	$\lg Kp$, (mole fraction^{-1})	$-Q$, kcal mol^{-1}	$-\Delta S$, e.u.	$\lg k_+$, (mole fraction s^{-1})	E_+, kcal mol^{-1}	$\lg k_-$, (s^{-1})	E_-, kcal mol^{-1}	$-\Delta H^*$ kcal mol^{-1}
(I)	COC_6H_5	Cl	4.77	2.8	12.4	29	3.8	5.3	1.0	17.7	3.3
(II)	COC_6H_5	CH_3	5.81	1.7	8.9	22	3.3	6.5	1.6	15.4	3.0
(III)	$CO_2C_2H_5$	Cl	5.24	1.9	7.8	18	5.7	4.4	3.8	12.2	2.6
(IV)	$CO_2C_2H_5$	CH_3	6.36	0.9	5.8	15	5.1	4.0	4.2	9.8	2.6

*ΔH is the enthalpy of the hydrogen bonds between the trisubstituted methanes and DMSO.[38]

Interesting regularities are manifested when the effects of remote (X) substituents and substituents adjoining the reaction centre (Y) are considered. Thus, for a series of isotypical compounds with the same substituent Y, the variation of X influences to a greater extent the activation energy for the protonation of the carbanion E_- than the activation energy for the deprotonation of the CH acid E_+. This is associated with the fact that the transition state of the exothermic reaction (9) resembles the initial reactant in conformity with the Hammond–Leffler postulate and its properties are determined mainly by the inductive interaction of the substituent with the reaction centre. Consequently the substituents X remote from the reaction centre should exert only a weak influence on the polarity of the C–H bond and the quantity E_+. The same substituents X are involved in the stabilisation of the carbanion via the conjugation mechanism and their influence on E_- is therefore more significant.

The replacement of the substituent Y = $COOC_2H_5$ by Y = COC_6H_5 for a constant X leads to an increase of the equilibrium acidity and the quantities Q and E_-, in conformity with the greater mesomeric effect of the benzoyl group. However, this entails an increase, albeit to a smaller extent, of E_+ and a decrease of the kinetic acidity, i.e. the Brønsted relation breaks down ($\alpha < 0$).

We interpreted the above features[108] in terms of the Bell–Evans–Polanyi potential curves (Fig.2). Fig.2 illustrates the variation of the energy of the C–H...N (family of curves I) and C^-...$H-N^+$ (family of curves II) systems with increase of the lengths of the C–H and N–H bonds respectively. In plotting the curves account was taken of the fact that (a) the substituents X in the arenesulphonyl group do not influence the form of the potential curves I but alter the position of the minimum in curves II determined by the stability of the carbanion and (b) that, for a substituent Y with a greater capacity for conjugation, a curve in family I should be steeper in the region of the transition state, since in the initial stage the energy of extension of the C–H bond involves a greater expenditure on the rearrangement of the structure.

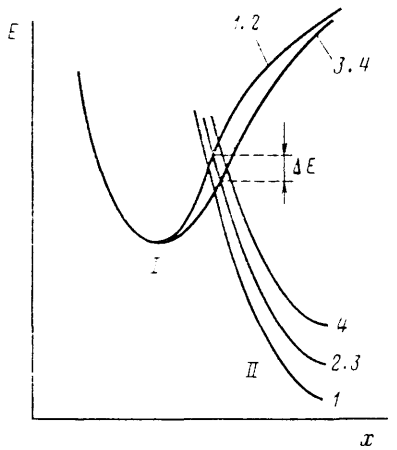


Figure 2. Cross-section through the potential energy (E) surface along the coordinate of the reaction involving proton transfer from $HC(Y)(SO_2CH_3)SO_2C_6H_4X$ to γ-collidine. Families of curves I and II refer respectively to the lengthening of the C–H and N–H bonds: 1) X = Cl, Y = COC_6H_5; 2) X = CH_3, Y = COC_6H_5; 3) X = Cl, Y = $CO_2C_2H_5$; 4) X = CH_3, Y = $CO_2C_2H_5$.

In the first place we shall compare compounds (II) and (III) which differ in the substituents X and Y but are characterised by similar values of pK_a, Kp, and Q. It follows from Fig.2 that the energies E_+ and E_- for compound (II) should be greater than for compound (III) by the same amount ΔE. This conclusion is consistent with the experimental results (Table 12).

For compounds (I) and (II) or (III) and (IV) (with Y = const.), the replacement of X = CH_3 by X = Cl leads to a decrease of E_+ (an increase of the kinetic acidity) and an increase of E_-, but, since $\Delta E_- > \Delta E_+$, this entails an increase of Kp and Q. On the other hand, on passing from Y = $COOC_2H_5$ to Y = COC_6H_5 (for X = const.), the quantities E_+ and E_- increase (the kinetic acidity falls), but, since the relation $\Delta E_- > \Delta E_+$ is maintained, Q also increases (i.e. the equilibrium acidity increases). Hence it is clear why in the pairs of compounds (I) and (II) or (III) and (IV) (i.e. with Y = const.) the equilibrium and kinetic acidities vary in parallel, while in pairs (I) and (III) or (II) and (IV) (with X = const.) their variation is antiparallel.

IX. THE ACIDITY OF UNSATURATED COMPOUNDS

The thermodynamic and kinetic acidities of hydrocarbons increase with increase of the amount of s character of the hybrid orbital forming the CH bond in the sequence $sp^3 < sp^2 < sp$. For example,

$$H_3C-CH_3\ (42) < C_6H_6\ (37) < H_2C=CH_2\ (36.5) < HC\equiv CH\ (25)$$

(the pK_a are indicated in brackets).[70] This is associated with the increase of the electronegativity of the carbon atom,

which increases the polarity of the C–H bond, and with increase of the stability of the carbanion as the energy of the orbitals of the free electron pair diminishes.

The rate of acid dissociation of ethylene and its derivatives has been scarcely investigated, since the base-catalysed proton transfer or isotope exchange reactions are accompanied by allyl rearrangements.

The hydrogen isotope exchange reactions involving benzene derivatives have been investigated.[70,98–101] It has been established that *o*-substituents accelerate the exchange (in the presence of potassium amide as the catalyst) in the sequence

$$CH_3 < H < (CH_3)_2N < C_6H_5 < CH_3O < C_6H_5O < CF_3 < F$$

and the rate of reaction is correlated with the inductive constants σ_I ($\rho = 11$). On moving away from the reaction centre, the influence of the substituents weakens and the correlation with σ_I can also break down. Thus the CF_3 group in the *m*-position accelerates the exchange to a greater extent than the fluorine atom, while the substituent CH_3O in the *p*-position diminishes the rate of exchange relative to unsubstituted benzene. These results suggest that the conjugation effect participates, apart from the inductive effect, in the stabilisation of the transition state or the carbanion. In the presence of electron-accepting substituents there is probably a possibility of the $\sigma-\pi$ interaction in the polar transition rate or in the carbanion.[98]

In the series of polysubstituted benzenes the rate of deuterium exchange increases, while the activation energy falls with increase of the number of electron-accepting substituents.[98,99] In order to understand the process mechanism, it is important to note that, when substituents in benzene or the nature of the base are varied, the results are described by the general Brønsted equation with $\alpha \approx 1$. The rates of protonation of the corresponding carbanions are independent of the structural changes ($\beta = 0$) and are similar in magnitude to the diffusion limit. Consequently, the role of conjugation in the stabilisation of the carbanion is small and the dissociation of the aryl C–H bond is not accompanied by a significant charge delocalisation and rehybridisation of the orbitals in the carbanion.[101,102]

Similar regularities are observed for acetylenic compounds. In an aqueous alcoholic medium the rate of deuterium exchange increases with increase of the inductive electron-accepting effect of the substituents in the sequence

$$HOCH_2CH_2 < HOC(CH_3)_2 < CH_3OC(CH_3)_2 < C_6H_5 < (C_2H_5O)_2CH < CH_3OCH_2.$$

Phenylacetylene remains outside the $k_+ = f(\sigma_I)$ correlation, which may be due to the resonance stabilisation of the carbanion, but the magnitude of the effect is small.[103]

The ionisation of acetylenes results in the formation of carbanions with a localised charge, since the *sp*-hybrid orbital of the free electron pair is orthogonal to the π orbitals of the triple bond and there is virtually no conjugation. The structure of the transition state resembles that of the product and the recombination of the acetylide ion proceeds at a rate which is limited by diffusion.[103–105] On the basis of the features enumerated above, substituted benzenes and acetylenes can be regarded as normal CH acids in terms of Eigen's classification.

X. THE PROTON-DONATING CAPACITY IN HYDROGEN BONDS AND CH ACIDITY

For compounds of the type $R_nX–H$ (where X are atoms of the main subgroups in Groups V–VII), it has been established reliably that, for a fixed X and variable substituents R, the strength of the hydrogen bonds X–H...B and the equilibrium acidity of the compound $R_nX–H$ vary in parallel. The same relation between the proton-donating capacity and acidity has been observed in a series of compounds R_nXH, provided that X represents atoms of elements of a single Period (X = O, N, or F). On the other hand, in the series of structurally isotypical compounds of elements of one Group but different Periods (X = N, P, As or O, S, Se) the variation of the proton-donating capacity and equilibrium acidity is antiparallel. However, for compounds with X–H groups the decrease of the proton-donating capacity is as a rule accompanied by a fall of kinetic acidity.[4]

For CH acids, virtually no comparisons have been made of the proton-donating capacity in hydrogen bonds and the thermodynamic and kinetic acidities. It has only been suggested[2] that the relatively low rates of ionisation of CH acids are caused by the weak capacity of the CH groups for the formation of hydrogen bonds. The data available at present make it possible to consider the relation between the proton-donating capacity and the CH acidity in greater detail.

It has been established[20,106] that the strength of the C–H...B hydrogen bonds between haloforms and electron donors of different types diminishes in the sequence

$$Cl_3CH > Cl_2BrCH > Br_3CH > F_3CH > I_3CH$$

and, with the exception of fluoroform, is correlated with the electronegativity of the halogens. The kinetic acidity diminishes on passing from iodoform to fluoroform:

$$I_3CH > Br_3CH > Cl_2BrCH > Cl_3CH > F_3CH \text{ (Refs.57–58).}$$

The replacement of one of the halogen atoms by a more complex electron-accepting substituent does not alter the above sequences.[34,80] Thus the variation of the proton-donating capacity in the formation of hydrogen bonds and of the kinetic acidity of compounds containing halogen atoms is antiparallel. If account is taken of the fact that in the series of compounds considered the variation of the kinetic and equilibrium acidities obeys the Brønsted equation, it becomes clear that the variation of the proton-donating capacity and of the thermodynamic acidity is antiparallel.

The above features are due to the fact that the proton-donating capacity in hydrogen bonds is determined primarily by the polarity of the CH bonds, which depends in its turn on the electronegativity of the halogen. Fluoroform, in the molecule of which the positive charge on the hydrogen atom is minimal because the $+M$ effect is a maximum for fluorine, is an exception. On the other hand, the acidity of haloforms is determined mainly by the stability of the carbanion, determined by conjugation involving the *d* orbitals and the $+M$ effect.[1]

The CF_3 group, interacting with the reaction centre of the acid and the anion predominantly via the inductive mechanism, has a parallel influence on the proton-donating capacity and the kinetic acidity. Thus the replacement of the chlorine atoms by the CF_3 groups increases the strength of the hydrogen bonds with DMSO from 1.6 kcal mol^{-1} for chloroform to 5.6 kcal mol^{-1} for $(CF_3)_3CH$ [28,29] and accelerates the deuterium–hydrogen exchange [the constants k_+ for the compounds $(CF_3)_2C_6H_5CH$, CF_3CHCl_2, $(CF_3)_2CHCl$, and $(CF_3)_3CH$ are in the ratios 1 : 2.3 : 651 : 4290].[60]

The substitution of the CF_3 group by the strong electron-accepting substituents NO_2 and CN strengthens the acidity but reduces the proton-donating capacity (Table 13). It is of interest to note that, for compounds (II) and (IV), which have similar equilibrium acidities, the activation energies for the abstraction of a proton are correlated with the strength of the hydrogen bonds. Presumably in the systems discussed the structure of the transition state is more like that

of the initial hydrogen-bonded molecular complexes than that of close ion pairs. This probably constitutes the cause of the parallel influence of substituents on the proton-donating capacity and the kinetic acidity.

Table 13. The enthalpies of the hydrogen bonds with DMSO and the activation energies for proton transfer from CH acids to amines.[1,29,93,94]

No.	CH acid	pK_a	$-\Delta H$, kcal mol^{-1}	E_+, kcal mol^{-1}
(I)	$(CF_3)_3CH$	7.0	5.63	—
(II)	$(CF_3)_2CHNO_2$	5.0	4.82	4.7
(III)	$(CF_3)_2CHCN$	0	4.75	—
(IV)	$CH_3CH(NO_2)_2$	5.2	2.23	7.9

In the series of dinitriles, parallel changes in the formation constants of the hydrogen bond and the equilibrium as well as kinetic acidities are observed. The introduction of a bromine atom into the malononitrile molecule increases the acidity and proton-donating capacity, while the introduction of the phenyl group diminishes these quantities (Table 14). The nature of CN substituents is such that they influence the reaction centres of the acids and anion via a single mechanism—the inductive mechanism (see Section VII). The introduction of these groups therefore leads to a parallel variation of the polarity of the C–H bonds and of the stability of the carbanions.

Table 14. The formation constants of the hydrogen bonds with HMPA and dimethylformamide (DMF) (in carbon tetrachloride) and the relative rate constants for the ionisation (in H_2O) of a series of dinitriles.[34]

CH Acids	K, litre mol^{-1} (HMPA)	K, litre mol^{-1} (DMF)	pK_a	k_+^{**}
$CHBr(CN)_2$	205	—	7.8	10^8
$CH_2(CN)_2$	60	11.4	11.1	10^6
$C_6H_5CH(CN)_2$	—	5.28	13.1*	1*

*The values of pK_a and k_+ are quoted for the compound $O_2NC_6H_4CH(CN)_2$.[63]
**The constant k_+ has been estimated from the data of Hibbert and co-workers.[62,63]

In the series of trisubstituted methanes of the type $HC(Y)(SO_2CH_3)SO_2C_6H_4X$ there is no general relation between the thermodynamic or kinetic acidity and the strength of the hydrogen bonds with electron donors (Table 12). A change in the nature of the substituent Y adjoining the reaction centre induces a change in the proton-donating capacity, which is in parallel with the change in the equilibrium acidity but is antiparallel in relation to the kinetic acidity. Within a series of isotypical compounds (for a fixed Y), the influence of a remote substituent X on the proton-donating capacity agrees better with its influence on the kinetic acidity than on the equilibrium acidity. These relations are caused by the initial reactant-like structure of the transition state in the dissociation reactions of the CH acids considered, whose energy, like the polarity of the C–H bonds, is determined mainly by the inductive influence of the substituents.

The proton-donating capacity and acidity of substituted bezenes increase after the introduction of electron-accepting substituents. Thus an increase of the number of chlorine atoms from 3 to 5 leads to an increase of the constant for association with HMPA [34] and to a decrease of pK_a from 34 to 30.[107] Since $\alpha = 1$ and $\beta = 0$ ($k_- = \text{const.}$) for substituted benzenes and K_a is therefore proportional to k_+, one may expect a correlation of the proton-donating capacity not only with the thermodynamic acidity but also with the kinetic acidity.

The character of the variation of the proton-donating capacity of the acetylenic compounds $RC{\equiv}CH$ can be inferred from the chemical shift of the signal due to the CH protons in associated species with pyridine,[48] which increases in the following sequence of substituents R:

$$HO(CH_2)_2<HOC(CH_3)_2<CH_3OC(CH_3)_2<C_6H_5<(C_2H_5O)_2CH.$$

The deuterium exchange rate constants increase in the same sequence.[103] Evidently, the inductive influence of R determines the proton-donating capacity and the kinetic or equilibrium acidity of the acetylenic compound, since the *sp*-hybrid orbital of the free electron pair in the acetylide ion is orthogonal with respect to the π orbitals and there are no effects of conjugation with the substituent. This applies also to the transition state whose structure resembles that of the product.[105]

Thus among CH acids there are a series of compounds differing in the character of the relations between the proton-donating capacity in hydrogen bonds and the acidity. These differences are caused primarly by the fact that the influence of substituents on the properties of CH acids discussed is exerted via mechanisms of different nature. Thus the proton-donating capacity of CH groups depends on their polarity and is therefore determined mainly by the inductive effect of the substituents. The equilibrium and kinetic acidities depend both on the inductive and mesomeric effects of the substituents. The predominance of particular mechanisms of the substituent influence is associated both with the structure of the acid and the carbanion and with the structure of the transition state.

Since the C–H...B hydrogen bonds are located on the coordinate of the deprotonation reaction of CH acids, we shall attempt in the first place to determine the relations between the proton-donating capacity in hydrogen bonds and the kinetic acidity. Analysis of the results presented above suggest that a parallel variation of ΔH and k_+ or E_+ should be observed in a series of acids for which the kinetic and equilibrium acidities are determined by the polar effects of the substituents which are virtually incapable of mesomeric interaction; either the transition state in the transfer of the CH proton resembles the initial reactant and the substituents of any type influence the kinetic acidity mainly via the inductive mechanism or the transition state of the reaction has a structure close to that of the carbanion, but the conditions for conjugation between the free electron pair and the substituents are lacking for steric reasons.

Evidently, when the Brønsted relation holds in the series of CH acids satisfying the conditions indicated, then the proton-donating capacity should be correlated not only with the kinetic acidity but also with the thermodynamic acidity.

The correlation between ΔH and $k_+(E_+)$ breaks down if a transition state, to the stabilisation of which the effects of the conjugation between the reaction centre and the substituents make a significant contribution, corresponds to the

deprotonation of the CH acids. Presumably in reaction series of this kind the form of the potential curve corresponding to the extension of the C–H bond depends on the nature of the substituent.

In comparing the properties of the C–H...B bonds and the CH acidity, we did not consider the questions of the properties of the $C^-...HB^+$ hydrogen bonds. In aprotic solvents these bonds determine in many respects the stability of the ion pair, while in protic solvents (SH) bonds of the type $C^-...HS$ play a significant role in solvation effects. Thus the problem arises of the relation between the electron-donating (proton-accepting) capacity of the carbanions in hydrogen bonds and their kinetic stability (basicity). However, there are so far virtually no literature data necessary for such a comparison. Experimental and theoretical study of hydrogen bonds involving carbanions is therefore urgently required.

The Photochemistry of Metallocenes

N.S.Kochetkova (deceased), M.-G.A.Shvekhgeimer, and L.V.Balabanova

The problems of the photochemistry of the dicyclopentadienyl derivatives of Group VIII metals are considered. Examples of the use of the photochemical reactions of metallocenes for the preparation of light-sensitive materials, inhibitors of the photoageing of polymers, catalysts of the photodecomposition of polymers, etc are presented.
The bibliography includes 125 references.

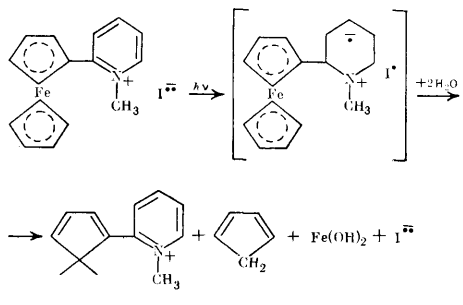
V. Practical applications of metalocenes in photochemical processes 1173

I. INTRODUCTION

The photochemistry of metallocenes (dicyclopentadienylmetals) has been developing vigorously mainly during recent years. The planned investigation of the photochemistry of ferrocene and its derivatives as well as ruthenocene and osmocene was begun about 10 years ago in a number of countries. Data obtained up to 1977 are surveyed in a monograph[1] published in 1979; later reviews devoted to the photochemistry of metallocenes are not available in the literature. The aim of the present review is to survey the literature data on the photochemistry of metallocenes published mainly during the last 10–12 years. Attention has been concentrated on the photochemistry of the cyclopentadienyl derivatives of Group VIII metals, since these are most readily available and are of interest from the practical point of view.

II. FERROCENE AND ITS DERIVATIVES

We shall consider the current ideas about the electronic configuration of the ground and certain excited states of ferrocene and ferrocenium salts. The details of the electronic configuration are still the subject of discussion and the results of theoretical calculations are not always consistent with the experimental data obtained.[2-12]



The distribution of the energy levels of ferrocene in the ground state has been investigated[13] on the basis of the EPR and photoelectron spectra (Fig. 1*a*). On photoexcitation, the ferrocene molecule passes from the $^1A_{1g}$ singlet state (or possibly from the $^1E_{2g}$ state) to the excited $^3E^*_{1g}$ triplet state (Fig. 1*b*). Oxidation results in the formation of the ferrocenium ion Fc^+ (doublet $^2A_{1g}$ state) (Fig. 1*c*). A similar estimate of the energies of the e_{1g} and a_{1g} levels of the ferrocenium ion constitutes the basis of the scheme presented in the monograph of Jeoffroy and Wrighton,[1] where these values are believed to be virtually identical.

The difficulties arising in the interpretation of the bands in the electronic spectra of ferrocene are indicated in another monograph.[14] For the interpretation of the bands in the electronic absorption spectra of ferrocene and other metallocenes, reliable experimental data are therefore required over the widest possible spectral range. To achieve reliability, studies by different and independent methods are essential.

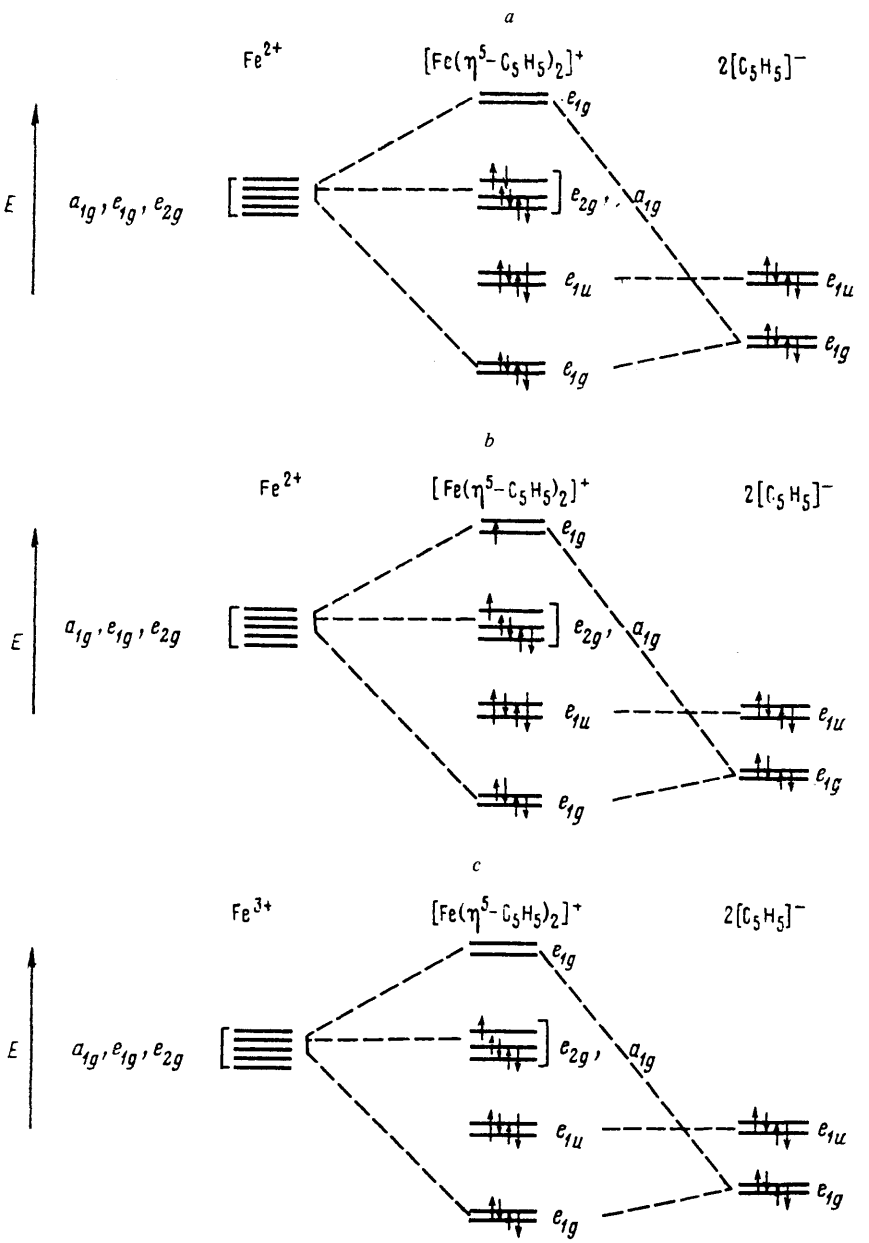
The view that the ferrocene system is extremely resistant to various types of radiation existed for a long time in the literature.[15] For example, it has been stated that ferrocene is stable under irradiation[17] and also that the Szillard–Chalmers reaction has been carried out with ferrocene[16] in which irradiation of ferrocene with fast neutrons results in the formation of a metallocene containing ^{59}Fe; it is remarkable that this process proceeds without significant decomposition of the ferrocene system. The resistance of ferrocene to the action of light in solutions in decalin, cyclohexane, and alcohols has also been noted.[18]

However, subsequent studies showed that ferrocene and its derivatives are capable of undergoing photodecomposition reactions. The first studies on the photodecomposition of ferrocene derivatives containing electron-accepting substituents linked directly to the cyclopentadienyl ring[19,20] and also separated from it by vinyl[21] of phenylene[22,23] groups were carried out by Nesmeyanov, Sazonova, and coworkers. The decomposition of α-ferrocenyl-*N*-methylpyridinium salts has been studied in greatest detail[24-27] and the photodecomposition mechanism presented in Scheme 1 has been proposed for them.

Scheme 1

According to this mechanism, the transfer of an electron from the anion to the pyridinium system results in the formation of a relatively unstable intermediate species which decomposes under the influence of irradiation giving rise to 2-cyclopentadienyl-1-methylpyridinium, cyclopentadiene, and iron hydroxide.

Traverso and coworkers[28–33] investigated the processes occurring in the photolysis of ferrocene and its derivatives in different solvents. A detailed study of the photodecomposition of ferrocene in the presence of CCl_4 and $CHCl_3$ [28] showed that the process proceeds in a more complex manner than had been supposed by Brand and Sneddon.[29] It was found that the quantum yield of the photodecomposition is much greater than unity and depends appreciably on the ferrocene concentration in solution. The abstraction of an electron under the influence of radiation can be accompanied by a secondary chemical interaction of ferrocene with the reactive radicals $CCl_3^{\cdot}$ and $CHCl_2^{\cdot}$. Traverso and Scandola[28] observed bands in the absorption spectra of the reaction products which had been shown earlier by Nesmeyanov et al.[6] to correspond to charge transfer from the metal to the cyclopentadienyl ring. This constitutes an important confirmation of the proposed mechanism. If ferrocene is in an excited state, then the electron initially passes from the orbital associated mainly with the metal to one associated mainly with the ligand and is then abstracted. The absence of the products of the photochemical oxidation of ferrocene itself in the case of spectroscopically inactive solvents cannot serve as an argument in support of the mechanism involving charge transfer to the solvent molecule according to Traverso and Scandola,[28] because the abstraction of an electron in these solvents by radiation may become reversible.



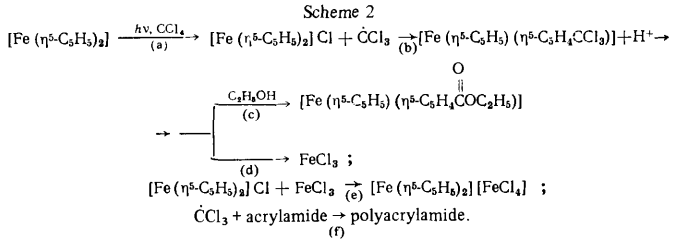


Figure. Energy level schemes for the ground (*a*) and excited (*b*) states of ferrocene (Fc^*) and the state of the ferrocenium ion (Fc^+) (*c*).

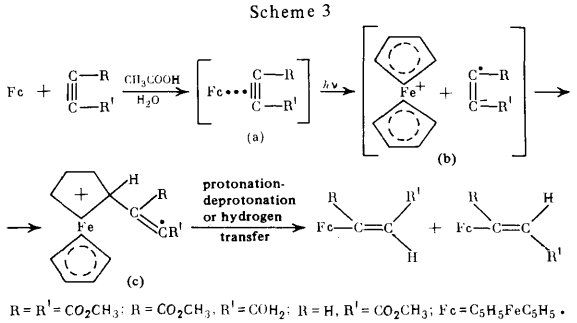
The photochemical behaviour of benzoylferrocene in solution in methanol, absolute ethanol, or 1-propanol under irradiation by monochromatic light in the range 313–472 nm has been investigated by Traverso et al.[30] Benzoylferrocene passes to an excited state and, after electron transfer, is oxidised to the corresponding benzoylferrocenium cation; the presence of a hydrogen bond between benzoylferrocene and the hydroxylated solvent facilitates this process. The authors[30] suggested that the substitution product is $RC_5H_4FeC_5H_5$, but were unable to identify it; it was isolated subsequently.[34–38]

The photolysis of ferrocene in alcohol in the presence of a mixture of halogenohydrocarbons has been studied.[34–38] The photolysis of ferrocene in ethanol in the presence of CCl_4 leads to the ethyl ester of ferrocenecarboxylic acid. When the photolysis is carried out in other alcohols, the reaction hardly occurs. Formylferrocene and ferrocenylmethanol are formed respectively in low yields in the presence of $CHCl_3$ and CH_2Cl_2.

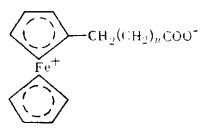


In the photolysis of ferrocene in the presence of halogenohydrocarbons initially all this results in the formation of ferrocenium halide and the radical of the corresponding halogenohydrocarbon (Scheme 2*a*). The subsequent course of the reaction can be different. In the presence of an alcohol, ferrocene substitution products are formed and the reaction proceeds with formation of a new C – C bond; in the presence of acrylamide, either the latter polymerises or ferrocenium salts are formed (see Scheme 2, stages *e* and *f*).[37]

Scheme 2

It has been established[38] that, when a mixture of ferrocene and dimethyl acetylenedicarboxylate is irradiated with ultraviolet light in an aqueous acetic acid solution, a mixture of dimethyl ferrocenylmaleate and dimethyl ferrocenylfumarate is formed. If acetylenedicarboxylic acid, methyl 3-carbamoylpropiolate, acetylenedicarboxylic acid dinitrile, or methyl propiolate are used instead of dimethyl acetylenedicarboxylate, the corresponding ferrocene derivatives are formed. It is noteworthy that acetylene derivatives containing electron-accepting substituents enter into the reaction in this case; it is believed[37,38] that the reaction mechanism involves the initial stage in which a charge-transfer complex is formed and then decomposes into the ferrocenium cation and a radical-anion (Scheme 3*b*); this is followed by the formation of the ferrocenium radical-cation (Scheme 3*c*), which is converted into methyl β-ferrocenylacrylate (for R = H) or into a mixture of derivatives of maleic and fumaric acids (for R = $COOCH_3$).[38]

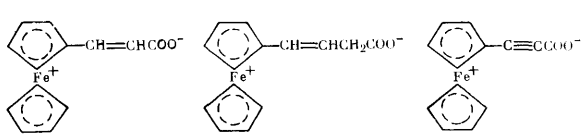
Scheme 3



R = R' = CO_2CH_3; R = CO_2CH_3, R' = COH_2; R = H, R' = CO_2CH_3; Fc = $C_5H_5FeC_5H_5$.

When acetone, acetonitrile, ethyl acetate, or methanol were used as solvents, the yield of substitution products was appreciably lower.

The use of nitrous oxide in the study of the photochemistry of ferrocene made it possible to follow the course of the electron transfer process and to estimate the quantum yield of the overall reaction from the amount of gaseous nitrogen evolved.[39–49] Apart from ferrocene,[39,40] the photochemistry of methyl-, 1,1'-dimethylphenyl-, and acetyl-ferrocenes[41,42] has been studied by this method. Electrochemical and photochemical data have demonstrated the similarity of the influence of the substituent on the abstraction of an electron from the ground and photoexcited states; the quantum yield was appreciably less than unity under these conditions.



Nitrous oxide has also been used in the study of the photochemical behaviour of ferrocenylalkane- and ferrocenylalkenecarboxylic acids[42–46] on irradiation with light at a wavelength of 254 nm. It was shown that the quantum yields of the processes vary linearly with the N_2O concentration. The authors suggest that the low quantum yield can be accounted for by the fact that the photoinitiated stage is not the only one occurring on absorption of light and is accompanied also by a dark reaction. Thus direct electron transfer from the ferrocenyl component of the molecule to N_2O is believed by the authors to be more probable than electron transfer to the hydroxylated solvent. This is demonstrated by the presence in the irradiated specimens of cyclopentadiene, detected by means of gas–liquid chromatography.

Subsequently the same workers[45–47] showed that on photoirradiation the electron can readily pass from the excited triplet state of the ferrocene molecule to an acceptor of the type N_2O; the lifetime of the excited triplet state is then extremely short, amounting to 1 μs. In an alkaline medium the product of such transfer exists in the form of a stable dipolar ion:

It was found that the electronic absorption spectrum of such a dipolar ion resembles that of ferrocenium salts. Chemical reduction led to the recovery of the initial acid. Thus the process proceeds without the decomposition of the ferrocene system.

In the same series of investigations[41,42] studies were made not only of the reactions of β-ferrocenylpropionic acid in aqueous alkaline media (borate buffer at pH 9–10) but also chain growth was achieved and the resulting γ-ferrocenylbutyric and δ-ferrocenylvaleric acids were studied in order to check that intramolecular electron transfer occurs on photoexcitation.[44] However, a chain of four–five carbon atoms with free rotation about a single bond can at some instant occupy a position such that the carboxylate anion is fairly close to the iron atom. The authors therefore subsequently investigated the photolysis of ferrocenylalkene- and ferrocenylalkyne-carboxylic acids in the molecules of which the double or triple bond rules out the possibility of the rotation of the chain and the approach of the "COO" group to the iron atom. The existence of the following dipolar ions was demonstrated experimentally:[45,46]

The dipolar ions are formed as a result of the irradiation of the corresponding acids with light at a wavelength of 240 nm in an aqueous borate buffer in the presence of N_2O. The author suggests that three processes take place under these conditions:[46] (1) photoexcitation of the molecule in the ground state to a short-lived triplet state (a first-order reaction); (2) reaction with N_2O, giving rise to the dipolar ion and N_2; (3) quenching of the excitation induced by the addition of alcohols.

Thus in solvating solvents and also in the presence of electron acceptors, both in solution and incorporated in the molecule of the test substance, ferrocene and its derivatives undergo complex photolytic and oxidation processes, which in some instances are accompanied either by substitution in the cyclopentadienyl ring with formation of new C–C bonds or by the decomposition of the ferrocene system.

When ferrocene and its derivatives are exposed to visible light in alcohol in the presence of oxygen, no less complex processes occur. However, they are not accompanied by the decomposition of ferrocene, its homologues and ferrocenium salts. The auto-oscillatory photochemical processes occurring in alcoholic solutions of ferrocene, octamethylferrocene, and the corresponding ferrocenium hexafluorophosphates on irradiation with visible light from a 500 W incandescent lamp have been described for the first time in a number of communications.[50-54] A periodic increase and decrease of the intensity of the bands in the absorption spectra of solutions of this substance were observed under these conditions. It was established that the period of the oscillation of the intensity increases with increase of the concentration of the solution, decreases with increasing temperature, and depends on the concentration of oxygen in the system. There is an oxygen concentration at which the period of the oscillations is a minimum.[52] A mechanism has been proposed for this multistage process with participation of alcohol and oxygen, in which ferrocene plays the role of the photosensitiser.[54]

The reaction between alcohols and alkyl isocyanates, catalysed by the light-sensitive ferrocene–$FeCl_3$ system, has been examined by Wilfutte-Steinert.[55] The kinetics of the interaction of t-butyl isocyanate with methanol in the presence of ferrocene at 25 °C have been investigated by infrared and ultraviolet spectroscopy in solution in the CCl_4–CH_2Cl_2 mixture under illumination with monochromatic light at 365 nm. After an induction period of 15 min, the rate of decomposition of t-butyl isocyanate obeys a zero-order kinetic equation; this is associated with the absorption of light by the $FeCl_4^-$ ions which are formed on irradiation of ferrocene in CCl_4 and absorb 99% of the incident light after 30 min of reaction. An ionic-chain mechanism with radical initiation has been proposed for the reaction. The initiation stages

$$Fe^{3+} + Cl^- \xrightarrow{h\nu} Fe^{2+} + \dot{C}l$$

$$\dot{C}l + RNCO \rightarrow RNCO^+ + Cl^-,$$

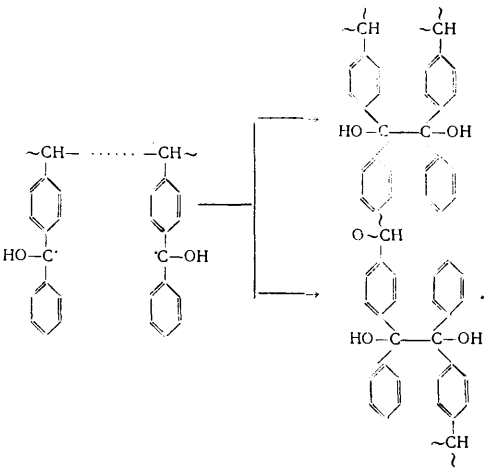
are accompanied by chain propagation reactions:

$$RNCO^+ + R'OH \rightarrow \overset{+}{R}NHCOOR' \rightarrow RNHCOOR' + RNCO^+.$$

The quantum yield of the reaction is 0.3. Another possible mechanism has been proposed for the chain propagation stage:

$$RNCO^+ + Fe^{2+} \rightarrow RNCO + Fe^{3+}.$$

The consumption of Fe^{3+} is compensated by the oxidation of Fe^{2+} by the ferrocenium cation.



Certain ferrocene derivatives, for example, ketones, behave specifically under illumination. It is known that aromatic ketones are readily converted into pinacones on irradiation. However, this type of reaction has not been observed for ketones of the ferrocene series: on irradiation in the presence of proton or electron donors, they give rise to the corresponding ferrocene alcohols:

$$Fc{-}COR \xrightarrow{h\nu} Fc{-}\overset{OH}{\overset{|}{C}}HR,$$

where R = H, CH_3, or C_6H_5.[56] In propanol this reaction proceeds with an insignificant quantum yield (~0.002). It has been stated[18] that the photodecomposition of acetylferrocene is hardly observed in isopropyl alcohol. However, when the reaction is carried out in the presence of reductants [$(C_4H_9)_3SnH$ and $(C_6H_5)_3SnH$], the photochemical reduction of acetylferrocene leads to the corresponding alcohols with a quantum yield higher by an order of magnitude (~0.02).[56] The authors believe that in the excited state the oxygen atom of acetylferrocene can have a distinctly radical character and that photoexcitation is due to the $d \cdot d$ transitions at the central iron atom and not the $n \cdot \pi^*$ transitions in the ligand. Consequently the reduction of ketones derived from ferrocene is due to the low energy of the excited state.

Sandez et al.,[57] who investigated the chemical behaviour of vinyl-benzophenone (VBP) polymers and VBP–vinylferrocene copolymers on irradiation, adhere to similar ideas. It has been found that the morphology of the polymer chains in the VBP polymer changes significantly as a consequence of the photochemical oxidation and intramolecular processes (cyclic and cross-linked structures appear–see Scheme 4).

Scheme 4

The polymer then becomes brittle and acquires some undesirable properties. On the other hand, irradiation of VBP–vinylferrocene copolymers in the presence of isopropyl alcohol does not entail significant changes in their physicochemical properties. These data permit the conclusion that ferrocene derivatives inhibit the photoageing processes in polymers.

A new absorption band has been observed in the electronic absorption spectrum of a solution of ferrocene in CCl_4[58] and was assigned to charge transfer to the solvent. The irradiation of this solution results in the formation of ferrocenium tetrachloroferrate $[C_5H_5FeC_5H_5]^+FeCl_4^-$.

The photochemical reactions of charge-transfer complexes (CTC) based on ferrocene or its derivatives and polyhalogenohydrocarbons (CBr_4) have been studied in detail recently.[60-64] The investigation of the spectroscopic characteristics of the CTC formed on interaction of CBr_4 with ferrocene or its derivatives showed that the ferrocene molecule forms a complex with three CBr_4 molecules.[59] The introduction of substituents into the ferrocene molecule alters the composition of

the CTC produced. Monosubstituted ferrocene derivatives form a complex incorporating two CBr_4 molecules. The introduction of substituents into both cyclopentadienyl rings alters the composition of the complex to one corresponding to the 1 : 1 ratio.

Investigation of the influence of the substituent on the position of the absorption band maximum in the electronic spectra of monosubstituted and heteroannular disubstituted ferrocene derivatives with electron-donating and electron-accepting substituents showed[4,6,11] that the shift of the long-wavelength band maximum at 440–560 nm resulting from the introduction of substituents into ferrocene is not great (3–15 nm), but it depends appreciably on the electronic character of the substituent. The 440 nm band undergoes a small hypsochromic shift in the case of electron-donating substituents and a bathochromic shift in the case of electron-accepting substituents.[6]

On the other hand, when CTC are formed, the influence of the substituents on the spectrum is much greater: the band shift amounts to 50–100 nm. The introduction of electron-accepting substituents into the ferrocene molecule causes a hypsochromic shift of the CTC band maximum, while the introduction of electron-donating (alkyl) groups results in a bathochromic shift. The greatest displacement of the CTC band maximum is observed in the electronic spectrum of the symmetrical octamethylferrocene;[10] λ_{max} for the ferrocene–CBr_4 CTC differs from λ_{max} for octamethylferrocene–CBr_4 CTC by 112 nm. All these factors permit the selection, by varying the chemical nature of the substituent in one or both cyclopentadienyl rings of ferrocene, of systems whose photosensitivities lie within a wide range in the spectrum.

The formation of CTC by ferrocene and its derivatives with tetranitromethane in methanol has been demonstrated.[64,65] The authors of both studies postulate the formation of a ferrocene-tetranitromethane CTC in accordance with the scheme

$$C_5H_5FeC_5H_5 + C(NO_2)_4 \rightarrow C_5H_5FeC_5H_5 \cdot NO_2 + C(NO_2)_3^{\cdot}.$$

It has been shown[65] that ferrocene derivatives such as vinyl-, acetyl-, 1,1'-dimethyl-, 1,1'-diethyl-, and benzoyl-ferrocenes also form CTC with nitromethane.

The photochemical reaction between ferrocene and iodine in water has been studied by flash photolysis.[66,67] It has been established that the photodissociation of the iodine molecule (I_2) is followed by the two-stage formation of ferrocenium tri-iodide:

$$C_5H_5FeC_5H_5 + I \rightarrow C_5H_5FeC_5H_5^+ I^-,$$

$$C_5H_5FeC_5H_5^+ I^- \xrightarrow{I_2} C_5H_5FeC_5H_5^+ I_3^-,$$

which proceeds much more vigorously than the recombination of iodine atoms.

The photoinitiated interaction of ferrocene with iodine in benzene has been studied by flash photolysis[68] and it has been shown that the reaction proceeds as follows:

(1) the iodine molecule initially undergoes photodissociation into atoms and an iodine-benzene CTC is formed:

$$I + C_6H_6 \rightarrow C_6H_6 \cdot I;$$

(2) this is followed by the oxidation of ferrocene with atomic iodine (or the oxidation of the iodine–benzene CTC) with formation of the ferrocenium iodide ion pair:

$$I \cdot C_6H_6 \rightarrow C_5H_5FeC_5H_5^+ I^- + C_6H_6;$$

(3) finally ferrocenium iodide reacts with another iodine molecule to form ferrocenium tri-iodide:

$$C_5H_5FeC_5H_5^+ I^- + I_2 \rightarrow C_5H_5FeC_5H_5^+ I_3^-.$$

It has been established that the last two processes have similar rates.

1. Ferrocenium Salts

Hitherto the photodecomposition of ferrocenium salts has not been studied in detail. It has been reported[58] that the photolysis of ferrocenium tetrachloroferrate in a $CCl_4 + C_2H_5OH$ mixture results in the formation of only ferrocene and a small amount of hexachloroethane owing to the recombination of the trichloromethyl radicals produced on irradiation.

The photolysis of ferrocenium chloride has been investigated[69] in aqueous acid $H_2O|CH_3OH|HCl$ media and the formation of ferrocene with a quantum yield of 0.029 was observed. In more dilute acid solutions, decomposition to inorganic iron (II) salts takes place

III. RUTHENOCENE AND OSMOCENE

In contrast to ferrocene, an emission spectrum has been observed for ruthenocene which is fairly well resolved at a low temperature. The presence in this spectrum of the $d \cdot d$ transition band at 510 nm and the ability of ruthenocene to quench excited triplet states are attributed to the presence of a triplet level in the energy spectrum of its excited molecule.[3]

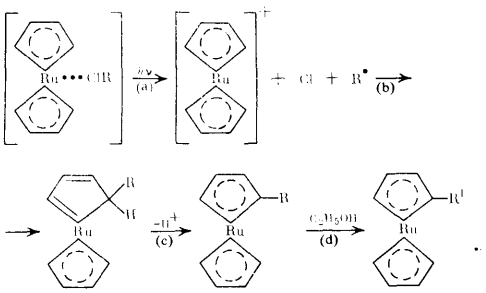
Independent studies by two groups of workers[2,70] showed that the photochemical behaviour of ruthenocene has much in common with that of ferrocene. On irradiation with light at a wavelength of 254 nm in cyclohexane, ruthenocene is inert, while in the presence of halogenohydrocarbons photolysis takes place, as for ferrocene, with the appearance of a charge-transfer band and oxidation to the ruthenocenium cation.

Thus, analogously to the photolysis of ferrocene, the process proceeds in accordance with the scheme

$$C_5H_5RuC_5H_5 + RCl \xrightarrow{h\nu} [C_5H_5RuC_5H_5]^+ Cl^- + R^{\cdot}.$$

Further irradiation leads to the appearance of turbidity in the solution and the precipitation of ruthenocenium tetrachlororuthenate. When the photolysis is carried out in the presence of acrylamide, the latter polymerises, which indicates indirectly the presence of radicals in the system. The quantum yield is high and, according to the data of different workers, assumes values ranging from 0.6 to 1. It may be that part of the ruthenocene is oxidised by a secondary reaction to ruthenocenium tetrachlororuthenate.

In later investigations, Traverso and coworkers[43] studied the photolysis of ruthenocene, benzoylruthenocene, and osmocene in the presence of tetracyanoethylene (TCE). The formation of complexes between the metallocene and TCE was then established by ultraviolet spectroscopy. Charge-transfer bands were observed at the boundary between the visible and infrared regions (720–830 nm). The authors discovered a linear relation between the position of the charge-transfer band maximum for the metallocene–TCE complexes in the electronic absorption spectrum in cyclohexane and the oxidation potential $E_{1/4}$; on this basis, they concluded that the TCE molecule is coordinated to the metal atom. In this connection the authors suggest that the difference between the energies of the two maxima on the absorption curve of the charge-transfer bands is associated with the difference between the energies of the two highest occupied orbitals of the metal. The difference between the energies of the $a_{1g}(d)$ and $e_{2g}(d)$ orbitals is 1452 cm^{-1} and corresponds to the difference between the ionisation energies obtained for the He-photoelectron spectra of ruthenocene and osmocene.[71] This result also constitutes an argument in support of the direct involvement of the metal atom in the bond with TCE, i.e. it is probable that the electron pair participating in the formation of the CTC is localised mainly at the metal.



The photolysis of the CTC involves the following processes:

$$C_5H_5MC_5H_5 \cdot TCE \xrightarrow{h\nu} [C_5H_5MC_5H_5 \cdot TCE]^* \rightarrow \begin{cases} \longrightarrow C_5H_5MC_5H_5 + TCE \\ \longrightarrow [C_5H_5MC_5H_5]^+ + TCE^{\cdot-}; \end{cases}$$

M=Ru, Os .

The quantum yield in the formation of TCE is 0.75–0.68 and is independent of the wavelength of the incident light.

Sujimori et al.[72] carried out the photochemical ethoxymethylation, formylation, and ethoxycarbonylation of ruthenocene on irradiation of the latter in alcohol in the presence of the corresponding halogenohydrocarbons; the yields amounted to 10–20%. In the case of $CHCl_3$, formylruthenocene is formed in 39–57% yield on irradiation from a light source fitted with a pyrex glass filter. The authors presented the following process mechanism:

The reaction proceeds analogously to that described above for ferrocene.

Thus the photochemistry of ruthenocene has much in common with that of ferrocene; the reactions of both metallocenes take place via two pathways: (1) the oxidation of the metallocene and (2) further reactions with formation of new C–C bonds.

IV. COBALTOCENE AND NICKELOCENE

When cobaltocene is irradiated with light at a wavelength of 254 nm, it is oxidised and the cobaltocenium cation, stable under the irradiation conditions, is formed readily.[73] This is confirmed by the possibility of the quantitative spectrophotometric determination[73] of the cobaltocenium cation in aqueous solution over a wide pH range.

Aqueous solutions of cobaltocenium salts exhibit not only light stability but also radiation stability.[74,75] It is noteworthy that the character of the ultraviolet spectra of the cobaltocenium cation remains unchanged also after prolonged heating of its aqueous solutions at 200 °C.[75] Thus the photochemical behaviour of cobaltocene differs appreciably from that of the other metallocenes.

In contrast to cobaltocene, when nickelocene is irradiated with light at a wavelength of 254 nm, a polymer is formed and the quantum yield is 0.007. The primary oxidation product (nickelocenium chloride) rapidly decomposes to Ni^{2+} and a yellow deposit of the polymer,[76] i.e. nickelocene is extremely unstable in relation to ultraviolet irradiation.

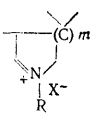
V. PRACTICAL APPLICATIONS OF METALLOCENES IN PHOTOCHEMICAL PROCESSES

Patent data on the use of ferrocene as the main component of a light-sensitive composition were published in 1965.[77–79] Apart from ferrocene, CBr_4 and tone-controlling compounds were introduced into the light-sensitive composition. On exposure to light from an incandescent lamp and subsequent thermofixation, brown-violet images were obtained.

Highly sensitive materials have been developed on the basis of ferrocene, CBr_4 and a polymeric binder.[80] Subsequent studies designed to improve the compositions based on a number of ferrocene derivatives led to the creation of a whole series of light-sensitive materials. Light-sensitive emulsions containing ferrocene derivatives, a halogenohydrocarbon, and indole have been developed. The ferrocene derivatives employed were 1,1′-diacetylferrocene, 1,1′-dipropionylferrocene, 1,1′-dibenzoylferrocene, 4-(dimethylamino)-benzoylferrocene, and ferrocenedicarboxylic acid. A characteristic feature of these emulsions is their photosensitivity in the visible region of the spectrum.[81,82] It has been established that, by introducing aromatic aldehydes[83,84] into these photosensitive emulsions, it is possible to obtain multi-coloured images. In this connection it has been stated that in the presence of aldehydes[85] a deepening of the colour of the resulting image is achieved and the image becomes more distinct; the causes of this phenomenon are not discussed in the relevant patent.

Copying materials for microfilming,[86] containing polyvinylcarbazole, ferrocene, halogenohydrocarbons, and aromatic aldehydes have been described. Light-sensitive compositions based on imidazole derivatives, halogeno-derivatives, and ferrocene have been developed in the Federal Republic of Germany.[87]

Later, as the chemistry of ferrocene developed, more complex ferrocene-containing compounds began to be introduced into light-sensitive compositions.[88] A photographic material in which an emulsion containing ferrocene derivatives having the general formula



$$X{-}C_5H_4FeC_5H_4{-}Y$$

X=CO(CH=CH)$_n$ Ar; n = 1, 2; Y=H, X

was deposited on baryta paper has been described.[89,90] An alcoholic solution of the test substance was deposited onto baryta paper and the latter was dried. The exposure was under an incandescent 500 W lamp for 5–11 min. In order to remove the unexposed sections, the emulsions were treated with solvents, which consisted of methanol or ethanol. The images obtained were predominantly of a yellowish-red colour.

It is noteworthy that water-soluble materials have also been developed on the basis of ferrocene in which the light-sensitive components were ferrocene-containing dyes[91] of the type

$$C_5H_5FeC_5H_4{-}(CH{=}CH)_{n+1}R' \quad \text{or} \quad C_5H_5FeC_5H_4{-}(CH{=}CH)_n{-}$$

R = alkyl; R′ = pyrylium salt;

X=Cl′, Br, I; n = 1–3; m = 1, 2.

When vinyl groups are introduced, a long conjugated system is created and the absorption maximum of these compounds undergoes a bathocromic shift. The dyes synthesised were used to obtain light-sensitive materials which suffered from the disadvantage of a comparatively low light-sensitivity: in order to obtain a visible image, the emulsions had to be exposed for 4–6 min under a 2000 W lamp and then heated to 150 °C.

Charge-transfer complexes based on ferrocene, vinylferrocene, and various electron acceptors, which possess light-sensitive properties, have been recommended as optical filters absorbing in the range 350–600 nm.[92]

A negative light-sensitive material, sensitive both in the ultra-violet and in the visible part of the spectrum, has been prepared from ferrocene, halogeno-derivatives, and tone-controlling compounds with addition of polystyrene dissolved in trichloroethane.[93]

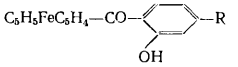
A light-sensitive composition for lithographic plates[94] has been obtained from a polymer with unsaturated ethylene groups or groups containing two or three chlorine or bromine atoms linked to one carbon atom and ferrocene derivatives (for example, thioacetylferrocene and 1,1'-dicinnamoylferrocene).

There have been a number of studies devoted to the mechanism of the intensification of the latent image in light-sensitive emulsions based on ferrocene.[95-97]

In 1971 a copying material containing the ammonium salt of ferrocenemonosulphonic acid or ferrocenedisulphonic acid or their mixture as well as a phenol residue containing the amino-, hydroxy-, or carbonyl groups in the *ortho*-position was developed in Japan in 1971.[98] A composition based on an organohalogen compound and a copolymer containing vinylferrocene and hardening on exposure to light has been patented.[99] Similar copolymers based on vinylferrocene are used in various photographic materials.[100] A patent[101] describes a positive material, sensitive to electrons and X-rays and other types of radiation, containing a copolymer of 1–30 mole % of vinylferrocene and 70–99 mole % of methacrylic acid.

A composition containing an organic halogen compound, aniline dyes, and ferrocene has been recommended for the formation of a coloured image.[102] A light-sensitive material for the formation of a black and white image by the dry method and based on ferrocene, organic dyes, and a halogeno-derivative giving rise to free radicals under the influence of light has been described.[103]

It is noteworthy that the entire patent literature contains as a rule only qualitative descriptions of light-sensitive compositions and emulsions based on them. In the literature there are virtually no physicochemical data and sensitometric and other characteristics of the materials obtained; it is therefore impossible to carry out an objective assessment of the light-sensitive characteristics of the proposed compositions or reach any conclusions about the likely usefulness of a particular composition from the standpoint of its practical applications.

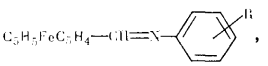


Metallocene derivatives are also used as photoconductors in electrophotography. Ferrocene, cobaltocene, and nickelocene have found the most extensive applications for these purposes.[104,105] Styrenebutadiene raw rubbers are used as binders and pyrylium salts are added as sensitisers.

The product of the condensation of formylferrocene with added organic halogeno-derivatives has been proposed for the preparation of polymeric ferrocene-containing emulsions for electrophotography.[106,107] A high-quality electrophotographic material has been obtained on the basis of polyvinylferrocene.[108] It permitted the repeated recording of an image.

When aromatic amino-derivatives, dyes, halogenohydrocarbons, and organometallic compounds[109] (ferrocene and cobaltocene) are added to a photoconductor based on polyvinylcarbazole or its brominated analogue, the photoconduction process is accelerated.[110] Thus a photoconductor containing cobaltocene can be exposed at 80 lux, while in the absence of added cobaltocene the exposure is 280 lux. It has been suggested that nickelocene be also used for these purposes.[111] A photoconducting composition suitable for the preparation of copying photoconductive emulsions based on polymeric compounds derived from formylferrocene has been obtained.[112]

It has been reported that metallocenes behave as photoinitiators in polymerisation.[113,114]



It is known that many ferrocene derivatives are capable of photostabilising various polymers.[115,116] For example, derivatives of hydroxybenzoylferrocene are used to stabilise polyolefins:[117]

R=OH, NO_2, C_2H_5, C_6H_5, $COCH_3$, COOH

Oxygen-containing,[118-120] silicon-containing,[121] and other derivatives of ferrocene[122] have been proposed as light stabilisers for polymers.

In order to improve the resistance of polyethylene to ultraviolet radiation, the oxime of acetylferrocene[123] or ferrocene-containing azomethines,[124] having the general formula

R = H, OH,

are introduced into the polymer.

The influence of ferrocene added to high-pressure polyethylene on the photodegradation of the polyethylene film has been investigated. It has been suggested that ferrocene and its derivatives catalyse the radical decomposition of the hydroperoxy-groups in polyethylene. The addition of ferrocene and its derivatives can be used to obtain materials which rapidly decompose under natural conditions.[125]

As can be seen from the foregoing, the photochemical processes involving metallocenes proceed as a rule via two pathways: either with the consumption of the metallocenes or with retention of the metallocene system and the formation of the product of substitution in the cyclopentadienyl ring. The photolysis of ferrocenium salts results in the formation of mainly ferrocene.

The photochemistry of ruthenocene has much in common with that of ferrocene. Analysis of the literature data on the photochemistry of metallocenes permits the conclusion that metallocenes containing an even total number of valence electrons are more stable, whereas those with an odd number of valence electrons are less stable.

Studies of the photochemical transformations in metallocenes are of great interest, since they make it possible to develop on the basis of these compounds materials which are finding practical applications in various systems for the recording, treatment, and replication of information.

Halogen Fluorides in Organic Synthesis

L.S. Boguslavskaya

The reactions of halogen fluorides with organic compounds are considered and the possibilities for their employment as selective fluorinating agents for the synthesis of organic mono- and poly-fluoro-compounds are discussed. The reactivities of halogen monofluorides are compared with those of their stoichiometric equivalents. The mechanisms of the reactions of halogen fluorides and their inorganic complexes are discussed.
The bibliography includes 160 references.

I. INTRODUCTION

The unusual practical value of organofluorine compounds for modern technology, medicine, and agriculture has stimulated chemists to seek continuously new and selective methods for the introduction of fluorine into an organic molecule. The endeavour to "tame" molecular fluorine, to bind it in a milder fluorinating agent, has for many years occupied the minds of chemists specialising in organofluorine chemistry. From this standpoint, halogen fluorides have attracted the attention of investigators for a long time.[1] Until recently, despite the well-developed technical methods for their synthesis and the commercial availability of some of them, these reagents have been hardly used in organic synthesis.[1-5] The idea arose that halogen fluorides are almost as corrosive as molecular fluorine[4] and therefore their applications are restricted to reactions with polyfluorinated compounds. It was difficult to expect that, being so corrosive, halogen fluorides would find applications in the controlled fluorination of polyhydro-compounds. In reactions with unsaturated polyhydro-compounds, only the stoichiometric equivalents of halogen monofluorides, namely "HalF *in situ*", obtained mainly from *N*-halogenoamides in anhydrous hydrogen fluoride, have been investigated.[4-6]

Nevertheless in recent years, preparative possibilities of halogen fluorides have been discovered and experimental data have accumulated which make it possible to regard certain halogen fluorides, particularly chlorine monofluoride, as promising selective fluorinating agents.

Chlorine monofluoride is of special interest also from the standpoint that it can be obtained and used in synthesis in two ways: gaseous ClF can be obtained from the elements and introduced into the reaction with the substrate in both non-polar and polar media; the "stoichiometric equivalents of ClF", obtained from *N*-chloroamides (or *N*-chloroamines) in HF, always react in a polar medium. Comparison of the results of these reactions permits well-founded conclusions about the mechanism of fluorination by halogen fluorides.

This review deals with the synthetic aspects of reactions involving fluorination by halogen fluorides and provides a critical survey of studies on the mechanism of these and related reactions.

II. THE SYNTHESIS AND PROPERTIES OF HALOGEN FLUORIDES

Halogen fluorides have been obtained and widely used by inorganic chemists because at one time they found applications in the atomic industry for the synthesis of uranium and other metal fluorides and also as powerful oxidants in rocket engineering.[2,3,5] Virtually all halogen fluorides have been synthesised directly from the elements. Gaseous chlorine monofluoride is obtained by passing stoichiometric amounts of chlorine and fluorine through heated copper or nickel tubes:[7-10]

$$Cl_2 + F_2 \xrightarrow{200-250^\circ} 2ClF\ .$$

The design and materials of the apparatus, the conditions of the synthesis, and the kinetics of the process have been described in detail in a monograph[2] and in recent communications.[8,10] In the laboratory, chlorine monofluoride can also be obtained by mixing theoretical amounts of chlorine trifluoride and chlorine at 350 °C [11] or by passing chlorine into a melt of alkali metal fluorides at 800–1000 °C:[12]

$$Cl_2 + MF \rightleftarrows MCl + ClF\ ;$$
$$M=K,\ Na,\ Li\ .$$

A method of synthesis of ClF by passing chlorine into a solution of SbF_5 in anhydrous HF at 35 °C has been patented.[13] Chlorine trifluoride is a low-boiling liquid and is an industrial product. The methods of its synthesis and apparatus have been described in detail.[1,2] ClF_3 is usually synthesised from chlorine monofluoride and fluorine or directly from chlorine and fluorine:

$$ClF + F_2 \xrightarrow{250-280^\circ} ClF_3\ .$$

Chlorine trifluoride is condensed, purified by fractionation, and stored in cylinders.

Chlorine pentafluoride (a low boiling liquid; at abient temperature—a gas) is difficult to obtain. It can be synthesised from chlorine trifluoride and fluorine by heating under

high pressure[14] or in quartz apparatus under ultraviolet irradiation:[15]

$$ClF_3 + F_2 \xrightarrow[250\ atm]{350^\circ} ClF_5 ;$$

$$ClF_3 + F_2 \xrightarrow[30^\circ]{h\nu} ClF_5 .$$

Bromine monofluoride is a low-boiling unstable liquid, which has been obtained from the elements at +10 °C and purified by successive condensation of the impurities.[16,17] BrF is usually contaminated with bromine and bromine polyfluorides owing to its tendency to disproportionate:[18,19]

$$Br_2 + F_2 \xrightarrow{10^\circ} 2BrF ;$$

$$3BrF \rightarrow Br_2 + BrF_3 .$$

Bromine trifluoride is a stable liquid and is manufactured industrially by passing purified fluorine into liquid bromine in copper apparatus with subsequent vacuum distillation of the product. The design of the apparatus and the technique of the synthesis have been described in detail:[1,2]

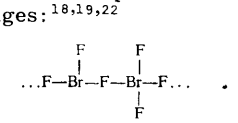
$$Br_2 + 3F_2 \xrightarrow{80^\circ} 2BrF_3 .$$

Bromine pentafluoride is an entirely stable product; it is produced industrially directly from bromine and fluorine:[1,2]

$$Br_2 + 5F_2 \xrightarrow{200^\circ} 2BrF_5 .$$

Among iodine fluorides, only IF_5 and IF_7 are stable. The methods of their synthesis from the elements have been described in detail.[1-3] Iodine pentafluoride can be obtained also from chlorine trifluoride and iodine, their interaction occurring with spontaneous combustion in accordance with the equation[2]

$$10\,ClF_3 + 3I_2 \rightarrow 6IF_5 + 5Cl_2 .$$



Iodine pentafluoride is a colourless liquid which can be stored in quartz or steel vessels.

Iodine heptafluoride is a colourless gas and has been obtained from the elements in platinum apparatus at high temperatures.[2] Iodine pentafluoride is formed initially and then absorbs fluorine under more severe conditions and is converted into IF_7:

$$I_2 + 5F_2 \rightarrow 2IF_5 ;$$

$$IF_5 + F_2 \xrightarrow{250-280^\circ} IF_7 .$$

Table 1 presents the physical properties of halogen fluorides and, for comparison, those of the molecular halogens. Halogen fluorides are polar compounds and have significant dipole moments. Chlorine and bromine monofluorides have comparatively high dissociation energies $E_d \cong 60$ kcal mol^{-1}. Hence the tendency of these interhalogen compounds to undergo heterolysis rather than homolysis is understandable. The dissociation energies of halogen polyfluorides (ClF_3, IF_7) are actually lower than that of molecular fluorine and hence one may expect their ready decomposition into free radicals. It is striking that the boiling points of halogen fluoride are significantly higher than might have been expected from their molecular weights. Their low volatility can be accounted for by the ability of these compounds to associate with formation of fluorine bridges:[18,19,22]

An important property of halogen fluoride is their amphoteric behaviour. Thus bromine trifluoride is capable of self-ionisation:[23]

$$BrF_3 \rightleftarrows BrF_2^+BrF_4^- .$$

Halogen fluorides react with Lewis acids and bases forming complex fluorine-containing cations and anions:[2,23,24]

$$XF_n + YF_m \rightarrow XF_{n-1}^+YF_{m+1}^- ;$$

$$XF_n + MF \rightarrow M^+XF_{n+1}^- .$$

Compounds of this type are interesting because they can be used as fluorinating agents, which are frequently more convenient to handle than the halogen fluorides themselves.

Table 1. The physical properties of the halogens and halogen fluorides.[2,5,20,21]

III. THE REACTIONS OF BROMINE AND IODINE MONOFLUORIDES

Bromine and iodine monofluorides are unstable compounds and have therefore been little studied as such in organic synthesis, although the reactions of their stoichiometric equivalents "BrF" and "IF" have been studied quite widely.

1. The Reactions of the Stoichiometric Equivalents "BrF" and "IF"

The *N*-bromoamide or *N*-iodoamide–anhydrous hydrogen fluoride systems[4,6] and more rarely the molecular halogens Br_2 or I_2 in anhydrous hydrogen fluoride[25-27] as well as Br_2–AgF [28,29] constitute the stoichiometric equivalents of BrF and IF. As will be shown below, this does not by any means imply that bromine and iodine monofluorides are actually formed in such systems. *N*-Halogenoamides of molecular halogens are sources of the electrophilic halogen, while HF or AgF provide the nucleophile—the fluoride anion.

In essence, the only application of these systems involves the addition of BrF and IF to a multiple bond. As a rule, halogenofluorination proceeds under mild conditions—at temperatures ranging from −80 °C to room temperature.[4,30] Electron-donating substituents at the multiple bond accelerate while electron-accepting substituents retard their reaction.[31] The halogenofluorination by such systems is a typical electrophilic addition reaction:

A multiplicity of preparative modifications of halogenofluorination depending on the type of unsaturated compound and the source of the electrophilic halogen are known. Oxygen-containing solvents, namely ether and tetrahydrofuran,[4,30] 70 : 30 HF-pyridine,[25,26,32] or anhydrous HF without a solvent[31] are used. The application of oxygen-containing solvents is not always desirable, since they can participate in the addition reaction as nucleophiles.[33,34] Halogenofluorination in a hydrogen fluoride–pyridine mixture gives fairly satisfactory yields in the case of phenylolefins.[25,26,32,35,36] Electrophilic halogenation of the aromatic ring does not then occur. The influence of substituents at the multiple bond on the regiospecificity and stereochemistry of the bromofluorination has been thoroughly investigated (Table 2).

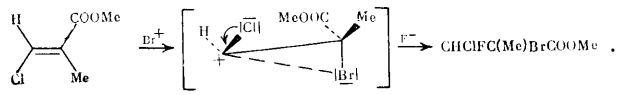
*The content of the *anti*-adduct.
**The *Z*-isomer is partly converted into the *E*-isomer during synthesis.

On the whole, the mode of addition of the electrophile and nucleophile expected for an electrophilic mechanism is observed. Since unsaturated compounds with electron-deficient multiple bonds, which usually react with the halogens via a free-radical mechanism, can be introduced into the bromofluorination reaction, it is of interest to compare the competing influences of the substituents on the mode of addition and the stereochemical characteristics of the bromofluorination.

The bromofluorination of 1,3-dichloroprop-1-enes (Table 2, Nos. 5 and 6) proceeds regiospecifically in such a way that the electrophilic bromine is directed to the central carbon atom, while the nucleophile F^- ion is directed to the terminal carbon atom:

$$CHCl=CHCH_2Cl \xrightarrow[HF]{>NBr} CHClFCHBrCH_2Cl .$$



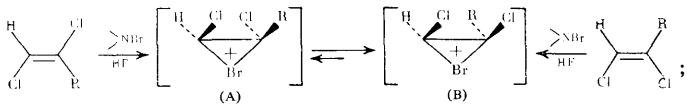
The chlorine atom attached to the multiple bond behaves as a *p*-donor and fully controls the mode of addition. The introduction into the 2-position of 1,3-dichloropropene of substituents delocalising the positive charge of the carbonium ion completely alters the mode of addition—the electrophile is directed to the terminal carbon atom, while the nucleophile goes to the central carbon atom (Table 2, Nos. 7–12):

$$CHCl=CRCH_2Cl \xrightarrow[HF]{>NBr} CHClBrCRFCH_2Cl ;$$

$$R=CH_3,\ Cl,\ F .$$

Overall, the CH_2Cl and CH_3, F, or Cl substituents exhibit a more powerful directing effect than the chlorine atom.

An analogous effect has been observed in the bromofluorination of acrylates. Methyl acrylate is brominated almost entirely contrary to the Markovnikov rule (Table 2, No. 13), while methyl methacrylate is brominated in accordance with the Markovnikov rule (Table 2, No. 14). *p*-Donor substituents have a significantly greater stabilising influence on the intermediate carbonium ion than the CH_3 group. This is readily seen in relation to the bromofluorination of the methyl esters of α-R-β-chloroacrylic acids (Table 2, Nos. 15–17):

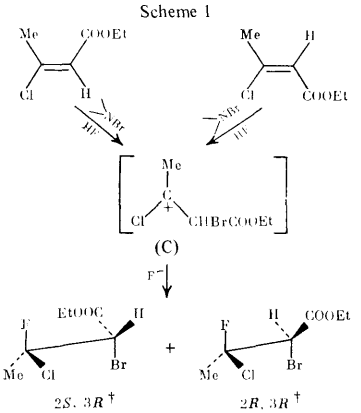


In the methyl ester of *E*-α-chloro-β-methylacrylic acid (Table 2, No. 15) the chlorine substituent fully controls the mode of addition—the reaction is regiospecific. The bromofluorination of the double bond in the methyl esters of αβ-dihalogenoacrylic acids is non-regiospecific (Table 2, Nos. 16 and 17). The phenyl group as the π-donor is a significantly more effective directing group than the halogen as the *p*-donor (Table 2, Nos. 29 and 30): the phenyl group controls the addition of BrF to 1-bromo-2-phenylethylenes:

$$CHBr=CHPh \xrightarrow[HF]{>NBr} CHBr_2CHFPh .$$

The bromofluorination of multiple bonds takes place mainly stereospecifically as an *anti*-addition reaction. In a number of instances (Table 2, Nos. 2, 3, 32, 34, and 36) this has been demonstrated reliably by the stereospecific dehydrobromination of the diastereoisomers obtained to the corresponding fluoro-olefins. The observed discrepancies, namely incomplete *anti*-stereospecificity (Table 2, Nos. 3, 10, 18, 19, 31, and 33) or *syn*-addition (Table 2, No. 36), can be convincingly accounted for by taking into account the known conditions governing the stability of bridged bromonium and open-chain carbenium ions, which are evidently intermediates in bromofluorination in hydrogen fluoride. The complete *anti*-stereospecificity of the addition of BrF to *E*-1,2-dichloroethylene and *E*-1,2,3-trichloropropene (Table 2, Nos. 3 and 10) can be explained by the fact that the bromonium ions (A) with transoid chlorine atoms are less stable than

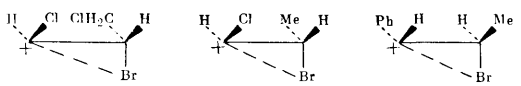
the ions (B) with cisoid chlorine atoms, just as *trans*-dihalogenoethylenes are less stable than *cis*-dihalogenoethylenes:[42,43]



(A) (B)

R = H, CH_2Cl.

Because of this factor, the partial rearrangement of the ion (A) to the ion (B) takes place. For this reason, the bromofluorination of *Z*-olefins is fully *anti*-stereospecific (Table 2, Nos.2 and 9), while the bromofluorination of *E*-olefins (Table 2, Nos.3 and 10) is only stereoselective (85 and 60% of the *anti*-adducts respectively). The non-stereospecific addition of BrF to the ethyl esters of *E*- and *Z*-β-chlorocrotonic acids (Table 2, Nos.17 and 18) can be accounted for by other causes[41] (Scheme 1). The addition of electrophilic bromine to the double bond in β-chlorocrotonates results in the formation of an intermediate which is in essence not a bromonium ion but an open-chain carbenium ion (C). This is promoted by the two geminal substituents (the methyl group and the chlorine atom) at the carbonium ion centre, which stabilise carbonium ions, and by the electron-accepting alkoxycarbonyl group at the vicinal carbon atom. As a result, the reaction is regiospecific and non-stereospecific.



Scheme 1

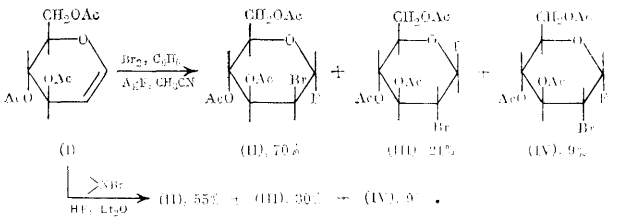
(C)

2*S*, 3*R*† 2*R*, 3*R*†

However, the examples in Table 2 (compounds Nos.5, 6, 14, 32, and 37–42) show that even a weak *p*-bridge bond in the asymmetric bromonium ions (D), (E), and (F) is sufficient for the fully regiospecific reaction to proceed as an *anti*-stereospecific process.

(D) (E) (F)

The deviations of the bromofluorination of phenylethylenes from *anti*-stereospecificity (Table 2, Nos.31, 33, and 35) are associated with the fact that during the reaction *cis*-olefins isomerise to the more stable *trans*-olefins.[35] In the case of the sterically very greatly hindered *cis*-1-t-butyl-2-phenylethylene, *syn*-addition is observed exclusively.



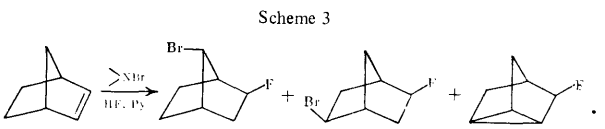
† One enantiomer is shown in Scheme 1 for each diastereoisomer. Owing to the incorrect designation of the sequence of substituents in terms of priority, in the original communications[31,41] incorrect names in terms of the *R*,*S*-system are given under the corresponding perspective formulae.

It has been reported[44–47] that cyclic unsaturated sugars, namely acetylated glucals, are iodofluorinated and bromofluorinated by *N*-iodo- and *N*-bromo-succinimide in hydrogen fluoride with formation of *syn*-adducts. In a later study[28] it was shown with the aid of ^1H and ^{19}F NMR that these reactions proceed predominantly as *anti*-addition and that the assignment of the configurations of the halogenated sugars in earlier studies[44–47] was incorrect.

A system containing a molecular halogen (Br_2, I_2), finely ground silver fluoride, and benzene or its mixture with acetonitrile as the solvent has been recommended[28,29,48] for the successful halogenofluorination of unsaturated sugars and other compounds which readily polymerise or rearrange in hydrogen fluoride.

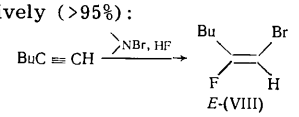
On treatment with both Br_2–AgF and *N*-bromosuccinimide in hydrogen fluoride, *anti*-adducts are formed from the glucal triacetate (I) (Scheme 2)—2-bromo-2-deoxy-α-D-mannosyl fluoride triacetate (II) and 2-bromo-2-deoxy-α-D-glucopyranosyl fluoride triacetate (III), together with a small amount of the *syn*-adduct, namely the β-anomer (IV).[28,29]

Scheme 2



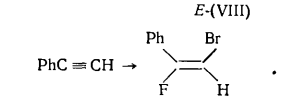
(I) (II), 70% (III), 21% (IV), 9%

(II), 55% + (III), 30% + (IV), 9%

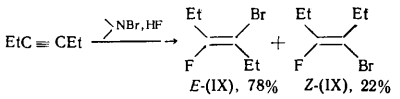


The bromofluorination of norbornene and related compounds by *N*-bromosuccinimide and hydrogen fluoride in ether or pyridine is accompanied by the Wagner–Meerwein rearrangement.[25,49–51] Norbornene gives rise to three main products (Scheme 3): 7-*anti*-bromo-2-*exo*-fluoronorbornane (V), 5-*exo*-bromo-2-*exo*-fluoronorbornane (VI), and 3-fluoronortricyclene (VII).

Scheme 3

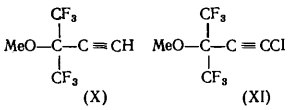


(V), 37% (VI), 35% (VII), 20%



The regiospecificity and stereochemistry of the bromofluorination of substituted acetylenes by *N*-bromoacetamide in anhydrous hydrogen fluoride has been investigated.[52] Vicinally substituted bromofluoroalkenes can be obtained with the aid of this reaction in satisfactory yields, but treatment of substituted acetylenes with the Br_2–AgF system resulted in the formation of bromination products only. The bromofluorination of terminal acetylenes takes place regiospecifically in conformity with the Markovnikov rule and *anti*-stereoselectively (>95%):

E-(VIII)



The product of the bromofluorination of hex-1-yne, namely *E*-1-bromo-2-fluorohex-1-ene (VIII), gradually isomerises on storage to the thermodynamically more favourable *Z*-isomer; a 60 : 40 mixture of the *E*- and *Z*-isomers of compound (VIII) is formed after one month, which indicates the kinetic control of the bromofluorination of hex-1-yne. Hex-3-yne is bromofluorinated non-stereospecifically with formation of 78% of the *anti*-adduct and 22% of the *syn*-adduct (IX):

E-(IX), 78% *Z*-(IX), 22%

The mixture of the bromofluoroadducts (IX) does not undergo a change in composition on storage for 15 months.

1,4-Dichlorobut-2-yne gives rise to only one bromofluoroadduct, probably as a result of the *anti*-addition, but the configuration of the resulting 2-bromo-1,4-dichloro-3-fluorobut-2-ene has not been demonstrated.[52] The influence of the structure of acetylenes on the ease of their bromofluorination has been noted: the halogenoacetylenes (X) and (XI) are not bromofluorinated at all under these conditions:

(X) (XI)

The observed facts show that the intermediates in the bromofluorination of acetylenes have the character of oriented π-complexes which differ from the classical carbonium ions; otherwise a lower stereospecificity would have been expected.

It has been reported that the iodofluorination of 1-phenylalk-1-ynes by methyl iodide difluoride (CH_3IF_2) takes place as *syn*-addition.[53]

2. Fluorination by Bromine and Iodine Monofluorides

Mixtures of stoichiometric amounts of bromine trifluoride and molecular bromine or of iodine pentafluoride and molecular iodine have been used as sources of bromine and iodine fluorides in reactions involving addition to perfluoro- and chlorofluoro-olefins[54–58] and also to alkyl perfluoroalkenyl ethers:[57]

$$BrF_3 + Br_2 \rightleftarrows 3BrF \ ;$$
$$IF_5 + 2I_2 \rightleftarrows 5IF \ .$$

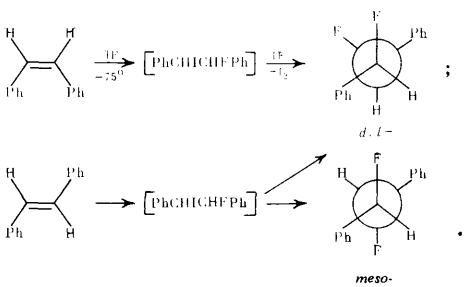
Evidence has been obtained that BrF is indeed formed in a mixture of bromine trifluoride and bromine.[59] The reactions of these systems with olefins have been achieved in steel apparatus in the temperature range from 20° to 150–170 °C. The corresponding adducts have been obtained in most cases in exceptionally high yields. The mode of addition of IF and BrF to certain olefins indicates an electrophilic mechanism of the reaction:[54–57]

$$CF_2{=}CH_2 \xrightarrow[100°]{IF_5-I_2} \underset{86\%}{CF_3CH_2} \ ;$$
$$CF_2{=}CFCF_3 \xrightarrow[20°]{BrF_3-Br_2} \underset{46\%}{(CF_3)_2CFBr} \ ;$$
$$(CF_3)_2CFCF{=}CFCF_3 \xrightarrow[40-50°]{BrF_3-Br_2} \underset{29\%}{(CF_3)_2CFCF_2CFBrCF_3} + \underset{29\%}{(CF_3)_2CFCFBrCF_2CF_3} \ ;$$
$$(CF_3)_2C{=}CFOMe \xrightarrow[0°]{BrF_3-Br_2} \underset{43\%}{(CF_3)_2CBrCF_2OMe} \ .$$

The interaction of ethyl perfluoroalkenyl ethers with the BrF_3–Br_2 system involves the substitution of the α-hydrogen atom in the ethyl group by fluorine together with the addition of BrF to the double bond:[57]

$$(CF_3)_2C{=}CFOEt \xrightarrow[60°]{BrF_3-Br_2} \underset{28\%}{(CF_3)_2CBrCF_2OCHFMe} \ .$$

The BrF_3–Br_2 system has been used for the substitutional fluorination of bromopolyfluoroalkanes.[60] The gradual addition of a solution of the bromofluoroalkane in molecular bromine to a mixture of BrF_3 with bromine at 0–50 °C leads to substitution products in a high yield:



$$CF_3CHBr_2 \xrightarrow[25-35°]{BrF_3-Br_2} \underset{92\%}{CF_3CHBrF} + \underset{5\%}{CF_3CHF_2} \ ;$$
$$CF_2BrCHBr_2 \rightarrow \underset{77\%}{CF_3CHBrF} \ ;$$
$$CF_2BrCBr_3 \rightarrow \underset{79\%}{CF_2BrCFBr_2} + \underset{4\%}{CF_2BrCF_2Br} \ .$$

A possible mechanism has been proposed for the substitutional fluorination taking into account the tendency of bromine to undergo self-ionisation:

$$2BrF_3 \rightarrow BrF_2^+BrF_4^- \ ;$$
$$-\overset{|}{\underset{|}{C}}Br + BrF_2^+ \rightarrow \left[-\overset{|}{\underset{|}{C}}{}^{\delta+} \cdots Br^{\delta-} \cdots Br^{\delta+}\begin{matrix}F\\F\end{matrix}\right] \rightarrow -\overset{|}{\underset{|}{C}}{}^{+} + Br_2F_2 \ ;$$
$$-\overset{|}{\underset{|}{C}}{}^{+} + BrF_4^- \rightarrow -\overset{|}{\underset{|}{C}}F + BrF_3 \ .$$

Since chlorine monofluoride readily enters into an analogous fluorination reaction in a non-polar medium (see below), it is extremely likely that a molecule of bromine monofluoride participates in the electrophilic debromofluorination.

In a recently published study[61] iodine monofluoride was obtained by passing molecular fluorine diluted with nitrogen into a solution of iodine in trichlorofluoromethane (Freon) at −75 °C. By adding olefins to the resulting cold IF solution in Freon, fluoroiodoalkanes were synthesised in satisfactory yields. 2-Fluoro-1-iodo-octane (70%), *trans*-1-fluoro-2-iodocyclohexane (64%), etc. have been obtained by this method. The iodofluorination of *cis*- and *trans*-stilbenes by this procedure is accompanied by further substitution of the iodine in the fluoroiodoadducts by fluorine. The unusual stereochemistry of these reactions has been noted: only *dl*-1,2-difluoro-1,2-diphenylethane has been obtained from *cis*-stilbene, while *trans*-stilbene gave rise to a mixture of the *meso*- and *dl*-diastereoisomers in proportions of 1 : 1:

IV. THE REACTIONS OF CHLORINE MONOFLUORIDE

Chlorine monofluoride is the only gaseous reagent among all the halogen fluorides which is stable under the usual conditions and is therefore the most convenient. ClF can be readily obtained from the molecular halogens (see Section II) and can be immediately brought into contact with the organic substrate in rigorously controlled amounts, which makes it possible to regulate the process. In recent years this reagent has attracted the continuous attention of chemists concerned with organofluorine chemistry, as shown by a recently published review.[62] The data obtained after the publication of this review illustrate the new possibilities for chlorine monofluoride in the fluorination of organic compounds and make it possible to consider certain general theoretical aspects of the reactions of electrophiles.

1. The Reactions of the Stoichiometric Equivalents "ClF"

The *N*-chloroamide–HF,[25] the hexachloromelamine–HF,[63] or the molecular chlorine–HF [63,64] systems serve as sources of "ClF". It has been reported that, in the presence of boron trifluoride, methyl hypochlorite is also capable of chlorofluorinating unsaturated compounds.[65] The conditions under which the reactions involving the chlorofluorination of unsaturated compounds take place differ little from the bromofluorination conditions; depending on the type of substrate, the reactant ratio, and the solvent, the yields attained (with respect to the initial alkene) are 30–80%.[25–27, 31,37,41,66–75] The regiospecificity and stereochemistry of the chlorofluorination of substituted olefins by the hexachloromelamine–HF system have been studied in greatest detail (Table 3).

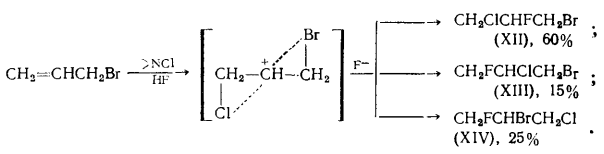

Table 3. The regiospecificity and stereochemistry of the chlorofluorination of substituted olefins by hexachloromelamine in anhydrous hydrogen fluoride.

*The content of the *anti*-adduct.
**The *E*-isomer is partly converted into the *Z*-isomer during synthesis.

As in the bromofluorination reactions, the expected regiospecificity and stereospecificity of the electrophilic addition of ClF to multiple bonds has been observed (cf. Table 2). Thus allyl alcohol and its derivatives are chlorofluorinated non-regiospecifically (Table 3, Nos.2–5). Derivatives of allyl alcohol give rise to 60–70% of adducts in conformity with the Markovnikov rule and to 30–40% of adducts contrary to the Markovnikov rule. The extensive migration of bromine from the allyl position to the central carbon atom [adduct (XIV), Scheme 4] has been demonstrated in relation to allyl bromide:

Scheme 4

The introduction of carbonium ion-stabilising substituents in the 2-position in the propene system (Table 3, Nos.6–9) makes the chlorofluorination reaction regiospecific and makes it conform to the Markovnikov rule:

$$CH_2{=}CHalCH_2X \xrightarrow[HF]{>NCl} CH_2ClCHalFCH_2X\ ;$$

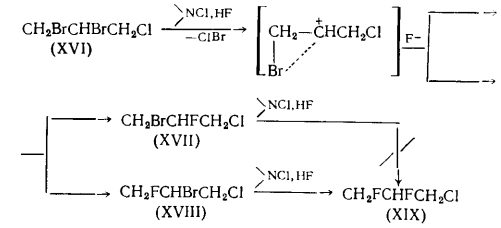
Hal=Cl, F, X=OH, Cl .

An analogous influence of the substituents is manifested in the chlorofluorination of methyl acrylate and its α-substituted derivatives (Table 3, Nos.15–18). The chlorofluorination of *E*- and *Z*-1,3-dichloropropenes is regiospecific and to a high degree *anti*-stereoselective (93–100%) (Table 2, Nos.10 and 11). As in the bromofluorination of these alkenes, the chlorine atom at the double bond controls the mode of addition: electrophilic chlorine is directed to the central carbon atom, while the fluoride anion is directed to the terminal carbon atom. Compound Nos.19 and 21 (Table 3) show that other regioselective chlorofluorination reactions can also be *anti*-stereospecific. The electrophilic chlorofluorination of the methyl esters of *E*- and *Z*-β-chlorocrotonic acids (Table 3, Nos.22 and 23) takes place non-stereospecifically due to the cause already considered (Scheme 1).

The substitution fluorination of certain organic bromo-derivatives can be achieved with the aid of systems consisting of compounds with an active chlorine atom and anhydrous hydrogen fluoride at temperatures between −10° and +10 °C.[76] Compounds with both N–Cl and O–Cl bonds are suitable as sources of electrophilic chlorine, for example, hexachloromelamine, trichloroisocyanuric acid, and trifluoroacetyl hypochlorite:

$$-\overset{|}{\underset{|}{C}}Br + >NCl + HF \rightarrow -\overset{|}{\underset{|}{C}}F + >NH + BrCl$$

(–OCl) (–OH)



N-Bromosuccinimide does not enter into this reaction. For successful fluorination, it is essential that either the reagent or the substrate should dissolve readily in anhydrous hydrogen fluoride. The best results (yield of fluoro-derivatives 50–70%) have been obtained with polyhalogenoalkanes containing bromine atoms at a secondary or tertiary carbon atom. The substitutional fluorination of 1,2-dibromo-3-chloroisobutane by the hexachloromelamine–hydrogen fluoride system, in which one equivalent of >NCl acts on one mole of the alkane, yields exclusively 1-bromo-3-chloro-2-fluoroisobutane (XV):

$$BrCH_2\underset{Me}{C}BrCH_2Cl \xrightarrow[HF]{>NCl} \left[BrCH_2\overset{+}{\underset{Me}{C}}CH_2Cl\right] \xrightarrow{F^-} BrCH_2\underset{Me}{C}FCH_2Cl$$

(XV)

On treatment with an excess of the electrophile, the primary bromine atom in the alkane (XV) is not substituted by fluorine. Evidently, the rate-determining stage in the substitution reaction is the electrophilic debromination of the substrate with formation of an intermediate carbonium ion, which is stabilised by capturing a fluoride ion. The substitutional fluorination by these systems does not always proceed regioselectively. Vicinal dibromides can give rise to both isomeric fluoro-derivatives, probably as a consequence of the formation of bridges bromonium intermediates (Scheme 5):

Scheme 5

On treatment of 1,2-dibromo-3-chloropropane (XVI) with one equivalent of hexachloromelamine in hydrogen fluoride, a mixture of the isomeric monofluorides (XVII) and (XVIII) was obtained in proportions of 3 : 1 in an overall yield of 60%. On treatment with an excess of the electrophile, the secondary bromide (XVIII) is converted preferentially into the chlorodifluoropropane (XIX). It is evident from the examples of the substitutional fluorination reactions presented here that the chlorine atoms in the molecule are not involved.

This fact shows unambiguously that chlorine monofluoride is not formed as such in the $\rangle$NCl–HF systems. As will be shown below, ClF readily substitutes bromine in primary bromides of the type of compounds (XV) and (XVII), while in anhydrous hydrogen fluoride it substitutes chlorine in primary chloro-derivatives.

2. Chlorination with Chlorine Monofluoride

Chlorine monofluoride readily reacts with both organic and inorganic hydroxy-compounds and some of their derivatives, forming the corresponding hypochlorites in accordance with the general mechanism[77–86]

$$ROH + ClF \rightarrow ROCl + HF .$$

Such processes usually proceed extremely vigorously with evolution of much heat; the final products (hypochlorites) are explosive. Caution must therefore be exercised in carrying out these reactions: the reagent must be introduced gradually, inert solvents must be employed, and the temperature must be rigorously controlled. Chlorine nitrate,[77,78] perfluoroalkyl hypochlorites,[79–81] CF_3OOCl,[82,83] acyl hypochlorites,[84,85] and chlorine trifluoromethanesulphonate[81,86] have been synthesised in this way in high yields. The above compounds have been used in subsequent syntheses as effective electrophiles.[62] ClF reacts with water in a more complex manner, forming $ClFO_2$, Cl_2, O_2, and HF.[87]

Chlorine monofluoride chlorinates aromatic compounds—benzene, chlorobenzene, and even nitrobenzene.[88] The *o*- and *p*-derivatives have been obtained from chlorobenzene and toluene in proportions of 2 : 1, while *m*-chloronitrobenzene has been synthesised from nitrobenzene.

3. The Addition of Chlorine Monofluoride to Multiple Bonds

Chlorine monofluoride adds to the heteroatomic multiple bonds C≡N,[89] N≡S,[90] S=O,[91,92] S=N,[93] C=N,[94–97] and C=O.[79,98–100] In certain cases such addition proceeds in the absence of catalysts. For example, sulphur trioxide readily interacts with ClF, forming chlorine fluorosulphate:

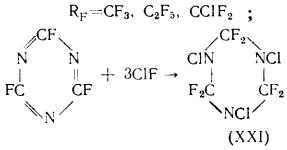
$$SO_3 + ClF \rightarrow ClOSO_2F .$$

Carbonyl fluoride reacts with ClF only in the presence of catalysts—Lewis acids or bases, forming trifluoromethyl hypochlorite:

$$COF_2 + ClF \xrightarrow{CsF} CF_3OCl .$$

The fluorides of carboxylic perfluoro-acids react with ClF in the presence of CsF. It has been suggested that caesium perfluoroalkoxide is formed initially and is then converted into the corresponding hypochlorite with regeneration of CsF:

$$R_FC(=O)F + CsF \rightarrow R_FCF_2OCs ;$$
$$R_FCF_2OCs + ClF \rightarrow R_FCF_2OCl + CsF .$$



Chlorine monofluoride activated by hydrogen fluoride adds to the carbonyl group of perfluoroketones. In this case the action of the catalyst is apparently directed to ClF and not the substrate:

$$ClF + HF \rightarrow Cl^+ \rightarrow Cl^+HF_2^- ;$$
$$R_F{}_2C{=}O + Cl^+HF_2^- \rightarrow \left[R_F{}_2C^+{-}OCl\right]HF_2^- \rightarrow R_F{}_2CFOCl + HF .$$

The nitriles of carboxylic perfluoroacids and cyanuric fluoride combine with ClF via their –C≡N and C=N bonds, the corresponding adducts being formed in high yields (70 to 90%):[101,102]

$$R_FC{\equiv}N + 2ClF \xrightarrow{-78-0^\circ} R_FCF_2NCl_2 ;$$
(XX)

R_F = CF_3, C_2F_5, $CClF_2$;

(XXI)

The chlorofluoroadducts, namely the *N*-chloroamines (XX) and (XXI), are themselves mild fluorinating agents.[102] Chlorocyanogen also combines with two moles of ClF and the resulting chloroamine is dechlorinated during the reaction to give the corresponding *N*-chloroimines:[103]

$$ClCN + 2ClF \rightarrow CF_2ClNCl_2 \rightarrow CF_2{=}NCl + Cl_2 .$$

Fluorinated isocyanates readily combine with ClF at room temperature:[95]

$$R_FN{=}C{=}O + ClF \rightarrow R_FNClC(=O)F ;$$
(XXII)

R_F = CF_3, CF_3CO, FCO, Cl .

Derivatives of *N*-chlorocarbamic acid (XXII) are formed in yields of 75–90%. The fluoroketone *N*-perfluoroacylimines,[104] *N*-halogenoimines,[96] and *N*-perfluoroalkylimines[70,89,97] react analogously with ClF. Chlorine monofluoride diluted with nitrogen, under conditions where the substrate is highly diluted with an inert solvent (CCl_4, 15–20 : 1 by volume), readily adds even to butadiene and styrene.[105,106] The addition of ClF to halogeno-olefins and certain derivatives of αβ-unsaturated carboxylic acids (esters and acid chlorides) takes place in solvents (CCl_4, CCl_2FCF_2Cl, $CHCl_3$) at room temperature without preliminary dilution of the reagent with an inert gas. The chlorofluoroadducts have been obtained in satisfactory yields and in a number of instances in very high yields (50–90%).[107,108]

The regiospecificity and stereochemistry of the chlorofluorination of substituted olefins by chlorine monofluoride in a non-polar medium and in anhydrous hydrogen fluoride have been investigated (Table 4).

The mode of addition of ClF to the double bonds of substituted alkenes depends on the substituents and the medium. Vinyl chloride and trichloroethylene are chlorofluorinated in Freon-113 in conformity with the Markovnikov rule (Table 4, Nos.1 and 4). The chlorofluorination of vinylidene chloride under the same conditions gives rise to 12% of the adduct formed contrary to the Markovnikov rule (Table 4, No.3) and is to a large extent accompanied by the elimination of a proton and the formation of trichloroethylene:

$$CH_2{=}CCl_2 \xrightarrow[\text{Freon, } 20-30^\circ]{ClF} \left[CH_2{-}\overset{+}{C}Cl_2 \leftrightarrow CH_2{=}CCl_2{}^+\right] \xrightarrow{F^-} CH_2ClCCl_2F + CH_2FCCl_3 ;$$
$$\xrightarrow{-H^+} CHCl{=}CCl_2 .$$

The chlorofluorination of allyl derivatives both in a non-polar medium and in hydrogen fluoride takes place non-regiospecifically (Table 4, Nos.6–10): adducts formed in conformity with the Markovnikov rule predominate in the mixture of isomers (60–70%) regardless of the type of allyl substituent.

Table 4. The regiospecificity and stereochemistry of the chlorofluorination of substituted alkenes by an equimolar amount of chlorine monofluoride (reaction carried out in $CHCl_3$ or $CF_2ClCFCl_2$*; the data for the reaction in HF are given in brackets**).

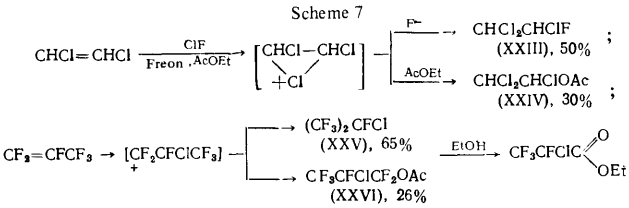
*15% (by volume) of alkene in chloroform or Freon.

**50% (by volume) of alkene in anhydrous HF.

***The halogenoalkenes are insoluble in liquid HF and their chlorofluorination in this medium was not therefore investigated.



****A 2–10-fold excess of ClF was passed into a solution of the alkene in Freon.

*****The reaction is non-stereospecific and the configuration of the diastereoisomeric adducts was not determined. The ratio of the diastereoisomers is given; it is seen from the figures quoted that one diastereoisomer predominates in a non-polar medium and the other in hydrogen fluoride.

The chlorofluorination of allyl bromide involves the migration of bromine from the allyl position to the central carbon atom; the ratio of the regioisomers (XII)–(XIV) is the same as in the coupled chlorofluorination by the hexachloromelamine–hydrogen fluoride system (see Scheme 4). The addition of ClF to Z- and E-1,3-dichloropropenes (Table 4, Nos.11 and 12) takes place regioselectively (98% of the Z-isomer and 80% of the E-isomer, in contrast to the complete regiospecificity in the coupled chlorofluorination of these olefins—cf. Nos.10 and 11 in Table 3) and *anti*-stereoselectively.

The electrophilic mechanism of the chlorofluorination of polyhalogenoalkenes, including tetrachloroethylene and perfluoropropene, by chlorine monofluoride in non-polar media has been confirmed by the involvement of an external nucleophile—ethyl acetate:[10] the chlorofluorination of dichloroethylene and perfluoropropene in Freon in the presence of ethyl acetate afforded up to 30% of the acetates (XXIV) and (XXVI) together with the chlorofluoroadducts (XXIII) and (XXV) (Scheme 7):

Scheme 7

The regio- and stereo-specificities are markedly different in the reactions of the esters of αβ-unsaturated carboxylic acids with ClF in a non-polar medium and in liquid hydrogen fluoride (Table 4, Nos.16–28). Methyl acrylate (Table 4, No.16) gives rise to regioisomers in proportions of 1 : 2.5 in $CHCl_3$ and 1 : 10 in HF, while for methyl methacrylate (Table 4, No.19) the corresponding ratios are 1 : 1 and 19 : 1. Nevertheless, these unsaturated compounds react with ClF via an electrophilic mechanism in both media: the reactions are extremely fast and, together with chlorofluoroadducts, give rise to products resulting from the involvement of the external nucleophile—acyloxychloroadducts.[107]

Dimethyl maleate and dimethyl fumarate readily combine with ClF in both $CHCl_3$ and HF. The addition takes place *anti*-stereospecifically in both media, which also indicates an electrophilic mechanism.

The esters of αβ-unsaturated acids containing more than two electron-accepting substituents at the multiple bond are smoothly chlorofluorinated only by the ClF–HF system (Table 4, Nos.20–23 and 26–28). The reactions in the instances investigated have been non-stereospecific. In order to complete the reactions of unsaturated esters containing electron-deficient multiple bonds, an excess of the reagent is required in a non-polar medium and the stereochemical result is completely different from that in HF (Table 4, Nos.26–28).

Chlorine monofluoride activated by hydrogen fluoride is an extremely effective electrophilic addend. No multiple bonds incapable of homophase chlorofluorination by this system for electronic or steric reasons have been found. Methyl perfluoromethacrylate, for which no electrophilic addition reactions had been known,[110] interacts smoothly with the stoichiometric amount of ClF in hydrogen fluoride.

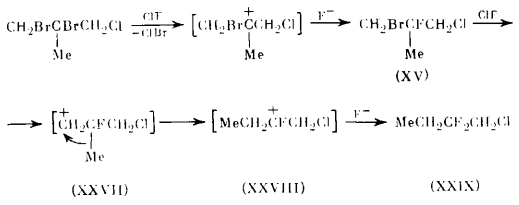
4. Substitution of the Halogens in Organic Halogenoderivatives by Fluorine

Chlorine monofluoride is an active agent for the selective substitutional fluorination of bromoalkanes and bromoesters. The reaction takes place when a stoichiometric amount of gaseous ClF is passed through a liquid bromoalkane or a solution of a bromoalkane in a suitable inert solvent (CCl_4, $CFCl_2$, $CFCl_2$) at temperatures between −50° and 50 °C.[111,112] Under these conditions, the chlorine atoms and alkoxycarbonyl groups in the substrate molecule are not involved. The yields are exceptionally high in most cases. Chlorine monofluoride abstracts a bromide anion from the organic substrate with formation of bromine monochloride and the

corresponding carbonium ion, which is stabilised by capturing a fluoride anion:

$$RBr + ClF \rightarrow ClBr + [R^+] \xrightarrow{F^-} RF .$$

The bromine monochloride evolved makes the reaction conditions milder, diminishing the risk of combustion of the polyhydro-substrate on contact with ClF. Naturally, for this mechanism of the substitution of bromine by fluorine, the usual bromide reactivity series is observed: tertiary > secondary > primary.



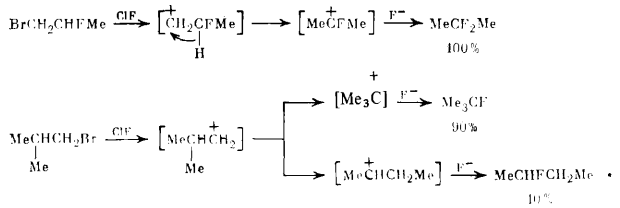
The most favourable conditions for the substitutional fluorination of bromo-derivatives obtain at temperatures in excess of 0–10 °C. At these temperatures, chlorine monofluoride debrominates almost any bromo-derivative with the exception of compounds of the type of R_FCF_2Br and RCHBrCOOR'.

At low temperatures (between −20° and −50 °C) in the case of unreactive substrates, the bromine monochloride evolved enters into a competing reaction with ClF, forming bromine trifluoride (T_m = 9 °C), which is frozen out from the reaction mixture. On fusion, BrF_3 reacts vigorously with the substrate. The reaction becomes uncontrollably explosive even with CCl_4. At temperatures in the range 20–40 °C almost the entire bromo-derivative reacts with ClF smoothly and selectively, giving rise to the corresponding fluorides.[112]

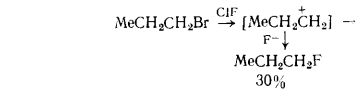
The high selectivity of the substitutional fluorination can be seen from the following example (Scheme 8).

When 1,2-dibromo-3-chloroisobutane is acted upon by one mole of ClF, the tertiary fluoride (XV) is formed regioselectively; the abstraction of the primary bromine atom on treatment with a second mole of ClF also takes place readily and is accompanied by the migration of the methyl group in the carbonium ion (XXVII). This results in the formation of the more stable α-fluorocarbonium ion (XXVIII), which captures a fluoride anion and gives rise to the geminal difluoride (XXIX):

Scheme 8

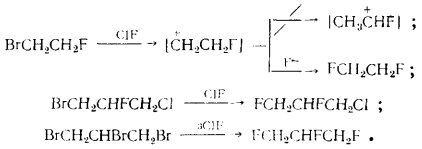


(XXVII) (XXVIII) (XXIX)

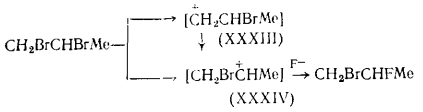


It is seen from this example to what extent gaseous ClF in a non-polar medium is a stronger electrophile than hexachloromelamine in hydrogen fluoride. The latter is incapable of abstracting a primary bromine atom from the halogenoalkane (XV) (see above). The debromination of the primary bromides is accompanied in most cases by the migration of the vicinal substituents—methyl groups and chlorine atoms. 1-Bromo-2-chloropropane (XXX) is readily fluorinated with migration of a chlorine atom. The primary bromoalkanes (XXX) and the isomeric secondary bromoalkane (XXXI) therefore give rise to the same fluorination product—1-chloro-2-fluoropropane (XXXII):

$$\underset{\text{(XXX)}}{MeCHClCH_2Br} \xrightarrow{ClF} \underset{\text{(XXXII)}}{MeCHFCH_2Cl} \xleftarrow{ClF} \underset{\text{(XXXI)}}{MeCHBrCH_2Cl} .$$



The driving force of all the migrations observed in substitutional fluorination is the formation of a stable carbonium ion. If migration can produce a stable tertiary carbonium ion, then a hydride shift takes place even in a non-polar medium:



In the fluorination of n-propyl bromide in Freon-113 at 0–10 °C the debromination of the substrate is also accompanied by a hydride shift, but 1-fluoropropane is formed together with 2-fluoropropane:

Primary fluorides can be obtained in non-polar media in all cases where the alternative hydride shift would have led to an insufficiently stable carbonium ion:[111,112]

Comparison of the relative rates of fluorination of n-propyl and isopropyl bromides showed that the difference between their reactivities is small (1 : 2).[112] Nevertheless 1,2-dibromopropane reacts selectively with one mole of ClF to form 1-bromo-2-fluoropropane:

Bearing in mind the tendency of the halogens (Br, Cl) to migrate, it is understandable why the primary cation (XXIII) formed on debromination rearranges to the more stable secondary cation (XXXIV), which in fact accounts for the high selectivity of the substitution.

A study of the relative rates of the substitutional fluorination of bromoalkanes in non-polar media by the method of competing reactions[112] established that the vicinal halogens very greatly retard the fluorination reaction. The following sequence of reactivities has been observed for secondary bromides:

$$MeCHBrMe \gg MeCHBrCH_2Cl \gg ClCH_2CHBrCH_2Cl .$$

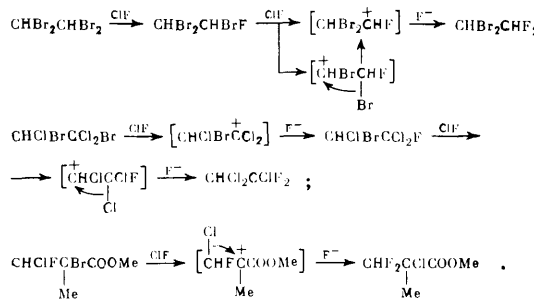
Analogously for primary bromides, we have

$$EtCH_2Br \gg MeCHClCH_2Br .$$

The geminal halogen atoms retard the fluorination reaction only very slightly. Thus ethyl bromide and 1-bromo-1-chloroethane are fluorinated at approximately equal rates, while in the series of dibromoethanes the following ratios of the rates of fluorination have been observed:

$$BrCH_2CH_2Br : BrCH_2CHClBr : BrCH_2CCl_2Br = 10 : 3 : 1 .$$

α-Halogenofluorides are formed exclusively under these conditions on reaction with a stoichiometric amount of ClF:



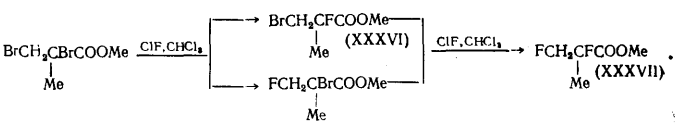
$$\underset{\text{(XXXV)}}{BrCH_2CHClBr} \xrightarrow{ClF} [BrCH_2\overset{+}{C}HCl] \xrightarrow{F^-} BrCH_2CHClF .$$

Such high selectivity is associated with the fact that, for example, in compound (XXXV) the bromine atom in the CH_2Br group is deactivated by the two vicinal halogens to

a much greater extent than the bromine atom of the CHClBr group is deactivated by one geminal and one vicinal halogen atom.

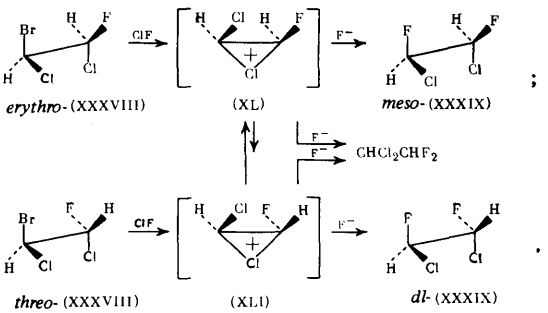
For the same reason, MeCHClBr is fluorinated incomparably faster than $ClCH_2CH_2Br$. Since the halogen atoms are distinguished by dual electronic properties, i.e. exhibit negative inductive and positive resonance effects, the resonance delocalisation of the positive charge of the α-halogenocarbonium ion is in all probability manifested already in the transition state of the debromination reaction, while the vicinal halogens do not show an anchimeric cooperation with the electrophilic dehalogenation.

The fluorine atoms exhibit a high resonance effect and do not tend to migrate, so that the substitutional fluorination of vicinal dibromoalkanes and polybromoalkanes leads to geminal difluorides:



A high selectivity is probably not to be expected in the fluorination of bromoalkanes where the CH_2Br and CHHalBr (or $CHal_2Br$) groups are located in positions more remote than the vicinal position.

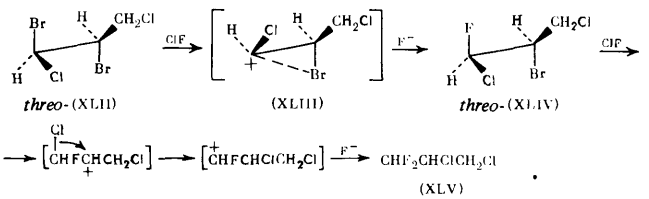
The ester group deactivates the bromine atom in the α-position. Methyl αβ-dibromopropionate reacts with ClF in a non-polar medium to form the product of the substitution mainly of the β-bromine atom:[111]



The introduction in the α-position of a substituent stabilising carbonium ions activates the α-halogen. For this reason, methyl αβ-dibromoisobutyrate reacts with one mole of ClF to form a mixture of the α-fluoro- and β-fluoro-regioisomers in proportions of 3 : 1, while treatment of the same mixture with a further mole of ClF results in the formation of methyl αβ-difluoroisobutyrate (XXXVII):

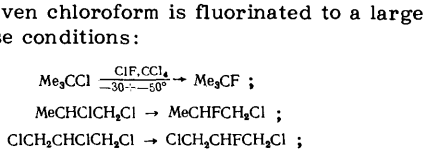
It is striking that in a non-polar medium the methyl group does not migrate on debromination of the primary bromide (XXXVI), while the debromination of the same compound in hydrogen fluoride entails the migration of the methyl group and the formation of the geminal difluoride, namely methyl αα-difluorobutyrate, and not the vicinal difluoride (XXXVII).[76] It is to be expected that the substitutional fluorination reactions proceeding via the dehalogenation stage will exhibit a low selectivity.

The fluorination of *erythro*- and *threo*-1-bromo-1,2-dichloro-2-fluoroethanes (XXXVIII) by chlorine monofluoride in the absence of a solvent proceeds non-stereospecifically[111] (Scheme 9). Mainly *meso*-1,2-dichloro-1,2-difluoroethane (XXXIX) (85% in a mixture of diastereoisomers) is formed from the *erythro*-isomer of compound (XXXVIII), while the *threo*-isomer gives rise to a mixture of equal amounts of the *meso*- and *dl*-isomers of compound (XXXIX).



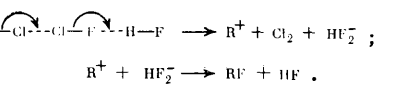
Scheme 9

The preferential retention of the configuration in the case of the *erythro*-isomer of compound (XXXVIII) is probably to be accounted for by the stabilisation of the intermediate carbonium ion (XL) by the interaction of the cisoid chlorine and fluorine atoms (cf. Section III above); in the case of the *threo*-isomer of compound (XXXVIII) there is no such stabilisation in the carbonium ion (XLI) and the reaction is non-stereoselective.



The substitutional fluorination of *erythro*- and *threo*-1,2-dibromo-1,3-dichloropropanes (XLII) takes place regiospecifically at the terminal bromine atom and mainly (85–90%) with retention of the configuration, which can probably be accounted for by the formation of the bromonium ion (XLIII) as a result of the involvement of the neighbouring bromine atom maintaining the configuration of the carbonium ion (Scheme 10):

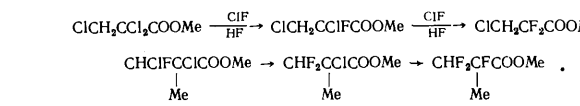
Scheme 10



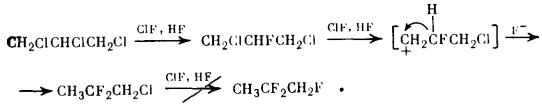
On treatment of 2-bromo-1,3-dichloro-1-fluoropropane (XLIV) with a second mole of ClF, the debromination is accompanied by the migration of a chlorine atom and the only fluorination product is therefore the geminal difluoride (XLV).

In the absence of special catalysts, chlorine monofluoride can substitute the chlorine atoms by fluorine in compounds which give rise to fairly stable carbonium ions following the elimination of Cl^-.[113] Reactions of this kind occur when ClF is passed into the corresponding substrate or its solution in an inert solvent at temperatures between −50° and −10 °C. t-Butyl chloride, 1,2-dichloropropane, and 1,2,3-trichloropropane are readily fluorinated in this way in nearly quantitative yields. Even chloroform is fluorinated to a large extent under these conditions:

The examples quoted demonstrate the high selectivity of the fluorination reaction: the primary chlorine atoms are not involved. For a more far-reaching fluorination, ClF must be activated by hydrogen fluoride or Lewis acids.[113]



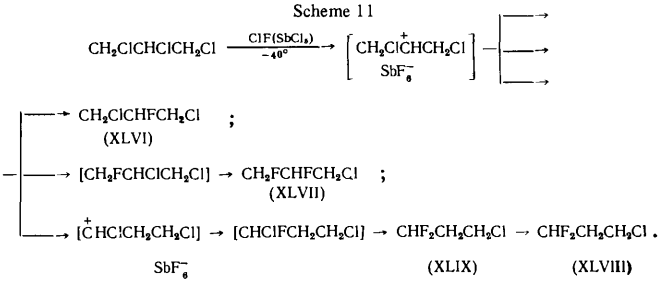
In anhydrous hydrogen fluoride, chlorine monofluoride readily substitutes the chlorine in organic chloro-derivatives by fluorine at temperatures between −60° and 10 °C. The reaction proceeds readily when gaseous ClF is passed into a solution or a stirred emulsion of the chloro-derivative in hydrogen fluoride:



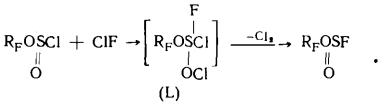
The reaction suffers from the same limitation as the substitution of bromine by fluorine: the chlorine atom of the CHCl group in the α-position relative to the alkoxycarbonyl group is not substituted. When one mole of methyl dichloropropanoate is treated with one mole of ClF, only the β-chlorine atom is substituted:

When a second mole of ClF is passed in, the chlorine atom in the α-position is not involved and the electrophilic attack by ClF is directed to the oxygen atom of the carbonyl group (see below). The introduction in the α-position of substituents stabilising carbonium ions promotes the substitution of the α-chlorine atom by fluorine:

Hydrogen fluoride used as a medium in substitutional fluorination promotes hydride shifts with formation of more stable carbonium ions. When 1,2,3-trichloropropane interacts with one mole of ClF, the central chlorine atom is substituted selectively and subsequent attack on the primary chlorine atom in 1,3-dichloro-2-fluoropropane is accompanied by a hydride shift, which results in the formation of a single product—1-chloro-2,2-difluoropropane, whose chlorine atom is not subsequently substituted under these conditions:

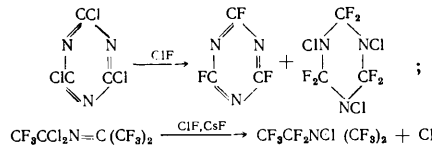


Catalytic amounts of antimony(V) halides (3–5%) enhance the fluorinating activity of chlorine monofluoride in a non-polar medium,[113] which can probably be accounted for by the formation of dichlorofluoronium hexafluoroantimonate,[114] in which the electrophilic activity of the chlorine is so high that the complex is capable of fluorinating Freon-113 to Freon-114 at temperatures between −40° and −60 °C.



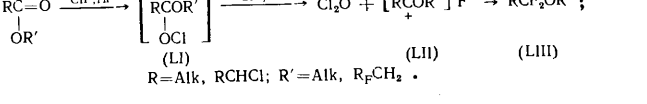
The substitutional fluorination by chlorine monofluoride catalysed by antimony salts is less selective than the fluorination in the absence of a catalyst or using the ClF–HF system. Thus considerable amounts of 3-chloro-1,2-difluoropropane (XLVII), 3-chloro-1,1-difluoropropane (XLVIII), 3-chloro-1,1-difluoropropane (XLIX), and 1,1,3-trifluoropropane (XLIX) have been obtained together with the main product, namely 1,3-dichloro-2-fluoropropane (XLVI), from 1,2,3-trichloropropane by its reaction with an equimolar amount of ClF in the presence of 5% $SbCl_5$ (Scheme 11):

Scheme 11



Fluorination by chlorine monofluoride thus has extensive preparative possibilities for the specific synthesis of various mono- and poly-fluorides by varying the temperature of the reaction and the catalytic additives.

Chlorine monofluoride is capable of substituting also the chlorine of acid chlorides in perfluoroalkyl chlorosulphites:[115]



Since such substitution does not occur on treatment with alkali metal fluorides at high temperatures, presumably the reaction proceeds via the electrophilic addition of ClF to the S=O group and subsequent dechlorination of the hypochlorite (L).

It has been suggested that the analogous chlorofluorination with subsequent dechlorination takes place on fluorination of cyanuric chloride, hexachloromelamine,[116] hexachlorobutadiene,[117] and certain chlorine-containing polyfluoroalkylimines[89] by chlorine monofluoride:

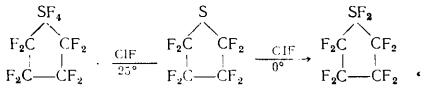
5. The Conversion of the Carbonyl Group into the Difluoromethylene Group

When chlorine monofluoride is allowed to react with a solution of an ester in anhydrous hydrogen fluoride at temperatures from −70° to −20 °C, the oxygen of the carbonyl group is smoothly substituted with formation of the difluoromethylene group.[118] The familiar reaction involving the addition to ClF to the carbonyl group probably takes place initially with formation of the hypochlorite (LI) (see above). On further interaction with ClF, the electrophilic elimination of the ClO group probably takes place and the stable carbonium ion (LII) is formed. The latter captures a fluoride anion and is converted into the αα-difluoroether (LIII):

The requirements for the stability of the intermediate ion (LII) are so stringent that the introduction of two electron-accepting substituents in the α-position relative to the carbonyl group prevents the reaction. For example, the RCF_2COO group cannot be converted under these conditions into RCF_2CF_2O. Since many examples of compounds of type (LIII), such as, for example, $MeCF_2OCH_2CF_2CF_2H$ are

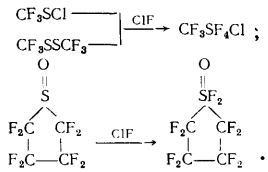
hydrolytically unstable, in their isolation from the reaction system it is necessary to avoid contact with water. Fluoroethers, for example, $ClCH_2CF_2OCH_2CF_2CF_2H$, which are potential anaesthetics and are fairly resistant to hydrolysis can be synthesised in this way.[119]

When the ethyl esters of acids are used as substrates, more far-reaching fluorination is observed. On treatment with three moles of ClF, ethyl chloroacetate gives rise to a high yield of 1-chloro-2,2,4-trifluoro-3-oxapentane:



$$ClCH_2COOCH_2Me \xrightarrow[HF]{3ClF} ClCH_2CF_2OCHFMe\ .$$

6. Oxidative Fluorination of Sulphur-containing Compounds



Chlorine monofluoride readily effects the successive oxidation of sulphur(II) to sulphur(IV) and sulphur(VI). Reactions of this kind have been thoroughly investigated in relation to perfluorinated sulphur-containing compounds and have been discussed in reviews.[62,120] We shall therefore quote only certain examples of such reactions achieved with high yields of the products. Perfluoroalkyl sulphides react smoothly with ClF at −78 °C, forming *SS*-difluorides, while at a higher temperature further oxidation of sulphur(IV) to sulphur(VI), accompanied by the partial dissociation of the C–S bonds, takes place:

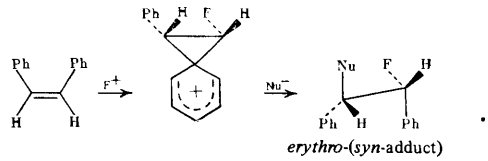
$$R_FSR'_F \xrightarrow[-78°]{ClF} R_FSF_2R'_F\ ;$$

$$CF_3SCF_3 \xrightarrow[20°]{ClF} CF_3SF_4CF_3 + CF_3SF_4Cl\ ;$$

Perfluoroalkanesulphenyl chlorides, disulphides, and sulphoxides are also readily oxidised and fluorinated under mild conditions:

7. Chlorine Monofluoride as a Member of the Series of Fluorine-containing Reagents with Electrophilic Halogens

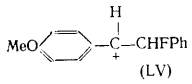
The reactions considered show that chlorine monofluoride is a typical electrophile, the majority of the reactions of which with organic substrates proceed via polar mechanisms, thoroughly investigated in organic chemistry, with formation of carbonium ion intermediates. On the whole, the observed facts (the mode of addition to multiple bonds as a function of the electronic nature of the substituents and the medium, the stereochemistry of the addition and substitution, and the skeletal rearrangements and migrations accompanying these reactions in non-polar and polar media or in the presence of antimony salts) are consistent with the predictions based on the extensive experience gained in the chemistry of carbonium ions. The observed specific features in individual reactions are not of fundamental importance, reflecting merely the influence of the medium, the counterion, and the neighbouring groups on the stability of the carbonium ions.



In contrast to other halogens, ClF does not tend to undergo homolytic reactions at the usual temperatures and, as a consequence of the considerable polarity of its bond (μ = 0.89 D), it adds via an electrophilic mechanism even to polyhalogenoalkenes in non-polar solvents, which implies that its reactivity is close to that of a powerful electrophile such as chlorine fluorosulphate.[121–125]

The high selectivity of ClF as a reagent and as a consequence the great preparative scope of its application in the synthesis of a wide variety of mono- and poly-fluorides proved to be somewhat unexpected. The majority of the related reagents containing an electrophilic halogen, namely chlorine and bromine fluorosulphates $FSO_2OCl(Br)$,[121–125] chlorine and bromine trifluoromethanesulphonates CF_3SO_2OCl. .(Br),[127–130] chlorine perchlorate ClO_3OCl,[131,132] perfluoroalkyl hypochlorites and hypofluorites $R_FOCl(F)$,[133–135] and perfluoroacyl hypochlorites and hypofluorites,[136–138] have been used for preparative purposes mainly in reactions with polyhalogeno- and perfluoro-compounds. Reactions involving electrophilic addition to multiple bonds and electrophilic debromination and dechlorination of organic halogeno-derivatives with formation of carbonium ions, which are stabilised by capturing the corresponding nucleophilic residue, are characteristic of these reagents as well as chlorine monofluoride. Polyfluoroalkyl fluorosulphates, trifluoromethanesulphonates, perchlorates, perfluoroalkyl ethers, and perfluoroacylates have been obtained with the aid of these reactions. It has been shown that even molecular fluorine is capable of adding at −78 °C to certain alkenes in Freons 11 and 12 via an electrophilic mechanism.[139]

The electrophiles enumerated have been investigated in reactions with a limited number of substrates and under different conditions, so that it is difficult to set up an electrophile reactivity series which includes also ClF. Nevertheless, presumably chlorine fluorosulphate, chlorine trifluoromethanesulphone, and chlorine perchlorate are stronger electrophiles than ClF. Thus chlorine fluorosulphate is capable of abstracting a chloride anion, in the absence of special catalysts at temperatures below 0 °C, from dichloroethane[123] and methyl chloroacetate;[140] chlorine perchlorate and trifluoromethanesulphonate debrominate compounds of the type R_FCF_2Br,[129,132] while chlorine monofluoride does not react with compounds of this kind under the conditions indicated.

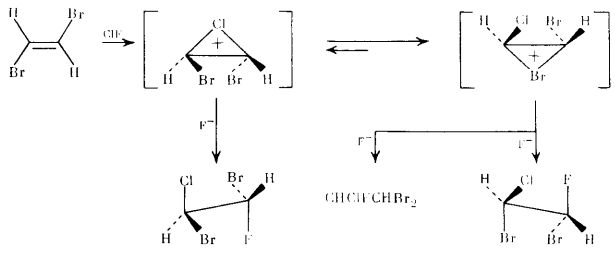


Comparison of the stereochemistries of the addition of electrophiles containing the O–Cl and O–F bonds and of chlorine monofluoride to unsaturated compounds merits attention. The *cis*- and *trans*-isomers of stilbene give rise preferentially to *syn*-adducts on reaction with reagents containing electrophilic fluorine: CF_3OF (70–80%),[136] CF_3CF_2OF (83),[134] CF_3COOF (100%).[137] The configurations of *erythro*- and *threo*-PhCHXCHFPh (X = CF_3O, CF_3CF_2O, or CF_3COO) in the studies quoted have been demonstrated reliably by NMR and do not give rise to any doubts.

The most convincing explanation of the causes of the *syn*-addition of these reagents to stilbenes is that the carbonium ion formed as a result of the electrophilic attack by fluorine is in essence a phenonium ion (LIV) as a result of the involvement of the neighbouring phenyl group, and the subsequent nucleophilic attack by this ion can lead only to the *syn*-adduct:[134,136,137]

erythro-(*syn*-adduct)

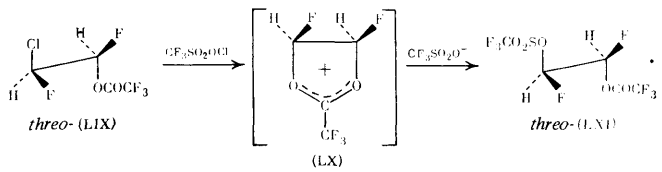
The entering fluorine atom, which behaves as a relatively ineffective neighbouring group, cannot compete with the phenyl substituent as regards its capacity to form a bridged cation. The introduction of electron-donating substituents in one of the aromatic rings of stilbene decreases the *syn*-stereospecificity of the electrophilic fluorination. since the intermediate under these conditions is the open-chain carbonium ion (LV), the attack on which by the nucleophile



(LV)

is equally probable on either side. The stereochemistry of the addition of these electrophiles to aliphatic olefins has not been investigated but a study has been made of the addition of chlorine and bromine trifluoromethanesulphonates to *cis*- and *trans*-difluoroethylenes and also to *trans*-dichloroethylene.[128] The complete stereospecificity of the addition reaction has been demonstrated: only one diastereoisomer has been obtained from each olefin. The NMR spectroscopic parameters have been calculated for the adducts obtained [*erythro*- and *threo*-$CF_3SO_2OCHFCHFCL$ (LVI) and also for the single diastereoisomer $CF_3SO_2OCHClCHClBr$]. It has been shown that the diastereoisomeric 2-chloro-1,2-difluoroethyl trifluoromethanesulphonates (LVI) have significantly different vicinal spin–spin coupling constants $^3J_{FF} = 19.5$ and 25.5 Hz. Tentative examination of the conformations of each diastereoisomer led to the assignment of their configurations: J_{FF} = 25.5 Hz and 19.5 Hz have been assigned to the *threo*- and *erythro*-isomers of compound (LVI). The assignment of the configurations of the esters (LVI) as *syn*-adducts and also the proposed mechanism involving a concerted *syn*-addition of chlorine and bromine trifluoromethanesulphonates to 1,2-dihalogeno-ethylenes[128] appear to be extremly doubtful.

Indeed it has been established[107] that ClF, which is a less effective electrophile, adds to similar unsaturated compounds via a two-stage electrophilic mechanism with the preferential formation of *anti*-adducts (cf. Table 4). Furthermore, it has been shown[111,141] that the constants $^3J_{FF}$ for the diastereoisomeric alkanes *dl*- and *meso*-CHClFCHClF are respectively 20.8 and 26.2 Hz, while those for *dl*- and *meso*-$(CHFCOOMe)_2$ are 9.1 and 13.9 Hz. Thus the character of the variation of the constants $^3J_{FF}$ as a function of the configuration is the opposite to that proposed for *threo*- and *erythro*-(LVI).[128]



If the substrate molecule contains substituents which compete with the leaving halogen atom for the carbonium ion centre, like the phenyl substituent in stilbenes, then the electrophilic addition of ClF to such substrates involves the formation of *syn*-adducts together with the *anti*-adducts.[142] The involvement of bromine atoms in the chlorofluorination of *Z*- and *E*-1,2-dibromoethylenes is so great that in the chlorofluorination of the *E*-olefin by the hexachloromelamine–hydrogen fluoride system mainly the regioisomer (LVIII) is formed together with the pseudo-*syn*-adduct, namely *threo*-(LVII) (90 and 10% in the mixture of isomers—Scheme 12). The chlorination of this alkene by chlorine monofluoride in Freon-113 proceeds non-regioselectively and non-stereoselectively, but the pseudo-*syn*-adduct, i.e. *threo*-(LVII), predominates in the mixture of isomers.

Scheme 12

	erythro-(LVII) (*anti*-)	(LVIII)(regio-)	*threo*-(LVII) (pseudo-*syn*-)
Hexafluoromelamine-HF	<1%	90%	10%
ClF-Freon-113	15%	17%	68%

It is therefore doubtful if the addition of chlorine and bromine trifluoromethanesulphonates to 1,2-difluoro- and 1,2-dichloro-ethylenes[128] involves stereospecific *syn*-addition, because the entering halogens are more effective neighbouring groups than the substituents already present in the alkene molecules. The substitution of the chlorine atoms by the trifluoromethanesulphonate group on treatment of *erythro*- and *threo*-2-chloro-1,2-difluoroethyl-1-trifluoroacetates (LIX) with chlorine trifluoromethanesulphonate probably does indeed take place with retention of the configuration[129] but not as a consequence of cyclic synchronous substitution, the real reason being that the trifluoroacetate group present in the molecules of compound (LIX) maintains the configuration of the carbonium ion (LX):

threo-(LIX) (LX) *threo*-(LXI)

It is to be expected that in the absence from the substrate of neighbouring groups maintaining the configuration of the carbonium ion, the substitution of the halogens by the trifluoromethanesulphonate group will proceed non-stereospecifically (cf. subsection 4 above).

Reactions involving the electrophilic elimination of the halogen are characteristic not only of the heteroatomic reagents with electrophilic halogens mentioned above but also of molecular chlorine, bromine, and iodine monochloride in their interactions with alkyl iodides in inert salts at temperatures between −78° and 25 °C:[143–145]

$$RI + Hal_2 \xrightarrow{-78^\circ} RHal + IHal;$$
$$Hal = Br, Cl.$$

The reaction is preceded by the formation of a complex between the alkyl iodide and the halogen, the decomposition of which results in the formation of a carbonium ion, which captures a halide anion. The typical carbonium ion rearrangements accompanying the substitution reaction confirm this mechanism. It has been shown in relation to the reaction of the optically active 2-iodo-octane with Br_2 and Cl_2 that the substitution takes place preferentially with inversion of the configuration.[143]

V. FLUORINATION BY HALOGEN POLYFLUORIDES AND THEIR INORGANIC COMPLEXES

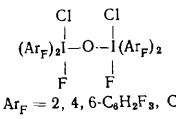
Halogen polyfluorides are extremely dangerous to handle.[1-4] Chlorine trifluoride ignites wood, plastics, and even concrete and gives rise to an explosion on contact with the usual organic solvents at −100 °C.[146] Bromine trifluoride is somewhat less dangerous. Nevertheless, at the usual temperatures, it reacts explosively even with chlorocarbons. Iodine pentafluoride is not quite so reactive. Only highly fluorinated Freons can be mixed safely with halogen polyfluorides at moderate temperatures. Numerous attempts to employ halogen polyfluorides for the specific synthesis of organic fluorides have led investigators to the conclusion that a common disadvantage of all these reagents is that they are completely non-selective and give rise to a very complex mixture of products.[1,2,147] For some time, this reduced the interest in halogen polyfluorides. However, in subsequent years halogen polyfluorides and their complexes have again attracted attention as fluorinating agents.

Methods of synthesis in high yields of *N*-bromoperfluoropiperidine[148] by treating trichlorohexafluoropiperidine with BrF_3 at −50 °C and also of isomeric octabromotetrafluorocyclohexanes $C_6F_8Br_4$ by treating hexabromobenzene with ClF_3, IF_5, or IF_7 in bromine at temperatures between −10° and 60 °C have been patented.[149] When certain nitriles were treated with BrF_3 in anhydrous hydrogen fluoride at temperatures between −20° and −15 °C, the corresponding trifluoromethylalkanes were obtained in high yields.[150] 2,2-Difluoropropane has been obtained from acetone under the same conditions (93%):

$$RCN + BrF_3 \xrightarrow{HF} RCF_3 ;$$
$$R=Me,\ Et,\ CH_2Cl ;$$
$$MeCOMe + BrF_3 \xrightarrow{HF} MeCF_2Me .$$

Ethyl methyl ketone and isopropyl methyl ketone reacts with bromine trifluoride in hydrogen fluoride with dissociation of the carbon chain. On treatment of perfluoroalkyl iodides with chlorine or bromine trifluoride, bromine pentafluoride, and elemental fluorine in perfluorohexane or in the absence of solvents at temperatures between −60° and −80 °C, perfluoroalkyl iodide difluorides and tetrafluorides were obtained. The conditions of the synthesis and the properties of the products have been described in detail.[146] Iodine pentafluoride is ineffective in this reaction, while the reaction with ClF_3 proceeds in accordance with the equations

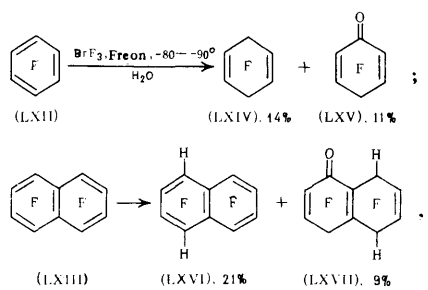
$$3R_FI + 2ClF_3 \rightarrow 3R_FIF_2 + Cl_2 ;$$
$$3R_FI + 4ClF_3 \rightarrow 3R_FIF_4 + 2Cl_2 ;$$
$$R_F=C_2F_5,\ C_4F_9,\ C_6F_{13},\ C_{10}F_2 .$$



When elemental fluorine is used, three products are formed simultaneously:

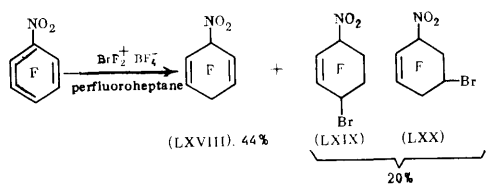
$$C_4F_9I + F_2 \rightarrow C_4F_9IF_2 + C_4F_9IF_4 + (C_4F_9)_2I^+IF_6^- .$$

Freshly prepared perfluoroalkyl iodide difluorides are slow-melting solids; on standing, they are converted into insoluble, infusible products, to which the structure $R_2I^+Y^-$, where Y can be IF_4^-, IF_6^-, or IF_8^-, has been attributed on the basis of X-ray diffraction analysis. A method has been proposed for the synthesis of diarylbromonium salts having the general formula $(XC_6H_4)_2Br^+BF_4^-$ by treating arenes,[151] organomercury compounds,[152] or tetra-arylstannanes[153] with BrF_3 and boron trifluoride etherate in methylene chloride and acetonitrile at −70 °C.

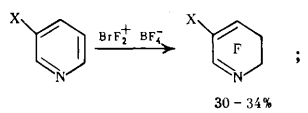


Interesting results have been obtained on treating aromatic polyfluoro-compounds with complexes of halogen fluorides.[154-157] Non-fluorinated arenes decompose and char on treatment with such complexes.[154]

Hexafluorobenzene and pentafluorobenzene do not react with IF_5 even at 120 °C. The reaction of trifluorobenzene and pentafluorobenzene with salts of the type $IF_4^+SbF_nCl_{6-n}$ in hydrogen fluoride, IF_5, or SO_2FCl at 15–50 °C with subsequent hydrolysis of the reaction mixture yielded aromatic derivatives of quinquevalent iodine—μ-oxotetrakis(polyfluoroaryl)dichlorodifluoroiodates:

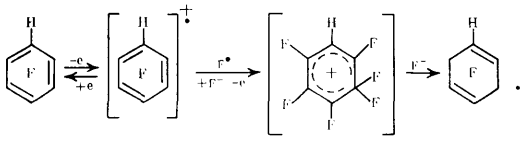


Ar_F = 2, 4, 6-$C_6H_2F_3$, C_6F_5 .



Bromine trifluoride reacts with pentafluorobenzene in Freon-114 or SO_2ClF with formation of bromopentafluorobenzene (27%); in an analogous reaction hexafluorobenzene (LXII) yields after hydrolysis perfluorocyclohexa-1,4-diene (LXIV) and hexafluorocyclohexa-2,5-dien-1-one (LXV); perfluoro-1,4-dihydronaphthalene (LXVI) and octafluoro-1-oxo-5,8-dihydronaphthalene (LXVII) are formed from octafluoronaphthalene (LXIII):[155]

Octafluorotoluene and 4*H*-heptafluorotoluene do not react with BrF_3 under these conditions, while pentafluoronitrobenzene and pentafluoropyridine do not react even at 20° to 30 °C. However, these compounds do react with difluorobromonium tetrafluoroborate $BrF_2^+BF_4^-$ at temperatures in the range between −80° and 0 °C. Pentafluoronitrobenzene is then converted into heptafluoro-1-nitrocyclohexa-1,4-diene (LXVIII) and a mixture of 4(5)-bromo-octafluoro-1-nitrocyclohex-2-enes (LXIX) and (LXX):



The fluorination of 3-halogenopyridines by this complex proceeds regiospecifically and leads to conjugated 3-substituted perfluoro-1-azacyclohexa-1,3-dienes:

X = Cl, F .

A similar study of the behaviour of aromatic polyfluoro-compounds in relation to BrF_3 and BrF_2^+ led Bardin et al.[155] to the conclusion that these reagents differ little in their electrophilicities, but the BrF_2^+ cation is a much stronger oxidant. Evidence is adduced in support of the view that the reactions of aromatic fluoro-compounds with bromine trifluoride and its complexes proceed via the one-electron

oxidation of the aromatic hydrocarbons with formation of radical-cations and their subsequent fluorination:[155–157]

It has been shown[158] that polyfluoroarenes are fluorinated via an analogous mechanism with xenon fluoride in hydrogen fluoride and by xenon fluoride complexes.

---o0o---

It follows from the data examined that halogen fluorides are promising fluorinating agents which are suitable for the synthesis of practically important organofluorine products. The development of organic synthesis of the basis of these reagents is only just beginning.

From the preparative standpoint, we believe that chlorine monofluoride is of greatest interest. This applies particularly to the substitutional fluorination reactions of organic bromo- and chloro-derivatives. The waste products in the fluorination of such compounds with hydrogen fluoride are hydrogen halides, whose utilisation constitutes a difficult problem. In the fluorination reactions with the aid of ClF the side products are molecular halogens, which can be employed in the synthesis of the initial substrates.

In contrast to the majority of other fluorinating agents, chlorine monofluoride has the unique ability to introduce successively into an organic molecule one, two, and more fluorine atoms by substitutional fluorination. This constitutes yet another advantage of this interesting reagent.

The theoretical aspects of the reactions of halogen monofluorides and polyfluorides are also of undoubted interest. Chlorine monofluoride and the related compounds of the type HalY, where Y is a residue of a strong acid, not only add to multiple bonds but also abstract halogens from organic halogeno-derivatives under mild conditions via an electrophilic mechanism, which is usually not characteristic of the majority of other electrophiles (for example, HHal, RSHal, etc.). This group of reagents does not fit the classification of electrophiles which provides for their subdivision into two categories—strong and weak—depending on whether or not skeletal rearrangements take place following their addition to the $>C=C<$ bond.[159]

There is apparently no need for such a general classification of all electrophiles. The reactions of carbonium ions, occurring in the second stages of electrophilic processes, are associated solely with the characteristics of the structure of these intermediates and with their tendency to rearrange under particular conditions.

The unambiguous demonstration of a two-stage mechanism of the addition of ClF to the majority of unsaturated compounds in a non-polar medium[108] makes it impossible to agree with the conclusion that the initial molecules interact intermolecularly without the conversion of the intermediate molecular complexes into carbonium ions in non-polar media.[160] This conclusion was reached[160] on the basis of a theoretical study of the mechanism of the electrophilic addition reactions from the standpoint of the conservation of orbital symmetry.

It is to be expected that in the immediate future halogen fluorides will occupy their due place both in the industrial synthesis of organofluorine products and in theoretical organic chemistry.

The Radiation Chemistry of Cellulose

B.G.Ershov and A.S.Klimentov

The radiation-chemical transformations of cellulose and the influence of various factors on the efficiency of these processes have been examined. Ionising radiation has a significant influence on the structural-morphological state of the polymer; the nature of the primary radical-ion radiolysis products has been discussed, and a quantitative description of the radiation degradation of cellulose has been given. The mechanism of the radiation-chemical transformations of cellulose, which provide a promising method for treating cellulose-containing raw material for the production of valuable products, has been discussed. The bibliography contains 131 references.

I. INTRODUCTION

Cellulose is one of the most widely encountered natural polymers, being the principal component of plant materials. The study of the radiation chemistry of this compound is therefore of considerable theoretical and practical importance. The use of penetrating ionising radiation can radically alter the technology of the treatment of plant raw material, since it facilitates considerably the conversion of the carbohydrate complex into the soluble state or increases its sensitivity to other methods of treatment, such as enzyme hydrolysis.

The use of radiation with a high penetrating power (γ-rays, X-rays, accelerated electrons) makes it possible to bring about chemical transformations in the bulk of the substance, and this, in particular, has found extensive practical application as a method for modifying polymers.[1-5] Not all the reactions taking place when a substance is irradiated are specific for radiation chemistry. Many of them also apparently take place under the influence of light, an electric discharge, cavitation processes, etc. Thus the study of the radiation-chemical reactions is also important for establishing the mechanism of the chemical reactions taking place after initiation by other methods.

Considerable attention has been and is being paid to the problem of the influence of penetrating ionising radiation on cellulose and cellulose-containing materials. This is due to a number of factors, among which the following are of primary importance. The physical and chemical properties of cellulose fibres can be changed in a directed fashion by the radiation grafting of various polymers on to them.[6,7] Penetrating radiation achieves effective sterilisation of cellulose-containing materials for medical purposes, and the conservation of good and animal feedstuffs.[8-10] Irradiation is used to accelerate and optimise the processes involved in the thermochemical and enzyme treatment of wood,[11-17] cellulose,[18-20] and cellulose-containing waste products,[21-23] to modify the physicomechanical properties of wood and to create new materials based on it,[24-26] to intensify the production of yeast[27-31] and cellulose paper production.[32-35] Finally, ionising radiation may find application in the technology of the treatment of non-edible plant materials (chiefly the waste products from the wood processing industry and agriculture) to obtain animal feedstuffs and food products.[21,36-38]

A systematic analysis of data on the radiation chemistry of cellulose was last carried out in the 1970's.[39] The present review summarises the experimental data obtained in recent years, discusses the influence of radiation on the properties of cellulose, and examines the main trends in radiation-chemical transformations of this important natural polymer. Since the final products of the radiation-chemical transformations of cellulose have not been studied in detail, because of the fundamental difficulties involved in the chemical analysis of the long polymer fragments, the possible mechanisms of the transformations will be discussed using available data on the radiolysis of various simple carbohydrates and oligosaccharides, which can (in a certain sense) be regarded as model compounds of cellulose.

II. INFLUENCE OF IRRADIATION ON THE STRUCTURE OF CELLULOSE

Each monomeric unit in cellulose has three hydroxyl groups, which form intra- and intermolecular hydrogen bonds. The presence of the branched system of hydrogen bonds determines to a considerable extent the physicochemical and mechanical properties of the polymer.

Cellulose is one of the polymers whose crystallographic characteristics have been studied most intensively for several decades. Nevertheless, there is still lack of agreement about the phase compositions of cellulose. As early as the 1930's, Kargin[40] suggested that the amorphous state of cellulose is thermodynamically stable and the only state possible. Later, he drew attention to the main indications confirming this viewpoint.[41] At the present time, however, the more generally accepted approach regards cellulose as a material with a crystalline structure containing quantities of an amorphous phase. Different models of the crystallographic lattices of cellulose and theories of the crystallinity of this polymer exist. In particular, four structural forms of cellulose have been established, of which the natural material is described as cellulose I.

The structural state of cellulose has been described in detail.[42-44] It is suggested that cellulose consists of small crystallites, made up of microfibrils, which are surrounded by regions of amorphous and polycrystalline phases.[45,46]

The dimensions and orientation of the crystallites and the ratio of the phases are determined by the nature of the previous treatment of the materials. The length of the polymer chains is appreciably greater than the size of the crystallities, so that the macromolecules are present in alternating regions with crystalline and amorphous structures.

The complex amorphous–crystalline system can be characterised by the degree of crystallinity and the degree of orientation. The crystalline phase is more closely packed, so that the rates of hydrolytic splitting differ considerably for these phases. Different methods for determining the degree of crystallinity of cellulose generally give different results. This is because the methods used make it possible to study different aspects and manifestations of the structural state. For example, X-ray diffraction characterises the degree of order of the polymer, whereas methods involving chemical reaction determine the accessibility of the different regions to the reactions, that is they characterise its structure only qualitatively. Nevertheless, it is assumed[42–46] that cotton cellulose contains ~65–75% crystalline fraction and ~25–35% amorphous fraction.

The different manifestation of structurally sensitive properties in different regions of cellulose, however, is not sufficient to enable them to be characterised as amorphous or crystalline phases. It is apparently more correct to say that cellulose contains regions with different ratios of intra- and intermolecular ordering.[47] From this viewpoint, cellulose is regarded as a single-phase system, in which, if an amorphous phase is present, its concentration does not exceed ~5%.[48–50] According to this hypothesis, cellulose contains imperfect regions, and its structure can be regarded as "liquid-crystalline" or "paracrystalline".[48–50] The indeterminacy of the interpretation of the structural state of the original cellulose makes it difficult to explain the data obtained after it has been exposed to ionising radiation.

The structure and intensity of the infrared spectra of cellulose is preserved after its irrdiation up to an absorbed dose of ~100 kGrad,[51] from which is was concluded that its structure is preserved under these conditions. X-Ray diffraction has shown that the phase state of cellulose[52,53] and cotton lint[54] remains unchanged at much higher doses.

Infrared (IR) spectroscopy is most convenient for the study of the structure of cellulose if the phase changes are not accompanied by a significant change in the chemical state. On irradiation, however, the process with the greatest influence on the IR spectra is the chemical transformation of cellulose, that is the formation of carbonyl and carboxyl groups, dehydrogenation, and dehydration. In the study of the influence of radiation on the structure of cellulose, the strong band in the range 3600–3000 cm^{-1}, due to OH group stretches, is of particular interest. It can be used to characterise the redistribution of OH groups with respect to hydrogen bond strengths. With interest in the absorbed dose, the maximum of the band due to the OH groups in the infrared spectrum of cellulose is displaced from 3400 cm^{-1} to 3440 cm^{-1}, accompanied by a change in the shape of the band.[53] Table 1 gives the values of ν_{OH}, and also the symmetry index of the band a/b, that is the ratio of the right-hand and left-hand parts of the half-width of the band due to the OH groups. The observed changes show that irradiation leads to breakdown of the ordered system of intermolecular hydrogen bonds, as a result of which the hydroxyl groups are involved in less stable hydrogen bonds.[55] The distribution of OH groups with respect to bond strengths becomes statistically less uniform (the value of a/b changes from 0.72 to 0.58). The irradiation of cellulose leads to the production of carbonyl and carboxyl groups. The intensity of the corresponding bands in the infrared spectra (bands at 1740 cm^{-1} for CO and at 3400 cm^{-1} for COOH) increases with increase in the absorbed dose, and the change in their ratio (D_{1740}/D_{3400}) indicates the preferential formation of carbonyl groups (Table 1).

The changes in the structure of cellulose brought about by the action of γ-radiation have been characterised not only by IR spectroscopy but also by X-ray diffraction.[52,53] Up to absorbed doses of 480–1180 kGrad, the structure of cellulose remains practically unchanged[52] (since the values of the crystallinity indices, determined by the published method,[56] remain unchanged). At absorbed doses greater than 2000 kGrad, the crystallinity index decreases considerably (Table 2), and at a dose of 9400 kGrad, X-ray diffraction indicates that cellulose can be characterised as having an amorphous structure.

Table 1. Changes in the infrared spectra of cotton cellulose γ-irradiated in a vacuum.[53]

Dose, kGrad	ν, cm^{-1}	a/b	D_{1740}/D_{3400}
0	3400	0.72	0
480	3410	0.67	0.4
2560	3420	0.65	1.1
9400	3440	0.58	3.7

Table 2. Physicochemical properties of γ-irradiated cotton cellulose.[53]

Dose, kGrad	β, %	$\overline{DP}_\nu$	c_s, %	$\overline{DP}'_\nu$	β′, %
0	73	911	10.3	205	78
5	73	575	10.9	189	78
10	73	505	11.3	159	78

Notes: β is the crystallinity index of the original cellulose, $\overline{DP}_\nu$ its viscosity-average degree of polymerisation, c_s the quantity of soluble fraction in the ethanolysis of the cellulose (% of the mass of the original specimen), $\overline{DP}'_\nu$ the viscosity-average degree of polymerisation of the insoluble residue, and β′ its crystallinity index.

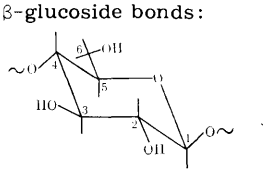
γ-Irradiation leads to the degradation of cellulose, revealed by a decrease in its degree of polymerisation. The changes in the degree of polymerisation of cellulose and in its solubility take place much more effectively (see Table 2) than the changes in the structure observed on the X-ray diffraction patterns. This apparently represents a situation where the method for the experimental determination of the degree of ordering of a substance in practice makes it possible to estimate only a certain particular characteristic. Thus X-ray diffraction indicates the existence of a highly ordered structure in cellulose up to high absorbed doses. At the same time, chemical methods for the analysis of the structure of cellulose, which to a large extent characterise the accessibility of the different parts of its molecule with respect to the reactions and breakdown of the system of intermolecular hydrogen bonds, indicate that γ-irradiation leads to the production of disordered defect regions. There is no contradiction here, however. X-Ray diffraction shows that

in the dose range studied, the structure of the primary crystals and the overall degree of crystallinity of cellulose remain unchanged. The increase in the ability of γ-irradiated cellulose to dissolve, however, is related to an appreciable decrease in its degree of polymerisation, and also to the formation of active chemical groups, i.e. carbonyl and carboxyl groups, which facilitate the conversion of the macromolecules to the dissolved state. Thus when irradiated cellulose is brought into contact with water, the products transferred preferentially to the solution are those containing acidic and aldehydic groups, and the total extractability increases with increase in the absorbed dose.[57]

The change in the degree of order of the cellulose structure on irradiation has been characterised by IR spectroscopy.[58] The parameter of the degree of ordering (φ) (the term "index of paracrystalline regularity" is used in the work cited) was the ratio of the intensities of the bands at 1370 cm^{-1} and 890 cm^{-1}. The parameter φ decreases almost exponentially with increase in the absorbed dose, and for a dose of ~2400 kGrad it decreases by a factor of e. Infrared spectroscopy apparently determines the degree of ordering of the largest macromolecules of cellulose, and it shows a closer correlation, compared with X-ray diffraction, with chemical methods for estimating its structural state. The observed character of the decrease in the degree of ordering of the cellulose structure with increase in the absorbed dose agrees with the decrease in its degree of crystallinity determined in Ref.59.

In the γ-irradiation of cotton fibres, even at an absorbed dose of ~10 kGrad, scanning electron microscopy detects unambiguously the breakdown of their morphologicaly structure.[58] Cracks lying parallel to the twisting axis of the fibre appear, and show a significant increase in their length and depth with increase in the absorbed dose. This process is apparently due to the rupture of intermolecular bonds in the fibrils and to a decrease in the strength of the surface interactions between them. Various problems of the morphology on irradiated cellulose materials were examined in Ref.34. The physicochemical processes taking place when cotton fibres are exposed to radiation lead to an appreciable decrease in their mechanical strength.[58,59]

Thus the action of ionising radiation leads to a decrease in the intra- and intermolecular ordering in cellulose, due to the breakdown of the system of intermolecular hydrogen bonds and to chemical transformations of the polymer.



III. RADICAL RADIOLYSIS PRODUCTS OF CELLULOSE

The radicals produced by the radiolysis of cellulose have been studied many times by EPR.[39,60,70] In spite of this, there was lack of agreement on their nature until recently. This was due to the fact that the studies were carried out under different conditions (temperature of irradiation, moisture content of the cellulose, absorbed doses etc.), and in the interpretation of the EPR spectra, no allowance was made for the actual conformation of the monomeric fragment of the polymer. As a result, the EPR spectrum of γ-irradiated cellulose was examined in different studies as, for example, consisting of a triplet and a quintet[39] or a quadruplet and a singlet.[69]

The radicals in γ-irradiated cellulose, and the kinetics of their accumulation and thermal transformations, have been studied.[71,74] Natural cotton cellulose, purified and dried for a long time at 313 K (in the presence of P_2O_5) and at 378 K, and also moist cellulose, containing two water weight fractions, were used. Cellulose hydrate (technical cellophane) and holocellulose were also studied. The most interesting data were obtained on the radicals obtained by irradiating cellulose at a low temperature (77 K). It may be assumed that under these conditions the species stabilised are the primary radical–ion products, whose subsequent chemical transformations determine the entire range of changes in the physicochemical state of cellulose. Specimens of natural and regenerated cellulose irradiated at 77 K acquire a bluish colour,[71,72] typically observed when electrons are captured by intermolecular traps in polar substances.[73–75] The colour disappears rapidly under the influence of visible light or when the specimen is heated to ~173 K. The changes which then take place in the EPR spectrum indicate the disappearance of the narrow singlet, due to the captured electron, with a g value equal to that for the free electron. The optical absorption maximum for the captured electron (e_{capt}) in cellulose hydrate lies at 540 ± 20 nm, and the half-width of the absorption band is 1.3 1 0.1 eV, which are close to the characteristics of the optical spectra of e_{capt} in vitreous polyhydric alcohols[75–78] and concentrated aqueous solutions of carbohydrates.[79,80] In this case, the stabilisation apparently takes place in the water micro-phase in cellulose with a vitreous structure, and also in the amorphous regions of cellulose in the electrostatic field of the oriented OH groups. The yield of this species is much lower than that of the other radicals.

The EPR spectra of natural cellulose and cellulose hydrate are practically identical, and (in addition to the e_{capt} signal) consist of the superposition of a triplet (component ratio close to 1 : 2 : 1), splitting between the components 2.6 ± 0.1 mT), a doublet (splitting 3.0 ± 0.2 mT), and a singlet with a low intensity.

The cellulose macromolecule includes D-glucose repeat units, joined by 1,4-β-glucoside bonds:

The three-dimensional structure of the D-glucose unit in the macromolecule is characterised by a pyranose ring with axially arranged hydrogen atoms. An analysis of the splitting constants indicates that the signals with the doublet and triplet HFS are due to radicals with a pyranose ring, formed as a result of the rupture of the C–H bonds in positions 1, 2, 3, or 4. This follows from the fact that the spectrum does not show the signals with splitting constants 1.7–1.9 mT, characteristic of radicals with α-protons.[81–83] Splitting values of 2.5–3.0 mT are characteristic of carbohydrate radicals with axial β-protons.[84–87] As a result of the removal of the hydrogen, the hybridisation of the carbon atom changes from sp^3 to sp^2, and the unpaired electron is transferred to the $2p_z$ orbital; in this position, it interacts effectively with the axial β-hydrogen atoms. The doublet signal must be due to the radical formed by the rupture of the C–H bond in position 1. In principle, the triplet signal may be due to any of the radicals produced as a result of the rupture of a C–H bond in positions 2, 3, or 4; it may also represent the superposition of EPR signals from three radicals produced in this way, differing little from one another. The most probable position for the localisation of the excitation energy, however, is the C(4) atom. This conclusion agrees with the fact that the C–H bonds broken are those in positions 1 and 4, which are weakened to the greatest extent as a result of the withdrawal of the electrons to the 1,4-β-glucoside bonds and the ring oxygen atom. A similar interpretation was proposed for the EPR spectra obtained in the sensitised photolysis[88] and radiolysis[89] of cellulose.

The appearance of the singlet signal can apparently be related to the presence of residual lignin in the cellulose. Thus the intensity of this signal is much greater in the EPR spectra of holocellulose and wood γ-irradiated at 77 K.[71] Unlike cellulose, these materials contain considerable quantities of lignin (particularly wood). Lignin γ-irradiated at 77 K gives a narrow symmetrical singlet with line width 1.0 ± 0.1 mT, which coincides with that observed for cellulose and wood.[72] This may indicate that the singlet signal in the spectrum of irradiated cellulose is due to a radical of the "lignin" type. The yields of the radicals, calculated for a linear accumulation section (G), are 3.4 radicals and 1.6 radicals per 100 eV for the γ-irradiation of specimens at 77 K and 300 K respectively.[71] The kinetics of the accumulation of the radicals is described effectively by the equation:

$$[R] = [R]_{lim}(1 - e^{-K_d D})$$

where the limiting concentration of the radicals $[R]_{lim} = G/K_d$ (K_d is the constant for the radiation disappearance of the radicals), and the absorbed dose $D = It$ (I is the dose power, and t the irradiation time). The values $K_d = 7.7 \times 10^{-3}$ kGrad^{-1}, calculated from this equation using published data,[71] are the same, within experimental error, for γ-irradiation at 77 K and 300 K, apparently indicating that the mechanisms of the annihilation of the radicals by radiation at these temperatures are the same. This value of K_d is characteristic of compounds with saturated bonds,[90] and indicates that there is no effective migration of the excitation in cellulose.

Thus when cellulose is exposed to ionising radiation, some of the "ejected" electrons, after thermalisation, are stabilised in intermolecular traps. Because of the "crystal-like" character of the structure of cellulose, however, the concentration of these traps is apparently insufficient to suppress effectively the recombination of the "electron-hole" ion pairs, bound to Coulombic interaction. The excitations produced as a result of the recombination are localised, leading to the rupture of the C–H bonds in the weakened positions 1 and 4 [$R_{C(1)}$ and $R_{C(4)}$ radicals respectively are formed]:

$$(RH)^* \rightarrow \dot{R} + H\ .$$

The hydrogen atoms dehydrogenate the elementary monomeric units of cellulose, again in positions 1 and 4. Another important fact is noteworthy. In very moist cellulose, γ-irradiated at 77 K, OH radicals are stabilised, and with increase in temperature these disappear, removing preferentially the hydrogen atoms in positions 1 and 4 of the carbohydrate fragment.[71,72] Thus the point of attack by the radical coincides with the point of rupture of the C–H bonds in the direct action of radiation on cellulose:

$$RH + H(OH) \rightarrow R_{C(1)}\,(R_{C(4)}) + H_2(H_2O).$$

The large amount of information on the EPR study of cellulose γ-irradiated at room temperature is fairly contradictory. Thus it has been reported[65] that the spectrum consists of the superposition of a singlet and a triplet. In Refs. 63, 64, and 67 it is reported that the EPR spectra of dried cellulose I and II after γ-irradiation are extremely similar, and consist of poorly resolved triplets. The EPR spectra produced when the dry specimens are brought into contact with water, and the spectra of specimens containing residual moisture, consist of three components for cellulose I, and five lines for cellulose II. An EPR spectrum containing five components was recorded in Ref.60. Under certain conditions, preliminary treatment of cellulose in the absence of oxygen gives signals with a doublet structure.[67,68]

The present authors[71,72] established that the EPR spectra of very moist cotton cellulose and cellulose hydrate, γ-irradiated at 77 K and then heated to 300 K, and also specimens γ-irradiated directly at 300 K, are practically identical and consist of a triplet with splitting between the components ~2.8 mT. When the specimens are subsequently heated, the total concentration of radicals decreases, the structure of the EPR spectrum changes, and there are grounds for assuming that it consists of the superposition of the EPR signals from several radicals (singlet, doublet, and triplet). At 330 K, a doublet signal with a splitting less than 1.5 mT predominates in the EPR spectrum.

These differences in the structures of the EPR spectra observed in cellulose γ-irradiated at room temperature are apparently due to the appreciable influence of the structure of the cellulose, its moisture content, and other factors, which are not taken into account in the preparation of the cellulose specimens and which influence the thermal stability of the radicals. As a result, at a given temperature (room temperature), radicals of several types, but with different concentration ratios, are stabilised in different specimens, leading to appreciable differences in the form of the EPR spectra.

Thus a study of the thermal stability of cellulose macroradicals[39,61–64,69,89] showed an appreciable increase in the rate of their disappearance or transformation in the presence of water, aqueous solutions of acids and alkalis, ammonia, etc. In thoroughly dried cellulose, the temperature of the intensive disappearance, corresponding to a decrease in the original concentration of radicals by a factor of two, corresponds to ~370 K, whereas in the presence of 2, 7, 11, and 24 mass % water it is displaced to 310, 260, and 210 K respectively.[89] This effect is attributed to the plasticising action of water on cellulose, leading to an increase in the molecular mobility in the polymer. The disappearance of the radicals is then limited by the mobility of the macrochains in the cellulose, and the actual nature of the radicals apparently has no significant influence on the rate of their disappearance. The thermal stability of ~15% of the macroradicals is independent of the water concentration, apparently because they are localised in crystalline regions which are not accessible to water.[89]

The disappearance of the macroradicals is characterised by a kinetic arrest; thus when a certain temperature is reached, the concentration of the particles, for a limited observation time, can be regarded as "stationary". Thus the disappearance of the radicals takes place as it were "in stages". The polychromatic kinetics are due to the physical non-uniformity of the polymer matrix, as a result of which a number of chemically identical processes with different values of the rate constants of the limiting stages take place, that is there is a distribution of the rate constants with respect to activation energies (from E_{min} to E_{max}). Analysis of the results established[89] that for dried cellulose, the pre-exponential factor in the Arrhenius equation is ~10^{-5} cm^3 s^{-1}, E_{min} = 96 ± 8 kJ mole^{-1}, and E_{max} = 155 ± 12 kJ mole^{-1}. For specimens containing ~50% water, the pre-exponential factor decreases to ~10^{-13} cm^3 s^{-1}, and E_{min} and E_{max} have the values 29 ± 2 kJ mole^{-1} and 46 ± 2 kJ mole^{-1} respectively.[89] A noteworthy feature is that in cellulose there may be a compensation effect, involving a decrease in the activation energy of the process with increase in temperature.[91] This feature leads to a decrease in the observed values of the activation energies for the disappearance of the radicals.

When cellulose is plasticised by water, the diffusion mobility of the macro-radicals increases by several orders of magnitude. The elementary act of their diffusion apparently involves the movement of the pyranose unit, in which the

radical state is localised, relative to the other units of the polymer. In dry cellulose, each unit is joined to its neighbours by three hydrogen bonds, but when water is introduced, these bonds are broken, leading to a decrease in the strength of the bonding to the polymer macromolecules. This is responsible for the plasticising action of water or other low-molecular substances on cellulose.

The results of the experimental study of the EPR spectrum show that no appreciable rupture of C–OH, C–C, or C–O–C bonds takes place when cellulose is γ-irradiated. The secondary reactions of the radicals obtained by the rupture of the C–H bonds in positions 1 and 4 lead to the rupture or breakdown of the molecular structure of cellulose.

IV. RADIATION-CHEMICAL DEGRADATION OF CELLULOSE

When polymers are irradiated, two opposed processes take place: cross-linking of the polymer chains, leading to an increase in the average molecular mass $\overline{M}$, and also their degradation, leading to a decrease in the value of $\overline{M}$.[1–5] These processes most frequently take place simultaneously, and polymers may undergo cross-linking or degradation, depending on which process predominates. Cellulose undoubtedly belongs to the second group; degradation is the main result of the action of ionising radiation on cellulose.[7,11,17,19,51,53,92–103]

1. Degradation of the Polymer According to a Random Law

Since the radiation-chemical processes involved in the rupture and cross-linking of polymer chains take place according to a random law, the changes in the molecular mass distributions of the macromolecules are described using statistical methods. The regular statistical features of the processes of cross-linking and degradation, taking place under the influence of ionising radiation, have been discussed in detail.[1,3,5] If the original polymer has a distribution with respect to degrees of polymerisation close to the most probable distribution, the degree of polymerisation will decrease during disordered degradation, but at the same time the most probable distribution will be preserved. For this case, the following equation is applicable:

$$\overline{DP}_n/\overline{DP}_n^0 = \overline{DP}_w/\overline{DP}_w^0 = 1/(1+s) \qquad (1)$$

where $\overline{DP}_n$ and $\overline{DP}_w$ are the number-average and weight-average degrees of polymerisation, $\overline{DP}_n^0$ and $\overline{DP}_w^0$ the corresponding original degrees of polymerisation, and s the number of ruptures taking place in the original polymer molecule. For the most probable distribution, $\overline{DP}_w = 2\overline{DP}_n$.

A system with a broader original distribution of the polymer with respect to degrees of polymerisation, compared with the most probable distribution, shows a slight deviation from relationship (1). It should be emphasised, however, that the most probable distribution in real situations is reached in the initial range of absorbed doses, used for the analysis of the dependence of the degree of polymerisation on the number of ruptures, that is on the absorbed dose, according to Eqn. (1). The number of bond ruptures s for a molecule with a degree of polymerisation $\overline{DP}_n$ is given by the equation

$$s = \frac{D\,\overline{DP}_n^0 m}{N_A E_d} \qquad (2)$$

where m is the molecular mass of the unit fragment of the polymer, and E_d is the energy required for the rupture of one bond. Eqn.(1) can be transformed as follows:

$$\frac{1}{\overline{DP}_n} - \frac{1}{\overline{DP}_n^0} = \frac{G^0 m D}{N_A} \qquad (3)$$

Here, G^0 is the initial radiation-chemical yield of the process of polymer degradation, that is the number of macromolecule ruptures corresponding to 100 eV of absorbed energy.

The molecular masses of polymers (M) or their degrees of polymerisation are determined by measuring the viscosity of their dilute solutions. For an unbranched polymer (in particular cellulose[104,105]), the following empirical relationship is applicable:

$$[\eta] = KM_v^\alpha \qquad (4)$$

where K and α are the parameters which depend on the chemical structure of the polymer, temperature, and the solvent used, and $[\eta]$ the characteristic viscosity. Depending on the configuration of the polymer macromolecule in the solution and the nature of the bonds formed with the solvent, the values of α vary in the range 0.6–1.0, corresponding to changes of only 1.82–2.0 in the expression in braces in Eqn.(5).[3] The value of M_v is related to the number-average molecular weight M_n by the expression

$$M_v = M_n\{(\alpha+1)\Gamma(\alpha+1)\}^{1/\alpha} \qquad (5)$$

where $\Gamma(\alpha+1)$ is the γ-function of α.

Thus the experimentally determined value of M_v and Eqns. (3) and (5) can be used to determine the yield of the degradation of the polymer G.

2. The Radiation Degradation of Cellulose

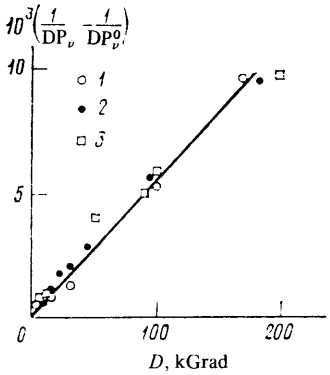
The first systematic study of the degradation of cellulose under the influence of a beam of accelerated electrons with an energy of 0.8 meV (for sulphite cellulose and cotton linter) was described in Ref.11. The degree of polymerisation was determined from the characteristic viscosity of the irradiated specimens in solutions of the complex of copper(II) with ethylenediamine. A regular decrease in the viscosity, which was practically the same for the specimens indicated, was established, that is the degree of polymerisation decreased with increase in the absorbed dose.

Since the determination of $\overline{DP}_v$ in Ref.11 was inaccurate, because of the absence of a reliable relationship between η and M in Eqn.(4), another method of calculation was proposed,[92] which did not use any direct relationship between η and M. This gave the following final expression relating η and the absorbed dose d:[92]

$$\eta = A(D+D_0)^\alpha \qquad (6)$$

where D_0 is the absorbed dose corresponding to the attainment of the most probable distribution of the polymer with respect to molecular masses, α the coefficient in Eqn.(4), and A a constant determined from the experimental dependence of η on $D + D_0$ in accordance with Eqn.(6). Treatment of the data from Ref.11 showed[92] that $\alpha = 0.71$ and $A = 4.9$. The value of K in Eqn.(4) was then taken as 5.9×10^{-4}, which gave a value of 10 for the cellulose degradation yield†.

The approach proposed in Ref.92 has the same disadvantages [the approximate determination of the parameter D_0 (7.5 kGrad and 10 kGrad for sulphite cellulose and cotton linter respectively) in Eqn.(6), and the arbitrary choice of the value of K in Eqn.(4)]; moreover, the treatment in Ref.92 was based on the fundamentally unjustified assumption that the yield of the cellulose degradation process remains constant and independent of the absorbed dose. In Ref.92 it was pointed out that the determination of the degradation



† According to Ref.58, the calculation of the yield in Ref.92 is erroneous, and the corrected value is only half the published value, that is 5.

yield has a low accuracy, because of a number of listed approximations in the calculation procedure.[3]

Later work[58] also used the approach proposed in Ref.92 and established that for cotton cellulose, $A = 4.0$, $\alpha = 0.78$, and $D_0 = 5$ kGrad. Taking from Ref.104 the value 1.71×10^{-4},[104] the value obtained[58] for the cellulose degradation yield was 4.5 ± 0.3.

There is apparently more justification for estimating the cellulose degradation yield using Eqns.(3) and (5), which are obtained from a statistical examination of the processes taking place. The degree of polymerisation in this case is determined from Eqn.(3), which relates it to the viscosity characteristics of the polymer solution. A solution of cellulose in Cd-oxene (a solution of the ethylenediamine complex of cadmium) is the most suitable for the measurement of the viscosity characteristics; this method has been widely used in recent years. According to Ref.105, the values of α and K in Eqn.(4) for this system are 0.94 and 7.1×10^{-3} respectively.

The dependence of $\overline{DP}_v$ for cellulose on the absorbed dose, constructed on the coordinates of Eqn.(3) (using data from Refs.53, 102, and 106), is shown in the Figure. It can be seen that Eqn.(3) is satisfied up to an absorbed dose of ~200 kGrad. In Ref.102, the characteristic viscosity was measured in a solution of the ethylenediamine complex of copper; the values of K and α were taken as 1.33×10^{-4} and 0.905 respectively.[107] In Refs.53 and 106, the characteristic viscosity was measured in Cd-oxene solutions. Since for the values of α used in the works cited[53,102,106] the number-average and viscosity-average degrees of polymerisation are related by the expression $\overline{DP}_v = (1.90\text{–}1.96)\overline{DP}_n$,[3] the radiation cellulose degradation yield, determined from the data given in the Figure, is 7.2 ± 0.2. The applicability of Eqn. (3) indicates that the radiation degradation of cellulose does in fact take place according to a random law.

Plot of $1/\overline{DP}_v - 1/\overline{DP}_v^0$ against the absorbed dose (*1*—Ref.53, *2*—Ref.102, *3*—Ref.106).

Eqns.(1) and (3) are applicable for the most probable distribution of the molecular weights of the polymer. For real specimens, which have a broad original degree of polymerisation distribution, some deviation from the linear relationship between $(\overline{DP}_v)^{-1}$ and the absorbed dose can be expected in the initial stages of the irradiation, as far as a certain dose D_0 corresponding to the attainment of the most probable distribution. It can be seen from the Figure, however, that if this deviation does take place for the data being considered at doses up to ~30 kGrad, it is very slight. At absorbed doses ≳ 200 kGrad, deviations from Eqn.(3) are observed, and the experimental data up to fairly large doses (~1000 kGrad) can be described effectively by the following empirical relationship

$$1/\overline{DP}_n - 1/\overline{DP}_n^0 = KD^m \ . \qquad (7)$$

According to Refs.53 and 102, the value of m in Eqn.(7) is 0.83; Ref.98 gives the value 0.73 (the dose D is expressed in kGrad).

The deviation of the experimental data at high absorbed doses from the relationship (3) predicted on the basis of simple statistical considerations is apparently due to the fact that irradiation is accompanied not simply by depolymerisation of the cellulose, and the rupture of the bonds in the macromolecules is accompanied by the formation and accumulation of radicals which are stable at room temperature, and also new functional groups. The latter are apparently formed at the points where the cellulose polymer chains are ruptured. The presence of these polar groups influences, firstly, the values of the effective characteristic viscosity of the solutions of the irradiated cellulose, used to determine the average molecular mass. Secondly, the C=O groups, like the free radicals, act as effective acceptors of electrons and excited states, formed during the irradiation of various substances. Thus their accumulation during radiolysis leads to a decrease in the rate of the subsequent degradation of the cellulose. This is indicated by the results of a study[57] which established a significant decrease in the rate of the degradation of cellulose specimens containing carboxyl groups (monocarboxycellulose).

The radiation degradation of cellulose is accompanied by a decrease in the width of the molecular mass distribution, and with increase in the absorbed dose, a monodisperse distribution is approached. A decrease in the polydisperse character of technical celluloses at high absorbed doses (500–1000 kGrad) has been noted.[70,108] It has also been established[109] that a change in the molecular mass distribution of cellulose takes place even at low doses. Thus the non-uniformity coefficient decreases from 1.3 for the original cellulose to ~0.4 for irradiated cellulose (for an absorbed dose of 3.2 kGrad). A similar picture is observed for the radiolysis of native dextran, consisting of D-glucose units, joined by a 1,6-glucoside bond.[110] The ratio of the average molecular masses $M_z : M_w : M_n$ is 3.5 : 2.0 : 2.0, whereas for the degradation of the macromolecules according to a randam law, this ratio should have been 3 : 2 : 1.[1,3] This difference is apparently due to the characteristic features of the molecular mass distribution on fractionation, where no account is taken of the final values of the molecular masses and their distribution in the separate factors.

V. CHEMICAL TRANSFORMATIONS IN IRRADIATED CELLULOSE

1. Gas Liberation During the Irradiation of Cellulose

The action of ionising radiation leads to extensive chemical transformations in cellulose. When cellulose is irradiated, gaseous products are liberated: hydrogen, carbon monoxide, carbon dioxide[39,51,111] and small quantities of methane.[111] In the initial stages of irradiation (up to ~200 kGrad), the accumulation of the products is proportional to the absorbed dose (in a vacuum). The radiation-chemical yields of H_2, CO, and CO_2 for an absorbed dose of ~500 kGrad are respectively 1.3, 0.8, and 1.6 in a vacuum, and 1.2, 1.7, and 3.3 in an oxygen atmosphere.[39,51] A similar percentage ratio of the yields of the gases in the dose range 50–2500 kGrad is given in Ref.111.

2. Redox Transformations of Cellulose

An important role in the radiation-chemical transformation of cellulose is played by processes of redox degradation. The copper number (c.n.), which characterises the reducing power, increases considerably with increase in the absorbed dose.[102,106] Analysis has shown that carbonyl and carboxyl groups are formed in irradiated cellulose[39,51,102] (Table 3).

Table 3. Chemical analysis of cellulose γ-irradiated at room temperature.[102]

Dose, kGrad	$10^{-19}N_1, g^{-1}$	$10^{-19}N_2, g^{-1}$	P.p.m.
0	0.32	1.90	1.3
8.8	0.71	1.97	1.9
20.6	0.90	2.01	2.8
45.2	0.94	2.11	3.8
94.6	1.48	2.23	6.2
183.0	2.20	2.36	11.2
406.0	2.99	2.59	24.6
908.0	4.11	2.78	46.5
1880.0	4.84	3.04	70.2

Notes. N_1 and N_2 are the numbers of carbonyl and carboxyl groups respectively in one gram of cellulose.

The radiation-chemical yield of carbonyl and carboxyl groups is slightly lower for irradiation in a vacuum or in a nitrogen atmosphere than for irradiation in an oxygen atmosphere.[39,51,98] The yields of carbonyl groups are higher than the yields of carboxyl groups.[102] Thus for a specimen of dry cellulose γ-irradiated at room temperature in a closed volume for an absorbed dose of 8.8 kGrad, the yields of carbonyl and carboxyl groups were 7.6 and 1.3 respectively.[102] For irradiation by accelerated electrons (dose 3.7 kGrad), the yields of these groups are 7.8 and 3.1.[102] Other workers[39,51,93] give appreciably higher values for the yields: 58 (for the CO groups) and 3.5 (for the COOH groups). A yield of 3.6 for the carboxyl groups was also obtained in Ref.19.

It can apparently be assumed with sufficient accuracy that the yield of carboxyl groups in the radiolysis of cellulose is 3 ± 1. The values of the yields of the carbonyl groups given in Refs.102, 39, 51, and 93 differ considerably, but the most reliable value is apparently ~7–8.[102] The unusually high value obtained in Refs.39, 51, and 93 is probably due to the conditions of the analysis (this involved the hydrolysis of the oligosaccharides extracted by aqueous solution from the irradiated cellulose). An equally high yield (~50) can be obtained from the data given in Table 3 if it is assumed that the copper number provides a quantitative characteristic of the concentration of carbonyl groups in irradiated cellulose. Their accumulation at high absorbed doses takes place according to the same law as the degradation of the macromolecules [Eqn.(3)]. The data in Ref.102 gave the following relationship

$$c = BD^m$$

where c is the concentration of carbonyl or carboxyl groups, and B is a coefficient equal to 6.8×10^{-7} mole g^{-1} or 1.8×10^{-7} mole g^{-1} for the carbonyl and carboxyl groups respectively. The value of n for the radiation accumulation of carbonyl and carboxyl groups was the same and equal to ~0.5. In Ref.98, in an interpretation of published data[93] on the accumulation of COOH groups, the exponent m was found to be 0.69.

Because of the high molecular weight of cellulose and other polysaccharides, the use of the methods of chemical analysis, in particular chromatography and mass spectrometry, to determine the final radiolysis products is practically impossible. It was previously noted[97,112,113] that irradiated cellulose contains water-soluble and water-insoluble fractions. From the water-soluble fraction it was possible to isolate components soluble in ethanol, among which cellobiose, glucose, 2-ketogluconic acid, arabinose, glyoxal, and a number of other complex acids were detected.[97] The hydrolysis of the water-soluble fraction of radiolysed cellulose gives xyloses, arabinoses, glucuronic acid, formic acid, and malonic dialdehyde.[21] The following values were obtained for the radiation-chemical yields for the formation of some of these compounds: 48.7 ± 2.4 for glucose, 10.1 ± 2 for xylose, 0.016 for malonic dialdehyde, and 2.3 ± 0.2 for formic acid. The formation of pentosans has been reported.[102]

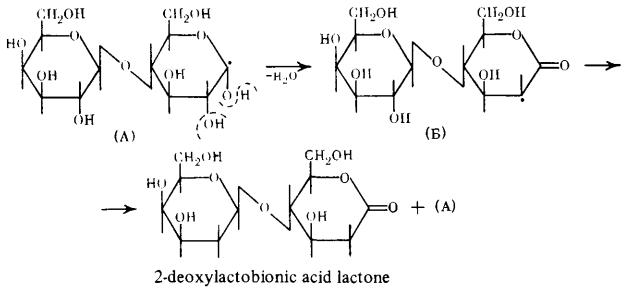
3. The Radiation-chemical Transformations of Various Model Carbohydrates

To establish the principal routes in the radiation-chemical transformations of cellulose and other polysaccharides, it is appropriate to use simpler carbohydrates, whose transformations, on the one hand, can model the chemical reactions taking place in polysaccharides, and on the other hand, can be studied by modern methods of chemical analysis.

These carbohydrates include cellobiose, which contains two glucose residues connected by a glucoside bond. This disaccharide can be regarded as a fragment of cellulose. In aqueous media, the greater part of the final radiolysis products of this carbohydrate (~98%) consists of glucose, gluconic acid, 5-ketoglucose, 4-deoxyglucose, 2- and 5-deoxygluconic acid, deoxyketoglucose, arabinose, dihydroxyacetone, ribose, erythrose, and various other compounds.[114,115] The mechanism of their formation involves the hydrolysis of radicals obtained by the rupture of the C–H bonds in positions 1 and 4 and partly 5.

The cellobiose decomposition yields depend on the nature of the gas saturating the aqueous solution. Thus in a nitrogen atmosphere, the radiation yield is 3.1, and increases to 6.5 when the solution is saturated with nitrous oxide.[116] Since in the last case the hydrated electrons formed are converted into OH radicals:

$$N_2O + e(aq) + H_2O \rightarrow N_2 + OH^- + OH\ .$$



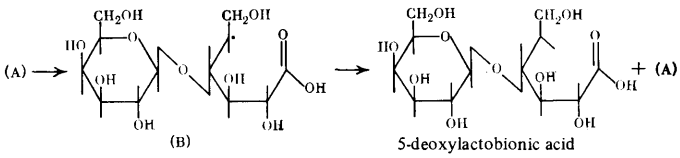
The observed doubling of the disaccharide decomposition yield most probably indicates that OH radicals play a decisive role in their radiation-chemical transformation. The role of the OH radicals most probably reduces to the removal of an H atom from the C(1) or C(4) atoms with the subsequent hydrolytic splitting of the radical at the glucoside bond.

According to Ref.117, the yield for the breakdown of the glucoside bond in cellobiose decreases by a factor of about 2.5 in the presence of oxygen. This is apparently due to the addition of an O_2 molecule to the C(1) or C(4) atoms with the formation of a peroxide radical and other transformation paths different from the rupture of the glucoside bond. Thus the radiolysis of aqueous solutions of cellobiose, as in the case of many other disaccharides (see the published monograph[118]), involves the rupture of glucoside bonds, oxidation, redox degradation, and the formation of deoxy- and deoxyketo-compounds.

A number of carbohydrates show appreciable radiation-chemical instability in the polycrystalline state. In this case the radiolysis is accompanied by the formation of a limited number of products. For example, the radiation-chemical

transformations of α-lactose monohydrate take place with a yield of 40–60 [119] according to three main schemes.[120]

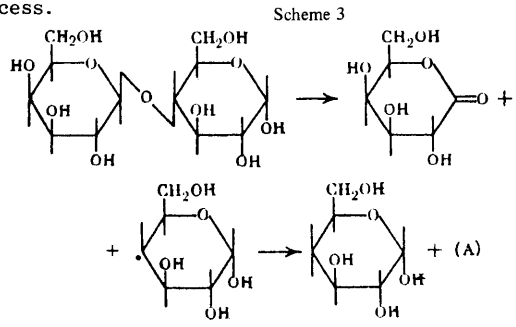
Scheme 1



2-deoxylactobionic acid lactone

The radical (A) formed on γ-irradiation loses water as a result of dehydration; this gives the radical (B), which removes an H atom from the C(1) atom of a neighbouring lactose molecule. This gives 2-deoxylactobionic acid lactone, and also a new radical (A). Thus a chain process is initiated, in which the yield of lactone is 20.

The reaction involving the radical (A) can also take place by another mechanism to give the radical (C). The radical (C) removes an H atom from a neighbouring molecule, and as a result of a chain mechanism gives the final product 5-deoxylactobionic acid with a yield $G = 40$.[120]



Scheme 2

5-deoxylactobionic acid

The rupture of the glucoside bond apparently takes place according to scheme 3 with the participation of a radical in which the electron is localised on the C(4) atom to give galactonic acid lactone ($G = 4.5$) and 4-deoxy-*D*-glucose ($G = 4.5$).[120] This process is not a chain reaction, unlike the two previous ones. The radical (A) is also generated in this process.

Scheme 3

Similar reactions take place in other systems. For example, the radiation-chemical transformations of 2-deoxy-*D*-ribose give 2,5-dideoxyerythropentonic acid with yield $G \geq 650$.[121] Crystalline *D*-fructose also decomposes under the influence of radiation, with a yield of 40–60.[122]

These examples show that for a number of carbohydrates, radiation-chemical decomposition takes place by a chain process. It is important to emphasise, however, that the yield of products associated with the rupture of the glucoside bond is low, and corresponds to the usual yields of the decomposition of substances by a non-chain mechanism. Thus 4-deoxy-*D*-glucose and galactonic acid lactone are formed by the rupture of the glucoside bond of α-lactose monohydrate by a non-chain mechanism with a yield of 4.5. This is an extremely important feature, since the yield for the degradation of cellulose (~7) indicates that a non-chain mechanism is most probable for the rupture of the glucoside bonds. Because of the contradictory nature, noted above, of the data relating to the yield of carbonyl groups (~7.6 [102] and ~58 [39,51,94]), however, a chain process in the radiation-chemical decomposition of cellulose by reactions analogous to those just examined cannot be finally excluded.

It has also been suggested that cyclic oligosaccharides—cycloamyloses—be used as model compounds imitating the radiation-chemical transformations of cellulose and other biological polysaccharides.[123,124] These compounds also do not have free reducing groups, that is aldehyde and keto-groups, whose presence in simple carbohydrates is responsible for the chemical properties which they exhibit.

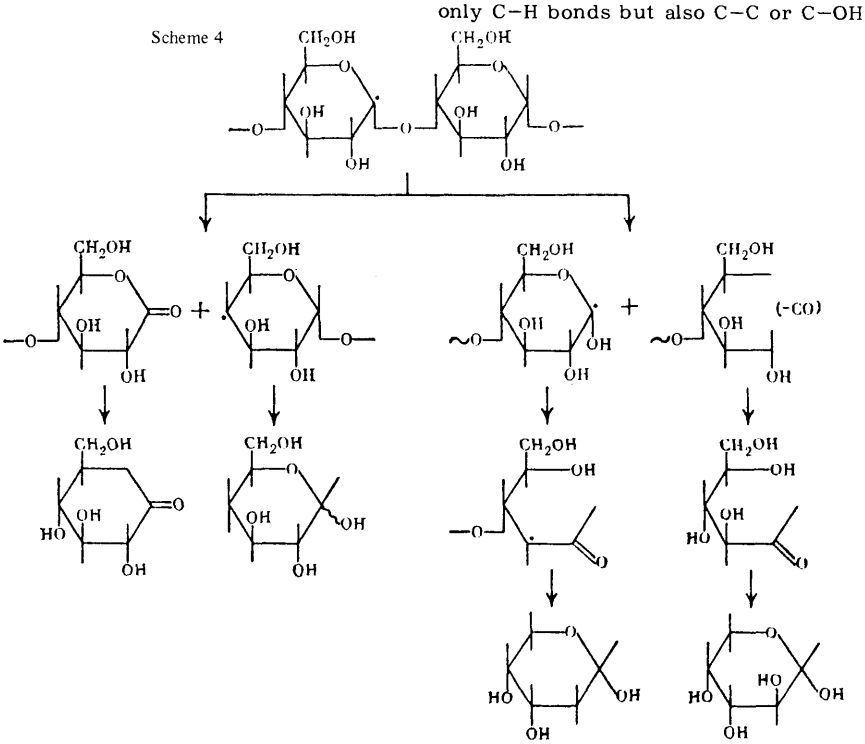
It has been reported[125] that the γ-irradiation of cyclohepta-amyloses to an absorbed dose of 15 kGrad gives maltohexaoses. Subsequent studies[123,124] of cyclohepta- and cyclohexa-amyloses showed that the presence of water influences the efficiency of their radiation-chemical decomposition (Table 4). The products did not contain significant concentrations of glucose or maltoheptaose. The chief products were gluconic acid lactone and maltohexaose. Similar transformations were observed in the γ-radiolysis of cyclohexa-amyloses. The products included the same lactone and maltopentaose, but not maltohexaose, which is the chief product of the acid hydrolysis of this compound.

Thus the action of ionising radiation on cycloamyloses leads to cleavage of the cyclic system. The nature of the transformations taking place in the dried substance demonstrates unambiguously the identical yields of the initial radiolysis products maltohexaose and acid on the one hand, and the yield for the decomposition of the amylose on the other. Thus the cleavage of the polysaccharide ring is accompanied by the formation of one molecule of maltohexaose and acid. It can be seen from Table 4 that the presence of water inhibits the decomposition of the polysaccharide. On drying in air at 378 K, a moisture content of about 1.5% is preserved, corresponding to a molar ratio water : substance of 1 : 1. The presence of one water molecule per molecule of the polysaccharide leads to a decrease in the decomposition yield by a factor of almost 2 (see Table 4).

The crystals of the cyclohepta-amyloses isolated from aqueous solution contain ~14.8% water; the same quantity of water is present in amylose which has been kept for a long time in air. In this case there are ten water molecules per molecule of the substance. The cyclohepta-amylose decomposition yield, calculated for the total absorbed energy, is 6.2. If however account is taken only of the energy absorbed by the polysaccharide, the yield is 7.5, as in the previous case.

From this examination it might be concluded that the radiolysis products of water (H atoms and OH radicals) do not take part in reactions with the cyclohepta-amylose; this is undoubtedly not the case, however. Their reaction is apparently not accompanied by the breakdown of the cyclic structure of the polysaccharide. The presence of water also leads to an appreciable decrease in the yield of acid compared with the yield of maltohexaose, apparently due to the participation of water in reactions with intermediate decomposition products of the polysaccharide.

A detailed chemical analysis of the final products of the radiation-chemical transformations of cycloamyloses has been carried out.[126] The data obtained confirm the previously



established fact[123–125] that the cleavage of the cyclic structure is the main process in cycloamyloses subjected to the action of radiation. By analogy with earlier studies of the radiolysis of simple carbohydrates,[118] it was suggested that the position of the keto-groups in the *D*-glucose residues produced in the radiolysis of the amyloses coincides with the position of the initial attack, that is with the localisation of the radical centres. These keto-groups are produced in irradiated carbohydrates as a result of the following reactions: a) disproportionation, or possibly the removal of hydrogen atoms from the α-OH group as a result of attack by primary or secondary radicals; b) radical rearrangement; c) removal of a molecule of water, alcohol, or CO; d) hydrolysis of acetal bonds if the radical centre is in an adjacent position; e) the formation of deoxy-groups as groups adjacent to keto-groups in a reaction following the addition of an H atom as a result of disproportionation.

Schemes for the radiation-chemical transformations of amyloses, proposed on the basis of these concepts, are given below.[123,124] It is assumed that the formation of the final radiolysis products is determined by the method by which the radical state is localised in the cycloamylose.

Scheme 4 illustrates chemical transformations involving radicals in which the electron density is localised on the C(1) atom [$R_{C(1)}$ radical]. Here and in subsequent schemes, the last stage corresponds to the hydrolysis of the oligosaccharides in aqueous solution to an identified monosaccharide. According to scheme 4, glucono-1,5-lactone is formed either by the hydrolysis of the glucoside bond closest to the radical centre or (preferentially) by the radical rearrangement C(1) ⇌ C(4). In the last case, electron transfer to the C(4) atom gives 4-deoxy-*D*-xylohexaose. The altered linear chain of the oligosaccharide will thus contain two functional groups at its ends, and the product will be a derivative of maltohexaose or maltoheptaose.

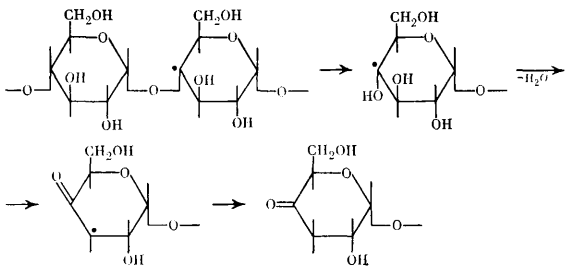
Other reactions involving the removal of CO and OH groups from the $R_{C(1)}$ radical have been proposed[123,124] to explain the formation of arabinose, ribose, and 2-deoxypentaose. The main product obtained according to scheme 5 is apparently *D*-arabinose.

Scheme 4

Scheme 5 shows the chemical changes in cycloamylose when the radical centre is localised on the C(4) atom [$R_{C(4)}$ radical]. The main result of the chemical transformations according to scheme 5 is the formation of 3-deoxyerythro-hexaose-4-ulose.

Table 4. Influence of the presence of water in a specimen of cyclohepta-amylose (CHA) on the yields of its radiation-chemical transformation*.[123]

Specimen	Decomposition of CHA	Formation of acid	Formation of maltohexose
Kept in air**	6.2	2.8	6.6
Kept in air at 378 K	7.4	7.5	7.5
Kept in a vacuum at 77 K	14.6	14.2	14.2
Aqueous 8×10^{-3} M solution	1.4	2.2	1.2



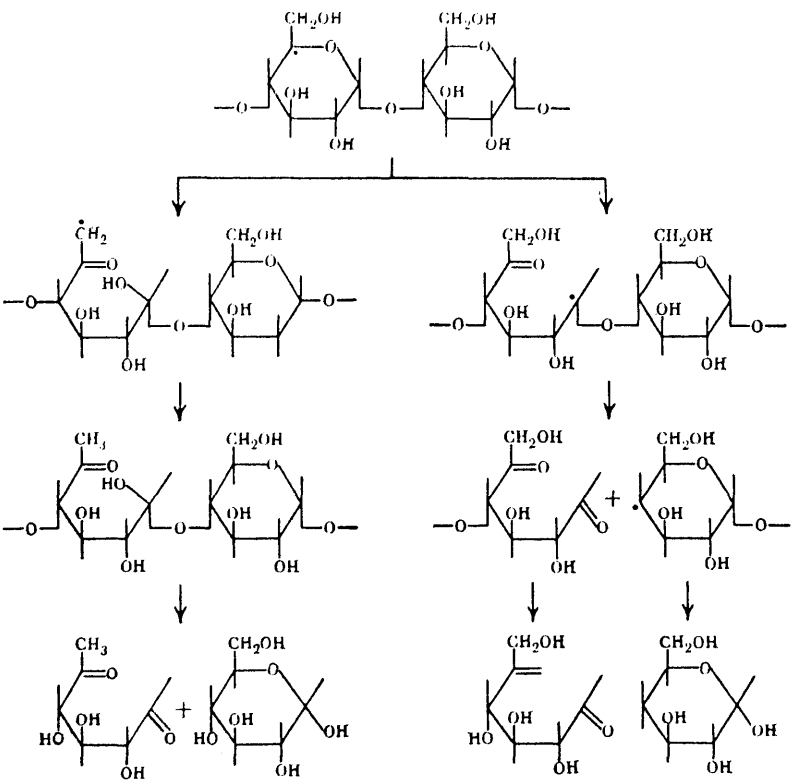
*The γ-irradiation of the specimens was carried out in a vacuum at room temperature. Dose power ~ 2.6×10^{17} eV g^{-1} min^{-1}, $D \sim 2 \times 10^{20}$ eV g^{-1}.
**The yields of H_2, CO_2, and CO were 3.1, 2.2, and 0.9 respectively.

Finally, scheme 6 reflects the possible transformations of amyloses with a reaction centre on the C(5) atom [$R_{C(5)}$ radical].

When the reaction takes place according to scheme 6, the radical rearrangement C(5) → C(1) gives a keto-group on the C(5) atom, and also a 4-deoxy-group.

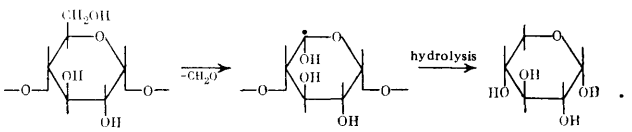
A number of identified compounds do not appear in the proposed general schemes. Some of them are apparently produced as a result of the transformations of radicals with localisation of the unpaired electron, for example, on the C(6) atom, or by more complex schemes based on the less probable process of radical formation by the rupture of not only C–H bonds but also C–C or C–OH bonds.

Scheme 5



VI. MECHANISM OF THE RADIATION-CHEMICAL TRANSFORMATIONS OF CELLULOSE

The examination of data on the radiation-chemical transformation of cellulose shows that in the initial stages of the interaction with ionising radiation, free radicals are produced in the polymer, with localisation of the electron density mainly on the carbon atoms in positions 1 and 4. The subsequent degradation of the macromolecules and the formation of carbonyl and carboxyl groups and various chemical compounds, are initiated by radical species. A quantitative comparison of the yield of radicals, measured by EPR, after the γ-irradiation of cellulose at 77 K (~3.6 [71]) with the yield of its degradation (7–8, see section IV) and with the yield of carbonyl (7.6 [102]) and carboxyl (3–4 [102,119]) groups after γ-irradiation or irradiation by accelerated electrons at room temperature, shows that all these yields are of the same order of magnitude. When account is taken of the difference in the accuracies of their determination, including chemical side reactions of cellulose during the chemical analyses, and also the influence of the conditions of the irradiation on the efficiency of the radiation-chemical decomposition of cellulose, the possible partial disappearance of radicals even at 77 K, and other factors, it can apparently be concluded that each case of damage to the cellulose macromolecule with the formation of a radical centre is accompanied by subsequent bond rupture and the formation of carbonyl and carboxyl groups at the point of rupture. Allowance must also be made for the fact that it is possible in principle to have chemical transformations of cellulose involving excited states, without the formation of intermediate radical–ion products.



The study of the mechanism of the radiation-chemical degradation of cellulose is extremely difficult, because of the difficulty of the chemical analysis of the functional groups of the macromolecules. Considerable valuable indirect information on the main routes of the chemical transformations of cellulose initiated by reaction of radiation has been obtained by studying the final radiolysis products of model compounds, particularly cycloamyloses. Comparison of the data obtained in the analysis of the products of the acid hydrolysis of aqueous extracts of irradiated cellulose and data on the radiolysis of cycloamyloses shows unambiguously that the radiation-chemical transformations of these compounds take place by the same mechanisms.[127] For example, the final radiolysis products of cellulose, as in the case of cycloamylose, do in fact, in accordance with scheme 4, contain arabinose and 2-ketogluconic acid, and in accordance with schemes 5 and 6, various deoxy- and deoxyketo-compounds are formed.[112,119] There is not only a qualitative correspondence in the chemical reactions but also good quantitative agreement in the efficiencies of the radiation-chemical decompositions. Thus chemical analysis (Table 4) indicates that for cyclohepta-amylose dried in air, the yields for the decomposition and the formation of acid and molecular gases practically coincide with the corresponding yields for cellulose (see section V).

Scheme 6

Mention must be made of the fact, difficult to explain, that the products of the acid hydrolysis of an aqueous extract of irradiated cellulose, in addition to glucose, also contain xylose,[19] and the yields of these monosaccharides are ~49 and ~10 respectively. The formation of glucose in the acid hydrolysis of cellulose is a common phenomenon. The detection of xylose in the hydrolysate in yields comparable with the yield of glucose is extremely unusual, however. Xylose, and also arabinose, have also been detected in irradiated starch.[128]

A mechanism has been proposed for the formation of xylose.[129] It includes the rupture of the C–H bond in position 6 and the removal of formaldehyde, with the subsequent transformation of the resulting radical to give xylose:

According to this mechanism, the radiolysis of cellulose should give formaldehyde with a yield equal to the yield of xylose; it was not detected, however. Formic acid was found, however (yield 2.3).[19] It might be assumed that it is formed from formaldehyde in the acid-containing aqueous solutions during the acid hydrolysis of aqueous extracts of irradiated cellulose. Its yield is appreciably lower than that expected for the above mechanism, however. It has therefore been suggested[19,113] that formic acid appears in the oxidative degradation of glucose. Thus the scheme proposed[129] for the formation of xylose apparently has not been proved.

Malonic dialdehyde has been detected in irradiated cellulose.[19] Its yield for dry cellulose is 0.016, and in neutral and acidic aqueous solutions the yields are approximately the same and equal to $(6–7) \times 10^{-3}$. In alkaline solutions, however, there is a significant increase in the yield, to 0.256. The dependence of the yield of this product on the dose in the last case passes through a maximum at a dose of 2.5 kGrad. The formation of malonic dialdehyde has been established in the radiolysis of simple carbohydrates.[130,131]

Thus in the radiation-chemical degradation of cellulose, carbonyl and carboxyl groups are produced at the ends of the molecular fragments. The subsequent hydrolysis of these low-molecular polysaccharides gives deoxy- and deoxyketo-sugars, complex and simple organic acids, sugars, and other compounds. Dehydrogenation and degradation of the glucopyranose rings take place with the liberation of appreciable quantities of hydrogen, carbon monoxide, and carbon dioxide. Radiation changes can also take place without rupture of the polymer chain, and may be accompanied by the production of new groups (CHO, CO, COOH, etc.) in individual units.

---o0o---

The analysis of data on the radiolysis of cellulose shows a fairly complex picture of radiation-chemical transformations taking place. At the present time it is possible to put forward only approximate general schemes for the mechanism of the degradation of the macromolecules and the formation of the final compounds, which are polysaccharides with various terminal groups. Subsequent studies of the radiation chemistry of this important natural polymer will make it possible to refine the mechanism of its radiolysis.

The questions which are apparently of greatest interest at present for the successful solution of a number of practical and scientific problems relating to the radiation processing of cellulose-containing materials are related to the search for methods of intensifying the degradation of cellulose and establishing the principal final products. For this purpose it is necessary to study the influence of temperature, moisture content, and various additives on the efficiency of the radiation decomposition of cellulose. The solution of these and other problems will facilitate the introduction of radiation methods into technological processes for the utilisation and processing of cellulose and cellulose-containing materials.

Selective Detectors in Gas Chromatography

L.Ya.Gavrilina, V.I.Zheivot, and O.A.Emel'yanova

The present state of selective gas-chromatographic detection has been examined. The principles, developmental trends, and characteristic features of selective detectors of 14 types have been described briefly, and examples of their practical application have been given. Particular attention has been paid to the use of these detectors in the analysis of micro-quantities of harmful chemical compounds in environmental materials.
The bibliography contains 184 references.

I. INTRODUCTION

The recent increase in interest in highly sensitive selective detectors is related to the extension of the range of problems being solved by gas chromatography, and also to an increase in the complexity of the compositions of the mixtures being analysed. This applies particularly to the analysis of environmental materials and specimens of biological origin, where the resolving power of the most efficient gas-chromatographic columns combined with highly sensitive universal detectors is insufficient for the complete separation and determination of all the components present in a specimen.[1] At the same time, however, it is often necessary merely to know whether compounds of a given class are present. This information can be obtained using a detector which reacts selectively only to compounds of the given class. The use of selective detectors is particularly promising in the analysis of pollutants in air and water, where it is necessary to determine traces of harmful substances in the presence of large quantities of the main components.

The action of selective detectors is based on the most varied properties of the substances being analysed, such as their ability to undergo ionisation, emit (or absorb) light, undergo chemical reaction, etc. Many of these detectors are fairly simple to construct and convenient to use, and are firmly established in everyday gas-chromatographic analytical practice. Examples include the electron-capture detector, which is sensitive to halogen-containing organic substances, nitro-compounds, and other substances which act as electron acceptors; the thermo-ionic detector, which has an increased sensitivity to nitrogen-, phosphorus-, and halogen-containing compounds; the flame-photometric detector (S- and P-containing compounds); and the radiometric detector, used to detect substances labelled with radioactive isotopes.

The terms "universal" and "selective" are to some extent arbitrary when applied to detectors. Thus the universal flame-ionisation detector, which is highly sensitive to practically all organic compounds, is insensitive to most gases and vapours of inorganic substances, and the radiometric detector, selective with respect to different types of radiation, is non-selective in the sense that it cannot determine whether the labelled substance belongs to a particular class of chemical compound. A detector is usually regarded as selective if its sensitivities for substances of two different classes differ by at least an order of magnitude.[2]

The present review of the literature of the past ten years examines the present state and examples of the practical application of the most frequently employed selective gas-chromatographic detectors: flame-photometric, plasma-emission, photo-ionisation, etc.
tography has been combined with infrared and mass spectrometry and with chemical ionisation are also discussed.

II. SPECTROSCOPIC DETECTORS

1. The Flame-photometric Detector

The action of the flame-photometric detector (FPD) is based on the recording of the emission spectra produced by the thermal heating of the specimen in a burner flame.[1,3-24] A hydrogen–air flame with added oxygen is usually employed. The combustion of substances whose molecules contain atoms of sulphur, phosphorus, nitrogen, selenium, tin, and various other elements gives excited species (for example S_2^*, HPO^*, etc.), which emit a characteristic spectrum.[1,3]

The design of the FPD combines the cell of a flame-ionisation detector (FID) with an optical scheme for measuring the light flux.[3] The flame of the FPD is richer in hydrogen than that of the FID. The conditions of mixing of the streams of carrier gas and auxiliary gases in the burner, and their total consumption, influence the sensitivity and stability of operation of the FPD. The optimum conditions may therefore be different for different versions of this detector.[1,3-7] To prevent overheating of the optics and sensitive elements, the flame is enclosed in a quartz or Pyrex tube, or light pipes may be used. The background emission of the flame is absorbed by interference filters, which transmit only light of the required wavelength (λ = 394 nm for sulphur compounds, and λ = 526 nm for phosphorus compounds). The sensitivity and selectivity of the FPD with respect to a given substance are determined by the intensity of the analytical line in the

spectrum and the width of the transmission band of the light filter. The use of filters with narrower transmission bands increases the selectivity and the useful signal : noise ratio, but decreases sharply the sensitivity of the FPD, since the intensity of the light flux is proportional to the square of the transmitted band width.

The flame-photometric detector is a flow detector. For phosphorus compounds, the magnitude of the signal (the area of the peak) is directly proportional to the flux of the substance.[3] For sulphur compounds, this relationship is logarithmic; the exponent in the equation relating the area of the peak to the mass velocity of the substance being analysed in the detector should theoretically be equal to 2, but in practice it takes values from 1 to 2.5 for different substances; this is due to the fact that excited species S_n^* may be formed in the detector flame in addition to the species S_2^*.[6,9]

The sensitivity threshold of the FPD is $(2-100) \times 10^{-12}$ g s^{-1} for phosphorus compounds,[3,4,6,7] and $(6-300) \times 10^{-12}$ g s^{-1} for sulphur compounds.[4-6,10] This corresponds to approximately 10^{-9} g of the element being determined in the specimen.[7] The sensitivity of the determination of substances containing nitrogen, boron, tin, and other elements is slightly lower.

The linear range of the FPD is 10^4-10^5 for phosphorus compounds,[3,7] but is much lower ($\sim 10^2$) for sulphur compounds.[6,11] It has been proposed that the linear range of operation of the FPD in the analysis of sulphur compounds be increased by adding traces of carbon disulphide vapour (2–4 mg s^{-1}) to the carrier-gas stream[6] or by treating the detector connections with sulphur compounds.[10] This also leads to a decrease in the detectable minimum.[12] The sensitivity of the FPD with respect to sulphur-containing compounds is 10^4-10^7 times greater than that with respect to hydrocarbons and alcohols, and depends on the ratio of the gas flow velocities and on the design of the detector.[13] A slight decrease has been observed, however, in the magnitude of the signal for sulphur compounds, when eluted from the gas-chromatographic column together with hydrocarbons. The different extent of the decrease in the sensitivity of the FPD with respect to sulphur and selenium compounds, difficult to separate, when methane is added to the carrier gas has been used to identify these substances when present together.[12]

The high selectivity and sensitivity of the FPD have enabled it to be used to determine traces of thiols and organic sulphides in air,[14] isopropyl methylphosphonofluoridate (Sarin)[15] and butyltin[16] in water, sulphur-containing pesticides in wheat,[17] and various sulphur compounds in specimens of soil and air in regions of petroleum discharge or spillage.[18,19]

In the quantitative analysis of micro-quantities of sulphur compounds, difficulties arise as a result of the tendency of these substances to undergo irreversible sorption in the connections, and also the fact that the molar signal of the FPD depends on many factors, so that special calibration is required.[24] As shown for the analysis of dipropyl sulphide using the "Meloy Laboratories" 100 AT FPD,[9] the magnitude of the detector signal depends on the nature of the solvent, the number of successive analyses, and the duration of the intervals between analyses; for low concentrations, the difference in the magnitude of the signal may reach 200%. It is recommended[9] that the FPD should be used for the quantitative determination of organosulphur compounds at concentrations not lower than 10^{-4} g ml^{-1}. The accuracy of the determination of traces of hydrogen sulphide in the concentration range $10^{-4}-10^{-7}$ vol.% using the FPD produced by the Dzerzhinskii Special Design Office, with preliminary concentration, has been confirmed.[20] These detectors show "memory effects", which are stronger, the lower the concentration of the trace component. To obtain results with a mean-square deviation of ±10%, thorough purification of all the gases and prolonged flushing of the gas lines of the chromatograph and the connections through which the specimen is passed are required. If various precautions are taken, the FPD can be used for the quantitative determination of the concentrations of carbonyl sulphide, hydrogen sulphide, and sulphur dioxide at the level of $10^{-2}-10^{-7}$ mass % with a standard deviation of 7–5%.[21]

2. The Chemiluminescent Detector

Chemiluminescent detectors (CLD) record the luminescence spectra of the products of the chemical reaction of the substances being analysed and the reagents ozone[25-32] or atomic oxygen,[33] supplied continuously to the detector. The spectra are recorded using photomultipliers and photon counters; monochromators and electronic noise filters are also used.[27]

Luminescence is shown by the products of the reaction of ozone (or atomic oxygen) with alkenes,[28,33] sulphur dioxide[28,29] and nitric oxide. The analysis of nitrogen-containing compounds involves their thermal decomposition to give nitric oxide, which is then oxidised by ozone to excited nitrogen dioxide, which gives a luminescence spectrum. It is considered[33] that the method using atomic oxygen is more selective than that using the reactions of the substance being analysed with ozone.

The sensitivity threshold of the CLD is $\sim 10^{-9}$ g s^{-1}, and the linear range is 10^4. The detection limit for alkenes can be lowered by a factor of 200 by adding to the carrier gas traces of carbon disulphide or hydrogen sulphide, which undergo intermediate radical reactions and facilitate the reaction of the alkenes with ozone.[28]

The chemiluminescent detector has been used to determine the concentration of trimethylamine in air,[26] nitrosamines in the environment,[27,30,31] unsaturated hydrocarbons in industrial atmospheres,[33] and sulphur dioxide[29] and other substances in the troposphere and stratosphere. Many of these substances cause breakdown of the ozone layer and smog formation.[32] The simultaneous recording of chromatograms using a chemiluminescent detector and a universal detector (for example the FID) makes possible the group analysis of the concentrations of paraffins and aromatic hydrocarbons.[33]

3. The Plasma-emission Detector

Plasma-emission detectors (PED) record the emission from excited atoms and recombined diatomic fragments, obtained by the decomposition of the molecules of the compounds being analysed with a high-temperature helium or argon plasma.[4,34-43] The plasma, with a temperature of 4000–10000 K, consisting chiefly of the ionised gas, is formed either directly in a direct-current arc or by induction heating of the gas in the electromagnetic field of a high-frequency generator.[36] The excitation of the atoms and molecules of the substances being analysed may take place under the influence of electron impact, and also in collisions with metastable argon or helium atoms. The use of helium is preferred, since it has a simpler photon background spectrum and its metastable atoms have a higher energy.

The PED is now used to determine up to 30 elements in organic compounds, including non-metals difficult to excite, such as C, N, O, F, etc. The selectivity of this multi-element detector is achieved by tuning the spectrograph to the zero line of the spectrum by means of a monochromator, and by correction for the background.[36,39] Thus the chromatogram of petrol, recorded at $\lambda = 279.83$ nm (manganese line),

gave only the peak of the tricarbonylcyclopentadienyl-manganese present. The use of multi-channel PED appears promising, particularly for elemental analysis, since the molar signal of this detector is proportional to the number of atoms of the given element in the molecule of the substance being analysed, and is practically independent of the type of functional group.[36]

The discharge is usually produced in a thick-walled quartz capillary tube (internal diameter 0.5–1 mm). The carrier gas from the column and an additional stream of the same gas (0.05–6 litre min^{-1}) are supplied to the tube. The optimum ratios of the velocities of these two streams, and their overall velocity, are different for different elements.[36,41] Models of this detector operating at atmospheric pressure and at a reduced pressure have been described. The detector operating at atmospheric pressure is preferable, since direct axial observation of the plasma emission is possible (and not observation through the wall of the discharge tube, which introduces additional distortion).[41] It is useful to place a valve or a four-way tap with an additional gas-chromatographic detector between the column and the PED, to remove solvent from the specimen and avoid overloading the plasma with it.[35]

These detectors are promising for the analysis of specimens taken from the environment. The small internal volume of the detectors has made it possible to use them with capillary gas-chromatographic columns.[37,41] They have been used to determine traces of organic compounds of lead, silicon,[42,43] mercury, selenium, arsenic,[36] boron,[40] and fluorine[39] in water, air, soil, and various food products using specimens containing 10–600 pg of the substance being analysed. The selectivity of the determination of these elements relative to carbon varies from 70 to 360000; the linear dynamic range of operation of the detector is 10^2–10^3, and the reproducibility of the results when the operating conditions are strictly observed is 1–5%.[41,43]

4. The Combination of Gas Chromatography and Infrared Spectroscopy

Absorption infrared spectroscopy, combined with gas chromatography, is used for the qualitative identification of substances from their absorption spectra in the infrared range.[44] Continuous analyses are carried out by combining the gas chromatograph with an infrared spectrometer in which rapid scanning of the spectrum is carried out. Extensive use has been made of Fourier transform infrared spectroscopy[1,45–50] where a computer is used to store data on the intensity of absorption at different wavelengths and then substract the background. The complete spectrum or chromatogram is then reproduced by summation of the intensities of absorption of the compound being analysed, either throughout the entire spectrum or in a selected part of it.

The resolving power of fast-acting infrared spectrometers is lower than that of the ordinary instruments,[49] but the possibility of rapidly obtaining comparative data on the magnitude of the light absorption by the substances being analysed in the selected range of the spectrum makes this method extremely selective. There are at least five specific "windows" in the infrared spectrum, characteristic of five classes of compound: for example, the ranges 2930–3000 cm^{-1} for alkyl derivatives of benzene,[49] and 700–900 cm^{-1} for polyaromatic hydrocarbons.[47] The sensitivity of the determination and the useful signal : noise ratio are increased considerably if the chromatogram is reproduced from the intensity of the absorption in the range of the spectrum specific for the given class of compound.[47,49] Thus Fourier transform infrared spectroscopy can be used for the group analysis of various compounds in complex mixtures. Quantitative analysis by this method has also been reported, but the linear range of operation is very short (less than an order of magnitude). The minimum detectable quantity of pyrene in a specimen of the aromatic fraction of crude petroleum was 710 ng.[47]

New attachments and connecting units are being developed, which make it possible to work even with small-capacity capillary columns without loss of efficiency.[1,46–48,50] The device proposed in Ref. 47 consists of a gold-plated twelve-face copper receiver, placed in an evacuated (~10^{-6} mmHg) and cooled (to 17 K) compartment, to which the substance from the column is supplied through a heated glass-lined steel capillary. As the receiver is rotated, the fractions of the substance are deposited in turn on its faces; the absorption spectra of the trapped fractions are recorded at the moment when the corresponding faces pass in front of the spectrometer objective. The carrier gas (99.999% pure nitrogen) is not frozen under these conditions.

5. The Fluorimetric Detector

The action of the fluorimetric detector is based on the ability of various substances to fluoresce when irradiated or heated.[24,44,51–54] The intensity of the fluorescence is measured using a spectrofluorimeter. Since very few substances fluoresce, this method is highly selective, and is used in combination with all forms of chromatography, including gas chromatography. Methods are available, for example, for determining traces of anthracene, chrysene, and benz-α-pyrene in the atmosphere.[52] The selectivity of this method can be controlled by choosing an appropriate radiation source. Detectors have been described for the analysis of traces of nitrogen dioxide[53] and other substances[54] in air, based on the use of their long-wave fluorescence, induced by laser irradiation. The detection limit for nitrogen dioxide was 6×10^{-5}% (without preliminary concentration). Preliminary freezing of the traces of nitrogen dioxide made it possible to lower the detection limit to 2×10^{-6}% (preliminary gas-chromatographic separation was not used). The minimum detectable quantity of sulphur-containing gases is 100 ng.[24]

6. The Atomic-absorption Detector

Atomic-absorption spectroscopy, developed initially for the analysis of metals in inorganic materials,[55] has recently been used increasingly, combined with gas chromatography, in the analysis of organometallic compounds.[56–61] Dissociation of the molecules of the substances being analysed to atoms and absorption by the latter of the light from a standard source take place in the flame (or in a heated graphite cell). The light source usually consists of a special lamp in which the cathode is made of the metal which is being determined. The use of light sources with a line emission spectrum, in which the width of the lines is smaller than the width of the lines of the spectrum excited (~10^{-2} nm), makes this method exceptionally selective; the use of a monochromator (spectrophotometer) is necessary, to increase the signal : noise ratio.[55] The absorption spectra of most elements, obtained in an atomic-absorption spectrometer, are exceptionally simple, since they contain only the resonance lines corresponding to absorption transitions from the ground levels.

The atomic-absorption detector has been used for the gas-chromatographic analysis of organic manganese carbonyl in air,[56] tetra-alkyllead,[58] metal chelates (chromium, iron, copper, and cobalt[59]), and organometallic compounds of gallium, indium,[57] tin,[60] and lead.[61]

The minimum detectable quantity of substance, calculated as the metal, corresponds to several nanograms in the specimen, and can be improved by preliminary concentration.[61] The necessary precautions are for the most part those characteristic of work with organometallic compounds.

III. IONISATION DETECTORS

1. The Photo-ionisation Detector

A large number of recently published papers describe the study and application of photo-ionisation detectors (PID) in gas chromatography.[1,2,4,62-76] This detector has been known for a long time,[4,62] but its construction was insufficiently convenient. The new version can be readily connected to a gas-chromatographic system, including a portable gas chromatograph, and it promises to become a standard detector for gas chromatography.[65]

The action of the PID is based on the ionisation of the molecules of the substances being analysed under the influence of ultraviolet radiation, and the recording of the resulting ion current. The sources of ultraviolet radiation which have been tested include helium (20.2 eV) and argon (11.7 eV) discharge lamps without windows,[63] hydrogen lamps with different windows transmitting quanta with energies of 9.5, 10.2, and 11.7 eV,[64,65,75] and dye lasers.[71] The use of discharge lamps without windows had the disadvantage that it was necessary to maintain a vacuum at the outlet from the chromatographic column. The most widely used source is a hydrogen lamp (10.2 eV) with an MgF_2 window, placed inside the ionisation compartment of the detector.

Unlike the flame-ionisation detector, which is destructive and requires the use of three gases (hydrogen, air, and an inert carrier gas), the PID is not destructive, since the ions recombine on the cathode and are blown from the detector; the PID requires only one carrier gas,[65,72] preferably argon or helium.[69]

The PID is a concentration detector; the areas of the peaks decrease sharply (almost exponentially[62]) with increase in the velocity of the carrier-gas stream; the optimum velocities lie below 10 ml min^{-1}, so that it appears promising to use PID combined with capillary columns, particularly when the radiation sources used are lasers, which make it possible to decrease considerably the volume of the detector.[71] The internal volume of a PID with a hydrogen lamp can be reduced to ~50 μl.[72-74] The efficiency of a system consisting of a capillary column with this PID is only 10% lower than that of a similar system with an FID. Its main characteristics (magnitude of the linear range, noise level, background current, and sensitivity) are comparable with those of the FID, and it is superior to the latter in its sensitivity to aromatic hydrocarbons.[63,72]

Under the influence of ultraviolet radiation, photochemical reactions take place in the photo-ionisation detector, and the following reactions can be regarded as the most important in the production of the signal in this detector.[77-82]

1. The primary photo-transformation — the absorption of a quantum of energy and the conversion of the molecules to the excited state.

2. The secondary reactions of the excited molecules: a) interconversion and triplet formation; b) photo-ionisation (removal of an electron and the formation of an ion pair); c) photo-decomposition (photolysis to give radicals or ions); d) photo-sensitisation (the breakdown of non-excited molecules to radicals or ions as a result of collision with excited sensitiser molecules); e) two-photon decomposition or ionisation; and f) photo-addition (photo-oxidation, photo-hydrolysis).

The probability and rate of a given reaction are determined by the energy of the photons of the excitation source, the structure and properties of the substances being analysed, and the conditions in the reactor (pressure, concentration of the substance, temperature, the presence of other substances, the flow velocity, etc.). If the energy of the exciting photons is greater than the ionisation potential of the substance being analysed, the most probable reaction is photo-ionisation, and it can be stated that this substance can be detected. In those cases where the ionisation potential of the substance is lower than the energy of the quanta, it may still be detected, although with a lower sensitivity, as a result of other reactions, for example reactions (d) and (e), whose probabilities depend on such characteristics of the molecules of the substance as the difference between the energies of the singlet (or triplet) excited levels and the energy of the ground singlet level, and the lifetime of possible triplet excited states. The Table gives as an example the values of the first adiabatic ionisation potentials and the characteristics of the excited states of various molecules. More extensive data can be found in the literature,[83-85] and also in Ref. 86, which gives the ionisation potentials for 500 organic substances.

Table. Values of the first adiabatic ionisation potential (IP), the excitation energies of the singlet (E^S) and triplet (E^t) states above the energy of the ground state, and the lifetimes of the triplets (τ) of various substances.[77,83-85,87-89]

Substance	IP, eV	E^t, eV	τ, s	E^S, eV
Methane	12.99	—	—	—
Ethane	11.65	—	—	9.15*
n-Butane	10.63	—	—	—
n-Pentane	10.35	—	—	—
n-Hexane	10.17	—	—	—
Ethylene	10.516	—	—	7.6*
But-1-ene	9.57	—	—	—
Methanol	10.85	—	—	6.9*
Ethanol	10.48	—	—	6.7
Acetone	9.69	3.38	10^{-3}	3.64
Acetonitrile	12.21	—	—	7.3*
Benzene	9.25	3.64	7	—
Phenol	8.50	3.53	—	—
Biphenyl	8.27	2.82	3.1	4.1
Naphthalene	—	2.64	2.3	3.9
Carbon tetrachloride	11.47	—	—	—
Water	12.59	4.76; 9.43	—	7.4
Oxygen	12.06	0.98**	0.05**	3—4*
Nitrogen	12.56	—	—	—
Nitrogen dioxide	12.3	—	—	—
Carbon dioxide	13.79	—	—	—
Sulphur dioxide	12.34	—	—	—

*For these substances, the values of E^S were estimated in the present work from the values of λ_{max} for the most intense absorption band in the ultraviolet range.[83-85]
**The energy and lifetime of the lowest excited singlet state are given (since the ground state is a triplet state).

A detector in which the lamp gives radiation with an energy of the quantum $h\nu$ = 20.2 eV is practically universal, and is used for the analysis of inert gases and all organic substances. A detector with a lamp for which $h\nu$ = 11.7 eV already shows some selectivity; it is not sensitive to simple gases, and gives a signal from aromatic hydrocarbons which is ~30% more intense than that from alkanes with the same

number of carbon atoms.[63] A higher selectivity is shown by detectors with lamps for which $h\nu = 10.2$ eV and $h\nu = 9.5$ eV. A detector with a lamp for which $h\nu = 10.2$ eV is not sensitive to simple gases and C_1–C_4 alkanes. C_5 and higher saturated hydrocarbons give a signal, but the sensitivity of the detector with respect to these compounds is lower than that for unsaturated and aromatic hydrocarbons. This behaviour of the detector is due to the high efficiency of the ionisation (that is the quantum yield of the photo-reaction) of compounds with a π-bond, whose electrons are localised to a much greater extent than the electrons of a mobile σ-bond.[63]

The relative molar sensitivity of the most widely encountered PID ($h\nu = 10.2$ eV) for n-alkanes (standard benzene) increases with increase in the number of carbon atoms, and that for polyaromatic compounds increases with increase in the number of benzene rings. It is greater for cyclic compounds and iso-alkanes than for the non-branched compounds. In general, for a given number of carbon atoms, the relative molar sensitivity increases in the order: n-alkanes < primary alcohols ≤ ethers < aldehydes < ketones. For substituted benzenes, electron-acceptor substituents decrease the sensitivity of the determination, and electron-donor substituents increase it.[68,69]

The fact that the relative molar sensitivity of the PID increases to a greater extent with increase in the number of π-bonds, particularly when conjugated, in the hydrocarbon molecule, compared with the increase in the number of carbon atoms has been used in a number of studies for the group identification of alkanes, alkenes, and aromatic hydrocarbons in mixtures,[63,70] and of phenols in car exhaust gases.[76] The substance at the outlet from the chromatograph is recorded simultaneously by two detectors, a PID and a universal FID, and their signals are compared. An equation has been proposed,[70] relating the ratio of the values of the normalised signals of these two detectors to the number of carbon atoms in the molecule of the substance, its ionisation potential, the number of electrons ionised in the molecule, and the energy of the photons. The experimental data almost always show sufficiently good agreement with the calculated results.

A photo-ionisation detector with interchangeable lamps has also been proposed, giving radiation with an energy of the quantum of 9.5 eV, 10.2 eV, and 11.7 eV; the lamp with $h\nu = 11.7$ eV can fulfil the role of FID.[75] Replacement of the lamps does not involve breakdown of the connections between the outlet from the column and the detector, and this is particularly important when working with brittle glass capillary columns. The ratio of the values of the normalised signals obtained with lamps with $h\nu = 9.5$ eV and 10.2 eV to the signals with the lamp with $h\nu = 11.7$ eV has been used to identify alkanes and aromatic and polyaromatic hydrocarbons in complex mixtures derived from petroleum, at the level of nanogram quantities. The higher selectivity of the PID with the lamp with $h\nu = 9.5$ eV with respect to polyaromatic hydrocarbons has been emphasised.[75]

The change in the sensitivity of the analysis of aromatic and aliphatic pesticides on going from the lamp with $h\nu = 9.5$ eV to the lamp with $h\nu = 10.2$ eV has also been used for their group identification in complex mixtures.[64]

The use as radiation source of a pulse laser emitting in the wavelength range 270–335 nm, which ensures the two-photon ionisation of substances which tend to form triplets (in particular naphthalene derivatives), has made possible the selective detection of these compounds.[71] The total energy of the two photons in the wavelength range indicated is 7.4–9.2 eV. By tuning the laser to a definite wavelength, it was possible to obtain the peak of only one substance on the chromatograms; the minimum detectable quantity was 10 pg. These chromatograms are shown in Fig. 1.

The choice of the solvent for the specimens being analysed is of considerable importance when working with PID, particularly in the determination of micro-quantities using preliminary concentration and extraction. The chief requirement which must be satisfied by the solvent is transparency in the wavelength range corresponding to the lamp used — a condition which is satisfied for substances with high values of the ionisation potentials and high energy levels of the excited states. Thus acetone, hexane, and aromatic hydrocarbons cannot be used as solvent when working with a PID with $h\nu = 10.2$ eV, since the background current which they give is too high. Only carbon tetrachloride has been found to be suitable for the analysis of chlorobenzenes in air and in human blood and urine using this PID.[67] Other workers,[63] who also used a PID with $h\nu = 10.2$ eV, used acteonitrile and spectroscopically pure methanol to extract pesticides concentrated on active carbon. Acetone has been used as solvent for the specimens in work with a laser source (3.7–4.6 eV), although it gave a peak due to possible multi-photon ionisation.[71]

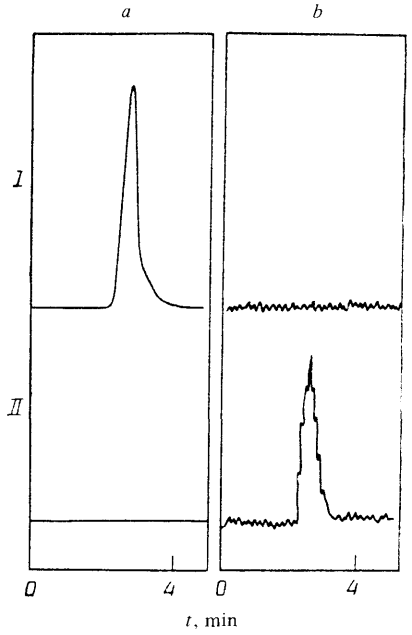

Figure 1. Chromatograms of anthracene (I) and phenanthrene (II), obtained using a PID with tunable selectivity at laser source wavelengths of 310.0 nm (*a*) and 285.0 nm (*b*). 1.3 m × 3 mm column containing 3% OV-17 on 80–100 mesh Chromosorb W; carrier-gas velocity (argon + methane in the ratio 90 : 10) 20 ml min^{-1}.[71]

The authors cited do not discuss the question of the behaviour of water in a PID. This question requires special study, since the sensitivity of gas-chromatographic detectors to water is a very important characteristic in the analysis of aqueous solutions and specimens of polluted air, water, and other environmental materials. The ionisation potential of water is greater than the energy of the quanta of the hydrogen lamps used in the PID (see Table), so that direct ionisation of its molecules is unlikely. Data have been published,

however, indicating considerable absorption by water in the ultraviolet range at 186–143 nm (6.67–8.67 eV) and 143–124 nm (8.67–10.00 eV) and the existence of a whole series of excited singlet and triplet states of its molecule.[87–89] The excited water molecules can sensitise the ionisation of other substances, eluted with it from a gas-chromatographic column. Many of these excited states of the water molecule are dissociative, and are accompanied by its breakdown to give chemically active radicals OH, H, and O, which can react with the molecules of other substances to form ions. The formation of charged and uncharged fragments of the water molecule is also possible as a result of its capture of electrons present inside the PID. All this can lead to a change in the sensitivity of the PID and an increase in its background signal at the moment when the water peak appears. Another important feature may be the deleterious influence of water vapour on the lamp window, particularly at high temperatures.

2. The Surface-ionisation Detector

The operation of the highly selective surface-ionisation detector (SID), first developed in the Soviet Union,[4,91] is based on the phenomenon of the ionisation of the molecules during their thermal desorption from a surface.

When organic substances are adsorbed on the surface of many metals, both reversible (multi-layer) adsorption and irreversible adsorption (chemisorption) take place. At high temperatures, the reversible adsorption is slight, whereas chemisorption increases with increase in temperature and with increase in the specific surface of the metal.[92] The desorption of chemisorbed molecules is often completed by their degradation, and the charge state of the species removed is determined by the nature of the charge distribution between the adsorbed molecule and the surface of the solid. For most substances, positive ions are formed.[91]

The most effective thermo-emitters for the ions of organic compounds are oxidised tungsten, molybdenum, nickel, and Nichrome, and non-oxidised tungsten, molybdenum, nickel, rhenium, and iridium. Mass spectrometry has been used to study the ability of substances of different classes to undergo surface ionisation, and the regular features of ion formation; at temperatures of 340–375 °C, amines, hydrazines, and some of their derivatives ionise readily; phosphines, arsines, and various oxygen-containing compounds (phenols, organic acids, and substances containing the benzoyl group) ionise less readily.[91,93]

Unlike many other selective detectors, the SID is selective not with respect to a heteroatom but with respect to a functional group on a heteroatom.[94] This provides the basis for the functional gas-chromatographic analysis of nitrogen-containing compounds, which involves the determination of the ratio of the heights of the peaks of each substance when chromatograms are recorded simultaneously using two parallel detectors: SID and FID. The study of 23 amines[95,96] showed that this ratio varies from 4 to 12 for primary amines, from 30 to ~300 for secondary amines, and from 700 to 6000 for tertiary amines. The existence of this clearly defined relationship between the ratio of the signals of these detectors and the type of amino-group made it possible to recommend this method for identifying amines. It is of course possible to have cases where the values of this ratio are similar for amines from different groups, but these substances generally have markedly different gas-chromatographic retention characteristics, and this is also taken into account in the identification. The selectivity of the SID with respect to amines is illustrated in Fig. 2. The SID also records the amides of carboxylic acids,[95,96] but with a lower sensitivity than in the case of the corresponding amines. The minimum detectable level is ~5×10^{-15} g s^{-1} (with respect to triethylamine), and the linear range is ~10^4–10^8. The selectivity with respect to hydrocarbons is ~10^5–10^8.[91]

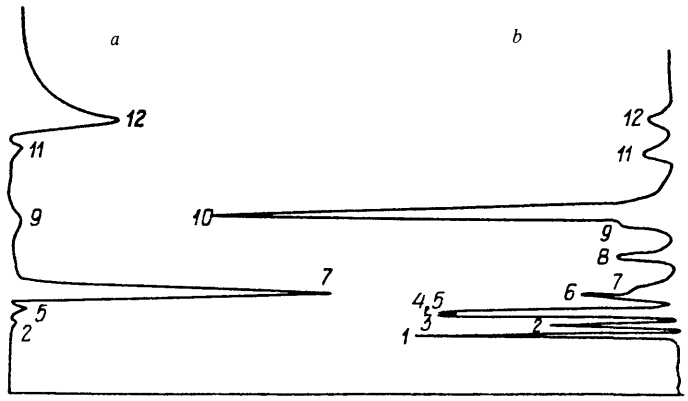

Figure 2. Chromatograms of a mixture of organic substances, obtained using an SID (*a*) and an FID (*b*) on a column containing PEG-1000 at 100 °C; emitter temperature 370 °C, velocity of air through the SID 75 ml min^{-1}. The stream of carrier gas (helium) from the column, 30 ml min^{-1}, was divided in the ratio 3:7 for the SID and the FID respectively; peaks on the chromatograms: *1*) diethyl ether, *2*) n-propylamine, *3*) methyl ethyl ketone, *4*) benzene, *5*) n-propylisobutylamine, *6*) isobutyl acetate, *7*) dipropyl-n-butylamine, *8*) di-isobutyl sulphide, *9*) pyridine, *10*) chlorobenzene, *11*) morpholine, *12*) methyl-n-octylamine, amplifier scale 1.9 × 10^{-8} A (*a*) and 10^{-10} A (*b*).[95]

The high sensitivity and selectivity of the SID make it possible to recommend it for the analysis of traces of various compounds with heteroatoms of the Va sub-group in air and other environmental materials. In general, it can be used for the analysis of substances which can be converted into amines.[91]

3. The Thermo-ionic Detector

The thermo-ionic detector (TID) was based on the flame-ionisation detector, and is familiar as a selective detector for phosphorus-, nitrogen-, and halogen-containing compounds.[1–4,23,44] Its action is based on the sharp increase in the rate of the ionisation of these substances in the presence of alkali metal vapour, so that it is sometimes called the "alkali" FID. The alkali metal salt is used in the form of a deposited layer or in the form of beads or a coating of a melt of the salt with quartz or a ceramic on a suitable holder, which are heated by a burner flame or electrically; the salt can also be introduced into the flame in the form of an aerosol.[97]

Single-flame and double-flame TID are used. In the latter, the lower part, which operates as an ordinary FID, is separated from the upper part by a grid covered with the alkali

metal salt. The products of combustion and ionisation from the lower compartment, after recombination, pass together with the alkali metal vapour into the zone of the flame of the upper burner, where specific ionisation of the molecules and fragments containing nitrogen, phosphorus, and halogen atoms takes place. Comparison of the chromatograms obtained simultaneously from the upper and lower compartments makes it possible to detect these substances in the mixtures being analysed.[3,4]

The mechanism of the ionisation in thermo-ionic detection is complex, and has not yet been fully studied. Depending on the design characteristics and operating conditions of the detector, the ionisation may take place preferentially either in the vapour phase as a result of collisions of the molecules of the substances being analysed or their fragments with the alkali metal atoms, or on the surface of an activator containing this metal. In the last case, the most important characteristics are the electronic work function and the temperature of the activator surface, and also the composition of the gaseous medium.[98]

The mechanism of surface ionisation has been realised in new TID models.[98–102] In the double-flame TID described in Refs. 99 and 100, ion formation takes place on a thermo-cathode made of platinum, nickel, or stainless steel (the cathode does not contain added alkali metal, and it is heated by the flame of the upper burner). The optimum cathode temperature is established by studying the dependence of the sensitivity of the detector on the rate of supply of hydrogen and air to the upper and lower burners. The double-flame TID is 10^2–10^3 times more sensitive than the ordinary TID. The sensitivity with respect to acetonitrile and methylene chloride is 8×10^{-10} g s^{-1} with a linear range of 10^3 and a selectivity with respect to hydrocarbons of 10^4. This detector has a simple design, its operation is stable, and it can be used in a standard chromatograph (in particular, the Tsvet-104 chromatograph).

Patterson and coworkers[1,98,102] proposed a flameless TID, which operates at low hydrogen concentrations, insufficient to support a flame, or in an inert gas (nitrogen) atmosphere. The electrically heated thermo-cathode consists of a rod with a ceramic covering containing a caesium compound; it is surrounded by a cylindrical ion collector. This TID shows a selective sensitivity with respect to nitrogen- and phosphorus-containing compounds (Fig. 3), depending on the concentration of the alkali metal on the surface of the thermo-electrode, its temperature, and the composition of the surrounding gas. At a temperature of 600–800 °C, selectivity is not observed; under these conditions, the source apparently becomes sufficiently hot for the formation of chemically active hydroxyl, hydrogen, and oxygen radicals, which may undergo ionic reactions on the surface and facilitate the ionisation of a large number of substances. The flameless TID has been used to identify environmental pollutants such as parathion (thiophos), methylparathion, malathion, nitrophenols, nitroglycerine, and other nitro-compounds. The minimum detectable quantity of nitrogen- and phosphorus-containing compounds is 10^{-14}–10^{-13} g s^{-1}, calculated for the heteroatom, with a selectivity with respect to hydrocarbons of 10^5; the linear range is 10^4–10^5.[98]

An apparatus and procedure for regulating the sensitivity of the TID with respect to substances of different classes by means of a displacement potential applied to the activator containing the alkali metal have been proposed.[102] The magnitude of the applied voltage determines the sign of the ions formed, which are collected by the collector (the burner jet acts as the second electrode; the activator is placed between the burner and the ion collector). The dependence of the magnitude of the TID signal on the displacement potential has been given for compounds of nitrogen, sulphur, phosphorus, and iodine. At definite values of the displacement potential, characteristic for each heteroatom, it is possible to take the signals of the corresponding substances from the chromatogram and hence to identify these substances. It is possible to record simultaneously chromatograms with and without the displacement potential.

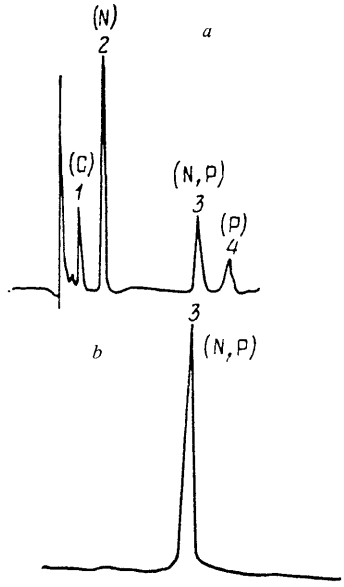

Figure 3. Comparison of the chromatograms of a mixture containing 4000 ng μl^{-1} heptadecane (*1*), 2 ng μl^{-1} azobenzene (*2*), 2 ng μl^{-1} methylparathion (*3*), and 4 ng μl^{-1} malathion (*4*) in iso-octane, obtained using a TID with a low (*a*) and with a high (*b*) concentration of caesium on the surface of the thermo-electrode in a hydrogen atmosphere containing air (*a*) and nitrogen (*b*); amplifier scale 128×10^{-12} A (*a*) and 16×10^{-11} A (*b*).[98]

The high selectivity and sensitivity of the TID, and the relative simplicity of its use, are leading to the extensive application of this detector in the analysis of micro-quantities of many harmful substances in natural materials. Methods have been described for the analysis of nitrogen-containing compounds and ammonia,[103] symmetrical triazines,[104] nitrosamines,[105] and derivatives of thiocarbamic acid.[106]

The sensitivity of the TID with respect to water has been studied;[99] although water itself does not give a signal, it decreases the sensitivity of the determination of other substances. In particular, the magnitude of the signal from a double-flame TID due to acetonitrile in the analysis of aqueous solutions was only half that in the analysis of alcoholic solutions. This was attributed[99] to a decrease in the temperature of the surface ionisation electrode.

4. The Electrical-conductivity Detector

The operation of the electrical-conductivity detector (ECD) is based on the decomposition of the substances being analysed to give ionogenic products; absorption and dissociation of these products then take place in a stream of water or other solvent, and the electrical conductivity of the resulting solution is measured continuously.[1,4,107] The decomposition of the substances can be carried out in an oxidising medium (by heating in oxygen or in air, by passing over heated copper oxide, etc.) or by heating in a stream of hydrogen in the presence of a catalyst. Organic substances containing sulphur, halogen, and nitrogen atoms in the oxidising version give mixtures $CO + CO_2$, $SO_2 + SO_3$, NO_x, HX, and H_2O, and in the reducing version NH_3, H_2S, HCl, CH_4, and H_2O.[108,110]

If conditions are created for dissolving carbon dioxide (oxidising version), the ECD operates as a universal detector. In this case the signal is proportional to the number of carbon atoms in the molecule of the substance being analysed. This detector is particularly convenient for chromatography in a stream of water vapour.[109] It is also possible to create conditions under which the measuring part of the detector contains only one of the above products, and the ECD then becomes exceptionally selective. Work in recent years has been devoted mainly to improving the selective version of this detector.[1,111–115]

The Hall detectors (Tracor 700) produced commercially have a high sensitivity and a small internal volume, so that they can be used with capillary gas-chromatographic columns and coupled with another detector, for example an FID.[1,114,115] The advantage of the latest model (700 A) over the earlier model is that it can be tuned for the selective detection of any of the following classes of substance: halogen-, sulphur, and nitrogen-containing compounds, hydrocarbons, and nitrosamines.[115]

The main parts of the ECD are the reactor with the furnace for converting the substances being analysed into the compounds detected; the absorber, in which the reaction gases are brought into contact with the solvent (de-ionised water, alcohol, or a suitable mixture); the separator for separating the solution from the insoluble gases; the cell for measuring the electrical conductivity; the system for circulating and regenerating the solvent; and electronic circuits for controlling the temperature of the reactor furnace and for measuring the electrical conductivity of the solution in the cell. In the 700 A model,[112] the reactor consists of a nickel capillary, which acts simultaneously as the catalyst; a quartz capillary can also be used. A scrubber is placed between the reactor and the measuring cell to extract interfering components from the mixture of decomposition products. The use of a bipolar pulse voltage, applied to the electrodes in the 700 A model (the duration of the pulses is one tenth that of the intervals between them) makes it possible to avoid such undesirable phenomena in the electrical conductivity measurement as polarisation of the electrodes, the capacity effect, and heating of the cell.

The magnitude of the ECD signal is determined primarily by the concentration of the product being recorded in the cell, its dissociation constant in the solvent, and the equivalent ionic conductivity due to the cations and anions. Selectivity of action is achieved by the correct choice of chemical decomposition reaction and absorption conditions, under which the required product is readily soluble and readily dissociated to give ions, while other substances either are insoluble in the solvent used or do not ionise in it.[1]

In the analysis of sulphur-containing compounds, the optimum conditions correspond to the combustion of the substance in oxygen or air at 800 °C in a nickel reaction tube with the use of pure methanol as electrolyte.[112,114,115] The hydrogen chloride which may be obtained from chlorine-containing impurities is removed in the scrubber by the action of silver; oxides of carbon are sparingly soluble in the alcohol, and their quantity is also restricted by removing the excess of solvent before introduction into the reactor. The yields of soluble oxides of nitrogen (from possible traces of nitrogen-containing compounds) are slight under these thermal decomposition conditions.

For the detection of nitrogen-containing compounds, the optimum conditions correspond to the reducing version; with decomposition in a nickel reactor, all nitrogen-containing compounds are detected, but when a quartz or gold reaction tube is used, nitrosyl compounds can be determined selectively.[1] The electrolyte in the absorber consists of a mixture of water and n-propanol (1:1). Hydrogen chloride and hydrogen sulphide obtained from chlorine- and sulphur-containing impurities are removed in the scrubber by the action of a suitable base; the ionisation constant of methane is too low, and it does not give a signal.

In the analysis of halogen-containing compounds using the ECD under both oxidising and reducing conditions, the hydrogen halide is formed, but reduction in a quartz tube at 800–900 °C gives a more favourable composition for the side products, which does not require the use of a scrubber.[1]

The molar signal of the ECD is directly proportional to the number of corresponding heteroatoms in the molecule of the substance being analysed, so that the ECD is particularly sensitive to compounds containing a large number of sulphur, halogen, or similar atoms. The detection limit is $(2–4) \times 10^{-12}$ g s^{-1} for N-containing compounds, 2×10^{-12} g s^{-1} for S-containing compounds, and 5×10^{-13} g s^{-1} for Cl-containing compounds, calculated for the heteroatom; the linear range is 10^4 for N- and S-containing compounds, and $10^5–10^6$ for Cl-containing compounds. The selectivity with respect to hydrocarbons is $10^5–10^6$.[1]

The ECD has been used successfully for the gas-chromatographic analysis of hydrogen sulphide and sulphur dioxide in air[108,112] and natural gas,[1] nitrogen- and sulphur-containing compounds in petroleum products,[114] nitrosamines, pesticides with a high sulphur content (malathion, parathion, trithion, etc.), polychlorinated biphenyls and other chlorinated insecticides in natural materials at the level of several nanograms or below in the specimen.[1,112,115]

5. Detectors Based on Electron Capture

The action of a group of selective gas-chromatographic detectors — electron-capture, aerosol-ionisation, plasma chromatographic, and mas-spectrometric with chemical ionisation — is based on similar ionisation processes, chief of which is the capture of thermal electrons by the molecules of the substances being analysed. In the first two detectors, the useful signal is the change in the concentration of electrons in the measuring cell at the moment when the substance being analysed passes through, and in the other two detectors the composition and properties of the ions formed are studied. The plasma chromatograph records the spectra of the mobility of the ions, and the mass spectrometer with chemical ionisation analyses the composition of the positive or negative ions.

The source of the electrons in these detectors is most frequently the β-radiation of radioactive elements (for example tritium or ^{63}Ni). The energy of the electrons of the β-rays, equal to 17.6 keV for tritium and 67 keV for ^{63}Ni, is too high to ensure the electron capture mechanism; the energy is lowered by flushing the ionisation compartment with a suitable carrier gas, which has a high electron affinity and a high

ionisation potential; this gas may be nitrogen, noble gas (argon, helium) containing 5–10% methane, and other gases and mixtures. As a result of elastic and inelastic collisions with the atoms and molecules of the carrier gas at atmospheric pressure, the electrons of the β-radiation lose their excess energy until their energy becomes suitable for reactions giving ion pairs: positive ions from the molecules (or atoms) of the carrier gas, and low-energy electrons (0–10 eV).

Other reactions may take place in parallel between electrons, ions, and neutral species (additives in the carrier gas, impurities, etc.). By selecting the carrier gas, its pressure, the magnitude and character of the voltage at the electrodes, the temperature, the velocity and direction of the flushing gas, and the design of the ionisation compartment, it is possible to achieve the required distribution of electrons with respect to energies in these detectors and to create conditions for particular ionisation reactions in them.

6. The Electron-capture Detector

The principles of the operation and practical application of the electron-capture detector (ECpD), which is the most widely encountered selective gas-chromatographic detector, have been examined in detail in many papers, monographs, and reviews.[1–3,44,110,116–128] Recent work has involved a detailed study of the mechanism of the reactions taking place in the ECpD and the production of the signal, and the search for ways of increasing the selectivity and sensitivity, extending the linear range, decreasing the volume, and optimising the design and operating conditions.

The theory of the ECpD[1,118,119] is based on the idea of an ideal-mixing reactor; it is assumed that the current of the detector is due entirely to electrons; the latter may disappear as a result of capture by the molecules of the substances being analysed and by recombination with positive ions, and also as a result of the wall effect and flushing.

According to Ref. 117, the magnitude of the measured current is determined not only by the electron density but also to a large extent by the field of the negative ions, which are localised close to the cathode under the influence of the counter current of the flushing gas.

New data on the composition of the ions and their behaviour inside the ECpD, obtained using a mass-spectrometric detector with chemical ionisation (MSCI),[122,129] plasma chromatography (PC),[130,131] and a system of two ECpD connected in series and operating under different supply conditions,[126] show better agreement with the field theory of electron-capture detection. In particular, it has been suggested that in the detector there is a centrally located zone of electrons; under pulse supply conditions, this zone becomes broader with increase in the time interval between the pulses, and during the pulse all the electrons leave the cell. In some cases it has been possible to estimate the contributions of the space charge of the negative ions[126] and the current created by the selective migration of positive ions[128] to the recorded ECpD signal.

The molar ECpD signal increases with increase in the number of atoms or functional groups with an electron affinity in the molecule of the substance being analysed, and a synergistic effect is observed when a certain number has been reached. This feature, and also the tendency for the relative sensitivity to be influenced by various factors such as the presence of impurities in the carrier gas, the electric field potential, the temperature of the detector, etc., make it difficult to carry out the theoretical calculation of the relative molar sensitivity coefficients, so that it is necessary to calibrate the detector in each specific case, although a whole series of correlations exists.[121,132,133]

A study of the influence of traces of oxygen in the carrier gas on the sensitivity of the ECpD with respect to various chlorinated hydrocarbons showed that the addition of 0–3.5% oxygen to the carrier gas leads to a sharp increase in the intensity of the signal of monochloroalkanes,[134] whereas the signal from polychlorinated hydrocarbons changes little. An increase in the sensitivity in the presence of oxygen has also been detected for dichloromethane,[136] carbon dioxide,[135] and polycyclic aromatic and related hydrocarbons,[137,138] and the difference in the magnitude of the signals obtained in the presence and in the absence of oxygen can be used, for example, for the qualitative identification of the structural isomers of polycyclic aromatic hydrocarbons in air.[138] Sensitisation of the ECpD is also observed when N_2O is added to the carrier gas.[139–142] This was attributed to reversible reactions of O_2 and N_2O with slow electrons, leading to the formation of the negative ions O_2^-, O^-, NO^-, etc., and if the substance can react with these species to give stable secondary negative ions, its appearance in the detector in fact leads to a decrease in the electron concentration, that is to the appearance of a signal.

An ECpD signal can be obtained from normal saturated hydrocarbons by increasing considerably the electric field by raising the voltage at the electrodes and using highly pure argon as carrier gas. With increase in the kinetic energy of the electrons, there is a change in the ionisation mechanism (use of the Penning effect).[143] These techniques lower the selectivity of the ECpD in the general sense, but they may be useful for solving particular problems, for example for determining Kovacs indices.[139,143] Usually, however, in the determination of retention indices in work with the ECpD, the standards used are some homologous series of electron-acceptor substances, such as esters of trichloroacetic acid[144] and n-bromoalkanes;[145] the latter have also been recommended for standardising the ECpD signal in quantitative analysis.

The introduction of electron-acceptor substituents into the molecule of the substance being determined is widely used to increase the sensitivity of the ECpD.[1,146] For example, the replacement of the chlorine atom in the methyl chloride molecule by an iodine atom leads to an increase in the signal by a factor of 10^4 with a methyl iodide detection limit of 3.1×10^{-14} g; the detection limit for N,N'-dipentafluorobenzoylpentafluoroaniline is 1.6×10^{-19} mole ($\sim 10^{-16}$ g).[147] The introduction of electrophors, however, should not lead to a significant decrease in the volatility of the substance, hindering its analysis.

Examples of the use of gas chromatography with an ECpD include the determination of micro-quantities of peroxyacetyl nitrate,[148] the chlorides of phosphorus, silicon, tin, and germanium, sulphur hexafluoride, phosphine, etc.[149] in air; 2,4-dichlorophenol and various forms of hexachlorocyclohexane in soil and plants;[150] and water in solvents.[151] The improvement of the design and the optimisation of the operating conditions of the ECpD have made it possible to extend the linear range to $(1–5) \times 10^3$,[152] improve the stability,[153, 154] decrease the volume, and use the ECpD in combination with capillary columns.[155,156] A method has been proposed for purifying a solvent (n-pentane) from contaminants which give a signal with this detector.[157]

7. The Aerosol-ionisation Detector

The action of the comparatively new aerosol-ionisation detector (AID) is based on the formation of large aggregates of molecules of the substance being analysed and some reagent, in order to increase their ionisation cross-section

when the ECpD is used.[158–160] AID models in which the processes of aerosol formation and ionisation either take place in different compartments[159] or are combined in a single compartment[160] have been described. The concentration of the reagent for generating the aerosol in the carrier gas (air) is 10^{-2}–10^{-3} vol.%. This gives sol particles containing tens of molecules. The temperature of the detector is determined by the stability of the aerosol used.

The development of the theory of this method has made it possible to calculate the minimum detectable quantity of substance from data on the values of the saturation current, the coefficient of adhesion of the ions to the aerosol particles, and the number of aerosol particles per unit volume.[159,160] The AID is selective and sensitive with respect to halogen-containing hydrocarbons, amines, organometallic compounds, SO_2, SO_3, NO_2, etc.[159,160] The reagents for the formation of the aerosol particles are selected with allowance for the chemical properties of the substances being analysed; trifluoroacetic acid is used for compounds with basic properties, and amines for acidic compounds; halogen-containing hydrocarbons are passed over heated copper oxide, and organometallic compounds are subjected to thermal decomposition. Additional reactions are also used to convert the substances being analysed into strong acids or bases, for example SO_2 into SO_3 with subsequent reaction with an amine. The linear range for all substances is 10^2; the limit of detection for different groups of substances varies in the range 10^{-11}–10^{-10} g s^{-1}.[158–160]

8. Plasma Chromatography

The name itself of this detector reflects the principle of its operation: in it, the plasma formed by the ionisation of the molecules of the substance being analysed is separated, and the ratio of the ions present in it is determined; this is essentially analogous to chromatography.[130,131,161–166]

The mechanism of operation and the fields of application have been reviewed.[161] The original ions are generated as a result of the interaction of the molecules of the carrier gas (purified nitrogen or air containing water vapour) with electrons, the source of which is ^{63}Ni foil. In the carrier gas (nitrogen), the positive nitrogen ions formed initially react with water molecules to give the ions NH_4^+ and NO^+ and the cluster ions $(H_2O)_nH^+$, $(H_2O)_nNO^+$, etc. When the carrier gas is air, the negative ions O_2^-, O_4^-, $(H_2O)_nO_2^-$, CN^-, CO_3^-, and CNO^- are also formed.[130,131,161,162,166] The relative concentration of the ions and their degree of hydration depend on the concentration of water vapour and on temperature. In addition to ions, the PC ionisation compartment also contains electrons with an energy of ~0.5 eV.[131,161,162,164]

The molecules of the substances being analysed enter the ionisation compartment and interact with the above ions and electrons to give new quasi-molecular and simple dissociative ions. The mixture of ions and carrier gas is directed for separation into a drift tube (usually by pulses of duration 0.25 ms at time intervals of 0–20 ms). The drift tube is flushed continuously with an additional counter current of gas (nitrogen, air, sulphur hexafluoride) at atmospheric pressure. The rate of movement of the individual ions in it, and in some cases the composition of the ions[162,166] depend not only on their mass and charge and the field intensity (as in the analyser of the mass spectrometer) but also on the size of the ions and on the mass, size, and polarisability of the molecules of the drift gas. The successive recording of the ions at the outlet from the drift tube gives the spectrum of their mobility, characteristic for each substance. To observe the mobility of large ions, it is preferable to use a drift gas with a high molecular mass, such as sulphur hexafluoride.[162]

The mobility spectra of ions with a mass of up to 400 are usually obtained in 20 ms. They are recorded using digital signal averagers, which make it possible to carry out the summation of several thousand such spectra in several minutes and present them in convenient form. The spectra are interpreted by comparing them with the spectra of the individual compounds, obtained under the same conditions, and also by comparing them with analogous spectra obtained by the MSCI method.[161,162]

PC is specially designed for the analysis of tracer quantities of materials (10^{-8}–10^{-14} g) and is more sensitive than, for example, the FID. Large specimens overload the detector, and as a result of secondary reactions the interpretation of the spectra is difficult. An important feature is that PC makes it possible to obtain the spectra of the mobility of positive and negative ions, and this makes it more informative. The ratio of the intensities of the spectra of the positive and negative ions provides an additional specific characteristic of a substance.

As in the sensitised ECpD, in PC the negative ions are formed only by substances which are electron acceptors, and the spectrum of the mobility of the negative ions makes PC selective with respect to the same classes of compound. There are both associative and dissociative mechanisms for the addition of an electron.[131,161] Thus monohalogeno-derivatives of aromatic hydrocarbons undergo dissociative splitting, and nitrobenzene shows only associative interaction, giving a negative molecular ion, whereas the halogen derivatives of nitrobenzene and nitrotoluene react by both mechanisms. There is a correspondence between the PC and MSCI data with identical reaction gases for alkanes, halides, nitroaromatic compounds, etc.[161] At the same time, these methods show appreciable differences. One of these is the ease of formation of the groups of ions M_2H^+ and M_3H^+ by polar substances (alcohols, esters, etc.[161]) in PC.

PC has been used for the qualitative identification of alcohols, alkyl halides, substituted and polynuclear aromatic compounds, aliphatic N-nitrosamines, and pesticides, various isomers of fluorotoluenes and picolines, and the methyl esters of toluic and phthalic acids.[131,161,165] There are as yet comparatively few published data on quantitative analysis.[130,161]

9. Mass Spectrometry with Chemical Ionisation

The combination of a gas chromatograph with a mass spectrometer and a computer is widely used to identify substances in complex multi-component mixtures, and various countries now produce standard commercial instruments: chromatograph–mass–spectrometers, fitted with libraries of mass spectra and computers.[44,167,168] Like the Fourier transform infrared spectrometer, the chromatograph–mass–spectrometer can act as a universal detector if the chromatogram is recorded with respect to the total ion current, or as a selective detector, if only ions with definite masses are recorded. MSCI at a low pressure ($\leq$ 1 mmHg) and at atmospheric pressure makes it possible to combine the fast action and informative character of mass spectrometric technique with the selectivity of detectors based on ion–molecule and electron–molecule interactions.[169–176] The spectra obtained by MSCI for the most part contain the peaks of the molecular ions and fragments of the molecules being analysed, which are simpler than the ions formed in the ordinary mass spectrometer as a result of the bombardment of the specimens by electrons in a high vacuum. It is possible to record the spectra of the positive and negative ions separately.

The selectivity of MSCI, as in the case of PC and the sensitised ECpD, can be controlled by creating the necessary set of working ions and electrons in the ionisation compartment

by appropriate selection of the source of primary electrons, the carrier gas (most frequently nitrogen), and the reagent gas (methane,[167,172] oxygen,[173,174] oxygen and methane,[175] ammonia,[176] etc.). The source of electrons in MSCI is ^{63}Ni at atmospheric pressure,[169,173,174] and a heated rhenium cathode at low pressure.[170,171,175,176] The composition of the working ions in the ioniser also depends on the concentration of traces of water and other substances in the gases used and on temperature.[130,169] The normal operation of the mass analyser in MSCI requires powerful vacuum pumps (for example two pumps with a speed of 800 litre s^{-1} are used simultaneously.[173])

MSCI combined with capillary gas-chromatographic columns has been used to analyse micro-quantities of aliphatic alcohols[172] and also polychlorinated and polybrominated benzenes in foodstuffs.[173–175] It is possible to determine selectively the most toxic 2,3,7,8-tetrachlorobenzo-*p*-dioxin in the presence of a large number (21) of isomers of this compound and other related substances.[174] The successive use of NH_3 and ND_3 as reaction gas made it possible to identify primary, secondary, and tertiary amines in a complex mixture of hydrocarbons and nitrogen-containing compounds (from the increase in the mass of the deuteriated molecular ion in the spectrum of the positive ions, compared with the protonated ion).[176]

MSCI is used mainly for the qualitative identification of substances in complex mixtures. The minimum detectable quantities of the substances being analysed is 10^{-9}–10^{-12} *g*.[169,172,174] Together with mass spectrometry, MSCI is also used to study the composition of the ions in other detectors (ECpD, PC, AID, and SID) to obtain a deeper understanding of the mechanisms of ionisation in these detectors and to determine the optimum conditions for their operation.[94,130,161,162]

IV. SOME CHARACTERISTIC FEATURES OF WORK WITH SELECTIVE GAS-CHROMATOGRAPHIC DETECTORS

The use of selective detectors raises a number of specific problems. One concerns qualitative analysis from the Kovacs indices, since almost all selective detectors are insensitive to n-paraffins, which provide a series of standards in this identification system. The introduction of phosphorus, sulphur, halogen, and other indices, and the use of reaction gas chromatography, are helping to solve this problem.[145,177,178] To increase the reliability of identification, selective detectors are often used in combination with universal detectors.[23,179–182] Success in these cases is to a large extent determined by the quality of the connections.[183,184]

The fields of application of many selective detectors overlap; for comparison of their data, it is proposed that selectivity coefficients for selected substances be normalised under standard conditions.[183]

The principal requirements to be satisfied by the gas-chromatographic system in work with highly sensitive selective detectors reduce to the use of thermally stable materials and sorbents, which do not contain elements or groups to which the given detector is sensitive. Dexsil 300, SE-30, OV-225, and other silicones, PEG-20000, and Versamid-900, deposited in small quantities on silanised inert carriers, are used as stationary liquid phases. Concentration is carried out using porous polymers and graphitised carbon black. Increased demands are made on the purity of the gases used.

Selective gas-chromatographic detection is now at the stage of intensive development. The appearance of fundamentally new methods has been accompanied by the revival of older and simpler methods on the basis of new techniques using new materials. The possibilities opened up by the use of selective detectors for the gas-chromatographic control of pollution in the environment are acquiring particular importance in connection with the improvement of measures for its protection.
