# Quantum-chemical Calculations in the Study of Antitumour Compounds

V.B.Luzhkov and G.N.Bogdanov

The results of quantum-chemical calculations on antitumour preparations concerning the mechanism of their action at the electronic and molecular levels and structure-activity correlations are discussed in this review. Preparations whose action involves alkylating and free-radial mechanisms, complex-forming agents, and antimetabolites are considered. Modern quantum-chemical methods for calculations on biologically active substances are described.
The bibliography includes 106 references.

I. Introduction 1
II. Characteristic features of the use of quantum-chemical methods in the study of biologically active compounds 2
III. Quantum-chemical calculations and the chemical mechanisms of the action of antitumour preparations of different classes 5

## 1. INTRODUCTION

The wide-scale employment of the ideas and methods of chemical kinetics and physical organic chemistry in experimental and clinical oncology have led to the creation of a new field of fundamental and applied research—the physical chemistry of cancer, founded by Academician N.M.Emanuel'.[1,2] In relation to the current problems of tumour chemotherapy, these approaches have been directed towards the study of the relation between the structure and chemical reactivity of antitumour compounds (ATC) on the one hand, and their biological effects on the other. ATC are distinguished from other types of medicinal preparations by including representatives from different classes of chemical compounds. For this reason, the antitumour effect of the preparations at the molecular level cannot be accounted for in terms of a single mechanism of their action.

Fundamental principles governing the creation of new effective antitumour preparations, which have been developed by Emanuel', include the classification of ATC in terms of their chemical reactivities.[3,4] This classification constitutes the basis of the study of the anticancer preparations at the electronic and molecular levels and the establishment of quantitative structure—activity correlations, in which quantum-chemical calculations play an important role.[4]

Modern quantum-chemical methods are widely used in studies on biomacromolecules and biologically active compounds (BAC). Recently ATC have also begun to be actively investigated by these methods. Whereas in 1976 the lack of information about calculations for ATC was noted in Pullman's monograph[5] on quantum-chemical calculations of the conformations of medicinal preparations, by 1984 several tens of articles devoted to quantum-chemical studies on preparations of this kind were already published in the world scientific

literature. This review contains information about quantum-chemical calculations of the electronic parameters of ATC molecules and about the modelling of the mechanisms of their biological action at the electronic and molecular levels.

## II. CHARACTERISTIC FEATURES OF THE USE OF QUANTUM-CHEMICAL METHODS IN THE STUDY OF BIOLOGICALLY ACTIVE COMPOUNDS

### 1. Quantum-chemical Calculations of the Electronic Structure

According to the postulates of quantum mechanics, the structure and properties of the molecule can be determined from its wave function $\Phi$. The wave function is found by solving the fundamental quantum-mechanical equation—the Schrödinger equation. As a result of the development of computer techniques, fairly accurate methods have been devised in modern quantum chemistry whereby the Schrödinger equations can be solved for the stationary states of many-electron and polyatomic systems to which BAC belong. Quantum-chemical methods in which $\Phi$ is formulated as an antisymmetrised product of the spin orbitals whose coordinate components (MO) are represented by linear combinations of atomic orbitals (LCAO) have come to be most widely employed in studies on BAC. The positions of the nuclei are assumed to be frozen (adiabatic approximation). The quantum-mechanical calculation reduces to finding the coefficients of the expansion of the MO in terms of the AO by solving the Hartree–Fock–Roothaan equations, which consist of a system of algebraic equations. Several monographs on the principles of quantum chemistry have now been published[6-9] and a more detailed exposition of questions concerning the computational methods, which are only briefly described here, may be found in them.

The quantum-chemical calculation yield information about the spatial distribution of electrons in the molecule and about the energy levels of the electrons. The total energy of the system includes contributions by the one-electron orbital energies and the integrals of the Coulombic and exchange interactions. Despite the approximations underlying it (in particular the neglect of the correlation energies of electrons), the application of the Hartree–Fock–Roothaan method makes it possible to estimate fairly accurately many phyisochemical characteristics of many-electron molecules. Depending on the approaches to the solution of the Hartree–Fock–Roothaan equations used, the quantum-chemical methods are divided into non-empirical (*ab initio*) and semiempirical.

The non-empirical methods are based on a rigorous solution of the Hartree–Fock–Roothaan equations. In the calculations account is taken of all the electrons in the molecule and of all the interelectron interaction integrals. An important feature of the *ab initio* calculations is the choice of the form of the AO basis set in terms of which the MO are expanded. Various representations of the AO in the form of Gaussian functions are used nowadays for calculations on polyatomic molecules. The total energy in non-empirical calculations using different selections of the AO basis set varies within the limits of several per cent relative to its lower limit attainable by the one-determinant Hartree–Fock method.[8] However, the accuracy of the calculation of the physical properties depends very greatly on the choice of the AO basis set. It has been noted in a review[10] that, for a correct calculation of the molecular geometry and the orbital energies (for example, for comparison with photoelectron spectra), it is sufficient to employ a minimal basis set; the calculation of the isomerisation energies and conformational properties requires the use of a two-exponent basis set; for the calculation on negatively charged ions and excited states, it is essential to employ a two-exponent basis set with allowance for diffuse orbitals; the exact calculation for van der Waals interactions, spin densities, and magnetic permeabilities makes it necessary to abandon the one-determinant approximation and to employ the multiconfiguration Hartree–Fock method with a basis set of two-exponent and polarisation functions.

The increase in the complexity of the sets of basis functions entails a sharp decrease in the molecular size susceptible to calculation, which is due to the increase in computing time required to evaluate the electronic integrals and to the limited capacity of the operating memory and the peripheral memory devices of the computer. For this reason the simplest possible basis sets are used for calculations on BAC,[11] the minimal STO-3G basis set being widely employed. Non-empirical calculations for a wide range of organic compounds in terms of this basis set reliably reproduced the equilibrium geometry of neutral molecules, the heats of atomisation, the dipole moments, and the molecular electrostatic potentials.

Much attention has been devoted recently to the development of *ab initio* methods disigned for the direct investigation of large molecules.[12] The computational aspects of the non-empirical calculations have in this instance certain unusual features; in particular, owing to the large interatomic distances within the molecule, there is a possibility of an appreciable diminution of the number of two-electron integrals differing appreciably from zero. It has been suggested that the number of integrals considered be reduced by a rigorous consideration of only the valence electrons and the employment of a model potential (MODPOT) for the electrons of the skeleton,[13] by variable [partial] retention of [diatomic] differential overlap (PRDDO;[14] VRDDO [15]), and by the ruse of the integrals for similar strucual fragments (MERGE).[16] It has been noted that, when the very latest CRAY computers with a vector processor are used, the integrals are calculated so rapidly that it becomes reasonable to recalculate them anew each time instead of reading them from a peripheral memory device.[17] In this case the computer memory stores several sets of indices of non-zero integrals. Such "approximate" non-empirical methods, whose accuracy differs little from that of the calculations in terms of the STO-3G basis set, permit an appreciable saving in computing time—VRDDO by 25%, VRDDO/MODPOT by a factor of 3, and PRDDO by a factor of 15 compared with STO-3G.[18] The gain in time increases with increase of the number of AO. The employment of the PRDDO and VRDDO methods is apparently optimal (in relation to the accuracy/computing time ratio) in calculations on BAC.[18]

Despite the endeavour to employ rigorous non-empirical methods, various approximate methods for finding the wave functions, referred to as semiempirical methods, arose in the course of the development of quantum chemistry. Their appearance is associated with the methodological and technical difficulties which occurred and still occur in rigorous *ab initio* calculations. In the semiempirical methods the Hartree–Fock–Roothaan equations are solved subject to a series of approximations in the formulation of the Hamiltonian, which are based on the allowance for the interaction of only some of the electrons of the molecule (electrons or valence electrons) and the neglect of some of the inter-electron repulsion integrals. The introduction of such approximations is compensated by employing, in constructing the Hamiltonian, semiempirical parameters selected on the basis of experimental data. By means of a correct choice of parameters in the semiempirical method, it is possible to reproduce correctly in qualitative terms certain physicochemical properties of the molecules and, in particular, their variation in series of related compounds. However, as a result of the loss of rigour in the treatment, certain molecular characteristics and

intermolecular interaction energies reproduced by the semiempirical methods are in principle incorrect. Therefore the use of semiempirical calculations makes it necessary to estimate in each case the scope of the approach selected for the solution of the given problem.

Computer programmes now exist for a whole series of different quantum-chemical methods which form a virtually continuous spectrum between simple schemes with complete neglect of differential overlap (CNDO) and rigorous *ab initio* approaches. The following approaches are employed most frequently in quantum biochemistry: different versions of the Hückel method, methods of the CNDO type (CNDO/2, CNDO/BW, CNDO/S), INDO, INDO/S, MINDO/2, MINDO/3, MNDO, VRDDO, and the *ab initio* STO-3G method. In the above list the methods are arranged in order of increasing rigour of the treatment of the Hartree–Fock–Roothaan equations. The practical choice of the method is usually dictated by its feasibility as regards its application on a given computer and by the character of the problem. In the USSR there is a library of quantum-chemical programmes (analogous to the library of QCPE computer programmes available in the USA),[19] which apply the majority of standard semiempirical and non-empirical methods. The programmes are designed for computers of the BESM-6 type, which remain the most widely used in scientific centres, and EC. A detailed comparison of the characteristics of Soviet and foreign computers and their scope as regards the solution of quantum-chemical problems may be found in the book of Shchembelov et al.[9]

## 2. Analysis of the Reactivities of BAC

In the first stage of a quantum-chemical study, one selects and determines the molecular structure of the test compound. Data on molecular structure can be obtained experimentally (by the X-ray diffraction and spectroscopic methods and by gas electron diffraction). In many cases such structural information is subsequently used directly to calculate the wave function. In those cases where experimental data are lacking or are incomplete, the equilibrium molecular structure is calculated by a quantum-chemical method. For this purpose, the total energy of the molecule, which is a function of the structural parameters (the atomic coordinates or the generalised coordinates), is minimised with respect to these parameters. The use of gradient optimisation methods in combination with an adequate choice of the methods for the calculation of the wave function itself, usually gives rise to a satisfactory quantitative agreement with experiment.[8] The conformational analysis of the BAC also constitutes a separate problem, which is important for the elucidation of the specific features of their interaction with receptors and for the synthesis of new medicinal drugs.[20]

The reactivities of BAC are usually analysed by considering the reactivity indices (RI). These are defined as the molecular characteristics, calculated quantum-chemically, from which one can infer the occurrence of a specific chemical reaction. A simple physical characteristic of the molecule can serve as an index of this kind. The expected value of such a physical property $M$ is calculated, in conformity with the postulates of quantum chemistry, by the formula

$$M = \int \Phi \hat{M} \Phi^* dV ,$$

where $\hat{M}$ is the corresponding $M$ operator and $\Phi^*$ is the complex conjugate of the wavefunction $\Phi$, and the integration is carried out over all the variables in $\Phi$. The characteristics which depend solely on the properties of the isolated molecule determine the changes in the electronic structure of the molecule at an early stage of the reaction and they are referred to as the static RI. The parameters which take into account the mutual influence of the reactants describe the properties of the molecule at an intermediate stage of the reaction and are referred to as the dynamic RI. The RI permit only a relative conclusion, i.e. they make it possible to infer the variation of reactivity in a series of related compounds. The main condition governing the applicability of the RI is that the principle of the linear variation of the free energies holds for the given series at all stages of the reaction, which means that, when the energies of the initial reaction stage for a series of $n$ compounds are arranged in the sequence $E_1E_2...E_n$, then this same sequence should hold also subsequently.

The principal RI characterising the energetic and structural parameters of molecules as well as the corresponding physicochemical (including spectroscopic) properties of the molecules are presented below (Fig.1).

The majority of the indices quoted are static. The significance of a particular index in each case is determined by the nature of the process investigated. In the case of a bimolecular reaction the overall expression for the energy of the interaction of the reactants $E_t$ can be obtained from perturbation theory:[8]

$$E_t = E_Q + E_{ind} + E_{ex} + E_{ct} + E_{disp} ,$$

where $E_Q$ is the energy of the Coulombic interaction, $E_{ind}$ the energy of the inductive interaction, $E_{ex}$ the energy of the exchange interaction, $E_{ct}$ the energy of the charge transfer interaction, and $E_{disp}$ the energy of the dispersion interaction. The total energy $E_t$ is itself the most general dynamic RI. The formulae for the different contributions to $E_t$ have been published.[8] When the reaction depends at some stage mainly on interactions of one kind, the expression which can be fitted to the corresponding interaction may serve as a satisfactory dynamic index. In such cases it is frequently possible to isolate also the static RI on the basis of which one can predict the reactivity in the series of substances investigated. For example, electrostatic interactions play an important role in the formation of hydrogen-bonded complexes and the corresponding index, the molecular electrostatic potential (MEP), is satisfactorily correlated with the total energy of the hydrogen bond.

The quantum-chemical analysis of the reactivities of BAC is nowadays performed in most cases for isolated molecules. Such models correspond to gas-phase reactions and the feasibility of transferring the results of calculations for such reactions to liquid-phase biological processes requires additional justification. According the Reichardt[21] the solvent exerts a stronger influence on the reactions in which the transition state of the molecule has a dipolar structure. The polarity of the solvent is then of decisive importance. In cases where the transition state is not characterised by an isopolar or free-radical structure, the influence of the solvent is small. In calculations of reactivities in such cases one can apparently restrict the treatment to the approximation of an isolated molecule. The solvent influences the conformational characteristics and the reactivity both via its macroscopic properties (dielectric constant, surface tension) and via specific solvation in which the strong interaction (hydrogen bonding, the formation of a π-complex) between the solvent and solute molecules is important. These effects are taken into account in quantum-chemical calculations within the framework of "continuous" models and "supermolecular" models,[22] but the methodological difficulties associated with allowance for solvation effects remain one of the problems in quantum chemistry.

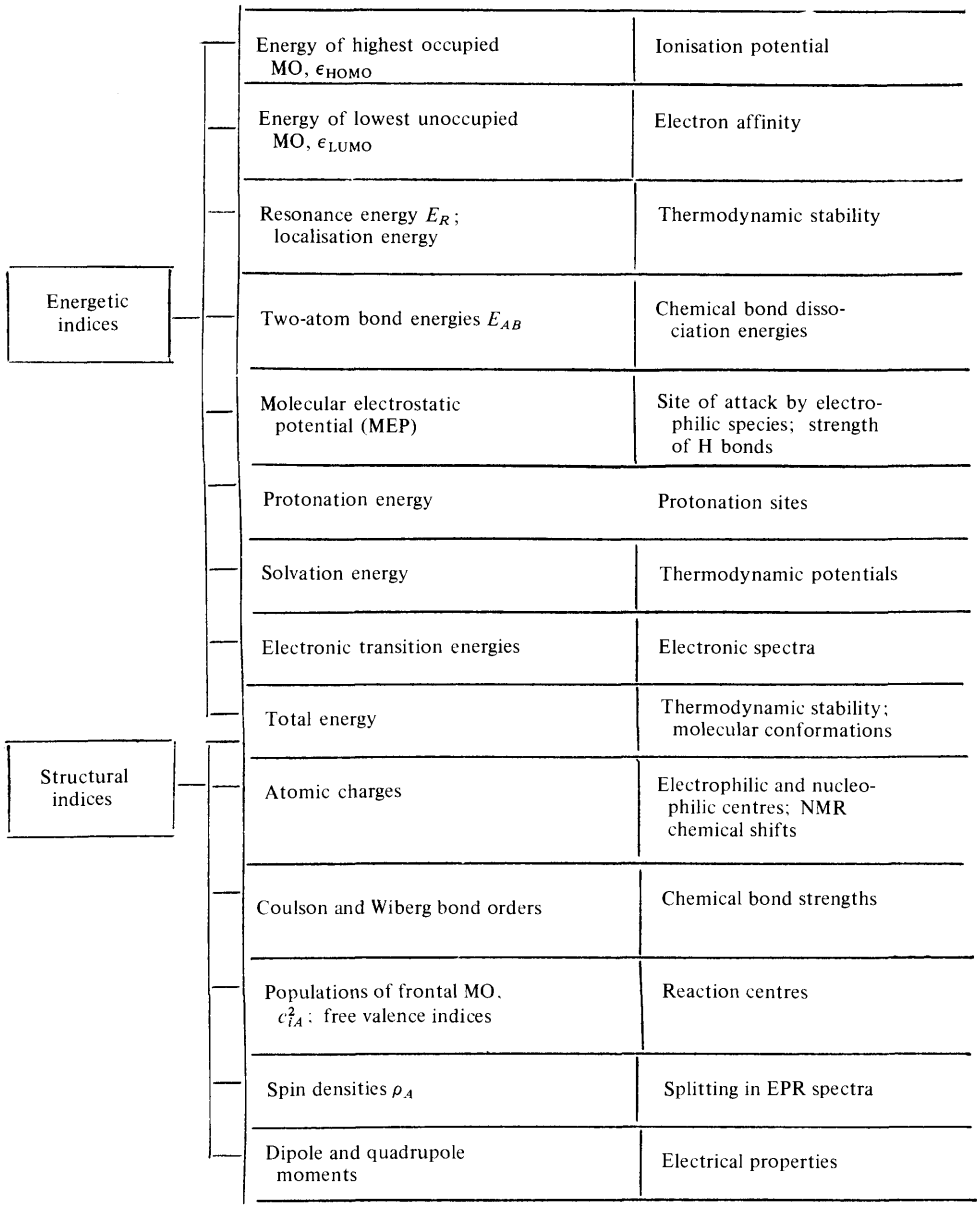

**Figure 1.** The reactivity indices used in the study of BAC and their physicochemical interpretation.

### 3. Statistical Structure–Activity Relations

The parameters of the electronic structure carry direct information only about chemical reactivity. In order to reach conclusions of a biological character, it is necessary to trace the relation between the RI (chemical interaction) and the biological effect of the compound. Quantum-chemical calculations sometimes make it possible to put forward a hypothetical model of the biological activity of just one preparation on the basis of the analysis of experimental data for its biological activity. However, it is more usual to calculate the electronic parameters for a series of compounds with similar structures for which the quantitative characteristics of the biological effects investigated are known, and then the question of the existence and nature of quantitative structure–activity correlations (QSAC) is investigated.[23,24] QSAC are usually analysed in terms of Hansch's model,[25] in which the rate of the biological response $k_{br}$ is represented in the form

$$k_{br} = Ack_r,$$

where $A$ is the probability that the BAC molecule reaches the receptor, $c$ the extracellular concentration of the BAC, and $k_r$ the rate of reaction between the BAC and the receptor. The biological effectiveness is determined by the concentration $c$ necessary to attain a specified level $k_{br} = \text{const}$.

A Gaussian relation governing the lipophilicity coefficient $\pi$, namely

$$\pi = \lg P_s - \lg P_0 ,$$

where $P_S$ and $P_0$ are the partition coefficients between water and octanol (octanol is used as the model of a lipid) of the given ($s$) and initial (0) compounds, is used for the quantity $A$ characterising the transition from the aqueous phase via the lipid membrane into the cell. The rate $k_r$ is determined from the Hammett equation $k_r = \rho\sigma$. The final equation relating $c$ to the parameters of the compound is

$$\lg(1/c) = K_1\pi - K_2\pi^2 + \rho\sigma + K_3 , \quad (1)$$

where $K_1$, $K_2$, and $K_3$ are constants found by regression analysis. In many cases it is possible to restrict the treatment to the consideration of only the linear terms of Hansch's equation. Such regression relations are also used with parameters of other types, for examples, those of the Free–Wilson and Cammarata models.[26–28] None of these models presuppose quantum-chemical calculations. However, it is now recognised that quantum-chemical RI offer greater possibilities for the analysis of structure–activity relations.[23,24]

A direct relation has been traced between the hypotheses underlying Hansch's equation and the condition governing the applicability of the RI. In each case it is then as a rule possible to select quantum-chemical parameters which are more effectively correlated with the $k_r$ than the Hammett constants. This has been responsible for the wide-scale application of RI in deriving relations of type (1). Numerous different simple static RI are used nowadays in QSAC. This hinders regression analysis and yields little information about the mechanism of the action of the preparation. It has been suggested[29] that statistically independent linear combinations of RI (principal components) be employed. Such an approach simplifies the statistical treatment but makes it difficult to interpret the mechanism of the action of the given compound. In our view the reliability of QSAC should be improved by employing complex dynamic RI which are more effectively correlated with the $k_r$.

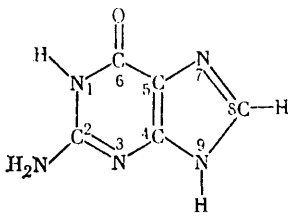
The transport properties of chemotherapeutic preparations, which depend both on the structural-functional characteristics of the ATC (molecular size, p$K$, and lipophilicity) and on the rate of blood flow, the permeability of cytoplasmic membranes, the rate of biotransformation etc., are important for the manifestation of the antitumour activity of such preparations.[30] The transport of chemicals across biological membranes diminishes with increase of the degree of ionisation and the molecular weight passes through an extremum (as a rule a maximum) as a function of the lipophilicity parameter $\pi$.[31] In view of its complexity, the real picture of the pharmacokinetic behaviour of the ATC in the organism and in the cell is very difficult to calculate theoretically. Hansch's equation reflects only the dependence of the biological response on the transport of the ATC across the membrane, which is in its turn specified as a function of the hydrophobic properties alone.

The experimental values of $\pi$ are as a rule used in QSAC. Theoretical estimates of $\pi$ are usually obtained with the aid of empirical additive schemes for series of related compounds.[32,33] The hydrophobic properties of the preparation can be inferred approximately also from quantum-chemical calculations for intermolecular interactions. A direct calculation of $\pi$ from the thermodynamic characteristics of the solute, evaluated by the CNDO/2 method, has been carried out for the conformers of prostaglandins.[34] A method has been proposed[35] for estimating $\pi$ from the charge distribution and the hyperconjugation indices of the isolated molecule. The fact that, according to thermodynamic equations, $\pi$ is proportional to the difference between the free energies of the substance dissolved in water and in the lipid phase can also be used in estimating the lipophilicity parameter. Qualitative agreement between the behaviour of $\pi$ and the hydration energies calculated in the electrostatic approximation using the MEP on the van der Waals surface of the molecule has been achieved[36] for a series of sterically hindered phenols.

Thus information about the electronic and molecular mechanisms of the action of the preparation can be obtained and new chemical structures with a potentially high activity can be synthesised on the basis of "quantum-chemical parameters–activity" correlations. Questions concerning the strategy of the employment of quantum-chemical calculations in the study of BAC were described previously in a series of reviews.[23,24,37] Detailed information about the mathematical methods whereby one can seek the relation between biological activity and chemical reactivity has been published.[38]

## III. QUANTUM-CHEMICAL CALCULATIONS AND THE CHEMICAL MECHANISMS OF THE ACTION OF ANTITUMOUR PREPARATIONS OF DIFFERENT CLASSES

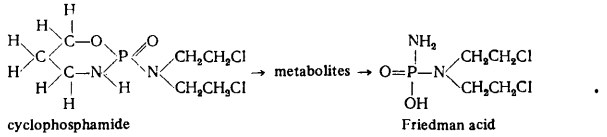
Antitumour preparations have come to be divided into classes as a function of their chemical nature, their origin, or the mechanism of their action. The classification[39] in which the ATC are divided into (1) alkylating agents, (2) antimetabolites, (3) various synthetic preparations, (4) medicinal drugs of natural origin (antibiotics, plant preparations, enzymes), and (5) hormonal preparations is widely used.



The classification of antitumour preparations in terms of the principle of chemical reactivity has been proposed by Emanuel'.[3,4] In this classification the ATC are divided into biochemically functionally active (analogues of compounds involved in cell metabolism) and chemically functionally active (characterised by a purely chemical interaction with cell molecules). The chemically functionally active ATC known at the present time are in their turn divided into groups in accordance with the chemical reactions which determine their antitumour activity. Here one encounters three main types of reactions: electrophilic reactions, complex formation, and free radical reactions. ATC with a combined mechanism of their action apparently also exist. In view of the latter factor, certain preparations, for example, the antitumour anthracycline antibiotics and sterically hindered phenols, cannot be at present assigned to a specific class. However, the classification in terms of the types of reactivity is more logical than others and can serve as a basis for the purposeful search for chemical compounds with a high antitumour activity. The results of quantum-chemical calculations on the ATC are presented below in conformity with their subdivision on the basis of their chemical reactivities.

### 1. Alkylating Agents

Alkylating compounds constitute an appreciable fraction of the antitumour agents known at the present time. Among the 58 preparations used and adopted for tests in the USSR and the USA and quoted in a monograph,[40] 23 exhibit an alkylating activity. In the course of metabolic reactions, such compounds form electrophilic species (carbonium ions), which are capable of alkylating DNA and enzymes, deactivating them thereby. The interest in alkylating agents as antitumour agents is associated with the hypothesis that the DNA in the vigorously dividing tumour cells is more susceptible to chemical action than in the normal cells at rest.



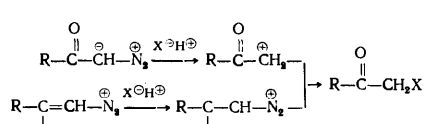
Many alkylating ATC exhibit simultaneously carcinogenic properties (the final effect of the preparation depends on the dose administered). For this reason, the conclusions and data concerning the reactivity of alkylating carcinogens are applicable to the alkylating ATC. The mechanisms of the reactions between the absolute chemical carcinogens (activated forms of carcinogens) and DNA have been examined in a review.[41] The authors note that only a small fraction of the reactions of the alkylating agents with the sites of nucleophilic attack in the DNA bases can proceed via the $S_N1$ mechanism. The $S_N2$ mechanism is commonest. Nucleic acids are alkylated to a greater extent by methylating agents than by ethylating agents. A satisfactory correlation has been observed between the carcinogenic activity of the compounds and the extent of the damage induced by them in the steric structure of the double helix of DNA.

The mechanism of the reactions of the carbonium ions $CH_3^+$ and $C_2H_5^+$ with guanine has been investigated by the non-empirical VRDDO method.[42] Potential surfaces for the reaction involving the addition of $CH_3^+$ (in the planar and pyramidal conformations) to guanine via the O[C(6)] and N(7) atoms have been calculated.

According to calculations, the attack on N(7) is preferable. The potential curves for the planar and pyramidal forms of $CH_3^+$ intersect at a distance of 3.7 a.u. from guanine. The intersection of the curves is due to the fact that, as it approaches guanine, the planar structure becomes less stable than the pyramidal structure. There are fundamental differences between the descriptions of the methylation and ethylation reactions of the DNA bases. The ionisation potential of $CH_3^+$ ($IP$ = 9.84 eV)[42] is higher than the ionisation potentials of the DNA bases, while the opposite is true of the ionisation potential of $C_2H_5^+$ ($IP$ = 8.38 eV). Because of this, account must be taken of the mixing of the wave functions for states with transfer of $e^-$, i.e. of configuration interaction, for a correct treatment of reactions of the type $A^+ + B$ in the case of $CH_3^+$. On the other hand, calculation for the reactions of the DNA bases with $C_2H_5^+$ can also be performed in terms of the one-determinant approximation.

A considerable proportion of alkylating agents contain the mustard gas group $N(CH_2CH_2Cl)_2$. The alkylating effect of this group is associated with the formation of a carbonium ion following the elimination of a Cl atom. Cyclophosphamide belongs to the class of widely used ATC of this kind:

The cyclophosphamide metabolites and not the cyclophosphamide itself are active in the organism. The atomic mechanism of the alkylating activity of cyclophosphamide has been investigated.[43-45] The author took into account the influence of the low-lying singlet ($S_n^*$) and triplet ($T_n^*$) excited levels on the reactivity of the ground state. The excited states play an important role in the study of dark reactions between molecules in view of their involvement in intramolecular and intermolecular charge transfer processes and spin–orbital interactions. The energies of the excited levels have been calculated by the CNDO/S method taking into account the interaction of singly excited configurations. The contribution due to the overlap of diffuse 3*d* AO of the P atom with the AO of all the atoms in the molecule was revealed by the calculations. In particular, the dipole moments of the transition between the excited levels are determined mainly (to the extent of 90%) by the interaction of 3*p* and 3*d* AO of P and 3*p* AO of Cl. The RI of the ground state (the charges and free valences on the atoms) differ little for cyclophosphamide and its metabolites—4-hydroxycyclophosphamide, 4-oxocyclophosphamide, aldophosphamide, carboxyphosphamide, and Friedman acid. The polarity (dipole moment) increases with the degree of metabolic transformations. For all the metabolites indicated, the HOMO form P = O bonds, while the LUMO are involved in intramolecular charge transfer with participation of both C–Cl groups.



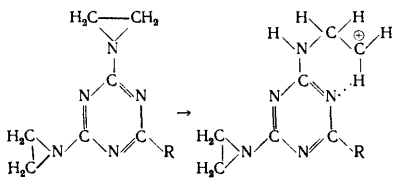
Comparison of the structures of the $S_n^*$ and $T_n^*$ excited levels of the cyclophosphamide metabolites and DNA bases showed that only Friedman acid has an arrangement of levels which ensures a satisfactory interaction with DNA. This conclusion agrees with data showing that Friedman acid has the most pronounced alkylating properties among all the cyclophosphamide metabolites and is at the same time capable of alkylating only nucleic acids but not enzymes. The ineffectiveness of the direct application of Friedman acid as a medicinal drug can be accounted for, according to the author,[45] by the poor transport properties of this compound in view of its high polarity.

The characteristics of the electronic structures of cytostatic agents comprising a series of phosphoric acid triamides have also been discussed.[46]

Electronic characteristics calculated by the CNDO/2 method and the antitumour activities of *p*-substituted diazoacetophenones.[4]

| R | $E_{HOMO}$ | $E_{LUMO}$ | Atomic charge, e | | Free valence index | Hammett constant σ | Inhibition of tumour growth, % | |
|---|---|---|---|---|---|---|---|---|
| | | | O | C | | | ARE | S-180 |
| $OCH_3$ | −10.959 | 1.916 | −0.375 | −0.186 | 0.122 | −0.27 | 79 | 70 |
| H | −11.013 | 1.896 | −0.372 | −0.172 | 0.114 | 0.00 | 64 | 63 |
| F | −11.144 | 1.441 | −0.343 | −0.162 | 0.066 | 0.06 | 30 | 44 |
| $NO_2$ | −11.697 | 0.959 | −0.324 | −0.158 | 0.050 | 0.78 | 25 | 32 |

A scheme for the interaction of alkylating preparations in the class of diazoketones with the acid groups of biomacromolecules has been analysed by means of the CNDO/2 method:[4]



Calculation of the energies of the frontal molecular orbitals, free valence indices, and negative charges on the oxygen atom and the methylidyne carbon atom established a correlation between these parameters, the Hammett constants, and the antitumour activity of diazoketones (see Table).

Preparations containing the ethyleneimine group occupy an important place among alkylating ATC. The activation of such compounds reduces to the opening of the ring at the N–C bond in the protonated ethyleneimine and the formation of the carbonium ion $X-NH-CH_2-CH_2^+$.

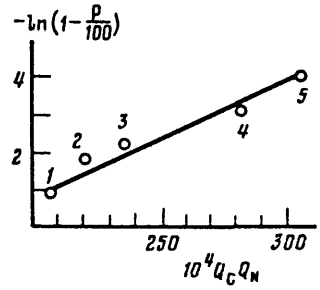
Complete structural data about the disposition of all the atoms in ethyleneimine have been obtained by a non-empirical calculation in terms of the 4-21 HF basis set using gradient optimisation of the geometry.[47] The nitrogen atom is $sp^3$-hybridised and a value of 13.9 kcal mol$^{-1}$ was obtained for the barrier to inversion (the experimental values are in the range 11.6–19.1 kcal mol$^{-1}$). The structures and thermodynamic functions of the monohydrate complexes of ethyleneimine have been calculated.[48] The energy of the electrostatic interaction for the complex with the N–H...O(I) bond, with a $H_2O$ molecule acting as the $H^+$ acceptor, is −7.3 kcal mol$^{-1}$, while for the complex with the N...H–O(II) bond, with water as the $H^+$ donor, it amounts to −7.1 kcal mol$^{-1}$. The theoretical values of the free energies $F$ and the equilibrium constants proved to be −0.05 kcal mol$^{-1}$ and 1.093 for (I) and 1.42 kcal mol$^{-1}$ and 0.092 for (II). Thus the hydration of ethyleneimine at the N–H bond is more stable.

MINDO/3 calculation for the mechanism of the opening of the ring of protonated ethyleneimine showed[49] that the direct conversion into the carbonium ion requires an appreciable activation energy (45 kcal mol$^{-1}$). When an external nucleophile is involved ($Cl^-$ was used in the above study[49]), the reaction barrier is lowered to 25 kcal mol$^{-1}$. Thus ring opening without appreciable external influences is extremely difficult. The one-stage nucleophilic ring opening process via the $S_N2$ mechanism is energetically the most favourable.

Preparations of the class of substituted ethyleneiminotriazines have been synthesised:[50]

The authors postulated the formation of a stabilised intermediate form of the carbonium ion—a cyclic intermediate. The energy $E_Q = Q_C Q_N r_{CN}^{-1}$ of the electrostatic interaction of the terminal carbon atom of the carbonium ion and the nitrogen atom in the triazine ring was adopted as a characteristic of the stability of the above products. The atomic charges in the intermediate were calculated by the CNDO/2 method. Comparison of $E_Q$ and the antitumour effect for a series of five preparations showed that the effectiveness of the preparation increases with increasing stability of the intermediate (Fig. 2). The authors suggested that this effect can be accounted for by the similarity of the structures of the cyclic intermediate and the limiting transition state in the nucleophilic attack on the molecule to be alkylated.

Certain principles of the chemical modification of the alkylating ATC have been examined.[51] Electrophiles are consumed in the organism both via non-specific reactions involving nucleophilic centres in various chemical compounds and via specific reactions with the DNA bases in tumour cells. The second channel, which is the target of chemotherapy, is much less probable than the first. An increase of the relative number of specific reactions with target molecules can be achieved, according to the authors,[51] by ensuring the preferential occurrence of the alkylation reactions via the $S_N2$ mechanism as a result of the intramolecular stabilisation of carbonium ions. We may note that in the general case the degree of stabilisation of such a heterocyclic intermediate increases with increase in the nucleophilicity of the heteroatom X in the sequence O < N < P < S and with decreased ring strain energy. As an example of the use of this concept, the mechanisms of the action of ATC based on phosphamide and diazoketones were examined.



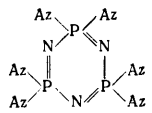


Figure 2. Dependence of the antitumour effect $P$ of ethyleneiminotriazines on $10^4 Q_C Q_N$ (correlation coefficient 0.98): 1) $C_2H_5$; 2) $OC_2H_5$; 3) $OCH_3$; 4) OPh; 5) $OCH_2Ph$.[50]

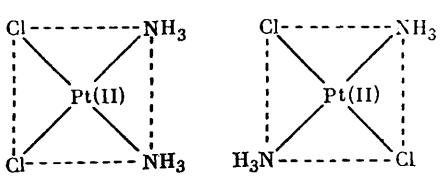
The conformational and electronic properties of the ATC in the group of aziridinocyclophosphazans have been investigated.[52–54] Using a computer, the disposition of the ethyleneimine groups in different crystalline forms of the preparations was analysed graphically.[53] The differences between the structures of the preparations associated with the influence of the substituents and solvent molecules in the crystal lattice reduce to differences in the orientations of the aziridine rings:

Quantum-chemical calculations (CNDO/2) of the barrier of the rotation of the aziridine group demonstrated the existence of three energy minima, corresponding to crystalline modifications of the preparations. For the three preparations, $N_3P_3Az_6$, $(NPAz_2)(NSOAz)$, and $SPAz_3$ (thiophosphamide), where $Az = -NCH_2CH_2$, the atomic charges and Wiberg indices were calculated by the CNDO/2 method.[54] All the experimentally detected crystalline conformations of these ATC were examined. The reactivities were analysed from the standpoint of the possible activity of these preparations as alkylating or intercalating agents for DNA.

The alkylation of DNA by the carbonium ions derived from the ethyleneimines was examined as a process involving the coordination of Lewis acids and bases. Analysis of the atomic charges led to the conclusion that the antitumour activity is determined by the acidity of the P atom. The phosphorus atoms in the preparations $N_3P_3Az_6$ and $(NPAz_2)(NSOAz)$, which are more ative than $SPAz_3$, are correspondingly more "acid". On the other hand, comparison of the charges in other ATC—*cis*-$Pt(NH_3)_2Cl_2$ and its inactive analogue $Pt(AzH)_2Cl_2$—showed that the Pt atom has a markedly "acid" character. The total charge on the Pt atom in the first Pt salt was 0.998 (calculation by the Xα method[55]). As a result of this, the coordination of the ethyleneimine groups to the Pt atom in $Pt(AzH)_2Cl_2$ is via the unshared electron pairs of the nitrogen and the formation of the corresponding carbonium ion is difficult. According to the authors, this in fact

accounts for the low antitumour activity of $Pt(AzH)_2Cl_2$. It was concluded that the manifestation of a high antitumour activity by an ethyleneimine-containing compound requires that the atoms linked to ethyleneimine should have the optimum positive charge (−0.35e). We may note that the specific value of the optimum charge is consistent with the calculation by the CNDO/2 method.



Quantum-chemical calculation (CNDO/2) of the electronic structure and stabilities of new classes of preparations of the type $[NP(CH_3)_2]_{3-x}.(NCNCH_3)_x$ and $(NPCH_3)_{3-x}.(NCNCH_3)_x$ ($x$ = 0, 1, 2, 3) [52] made it possible to predict that the compounds with $x$ = 1 and 2 may exhibit more effective antitumour properties than the familiar preparations $N_3P_3Az_6$. The authors' conclusions[52] have been confirmed by biological tests.

Thus the available data permit the following conclusions about the electronic mechanisms of the alkylation reactions: (1) in a specific calculation of the reaction mechanisms, it is apparently essential to take into account charge transfer states; (2) in ethyleneimine-containing ATC, the atoms close to this group play an important role. In particular, since the opening of the aziridine ring requires the involvement of an external nucleophile,[49] the nucleophilic centres of the molecule itself can in our view function as such a nucleophile. These centres are capable of subsequent participation in the intramolecular cyclisation of the carbonium ion, stabilising it, which can apparently promote the selective interaction of this carbonium ion with the nucleophilic centres of DNA.[50,51]

## 2. The Formation of Complexes by Antitumour Compounds

According to Emanuel's classification, preparations the mechanism of whose therapeutic action is associated with the formation of molecular complexes with biomacromolecules should be classified as complex-forming ATC. At the present time this class includes metal complexes and salts (in the first place platinum complexes and gallium nitrate) and intercalating agents. The principal target of these preparations is DNA.

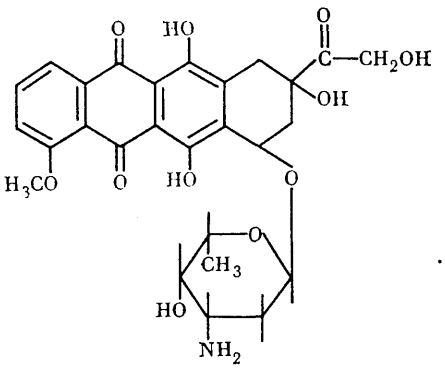
The most familiar of the platinum-containing preparations is "*cis*-chlorodiaminoplatinum". The ATC based on paltinum(II) form "intercalating" intermolecular and intramolecular cross-links with DNA.[56] The cross-links are formed mainly via the 6-amino-groups of the adenine residues of the opposite chains of DNA and the N(7) atoms of the guanine residues in the G–G pairs. The electronic structure and the parameters of the reactivity of the metal salts have been calculated.[55,57–64]

*cis*-Pt(II) *trans*-Pt(II)

The electronic structures of the platinum complexes $PtCl_4^{2-}$, $Pt(NH_3)_4^{2+}$, *cis*-$Pt(NH_3)_2Cl_2$, *trans*-$Pt(NH_3)_2Cl_2$, and $Pt(CN)_4^{2-}$ have been calculated in terms of the approximation of the extended Hückel method (EHM) with adjustment for self-consistency on the basis of the density matrix in terms of the relativistic basis set ($5s_{1/2}$, $5p_{1/2}$, $5p_{3/2}$, $5d_{5/2}$, $6s_{1/2}$, $6p_{1/2}$, $6p_{3/2}$) and the Pt(II) AO.[57] Quasi-relativistic corrections were taken into account in terms of the "frozen" spin approximation. In constructing the Hamiltonian, corrections were introduced to take into account the external stabilising potential. The main contribution to the coefficients of the HOMO of *cis*-Pt(II) comes from the ligands, but there is an admixture of the 5*d* and 6*s* AO of platinum. On the other hand, in the case of *trans*-Pt(II) 6*p* and 5*p* AO of platinum contribute an admixture to the HOMO. The difference between the antitumour activities of these preparations (*trans*-Pt is inactive) may be associated with this factor according to the authors. Calculations were made for the complexes of *cis*-Pt(II) with guanine and the guanine-cytosine pair coordinated to the O[C(6)] and N(7) atoms. The possible mechanism of the molecular action of *cis*-Pt(II) involves the dehydrogenation of the N(1) atom of guanine, although a weakened N(1)–H bond has not been observed in the complexes investigated.

Calculations for *cis*- and *trans*-Pt(II) by the SCF-Xα method, which is widely used for calculations on organometallic compounds, did not reveal any significant differences between their electronic structures.[55] It has been suggested that the differences between the biological activities of these isomers are associated with steric and not electronic factors.

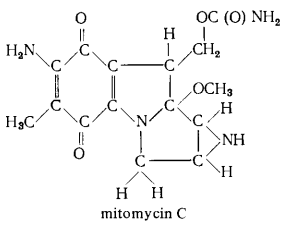
The characteristics of the structure of the hydrate complexes of dichloroaminoplatinum have been investigated[61] by the LCAO-MO method in the Mulliken–Wolfsberg–Helmholz version with adjustment for self-consistency with respect to the charges. In the complexes $[Pt(NH_3)_2XY]^{n+}$ (X, Y = Cl, $H_2O$; $n$ = 0, 1, 2), the chemical bond with the ligand is formed via the 6*s* and 5*d* AO of platinum. The aquo-complexes $[Pt(NH_3)_2(H_2O)_2]^{2+}$, formed in the course of hydrolysis, possess effective electron-accepting properties and should readily interact with the nucleophilic sections of DNA. According to the calculation, *trans*-Pt(II) is more acid and is more readily hydrolysed than the *cis*-isomer. This result agrees with experimental data. It has been concluded that there is a possibility of the rapid deactivation of *trans*-Pt(II) in the organism as a result of hydrolysis, which the authors used in face to explain the absence of an antitumour effect by this compound. In our view, this explanation is better founded and more likely than the hypotheses put forward by Barber et al.[57] and Boudreaux and Carsey.[57]



The structure–activity relations for a series of 26 dichloroaminoplatinum(II) complexes have been investigated.[62] The following RI were calculated by the INDO method (with special parametrisation for calculations on metals[63]): the frontal densities $f^N$, the binding energies of the complexes $W_b$, the molecular volume $V_M$, the electrostatic potential and the electric field strength $E$, and the energy $V_2$ of the polarisation interaction of the complex with a single charge. The RI were compared with the logarithms of the doses inducing the death of 50% of the animals ($LD_{50}$), 90% inhibition of tumours ($TD_{90}$), and their ratios. The two-parameter linear regression with the highest statistical reliability has the form

$$\lg(LD_{50}) = 0.0021\,(\pm 0.0008)\,W_b + 4.06\,(\pm 1.4)\,V_2 + 8.34\,(\pm 1.2),$$
$$r = 0.820,\ S = 0.37,\ F(2.23) = 23.65,$$

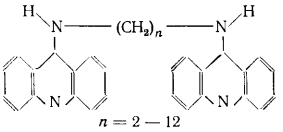
where $r$ is the multiple correlation coefficient, $S$ the standard deviation of the regression line, and $F(2.23)$ the value of the $F$-statistic. A relation with a correlation coefficient $r$ = 0.817 between $\lg(LD_{50})$, on the one hand, and $V_M$ and $V_2$ on the other, was also obtained. Thus the toxicity of the preparations is higher the greater the polarisability of the complex, the less stable the molecule, and the greater its molecular volume. However $V_M$ and $E_b$ have a high mutual correlation coefficient and the authors were unable to discover which of these quantities must be excluded from consideration. The quantity $\lg(TD_{90})$ is less well correlated with electronic parameters. The regression equation with the best correlation coefficient $r$ = 0.626 includes $E^2$ and $f^N$.



Since the electric field vector $E$ is directed at right angles to the plane of the intercalation complex, the correlation between $\lg(TD_{90})$ and $E^2$ casts doubt on the intercalation mechanism of the action of *cis*-Pt(II).

The anthracycline antibiotics belong to the class of ATC capable of reacting with DNA via intercalation. The conformational analysis of anthracycline antibiotics has been carried out:[65-67]

Attention has been concentrated on the determination of the equilibrium orientations of the sugar residue and the hydroxy-groups relative to the anthracycline chromophore. Calculation for adriamycin by the force field method (with and without allowance for the influence of the aqueous environment) indicates the formation of intramolecular hydrogen bonds between the hydroxy- and keto-groups of the chromophore.[66] Three equilibrium positions have been found for the carbohydrate fragment. The conformation which corresponds to that observed in the crystal has an energy higher by 3 kcal $mol^{-1}$ than that of the lowest-energy conformation. The absolute energy minimum obtains for the conformation in which there is a hydrogen bond between the hydroxy-group in the 6-position and the O atoms of the sugar residue. The third equilbrium conformation, which corresponds to the almost parallel disposition of the carbohydrate residue relative to anthraquinone, is destabilised to the extent of 9.5 kcal $mol^{-1}$ relative to the most stable conformation. The influence of the solvent on the relative stabilities of the conformers is insignificant. It follows from the proposed model that, for the equilibrium conformation found, there is a possibility of an additional stabilising interaction of the protonated $NH_3^+$ group of the sugar ring of the anthracycline and the phosphate groups of the DNA double helix. The conformations of the form of the antibiotic with a protonated sugar residue are identical to those in the neutral state.[66]



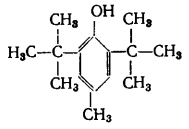
The characteristic features of the intercalation by the antitumour antibioltic mitomycin C have been investigated:[68]

mitomycin C

The interactions of the antibiotic with the model guanidine-(3',5')-cytidine dinucleotide and all possible pairs of nucleic acid bases were examined. The intermolecular interaction energy was calculated on the basis of two additive schemes—purely empirical and imitating the results of non-empirical calculations. The orientation of the antibiotic was varied within wide limits. All the optimum positions found are located at the site of the major groove of DNA. The non-planar part of the antibiotic molecule interferes with the complete intercalation of the planar quinonoid part. The intercalation on the side of the minor groove gives rise to a relatively unstable complex as a consequence of the weak overlap of the aromatic rings. The two methods of calculation yielded somewhat contradictory data concerning the optimum orientation of the axis of the quinonoid fragment relative to the dinucleotide. An increased specificity in the intercalation of any one pair of DNA bases by the antibiotic was not found.

The relation between the antitumour activity and the characteristic features of the intercalation has been investigated for a series of diacridines.[69] The RI for the neutral forms of 27 compounds were calculated by the CNDO/3R method.

Three molecular conformations were examined: (1) the planar conformation with a symmetry axis; (2) the planar conformation with a symmetry centre; (3) the non-planar conformation with a parallel arrangement of acridine rings. These conformations correspond to different models of the intercalation by one or simultaneously two acridine rings in DNA. QSAC have been investigated for the indices of the inhibition of the *in vitro* growth of P388 cells ($I_{50}$) and the toxicity ($LD_{10}$) in mice. It follows from the analysis of the QSAC that the molecular size is correlated with $\lg(I_{50})$ and $\lg(LD_{10})$. The length of the alkyl chain between the rings does not influence the biological indices. The stability of the bonds involving the nitrogen atom in the acridine ring has a positive correlation coefficients with $\lg(LD_{10})$. For the planar forms, the energy of the N–H bond has a negative correlation coefficient with toxicity and a positive correlation coefficient with the effectiveness of the inhibition of the P388 leukaemia. According to the authors,[69] the latter factor shows that the biological activity is associated with the freedom of the rotation of the planar part of the molecule about the C–N bond relative to the intercalated acridine ring.



Together with the intercalation mechanism of the cytotoxic activity, alternative mechanisms of the action of a series of antibiotics are now being considered. Thus the biological effect of the anthracycline antibiotics may be based on the formation of free-radical intermediates of the semiquinone type and active forms of reduced oxygen.[70] The molecular mechanisms of the action of mitomycin C includes the formation of reactive polyfunctional intermediates—carbonium ions and semiquinone free radicals—which leads to alkylation and cross-links between the complementary chains of DNA.[71]

### 3. Compounds whose Activity Has a Free Radical Mechanism

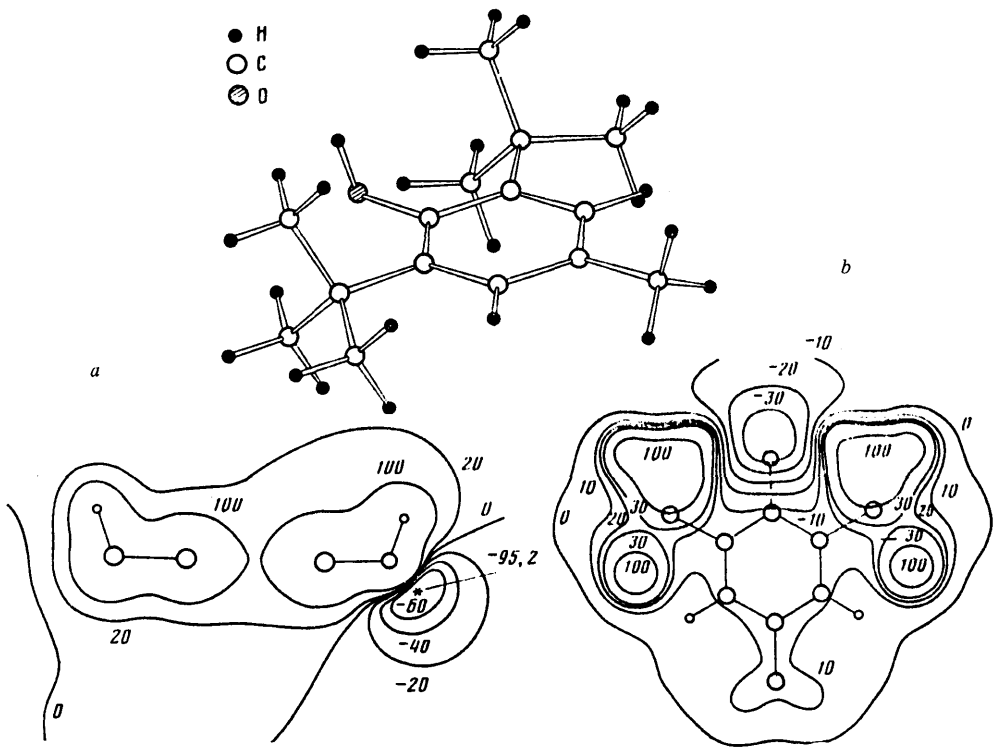
It has now been established that many metabolic and pathological processes in the cell proceed via a free-radical mechanism.[1,70-72] This applies in the first place to $e^-$ transfer reactions in the enzymic oxidation and reduction of substrates of different nature and to the lipid peroxide oxidation reactions. The products of the metabolism of many BAC are free-radical in nature (an unpaired electron is present). The intensification of the formation of free radicals in tumours is characteristic of specific stages in tumour development and this is why the inhibitors of free-radical processes can inhibit the growth of malignant formations.[1] Thus

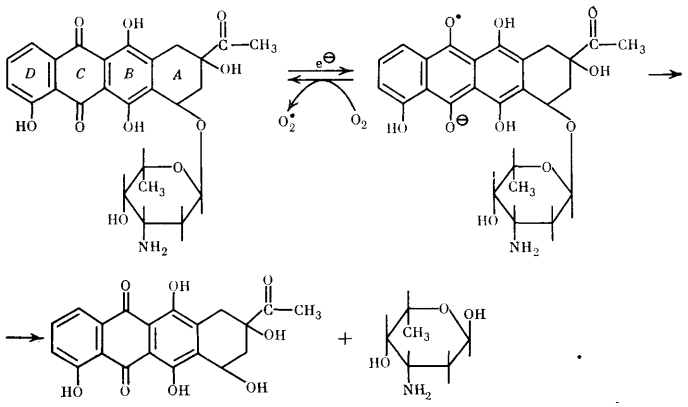
compounds whose antitumour activity is associated with the inhibition of free-radical processes in tumour cells or is determined by free-radical products of their metabolism should be classified as ATC whose activity has a free-radical mechanism.

Compounds belonging to the group of sterically hindered phenols are included among the bioantioxidants used to fight tumour processes. The preparation dibunol (2,6-di-t-butyl-4-methylphenol) is used as an ATC in therapeutic practice.

dibunol

The conformational properties and reactivity of dibunol and its metabolites (aryloxy-radical, 2,6-di-t-butyl-4-hydroxymethylphenol, and 2,6-di-t-butyl-4-carboxyphenol) have been investigated by the MINDO/3 and INDO methods.[36] A partial optimisation of the geometry has been carried out for two conformations of dibunol, which correspond to two forms of associated species with solvent molecules. In one of them (I), the proton of the OH group lies in the plane of the benzene ring, while in the other (II) the OH group is rotated by 90° relative to the plane of the ring. According to the calculations, the conformation (II) is more stable than the conformation (I) by 1.2 kcal $mol^{-1}$. For both dibunol and for its aryloxy-radical, the C–O bond lies outside the plane of the ring. It follows from the MEP maps which have been constructed (Fig.3) that there is a deeper potential minimum in the conformation (II) (−95.2 kcal $mol^{-1}$) than in the conformation (I) (−88.4 kcal $mol^{-1}$). In the conformation (I) the proton and the unshared electron pair of the OH group are more shielded by the t-butyl substituents than in the conformation (II). The hydrophilic properties of dibunol and its metabolites have also been estimated.[36] The energy of the electrostatic interaction of the phenols with a water molecule averaged on the van der Waals surface was adopted as a measure of hydrophilicity. The conformation (II) is stabilised to a greater extent by the interaction with water than the conformation (I). The hydrophilicity indices are in satisfactory qualitative agreement with the experimental values of the lipophilicity parameter $\pi$ for the phenols considered.





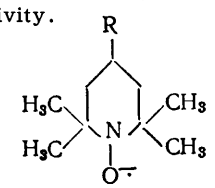


**Figure 3.** Projection of the three-dimensional structure of dibunol and the isopotential MEP maps (kcal $mol^{-1}$): *a*) in the plane of the OH group; *b*) in the plane located 1.5 Å above that of the benzene ring.[36]

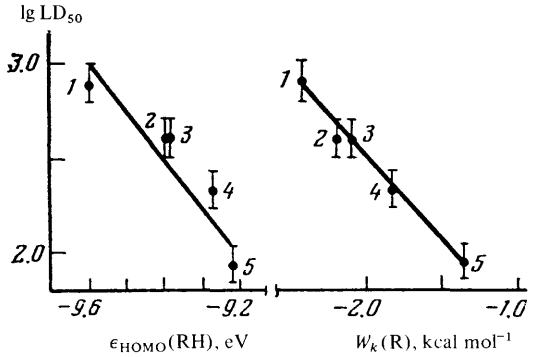
The antitumour anthracycline antibiotics (AAA) may be included among the ATC whose activity has a free-radical mechanism. They act on various cell organelles—they intercalate DNA, are bound to membranes, and form radicals of the semiquinone type in enzymic reduction. The free semiquinone radicals of AAA are capable to exhibiting biological effects of two types: (1) they can generate the toxic superoxide radical-anions $O_2^{\cdot-}$ as a result of oxidation by molecular oxygen;[70,72] (2) they can bind to DNA—tentatively via an oxidative alkylation mechanism.[73]

Studies on the conformational properties of AAA and the characteristic features of the intercalation of DNA have already been considered.[65-67] The oxidation-reduction properties and reactivities of four antibiotics (rubomycin, carminomycin, adriamycin, and aclacinomycin A) and their free radicals have been investigated by the quantum-chemical INDO method and by EPR.[74,75] In order to take into account the influence of the solvent, tne hydrate complexes of the antibiotics were examined. It was shown that in the presence of $H_2O$ molecules, the hydroxy- and keto-groups of the anthraquinone chromophore can form intermolecular hydrogen bonds with the solvent more readily than the intramolecular hydrogen bond with one another. According to the calculation, the principal splittings in the EPR spectrum of the radical-anion are associated with the protons of the *A* ring. Wiberg analysis of bond order showed that the glycosidic C–O bond between the *A* ring and the sugar residue is weakened in the radical-anions. In view of the weakening of this bond, one can postulate the possibility of the spontaneous abstraction of the sugar residue. This has been confirmed experimentally by observing the solubility of AAA in their reduction in an aqueous medium.[74] The appearance of the EPR signal of the radical-anions is accompanied by the formation of a deposit in the reaction mixture which may be associated with the elimination of the carbohydrate fragment and the formation of the antibiotic aglycones, which are sparingly soluble in water. Comparison of the energies of the frontal MO, characterising the redox properties of the AAA, with the toxic doses $LD_{50}$ did not reveal a relation between these characteristics. Thus the differences between the toxicities of the antibiotics could not be linked by a simple relation to the capacity of their radical-anions for oxidation by molecular oxygen.

The stable nitroxy-radicals are used to modify ATC, for example anthracycline antibiotics, and themselves exhibit a weak antitumour activity.

Calculations have been made[76,77] by the INDO method of the electronic structures of 7 derivatives of the piperidin-*N*-yloxy-radicals and their reduced forms—anions and hydroxylamines. For the series of radicals investigated, a weak dependence of the electronic characteristics of the $N-O^{\cdot-}$ fragment on the nature of the substituent was observed, which has been attributed to the appreciable localisation of the MO of the oxy-group and of the substituent in the 4-position. For all the species examined, the electron in the anion is localised at the oxy-group. The redox properties of the radicals were estimated from the differences between the total energies of the anions and radicals and from the energy $\varepsilon_{HOMO}$ of the anions and hydroxylamines. It was established that only the HOMO energies describe correctly the experimental reduction potentials. In order to estimate the transport properties of the radicals, the average electrostatic energies $W_h(R^{\cdot-})$ of the interaction with a $H_2O$ molecule on the van der Waals surface of the nitroxy-radicals[77] were calculated analogously.[36] The electronic parameters of the compounds investigated were compared with data for their acute toxicity and antitumour activity. The inhibition coefficients $\kappa$, characterising the antitumour activity have virtually identical values ($\kappa = 1.0-1.1$) for the radicals studied. Presumably $\kappa$ is determined by the electronic parameters, which are constant in this series.



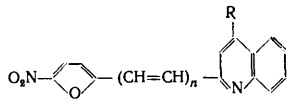


**Figure 4.** Dependence of the toxicity $LD_{50}$ of piperidin-*N*-yloxy-radicals on the hydration energy $W_h(R)$ (correlation coefficient 0.99) and the energy $\varepsilon_{HOMO}(RH)$ (correlation coefficient 0.94): 1) =O; 2) OH; 3) NHC(O)$\overline{NCH_2CH_2}$; 4) OC(O)NHPh; 5) $CH_2NH_2$.[77]

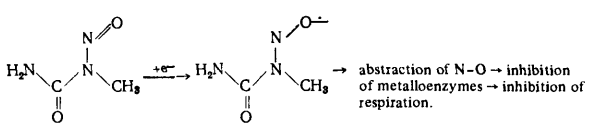
The results of the calculations support the current hypothesis that the antitumour activity of the nitroxy-radicals is associated with their antiradical properties,[1] since the spin densities on the $N-O^{\cdot-}$ fragment, which to a large extent determine its reactivity, remains constant in the series considered. Three statistically significant relations of the type of the Hansch equation between $LD_{50}$, on the one hand, and $W_h(R^{\cdot-})$, $\varepsilon_{HOMO}(R^-)$, and $\varepsilon_{HOMO}(RH)$, on the other, have been obtained.[77] According to these correlations, an increase in the hydration energy and the enhancement of the electron-accepting properties of the nitroxy-radical lower its toxicity (Fig. 4). In the organism, the radicals are rapidly reduced and exist mainly in the form of hydroxylamines. It has been concluded that the oxidation reactions of their reduced forms, leading to the formation of toxic products of the reduction of molecular oxygen, may be responsible for

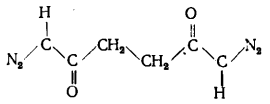
the toxicity of these species. In view of the dependence of $LD_{50}$ on $W_h(R^-)$, one can then assume that biological membranes owe the sites at which chemical reactions responsible for the toxic effect take place.

A broad spectrum of the antitumour activity (in experimental animals) is characteristic of vinylquinoline derivatives of 5-nitrofuran.



$n = 1,2$

The molecules of these compounds contain two groups which are potentially capable of exhibiting an antitumour effect—the nitro-group and the quinoline ring. It is so far not clear which of these groups is responsible for the antitumour activity. It is known that other types of biological activity of nitrofuran derivatives (antibacterial activity, the formation of nitrosyl complexes, and the generation of superoxide radicals-anions $O_2^-$) are associated with the reduction of the nitro-group. Quantum-chemical calculations (INDO, MINDO/3) of the electronic, conformational, and spectroscopic properties of a wide range of nitrofuran derivatives have been carried out[78] and it has been shown that the nitro-group determines the pronounced electron-accepting properties of 5-nitrofuran derivatives. The unpaired electron in the radical-anions of the vinylquinoline derivatives is localised mainly at the nitro-group (according to the calculation with allowance for the specific solvation of the $NO_2$ group). The electron-accepting properties of compounds of the vinylquinoline series are close to those of other derivatives of 5-nitrofuran with a high biological activity. A correlation between the electronic constants of the substituents and the antitumour activities of nitrofurans has also been observed.[79]

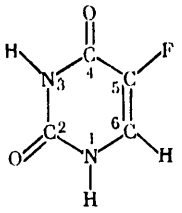


Free-radical mechanisms of the biological activity have also been proposed for two ATC derived from nitrosourea and 1,2-bisdiazoacetylethane (diazan), which have been traditionally regarded as alkylating preparations.[1,3]

The study of the electronic structures of the radical-ions of nitrosoalkylureas made it possible to predict initially[80] and then confirm experimentally the existence of a new pathway leading to the metabolic transformations of the nitrosourea, which involves the formation of nitrosyl complexes by haem-containing enzymes:[83]

The electronic parameters of the neutral state and the radical-anions of nitrosourea, in nitrosomethylurea, nitrosoethylurea, and their decomposition products (an aminoaldehyde and a nitrosamine) have been calculated by the INDO method[80,81] and by the MNDO and *ab initio* methods.[82] The electron-accepting properties and the ionisation potentials increase as follows in the series of alkyl substituents: $H < CH_3 < C_2H_5$. Both on ionisation and on capture of $e^-$, the greatest change in the charge takes place on the nitroso-group. The spin density in the radical-ions is also localised mainly on the nitroso-group. The mechanism of the decomposition of the radical-anions has been proposed on the basis of the analysis of the Wiberg bond orders.[80,81] When $e^-$ is transferred to alkylnitrosourea, the N–N bond order is appreciably weakened (by 0.2 e.s.u.), i.e. elimination of the NO group becomes possible either spontaneously or via the formation of a complex with an iron atom (in model systems). In the enzymic reduction of the preparation, the formation of a complex with the $Fe^{2+}$ atom in the active centre is apparently followed by the synchronous transfer of $e^-$ to the preparation, a weakening of the N–N bond, and the elimination of the NO group. The formation of nitrosyl complexes leads in the first place to the inhibition of the respiratory chain, but it may be that the antitumour effect is also associated with this factor. The finding that the greatest weakening of the N–N bond is characteristic of methylnitrosourea,[80] which exhibits the greatest antitumour activity among the above three preparations, merits attention.

Quantum-chemical calculations for diazan as an ATC have been carried out.[84,85] The study of Kartsev et al.[84] was devoted to the X-ray diffraction and quantum-chemical (CNDO/2) investigation of the structure of the diazan molecule:



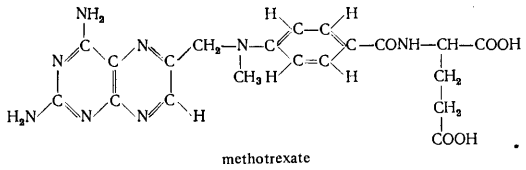
diazan

Luzhkov et al.[85] analysed the reactivity of diazan from the standpoint of its free-radical reactions. For this purpose, a study was made by the INDO and EPR methods of model oxidation-reduction reactions of these preparations. The EPR signal of free radicals of the type $X-CH_2-CH_2^{\cdot}$ (X represents the diazoketone fragment), which are capable of adding to biomolecules, was recorded in aqueous solutions of diazan in the presence of hexacyanoferrate(III), a powerful acceptor, on irradiation with light ($\lambda$ = 340–380 nm). The equilibrium conformation of diazan was determined by means of a quantum-chemical calculation and the changes in its electronic structure in $e^-$ transfer reactions were calculated. Both electron capture and electron elimination entails a rearrangement of the system of conjugated $\pi$ electrons in one of the two diazoketone fragments. The maximum spin density is localised on the oxygen atom in the radical-cation. The elimination of an electron is accompanied by the destabilisation of the structure of the diazoketone fragment. According to the calculations, the diazan molecule is a weak electron donor with $IP$ = 9.1 eV. However, when the diazo-group is displaced from the plane of the diazoketone, the ionisation potential is reduced by 0.5 eV. Presumably this conformation corresponds to the transition state in the enzymic oxidation of the molecule. Thus, as the molecular level, the activity of diazan can be attributed to its enzymic oxidation and to the alkylating activity of the $X-CH_2-CH_2^{\cdot}$ radical formed on decomposition of the diazan radical-cation.

## 4. Antimetabolites and Certain Other Types of Preparations

An important class of antitumour preparations comprises antimetabolites. Their activity is based on structural similarity to vitally important products of cell metabolism—nucleic acids, aminoacids, and enzyme substrates. By entering into biochemical reactions instead of the true metabolites, antimetabolites suppress the vital activity of the cell. There exist antimetabolites capable of acting selectively on actively dividing tumour cells.

Calculations have been made on 5-fluorouracil (5FU)—a preparation widely used in clinical practice.[86-89]

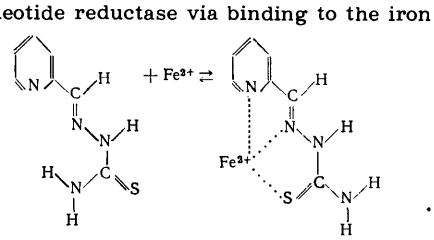


5-fluorouracil

5FU is a powerful inhibitor of the enzyme thymidylate synthetase, which is involved in an important stage in the synthesis of DNA—the methylation of uridine monophosphate to thymidine monophosphate. The differences between the reactivities of 5FU and pyrimidine bases have been deduced with the aid of quantum-chemical calculations. The relative stabilities of six lactim–lactam 5FU tautomers have been examined[89] with total optimisation of the geometry in terms of the 3-21 basis set of split Gaussian functions. The lactam form is the most stable both for the isolated tautomers and when account is taken of the interaction with water.

The reactions of uracil, thymine, 5FU, and 5-trifluoromethyluracil (which also exhibits an antitumour activity) with $O_3^{2-}$, adopted as a model of their interactions with thymidylate-synthetase, has been investigated.[87] As for the enzyme, a two-stage mechanism of the interaction was considered: (1) nucleophilic attack on the C(6) atom; (2) electrophilic attack on the C(5) atom in the 6-*S*-anion formed in the first stage. The quantum-chemical calculation was performed by the non-empirical method in terms of a basis set of floating spherical Gaussian functions and with subdivision of the molecule into fragments. It follows from the populations and bond orders involving the HOMO and LUMO that the specificity of the nucleophilic attack on C(6) and electrophilic attack on C(5) of the anion is determined by electronic factors. Both reactions take place with participation of $\pi$ electrons. The F atom has a complex influence on the rate of the overall reaction. As a consequence of the resonance interaction, the electron density on the C(6) atom in 5FU is higher than in uracil, which should retard stage 1. On the other hand, it follows from the analysis of the electron population and the additionally calculated protonation energies that the influence of the F atom in the anion leads to an increase of the basicity of the O[C(2)] atom. The energies of the protonation of O[C(2)] decrease in the same sequence as the overall rate constants for the reactions with bisulphite: 5FU > uracil > thymine. This correlation agrees with indirect experimental data indicating the importance of the mechanism of the protonation reaction and suggests that the protonation of O[C(2)] determines the rate of the overall reaction. It has thus been explained why 5FU interacts with the enzyme more effectively than uracil. Data have also been published[86,88] concerning the interpretation of the photoelectron spectra of 5FU and pyrimidine bases as well as the energies of their complexes.

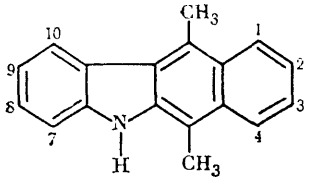
The correlations of quantum-chemical RI with the ability to inhibit dihydrofolate reductase (DHFR) have also been investigated for several classes of compounds.[90-95] DHFR is involved in the conversion of folic acid into tetrahydrofolic acid, which is essential for the synthesis of nucleic acids. Antimetabolites inhibiting DHFR inhibit the growth of tumours. In this connection new effective inhibitors of this enzyme are being sought. Calculations have been made for compounds of the class of quinazolines (series of 25 [90] and 48 [91] preparations), pteridines and triazines[97] (17 compounds), and diaminobenzylpyrimidines[93] (23 compounds). RI analogous to those for which calculations had been made by Abdul-Ahad and Webb[62] were studied in other investigations.[90-92] The potentials of interactions with trial species ($H^+$, $O^-$, $CH_3^+$) were calculated for diaminobenzylpyrimidines and six new descriptors were proposed on the basis of a description of the effects of interaction with the active centre. Despite the fact that statistically reliable regressions have been obtained between certain RI and the DHFR inhibition rate constants, the final conclusion concerning the mechanism of the interaction of the preparations with the enzyme was not reached. Nor is it stated whether the relations established were used to synthesise new ATC. The importance of the electronic parameters of the pyrimidine ring for quinazolines was noted. In particular, the localisation of $\pi$ electrons in the pyrimidine ring is unfavourable for the manifestation of activity.[91] In the case of triazines the regressions for enzymes derived from normal and tumour tissues are very similar.[92] It was concluded that such QSAC are unsuitable for use in the search for substances with an enhanced specificity towards tumours.



A non-empirical calculation of the energy of the binding of methotrexate, a preparation used in chemical practice, to DHFR has been carried out:[96]

methotrexate

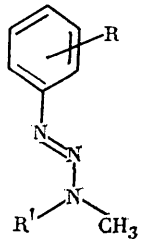
The coordinates of the atoms of the enzyme–substrate complex were taken from X-ray diffraction data. The atoms of the active centre in DHFR were modelled by point charges, which made it possible to take into account their influence without calculating the integrals for the electron–electron interaction. It was assumed that the environment of the substrate includes 17 aminoacid residues. The methotrexate molecule was divided into six fragments because of the impossibility of carrying out the calculation for the molecule as a whole and the binding energy was calculated on the basis of an additive scheme. The value obtained (−62.69 kJ $mol^{-1}$) agrees with experimental estimates within the limits of 10 kJ $mol^{-1}$. According to the authors, the procedure proposed for the calculation of the energy of binding to the active centre is fairly simple and can be used for the screening of preparations.



Semiempirical quantum-chemical calculations have been made[97-100] for yet another class of antitumour antimetabolites—derivatives of thiosemicarbazone (TSC). The mechanism of the action of these substances consists in the inhibition of ribonucleotide reductase via binding to the iron atom.

Calculation of the energies of the conformers of the pyridine derivative of TSC (PPP and PCILO methods with allowance for the Coulombic interaction with the solvent) showed that the given molecule has different equilibrium conformations in the free state and in the complex with $Fe^{2+}$.[100] The equilibrium configuration of the complex is identical with that

established crystallographically. The character of the binding of $Fe^{2+}$ and $Fe^{3+}$ ions to TSC derivatives has been investigated[97] by the extended Hückel method and from the electronic absorption spectra. There is a possibility of $Fe^{2+}$ forming an ionic complex with the neutral form and a covalent complex via the S atom with the forms of TSC deprotonated at one of the nitrogen atoms. Analysis of the absorption spectra of TSC and its homologues containing the methyl or morpholinyl group instead of one of its labile protons supports the operation of a covalent mechanism of the binding of $Fe^{2+}$ and of an ionic mechanism of the binding of $Fe^{3+}$. It follows from the calculations of the total energies that the $Fe^{2+}$ complexes with neutral molecules are more stable than those with the deprotonated forms. However, the binding of iron can reduce somewhat the $pK_a$ of the N–H group of the ligand. It follows from the EHM calculations for five pyrimidine and pyrazine derivatives that charge interactions play a decisive role for ionic binding, while the distribution of frontal densities is of decisive importance for covalent binding. Correlations between the RI of the anions of the isoquinoline derivatives of TSC (15 compounds) and their antitumour activities have been investigated.[98] On the basis of the model of the molecular activity employed, it was impossible to describe the changes in capacity to inhibit ribonucleotide reductase. Analysis of the distribution of the MO coefficients of TSC derivatives showed[99] that in the active preparations the HOMO corresponds to the unshared electron pair of the S atom, while in the inactive preparations it corresponds to the $\pi$ electrons of the S atom.



A quantum-chemical calculation (CNDO/2) for the antitumour antibiotics ellipticine, olivacine, and 2-methylellipticine has been carried out.[101] The stability of their oxidation products in the organism has been investigated. Hydroxylation proceeds most readily via the epoxide → diol (*trans*) → hydroxy-form pathway.

ellipticine

It has been shown that 9-hydroxy-isomer, which is the principal metabolite of these ATC, is less stable than the 7-, 8-, and 10-hydroxy-isomers. The antitumour activities of these compounds may be associated with the oxidation of the hydroxy-form to the quinone imine form. The ionisation potentials, calculated taking into account the solvation effects in terms of the approximation of virtual charges, did indeed show that the more active 9-hydroxyellipticine is oxidised more readily than hydroxyolivacine.

Correlations between electronic structure and antitumour activity have also been investigated for dimethyltriazene derivatives.[102–104] The molecular mechanism of the antitumour activity of these compounds is so far obscure. A series of RI have been calculated[102] for 15 derivatives of dimethylphenyltriazene.

The two-parameter QSAC obtained contain terms associated with the properties of the benzene ring, which may be due to the influence of this group on the transport of the preparation across membranes. Definite hypotheses concerning the mechanism of the biological activity could not be reached from the analysis of the terms of the regression equation referring to the triazene group Two types of QSAC have been established[104] for phenyltriazenes as a function of the type of tumour. A relation with the energy of the secondary protonation of the triazene group has been obtained for sarcoma-180, but no relation has been found between the activity in relation to leukaemia L1210 and the properties of this group. Such negative results may be accounted for by the fact that, according to Meyers,[105] phenyltriazenes may exhibit an immunostimulating activity rather than a cytotoxic activity.

---o0o---

Quantum-chemical calculations in the field concerned with the synthesis of new medicinal drugs have their advantages and limitations. Modern quantum biochemistry with its great potential computational capacity can be regarded as a physicochemical approach close to the experimental one. Its objects are molecular models with a relatively small number of atoms. Quantum-chemical calculations for such models yield a general picture of the structure of electron shells and make it possible to estimate properties which are difficult to observe experimentally. Direct conclusions based on the results of calculations are concerned with the effect of BAC on biological objects at different molecular levels. It is apparently impossible to understand all the properties of the organism at the cellular and even supermolecular level on the basis of calculations for the most complex system. For example, quantum-chemical calculations are clearly inadequate for the description of the functioning of individual components of the ribosome. Quantum chemistry cannot and should not replace the experimental methods for the investigation of living organisms. Nevertheless, many events at the level of the cell and the organism ultimately reduce to processes at the molecular and electronic level. Szent-Gyorgyi stated that, whatever our approach to biology—from the side of matter or from the side of energy—we arrive at electrons in one way or another.[106] Quantum-chemical calculations are in fact most useful in the study of such phenomena.

From the investigations described above, it is evident that in recent years quantum chemists have obtained notable results in the study of the electronic structures and reactivities of the ATC and their metabolites, sections of DNA, and peptides which are vulnerable to the action of damaging factors. Interest has recently arisen in studies of the interaction of BAC with the active centres of enzymes. Such processes belong to the class which is difficult to investigate experimentally. It may be expected that quantum-chemical calculations will in fact provide in future a detailed molecular picture of enzyme processes on the basis of which it will be possible to select molecules with a potentially high specified activity, including antitumour activity.

Quantum biochemistry is developing at the junction between quantum mechanics, chemistry, and biology. For this reason, it is important to reach conclusions based on calculations for BAC in such a way that they can be understood by the majority of those who work in these fields. Problems concerning computational methods can be understood only by specialists. The results described in the language of the simplified MO theory may be accessible to a fairly large number of organic chemists and physical chemists capable of understanding the result of a theoretical study provided that it is presented in the form of the formula

of a chemical compound. Clearly, absolute conclusions about the best structure of the BAC are apparently not to be expected from specialists in the field of quantum chemistry. However, on the basis of calculations, it is possible to discover a fairly narrow range of several potentially active compounds and to employ them subsequently for experimental tests. At the present time, the majority of quantum-chemical studies concerning calculations on ATC have not as yet yielded practical conclusions. However, in many scientific centres, where there is close contact between theoreticians and experimenters, the structure–activity correlations based on RI already constitute a working instrument in the primary prediction of new active structures.

# The Structure of the Active Centres and Stereoregulation in the Ionic-Coordination Polymerisation of α-Alkenes and 1,3-Dienes on Ziegler-Natta Catalysts

K.S.Minsker, M.M.Karpasas, and G.E.Zaikov

The development of theories of the mechanism of the stereospecific polymerisation of α-alkenes and dienes on Ziegler-Natta catalysts has been examined. Theories of the formation and structure of the active centres, the role of the heterogeneous component of the catalyst, the mechanism of chain initiation and growth, and the mechanism of stereoregulation in the polymerisation of alkenes and dienes have been discussed.
The bibliography contains 115 references.

## I. INTRODUCTION

An important contribution to the development of the chemical kinetics of processes including polymerisation and polymer degradation was made by Academician N.M.Emanuel'. In his work, particular attention was paid to the study of radical reactions, and also reactions involving complexes and various ionic coordination compounds†.

Ziegler–Natta catalysts involving the salts of metal groups IV–VIII and organic compounds of groups I–III of Mendeleev's periodic system of the elements have been used for more than 30 years for the industrial production of stereoregular polymers of a number of α-alkenes and dienes. There is still lack of agreement, however, on the mechanism of polymerisation and stereoregulation in the presence of these catalysts. The present review examines existing theories in this field.

The following abbreviations are used: M represents a metal from groups I–III, M′ a transition metal, $\bar{P}$ the degree of polymerisation, OMC an organometallic compound, OAC an organoaluminium compound, MA a macromolecule, AC an active centre, PAC an active centre at the physical adsorption stage, CAC a chemical adsorption centre (a potential polymerisation AC), and MO a molecular orbital.

## II. NATURE OF THE ACTIVE CENTRES AND MECHANISM OF POLYMERISATION

### 1. Empirical Schemes

One of the first mechanisms, namely the stepwise anionic reaction mechanism, was proposed for the process in 1955 by Ziegler and co-workers.[1] The scheme is based on the following reactions: 1) the stepwise addition of the OAC to the alkene, and 2) the displacement of the Al atom from the alkene chain with the participation of $TiCl_4$ (al = 1/3 Al), which controls the ratio of reactions (1) and (2) in scheme 1:

Scheme 1

$$R(CH_2{-}CH_2)_n\text{al} + C_2H_4 \rightarrow R(CH_2{-}CH_2)_{n+1}\text{al} \qquad (1)$$

$$R(CH_2{-}CH_2)_{n+1}\text{al} \xrightarrow[TiCl_4]{C_2H_4} R(CH_2{-}CH_2)_n{-}CH{=}CH_2 + RAl \qquad (2)$$

This mechanism was very quickly rejected. In particular, according to Ref.1, more easily ionised OMC (Na or K pentyls) should form more active catalytic systems than $R_3Al$. This does not agree with the experimental data, however. Moreover, according to the Ziegler mechanism, the individual OMC should also bring about the polymerisation of α-alkenes to macromolecular polymeric products, but this does not take place. There are many other examples where the Ziegler theory does not agree with the experimental data, in particular the reliably established fact that the transition metal–carbon bond plays an active role in chain growth.

In the period 1955–1960, a large number of papers were published, which not only discussed the anionic mechanism[2-4] but also successively put forward the ionic-coordination,[5-18] free-radical,[19-21] cationic,[22,23] and radical-ion[24-26] mechanisms for the process.

The free-radical mechanism, based on the reactions:

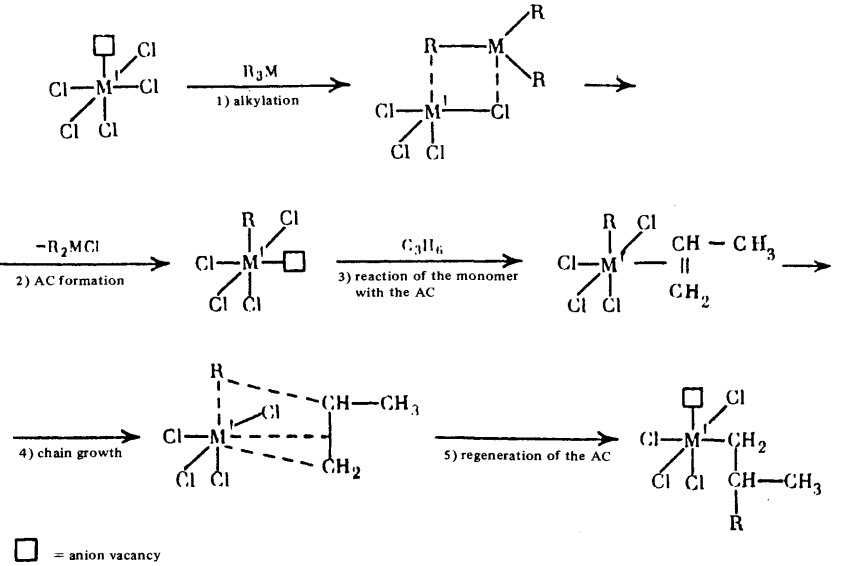
$$R_3Al + TiCl_4 \rightarrow RTiCl_3 + R_2AlCl$$
$$RTiCl_3 \rightarrow R^{\cdot} + TiCl_3$$

was also quickly rejected, since it did not explain many fundamental experimental data, in particular the following: a) radical chain transfer agents do not influence $\overline{P}$ for the polymers, b) familiar inhibitors of free-radical reactions have a positive influence on the process (the reaction rate, $\overline{P}$, and the stereospecificity of the process increase), c) change in the nature of the components of the Ziegler–Natta catalyst generally leads to a change in the reactivity of the monomers in copolymerisation, d) the time of existence of the growing MA is much greater than that in free-radical polymerisation, e) the formation of "live" polymer chains is possible,[27–30] etc.

The cationic mechanism was also rejected, even if only because the order of activity of the monomers in complex formation with Ziegler–Natta catalysts (butadiene > isoprene > styrene > isobutylene > α-methylstyrene) differs markedly from the order of the activities of these monomers in their reaction with Lewis acids.

The ion–radical mechanism:

$$A^{\cdot} + C_2H_4 \rightarrow A{-}CH_2{-}CH_2^{\cdot} \rightleftarrows A^{+-}CH_2{-}CH_2^{\cdot}$$
$$A^{\cdot} = \text{radical}$$



also does not agree with many of the above experimental data. This mechanism does not explain the chain termination associated with the removal of the MA from the catalyst surface, or the presence in the MA of organic groups previously present in the OMC.

Beginning in the nineteen-sixties, various versions of the ionic-coordination mechanism of polymerisation on Ziegler–Natta catalysts, which takes account of the important role of the reaction of the OMC with the M′ salts in the production of the AC, were accepted, and for more than 20 years now, two theoretical schemes have coexisted and been widely discussed, based on: a) the single-metal model of the AC,[4,16,17,31–49] etc., and b) by two-metal model of the AC,[2,5,7–11,13–15,18,50–61] etc.

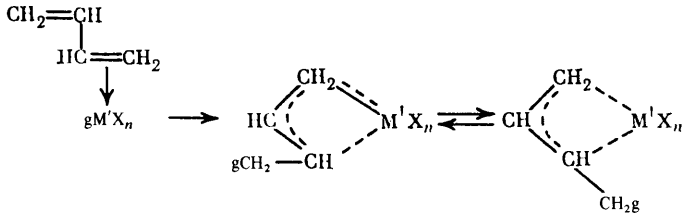
*a) Single-metal Model of the Active Centre*

Without going into details of all the proposed schemes, it can be stated that the single-metal model of the AC includes the alkylation of M′ without a change in its oxidation state. Chain initiation and growth in the polymerisation take place by the insertion of the alkene at the M′–C bond. The specific feature of the mechanism of polymerisation on Ziegler–Natta catalysts is that all the stages controlling the process, that is the initiation, growth, and all forms of limitation of the chains, involve highly active alkyl radicals, forming weak covalent bonds with M′.

The essential features of the process are most fully reflected by the Cossee–Arlman scheme.[17,33,34] According to this scheme, the active beginning of the polymerisation is due entirely to M′ and its ligands. On the edges of the $M'X_n$ crystals, AC are formed, having one anion vacancy in the octahedral coordination sphere of M′. The coordination of the monomer to the AC leads to the rupture of the C=C bond and the insertion of the monomer at the M′–C bond. The migration of the gorwing chain restores the complex to its original state, so that the addition of the next monomeric unit becomes possible:

The fact that the OMC of the most electropositive metals are suitable for obtaining active catalytic systems is due to their high alkylating power.

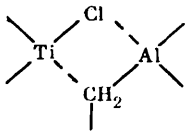
During growth, the chain oscillates between two positions on the $(M')^{n+}$ ion, increasing by one unit each time. In the Cossee–Arlman scheme as modified by Rodriguez and Van Looy,[59] the migration of the growing MA is not regarded as essential.



Later papers, for example Refs.36–40, while retaining the main ideas of Cossee given above, examined individual aspects of the problem in more detail. In particular, it was suggested[39] that the catalytic process is not a purely surface phenomenon, and that all the M' atoms take part in the reaction. The use of $(TiCl_3.AlCl_3)$–$R_2AlCl$ leads to the production of the characteristic crystal structure of $Ti_8Cl_{24}.Al_2Cl_6$, which contains cavities whose dimensions allow $R_3Al$ and the monomer to diffuse to M'. $R_3Al$ alkylates $TiCl_3$, after which the process develops according to the Cossee–Arlman scheme.[33]

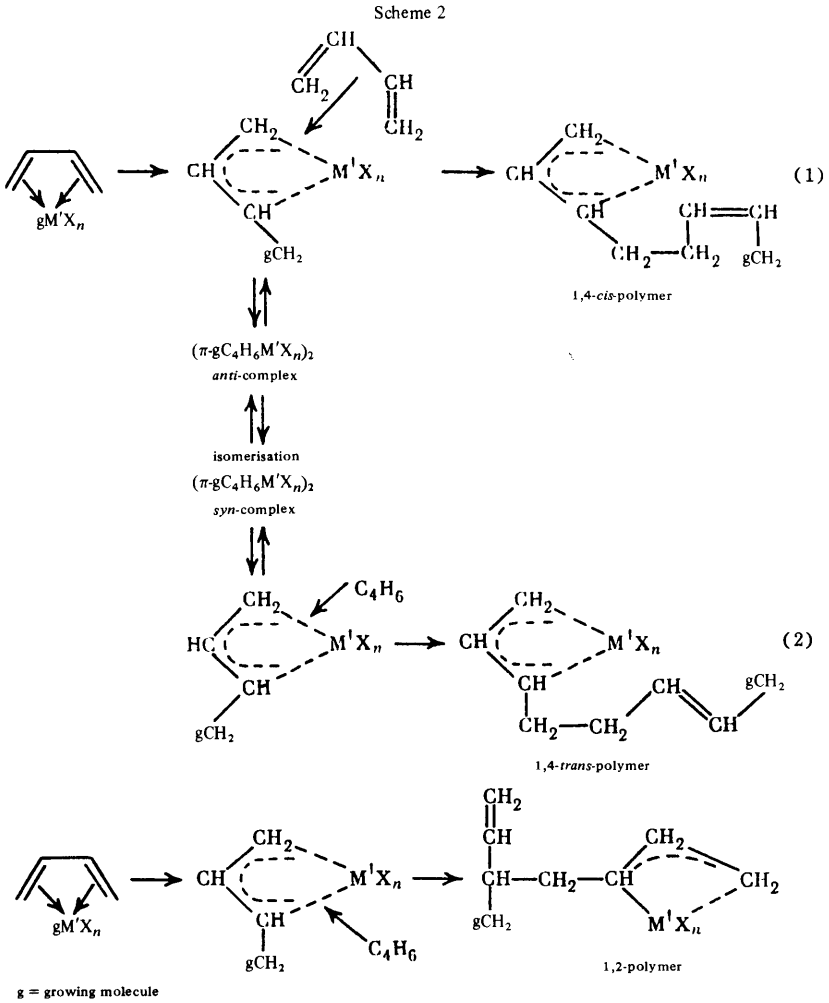
In Ref.40, a general mechanism was proposed for both the polymerisation of the monomers and the metathesis processes (see Ref.62).

Dolgoplosk and co-workers[36–38] suggest that in the polymerisation of dienes the initiation involves a π-allyl complex in the *anti*-conformation. The diene takes part in the process almost always as a bidentate ligand:



If however the AC has only one anion vacancy, the diene can coordinate only through one C=C bond in the trans conformation:

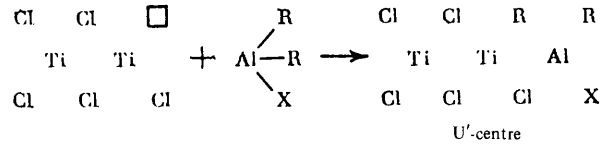
Scheme 3



*b) The Two-metal Model of the Active Centre*

The polymerisation mechanism for the two-metal model of the AC assumes the existence of complexes formed by the M' salt and the OMC, of the type

Scheme 2



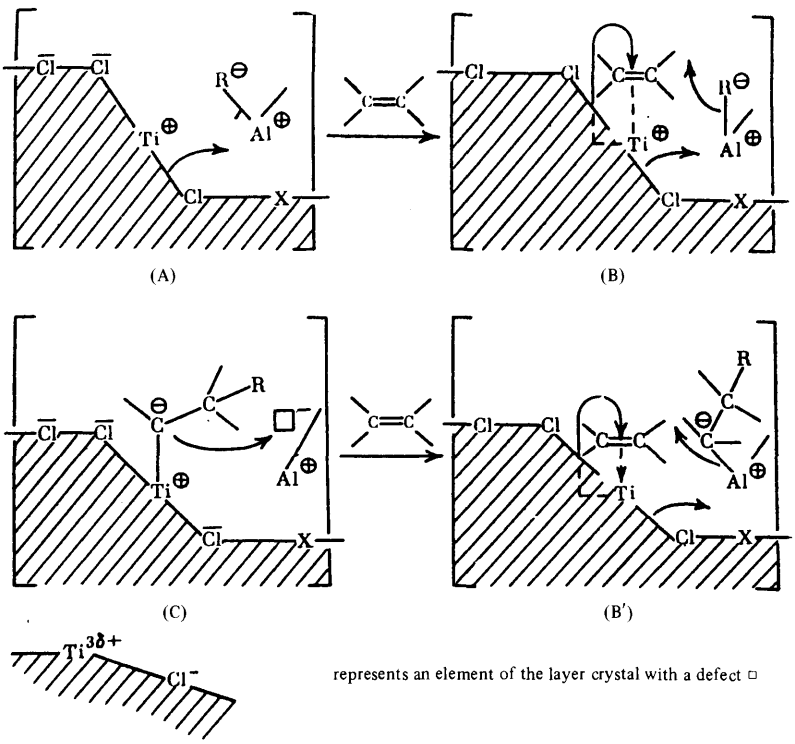
The polymerisation involves the formation of a complex by the catalyst with the monomer. Since the electropositive nature of the atom M′ increases with decrease in its oxidation number, only compounds of M′ with low oxidation numbers can show catalytic activity. The $(M')^{n+}$ cation initiates the process, and the negatively charged ionic complex of the

OMC ($R_3^-$, $-\overset{|}{\underset{|}{Al^+}}$) brings about the growth of the MA.

According to Refs.7, 11, 19, 52, etc., chain growth takes place in the surface layer of the crystal lattice of a mixed salt of M′, in particular $TiCl_3.R_2AlCl$. The role of $TiCl_3$ reduces to the activation and stabilisation of the OAC, and the negatively charged $R^{\delta-}$ group initiates the "unwinding" of the MA from the Ti atom, which forms a complex with the monomer molecules.

According to Refs.11 and 18, the reaction of the heterogeneous ($M'X_n$) and homogeneous ($R_mM$) components gives impurity crystals containing surface electronic defects of the "colour centre" type. One route for their formation involves the chemisorption of the OMC on the ionic lattice of the M′ salt ($R_3Al$ on $TiCl_3$), primarily in the positions of existing crystal defects.

Real crystals of M′ halides (the heterogeneous component of the Ziegler–Natta catalysts) always have an excess of negative charge. The chloride ions are removed more easily from the edges of the crystalline plate than from its centre.[33] As a result, in real crystals the Cl vacancies are situated at the edges of the crystals and in the positions of the dislocations, where polymerisation takes place preferentially.[64,65] Thus the crystal lattice of $TiCl_3$ is completed by the cationic fragment $R_2Al^+$, which is formed from $R_3Al$ in the field of the surface $Cl^-$ anions. An impurity crystal is formed. Since crystals of this type are essentially ionic systems, for which it is advantageous to remain electrically neutral, this requires the "formation", conjugated with the above process, of a vacancy in the region of which $R^-$ is localised. In the process, on the one hand, the anion defect is "saturated", and on the other hand the unstable $R^{\delta-}$ is stabilised. The crystal lattice defect produced—a potential polymerisation AC—is called a U′-centre:[11,18]

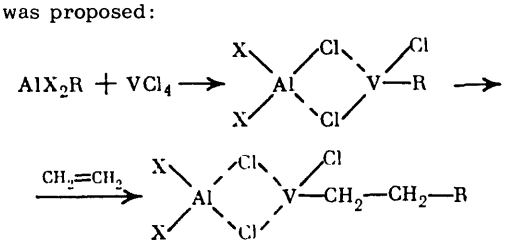


U′-centre

The polymerisation always involves the formation of a ternary complex $\rangle C{=}C\langle .M'X_n.R_nMX_{3-n}$ ($n$ = 3–1), so that the heterogeneous component should be capable of forming a complex not only with the OMC but also with the monomer. In the case of ionic solids, the adsorption capacity is related to the defect nature of their structure and depends on temperature, the concentration of foreign impurities in the form of other structural defects which can take part in electronic processes, etc.

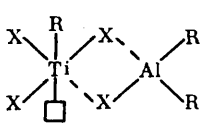
The monomer, chemisorbed on the potential AC, reacts with M′, which contains partly filled *d* orbitals (for example Ti), to form a molecular complex similar in character to the familiar π-complexes of alkenes with Pt, Cu, and Ag.[18]

The reaction of $M'Cl_n$ with the monomer takes place by a donor–acceptor mechanism, and that with the OMC by an acceptor–donor mechanism to give an impurity ionic crystal. As a result, $R^{\delta-}$ of the OAC acquires an increased negative charge. Electron transfer becomes possible through the closed system:[18]



represents an element of the layer crystal with a defect □

The scheme assumes simultaneous electrophilic and nucleophilic attack on the monomer molecule by the components of the catalytic complex, so that the heterogeneous catalytic polymerisation of alkenes and dienes under the influence of Ziegler–Natta catalysts can be regarded as "push–pull" reactions, involving the successive introduction of the monomer, its coordination, attack by $Ti^{3+}$ and R–Al$<$, and insertion at the Ti–C bond to give the MA, that is the operating principle of an automatic conveyer is established. As a result of cooperative synchronous electron transfer processes (the "concerted" mechanism), a σ-bond is formed between a carbon atom of the $R^{\delta-}$ group and a neighbouring carbon atom of the monomer. The group R, belonging initially to the OAC, becomes the terminal group in the MA formed; this leads to the reappearance of an active group $R^{\delta-}$, larger by one monomer unit, and localised on the anion vacancy, and the AC is regenerated.



In this scheme, the nature of the interaction of the catalytic system and the monomer, and also the stability of the ternary complexes formed, should naturally be influenced by all the parameters characterising the heterogeneous component, and also its structural-chemical features, in particular the crystallographic radius, the magnitude of the charge, the ionisation potential of $(M')^{n+1}$, the crystal lattice structure, etc., and this is confirmed by a large amount of experimental data. An important role is also played by the atomic radius of M, the polarity of the M–C bond in the OMC, the chemical nature and structure of the monomer, the electron affinity of the monomer, polar and steric factors, etc.

These ideas are consistent with practically all the experimental data, including the effect of the modification of Ziegler–Natta catalysts by ethers, amines, sulphides,[27,28] aromatic compounds,[66,67] oxygen, and peroxides,[30] and are fairly universal. (By ignoring various features, it is possible to arrive at the schemes mentioned above, proposed in Refs.1, 6, 9, 10, 14, 15, 17, 57, 58, etc.).

In the polymerisation mechanism schemes described above, based on the two-metal model of the AC, it is assumed that both the atoms M′ and M are in the first coordination sphere of the AC. In some papers[60,61,68–70] it is postulated that M′ is in the second coordination sphere of the AC# and influences the polymerisation only through the electronic structure of the complex formed. For example, in Ref.70 the following scheme was proposed:

A similar viewpoint is held by the authors of Refs.60 and 61, who proposed the following AC structure:

They do not however take account of the fact that in heterogeneous systems, AC of this type probably cannot be formed.

Thus the first, almost twenty-year, period of the study of various aspects of the chemistry and technology of polymerisation on Ziegler–Natta catalysts is characterised by the appearance of a large number of different empirical schemes, but often without detailed consideration of the problem and observation of the fundamental requirement that the theoretical postulates correspond to all the available experimental data. It is therefore possible to exclude from consideration the purely ionic, radical–ion, and free-radical polymerisation mechanisms. The examination of ionic–coordination polymerisation on Ziegler–Natta catalysts is now based essentially on one of the two concepts of single-metal or two-metal catalysis, differing in the structure of the AC and the mechanism of the process.

Up to the present, the Cossee–Arlman scheme (Refs.41 to 49, etc.) with a single-metal model of the AC has been most popular. At the same time, its fundamental unsatisfactory features are well known. This scheme: a) does not make specific the role of the OMC in the regulation of the activity and stereospecificity of Ziegler–Natta catalysts; b) does not explain why in many cases the OAC influences the activity and stereospecificity of the catalysts, and why organozinc compounds, which are good alkylating agents, give less active and less stereospecific active centres; c) does not explain why electron-donor ligands (amines, arenes) improve considerably the activity and stereospecificity of Ziegler–Natta catalytic systems; d) does not explain why only a small proportion of the alkylated M′ starts polymer chains, etc. Another weak feature of the scheme is the oscillating migration of the growing MA chain during polymerisation.

An attempt has been made[59] to eliminate these unsatisfactory features of the Cossee–Arlman scheme while retaining its basic postulates; its was suggested that the AC is a four-coordinate alkylated M′ atom with two anion vacancies, one of which is subsequently occupied by the OAC. This treatment, however, leads essentially to the fundamentally different two-metal AC structure.

Thus early empirical schemes, based entirely on a logical analysis of experimental data and general theoretical postulates, have not produced a satisfactory simple theory of the mechanism of catalysis in polymerisation on Ziegler–Natta catalysts. In a short period of time (less than 10 years) quantum-chemical studies have provided a deeper understanding of the problem.

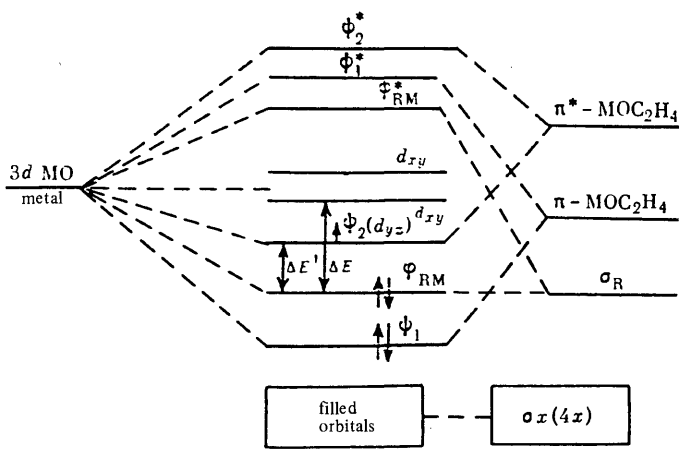
## 2. Present-day Trends

The principal unsatisfactory features of early empirical theories of the mechanism of polymerisation on Ziegler–Natta catalysts are a restricted approach to the solution of the problem, the hypothetical nature of the choice of the AC model, the neglect of the characteristic features of the structure of the heterogeneous component, etc. This explains the development of a large number of theories and the lack of unambiguous solutions, and it should be borne in mind that it is impossible to determine the mechanism of polymerisation on Ziegler–Natta catalysts using only existing experimental methods.

Although the single-metal AC model appears simpler, it is being used and developed intensively. There are however no grounds for neglecting the two-metal AC model, which provides a much more convincing interpretation of the mechanism of polymerisation on Ziegler–Natta catalysts in sufficiently good agreement with practically all experimental data, many of which cannot be explained by other hypotheses, including the Cossee–Arlman single-metal catalysis scheme.[17,33,34]

#Particularly in the case of homogeneous Ziegler–Natta catalysts.

The following reliable and generally accepted experimental facts must always be borne in mind: a) the AC are formed only by the reaction of both components of the catalytic system; b) all stages of the catalysis involve the M′ atom and the surrounding ligands, and the M compounds; c) the polymer chain grows in "hairlike" fashion, and one of the substituents R of the OMC molecule is situated at the end of the MA being formed; d) the rate of the process and the structure of the polymer are determined by the nature of not only M′ but also the OMC, that is by the structure of the AC, which in turn depends on the nature of the ligands in the coordination sphere (monomer, counter-ion, co-catalyst, modifying additives, solvent, and any other added reagent with electron-donor or electron-acceptor properties); e) the oxidation state of M′ (Ti, V, Cr) in the AC is generally 3+; f) the growing MA are arranged in spirals and are concentrated chiefly on the side faces and dislocations at the points where the M′ ions appear on the crystal surface; g) polymerisation on Ziegler–Natta catalysts is characterised by relatively low activation energy values ($E_{act}$).



At the same time, many problems of specific polymerisation under the influence of Ziegler–Natta catalysts cannot be solved experimentally by existing methods. This applies particularly to the structure of the AC, the separate stages of chain initiation, growth, and termination, etc. A number of fundamental problems can be solved by combining experiment with modern methods of calculation and process modelling using the techniques of quantum chemistry, numerical experiment (monte Carlo, molecular dynamics), etc.[17,68,69,71–108]

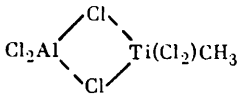
*a) Modelling the Process of Polymerisation on Ziegler–Natta Catalysts*

The determination of the mechanism of ionic–coordination polymerisation on Ziegler–Natta catalysts is directly related to the determination of the structure of the AC.

A characteristic feature of the first studies[71–75] was the investigation of various particular problems regarding AC, selected according to the subjective opinions of the research workers. The mechanism of polymerisation on both single-metal[17,76–85] and two-metal[68,69,75,86–96] AC was examined.

*Single-metal model of the active centre.* The first paper applying quantum mechanics to polymerisation on Ziegler–Natta catalysts was published by Cossee.[17] It examined a simplified molecular diagram of an octahedral alkylated complex $M'Cl_4R$ and ethylene:

In the formation of the complex of the alkene with $RTiCl_4$, $\Delta E$ in the diagram corresponds to the energy which must be acquired by the electron taking part in the antibonding of the Ti–C bond. A high value of $\Delta E$ facilitates the preservation of the Ti–C bond in the absence of the alkene. When the alkene is bound in the complex, the interaction of the *d* orbitals of M′ and the $\pi^*$ antibonding orbitals of the monomer produces a new energy level $\psi_2(d_{yz})$, which lies below the energy level of the 3*d* orbital of the original M′, and the excitation of the electron of the M′–C bond ($\phi_{RM}$) can take place much more easily. The Ti–C bond therefore readily undergoes homolysis. If $\Delta E'$ is smaller than the difference in the critical energies,[97] the R group is "ejected" as a radical, which in a coordinated process subsequently adds on to the nearest carbon atom of the alkane. At the same time, a C atom of the alkene adds on to M′. When the reaction is repeated, the R group returns to its original position. According to Cossee's model,[17] only some M′ ensure the necessary conditions for the process. According to the MO diagram, for the M′ compound to show catalytic activity it is not essential to have an electron in each of the orbitals $d_{yz}$, $d_{xz}$, and $d_{zy}$. The $\psi_2(d_{yz})$ orbital, however, must not contain two electrons simultaneously. This means that only $(M')^{n+}$ ions having 0–3 unpaired *d* electrons are suitable as catalysts. The specific action of the M′ ion is possible only when the 3*d* level of M′ lies between the bonding and antibonding energy levels of the alkenes. Later analogous MO studies[77] of the complexes $CH_3TiCl_3$, $CH_3TiCl_4$, $CH_3TiCl_4.CH_2{=}CH_2$ by the Wolfsberg–Helmholz–Ballhausen method added nothing new to these ideas.



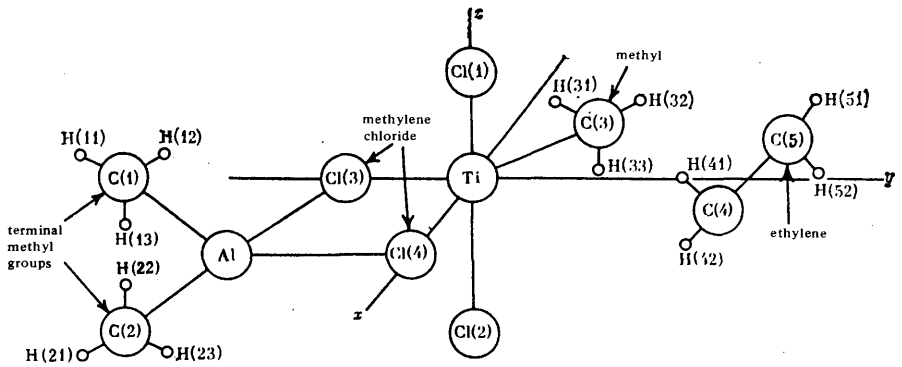
In Ref.76, the Hückel extended iteration method was used to study the migration of the $CH_3$ group to a coordinated ethylene molecule on the signle-metal AC $Ti(Cl/2)_4CH_3$ and to confirm the data of Ref.17; thus the *d* level of M′ lies between the $\pi$ and $\pi^*$ levels of ethylene, the bonds between R and the Ti atoms are localised, and the corresponding levels lie only 16000 $cm^{-1}$ below the non-bonding $d_{xz}$ and $d_{yz}$ orbitals of M′. The chief difference between the Ti–C bond and the Ti–Cl bond lies in the much lower electronegativity of the two interacting atoms (the overlap integrals are the same in both cases). The results of the calculation indicated that the low kinetic stability of the Ti–C bond is due to the small energy difference between the MO bonding M′ to C and the unoccupied *d* orbitals.

Subsequent studies cast doubt on Cossee's conclusion that the driving force of the reaction is the decrease in the strength of the Ti–C bond resulting from the manifestation of $\pi$-acceptor properties by the alkene on coordination to M′.[41,42] The process of polymerisation on the Ziegler catalytic systems $[CH_3TiCl_4.C_2H_4]^n$ (the charge $n$ = 0, −1, −2) and $Ti(CH_3)Cl_3.C_2H_4$ was studied on the basis of Cossee's scheme using CNDO and SCF $X_\alpha$-SW methods.[78–80] The assumption that there is extensive overlap of the $3d_{yz}$ orbital of Ti and the $\pi^*$ orbital of ethylene, which is the basis of many postulates of Cossee's theory, and hence of the driving force of the polymerisation reaction, was not confirmed. Moreover, according to Ref.78, Cossee's polymerisation mechanism can apply only in particular cases. The results obtained in Refs.78–80 agreed with the results of quantum-chemical studies assuming a two-metal model for the AC.[68,69]

Semi-empirical MO calculations of a hypothetical reaction path assuming that intermediate compounds of the metallocyclopentane type are formed in the polymerisation of alkenes were carried out in Ref.79. It should be noted, however, that the polymerisation scheme proposed in Ref.79 is not consistent with the experimental data.

The concept of the single-metal catalysis of polymerisation on Ziegler–Natta catalysts was developed systematically in a recent series of papers.[81–85] In these studies, the CNDO/2 and MINDO/3 methods were used to study the complexes $[RTiCl_4]^{2-}.C_2H_4$ (Cossee's AC model) and $Al(CH_3)_3.C_2H_4$, $AlH_3.C_2H_4$, and $(CH_3)_2AlH.C_2H_4$. The latter were chosen to investigate the general regular features of the catalytic transformations of α-alkenes. The studies gave the following results: a) a two-stage reaction path involving the formation of a π-complex by the alkene with the Ti ion is energetically favourable; b) the insertion stage requires only a small $E_{act}$ and is accompanied by the formation of a stable *cis*-configuration of the alkyl and the growing MA; after the insertion of the monomer, *cis–trans* isomerisation is possible; c) the limiting stage is the coordination of the alkene with rearrangement on the AC of the growing end of the MA under the influence of the coordinated monomer; d) a stable AC structure is formed by a Ti ion with four octahedrally arranged $Cl^-$ ions and one R group. The activation energy of the stages involving the coordination and insertion of the monomer with the participation of the AC is made up of the energy of rupture of the π-bond of the alkene and the energy required to change the coordination state of the AC. An analysis of experimental data on the polymerisation of alkenes on the individual compounds $M'R_n$ or $M'X_m.R_{n-m}$ (R = methyl, benzyl, neopentyl, tetramethylallyl, or allyl; X = halogen or cyclopentadienyl) also established[85] that the presence of a M'-C σ-bond in the individual compounds is not a sufficient condition for their catalytic activity in the polymerisation of alkenes. Particular importance is assigned to the coordination state of $M'X_mR_{n-m}$ ($M'R_n$). It is only when octahedral structures are formed in the AC–alkene complexes that sufficiently stable π-complexes can be produced on the AC. Data from other papers were also confirmed: in single-metal Ziegler catalysis, the $3d-\pi^*$ molecular orbital overlap is extremely slight, and the Ti–C bond is determined almost entirely by the highest bonding orbital of the alkene complex.[81–85]

*The two-metal model of the active centre.* In one of the first papers,[68] the polymerisation of ethylene under the influence of a homogeneous catalytic system was studied by the CNDO method.

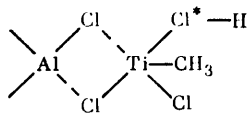


It was found that there is comparatively little perturbation of the electronic structure of ethylene in the complex, and extensive polarisation of the Ti–C bond. The authors cited assume that the R group and the monomer, at all microstages of the growth of the polymer chain, can remain joined to the Ti atoms, and that practically no energy is required for the rupture of the bonds. The driving force of the displacement of the $R^{\delta-}$ group may be the reaction of the slight positive charge in the monomer (in the complex) and the fairly strong negative charge of the terminal C atom of the R group (the growing chain). Comparision of the intermediate π-complex of ethylene and the compound formed by the insertion of the monomer shows that the energy of the complex not containing the alkene is lower. The optimum structure in this case is a trigonal bipyramid without a vacant position. Thus when the alkene is coordinated to the AC, rearrangement of the complex takes place to give a trigonal bipyramid–octahedron, accompanied by the production of a vacant position. The energy required for the rearrangement can be regarded as $E_{act}$ for the chain growth reaction.

The results of the calculations led to some general conclusions:[68] 1) the high activity of Ziegler–Natta catalysts in the polymerisation of alkenes is due to the increased lability of the C–M' bond in the AC compared with typical ionic AC and to the geometry of the complex of the monomer with the AC, favourable for the insertion of the alkene at the C–M' bond, 2) the contribution of the dative interaction of the $Ti^{3+}$–alkene bond is slight, and there is little $3d-\pi^*$ orbital overlap, 3) the properties of the $Ti-CH_3$ bond are determined almost entirely by the highest bonding orbital of the alkene complex (the contribution of the Ti atom to this bond is practically associated only with the *d* orbitals of M'), and 4) the OAC has no significant influence on the energy levels of the AC, which are of decisive importance for the polymerisation process. The role of the OAC when soluble catalysts are used reduces to the stabilisation of an AC structure with a high coordination number for the $M'(Ti^{3+})$ ion as a result of the formation of bridging bonds between M and M'. It should be noted, however, that the last conclusion is not completely correct, and that the function of the OAC in ionic–coordination catalysis is probably more varied (Refs.11, 71, 75, 86, 87, 93, 95, etc.).

The results of a study[96] of polymerisation in the presence of homogeneous Ziegler–Natta catalysts ($Ti(OCH_3)_4-R_3Al$) practically coincided with the conclusions reached in Ref.68.

A non-empirical SCF LACAO MO method (the restricted Hartree–Fock (RHF) method)[69] was used to carry out a calculation for the reaction $TiCl_4 + (CH_3)_3Al + C_2H_4 \rightarrow TiCl_4.(CH_3)_3Al.C_2H_4$, modelling the polymerisation of alkenes on Ziegler–Natta catalysts.

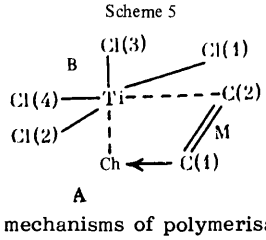


According to the calculation, the polymerisation takes place in three main stages: 1) the coordination of ethylene to $TiCl_4(CH_3)_3Al(AC)$, accompanied by the transfer of the $CH_3$ group of the AC from the trigonal position originally occupied to an octahedral position, 2) the reaction of ethylene with the $CH_3$ group of the AC and the rupture of the π-bond of ethylene, and 3) the formation of the MA. Following Refs.11 and 17, a "concerted" mechanism of polymerisation is assumed.

Unfortunately, the authors of Ref.68, 69, and 96 ignored the equally well argued model of the two-metal AC, according to which the cocatalyst (or a fragment of it) is situated on the same side of the M′ atom as the growing chain and the monomer coordinated to the AC. This version is possible in both homogeneous and heterogeneous Ziegler–Natta systems.

The two-metal model of the AC has been used in a series of interesting papers.[71,75,93–95]

The unrestricted Hartree–Fock (UHF) method in the CNDO approximation with allowance for configuration interaction (CI)§ has been used to study the homolysis of the metal–carbon σ-bond in OMC of Ti and Al atoms. A model was proposed, explaining from a single viewpoint the at first sight contradictory data on the relative stability, thermal stability, and reactivity of the M–C bond in different OMC. A fundamental difference between the Ti and Al atoms is the ability of M′ to change its oxidation state with relatively slight deformation of the M′–C bond. The decisive factors in this case are not only the similarity in the energies of the *s*, *p*, and *d* atomic orbitals but also the less diffuse character of the *d* atomic orbitals compared with *s* and *p* orbitals. For the same excitation energy, this rearrangement ensures greater deformations of the M′–C bond and facilitates the formation of a partly bound alkyl ligand, capable of taking part in subsequent concerted processes in the coordination sphere of M′. The magnitude of $\Delta E_{S_0 \to T_j}$ (the energy of the transfer to the lowest triplet excited electronic state) in compounds of the same type formed by a given M′ correlates with the relative elongation of the bond after which the change in the oxidation state of M′ begins. The lower $\Delta E_{S_0 \to T_j}$, the more labile the Ti–C bond, that is $\Delta E_{S_0 \to T_j}$ can be used as an indication of the reactivity of the OMC. The AC most probably have a two-metal structure:



It is assumed that there is no coordination vacancy on the Ti atom. The alkene displaces the saturated fragment $C_\gamma RR^*$ of the growing MA, overcoming the energy barrier to insertion at the Ti–R bond. Preference for the AC with a two-metal structure is also observed for homogeneous Ziegler–Natta systems: $L_2TiRCl.AlCl_3$ (L = Cp, Cl; R = Cl, $CH_3$, $C_2H_5$, $C_4H_7$).[95] The activity of the Ti–C bond in catalysis is due to the ease of formation of a "quasi-octahedral" structure by the Ti atoms in the complex.

§For comparison, the same calculations were repeated by the restricted Hartree–Fock (RHF) method, widely used in quantum-chemical calculations for coordination–ionic polymerisation. It was noted that the observed change in the oxidation state of M′ with deformation of the σ-bond (UHF calculation) cannot be detected by the usual quantum-chemical methods taking no account of the dynamics of the correlation contribution to the energy (RHF method without allowance for CI).

Unfortunately, Refs.71, 75, and 93–95 gave no answer to the question of the geometric structure of the AC and the mechanism of polymerisation on Ziegler–Natta catalysis.

Thus modern methods for studying the ionic–coordination polymerisation of α-alkenes and dienes by quantum-chemical methods have made it possible to extend theories of the characteristic features of the electronic structure of the assumed AC and the catalytic complexes formed with and without the participation of the monomer, and also to refine various details of the mechanism of the polymerisation processes. At the same time, the studies carried out are not free from serious defects. In particular, in most studies the structure of the AC (single-metal or two-metal model), as already noted, is assumed in advance in accordance with the subjective opinions and tastes of the authors. The calculations, particularly those relating to the stage of AC formation, generally did not take account of the characteristic features of the structure of the surface of the heterogeneous component of the catalysts, and the position of the OMC was not studied, and was usually assumed *a priori* (before the calculations). These are essentially incorrect assumptions. It is sufficient to note that the phase state of the catalyst and the position of the OMC influence the steric environment of the AC being formed and their electronic structure, so that stereoregular polymers, for example isotactic polyalkenes, are formed in heterogeneous systems, whereas syndiotactic or atactic polyalkenes are formed in homogeneous systems with similar compositions. It may be stated that the use of quantum chemistry has shown that the two-metal model is highly probable. This is confirmed, in particular, by the results of a study[86] of the polymerisation of ethylene by the CNDO method. Two AC models, the single-metal model of Cossee[17] and the two-metal model (scheme 4 [18]), were compared under identical conditions. The authors examined the stages of coordination and insertion of the monomer (M) (shown by the arrow in scheme 5 below), in the course of which the monomer is displaced from the original coordination position into the position previously occupied by the chain, increasing by two carbon atoms the distance between the growing MA (Ch) and the Ti atom.

Scheme 5

A

Comparison of the mechanisms of polymerisation from the dependence of the energy of the system, the charges on the atoms, and the bond orders on the reaction coordinate indicates unambiguously a preference for the two-metal model of the AC,[11,18] according to which the cocatalyst ($R_3Al$) is on the same side of the Ti atom as the monomer and the growing MA (position A), compared with the single-metal AC model of Cossee,[17,33] in which $R_3Al$ is on the other side of the Ti atom from the monomer and Ch (position B). According to Ref.86, the growth of the MA most probably takes place with the participation of the $Al–R–Ti^{\delta+}$ group. The organoaluminium compound coordinated to Ti chloride takes direct part in the addition of the monomer to the growing chain by simultaneous nucleophilic (by $R–Al\lesssim$) and electrophilic by $Ti^{\delta+}$) attack on the monomer (the "concerted" mechanism), as previously assumed in Refs.11, 18, 69, 76, etc. The OAC plays an active role by stabilising the monomer on coordination to the AC, facilitates its introduction into the growing MA, and decreases $E_{act}$ for the polymerisation process.

### 3. Recent Progress

A distinguishing feature of papers published in the period 1980–1982 [87–92] was the combination of quantum-chemical calculations (in the CNDO approximation), empirical methods ("atom–atom" potentials), and numerical experiment methods (Monte Carlo). The dynamics of the formation of the AC produced by the reaction of organic compounds of M (Li, Na, Be, Zn, Mg, Al, etc.) with salts of M′ (Ti, V, Cr, etc.) were examined. In the calculations, account was taken of the real structure of the surface of the heterogeneous component of the catalyst. The polymerisation process was studied for a number of α-alkenes (ethylene, propene) and 1,3-dienes (butadiene, isoprene, piperylene, 4-methylpenta-1,3-diene, etc.).

The studies carried out have made it possible to determine much more reliably the characteristic features of the structure of the AC and the effect of stereoregulation in the polymerisation of α-alkenes and dienes in the presence of Ziegler–Natta catalysts.

#### *a) Structure of the Active Centres*

The process of AC formation by the reaction of the components of the catalytic system takes place in two stages. [87–91] In the first stage, at large intermolecular distances between the OMC and the crystal of the M′ salt, the reaction between the components of the catalytic system is due to Coulombic and dispersion forces; reversible physical adsorption takes place, accompanied by the orientation of the components of the Ziegler–Natta catalyst relative to one another without change in their structure, and the frequency with which the subsequent non-equilibrium stages of the reaction take place on a particular AC is proportional to the equilibrium population of this centre at the stage of physical adsorption.

The second stage is the chemical adsorption of the OMC on the crystal of the M′ salt. Here the principal role is played by exchange forces, which bring about a redistribution of the charges and a change in the structure of the interacting components. The process of chemical adsorption leads to the formation of the AC.

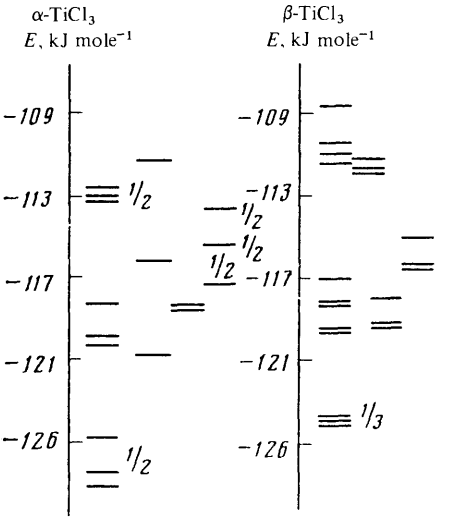


**Figure 1.** Energy level spectrum of the interaction of the physical adsorption of $(CH_3)_2AlCl$ on the surface of α- and β-$TiCl_3$.

For each system there are several types of physical adsorption centre with different energies (Fig.1) and structures (Figs.2 and 3). Among these it is possible to distinguish

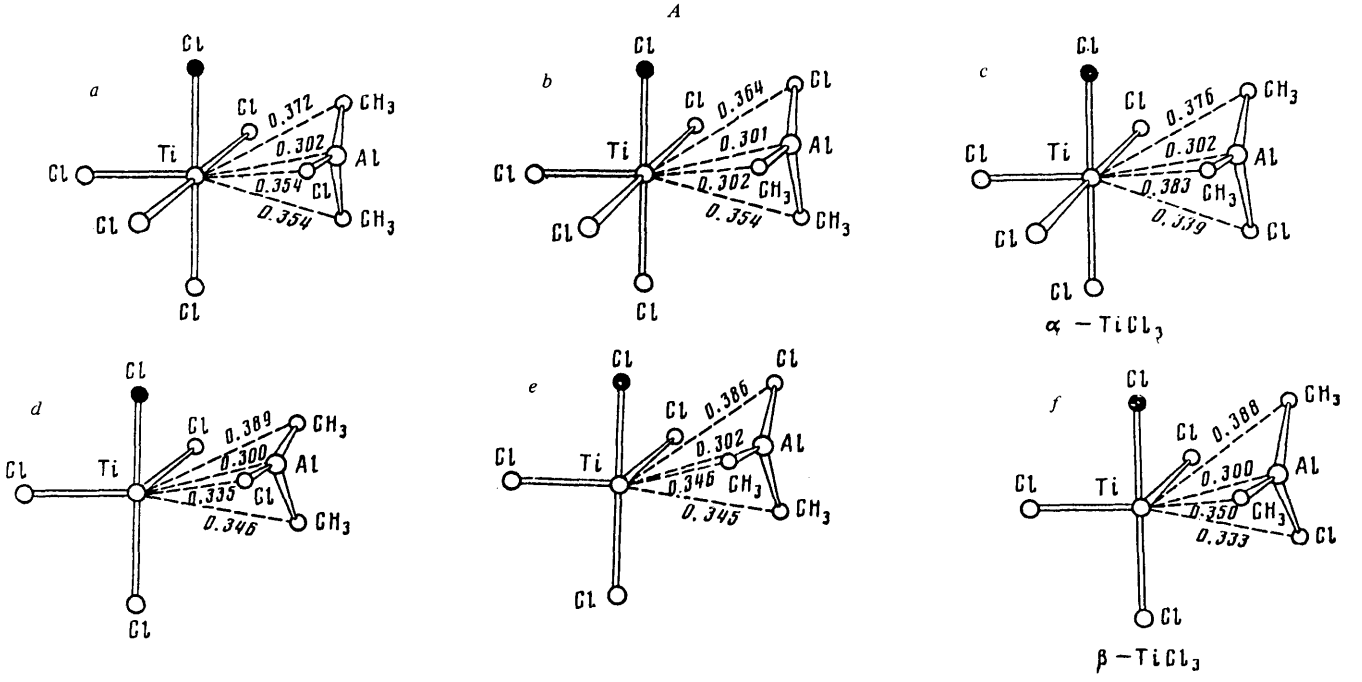

**Figure 2.** Structure of the physical adsorption centres of organometallic compounds on the surface of α- and β-$TiCl_3$ crystals (configurations corresponding to the energy minimum, distances given in nm): *A*) $Al(CH_3)_2Cl$ (*a–c*—PAC-1, *d–f*—PAC-2); *B*) $Be(CH_3)_2$, $Mg(CH_3)_2$ (*a,b,d,e*—PAC-1, *c,f*—PAC-2); *C*) $NaCH_3$ (*a–c*—PAC-3).

centres of the same type with identical three-dimensional structures: PAC-1 (physical adsorption centres formed mainly on the surface of the crystals of $TiCl_3$ and $VCl_3$), PAC-2 (β-$TiCl_3$, $CoCl_2$, $NiCl_2$), and PAC-3 ($CrCl_3$, $CoCl_2$, $TiCl_3$) (Figs.2 and 3). Estimation of the equilibrium populations (the relative concentration or proportions of different PAC) showed[87-89,91] that the populations (proportions) of the various specific PAC distinguished above are probably related to the yields of isotactic polyalkenes and *trans*-poly-1,4-dienes (PAC-1), atactic polyalkenes and

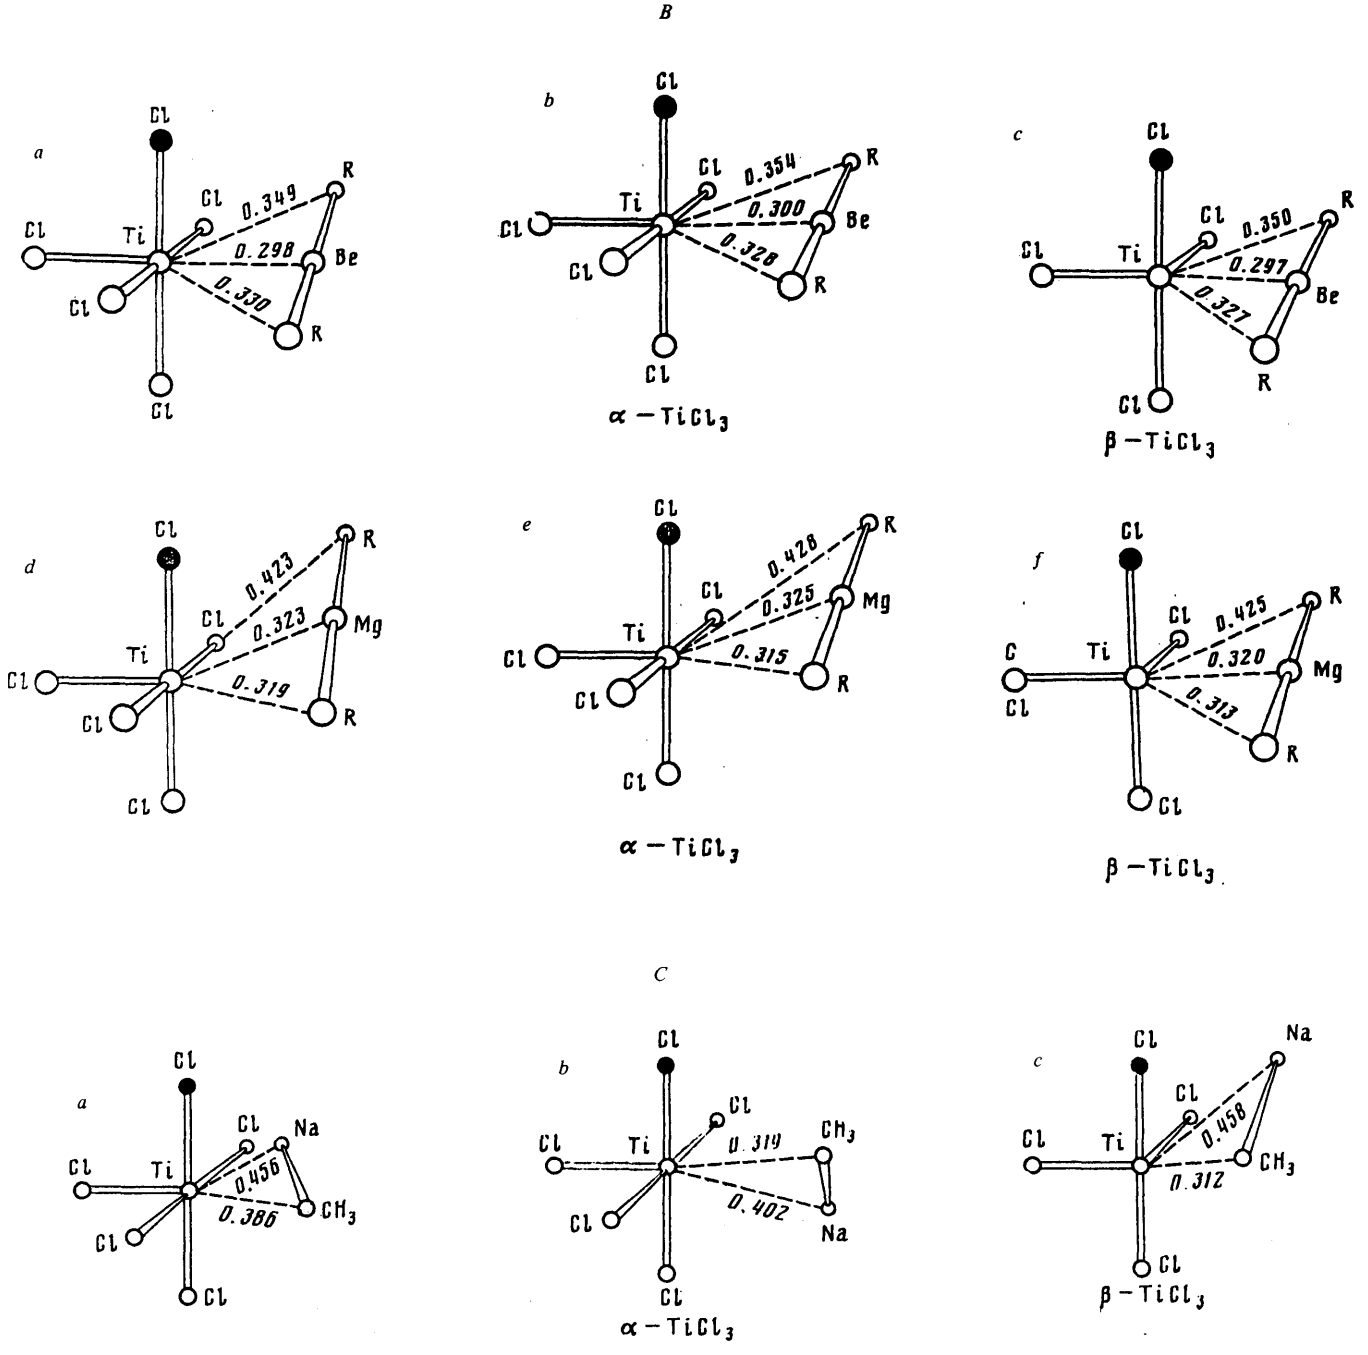

Figure 2 (contd.).

*cis*-poly-1,4-dienes (PAC-2), and atactic polyalkenes and poly-1,2(3,4)-dienes (PAC-3) respectively (Table 1).

The use of the Monte Carlo method[90] made it possible, in calculations of the populations of the PAC, to take account of not only the depth of the potential wells of the energy surfaces in the sorption of the OMC on the crystal, but also their form. At the stage of the physical adsorption of $R_nM$ on the surface of the $TiCl_3$ crystals, the quantitative composition of the centres which on chemisorption are transformed into stereospecific AC was determined. The OMC molecule is fairly firmly fixed on the surface of the crystal, preserving a definite orientation. An important feature is that in the physical adsorption of different OMC on the crystal surface of $M'Cl_3$, structures of the PAC-1, PAC-2, and PAC-3 type with similar geometries are formed, that is the stereospecificity of the action of the Ziegler–Natta catalysts is probably established.

The transformation of the physical adsorption centres into AC in the chemisorption and insertion of the monomer into the growing chain has been examined in detail for the system $(CH_3)_2AlCl–TiCl_3(VCl_3)$.[91] The energy of the configuration was determined using a modified "two-atom complex" method, in which the bond index was used to take account of the directed character and saturated character of the bonds (calculation by the CNDO/2 method).

*Isotactic polyalkenes; **PI = polyisoprene.

In the formation of the AC in a system of the type $M'Cl_n \cdot R_mMCl_{3-m}$, the initial stage is the formation of a bridging bond between Ti and Al;[91] the OMC completes the crystal lattice, forming a U' centre similar to that previously described in Refs.11 and 18; the Al atom occupies a position equivalent to the position of Ti; and the alkyl group R occupies a position close to the position of Cl in the layer crystals of $TiCl_3$ (the two-metal AC model). The most important feature of the AC formed (CAC-1, Fig.4*a*) is the formation, with the participation of the R group of the OMC and the M' and M atoms, of a three-dimensional "tent" structure, which plays an important role in the orientation of the monomer in the stereospecific polymerisation process. The AC geometry obtained from the calculations differs little from that proposed in Ref.86 for the two-metal Ti–Al AC model. In the presence of β-$TiCl_3$ and the OMC, in addition to CAC-1, appreciable quantities of other centres, in particular CAC-2 (Fig.4*b*), are also formed on the crystal surface. Their structure in many respects is similar to that of CAC-1, but an important difference is that the Ti atoms react with two R groups (two bridging bonds are formed between the M' and M atoms), so that a different AC coordination sphere is produced, which sterically resembles a "flower" and which is also responsible for the specific orientation of the corresponding monomers in ionic–coordination polymerisation on Ziegler–Natta catalysts.

Thus the combined approach using different methods of study has apparently made it possible: a) to determine clearly the dynamics of formation of the AC while avoiding the main unsatisfactory feature of practically all studies in this field, namely the hypothetical nature of the choice of the AC model; and b) to determine the structure of the polymerisation AC formed on the crystal faces and to show with a much higher probability that the AC of Ziegler–Natta catalysts have a two-metal structure (both components of the catalyst determine the structure of the AC and the mechanism of polymerisation).

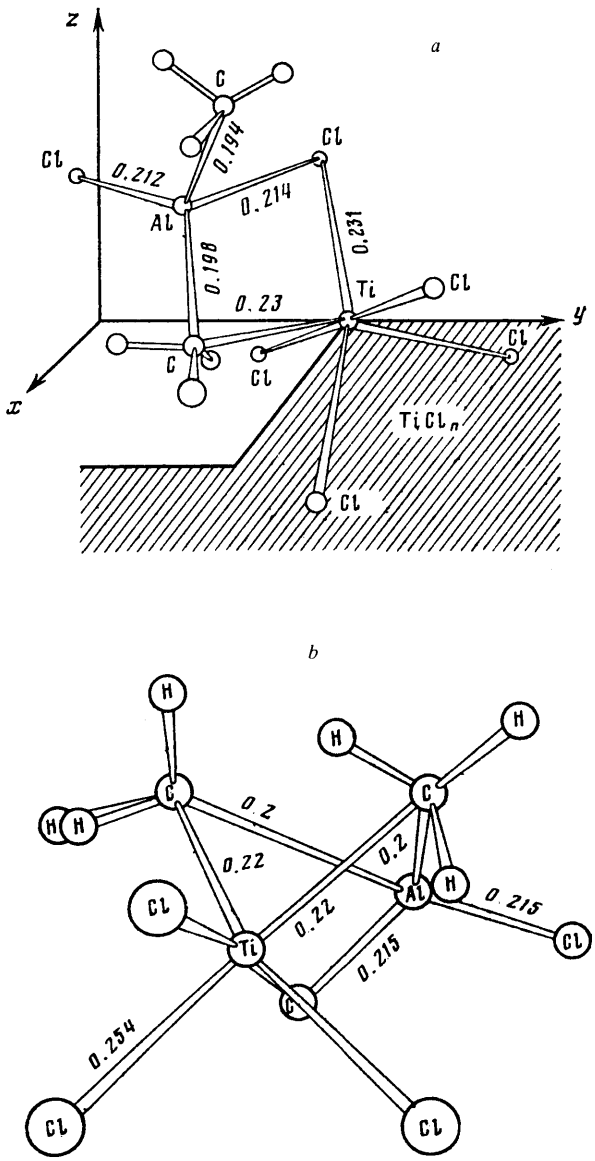

**Figure 4.** Geometry of the model active centre for the catalytic systems (distances given in nm): *a*) α-$TiCl_3$–$Al(CH_3)_2Cl$ (CAC-1); *b*) β-$TiCl_3$–$Al(CH_3)_2Cl$ (CAC-2).

## III. MECHANISM OF STEREOREGULATION

### 1. Empirical Theories

In the polymerisation of α-alkenes and 1,3-dienes under the influence of Ziegler–Natta catalysts, polymers with different micro-structures are obtained, depending on the nature of the components $M'X_n$ and $MR_m$ selected (Table 1). However, although the nature of the AC and the mechanism of the process in the first 10–20 years after its discovery were the subject of a large number of experimental and theoretical studies, the authors of published papers preferred at best to restrict themselves to general phrases about the mechanism of stereoregulation. The existing opinions were essentially probabilistic. Before 1960, no special consideration was given to the question of stereoregulation in polymerisation on Ziegler–Natta catalysts. Since 1960, increasing attention has been paid to this question, and published papers have been specially devoted to the study (including studies by essentially new methods) and interpretation of the surprising property of Ziegler–Natta catalytic systems, namely their ability to give stereoregular polymers based on α-alkenes and dienes with a high steric purity.

#### *a) Mechanism of the Stereoregulation of α-Alkenes*

*The single-metal model of the active centre.* In one of the first papers[6] it was assumed that the stereospecificity of action of the $TiCl_3$–$(C_2H_5)_3Al$ system is due to electrostatic factors. The monomer, situated between the positively charged and negatively charged ions of the catalytic complex, occupies a rigorously definite spatial position.

Cossee and Arlman[33,34,63] assumed that the octahedral $RTiCl_4$ group is positioned unsymmetrically (does not have a plane of symmetry), and that the positions of the R group and the coordination vacancy in the lattice are non-equivalent, from both the steric viewpoint and the viewpoint of

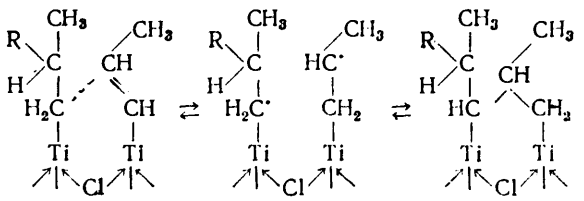
ionic character. This situation predetermines the configuration of the asymmetric carbon atom, that is it allows only one orientation of the coordinated alkene molecule, and this explains the stereospecificity of the action of Ziegler–Natta catalysis.

There are two possible reaction paths: a) after rearrangement, the R group remains in the new position, the monomer is coordinated in the newly formed vacancy, and the whole process is repeated, leading to the alternate participation of the anion vacancy in the acts of chain growth and to the formation of a syndiotactic polymer; b) the longer R group returns to the original position before the introduction of the next monomer molecule. This leads to the repeated introduction of each successive monomer unit into the chain with the preservation of a stereospecifically identical position. In particular, an isotactic polymer is formed in this way. The preference for the isotactic or syndiotactic configuration is determined by the ratio of the rates of the return of the R group to the original position and the introduction of the monomer into the growing chain.

In Ref.98, the migration of the growing MA is not regarded as essential. It is assumed that the insertion of the monomer at the M–C bond takes place without coordination. This suggestion does not appear convincing, however.

In Refs.99 and 100 it was suggested that the stereospecific control is determined by steric factors, namely the reaction of the alkene with the growing chain and the nearest M′ atom.

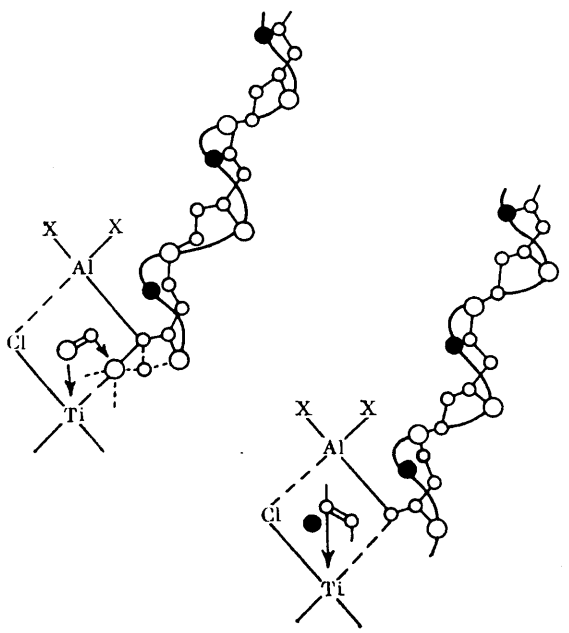
According to Regs.49 and 101, there are two types of AC on the surface of $(C_2H_5)_3Al[(C_2H_5)AlCl]–TiCl_3$ systems: a) stable AC on which isotactic polymers are formed; and b) unstable AC, which give atactic polyalkenes. The ratio of the centres determines the micro-structure of the MA formed.



*The two-metal model of the active centre.* As suggested in Ref.5, the formation of macro-chains with the isotactic configuration of the pseudo-symmetrical carbon atom on a heterogeneous AC is due to the asymmetric character of the assumed two-metal AC. Complex formation by the AC and the alkene takes place with opening of the π-bond of the monomer and the production of *d*- and *l*-configurations, depending on the structure of the AC.

According to Ref.7, the stereospecificity of action of Ziegler–Natta catalysts is determined only by the structure of the monomer, whereas according to Ref.52 it depends only on the quantity of $Ti^{2+}$ ions involved in the polymerisation. Isotactic polyalkenes and poly-1,2-dienes, and also *cis*-poly-1,4-dienes, are formed on isolated $Ti^{2+}$ ions. Syndiotactic polymers and *trans*-poly-1,4-dienes are formed with the simultaneous participation of two $Ti^{2+}$ ions.

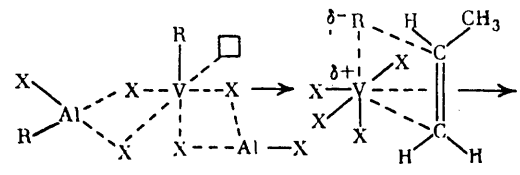
In Ref.8 it is stated that the stereospecificity of the MA is determined when the monomer is coordinated, as a result of its orientation by the ions of the catalytic complex fixed on the surface of the heterogeneous catalyst (that is by electrostatic factors). The monomer then enters the anionic complex. The existence of hydrogen bonds between the methyl groups and the most electronegative atoms (chlorine) in the complex prevents the free rotation of the growing MA chain.



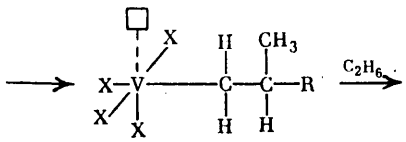
A similar viewpoint was put forward in Refs.10, 13, etc. According to Ref.13, the growing MA moves along breaks in the layers of the $TiCl_2$ and $TiCl_3$ crystals.

In Ref.12 it was assumed that a six-membered complex is formed in the transition state; the OMC serves only to form the initial active M–C bond, which takes no further part in the process:

The presence of hydrogen bonds between successive monomeric units of the growing MA and the AC predetermines the stereospecificity of the growth reaction.

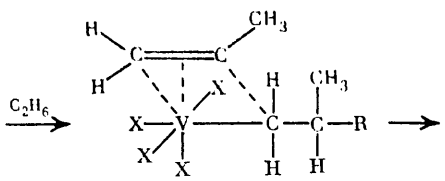


According to Ref.102, the growing MA is a spiral, and the rate of the addition ensuring the symmetry of the spiral is greater than that of any other addition, so that an isotactic polymer is formed from α-alkenes.

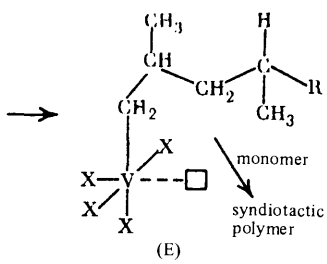


In Ref.59, the stereospecificity of Ziegler–Natta catalysts was attributed to steric factors. In the opinion of the authors cited, the monomer forms a complex with an alkylated octahedral M′(Ti) atom, situated on the lateral faces and defects of an $M'X_n$ crystal with two vacancies, by only the one most probable method, in such a way that the R substituent is directed away from the R groups on the M(Al) atom.

In Ref.103, a scheme for the formation of syndiotactic and atactic polyalkenes was proposed, for the case of the



homogeneous $VCl_4$–$(C_2H_5)_2AlCl$ system:



(A) (B)

(C)

(D)

(E)

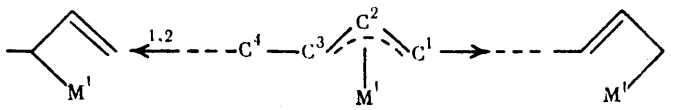
It is assumed that: a) the coordination of the monomer leading to "head to tail" addition is energetically most favourable; b) the orientation of the $CH_3$ group in the monomer chain, which leads to syndiotactic addition as a result of methyl–methyl interactions, is more favourable than the orientation leading to isotactic addition; c) rotation about the R–M' bond is hindered by steric factors; d) when the barrier to rotation is overcome, for example by increasing the temperature or by using M'(V) complexes with small ligands, the preference for any one orientation of the $CH_3$ group of the entering monomer disappears, so that an atactic polymer is formed.

Thus in all the papers examined above, the stereospecificity of action of Zielger–Natta catalysts is attributed to steric and (or) electrostatic factors, but no clear details of the process are given.

It seems obvious that for the same catalysts, the mechanism of stereoregulation in ionic–coordination polymerisation should be the same for α-alkenes and 1,3-dienes. Stereoregularity in the case of dienes, however, assumes the possibility of not only the isotactic and syndiotactic construction of the MA (1,2- or 3,4-) but also *cis*-, *trans*-, and other forms of isomerism (Table 1). Thus for the polymerisation of dienes, many workers have proposed specific mechanisms relating only to these compounds.

*b) Mechanims of the Stereoregulation of Dienes*

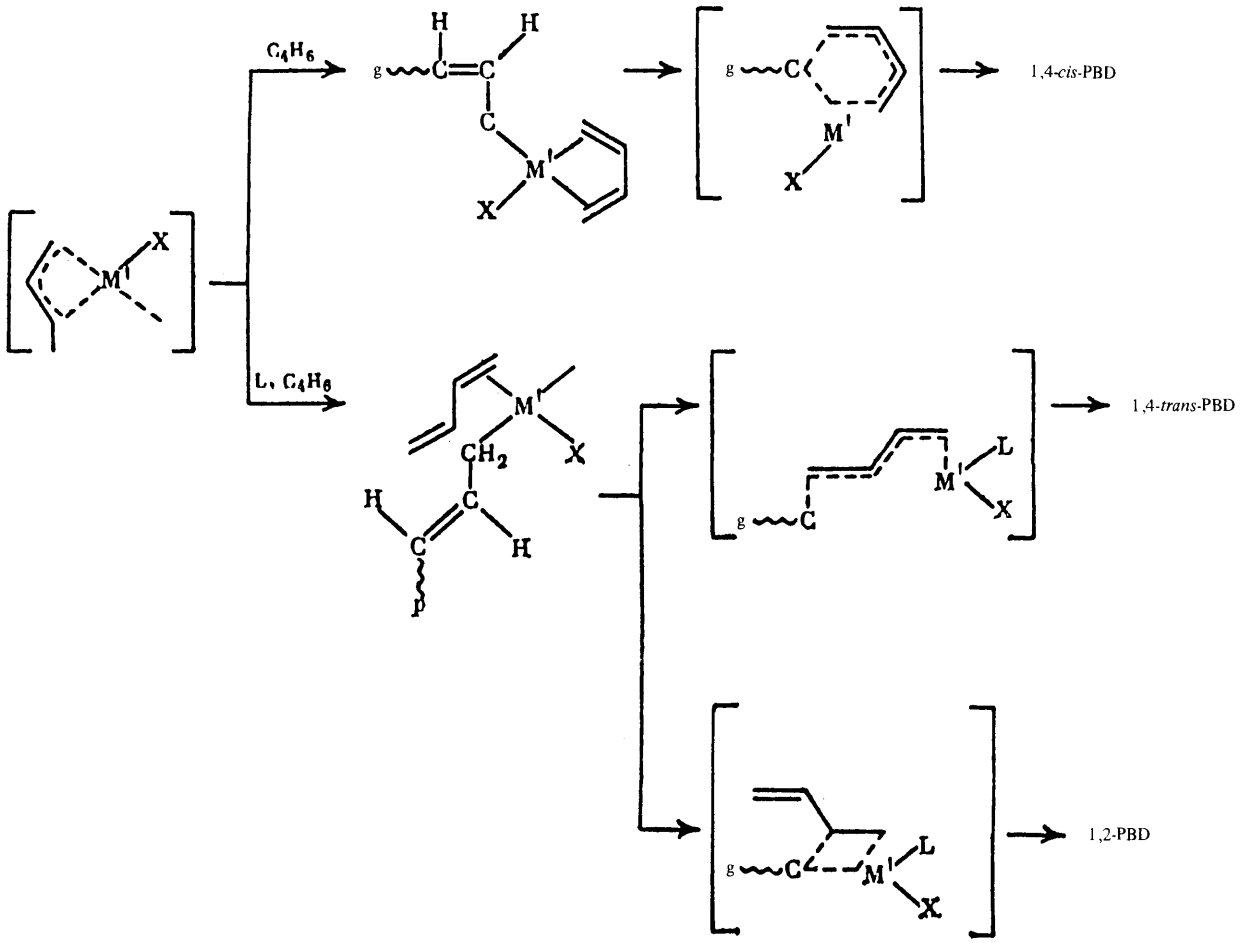
*Single-metal models.* Arlman,[34] using Cossee's model, related the formation of 1,4-*trans*- or 1,4-*cis*-structures to unidentate or bidentate coordination of the monomer to the AC, determined by the accessible space around the M' ion. Unidentate coordination of the monomer leads to the formation of 1,2-, 3,4-, or 1,4-*trans*-units, and bidentate coordination gives 1,4-*cis*-units. A similar view was put forward in Ref. 104. The probability of a given type of coordination is determined by the electronic structure of the M' atom. 1,4-*cis*-Polydienes are obtained when the energy levels of the bonding orbitals of M' and the highest occupied MO of the monomer are close together; when the energy levels differ considerably, polymers with the 1,2- or 1,4-*trans*-structures are formed. The electronegativity of the ligands, which influences the position of the energy levels of the MO of the transition metal, is an important factor in stereoregulation. A similar approach to the examination of the mechanism of stereoregulation was used in Refs. 105 and 106.



In detailed papers by Dolgoplosk and co-workers,[36–38] the stereoregularity of the MA is related not to the type of coordination of the monomer to the AC but to the configuration of the π-alkenyl unit of the growing MA. At the coordination stage, the diene almost always acts as a bidentate ligand. The introduction of the diene into the chain leads to the formation of a π-allyl complex in the *anti*-conformation. The ratio of the *cis*–*trans* units in the MA is determined by the ratio of the rates of the growth of the chain and the *anti*–*syn*(*cis*-*trans*)-isomerisation of the terminal unit in the AC (scheme 2).

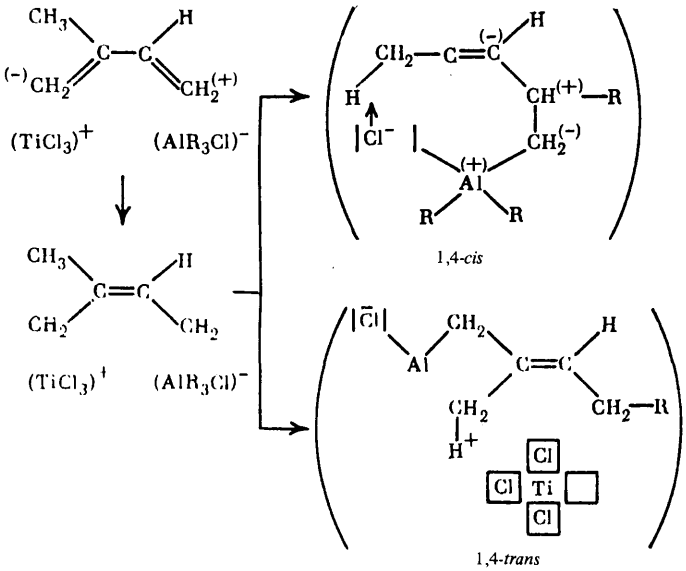
Electron-donor solvating agents, which shield M', increase the lifetime of the terminal unit in the AC, and hence the proportion of *anti*–*syn*-isomerisation. On an AC having only one anion vacancy, dienes are chemisorbed through one double bond (unidentate) in the transoid conformation and enter the chain with the formation of a *syn*-unit (scheme 3). According to scheme 2, reaction (1) leads to the formation of a *cis*-unit, and reaction (2) (isomerisation) to the formation of a *trans*-unit. If the rate of growth is much greater than the rate of isomerisation, the system correspondingly forms chiefly 1,4-*cis*-polydienes.

NMR studies of π-crotylnickel iodide and π-allylnickel fluoroacetate[43,107] showed that the growing terminal group has the *syn*-π-allyl configuration, irrespective of whether *cis*- or *trans*-polymerisation takes place. Thus the 1,4-*cis*- or 1,4-*trans*-polymerisation of dienes can be explained[107] by the intramolecular coordination (*syn*–*anti*) of the double bond situated next to the π-allyl bond at the end of the MA. In this case the *syn*-form, as in the theory of Dolgoplosk,[36–38] favours *trans*-polymerisation, whereas the *anti*-form favours the *cis*-polymerisation of the dienes. At the same time it should be borne in mind that the coordination of the penultimate double bonds of the growing polybutadiene chain is most probably excluded.[106]



The concept of π-allyl control of stereospecificity is also supported by other authors.[108] In their opinion, in the polymerisation of dienes a π-allyl bond is formed between the M' atom and the last unit of the growing MA. The π-allyl unit contains two reactive atoms, C(1) and C(3). The reaction of the sorbed monomer with C(1) leads to the production of 1,4-*trans*- or 1,4-*cis*-polymers (depending on whether the structure of the allyl group is *syn* or *anti*),

whereas the reaction with C(3) gives 1,2-structures:



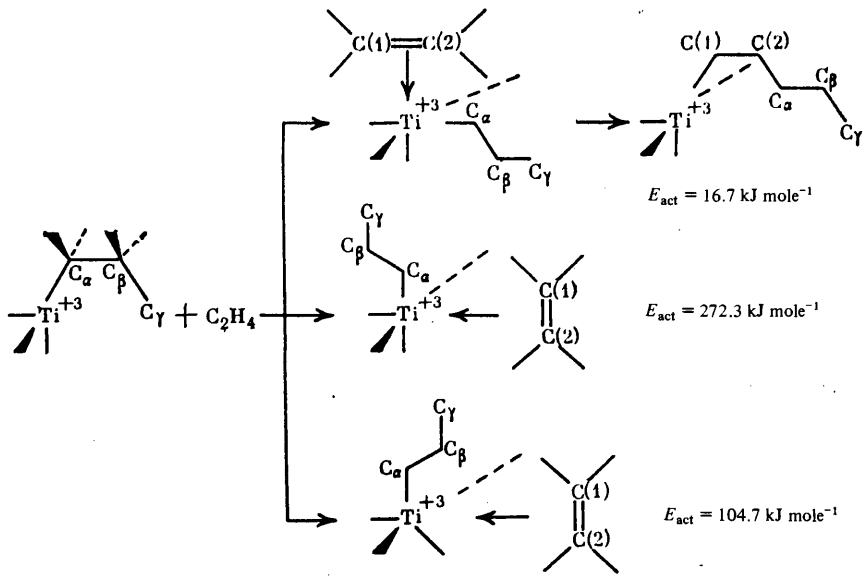
Here, the sorbed monomer reacts with the less extensively substituted and hence more reactive carbon atom. In a later paper by the same authors[109] it is also stated that the formation of 1,4-*trans*-polymers depends on the type of catalyst and may take place either with the coordination of only one C=C double bond to the AC, or with the coordination with the monomer through two double bonds with the formation of an *anti*-butenyl group and subsequent *anti–syn*-isomerisation. According to Ref.109, the formation of isotactic (*erythro*-di-isotactic) and syndiotactic (*threo*-disyndiotactic) polydienes is determined by the reaction of the monomer molecules with the ligand environment or with the butenyl group of the AC.

Various authors have tried to summarise the available experimental results and schemes for the mechanism of the stereospecific polymerisation of dienes. In particular, in Ref.43 the mechanism of formation of stereoregular polybutadienes (PBD) in solution is represented by the scheme:

*Two-metal models.* According to Ref.8, the polymerisation of dienes takes place on ionic complexes $(TiCl_3)^+(AlR_3Cl)^-$, like the polymerisation of α-alkenes. The chief factor determining *cis*- or *trans*-addition is the geometric configuration of the monomers.

This hypothesis does not explain many familiar experimental facts, in particular why 1,4-*trans*-polydienes are mainly formed in the presence of α-$TiCl_3$, and 1,4-*cis*- and 1,4-*trans*-polydienes on β-$TiCl_3$.[41-49]

In Ref.110 it is considered that the structure of the polymers formed is determined only by the geometric structure of the crystal lattice of the heterogeneous component. This hypothesis, however, applies only to the polymerisation of isoprene on $TiCl_3$, and does not deal with the stereospecificity of action of other catalysts and monomers. It also does not explain the role of the cocatalyst and the influence of various additives on the stereoregulation process.



Thus to explain the stereospecific action of Ziegler catalysts for the polymerisation of dienes, research workers have introduced not only electrostatic but also steric factors and various data on the structure of the monomers (polymers).

Two main views regarding the mechanism of stereoregulation in the polymerisation of dienes in the presence of Ziegler–Natta catalysts are widely discussed in the literature: a) the theory of *cis–trans* geometric control, which takes account of the presence of two C=C bonds in the conjugated dienes and hence the possible coordination of the diene through one or two double bonds to the AC (unidentate and bidentate coordination); and b) the theory that the configuration of the polymers is determined by the π-alkenyl polymer–M′ bond (the *anti*-form facilitates the formation of *cis*-units). The schemes put forward, however, do not provide a convincing interpretation of many available experimental data, for example the influence of the nature of M′ on the stereospecificity of action of Ziegler–Natta catalysts, etc.

## 2. Present-day Trends

### *a) Mechanism of the Stereoregulation of α-Alkenes*

Detailed studies of the mechanism of stereoregulation in polymerisation on Ziegler–Natta catalysts using quantum-chemical methods were begun comparatively recently, and only a few have as yet been published. Two series of studies are noteworthy. In one series[81-85] it was shown that there are three possible paths for the introduction of the monomer into the coordination sphere of M′ in AC with the *cis*-structure of the growing MA.

The smallest $E_{act}$ corresponds to the introduction of the monomer on $C_\alpha$ side, after which *cis–trans*-isomerisation is possible. The energetic non-equivalence of the different paths for the introduction of the monomer into the AC with the *cis*-configuration of the growing MA eliminates the need for the migration of the R group from one octahedral position to another, as in the Cossee mechanism. The active centre with the *cis*-MA leads to the formation of isotactic polymers, and that with the *trans*-MA to the formation of atactic polymers. The probability of the *cis–trans*-isomerisation of the R group of the AC, however, depends on the structure of the surface of the Ziegler–Natta catalyst and the presence of various adsorbed reagents in the immediate environment.

In Refs.111 and 112 the Cossee model was used to estimate the energy of the non-bonding interactions in the coordination of the monomer with the AC on the surface of the crystal for different cases of diastereo-isomerism, and it was concluded that the stereospecificity of Ziegler–Natta catalysts is due to the chirality of the ligand environment of the catalytically active Ti atom. The latter determines the orientation of the first C–C bond of the chain, which influences the subsequent mode of insertion of the monomer. In the case of the alkylation of Ti chlorides by trimethylaluminium, however, the system is not stereospecific with respect to the polymerisation of alkenes. An obvious meritorious feature of these studies is that, as in Refs.87–92, account was taken of the real surface of the heterogeneous component.

*b) The Mechanism of the Stereoregulation of 1,3-Dienes*

In Ref.113, from an analysis of the MO diagram of the active catalyst–monomer complex, it was suggested that the microstructure of polybutadiene is determined by the mode of coordination of the monomer (bidentate or unidentate), and depends on the electron density at the M′ atom. The probability of coordination of a given type is determined by the difference in the energy levels of the bonding molecular orbitals of M′, which accepts electrons from butadiene, and the highest occupied MO of butadiene. When these levels are close together, 1,4-*cis*-polydienes are obtained; when they differ considerably, polymers with 1,2- or 1,4-*trans*-structures are formed. The electronegativity of the ligands, which influences the position of the energy levels of M′, obviously also influences the stereospecificity of action of Ziegler–Natta catalysts.

Thus the quantum-chemical study of stereoregulation has apparently not made it possible to extend significantly the empirical theories and has only confirmed that the stereospecificity of action of Ziegler–Natta catalytic systems is due to both steric and electrostatic factors.

## 3. Recent Progress

In Refs.87–92 it has been clearly shown that the stereospecificity of action of Ziegler–Natta catalysts is determined by the three-dimensional structure of the coordination sphere of the AC and by the chemical character of the monomer, and it has been shown that the nature and mechanism of stereoregulation are the same for the polymerisation of α-alkenes and dienes.

*a) Polymerisation of α-Alkenes*

Stereoregulation in the polymerisation of α-alkenes is determined by the geometric structure of the AC.[87–90] The use of α-$TiCl_3$–$R_2AlCl$ on a titanium trichloride surface leads to the formation of one of the most frequently encountered OMC configuration with an energy $E_1 = -127.61$ kJ mole$^{-1}$ and $F_1 = 38\%$ ($F_i$ is the fraction of the individual configuration with energy $E_i$ in the total balance of the PAC; $i = 1$, 2, 3, etc.), and also configurations with similar structures with $E_2 = -126.78$ kJ mole$^{-1}$, $F_2 = 27\%$ and $E_3 = -125.1$ kJ mole$^{-1}$, $F_3 = 14\%$ (*a–c* in Fig.2*A*). The last two configurations differ from the first only in the "interchange" of the Cl atom and the $CH_3$ group, while the position of the Al atom remains unchanged. The total contribution of these configurations is about 80%.

For β-$TiCl_3$ a large number of different versions of the arrangement of $R_2AlCl$ on the crystal surface has been found, but in this case also it is possible to distinguish three most favourable configurations with energies of −120, −124.68, and −119.9 kJ mole$^{-1}$ (*d–f* in Fig.2*A*). The total contribution of these configurations is much smaller than in the case of α-$TiCl_3$, and amounts to 30%; as in the case of α-$TiCl_3$, these configurations differ only in the interchange of the Cl atom and the $CH_3$ group while the position of the Al atom remains unchanged. Moreover, it has been found that the geometry of the PAC has much in common for the different forms (α and β) of $TiCl_3$. In both cases there is a good correspondence between the yield of stereoregular polymers of alkenes and the proportions of PAC-1. The only difference between the α- and β-forms of $TiCl_3$, which have hexagonal close-packed Cl atoms, but which differ in the positions of the Ti atoms, is that when α-$TiCl_3$ is used the quantity of PAC-1 formed is approximately 80% of the total (Fig.2*A* and Table 1), and the MA obtained are correspondingly highly isotactic, whereas when β-$TiCl_3$ is used the proportion of these PAC is only 30%.

An important feature is that PAC with similar structures (Fig.2*B*) are also formed in the systems $R_2Be$–α-$TiCl_3$ ($F = 94\%$), $R_2Be$–β-$TiCl_3$ ($F = 50\%$), $R_2Mg$–α-$TiCl_3$ ($F = 75\%$), and $R_2Mg$–β-$TiCl_3$ ($F = 20\%$),[89,90] etc. Here also there is good agreement between the yield of isotactic polyalkenes and the PAC-1 population (Table 1).

The geometries of PAC of the same type formed on the surface of α-$TiCl_3$ and β-$TiCl_3$ in combination with different OMC are practically identical (Fig.2).

The chief difference between the PAC-1 configurations distinguished and other configurations formed as a result of the sorption of OMC on the crystals is the unique position on the $TiCl_3$ surface of the weakly bound Cl and Ti atoms and the M and Cl atoms and R groups of the OMC molecule, as a result of which, when the monomer molecule approaches, the C=C bond may be attacked simultaneously by both the Ti atom and the RA1< fragment (Fig.3). The "push–pull" mechanism corresponds to the concept of the two-metal catalysis[11,18] of the polymerisation of α-alkenes (schemes 4 and 5). A propene molecule on the crystal surface is probably fixed only in one position in which the $CH_3$ group of propylene is directed away from the surface, leading to an isotactic sequence in the addition of the monomeric units of the MA in the polymerisation of propene on Ziegler–Natta catalysts.

A similar process is characteristic of the specific PAC of the same type formed by the combination of various OMC with the α- or β-forms of $TiCl_3$, $VCl_3$, etc., and is not observed on other PAC (for example those formed by the reaction of $TiCl_3$ with RNa or $R_2Zn$), whose structures differ from that of the centres given in Fig.3*a*. An example is the

configuration with $E = -119.66$ kJ mole$^{-1}$ ($S = 3\%$) on the surface of $\alpha$-$TiCl_3$ (Fig.3*b*). In this case the OAC molecule is coplanar with the crystal surface, and a specific arrangement of the atoms, as in PAC-1, is not observed. A propene molecule may be fixed on an AC of this type in several positions, leading to non-stereoregular polymerisation.

Additional confirmation that the PAC-1 are responsible for the production of isotactic polyalkenes is provided by the fact that with increase in temperature from 300 K to 330 K, according to calculations for $R_2AlCl$–$TiCl_3$ systems, the proportion of stereoregular AC of the same type decreases by an average of 5% (the value at 330 K is 75% and 25% for $\alpha$- and $\beta$-$TiCl_3$ respectively[87]). This agrees with experimental data on the yield of isotactic polypropylene in the polymerisation of the monomer.[114] In accordance with experiment[41,42] and calculations,[87,88] on going from the solid surface to the catalyst solution, the appearance of the corresponding energy spectrum in the reaction of $M'Cl_n$ with the OMC becomes impossible, and the formation of stereoregular polymers of $\alpha$-alkenes is excluded.

The calculation for systems containing NaR [89] showed three configurations: one on $\alpha$-$TiCl_3$ with an energy of $-135.14$ kJ mole$^{-1}$, and two on $\beta$-$TiCl_3$, with energies of $-117.83$ kJ mole$^{-1}$ (Ti atom with one vacancy) and $-114.65$ kJ mole$^{-1}$ (Ti atoms with two vacancies) (Fig.2*C*). This system does not contain centres whose structure might be similar to PAC-1 when the $\alpha$- and $\beta$-forms of $TiCl_3$ are used (Figs.2*A* and 2*B*), as in the previous systems. The arrangement of NaR on the surface of the $TiCl_3$ crystal is similar to the arrangement of the OAC in a non-stereospecific centre, in which one of the R groups is closer to the Ti atom than the Al atom. Polymerisation in the $TiCl_3$–RNa system takes place as on the non-stereospecific (for $\alpha$-alkenes) centres PAC-3 in $TiCl_3$–OMC systems (Fig.3*b*). The difference between these catalytic systems is revealed by the fact that in the presence of NaR all the centres are non-stereospecific for the polymerisation of $\alpha$-alkenes, whereas in the other systems involving OMC, non-stereospecific AC make up only a fraction of the total number. Thus for each system there are several types of PAC, and stereospecific PAC are encountered in catalysts containing both $\alpha$-$TiCl_3(VCl_3)$ and $\beta$-$TiCl_3$. The calculated proportions of stereospecific centres in the above series of systems correlates with the experimental yields of isotactic polypropylene and other polyalkenes (Table 1).

The stereospecificity of the AC depends both on the nature of the OMC and on the nature of the arrangement of the OMC on the surface of the $M'X_n$ crystal. In catalysts containing compounds of metals of the first group, there are practically no stereospecific PAC either in brown $\beta$-$TiCl_3$ or in the violet $\alpha$- and $\gamma$-forms of $TiCl_3$. In heterogeneous catalysts based on $TiCl_3$ and OMC of the metals of the second and third groups, stereospecific AC are mainly formed, and their concentration is appreciably greater in the systems with the $\alpha$-, $\gamma$-, and $\delta$-forms of the $TiCl_3$ crystal, correlating with the yield of isotactic polyalkenes.

*b) Polymerisation of Dienes*

The formation of specific polymerisation centres of the same type, determining the stereo-isomerism of the macromolecules, when MOC are adsorbed on an $M'Cl_n$ surface is a general phenomenon for processes involving both polyalkenes and polydienes.

A strict correlation is observed between the yield of 1,4-*trans*- and 1,4-*cis*-polydienes in the polymerisation of dienes in the presence of different forms of $TiCl_3$ and OMC and the proportions of PAC-1 (CAC-1) and PAC-2 (CAC-2) respectively (Table 1)¶. An interesting feature is that calculations carried out for catalysts based on $\alpha$-($\gamma$-)$TiCl_3$–OMC and $CrCl_3$–OMC revealed differences in the nature of the change in the proportions of 1,4-*trans*- and 1,2-polydienes with change in the temperature of preparation of the catalyst. The results of the calculations were confirmed experimentally (Table 2). On the CAC-1 ("tent") in the polymerisation of dienes, the formation of 1,4-*trans*-units is energetically favourable, and in the process of chain growth there is no hindrance to the physical adsorption of the subsequent monomer molecules (Fig.5).[92] The unidentate coordination and the energetically favourable character of the formation of 1,4-*trans*-polydienes, brought about by the presence of the CAC-1 ("tent"), are responsible for a number of characteristic features of the polymerisation of dienes in the $AlR_3$–$\alpha$-$TiCl_3$ system: the formation of up to 80–90% 1,4-*trans*-polydienes and a correspondingly small proportion of 1,2- and 3,4-structures, and a decrease in the rate of polymerisation of substituted dienes (isoprene, pentadiene, etc.) compared with butadiene, because of the definite steric hindrance to the approach of the molecule to the CAC-1 on the side of the substituent. This effect may also explain the anomalous behaviour of 1,4-diphenylbutadiene and 4-methylpenta-1,3-diene in their polymerisation in the presence of Ziegler–Natta catalysts.[92] 1,4-Diphenylbutadiene is not polymerised for steric reasons, as can be clearly seen from Stuart–Briegleb models. For the same reasons, 4-methylpenta-1,3-diene forms practically only 1,2-poly-4-methylpentadiene.

Table 2. Dependence of the yield of stereo-isomers of polybutadiene on the temperature of the preparation of the catalytic complex in systems involving $CrCl_3$ and $TiCl_3$.

| Catalytic system | $T^*_{prep}$, °C | Proportion of AC, % (calculated) | | Yield of polybutadiene, % | |
|---|---|---|---|---|---|
| | | PAC-1 | PAC-3 | 1,2- | 1,4-*trans* |
| $CrCl_2 + AlR_3$ | 40 | 45.9 | 54.1 | 36.3 | 63.7 |
| | 50 | 46.3 | 53.7 | 39.4 | 60.6 |
| | 60 | 47.1 | 52.9 | 27.8 | 72.2 |
| | 70 | 47.6 | 52.4 | 25.6 | 74.4 |
| | 80 | 48.1 | 51.9 | 24.7 | 75.3 |
| $\gamma$-$TiCl_3$+$AlR_3$ | 40 | 80 | 20 | 10 | 90 |
| | 50 | 79.5 | 20.5 | 7 | 92 |
| | 60 | 79 | 21 | 11 | 87 |
| | 70 | 78.5 | 21.5 | 12 | 86 |
| | 80 | 77 | 23 | 13 | 85 |

*$T_{prep}$ is the temperature of preparation of the catalytic complex.

Note. Al/Cr = 2, [$CrCl_3$ = 0.01 M, [M] = 2.5 M; Al/Ti = 2, [$TiCl_3$] = 0.04 M, [M] = 1 M; polymerisation temperature 50 °C.

On CAC-2, which have an essentially different steric structure ("flower") and which are formed, for example, when $\beta$-$TiCl_3$ is used in combination with $R_3Al$ or $R_2AlCl$, bidentate coordination of the monomers with the formation

———.

¶ The chemical adsorption centres (CAC) are formed at the stage of the chemical adsorption of the OMC on the surface of the heterogeneous component of the catalyst from the corresponding PAC.[91,92]

of 1,4-*cis*-polydienes is energetically favourable, as observed in practice.[115] Growing MA with the 1,4-*cis*-configuration of the units show the least steric hindrance to the approach of the monomer to the catalytically active Ti atom.

A third type of AC (CAC-3, "wicket") (Fig.3*b*), practically indistinguishable from PAC-3 and characterised by a large coordination sphere volume, has been detected. These AC show a weak interaction between the components of the catalytic complex $M'X_n$ and the OMC. Analysis of the experimental data (Table 1) indicates that 1,2(3,4)-polydienes are most probably formed on CAC-3.

Thus CAC-1 are stereospecific in the polymerisation of α-alkenes and dienes, CAC-2 are not stereospecific in the polymerisation of α-alkenes, but give 1,4-*cis*-polydienes,

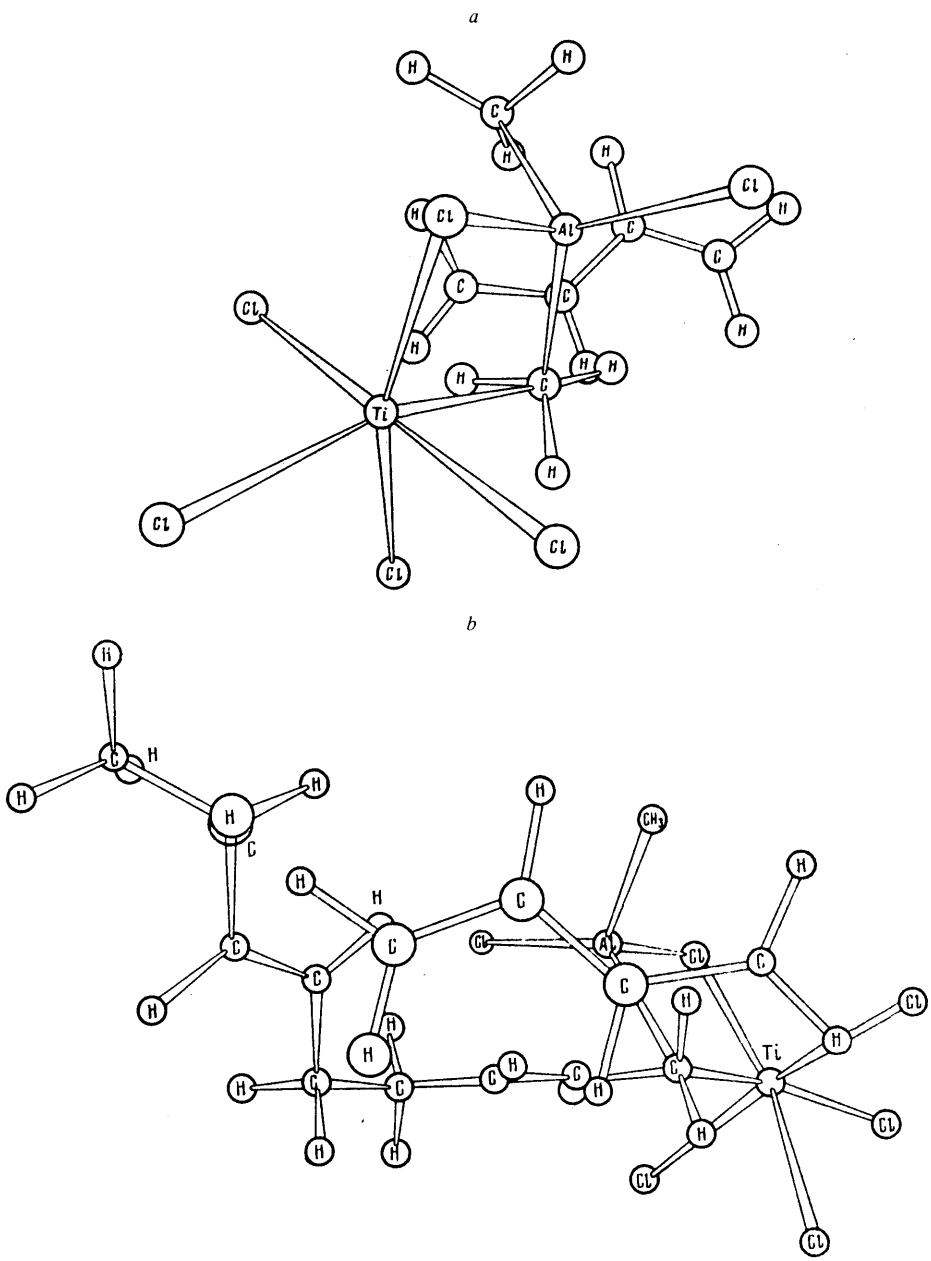


**Figure 5.** *a*) The coordination of butadiene with an active centre (stage of physical adsorption on the AC); *b*) physical adsorption of butadiene on an active centre with a growing 1,4-*trans*-polymer chain.

and CAC-3 bring about the non-stereospecific polymerisation of α-alkenes and dienes with the formation of atactic polyalkenes and 1,2(3,4)-polydienes. A theoretical base has been developed, which makes it possible, without carrying out tedious experimental searches, as has been done up to the present, to select in a first approximation (without allowance for kinetics) new Ziegler–Natta catalysts for the stereospecific polymerisation of α-alkenes and dienes.

## IV. SUMMARY

Since the discovery of stereospecific polymerisation by Ziegler and Natta, a very large number of experimental and theoretical studies of the nature of the AC and the mechanism of stereoregulation have been published.

In the first twenty-year period (1954–75), a large number of hypothetical ideas were put forward, based on a limited amount of experimental material. It was shown that polymerisation on Ziegler–Natta catalysts is an ionic–coordination process in which the AC has a stereoregulating action on the micro-structure of the macromolecules. Two models of the AC, single-metal and two-metal, have been discussed. Although the polymerisation scheme on single-metal AC has been adopted by most workers, there are nevertheless many experimental data which are fundamentally inconsistent with this and similar theories. Polymerisation schemes involving AC with a two-metal structure are much more probable. The stereoregulating action of Ziegler–Natta catalytic systems is due to steric and (or) electrostatic factors.

The use of quantum-chemical calculations essentially has not led to an improvement in existing theories. They have merely confirmed various particular details of the process, or, at best, refined or slightly extended theories of the characteristic features of the electronic structure of AC. This at first sight unexpected result has a quite definite cause, namely the *a priori* selection of the structure of the AC in the quantum-chemical calculation, generally without allowance for the real structure of the $M'X_n$ and the OMC molecules, in accordance with the subjective sympathy of the authors for the single-metal or two-metal model of the AC.

At the same time, the comprehensive approach to the theoretical study and modelling of the process using semi-empirical and empirical methods of calculation and numerical experiment at all stages, from the physical adsorption of the homogeneous organometallic component on the real surface of the heterogeneous component of the Ziegler–Natta catalytic system to the formation of the AC and their participation in the process of polymerisation and stereoregulation, has enriched the theories with new and fruitful ideas, and hence made possible a new approach to the development of the theory of the processes of ionic–coordination stereospecific polymerisation of alkenes and dienes. In particular, the structure of the AC and the dynamics of their formation have been determined, and it has been shown that the stereospecificity of action of Ziegler–Natta catalysts is determined by the structure of the coordination sphere of the catalyst, and that stereoregulation takes place by a single common mechanism in the polymerisation of alkenes and dienes. Three types of adsorption centre differing in their three-dimensional structure have been identified: CAC-1, "tent" (isotactic polyalkenes and 1,4-*trans*-polydienes are formed), CAC-2, "flower" (atactic polyalkenes and 1,4-*cis*-polydienes), and CAC-3, "wicket" (atactic polyalkenes and 1,2(3,4)-polydienes).

Thus the traditional and up to the present the only empirical method for finding new effective Ziegler–Natta catalysts by tedious experimental searches can be replaced by numerical experiments involving the estimation of the proportion of stereoregulating AC determining the stereoisomerism of the MA formed.[87–92]

Naturally, there are a number of unsolved problems, such as the influence of various modifying additives on the rate of polymerisation and the properties of the AC, the detailed mechanism of the excitation of the polymerisation of alkenes and dienes, and the influence of the kinetics of polymerisation on the yield of the stereo-isomers of alkenes and dienes in the presence of specific Ziegler–Natta catalysts and monomers.

Another unresolved problem is the apparently fundamental question of the justification for classifying individual organometallic compounds of transition metals, showing stereospecificity in the polymerisation of dienes and cycloalkenes,[36–38] as Ziegler–Natta catalytic systems. The possible production of stereoregular polydienes in the presence of individual M′ compounds is the main argument used by supporters of the concept of single-metal catalysis. These compounds apparently represent a new generation of organometallic catalysts of the stereospecific polymerisation of dienes and cycloalkenes, and they should not be regarded as classical Ziegler–Natta catalysts. They apparently represent a unique new type of stereospecific catalyst. It is more correct to regard them as a separate class and to call them Dolgoplosk catalysts in honour of the leader of the school which has established priority in the development of the synthesis of individual transition metal OMC and the study of their catalytic activity and the mechanism of stereoregulation in stereospecific polymerisation, the copolymerisation of dienes, and metathesis (Refs.36–38, 62, etc.). This should lead in the near future to the general acceptance of the mechanism of two-centre catalysis in the stereospecific coordination–ionic polymerisation of alkenes and dienes on Ziegler–Natta catalysts. This, together with a deeper understanding of the processes of catalysis and stereoregulation, will provide a basis for the further development of improved methods for the directed control of the stereospecific polymerisation of alkenes and dienes.

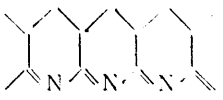
# The Reactions of Nitrile-containing Polymers

E.N.Zil'berman

The present review deals with chemical aspects of the reactions of polyacrylonitrile and related polymers, based on the reaction of the C≡N groups, the polymer-analogue transformations of polynitriles under the influence of water, alcohols, carboxylic acids, nitrogen-containing organic compounds, hydrogen sulphide, and other nucleophilic reagents, and the reaction of polynitriles with electrophilic reagents. Reactions undergone by the polymers but not by mononitriles, and reactions whose mechanisms are different for poly- and mononitriles, have been distinguished. The review cover the literature of the last 15 years. The bibliography contains 143 references.

CONTENTS

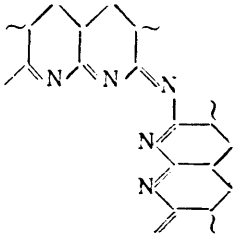
I. Introduction 39
II. Intra- and intermolecular reactions of CN groups 39
III. Hydration and hydrolysis 41
IV. Other electrophilic reactions 43
V. Nucleophilic and other reactions 44



## I. INTRODUCTION

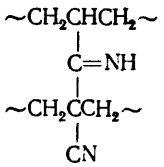
As a consequence of the high and varied reactivity of the cyano-group, the properties of nitrile-containing polymers can be modified comparatively easily by treating these polymers with various reagents. A number of reactions of polynitriles, primarily reactions based on the hydrolysis of polyacrylonitrile (PAN), are widely used in industry. The reactions of nitrile-containing polymers have been reviewed in monographs[1,2] covering the literature for the period 1967–1970. In recent years, however, a large number of studies of fundamental importance have been carried out on the chemical transformations of macromolecular compounds containing nitrile groups. The present review is based mainly on papers published during this period. Of earlier work, only important studies not dealt with in Refs. 1 and 2 have generally been examined. The present review does not deal with work on the intramolecular reactions of the nitrile group with other functional groups to give heterocyclic compounds, since these reactions, which are used, in particular, to obtain heat-resistant polymers ("polyheteroarylenes"), were reviewed recently.[3]

The thermal treatment of polymers containing blocks consisting of nitrile-containing units leads to polymerisation at the CN groups to give polyazomethines (azapolyenes). This polymerisation can take place at the same time as the polymer-analogue reactions of polynitriles, and, as shown below, in a number of cases it precedes other transformations of the macromolecules. The present reivew begins with an examination of the influence of various reagents and functional groups (present in the original polymers or formed during thermal decomposition) on the polymerisation at the CN groups. The review does not examine the many studies of azapolyenes not concerned with the chemical nature of the observed conformations, studies of the thermal decomposition of CN-containing polymers at temperatures above 200–300 °C, or studies of the volatile products formed in the thermal decomposition of nitrile-containing polymers.



## II. INTRA- AND INTERMOLECULAR REACTIONS OF CN GROUPS

Heating (100–200 °C) polymers rich in acrylonitrile and methacrylonitrile units leads to the intramolecular reaction of neighbouring nitrile groups to give sections with a ladder structure, for example:



This reaction[1,2,4,5] continues to attract considerable attention, chiefly because it is a basic reaction in the degradation of nitrile fibres, accompanied by discolouration, and also because polymerisation at the CN groups of PAN is the first stage in the production of carbon fibres.

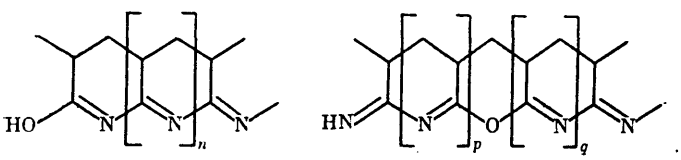
When PAN is heated, the intramolecular transformations are evidently accompanied by intermolecular reactions of the CN groups, leading to cross-linking of the polymer chains:[6,7]

The sections consisting of condensed rings are relatively short. They are formed by not more than 3–5 neighbouring units, and this is apparently related to the atactic structure of PAN.[6,8–11] The intermolecular reaction gives not

only N–C bonds, as shown above, but also C–C bonds:

Structure formation by the macromolecules during polymerisation makes the products insoluble. The ladder polymer based on polymethacrylonitrile (PMAN), after polymerisation at the CN groups, remains soluble in various solvents. This is related to the fact that PMAN does not contain relatively mobile α-hydrogen atoms, which in the case of PAN are responsible for the formation of intermolecular C–C bonds; steric factors also prevent intermolecular interaction.[1] When CN-containing polymers are heated to 200 to 250 °C, other processes accompanying structure formation, namely the rupture of polymer chains and the liberation of volatile degradation products, take place more intensively, and dehydrogenation or oxidative dehydrogenation leads to aromatisation of the condensed rings. The chains are broken much more easily in dimethyl sulphoxide (DMSO) solution than when the solid polymer is heated.[12] The slowest stage in the various successive transformations of PAN and similar polymers, however, is cyclisation, that is the rate of polymerisation at the CN groups determines the overall rate of the process.[13]

The presence of isotactic sequences in the PAN chain creates the most favourable conditions for the formation of polyconjugated systems. Increase in the concentration of these sequences is accompanied by an increase in the length of the conjugation chains in PAN subjected to thermal treatment.[5,14–16] An important part in the kinetics of the transformations of PAN is also played by the conformation of the polymer chain.[5]



The treatment with nucleophilic reagents of polymers whose macromolecules contain blocks consisting of nitrile-containing units, or the introduction of nucleophilic functional groups into the macromolecules of these polymers, initiates polymerisation at the CN groups. A marked increase in the rate of formation of polycyclic structures in the thermal decomposition of nitrile-containing polymers is achieved in the presence of carboxyl groups.[1,17–26] When substituted acetic acids are added to PAN, intensive polymerisation at the CN group takes place even at 100 °C, and its rate increases with increase in p*K* for the acid. The rate of the process is also increased by hydrogen chloride.[27] The lower initial temperature of cyclisation in copolymers of acrylonitrile and vinylidene chloride, compared with PAN, is apparently due to the action of the hydrogen chloride liberated in the dehydrochlorination of the copolymer.[28] Strong discolouration in copolymers in which CN groups predominate is observed at 85 °C in the presence of benzenesulphonic acid.[19] Zinc chloride is an effective catalyst for the polymerisation.[29]

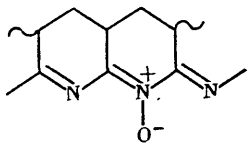
Derivatives of acids initiate the cyclisation and discolouration. In copolymers of acrylonitrile with esters of acrylic and methacrylic acids,[30] vinyl acetate,[25–31] acrylamide,[18,32] acrylamidoxime,[18] acrolein, and methyl vinyl ketone,[33] polymerisation at the nitrile groups is more rapid and begins at lower temperatures than in the case of PAN. The cyclisation of copolymers containing methyl acrylate or methyl methacrylate units is accompanied by the elimination of methanol. The temperature at which oligomerisation at the CN group starts in an inert atmosphere is lowered when PAN contains a small quantity of acrylothiamide units. In the presence of aqueous ammonia solution, thioamide groups initiate the reaction even at 90° and lower temperatures. Conditions have been found, in which partial polymerisation at the CN groups in the macromolecules of PAN fibres containing $CSNH_2$ groups gives fibres with a high heat resistance and an appreciable modulus of elasticity at increased temperatures.[34]

Polymerisation initiators include phenols,[35] alcohols,[20,21] imides,[1] and aliphatic amines.[1,17] In the polymerisation of the CN groups of PAN, initiated by trialkylamines, at the boiling point of the solvent (dimethylformamide (DMF), dimethylacetamide DMA), polymers with comparatively little structure formation, soluble in formic acid, are obtained. The characteristic viscosity of the polymers increases when phenols are used as co-initiators.[36] The rate of cyclisation of PAN is possibly also increased by ketimine groups[17] and by the amino-groups formed in enamines by the tautomeric transformation of N-substituted imino-groups ($\rangle CH-\dot{C}=N- \rightleftharpoons \rangle C=\dot{C}-NH-$).[24]

Polymerisation at the CN groups is also initiated by alkali metal hydroxides[12,37,38] and alkoxides,[20,39] including the polymeric compounds $NaO(CH_2CH_2O)_nNa$,[38,40] aqueous sodium carbonate solution,[19] potassium cyanide,[41] and other alkaline inorganic compounds. In the presence of bases, the reaction takes place at room temperature. Initiators with basic properties also bring about other reactions of polynitriles, in particular reactions ending in chain rupture.[37]

When PAN is heated in the presence of solutions of alkali metal hydroxides in DMSO, conjugated chains of two types are formed:[42]

Under the influence of organotin compounds (tributyltin methoxide, dibutyltin dimethoxide, etc.), polymerisation at the nitrile groups of PAN and PMAN takes place at 120 °C and 70 °C respectively.[43]



It was suggested[44] that polymerisation at the CN groups and discolouration of the polymer are initiated by β-ketonitrile groups present as defects in the PAN structure. It was later shown, however, that these groups have no significant influence on the transformations of PAN.[45]

Some authors have proposed a free-radical mechanism for the initiation of polymerisation at CN groups.[18,27,30,46]

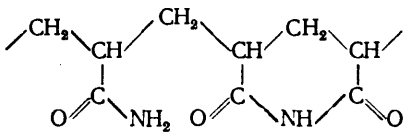
In the absence of appreciable quantities of catalytically active impurities or structural defects, polymerisation at the CN groups may be preceded by intramolecular reactions involving the nitrile group and an α-hydrogen atom, whose products then directly initiate the polymerisation.[1,11,29] This suggestion is confirmed by the comparative stability to polymerisation of thoroughly purified PMAN, poly-α-phenylacrylonitrile, and other nitrile-containing polymers whose units do not contain mobile α-hydrogen atoms.[29]

Particular attention is being paid to the influence of atmospheric oxygen on the transformations of PAN.[9,22,47,48] It can now be taken as established that the presence of oxygen lowers the temperature threshold above which cyclisation, aromatisation, and structure formation in PAN take place.[8,22] The presence of oxygen also lowers the temperature of the start of dehydrocyanidation, intermolecular redistribution of hydrogen with the formation of

ammonia, and rupture of the polymer chains.[8,48] In addition, the reaction with oxygen leads to oxidative dehydrogenation of PAN.[8] According to Ref.44, the imino-groups in the conjugated chains are oxidised by atmospheric oxygen to give chromophoric nitrone groups, so that the colour of the polymers becomes more intense:

Carbonyl groups, which may also be formed by the hydrolysis of ketimine groups, also appear in PAN macromolecules during thermooxidative degradation.[8,12,24,44,45,49-51]

Since polymerisation at the nitrile groups is accompanied by discolouration of the polymer and a deterioration in its solubility, the use of stabilising reagents which suppress these processes may sometimes be of interest. Dienophiles (maleic anhydride, acrylamide, etc.) are effective PAN stabilisers.[52,53] The effect of these substances is based on a Diels–Alder reaction with the *cis*-azadiene sections of the polyconjugated chains;[53] this leads to rupture of the conjugated chain (a decrease in the intensity of the colour) and probably also to some extent prevents the growth of this chain. Dienophiles apparently have a stabilising action under the conditions of the thermal treatment of PAN, but do not influence the colour of the polymer which has previously been heated and kept in contact with air; they are also ineffective if the thermal treatment is combined with oxidation of the polymer, catalysed by various metal ions. This is explained by the appearance of $=\overset{+}{N}-\bar{O}$ groups in the macromolecules (see above).[53,54]



The temperature at which polymerisation of the CN groups of PAN begins is raised, and the extent to which these groups are involved in cyclisation is decreased, if small quantities of inert units (styrene, methylstyrenes, 2-vinylpyridine), dividing the polynitrile chain into relatively small blocks, are introduced into the macromolecules.[30] The inclusion of α-methylstyrene units in the macromolecules of PAN or the copolymer of acrylonitrile and vinyl acetate leads to an appreciable increase in the activation energy of the initial stage of the thermal degradation of the polymers.[55]

Intermolecular reactions involving polymerisation at the nitrile groups and trimerisation to give s-triazines can be used to harden oligomers and polymers containing infrequent (isolated) CN groups.[3]

## III. HYDRATION AND HYDROLYSIS

The hydration and hydrolysis of the nitrile groups in polymers, as in low-molecular-weight compounds,[2] takes place chiefly in the presence of acids and bases.

Treatment with 75–95% sulphuric acid converts the nitrile groups of PAN into amide, imide, and carboxyl groups.[56] The structure and properties of the reaction product depend on the original $H_2SO_4$ concentration and the other reaction conditions.[39] In the presence of 70% sulphuric acid at room temperature, polymers with a high heat resistance, consisting of acrylonitrile and acrylamide units, were obtained. The nitrile units in these polymers are present in blocks. The polymers obtained from PAN in 80–90% sulphuric acid contain 25–30% units with amide groups and 75–70% units with imide groups:

An acrylomide homopolymer could not be obtained from PAN, because in the presence of sulphuric acid the amide groups in the 1,3-positions readily undergo cyclisation. However, in the copolymer of acrylonitrile and isobutylene with the 72 : 28 composition, in which the average length of the polyacrylonitrile blocks is ~3, imidisation is suppressed to a considerable extent; in the presence of 80% sulphuric acid, the nitrile groups are almost quantitatively converted into amide groups.[39]

Treatment of PAN with 65% nitric acid at −8 °C has been used to synthesise a polymer consisting chiefly of acrylonitrile and acrylamide units,[57] with a structure similar to that of the polymer obtained from PAN and 70% sulphuric acid.[39] The nitrile groups in PAN are also hydrated by the action of concentrated hydrochloric acid in DMF [58] and on prolonged treatment in an atmosphere of hydrogen chloride.[59,60]

The use of more dilute sulphuric acid than that indicated above, in the reaction of PAN or the copolymer of acrylonitrile and isobutylene, leads to hydrolysis of the nitrile groups, that is to the formation of carboxyl groups.[39,61] Treatment of PAN with 60% $H_2SO_4$ at 95 °C gave polymers partly or completely soluble in aqueous alkali solutions. The carboxyl groups increase the rate of hydrolysis of neighbouring nitrile groups.[39] According to Ref.61, PAN with an increased isotacticity undergoes racemisation under the conditions of hydrolysis with sulphuric acid; the concentrations of iso- and syndiotactic sequences in the product were equal.

The nitrile groups in copolymers of acrylonitrile with butadiene are hydrolysed in the presence of mixtures of zinc chloride and water at 140–170 °C.[62] This reaction takes place in the vulcanisation[63] of butadiene–nitrile rubber by zinc chloride and water. The cross-linking of the macromolecules is to a large extent due to the intermolecular addition of the carboxyl groups formed in the hydrolysis to the C=C double bonds to give ester groups.

In practice, the most important polymer-analogue transformation of PAN is its alkaline hydrolysis. The water-soluble polymers obtained by hydrolysing PAN and copolymers containing more than 50% acrylonitrile groups have found extensive application as thickeners, flocculants, and protective colloids, in the preparation of coatings for textile materials, in the dressing of leather, etc.[19,64-69] The hydrolysis of PAN is most frequently carried out at 90–100 °C by NaOH and an excess of water.[70,71] The hydroxides of other alkali and alkaline earth metals, sodium silicate, trisodium and tripotassium phosphates, and sodium sulphide are also used.[72-74] The alkaline hydrolysis of copolymers of acrylonitrile with vinyl acetate in the presence of DMF, DMSO, and DMA has been described.[75] The high-temperature (180–220 °C) hydrolysis of PAN has been carried out successfully in the presence of aqueous solutions of urea, which under these conditions is hydrolysed to ammonium carbonate, which is directly responsible for the conversion of the CN groups into $CONH_2$ and $COONH_4$ groups.[76] The product of the alkaline hydrolysis of PAN is usually an aqueous solution of the polymer. To obtain

the polymer as a powder, the hydrolysis of PAN is carried out using the stoichiometric quantity of water in the presence of propan-2-ol or various other water-soluble organic substances.[77,78]

The alkaline hydrolysis of PAN takes place in two stages. In the first, heterophase, stage, the colour of the polymer changes sharply from white through dark red to yellow. In the second, homophase, stage, the intensity of the colour of the reaction mixture decreases to pale straw-yellow.[79] The change in colour is due to the characteristic mechanism of hydrolysis of the polymers, which contain blocks with nitrile-containing units arranged in sequence. Although the hydrolysis of an isolated nitrile group begins with hydration to the amide group,[2] the hydrolysis of these polymers takes place (at least to an appreciable extent) with the intermediate formation of chromophoric polyazomethine sections, which are then hydrolysed to amide and carboxyl groups. This sequence of reactions in the alkaline hydrolysis of PAN is the reason for the high initial rate of this process, which is at least ten times the rate of hydrolysis of an isolated CN group.[80]

According to this hydrolysis scheme, the change in the colour of the reaction mass in the hydrolysis of copolymers of acrylonitrile depends on the distribution of the units of the comonomers in the macromolecules.[78,80] The colour is less intense in copolymers with low values of the average length of the acrylonitrile blocks. In the case of copolymers of acrylonitrile containing methyl acrylate and vinyl acetate groups, the process begins with the hydrolysis of the ester groups. The duration of the heterophase stage in the hydrolysis of these copolymers, and also copolymers with acrylic acid, is much shorter than that observed in the hydrolysis of the homopolymer of acrylonitrile. The presence of chemically inert and hydrophobic propylene units in copolymers with acrylonitrile, on the other hand, leads to an increase in the duration of the first stage of the hydrolysis.[80] The rate of the homogenisation of the reaction mixture in the alkaline hydrolysis of PAN is also increased in the presence of surface-active substances such as methylcellulose and polyvinyl alcohol.[79] With a deficit of NaOH (less than 50–60 mole % of the concentration of nitrile units in PAN) at 95 to 100 °C, the process stops at the first stage, that is a coloured water-insoluble polymer is obtained.[79]

An important characteristic feature of the alkaline hydrolysis of cyano-containing polymers, not observed in the case of low-molecular-weight nitriles, is the existence of a limiting degree of conversion.[79–81] For example, when PAN was heated (92–96°) for a long time in the presence of an equimolar (relative to the nitrile units) quantity of alkali, that is sufficient to convert all the nitrile groups into carboxylate groups, a polymer containing sodium acrylate and acrylamide units in the molar ratio 79 : 21 was obtained. Increase in the hydrolysis time above a definite limit, in spite of the presence of free alkali, did not lead to a further increase in conversion.[79] Increase in the excess of alkali and its concentration leads only to a slight increase in the limiting conversion of nitrile groups into carboxyl groups.[79,82] The concentration of amide groups in PAN subjected to alkaline hydrolysis decreases sharply with a marked increase in the reaction temperature. Thus when an equimolar quantity of NaOH is used, the limiting conversion of acrylonitrile units into sodium acrylate units is 94% at 170°, and almost 100% at 250°.[83] The explanation for the limitation of the degree of formation of carboxylate groups is that the accumulation of $COO^-$ anions in the macromolecules during hydrolysis leads to an increase in the electrostatic repulsion between the polymer chains and the $OH^-$ anions, as a result of which the effective rate constant of the hydrolysis decreases continuously to zero.[84–86] Increase in temperature makes it possible to overcome the electrostatic repulsion, but at 140 °C an increase in the degree of degradation (rupture) of PAN molecules is observed.[82]† The inclusion of negatively charged units in the macromolecule leads to additional limitation of the degree of hydrolysis of the CN groups. For example, a study of the alkaline hydrolysis of copolymers of acrylonitrile with sodium vinyl sulphonate established that with increase in the proportion of units of the second monomer in the copolymer, there is a slight decrease in the degree of hydrolysis of the acrylonitrile units with an increase in their degree of hydration.[89] The maximum degree of conversion of nitrile groups into carboxylate groups in copolymers of acrylonitrile with methyl acrylate (17 mole %) and acrylic acid (26 mole %) was comparatively low (72–70% at 92–96 °C), in spite of the fact that in the initial period the process took place readily.[80] The low degree of conversion in these cases is evidently related to the fact that there is electrostatic repulsion between the $OH^-$ ions and $COO^-$ groups formed both from acrylonitrile units and from methyl acrylate or acrylic acid units. On the other hand, the products of the hydrolysis of copolymers of acrylonitrile containing vinyl acetate units, which are hydrolysed to uncharged vinyl alcohol units, show a slightly higher limiting degree of hydrolysis of the CN groups, compared with the hydrolysis products of PAN.[80] Under the conditions of the alkaline hydrolysis of the copolymer of acrylonitrile and vinyl acetate, in which the nitrogen-containing units show limiting conversion, the units with ester groups are converted quantitatively into vinyl alcohol groups.[78]

In the case of copolymers of butadiene and acrylonitrile (in the mass ratio 82 : 18)[90] and acrylonitrile, butadiene, and styrene (ABC-copolymer,[91] in which the nitrile groups are mostly isolated, and also cyanoethylcellulose,[92] alkaline hydrolysis is analogous to the hydrolysis of low-molecular-weight mononitriles. Nevertheless, the limiting conversion of the CN groups in the hydrolysis of the ABC-copolymer is lower than in the hydrolysis of PAN, due to steric hindrance created by the branching of the macromolecules of the graft ABC-copolymer.[91] The rate of hydrolysis of the CN group is greater than that of the de-esterification of cyanoethylcellulose.[92]

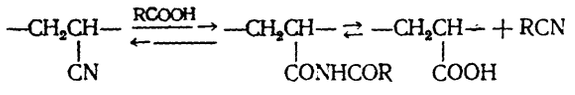
In some studies the alkaline hydrolysis of PAN is combined with secondary transformations of the polymer. Thus a process has been developed for the direct esterification of PAN[93] by the reaction of the resulting carboxyl groups with dimethyl sulphate, and also for the synthesis of a polymer containing sodium acrylate and vinylimine units, by the Hofmann reaction of the amide groups.[94] The production of a polyampholyte, whose macromolecules contain COOH and $NH_2$ groups, from PAN, aqueous NaOH solution, and bromine, is explained by the fact that initially, the reaction with alkali gives carboxylate groups and polyconjugated sections $(-\overset{|}{C}=N-)_n$, which then react with hypobromite, undergoing transformations analogous to the Hofmann rearrangement.[95]

---

†The macro-chains of PAN[87] and the copolymer of styrene with acrylonitrile[88] in the presence of potassium hydroxide or t-butoxide in DMSO are broken even at room temperature. The addition of monomers polymerising by an anionic mechanism (4-vinylpyridine, propylene oxide) leads to the formation of block copolymers.

Weakly acidic cation exchangers have been obtained by treating a polyacrylonitrile fibre, consisting of acrylonitrile, methyl acrylate, and itaconic acid units (92.2:6.3:1.5), with an alkaline hydrolysing agent and hydrazine hydrate as structure-producing agent.[96]

A recent paper[97] described the hydration of the CN groups of PAN in a neutral medium in the presence of manganese(IV) oxide or Raney copper as heterogeneous catalyst. In aqueous potassium thiocyanate solutions at 80 °C, up to 50% of the nitrile groups are converted into amide groups, with a simultaneous side reaction involving polymerisation at the CN groups.



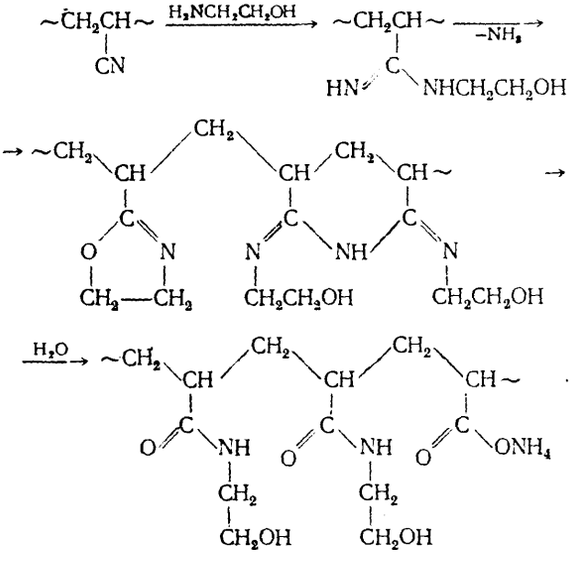
Unlike mononitriles, PAN and PMAN react with water in the absence of specially added acids or alkalis. At a temperature of 230–250 °C and a pressure of 30–40 thousand atm, these polymers react with water, becoming water-soluble;[98] it was assumed that under these conditions the nitrile groups are hydrated quantitatively to give the corresponding carbo-chain polyamides. It was later found, however, that when heated in the presence of water, PAN undergoes hydrolysis, which takes place even at 160 °C and a pressure corresponding to the vapour pressure of the components of the reaction mixture.[99] This process, like the alkaline hydrolysis, begins with polymerisation at the nitrile groups, after which the $(-\overset{|}{C}=N-)_n$ blocks are hydrolysed to give amide and carboxyl groups.[100] The ammonia liberated catalyses both these reactions and the direct hydration of the nitrile groups to amide groups according to the usual scheme characteristic of low-molecular-weight compounds. The liberation of ammonia in the hydrolysis is responsible for the autocatalytic character of the process. Because of the high temperature of the process, hydrolysis is accompanied to a slight extent by rupture of the polymer chains. The limiting degree of hydrolysis of PAN by this method is high and is 60–65% at 200 °C; the remaining groups are acrylamide groups. The existence of a limiting degree of hydrolysis in this case is related to the reversible character of the hydrolysis of the amide groups in the absence of acids or alkalis.[101]

## IV. OTHER ELECTROPHILIC REACTIONS

The CN groups in polynitriles react not only with water but also with other oxygen-containing compounds and with nitrogen- and sulphur-containing and other nucleophilic reagents.

The nitrile groups of copolymers of styrene and *p*-cyanostyrene are converted into ester groups in high yield by heating the copolymers with an excess of methanol and hydrogen chloride in tetrahydrofuran.[102] The reaction apparently involves the intermediate formation of orthoester groups. PAN undergoes direct esterification by methanol and sulphuric acid, and also of methanol, dimethyl sulphate, and catalytic quantities of sulphuric acid.[103] Like hydrolysis in the presence of sulphuric acid,[61] esterification is accompanied by racemisation.

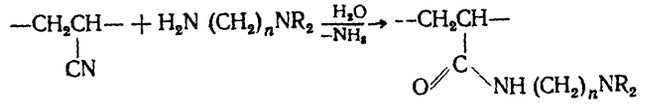
The copolymer of styrene with acrylonitrile (in the molar ratio 61:39), in which the nitrile-containing groups are practically isolated, reacts at 160–220 °C with carboxylic acids according to the scheme



the copolymers obtained, up to 77% of the acrylonitrile units are converted into N-acylacrylamide and acrylic acid units. $T_c$ decreases on going to polymers modified by acids with higher molecular weights.[104]

Copolymers of butadiene with acrylonitrile are vulcanised by dibasic carboxylic acids in the presence of anhydrous $ZnCl_2$, which accelerates the process and also directs the reaction of the CN and COOH groups towards the preferential formation of secondary amide bridges (-CONHCO-). The frost resistance of the vulcanisates obtained is greater than that of sulphur vulcanisates.[105]

In copolymers of methacrylic acid with methacrylonitrile, the intramolecular reaction of CN and COOH groups takes place even at 150 °C to give glutarimide units.[106] When the macromolecules contain polynitrile blocks, polymerisation at the CN groups takes place simultaneously, accompanied by discolouration of the polymer.[22,106] On heating, neighbouring carboxyl-containing groups give cyclic anhydride groups. Polymers containing imide heterocycles in the macromolecules have high vitrification temperatures.[39]

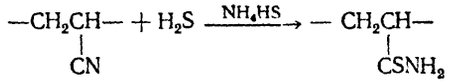


Polyacrylonitrile reacts with aniline on heating in the presence of metallic sodium or aluminium chloride to give polymers containing up to 30% N-phenylacrylamide units. The polymers isolated, which have a high proton-accepting power, also contained appreciable quantities of acrylic acid units.[107]

PAN reacts with an excess of 2-aminoethanol at 90 °C to give a water-soluble polymer.[108] The modification of PAN begins with the nucleophilic addition of 2-aminoethanol to the CN group and the formation of N-hydroxyethylamidine units. If these units are isolated, they subsequently undergo intramolecular condensation to give oxazoline fragments; neighbouring $-C(=NH)NHCH_2CH_2OH$ groups, however, as a result of condensation give N,N'-bis-(2-hydroxyethyl)glutarimidine fragments. The polymer obtained is easily hydrolysed, so that the modified units are converted chiefly into N-(2-hydroxyethyl)acrylamide and ammonium acrylate units:

Polyacrylonitrile, and also the copolymer of acrylonitrile and 5–10% vinyl acetate, in the presence of water at 115 to 120 °C reacts with an excess of N,N-dimethyl-1,3-diaminopropane or other primary–secondary primary–tertiary aliphatic diamines to give cationic polyelectrolytes, in which

dialkylaminoalkylacrylamide units predominate:[109]



Similar transformations in these mild conditions are known for malono-, succino-, and glutaronitrile.[2] Since the mononitriles do not undergo these reactions, and polynitriles acquire a dark colour at the start of the reaction and the infrared spectrum indicates they contain C=N groups,[109] the ammonolysis–hydrolysis being considered, like alkaline hydrolysis, apparently begins with polymerisation at the C≡N groups, after which the polyconjugated sections of the macromolecules react with the amine and water.

Structured polymers have been obtained by treating PAN with hydrazine hydrate in DMF.[2,110] The cross-linking of the macro-chains is apparently partly based on the reaction of two nitrile groups with two hydrazine molecules to give 4-amino-1,2,4-triazole rings, containing macromolecular residues as substituents in positions 3 and 5.[2] Polyacrylonitrile fibres modified by treating with hydrazine are used as starting materials for further transformations,[111–114] in particular to obtain carbon fibres with good mechanical properties.[115] The modification of PAN and copolymers of acrylonitrile with aqueous solutions of hydrazine gives not only a three-dimensional network but also basic groups, which give the polymers chemisorption properties. Fibrous anion-exchangers obtained from copolymers of acrylonitrile with acrylic acid and hydrazine hydrate have a fairly high exchange capacity and are used in sorption processes.[116]

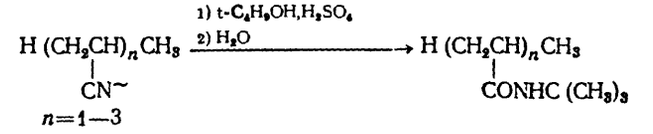
The reaction of PAN with hydroxylamine gives polyacrylamidoxime.[2,117] Polymer-analogue transformations of this polymer have been described.[118–120] Partial amidoximation of a polyacrylonitrile fibre at 90 °C has been used to obtain an anion-exchange and complex-forming fibrous sorbent.[121] The amidoximation of polyacrylonitrile chains grafted to cellulose fibres and to polypropylene has been carried out.[122]

In the reaction of PAN, copolymers of acrylonitrile and styrene or butadiene, and other CN-containing polymers, with dicyandiamide (100°, in mixtures of DMSO and methylcellosolve), more than 80% of the nitrile groups take part in the formation of 4-substituted, 2,6-diamino-s-triazine rings. The polymers obtained, containing triazine substituents in the macromolecules, have an increased thermal stability.[123]

Hydrogen sulphide adds on to the nitrile groups of PAN in DMSO or DMF in the presence of ammonium hydrogen sulphide or the salts of hydrogen sulphide with various secondary and tertiary amines as catalysts:[124]

The degree of thioamidation reaches 50–55% of the theoretical. The rate and the limiting degree of thioamidation increase with increase in the basic strength of the amine used as catalyst, and with increase in the reaction temperature. Increase in temperature, however, also increases the rate of side reactions. Thus in the reaction of PAN with hydrogen sulphide in the presence of ammonium hydrogen sulphide in DMF, more or less selective thioamidation is observed only at 0°, and at higher temperatures, amide and other functional groups are also formed.[124]

A polymer consisting of acrylonitrile and acrylothioamide units was also obtained by treating PAN with ammonium hydrogen sulphide alone in DMF. The polymer modified in this way retains its linear structure.[125] A modified polymer containing 7 mole % thioamide groups was used to obtain fibres.[126] Thioamide groups have been introduced into a prepared PAN fibre by treating it with aqueous solutions of ammonium[127] or sodium[128] sulphides, leading to a marked increase in the heat resistance and the stability of the fibre to repeated deformation at high temperatures. According to Ref.129, nitrile-containing fibres thioamidated with sodium sulphide solution have a high sorptive power with respect to the platinum group metals.

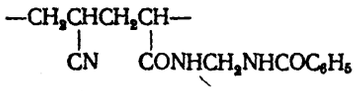


The addition of hydrogen sulphide to the nitrile groups of poly-α-chloroacrylonitrile has been described.[130] As in the polymerisation of the CN groups of PAN and in its alkaline hydrolysis, acrylic acid, methyl acrylate, and vinyl acetate units have an activating action on the thioamidation, whereas the rate of the thioamidation is decreased when the macromolecules contain styrene units.[131] Moreover, the initial effective rate constant for the thioamidation of the CN groups of PAN is 10–100 times that for the thioamidation of acetonitrile. This constant decreases rapidly, however, with increase in the degree of transformation of the CN groups.[132] Thus there is an analogy between thioamidation and various other reactions of polynitriles examined above. On this basis, and in view of the ability of thioamide groups to initiate polymerisation at the CN groups, it may be assumed that the thioamidation of polynitriles, like their alkaline hyrolysis, takes place at least partly via a stage involving the intra- and intermolecular cyclisation of CN-containing polymers.

The electrophilic reactions of nitrile groups in polymers also include reactions leading to the formation of a new C–C bond, for example the reaction of butadiene–nitrile rubber with resorcinol in the presence of HCl and $ZnCl_2$ (Hoesch synthesis), as a result of which up to 10% of the acrylonitrile units are converted into vinyl 2,4-dihydroxyphenyl ketimine units, and as a result of subsequent hydrolysis into vinyl 2,4-dihyroxyphenyl ketone units.[133] Polymers containing ketimine and ketone groups have also been obtained by the reactions of Grignard reagents with the copolymer of styrene and *p*-cyanostyrene,[102] and also PAN.[45]

## V. NUCLEOPHILIC AND OTHER REACTIONS

In recent years it has been possible to carry out the polymer-analogue transformations of polynitriles using the most familiar nucleophilic reaction of CN groups, namely the Ritter reaction.

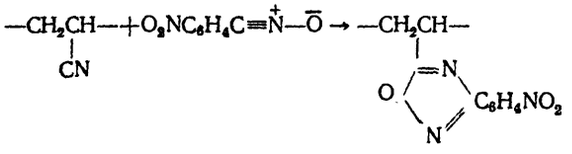


In the reaction of compounds which are low-molecular-weight models of PAN with t-butyl alcohol in tetramethylene sulphone in the presence of sulphuric acid at 25–40 °C, the nitrile groups are converted in high yield into N-t-butyl amide groups:

On going from the monomeric to the dimeric and trimeric models, the rate constant increases to a very slight extent that is in this reaction the neighbouring groups have no significant influence on the reactivity of the CN groups.[13] A study of the reaction of high-molecular-weight PAN with t-butyl alcohol under the same conditions established that the reaction has a limiting degree of transformation (abou 55%), which increases with increase in temperature and v decrease in the concentration or molecular weight of the original PAN. The polymer obtained has a much highe

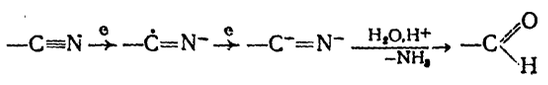
than the original PAN, and the heat resistance of the modified polymer is determined by the degree of transformation of the nitrile groups.[135]

In tetramethylene sulphone in the presence of sulphuric acid, the CN groups of PAN undergo the Ritter reaction with N-hydroxymethylbenzamide, N-hydroxymethylphthalamide, and other N-hydroxymethyl-substituted amides and imides.[136] The polymers formed, for example



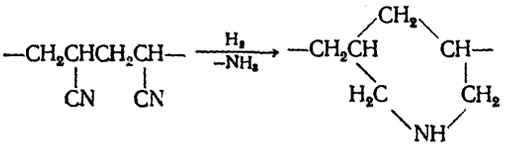
unlike the corresponding homopolymers obtained by radical polymerisation, for example poly(N-benzamidomethylacrylamide), show a greater tendency to undergo structure formation, and this is attributed, in particular, to the liberation of formaldehyde under the conditions of the polymer-analogue transformations and its reactions with the CN groups of different macromolecules to give methylene-bis-amide bridges

The vulcanisation of copolymers of butadiene, acrylonitrile, and vinylidene chloride at 142 °C under the influence of anhydrous zinc oxide is possibly based on the nucleophilic reactivity of the nitrile group.[137] The presence of ZnO leads to the partial dehydrochlorination of the vinylidene chloride units, and the $ZnCl_2$ (or $HZnCl_3$) catalyses the subsequent formation of the N–C bond as a result of the reaction of the nitrogen of the CN group with the carbon atom of another polymer chain having an increased electrophilic reactivity.



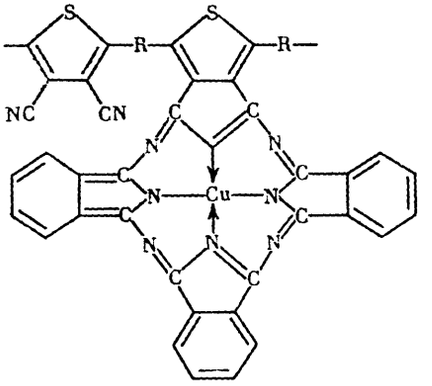
The 1,3-dipolar cyclo-addition of 4-nitrobenzonitrile oxide to the CN groups of copolymers of acrylonitrile with styrene and with vinylidene chloride, giving 1,2,4-oxadiazole heterocycles, was recently described:[138]

The syntheses were carried out in γ-butyrolactone by heating at 130 °C the copolymer with the chloride of 4-nitrobenzohydroxamic acid, which under these conditions undergoes dehydrochlorination to the nitrile oxide. The degree of conversion of the nitrile groups is 30–50%.



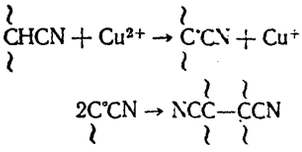
The reduction of the CN groups of polymers to aldimine or amino-groups has been described. The nitrile groups of carbo-chain polymers are partly reduced by tin(II) chloride in the presence of hydrogen chloride to aldimine groups, which on subsequent hydrolysis are converted into aldehyde groups (the Stephen reaction).[2] The use of this reaction to modify butadiene–nitrile rubber leads to an increase in the strength of the vulcanisates.[139]

The reduction of the nitrile groups in macromolecules by the radical-ions formed in the reaction of metallic sodium with naphthalene or hexamethylphosphoramide has been described. Aldehyde groups are produced in the polymers:[140]



The intermediate products of this reaction initiate the graft polymerisation of styrene and methyl methacrylate, evidently an anionic mechanism.

In the presence of Raney nickel or other catalysts, the CN groups of PAN dissolved in DMF are partly hydrolysed (140–185 °C, 65–185 atm).[56,141] Since the CN groups occupy the 1,3-positions in the macromolecules, hydrogenation is accompanied by cyclisation, to give mainly piperidine rings:



Acrylamide and acrolein units were also found in the modified polymer.

When hetero-chain polyamides whose chains contain 3,4-dicyanothiophene rings are heated (200–250 °C) with 1,2-dicyanobenzene and copper acetylacetonate, approximately 50% of the dicyanothiophene units are converted into phthalocyanine-like units:

The polymers obtained have an increased thermal stability.[142]

Butadiene–nitrile rubbers are cross-linked in the presence of copper(II) salts by a free-radical mechanism. The >CHCN group probably forms with $Cu^{2+}$ a redox system in which there is one-electron transfer from the polarised CH bond to the cation, and the recombination of the radicals obtained leads to structure formation in the polymer:[143]

---o0o---

The the reactions of nitrile-containing polymers can be divided into three groups. The first group consists of reactions taking place according to schemes familiar for low-molecular-weight nitriles. Because of the difference in the steric, polar, and other factors, the quantitative characteristics may differ considerably for the reactions of the low- and high-molecular-weight compounds. The second group also consists of reactions familiar for low-molecular-weight compounds, but in this case the transformations of the high- and low-molecular-weight compounds take place by different schemes. The third group consists of reactions which are specific for nitrile-containing polymers. The reactions of practical importance involving cyclisation and

polymerisation (third group) and various hydrolysis reactions (second group), for which reliable schemes for the transformations of the CN groups have been established, are now being studied in most detail, and methods for the control of these transformations have been developed. There is comparatively little published information, however, on the electrophilic reactions of polynitriles with various oxygen-containing (except water), nitrogen-containing, and other reagents, or on the nucleophilic reactions of polynitriles. In view of the reactivity of the CN group and the extensive use of compounds containing this group in synthetic organic chemistry, the possible applications of polynitriles as starting materials for the production of new polymers are far from exhausted. Since polynitriles are readily available, the detailed study of the known reactions of these polymers and the further extension of the range of reagents used for modification will undoubtedly produce promising results.

# Electronically Excited Atoms and Molecules in Solid-Gas Systems

I.A.Myasnikov, E.I.Grigor'ev, and V.I.Tsivenko

The formation, emission, and deactivation of electronically excited atoms and molecules in solid-gas systems have been examined. The mechanisms of these processes and the influence of the nature of the solid on their course have been discussed. The bibliography contains 175 references.

CONTENTS

I. Introduction 49
II. The formation and emission of electronically excited atoms and molecules into the gas phase from a solid surface 50
III. The deactivation of electronically excited atoms and molecules on a solid surface 57

## I. INTRODUCTION

In recent years there has been a marked increase in interest in the study of excited states on a surface and in particular electronically excited atoms and molecules in heterogeneous systems. This is related to the development of plasma and radiation chemistry, laser technology, and photocatalytic processes, in which the participation of electronically excited atoms and molecules is obvious, although it has been insufficiently studied.[1] Moreover, there are experimental data which indicate that electronically excited molecules are formed in thermal heterogeneous processes. In particular, certain reactions take place by a heterogeneous–homogeneous mechanism, that is electronically excited atoms and molecules are emitted into the gas phase in the course of the reaction. Thus it is clear that for an understanding of the mechanism of many heterogeneous reactions in a solid–gas system it is important to know the properties and behaviour of electronically excited atoms and molecules.

The present review deals primarily with long-lived species. The long radiative lifetimes of some electronically excited atoms and molecules in the gas phase suggest that on solid surfaces also, their stability will be sufficient for them to take part in surface processes such as the luminescence of adsorbed molecules and the formation and emission of electronically excited atoms and molecules from solid surfaces under the influence of light, chemical, mechanical, and other factors. The results of the study of the deactivation of electronically excited atoms and molecules on solid surfaces of different kinds are of considerable interest. The deactivation is due to the exchange of the excitation energy with the solid or with an adsorbed layer, and also to chemical reaction with the surface of the adsorbent (chemisorption) and with the adsorbed species—molecules and radicals.

Information of different kinds on the behaviour of various electronically excited atoms and molecules at a solid–gas interface has been published. The experimental data are generally qualitative in character. The largest number of publications in this field has been devoted to electronically excited oxygen molecules (singlet oxygen $^1O_2$); data have also been published on electronically excited nitrogen molecules, metal atoms, and metastable inert gas atoms.

## II. THE FORMATION AND EMISSION OF ELECTRONICALLY EXCITED ATOMS AND MOLECULES INTO THE GAS PHASE FROM A SOLID SURFACE

Recent reviews[1-11] contain varied information on the formation of electronically excited atoms and molecules and their emission from solid surfaces. New data, not discussed in these reviews, have recently been published[12,13] on the mechanism of the photosensitised formation of singlet oxygen in solid–sensitiser–oxygen systems. It has also been found[15-18] that emission of singlet oxygen from solid surfaces takes place in many dark and photo-heterogeneous processes. The surface and the adsorption layers have been excited by different methods: the chemical reaction of oxygen atoms with metal oxides,[17,19-21] mechanochemical processes,[15] the thermal decomposition of catalysts,[16,23] the illumination of catalysts containing transition metal ions,[18,24,25] etc.

### 1. The Photosensitised Formation of Electronically Excited Oxygen Molecules in Heterogeneous Systems

The idea that singlet oxygen ($^1O_2$) is formed in the reaction of a triplet dye molecule with oxygen by the transfer of the triplet excitation energy was first put forward by Kautsky,[26] who observed the simultaneous quenching by oxygen of the phosphorescence of trypaflavine adsorbed on silica gel and oxidation of the leuco-base of Malachite Green, adsorbed on other silica gel granules. The oxidation took place in a narrow pressure range $(1.56-3.12) \times 10^{-3}$ hPa† oxygen. It was suggested that the oxidation involved electronically excited oxygen molecules, formed by the reaction

$$T + {}^3O_2 \rightarrow S_0 + {}^1O_2$$

where T and $S_0$ represent respectively the triplet-excited and ground states of the dye molecule, and $^3O_2$ and $^1O_2$ the ground and singlet-excited states of oxygen. Since the sensitiser and the substrate being oxidised were separated in space, the singlet oxygen could pass into the gas phase. It should be noted, however, that the oxidation stopped when the distance between the particles with the adsorbed dye sensitiser and with the substrate being oxidised was increased to several millimetres.

The discussion of the nature of the oxidising agent in these systems continued for many years. Thus according to the hypothesis of Weiss,[27] the oxidising agent could be the oxygen radical-anion $O_2^{\cdot-}$. Later, Weiss adopted the views of Franck and Livingston,[28] who suggested that hydrogen peroxide is formed in this process. The radical-anion removes a hydrogen atom either from the dye sensitiser[28] or from a water molecule adsorbed on silica gel.[29] As pointed out by Terenin,[30] however, energy considerations indicate that the $O_2^{\cdot-}$ radical-anion cannot oxidise the leuco-compound, and the formation of hydrogen peroxide should lead to an irreversible chemical change in the dye sensitiser. The energy of the triplet level of trypaflavine (48 kcal mole$^{-1}$) is insufficient for the removal of a proton from water molecules adsorbed on silica gel.[31] In the opinion of other authors,[32,33] the reactive species is a metastable complex (moloxide) formed by the triplet dye molecule with oxygen. Under the conditions of Kautsky's experiment, however, this complex cannot leave the surface and reach the substrate being oxidised.

Rosenberg and co-workers[34,35] studied the influence of gases on the quenching by oxygen of the phosphorescence of trypaflavine adsorbed on silica gel, and suggested that a vibrationally excited oxygen molecule is formed in the reaction of oxygen with the triplet sensitiser molecule.

Recently, a number of workers have interpreted the data obtained in the study of systems of this kind in terms of singlet oxygen formation.

Thus the dye-photosensitised (including trypaflavine-sensitised) decrease in the strength of textile fibres has been attributed[29,36] to the participation of singlet oxygen. This effect was observed in the absence of water at an oxygen pressure of $10^{-3}$ hPa; the sensitiser (a film of dye or a coloured fibre) was situated at a distance of several millimetres from the textile fibre being oxidised.

The dye- (eosin and Methylene Blue) sensitised oxidation by oxygen of diphenylanthracene and rubrene, separated from the sensitiser by layers of barium or cadmium stearate with different thicknesses (up to 500 Å), has been studied.[37] In the opinion of the authors cited, singlet oxygen is formed in this case, and can diffuse through the stearate layers and oxidise the substrate molecules.

The oxidation of various organic substances in solution, photosensitised by dyes (Rose Bengal, eosin, fluorescein, etc.) deposited on chloromethylated polystyrene, has been studied.[38] Analysis of the products indicated that the oxidation is brought about by singlet oxygen, formed in the reaction of a triplet dye molecule with oxygen.

The oxidation of anthracene and 2-methylbut-2-ene in solution, photosensitised by Rose Bengal and eosin deposited on Amberlite IRA-400 ion exchange resin and by Methylene Blue deposited on Amberlite IRS-200, has been observed.[39] From the fact that the compounds obtained were identical to the products of oxidation by singlet oxygen, it was concluded that singlet oxygen is involved in the reaction.

The oxidation of tetramethylethylene, 1,3-diphenylisobenzofuran, etc. in solution, photosensitised by Rose Bengal and Methylene Blue adsorbed on silica gel and alumina gel, has been studied.[40] The efficiency of the oxidation was approximately the same in heterogeneous and homogeneous systems. The experiments of Ref.26 were also repeated using Rose Bengal adsorbed on silica gel as the sensitiser, and 9,10-diphenylanthracene adsorbed on other silica gel particles as the substrate being oxidised. When oxygen (pressure 6 hPa) was passed through a "fluidised bed" of the catalyst with illumination by a xenon lamp for 2.5 h, the degree of oxidation was 50%. It was suggested that the oxidation involves singlet oxygen.

The photosensitised formation of singlet oxygen has been detected[41,42] using a thin film of Rose Bengal as sensitiser. The conclusion that singlet oxygen is formed was reached by analysing the oxidation products of rubrene.

The photo-oxidation of the surface of a single crystal of anthracene in an oxygen atmosphere has been studied.[43] The composition of the products indicated that the reaction takes place under the influence of singlet oxygen.

Thus the conclusion that singlet oxygen plays a decisive role in photosensitised oxidation in heterogeneous solid–dye–oxygen systems was based on the fact that the products of the photosensitised oxidation and the direct action of singlet oxygen were identical. The corresponding comparison for solutions was first made in Refs.44 and 45. Other workers[46,47] studied the oxidation of substances deposited on various supports (cellulose, silica gel, etc.) by singlet oxygen, obtained in different ways. Thus in Ref.46, various substances adsorbed on silica gel were oxidised by singlet oxygen formed by heating the triphenyl phosphite–ozone adduct. The products obtained by oxidising tryptophan, thymine, and uracil, adsorbed on silica gel, by singlet oxygen obtained in a radiofrequency discharge were also identified. In Ref.47, 9,10-dimethylanthracene and other substances,

† 1 hPa = 100 Pa ≅ 0.75 Torr (Editor of Translation).

adsorbed on cellulose and silica gel, were oxidised using singlet oxygen formed in a ultrahigh-frequency discharge. On the basis of these studies, it was suggested[48] that photosensitised oxidation in systems with the sensitiser and the substrate being oxidised separated in space could be used to test for the formation of singlet oxygen. It is only recently, however, that is has been possible to observe the luminescence of singlet oxygen ($^1\Delta_g$) in the gas phase with photosensitisation by a dye film (Rose Bengal).[49,50]

Recently, semiconducting detectors were used to detect singlet oxygen in the gas phase.[17,51] This method is based on the change in the electrical conductivity of thin oxide films (ZnO, $TiO_2$, CdO, etc.) as a result of the adsorption of atoms and molecules.[22,114,134] The procedure requires the use of not only semiconducting films but also additional apparatus and methods for the selective determination of the concentration of the gas being determined. Singlet oxygen is detected in the presence of oxygen atoms using an apparatus in which the oxygen atoms are deactivated on the surface of mercury or silver oxides.[17,51] The influence of ordinary (triplet) oxygen can be practically eliminated either by lowering the temperature of the detector or by oxidising it beforehand.[51,113] In Ref.12, semiconducting detectors, and also calorimetry, showed unambiguously that the illumination of dyes (trypaflavine, Rose Bengal) adsorbed on quartz, and a film of trypaflavine, leads to the formation and emission of singlet oxygen into the gas phase.

The proof that singlet oxygen is formed when heterogeneous solid–sensitiser–oxygen systems are illuminated, and the quenching of the phosphorescence of the adsorbed sensitiser, observed simultaneously, confirm the view[26] that singlet oxygen is formed by the reaction of oxygen with a triplet molecule of the sensitiser. It should be noted, however, that the quenching of the phosphorescence of the sensitiser by oxygen indicates only that singlet oxygen is formed, and to investigate its subsequent behaviour (the regular features of emission into the gas phase) it is necessary to study its desorption.

Since the concentration of singlet oxygen in the gas phase is directly proportional to the intensity of excitation,[12] the change in the intensity of the phosphorescence of the adsorbed sensitiser in the reaction with oxygen is apparently given by an equation of first order with respect to the triplet molecules of the sensitiser.[34,52] The change in the intensity of the phosphorescence of the adsorbed sensitiser with change in the oxygen pressure[35] corresponds to the change in the concentration of singlet oxygen in the gas phase. Thus the intensity of the phosphorescence of the sensitiser decreases, and the concentration of singlet oxygen in the gas phase increases, with increase in the oxygen pressure. With further increase in the oxygen pressure, the intensity of the phosphorescence of the sensitiser becomes close to zero (that is all the triplet molecules of the sensitiser are quenched), but the concentration of singlet oxygen formed is a maximum, and its concentration in the gas phase is determined only by homogeneous–heterogeneous deactivation processes.[12,13] The rate constant for the reaction of a triplet molecule of trypaflavine adsorbed on quartz is $5 \times 10^9$ litre $mole^{-1}s^{-1}$. The calculation was based on the assumption that the singlet oxygen is formed by the transfer of the energy of the sensitiser molecule to oxygen in a short-lived collision complex. This value agrees satisfactorily with published data[34,52,53] obtained by measuring the quenching by oxygen of the phosphorescence of trypaflavine adsorbed on silica gel. In the works cited it was again assumed that the quenching of the phosphorescence of the sensitiser by oxygen takes place in a short-lived collision complex formed by the triplet molecule of the sensitiser and oxygen.

In this case also, however, it is necessary to take account of the specific features of heterogeneous systems. Thus the quenching of the phosphorescence of trypaflavine adsorbed on silica gel does not obey the Stern–Volmer relationship. In Refs.53–59, the regular features of the change in the intensity of the phosphorescence and the lifetime of the triplets of trypaflavine adsorbed on silica gel with change in the oxygen pressure in the gas phase were explained in terms of the dynamic character of the quenching (according to Terenin[60]), that is the process takes place in a short-lived collision complex. Thus from the practically instantaneous and ready reversal of the quenching as far as −60 °C it was concluded[55] that the form of the quenching curves is independent of the adsorption of oxygen. In Ref.53 it was established that all the luminescence centres of trypaflavine adsorbed on silochrome react with oxygen at the same rate at all stages of the non-exponential quenching of the phosphorescence, and it was concluded that the quenching is dynamic in character. In Refs.54 and 56–58 the deviations from the Stern–Volmer relationship were attributed to the molecular-sieve and trajectory effect. The sensitiser molecules may be situated in macro-pores of the adsorbent, readily accessible to oxygen, or in micro-pores (cracks), which are not readily accessible. The distribution of the sensitiser in the macro- and micro-pores determines what fraction of the triplet molecules of the sensitiser will contribute to the phosphorescence, and what fraction will be quenched. It is difficult to imagine, however, that a pore which is accessible to the fairly large molecule of the sensitiser (trypaflavine) will not be filled by oxygen molecules, whose dimensions are appreciably smaller. Moreover, it was assumed that only part of the trajectory of the random movement of the active product of the photodissociation of the trypaflavine molecule (polaron, H, exciton, etc.) in the matrix is accessible to oxygen molecules. Thus in the opinion of the authors cited, the nature of the solid on which the sensitiser is adsorbed has a decisive influence on the quenching of the phosphorescence of the sensitiser (and hence the formation of singlet oxygen). As noted in Ref.53, the regular features of the quenching of the phosphorescence of adsorbed trypaflavine can also be explained by assuming that there is a distribution of the luminescence centres with respect to lifetime. This view was put forward in Ref.61. It was found that trypaflavine is adsorbed as monomers and dimers, and that the lifetime of the triplets in the dimeric form is shorter than for the monomeric form. Moreover, the lifetime of the triplets of the adsorbed trypaflavine was independent of the oxygen pressure over a wide range ($10^{-6}$–1 hPa), whereas the intensity of the phosphorescence changed by several powers of ten. It was therefore suggested that a decisive role in the quenching of the phosphorescence of adsorbed trypaflavine is played by adsorbed oxygen. In Ref.62, the quenching of the phosphorescence of biphenyl, naphthalene, and chloronaphthalene on silica gel was brought about by adsorbed oxygen, that is the quenching was static in character.

There are thus two views of the quenching of the phosphorescence of adsorbed molecules by oxygen and the associated formation of singlet oxygen. Up to the present (see earlier reviews[2–11]) the predominant view has been that singlet oxygen is formed in a short-lived collision complex (triplet sensitiser molecule–oxygen), that is the dynamic mechanism of the quenching of the phosphorescence has been assumed. Recently, however, direct proof that adsorbed $O_2$ molecules take part in the formation of singlet oxygen has been obtained. Thus in Refs.12 and 13 it was shown that singlet oxygen is formed with the photosensitisation of trypaflavine adsorbed on quartz, or a film of trypaflavine, and previously adsorbed oxygen.

The formation and emission of singlet oxygen into the gas phase was observed under conditions of continuous evacuation at a residual gas pressure of $10^{-6}$ hPa, and the intensity of the emission decreased regularly with time. The emitting power of these systems was preserved for several tens of minutes, evidently due to oxygen adsorbed on the surface. At an oxygen pressure in the gas phase of $10^{-6}$ hPa, the quenching of the phosphorescence of adsorbed trypaflavine is not observed.[35] Moreover, singlet oxygen is not formed if the sensitiser is evacuated for several hours at a temperature of ~100 °C.

Similar data were obtained using vanadium[24] and molybdenum[25] ions deposited on quartz as sensitiser. The results of these experiments show convincingly that adsorbed oxygen plays a decisive role in the formation of singlet oxygen in heterogeneous systems. The residence time of the oxygen molecule on the solid surface, even in the case of physical adsorption, is greater by several powers of ten than the lifetime of the collision complex, so that the efficiency of the formation of singlet oxygen should be greater by several powers of ten in this case. Thus in the gas phase the efficiency of the formation of singlet oxygen is ~$10^{-3}$ (from data on the quenching of the phosphorescence of the sensitiser[9]), whereas in solutions it is close to 1, because of the cage effect.[63-65] In Ref.40 it was shown that the efficiency of the photosensitised oxidation in heterogeneous systems is not lower than that under homogeneous conditions for solutions. According to Ref.61, for trypaflavine adsorbed on silica gel, the efficiency of the formation of singlet oxygen is close to 1. The question of possible centres for the adsorption of oxygen can be considered. It may be assumed that oxygen is adsorbed on the surface of the solid, migrates over the surface, and collides with triplet molecules of the sensitiser. Simple calculation of the concentration of singlet oxygen in the gas phase shows, however, that in this case the efficiency of its formation should be much smaller than 1. It is natural to assume that the oxygen molecules involved in the quenching are adsorbed on the molecules of the sensitiser.

The quenching by oxygen of the phosphorescence of trypaflavine adsorbed on silica gel is a practically activationless process.[34,53] On the other hand, in Refs.12 and 13 it was found that the concentration of singlet oxygen in the gas phase increases considerably with increase in the temperature of the sensitiser. The concentration of singlet oxygen in the gas phase is apparently determined by the desorption of singlet oxygen from the surface. It is still not clear from which centres the singlet oxygen is desorbed, that is whether it is desorbed from a sensitiser molecule or from the quartz surface. The increase in the concentration of singlet oxygen in the gas phase with increase in the temperature of the sensitiser, detected in Ref.13, can be attributed to a decrease in the residence time of the singlet oxygen molecule either on the quartz surface or on the sensitiser molecule. Correspondingly, the activation energy of the effective rate constant for the formation of singlet oxygen, 10 kcal mole$^{-1}$,[13] can be taken as the heat of adsorption of singlet oxygen on the quartz surface or as the heat of adsorption on the sensitiser molecule. In Ref.34, the quenching by oxygen of the phosphorescence of trypaflavine adsorbed on silica gel stopped at the temperature of liquid nitrogen. The heat of adsorption of singlet oxygen, calculated with allowance for this experimental fact, was found to be 6 kcal mole$^{-1}$. Unfortunately, there are no direct data on the adsorption characteristics of singlet oxygen.

Thus it is not yet possible to give a definite answer to the question raised. The estimated activation energy of the desorption of oxygen from the surface of trypaflavine (12 kcal mole$^{-1}$),[66] however, indicates that desorption of singlet oxygen from the sensitiser molecule is more probable.

A possible scheme for the formation and emission of singlet oxygen into the gas phase is given below:

$$^1S_0 + {}^3O_2(gas) \rightleftarrows [^1S_0 \ldots {}^3O_2(ads)]$$
$$[^1S_0 \ldots {}^3O_2(ads)] \xrightarrow{h\nu} [^1S_1 \ldots {}^3O_2(ads)]$$
$$[^1S_1 \ldots {}^3O_2(ads)] \rightarrow [^3S_1 \ldots {}^3O_2(ads)]$$
$$[^3S_1 \ldots {}^3O_2(ads)] \rightarrow [^1S_0 \ldots {}^1O_2(ads)]$$
$$[^1S_0 \ldots {}^1O_2(ads)] \rightarrow {}^1S_0 + {}^1O_2(gas)$$

where $[^1S_0 \ldots {}^3O_2(ads)]$, $[^1S_1 \ldots {}^3O_2(ads)]$, $[^3S_1 \ldots {}^3O_2(ads)]$, and $[^1S_0 \ldots {}^1O_2(ads)]$ are the complexes of oxygen with the sensitiser molecule in the ground state $^1S_0$, the singlet excited state $^1S_1$, and the triplet state $^3S_1$, and $^3O_2(gas)$, $^1O_2(gas)$, $^3O_2(ads)$, and $^1O_2(ads)$ the ground and singlet excited states of oxygen in the gas phase and in the adsorbed phase respectively. The nature of the complex in which singlet oxygen is formed must be determined in each specific case.

Until recently it was usually assumed that singlet oxygen is formed in a short-lived collision complex with transfer of energy,[9] and not in a complex with charge transfer, except in the case of aromatic substances.[67] It has been found, however, that the formation of singlet oxygen in a complex with charge transfer is characteristic of alkenes[10] and a number of other substances.[4,68] As noted in Ref.69, the detection of magnetic effects (the influence of a magnetic field and chemical polarisation of the nuclei) in a number of cases helps to decide between energy transfer and electron transfer processes. A detailed review of the influence of a magnetic field on the reaction of triplet molecules with oxygen has been published.[70] There is apparently only one published paper on the influence of a magnetic field on the efficiency of the formation of singlet oxygen in heterogeneous systems. This is a paper by Frankevich and Sokolik[71] on the solid-phase photo-oxidation of tetracene. The reaction of oxygen with tetracene molecules in the triplet state gives a charge-transfer complex with a lifetime of 10 s at room temperature. The application of a magnetic field ($H$ = 2 kOe) increases the rate constant for the reaction of oxygen with the triplet molecule of tetracene (that is the efficiency of the formation of singlet oxygen) by 50 ± 10%. The authors cited consider that all the singlet oxygen formed is used up in the oxidation of tetracene. The existence of emission by singlet oxygen from the surface of tetracene into the gas phase does not cast doubt on the main conclusions of the work cited, but it must be taken into account in the explanation of the temperature dependence of the rate of the photo-oxidation of tetracene.

This work clearly demonstrates the important information that can be obtained by studying the influence of a magnetic field on the efficiency of the formation of singlet oxygen in heterogeneous systems.

In Ref.4 it was suggested that singlet oxygen is formed via an intermediate moloxide stage. In a recent theoretical paper,[72] the quenching of the phosphorescence of ethylene by oxygen (and the formation of singlet oxygen) was also attributed to moloxide formation.

It is also possible to use inorganic molecules deposited on a solid surface as sensitiser. Thus when a quartz surface promoted by vanadium[18,24] or molybdenum[25] ions is illuminated in the presence of oxygen, singlet oxygen is formed and emitted into the gas phase. From the regular features of the emission of singlet oxygen in $V/SiO_2$ and $Mo/SiO_2$ systems, and also from data on the quenching by oxygen of the phosphorescence of transition metal (vanadium, molybdenum) ion complexes on a quartz surface,[73] the following mechanism can be proposed for the formation and emission of singlet oxygen into the gas phase in these systems.[18,24] When the $V/SiO_2$

system is illuminated, surface charge-transfer complexes are formed:[74]

$$|V^{5+}O^{2-}| \xrightarrow{h\nu} |V^{4+}O^{-}|_s^*$$

where s = surface. In the quenching of the phosphorescence of the complex on the surface of the adsorbent, the excitation energy of the complex is transferred to the adsorbed oxygen molecule to give singlet oxygen, which is subsequently desorbed. In this case the dependence of the concentration of singlet oxygen in the gas phase on the intensity of the exciting light and the oxygen pressure is similar to that for solid–dye–oxygen systems.[12,13] A decrease in the concentration of the metal–oxygen complexes on the quartz surface, brought about by preliminary photo-reduction of the specimen with hydrogen (when the V and Mo complexes decompose[75]), leads to a decrease in the intensity of the liberation of singlet oxygen.

With increase in the temperature of the sensitiser, the concentration of singlet oxygen in the gas phase increases. The activation energy of this process is 1.5 kcal mole$^{-1}$. This value is appreciably lower than the activation energy of the formation and emission of singlet oxygen into the gas phase when a dye (trypaflavine) is used as sensitiser.[13] It has been suggested[24] that the increase in the intensity of the emission of singlet oxygen with increase in the temperature of the sensitiser in this case is related to a decrease in the residence time of the singlet oxygen on the surface of the adsorbent, and to a consequent decrease in the rate of the deactivation of singlet oxygen on the solid surface.

Thus in the investigation of the mechanism of photo-oxidative processes on deposited catalysts it is apparently necessary to take account of the extremely probable role of singlet oxygen molecules. It also follows from Refs.15, 18, 24, and 25 that some oxidative photo-heterogeneous processes may take place by a heterogeneous–homogeneous mechanism.

## 2. The Influence of the Nature of the Sensitiser Carrier on the Efficiency of Formation of $^1O_2$

There are practically no published data on the influence of the solid on the photosensitised formation and emission of singlet oxygen into the gas phase. In a number of cases it is difficult to relate unambiguously the change in the efficiency of the formation of singlet oxygen to a specific mechanism of the influence of the solid.

Thus for example the quenching of the phosphorescence of trypaflavine adsorbed on silica gel does not obey an exponential law.[77–79] In Ref.77, the phosphorescence quenching curves were represented as the sum of two exponents, corresponding to two metastable levels of the sensitiser molecule. In Ref.79 this suggestion was rejected on the basis of the fact that the phosphorescence quenching curve is non-exponential at low temperatures, when the lifetime and phosphorescence spectra are independent of temperature. The non-exponential nature of the quenching of the phosphorescence, which could not be represented as the sum of two exponents, was attributed to a difference in the nature of the trypaflavine adsorption centres on the silica gel.

In Ref.82 it was found that the kinetics of the quenching of the phosphorescence of naphthalene and anthracene adsorbed on $\gamma$-$Al_2O_3$ at degrees of covering $\ll 1$ do not obey an exponential law, but are described by a sum of two exponents. The observed regular features were attributed to a difference in the nature of the adsorption centres. In Ref.78, a mechanism for the quenching of the phosphorescence was proposed, involving the reversible dissociation of the excited sensitiser molecule and the migration of one of the products ($HO_2$, $H^+$, exciton, etc.) in the cage. In Ref.61, the deviation from the exponential relationship was attributed to the presence of monomeric and dimeric forms of the sensitiser. The phosphorescence which was quenched rapidly was assigned to sensitiser dimers, and that which was quenched more slowly was assigned to the monomers. This view is confirmed by the fact that the changes in the absorption and luminescence spectra of trypaflavine adsorbed on silica gel are slight compared with aqueous solutions, indicating that trypaflavine is physically adsorbed on the silica gel surface.[77] This is also indicated by the fact that the form of the phosphorescence quenching curve is independent of the pH at which the adsorption is carried out.[79] In Refs.80 and 81 it was shown that the chemisorption of the dye takes place only if the overlap integral of the wavefunctions of the adsorbate and the adsorbent is sufficiently large to displace the hydrogen bond.

In Ref.61, therefore, the form of the curve for the quenching by oxygen of the phosphorescence of adsorbed trypaflavine was attributed to a difference between the efficiencies of the reaction of oxygen with the triplets of trypaflavine in the monomeric and dimeric forms (and hence a difference in the efficiences of the formation of singlet oxygen). The values are 0.980 ± 0.05 for the monomeric form, and 0.86 ± 0.04 for the dimer.

A decrease in the sensitivity of the phosphorescence of adsorbed trypaflavine to the presence of oxygen on dehydroxylation of the silica gel has been observed.[55] The opposite conclusion was reached, however, in a study[83] of the influence of the moisture content and nature of the support on the quenching by oxygen of the phosphorescence of various adsorbed organic substances (including substances adsorbed on silica gel).

It was also found[18,25] that adsorbed vanadium and molybdenum ions are good sensitisers of the formation of singlet oxygen, but when an oxide phase appears, singlet oxygen is not formed. The quartz surface on which the ions are adsorbed takes part in the formation of surface complexes which photosensitise the formation of singlet oxygen. When a bulk oxide phase is produced, these complexes are not formed,[14] and singlet oxygen is not generated.

Thus the carrier influences the nature and state of the sensitiser, and this may be revealed by a change in the nature of the deactivation of its excited states. In addition, dimerisation or aggregation of the sensitiser and modification of its electronic structure by the adsorbent are possible. All this must be taken into account in the study of the photosensitised formation and emission of singlet oxygen into the gas phase in heterogeneous solid–gas systems.

The nature of the solid may also influence the formation and emission of singlet oxygen into the gas phase. Thus the formation of singlet oxygen has been studied in experiments in which the support for the sensitiser (trypaflavine) was zinc oxide, whose electronic properties could be altered.[84] The formation and emission of singlet oxygen into the gas phase was observed only after extensive oxidation of ZnO. After the reduction of the oxidised zinc oxide in the course of the experiment, the formation of singlet oxygen stopped. This result can be understood if account is taken of the effect of the spectral sensitisation by dyes of the photoconductivity of zinc oxide.[60] When oxygen is adsorbed on the surface of zinc oxide, thermally activated capture of electrons takes place on the surface levels of the adsorbed oxygen. According to Ref.85, it is on these levels that effective transfer of the excitation energy of the adsorbed sensitiser takes place. In reduced ZnO, the concentration of surface ionised zinc is high.[86] When oxygen is adsorbed, a high density of surface levels is created, and effective transfer of the excitation energy of the sensitiser (trypaflavine) to the support (zinc oxide) takes place. When ZnO is treated

with oxygen atoms (extensive oxidation), the quantity of surface superstoichiometric zinc atoms and the density of surface levels decrease sharply.[86] In this case the transfer of the excitation energy of the sensitiser to oxygen, that is the formation of singlet oxygen, becomes more effective.

In addition to the transfer of the energy of electronic excitation of the sensitiser to the solid, its vibrational degradation as a result of the interaction of the sensitiser molecule with the solid is also possible. The formation and emission of singlet oxygen into the gas phase with photosensitisation by a film of dye (trypaflavine) has been detected.[12,13] The dye molecules in the solid phase to a large extent retain their individual properties, since they are joined by weak dispersion forces.[60] A film of this kind can be regarded as a strongly absorbing surface layer on a support. It is apparently these characteristic features of the behaviour of the dye molecule in the solid phase that determine the regular features of the formation and emission of singlet oxygen into the gas phase. A hundred-fold increase in the rate constant for the degradation of the energy of the triplet excitation of the sensitiser compared with the adsorbed state has been detected.[84] This increase was related to the vibrational degradation of the excitation energy of the sensitiser as a result of reaction with the support. Thus in the study of the regular features of the formation and emission of singlet oxygen into the gas phase in heterogeneous solid–sensitiser–oxygen systems it is necessary to take account of the distribution of the excitation energy of the sensitiser between the solid and oxygen.

The dependence of the concentration of singlet oxygen in the gas phase on the oxygen pressure with sensitisation by adsorbed trypaflavine differs considerably for silica and quartz surfaces.[13] In the case of silica gel, the formation and emission of singlet oxygen into the gas phase is observed in a narrower range of oxygen pressures, and its maximum concentration is displaced to low pressures. This difference can be attributed to the effective deactivation of singlet oxygen in the pores of the silica gel. Thus the efficiency of sensitisers adsorbed on silica gel is low in photo-oxidation processes.

The influence of the adsorption characteristics of singlet oxygen on the efficiency of its formation and emission into the gas phase has not been studied, since there are no data on the adsorption of singlet oxygen.

The photosensitised formation of singlet oxygen when the role of the sensitiser is played by the solid is of considerable interest. Thus even in Ref.87 it was suggested that when zinc oxide with oxygen adsorbed on its surface is illuminated, the formation and emission of singlet oxygen into the gas phase should take place in the intrinsic absorption band. It has recently been suggested that singlet oxygen is formed in the photo-desorption of oxygen from zinc oxide[88] and in the photocatalytic osidation of hydrogen on potassium bromide.[89] No direct proof that singlet oxygen is formed was given, however.

In addition to the mechanism examined (it can be described as physical), which involves the transfer to oxygen, most probably adsorbed, of the energy of optical excitation by surface centres or adsorbed molecules, a chemical mechanism also exists. Its chief characteristic is the chemical reaction taking place on the surface to give singlet oxygen. Thus data have been obtained,[90] indicating that singlet oxygen is formed when a highly hydroxylated titanium dioxide surface is illuminated. The authors of the works cited, who had previously carried out extensive work on the photo-desorption of oxygen from the surface of $TiO_2$, found that when titanium dioxide, previously activated with chlorine and impregnated with a solution of caesium anthracene-9,10-bis(ethanesulphonate) (AES), which is an effective absorber of singlet oxygen, was illuminated, the quantity of oxygen desorbed was much smaller than in the absence of AES. It was concluded that in this system, singlet oxygen is formed on the $TiO_2$ surface. The mechanism of formation of $^1O_2$ includes: 1) the formation of $H_2O_2$ in the course of the photo-desorption of $O_2$ from the hydroxylated $TiO_2$ surface; 2) the oxidation of surface chloride ions to $ClO^-$ when $TiO_2$ is illuminated in an $O_2$ atmosphere; and 3) the reaction of surface $ClO^-$ ions with hydrogen peroxide:

$$ClO^- + H_2O_2 \rightarrow H_2O + Cl^- + {}^1O_2$$

Thus in this system the mechanism of formation of $^1O_2$ is chemical in character, like the homogeneous production of $^1O_2$ as a result of the reaction of $H_2O_2$ with the $ClO^-$ ion in solution.[91]

The liberation of singlet oxygen after heating a sensitiser previously irradiated with light at a low temperature has been observed.[92,93] Thus in Ref.93, alcoholic solutions of Rose Bengal and Methylene Blue were illuminated at −60 °C, and singlet oxygen was liberated after heating to room temperature. In Ref.92, illumination of polyvinylnaphthalene at 0 °C followed by heating without illumination to 30 °C also led to the emission of singlet oxygen. In the opinion of the authors cited, singlet oxygen is formed by the decomposition of peroxides stable at a low temperature, which in turn are produced as a result of the reaction of the substances inidcated with singlet oxygen. Thus accumulation of singlet oxygen, which is subsequently readily liberated, takes place.

Many questions have still to be answered. Thus it is not clear whether the singlet oxygen in heterogeneous systems is produced in the state $^1\Delta_g$ or $^1\Sigma_g^+$, there are no accurate data on the efficiency of its formation, the possible formation of singlet oxygen by reaction with singlet-excited molecules has not been studied, and a number of other problems, which have been successfully resolved for homogeneous systems, still remain.

The general character of the problems examined for the case of singlet oxygen has been demonstrated[94] in a study of the triplet–triplet transfer of energy from solid organic substances (naphthalene, 9,10-anthraquinone, etc.), excited by light, to molecules of the gas phase (penta-1,3-diene), leading to the *cis–trans* isomerisation of these molecules.

### 3. The Formation of Electronically Excited Oxygen Molecules as a Result of the Adsorption of Oxygen, Chemical Reactions, and Structural-chemical Transformations on Solid Surfaces

EPR has been used to study the reaction of oxygen with chromium ions deposited on silica gel, and the formation of the complex $[Cr^{5+}O_2]$ was detected.[159] The parameters of the EPR spectrum of this system agreed with the suggestion that the $O_2$ molecule in this complex is in the singlet-excited state. An analysis[161] of a large number of EPR studies of complexes of $O_2^-$ radical-ions with $Ti^{4+}$ and $V^{5+}$ ions showed that the ground state of molecular oxygen in the coordination sphere of these metals must be singlet.

The adsorption of oxygen on the (100) and (110) faces of a single crystal of copper has been studied.[160] Ultraviolet photoelectron spectroscopy identified several forms of adsorbed oxygen, including a molecular form, stable at temperatures of 100–300 K, whose photo-electron spectrum consists of three bands. The authors cited consider that this form is an electronically excited $O_2$ molecule in the state $^1\Sigma_g^+$ (for the triplet $O_2$ molecule the photo-electron spectrum consists of five bands). This state of singlet oxygen, which is unstable in the gas phase, in the opinion of the authors cited is stabilised on the copper surface as a result of adsorption, and can react with various molecules.

The formation and emission into the gas phase of excited oxygen molecules can take place during the recombination of O atoms (a strongly exothermic reaction, $Q = 118$ kcal mole$^{-1}$) on solid surfaces. Thus it has been shown[76] that an appreciable proportion of the energy liberated in the recombination of oxygen atoms on metal surfaces is carried into the gas phase. The authors cited, however, do not indicate precisely in which energy state (vibrationally or electronically excited) the oxygen molecules leave the surface. In Ref.21 it was proved spectroscopically that electronically excited $^1O_2$ molecules are formed during the recombination of O atoms on nickel films. The authors cited consider that the production of an electronically excited $^1O_2$ molecule by the reaction:

$$NiO + O \rightarrow Ni + {}^1O_2 \quad (1)$$

is unlikely. The formation of the $^1O_2$ molecule in this system may take place by the reaction of an adsorbed O atom and an O atom leaving the gas phase:

$$NiO.O(ads) + O(gas) \rightarrow NiO + {}^1O_2 \quad (2)$$

Here, the excitation energy is determined by the dissociation energy of $O_2$ after subtraction of the energy of the bond formed by O(ads) with the NiO surface.

The emission of singlet oxygen as a result of the recombination of O atoms on Pyrex has been detected.[158] The probability of the formation of $^1O_2$ in this process is 0.2–0.4 (depending on the conditions of the experiment).

$^1O_2$ molecules can also be obtained as a result of the reaction of oxygen atoms with metal oxides. Mercury oxide has been studied in most detail in this connection. Even in early studies of the formation of singlet oxygen in electrical discharges in oxygen[19,20] it was noted that when the stream of active particles from the discharge passes over a film of mercury oxide there is a significant increase in the concentration of singlet oxygen in the gas phase, determined from the intensity of the spectral bands of $^1O_2$. The authors cited[20] consider that the singlet oxygen molecules are formed as a result of the reaction of oxygen atoms with mercury oxide.

In Ref.17, semiconducting detectors of singlet oxygen were used for the first time to study the emission of $^1O_2$ in this system. The O atoms were generated on a platinum filament and diffused to a film of HgO.

The dependence of the intensity of the signal of the detector (which was at room temperature) on the temperature of the thermal-decomposition filament was used to calculate the activation energy (53 kcal mole$^{-1}$) of this process, which was found to be approximately half the energy of rupture of the bond in the oxygen molecule. The result indicates that the magnitude of the signal in these experiments is proportional to the concentration of singlet oxygen, and that the emission of $^1O_2$ from the HgO surface is a reaction of first order with respect to oxygen. According to data on the change in the electrical conductivity of the detector, the ratio of the intensities of the fluxes of the O atoms falling on the HgO surface and the $^1O_2$ molecules leaving is close to 1, that is this reaction has a high efficiency.

The data obtained agree with the mechanism proposed in Ref.20:

$$HgO + O \rightarrow Hg + {}^1O_2 \quad (3)$$

The activation energy of reaction (3) is 5 kcal mole$^{-1}$, which is characteristic of processes involving oxygen atoms.[86]

As shown by Eqn.(3), the oxygen atoms reduce the mercury oxide surface, and this was observed visually from the darkening of the HgO film. As reduction proceeds, another process, competing with reaction (3), begins to play a larger role, namely the oxidation of the newly formed mercury atoms, leading to a decrease in the intensity of the flux of $^1O_2$ molecules from the HgO surface:

$$Hg + O \rightarrow HgO$$

During the experiment, the high initial intensity of the $^1O_2$ flux decreased regularly to a stationary value. Thus with a constant flux of primary active species, that is O atoms, the state of the HgO surface reflects redox reactions taking place simultaneously to establish a stationary flux of $^1O_2$ molecules into the volume.

Comparison of the results with published data[20,96] indicates that metal oxides whose surface layers can be even partially reduced by oxygen atoms (for example lead, silver, or mercury[96]) liberate $^1O_2$ molecules in the course of this reaction. This effect is observed because the energy of the bond formed by oxygen in the surface layer of, for example, PbO is half the standard enthalpy of formation of this oxide[97] and amounts to 40 kcal mole$^{-1}$. In other words, the emission of $^1O_2$ in reactions of this kind is possible only for those oxides whose surface oxygen atoms are relatively weakly bound in the crystal lattice.

Zav'yalov and Myasnikov[15] described for the first time a study of the formation and emission of singlet oxygen when a disordered quartz surface was heated in an oxygen atmosphere. In this case the energy necessary for the excitation and emission of the oxygen molecules is accumulated during the preliminary disordering of the surface layer of the solid, and is liberated during the relaxation of the disordered surface. It was discovered for the first time that singlet oxygen is liberated when quartz, freshly ground in oxygen (0.13 hPa) or in a vacuum, is heated in $O_2$. The temperature dependence of the intensity of the $^1O_2$ flux from the quartz surface in the range 200–600° is given by a curve with a maximum at 400 °C. The ascending branch of the curve corresponds to an intensification of the ordering of the structure of the surface layer (annealing of defects) with increase in temperature, and the descending branch is possibly related to a decrease in the concentration of defects in the surface layer of the adsorbent. It was noted that the emission of $^1O_2$ molecules is accompanied by a decrease in the intensity of the EPR signal, apparently as a result of the annealing of paramagnetic defects in the quartz. It is significant that the emission of $^1O_2$ molecules was not observed on fused quartz (which does not contain surface paramagnetic defects).

On isothermal heating, the rate of the liberation of singlet oxygen gradually decreases, and the kinetics of this process do not obey the equation for a unimolecular reaction. Thus the formation and emission of singlet oxygen molecules from the quartz surface are more complex than the simple decomposition of surface compounds with the liberation of $^1O_2$ into the gas phase, and are apparently determined by the annihilation of defects in the quartz layers next to the surface in the presence of $O_2$.

Another method can also be used to activate a quartz surface with respect to $^1O_2$ emission. In Ref.98 it was discovered that when a quartz vessel in which a stoichiometric $H_2 + O_2$ mixture had previously been exploded was heated under programmed conditions to temperatures of 400–500 °C at an $O_2$ pressure of 0.13 hPa, emission of singlet oxygen into the gas phase begins. The temperature dependence of the emission of $^1O_2$ in this case is similar to that for the surface of ground quartz. Thus for quartz surfaces "perturbed" in different ways, the relaxation of the disordering of the surface layers in the presence of $O_2$ is accompanied by the production of singlet oxygen. The result is also of interest in relation to the participation of the walls of a reaction vessel in the production and emission of excited species in chain processes taking place at low pressures.

The conditions of the formation and emission of singlet oxygen from the surface of an Li–Sn–P catalyst have been studied.[16] When oxygen (4 hPa) or air is blown through a U-shaped quartz reaction vessel containing tablets of an oxide catalyst (58.4% Sn, 10% P, and 1.5% Li), heated to 650 °C, singlet oxygen is liberated into the volume, as established from the change in the concentration of a solution of rubrene in hexadecane, placed in a cell separated from the reaction vessel (rubrene is a specific reagent for singlet oxygen[7]). More than 20 oxide catalysts were studied. The intensity of the emission of singlet oxygen from the catalyst surface was estimated from the degree of transformation of rubrene 1 h after the start of the experiment. This quantity was 30–50% for the lithium–tin–phosphate catalysts, and 1% in the absence of lithium, as in the case of manganese and cobalt oxides.

The rate of the liberation of $^1O_2$ increased with increase in temperature. The duration of the emission was 4 h. The process did not stop when oxygen was replaced by argon. The authors cited concluded that this indicates that $^1O_2$ is formed with the participation of surface oxygen on centres which break down in the course of the reaction or on the decomposition of unknown impurities in the catalyst. It is suggested that lithium in this system is converted into the superoxide, facilitating the generation of singlet oxygen. Singlet oxygen was not liberated when other catalysts, ZnO, $Ag/Al_2O_3$, $CaO/Al_2O_3$, $Cr_2O_3/Al_2O_3$, etc. were heated.

The emission of singlet oxygen from the surface of vanadium pentoxide, a widely encountered oxidation catalyst, has been observed.[23] $^1O_2$ molecules are emitted into the gas phase when $V_2O_5$ powder is heated in an atmosphere of ordinary oxygen to 300–500 °C. The initial intensity of the liberation of $^1O_2$ increases with increase in temperature. At a constant $O_2$ pressure (0.13 hPa) and a constant temperature, the emission of $^1O_2$ continues for several hours. The activity of the catalyst is restored after heating in $O_2$ at a temperature of 600 °C and atmospheric pressure. In contrast to the experiments at low $O_2$ pressures, the intensity of the $^1O_2$ flux remains unchanged with time at atmospheric pressure. From this the authors cited conclude that the emission of singlet oxygen from the $V_2O_5$ surface may be due to reversible structural-chemical transformations in the catalyst, taking place at high $O_2$ pressures and high temperatures. The observation that continuous emission of $^1O_2$ from a $V_2O_5$ surface takes place at atmospheric pressure of oxygen is important for an understanding of the mechanism of stationary oxidation reactions on this catalyst.

This is confirmed by the results of a comparison[99] of the regular features of the emission of singlet oxygen from a vanadium pentoxide surface and the oxidation of naphthalene on the same catalyst. The intensities of the two processes (the emission of $^1O_2$ and the formation of phthalic anhydride) changed in the same sense with change in the conditions of the experiments (treatment of the catalyst with the reaction mixture, heating in a vacuum, etc.). It was also established that naphthaquinone, one of the intermediate products of the oxidation of naphthalene, is formed at a low concentration of singlet oxygen. Thus the participation of singlet oxygen in the heterogeneous catalytic oxidation of organic substances was proved experimentally for the first time for the case of the oxidation of naphthalene to phthalic anhydride on a vanadium catalyst. These data indicate that singlet oxygen plays an important role in oxidation processes taking place by both heterogeneous and heterogeneous–homogeneous mechanisms.

Finally, it is appropriate to draw certain conclusions about the regular features of the emission of singlet oxygen from solid surfaces into the gas phase. The improvement of old methods for detecting singlet oxygen and the development of new methods, in particular the use of semiconducting $^1O_2$ detectors,[17,51] have made it possible to extend considerably the range of the study of physico-chemical processes leading to the formation and emission of singlet oxygen and to establish various characteristic features of their mechanism. In all cases, singlet oxygen is formed as a result of the transfer of excitation energy from a solid or an adsorbed layer to oxygen molecules. The source of this energy may be light (photochemical reactions), the energy of the recombination or reaction of atomic oxygen with metal oxides (chemical reactions), thermal energy (the decomposition of various metal oxides), or energy liberated in the disordered surface layers of a solid during their ordering (structural-chemical processes). All this indicates that it is highly probable that singlet oxygen also appears in other processes in which a solid is excited in the presence of oxygen, for example under the influence of electrons, ions, radiation of different kinds, and in general as a result of reactions leading to marked and reversible breakdown of the structure of the surface layers of solids.

Particular mention may be made of the as yet limited data[159–161] on the possible formation of singlet oxygen on the surface of solids as a result of the adsorption of $O_2$. An early suggestion,[162] subsequently discussed repeatedly,[1,163] proposed that the surface compounds formed on the chemisorption of molecules could be regarded as electronically excited states of these molecules. This idea has been confirmed for the case of $^1O_2$. In a number of cases, marked perturbation of the adsorbed oxygen molecules takes place, and the singlet-excited state of $O_2$ is produced. Thus in the case of oxygen there is apparently an analogy between the properties of electronically excited and surface-coordinated molecules.

## 4. The Formation and Emission of Electronically Excited Metal Atoms and Nitrogen Molecules from Solid Surfaces

There are few published data on the emission of electronically excited nitrogen molecules from solid surfaces.

A number of papers by Mannella and co-workers,[100–102] published in the nineteen-sixties, described the luminescence of the surfaces of cobalt and nickel during the simultaneous recombination of nitrogen and oxygen atoms. The experiments were carried out in a flow system at a pressure of 1.3 hPa. The stream of nitrogen and oxygen atoms, obtained in a discharge, was passed over the surface of metallic nickel or cobalt inserts embedded in a glass tube. The luminescence of the gas was recorded at the outlet from the reaction zone. The luminescence spectra in the case of cobalt showed the first positive bands of nitrogen. The authors cited consider that electronically excited $N_2(B^3\Pi_g)$ molecules, with an excess of vibrational energy ($v = 6, 8$), are formed on the cobalt surface and are desorbed into the gas phase, where they emit light as a result of the transition:

$$N_2(B^3\Pi_g) \rightarrow N_2(A^3\Sigma_u^+) + h\nu$$

In the case of nickel, the luminescence spectrum of the gas shows both the first positive bands of nitrogen and the β-bands of nitric oxide. The authors cited suggested that the species desorbed from the nickel surface are electronically excited $NO(B^2\Pi)$ molecules, which subsequently either lose energy:

$$NO(B^2\Pi) \rightarrow NO(X^2\Pi) + h\nu \ (\beta\text{-band of NO})$$

or react with nitrogen atoms:

$$NO(B^2\Pi) + N(^4S) \rightarrow N_2(B^3\Pi_g) + O(^3P)$$

$$N_2(B^3\Pi_g) \rightarrow N_2(A^3\Sigma_u^+) + h\nu \ (\text{first positive band of nitrogen})$$

In Ref. 102, the luminescence of $N_2^*$ molecules above a nickel surface was observed only in the presence of O atoms.

The emission of various electronically excited atoms and molecules from solid surfaces also takes place as a result of electron bombardment. The extensive literature on electronically stimulated desorption (ESD) includes recent papers on the ESD of excited species. The ESD of excited Na, K, and Li atoms from NaCl, KCl, and LiF surfaces has been studied.[103,104,164] The intensity ($I$) of the resonance emission of the excited atoms was measured, and the dependence of $I$ on the energy ($E$) of the electron beam (20–1000 eV) determined. The $I = f(E)$ curves for NaCl showed characteristic features which correlate with the energies of the electron levels of Na and Cl ions in the halide lattice. For example, for Na the luminescence appearance threshold (32 eV) is close to the 2$p$ level of Na (31 eV), and the increase in $I$ at 65 eV is associated with the 2$s$ level of Na (63 eV). The fine structure at 200 eV on the $I = f(E)$ curve corresponds to the 2$p$ level of Cl (200 eV and 202 eV). A mechanism was proposed for the ESD of Na*, according to which $Na^{2+}$ ions are formed in the first stage. Subsequently, an Auger process produces $Na^+$ ions, which pass through the matrix next to the $Cl^-$ ions in the surface layer and are neutralised with the formation of a resonance excited Na* atom. The radiative deactivation of Na* takes place beyond the NaCl surface.

A characteristic feature is that the excitation of the Na, K, and Li atoms takes place on the surface of the crystals, and not in the gas volume. This conclusion is based on the following facts: 1) the vapour pressure of the metals, determined by the temperature of the surface in the electron emission zone, is too low, and 2) slight displacement of the crystal target from the direction of the electron beam leads to disappearance of the effect.

The authors cited also found that excited hydrogen atoms and hydroxyl radicals are emitted in addition to metal atoms.

An energy analysis of the ESD relationships for excited alkali metal atoms[165] established that the transfer of the energy of the electrons takes place as a result of the formation of holes in the inner levels of the atoms. In subsequent stages, various electronic processes produce excited metal atoms, which are ejected from the surface. A characteristic feature is that the atoms are desorbed in the first (lowest) excited state.

The ESD of excited atoms and ions from different surfaces was described in Refs. 166–168. When a glass surface was irradiated with an electron beam (300 eV) at low cadmium vapour pressures ($10^{-3}$ hPa), emission of excited cadmium ions took place, detected by the luminescence at 441.6 nm and 537.8 nm.[166] The same authors[167] previously detected the emission of excited cadmium ions from the surface of silvered copper.

Mass spectrometry has been used[168] to study the ESD of hydrogen ions and atoms from an Ni (111) surface covered with a film of water. It was found that at an electron energy of 22–30 eV, $H^+$ ions are ejected into the volume, whereas at 35 eV, electronically excited metastable H atoms in the (2$s$) state are ejected. It is emphasised that the metastable hydrogen atoms are not formed from $H^+$ ions, since the energy of the ejected H atoms is 4–5 eV higher than the energy of the desorbed $H^+$ ions.

Finally, emission in an electronically excited state takes place during the ionic sputtering of materials. Charged and neutral species in different states are formed on the surface and ejected into the gas phase.

Data on the emission of the species produced when solid surfaces are bombarded by inert gas or hydrogen ions with energies from 1 to thousands of eV have been reviewed.[169] Spectroscopic methods have been used to detect the excited species formed in various processes: 1) the scattering of the excited state of the atoms of the primary beam; 2) the emission from the excited state of atoms, molecules, or complexes formed from the atoms of the target; and 3) the formation of excited states of adsorbed molecules. The materials studied were mainly metals, and some metal oxides.[170] The mechanism of the emission by excited atoms and ions has recently been studied using a new spectroscopic method, involving the measurement of the Doppler shift of the fluorescent atoms ejected from metal surfaces during ionic sputtering (the fluorescence is excited by a laser light beam). For example, the yields and velocity distribution of sputtered barium atoms in the ground and metastable states Ba($^1S$) and Ba($^1D$) have been measured, and the influence of oxygen on these characteristics studied.[171] In Ref. 172, a similar study was carried out using metastable Fe* atoms sputtered from an iron surface. Studies in this field are developing rapidly.

The reported observation[173] of the formation of excited Na atoms on an NaCl surface during the recombination of deuterium atoms is of interest. On thin films of NaCl, for which the coefficient of the heterogeneous recombination of D atoms is high, the spectrum of the luminescence observed corresponds to the D line of sodium atoms. It is not clear, however, whether emission of Na* atoms takes place in this case.

Overall, it appears that published data on the emission of excited metal atoms deal only with the cases of the "strong" perturbation of solid surfaces by electron or ion bombardment. There are practically no published data on the emission of these species under "mild" conditions (chemical and structural-chemical processes, ultraviolet irradiation, etc.).

## III. THE DEACTIVATION OF ELECTRONICALLY EXCITED ATOMS AND MOLECULES ON A SOLID SURFACE

In the reaction of electronically excited atoms and molecules with a solid surface, their deactivation can take place by the following paths: 1) relaxation of the excited state as a result of the dissipation of the excitation energy in the adsorbed layer and in the surface layers of the solid, which may involve both phonons and the electronic sub-structure of the crystal; 2) chemical reaction with atoms of the surface or the adsorbed layer; and 3) luminescence of electronically excited molecules in the adsorbed layer.

From a comparison of the values of the coefficients of the heterogeneous deactivation $\gamma$ of electronically excited atoms and molecules (the terms deactivation, relaxation, or accommodation coefficient are also used), it is difficult to decide which deactivation channel predominates, since the value of $\gamma$ gives a representation of the overall activity of different materials with respect to their reaction with excited species.

As shown below, in a number of cases it is possible to reach a conclusion about the mechanism of deactivation from the dependence of the value of $\gamma$ on the conditions of the experiment, which alter the properties of the solid which are "sensitive" to the transfer of the energy of the excited atoms and moelcules. There have been practically no studies of the microscopic mechanism of the heterogeneous deactivation of electronically excited molecules.

Data have been published on the reactions of various solid surfaces with singlet oxygen, metastable inert gas atoms and nitrogen molecules, and triplet molecules of organic substances.

## 1. Electronically Excited Oxygen Molecules

The heterogeneous deactivation of singlet oxygen has been studied in most detail. It is appropriate to examine three classes of surface differing in their activity with respect to the deactivation of $^1O_2$ ($^1\Delta_g$) molecules: dielectrics ($\gamma = 10^{-5}-10^{-3}$), metal oxides ($\gamma = 10^{-4}-1$), and metals ($\gamma = 10^{-5}-1$).

Most values of $\gamma$ on glass and quartz surfaces have been obtained by studying the gas-phase reactions of singlet oxygen, since the reaction vessels are usually made of these materials. The studies are usually carried out in a flow apparatus, and the singlet oxygen is obtained by a discharge in oxygen. This procedure has a number of significant unsatisfactory features: firstly, in a flow apparatus it is difficult to achieve the necessary cleanliness of the surface, since lubricant vapour is present, contamination from the gas phase is possible, etc.; secondly, in the generation of singlet oxygen in a discharge there are active products (oxygen atoms, ozone, etc.), which modify the surface. Moreover, at a high concentration of singlet oxygen the surface may again be modified, and this should lead to a change in the heterogeneous deactivation coefficient. For example, in Refs.106–109, 118, and 158, the coefficient of the deactivation of singlet oxygen on Pyrex varied from $7.6 \times 10^{-6}$ to $5 \times 10^{-5}$. These results show convincingly that the magnitude of the coefficient of the heterogeneous deactivation of singlet oxygen is influenced considerably by the conditions of the experiment. This conclusion is confirmed by studies[2,140] in which a change in $\gamma$ in the course of the experiment was observed, indicating that the surface is modified during the measurements. In Ref.105, the value of $\gamma$ on silicon increased slowly with time. In the works cited, no mechanism was proposed for the deactivation of singlet oxygen, and all the values were obtained only for room temperature.

Thus to investigate the mechanism of the deactivation of singlet oxygen on a solid surface, it is necessary to carry out studies under clean conditions (high vacuum, absence of surface contaminants, a selective source of singlet oxygen) and at low concentrations of singlet oxygen.

Attempts have been made to satisfy these conditions.[112] The experiments were carried out under diffusion conditions, and the surface was treated by heating at 250–300 °C in a high vacuum ($10^{-7}$ hPa), achieved using oil-free magnetic-discharge and zeolite pumps. Singlet oxygen was obtained by photosensitisation by an adsorbed dye (trypaflavine). The gas phase did not contain any other active species. The concentration of singlet oxygen in the gas phase ($10^{10}$ cm$^{-3}$) was measured using semiconducting detectors. With increase in the temperature of the surface, the deactivation coefficient of singlet oxygen on glass decreases, and at 373 K is equal to $10^{-6}$ ($\gamma = 10^{-5}$ at 293 K). The activation energy of the change in $\gamma$ is negative and equal to 6 kcal mole$^{-1}$. $\gamma$ is independent of the oxygen pressure in the range $1-10^{-2}$ hPa. These data indicate that on a glass surface, singlet oxygen is deactivated as a result of physical adsorption with subsequent transfer of energy to the solid; this process is analogous to the relaxation of vibrationally excited nitrogen molecules on silver and Teflon at low temperatures.[111] The mechanism of the deactivation corresponds to the following scheme:

$$^1O_2 + Z \underset{k_{-1}}{\overset{k_1}{\rightleftarrows}} {}^1O_2Z$$

$$^1O_2Z \xrightarrow{k_2} {}^3O_2Z$$

where $Z$ is an adsorption centre.

If the rate of deactivation of $^1O_2$ is much lower than the rate of desorption ($k_2 \ll k_{-1}$), the adsorption of singlet oxygen on the surface can be regarded as a quasi-equilibrium process, and described by the Langmuir isotherm. Since the concentration of singlet oxygen is low, it can be assumed that the adsorption takes place in the Henry range. Thus

$$\gamma = \frac{4k_H k_2 kT}{\bar{v}} \frac{S}{V}$$

where $k_H$ is the Henry constant, $S$ the surface area, $V$ the volume, $k$ the Boltzmann constant, $P$ the temperature, and $\bar{v}$ the average velocity of the particles.

The scheme describes the experimental results satisfactorily. The activation energy for the change in $\gamma$ in this case is equal to the heat of adsorption of singlet oxygen on the glass surface.

The Henry constant can be estimated by the method of Zweitering and Krevelen:[141]

$$k_H = \frac{N_A}{(2\pi MRT)^{1/2}} \tau_0 \exp(Q/RT)$$

where $N_A$ is Avogadro's number, $M$ the molecular mass of the gas, $R$ the gas constant, $\tau_0$ the period of one vibration of the adsorbed molecule in a direction perpendicular to the surface, and $Q$ the heat of adsorption.

The measured coefficient of the heterogeneous deactivation of the species ($10^{-5}$ at room temperature) and the heat of adsorption (6 kcal mole$^{-1}$) can be used to estimate the relaxation time of the energy of singlet oxygen on the glass surface:

$$\tau_{rel} = k_3^{-1} = \frac{4k_H kT}{\gamma \bar{v}} = \gamma^{-1}\tau_0 \exp(Q/RT)$$

For $\tau_0 = 10^{-12}-10^{-13}$ s, $\tau_{rel} = 10^{-3}-10^{-4}$ s. This value is very much higher than the relaxation time of vibrationally excited nitrogen molecules on glass ($10^{-8}$ s),[111] apparently because of the difficulty of the relaxation of the comparatively high energy (1 eV) on the surface.

In Ref.89, the relaxation time of singlet oxygen on a KBr surface was found to be greater than $10^{-2}$ s. In Refs.110 and 142, the factors influencing the heterogeneous deactivation of singlet oxygen were investigated by another method. The temperature dependence of the coefficient of the heterogeneous deactivation of singlet oxygen on quartz was determined by the standard method (flow system, $^1O_2$ produced by an ultrahigh-frequency discharge in oxygen) at temperatures of 350–900 K. In addition, the surface was modified by the adsorption of gases, as in Refs.143 and 150. The value of $\gamma$ was measured by estimating the degree of deactivation of $^1O_2$ on a quartz rod introduced into the reaction vessel or directly on the walls of the cylindrical quartz reaction vessel. In the first case, in the temperature range 520–830 K at an $O_2$ pressure of 0.6 hPa, $\gamma = (7.4 \pm 0.5) \times 10^{-3}\exp(18.5 \pm 1.0/RT)$, where the activation energy is given in kJ mole$^{-1}$. In the second case, with increase in temperature from 350 K to 600 K, $\gamma$ increases from $1.1 \times 10^{-4}$ to $1.8 \times 10^{-3}$ (the activation energy is 18.5 kJ mole$^{-1}$), but with further increase in temperature it remains unchanged up to 900 K. The values of $\gamma$ differ by a factor of approximately 10, apparently due to a difference in the concentration of deactivation centres. Under the chosen conditions, the value of $\gamma$ was independent of the oxygen pressure. When $H_2O$, $NH_3$, or oxygen atoms were added to the stream of oxygen, the concentration of $^1O_2$ increased, indicating a decrease in the deactivation of $^1O_2$. The addition of Ar, $H_2$, CO, or $C_2H_4$ had little influence on the deactivation. These data confirm the chemisorption mechanism of the deactivation of $^1O_2$ on the surface centres of quartz. When the quartz has been heated, the number of free centres increases (and $\gamma$

increases), and when active gases are introduced, the centres are blocked ($\gamma$ decreases). The nature of these centres has not yet been determined. The authors cited[110,142] consider that these centres may be radical peroxide forms of oxygen.

After the adsorption of benzene on the glass surface, $\gamma$ was found to be $4 \times 10^{-5}$.[143]

When all the material on the deactivation of $^1O_2$ on quartz and glass surfaces is reviewed, it is possible to make some generalisations. At temperatures close to room temperature, the deactivation coefficient is $10^{-5}$, and the deactivation mechanism apparently involves the physical adsorption of $^1O_2$. At higher temperatures and concentrations of singlet oxygen, deactivation takes place by a chemisorption mechanism. The nature of the adsorption centres and the mechanism of the relaxation of the energy of $^1O_2$ on the glass surface is still not clear.

The deactivation of singlet oxygen on the surface of metal oxides has been studied for the case of zinc and oxide.[112] With increase in temperature, the value of $\gamma$ increased from $10^{-4}$ to $10^{-2}$, and the activation energy of the change in $\gamma$ was 25 kcal mole$^{-1}$. $\gamma$ decreased with increase in the oxygen pressure (in the range $5 \times 10^{-2}$–2 hPa). It was suggested that in this case the deactivation of singlet oxygen takes place as a result of its chemisorption on the zinc oxide surface:

$$^1O_2 + Z \underset{k_{-3}}{\overset{k_3}{\rightleftarrows}} {}^1O_2Z$$

$$^3O_2 + Z \underset{k_{-4}}{\overset{k_4}{\rightleftarrows}} {}^3O_2Z$$

$$^1O_2Z \xrightarrow{k_5} {}^3O_2Z$$

where $Z$ is an adsorption centre.

According to this scheme, the loss of the energy of electronic excitation is due to the formation of a chemical bond, that is chemisorption. If the residence time of the singlet oxygen molecule in the adsorbed state is greater than the time for the loss of the excitation energy, that is $k_{-3} \ll k_5$, then in accordance with the method of stationary concentrations it is possible to write:

$$\gamma = \frac{s_1}{s_1[^1O_2]/[^3O_2] + s_2} \cdot \frac{4k_{-4}[Z]}{\bar{v}[^3O_2]} \qquad (5)$$

where $s_1$ and $s_2$ are the adhesion coefficients of $^1O_2$ and $^3O_2$, and $\bar{v}$ the average velocity of the particles. It follows from Eqn.(5) that $\gamma$ should decrease with increase in pressure, in agreement with the experimental data. The temperature dependence of $\gamma$ is determined by the rate constant of the desorption of $O_2$ from the zinc oxide surface (that is $k_{-4}$). Increase in temperature leads to an increase in the number of free centres for the chemisorption of $^1O_2$, and $\gamma$ increases. The measured value of the activation energy of the change in $\gamma$ (25 kcal mole$^{-1}$) agrees with published data for the activation energy of the desorption of oxygen from a ZnO surface (23 kcal mole$^{-1}$).[114] Under the conditions of the experiment, equilibrium chemisorption of oxygen on the zinc oxide surface is achieved, since $\gamma$ changes little with time. The nature of the centres for the chemisorption of singlet oxygen is of considerable interest. Thus the electrical conductivity of a film of zinc oxide decreases under the influence of $^1O_2$.[17] The decrease in the concentration of conductivity electrons may take place as a result of the formation of a chemical bond between a singlet oxygen molecule and a superstoichiometric ionised surface zinc atom. In this case the coefficient of the heterogeneous deactivation of singlet oxygen on the zinc oxide surface should decrease with decrease in the concentration of zinc atoms, as observed experimentally.

In the reaction of electronically excited molecules, which are chemically inert with respect to zinc oxide (for example the triplet molecules of benzophenone or diacetyl and excited inert gas atoms), the excitation energy of the molecules is transferred to the layer of zinc oxide next to the surface, and the electrical conductivity of the film increases.[144,145] If the surface of the zinc oxide film is deactivated with respect to the chemical action of singlet oxygen, that is if the concentration of zinc atoms acting as chemisorption centres is decreased considerably, a similar effect should be observed. In fact, it has been found[113] that when a source of $^1O_2$ (an ultrahigh-frequency discharge, a photochemical source, or the reaction HgO + O) is included, the electrical conductivity $\sigma$ of the film at the initial moment increases, passes through a maximum, and then decreases. The result can be understood if it is assumed that in the reaction of $^1O_2$ with the ZnO film, two processes take place simultaneously (but at different rates), one of which (the more rapid) is associated with the transfer of the energy of the $^1O_2$ molecule to zinc oxide and hence with an increase in $\sigma$, while the other (the slower) is associated with the chemisorption of $^1O_2$ on the zinc atom impurity centres responsible for the impurity conductivity of ZnO. The extremal character of the change in $\sigma$ is attributed to the competition between these two processes. This system is characterised by chemical deactivation of $^1O_2$. These experiments lead to certain conclusions about the mechanism of the transfer of the excitation energy of singlet oxygen in ZnO. The existence of the donor signal of the change in the electrical conductivity $\sigma$ on the adsorption of $^1O_2$,[113] which was also observed in the reaction of $^1O_2$ with a single crystal of ZnO in a solution of electrolytes,[146] indicates that the excitation energy is transferred to the surface layers of ZnO and brings about the ionisation of fine traps and the ejection of electrons into the conductivity band. The same results were obtained in experiments with zinc oxide photo-currents photosensitised by dyes.[85] Two mechanisms of the photosensitisation have been discussed. One assumes that the excitation energy is transferred to the semiconductor, and the other that the excited dye is ionised. When singlet oxygen is adsorbed on the surface of the semiconductor, the second mechanism is unlikely, since it is difficult to imagine the formation of positive oxygen ions.

There are few published data on the reaction of $^1O_2$ with other metal oxides. The adsorption of $^1O_2$ on magnesium, nickel, and cobalt oxides has been studied.[147,148] On MgO there is weak adsorption of $^1O_2$, which decreases with increase in temperature from −78 °C to 20 °C (the adsorption of ordinary triplet oxygen on MgO increases with increase in temperature). The adsorption of $^1O_2$ on NiO takes place with a greater intensity than on MgO, and is independent of temperature. In the case of $Co_3O_4$, no differences in the adsorption of singlet and triplet oxygen could be observed. The authors cited did not examine the mechanism of the reaction of $^1O_2$ with the oxides. On the surface of cobalt oxides, the coefficient of the heterogeneous deactivation of $^1O_2$ is high (~1).[152] This property has been made the basis of a calorimetric method for measuring the concentration of $^1O_2$. The mechanism of the reaction of singlet oxygen with cobalt oxides is not clear. The strong heating of the $Co_3O_4$ film may be due not only to a thermal mechanism of deactivation but also possibly to a chemisorption mechanism, involving the heat of chemisorption.

The heterogeneous deactivation of singlet oxygen on a dye surface (trypaflavine) has been studied.[66] With increase in temperature from 293 K to 343 K, $\gamma$ increases from $10^{-3}$ to $10^{-2}$. The same dependence of $\gamma$ on the $O_2$ pressure was observed for zinc oxide, so that the deactivation of singlet oxygen takes place by a chemisorption mechanism, and the

activation energy of the change in $\gamma$ is the activation energy of the desorption of oxygen from the dye surface.

The heterogeneous deactivation of $^1O_2$ on metal surfaces has been the subject of a number of studies. The concentration of $^1O_2$ was measured from the singlet oxygen luminescence. The experiments were carried out at pressures of from tenths to several hPa, in a flow system. The following values of $\gamma$ were obtained at room temperature:[105] Al ($5.9 \times 10^{-5}$), Ti ($6.5 \times 10^{-5}$), Mo ($8.0 \times 10^{-5}$), Nb ($1.2 \times 10^{-4}$), Pt ($4.0 \times 10^{-4}$), Cu ($8.5 \times 10^{-4}$), Ni ($2.7 \times 10^{-3}$), Fe ($4.4 \times 10^{-3}$), and Ag ($1.1 \times 10^{-2}$). The results of the measurements for Ag, Pt, and Al agree with the data obtained by other authors, for example in Ref.115. On a stainless steel surface, $\gamma$ varied from $7.6 \times 10^{-6}$ to $1.3 \times 10^{-5}$ at room temperature.[149] The coefficient of the heterogeneous deactivation of singlet oxygen on a gold surface with previously adsorbed HCl is $(1-3) \times 10^{-3}$.[150] On an annealed Au specimen, the value of $\gamma$ changed from $5 \times 10^{-2}$ to $2 \times 10^{-1}$ in the temperature range 300–900 K. The adsorption of water at 300 K led to a decrease in $\gamma$ by a factor of 20.[142,151] In the opinion of the authors cited, these results confirm that the deactivation of $^1O_2$ on an Au surface takes place by a chemisorption mechanism:

$$AuO + O_2(^1\Delta_g) \rightarrow AuO{-}O_2(^1\Delta_g) \rightarrow AuO + O_2(^3\Sigma_g^-)$$

It was suggested that the bond formed by the chemisorbed $^1O_2$ with gold oxide is strong, and that its energy is transferred to some degrees of freedom of the metal. Ordinary oxygen is not chemisorbed on these centres, and is readily liberated into the gas phase. By analogy with the gas-phase reactions of excited species, the proposed mechanism was described as an excimer mechanism. On a strongly hydroxylated gold surface, the chemisorption of $^1O_2$ is impossible, the value of $\gamma$ is much lower, and the deactivation mechanism is different.

Other regular features were observed for platinum. On the surface of a Pt wire, $\gamma$ increases from $10^{-3}$ to $10^{-1}$ with increase in temperature from 300 K to 450 K. The value of $\gamma$ is almost independent of the $O_2$ pressure in the range 0.17–6.0 hPa. The effective activation energy decreases with increase in temperature, from 46.5 kJ mole$^{-1}$ at 300 K to 0 at 450 K. The addition of water and hydrogen does not influence the rate of the deactivation of $^1O_2$, but the introduction of CO (7%) decreases $\gamma$ at 400 K by a factor of ten. The authors cited consider that these results are consistent with a chemisorption mechanism. The increase in $\gamma$ with temperature was related to an increase in the number of active centres on the surface, and the limiting stage is the adsorption of singlet oxygen on the free centres. These centres may be various forms of adsorbed oxygen. The action of CO involves either the blocking of these forms of oxygen or their removal from the surface as a result of a chemical reaction.

The value of $\gamma$ for nickel was found to be close to 1.[157]

Thus on metal surfaces the values of the coefficients of the heterogeneous deactivation of $^1O_2$ differ by several powers of ten, from $10^{-5}$ for Al to 1 for nickel. It should be noted that these values relate rather to the oxidised surface of the metals, since the measurements were made under fairly "severe" conditions (a high concentration of $^1O_2$ in a stream of oxygen). The results of the measurements depend on the conditions of the evacuation and the treatment of the specimens, particularly at high temperatures, and also on the composition of the adsorption layer. Thus in the discussion of a particular value of $\gamma$ it is necessary to specify clearly the conditions of the experiments. There are few published data on the heterogeneous deactivation of the $^1O_2$ molecule in the state ($^1\Sigma_g^+$). The deactivation coefficient of this species was determined by measuring the intensity of the 7618 Å line in a stream of oxygen, passed through a discharge and mercury oxide, after reaction with a metal insert. According to Ref.115, for $^1O_2(^1\Sigma_g^+)$, $\gamma$ has the values 0.3 (Fe), 0.25 (Al), 0.9 (Cu), 0.6 (Ag on Pt), and ~0 for pure Pt. Thus on all these metals (except Pt) the deactivation coefficient is very high. For a glass surface, the following values of $\gamma$ were obtained: $10^{-3}-10^{-2}$,[116] $1.5 \times 10^{-2}$,[117] $0.9 \times 10^{-2}$,[118] $10^{-2}$,[119] and $2 \times 10^{-2}$.[107] The average value of the deactivation coefficient of $^1O_2(^1\Sigma_g^+)$ on glass is $10^{-2}$, which is $10^3$ times that for the state ($^1\Delta_g$). The lowest value of $\gamma$ was obtained for a glass surface covered with a halocarbon lubricant, $1.1 \times 10^{-3}$.[154] The shrot lifetime and the high efficiency of the deactivation of $^1O_2(^1\Sigma_g^+)$ are the chief reasons for the considerable experimental difficulty of measuring $\gamma$, and this explains why few papers on this topic have been published. The published data indicate that the efficiency of the deactivation of singlet oxygen depends markedly on the excitation energy. The deactivation coefficient is higher (by a factor of $10^2-10^3$) for the ($^1\Sigma_g^+$) state which has a higher energy than $O_2(^1\Delta_g)$, and this is related to the high efficiency of the conversion of the state ($^1\Sigma_g^+$) into ($^1\Delta_g$) on collision with the surface, and probably to the high chemical activity of the state ($^1\Sigma_g^+$). For oxygen in the $A\,^3\Sigma_u^+$ state with even higher energy, the deactivation coefficient on glass is ~1.[153]

In spite of the progress made in the study of the mechanisms of the deactivation of singlet oxygen on solid surfaces, all the studies discussed above have a significant unsatisfactory feature. In these studies the state of the surface was not examined by structure-sensitive methods, and this is necessary in the determination of the singlet oxygen adsorption centres.

### 2. Metastable Inert Gas and Mercury Atoms and Nitrogen Molecules

The heterogeneous deactivation of the metastable atoms of inert gases (MAIG) on metal surfaces is accompanied by secondary electron emission (SEE). There are two SEE mechanisms:[120,121] a two-stage mechanism based on the resonance ionisation (RI) of an incident excited atom, followed by Auger neutralisation (AN) of the ion formed, and a single-stage mechanism involving Auger deactivation (AD).

The mechanism predominating is determined by the position of the excitation level of the incident atom relative to the Fermi level of the metal, and by the ratio of the work function of the electron and the ionisation potential of the excited atom. For clean metal surfaces with a high work function, deactivation takes place by an RI + AN mechanism. If the ionisation potential is smaller than the work function, the process takes place by an AD mechanism. It should be noted that the presence of an adsorbed layer, which changes the work function and the conditions on the metal surface, may lead to a change in the deactivation mechanism, and in a number of cases to the existence of both mechanisms.[95] An important feature is that, irrespective of the deactivation mechanism, the SEE efficiency is high. This makes it possible to use the magnitude of the emission of secondary electrons to estimate the intensity of the heterogeneous deactivation on metal surfaces. No systematic quantitative determinations of the coefficients of heterogeneous deactivation $\gamma$ for different metals have been carried out. Published data[95] indicate that on metals, the value of $\gamma$ is close to 1.

The study of the scattering of atoms and the ejection of electrons has recently been described. Thus the reflection of a beam of He* atoms from different surfaces has been studied by measuring the concentration of He($^1S$) atoms in

the gas phase.[121] The reflection coefficient of the He* atoms was $10^{-6}$ for Cu (110), $5 \times 10^{-6}$ for Pd (110), $1.5 \times 10^{-4}$ for polycrystalline W, $3 \times 10^{-3}$ for Pd covered with CO, and $5 \times 10^{-4}$ for oxidised Pd. Thus only a negligible fraction of the incident metastable He atoms are reflected from the surfaces of these metals, and the deactivation coefficient $\gamma$ is close to 1. In the same work it was found that the reflection coefficients of He*, Ne*, and Ar* atoms from the surface of single crystals of LiF and NaCl are also extremely low and are respectively $2 \times 10^{-4}$, $4.6 \times 10^{-2}$, and $2 \times 10^{-4}$ (LiF), and $1.2 \times 10^{-4}$, $2.8 \times 10^{-3}$, and $10^{-4}$ (NaCl), that is for the surfaces of these dielectrics, as in the case of metals, the deactivation coefficient is close to 1. The authors cited consider that these similar values of the reflection coefficients of the excited atoms for metals and dielectrics indicate that these quantities are independent of the nature of the surfaces. This conclusion, however, does not agree with the data obtained by other workers.

The reaction of beams of He atoms with the surface of the (110) face of a single crystal of tungsten was studied in Ref.122. It was established that the quantity of atoms reflected depends on the angle of incidence of the beam ($\theta$ is the angle between the direction of the beam and the normal to the surface). At low values of $\theta$, a small fraction of the atoms (less than 10%) is reflected, and the coefficient $\gamma > 0.9$. At high values of $\theta$ (70–80°), 50–60% of the incident metastable atoms are reflected, and $\gamma$ is 0.4–0.5. It was also found that for a clean surface, the yield of emitted electrons also depends markedly on the angle of incidence of the excited species, amounting to 5–8% at low angles of incidence and increasing markedly at high values of $\theta$ (60–80°). For an oxidised W surface, the yield reached 40%.

Comparison of published data[120–122] shows that: 1) the deactivation coefficient on metals may be lower than 1; 2) the yield of secondary electrons depends on the magnitude of the angle of incidence of the atoms and the presence of an adsorbed layer on the metal surface, so that the determination of the value of $\gamma$ from the emission of secondary electrons and the comparison of these values for different metals must be carried out with great care; and 3) the presence of an adsorbed layer on the metal surface leads to an increase in the yield of secondary electrons and the reflection coefficient of the metastable atoms.

It should be noted that in the works cited, the experiments were carried out with beams of atoms only on metal single crystals. It may be assumed that the coefficient $\gamma$ will not always be equal to 1 in the case of polycrystalline metal surfaces under flow or diffusion conditions.

There are very few published data for non-metal surfaces. The deactivation coefficients of metastable atoms on semiconductors and dielectrics have not bee measured, and there is no method for studying heterogeneous deactivation for non-metals which is an informative as the SEE method for metals.

Optical methods for recording metastable atoms (MA) in the gas phase, for example laser-induced fluorescence spectroscopy,[123] have not yet been used to study the heterogeneous deactivation of MA, and the traditional absorption-spectroscopic method for measuring rhe concentrations of these species in a flow system has been found to be unsuitable.[124,125] For these reasons, there are few published papers on the heterogeneous deactivation of MA on non-metal surfaces. Apart from the work examined,[121] there are only a few published studies. In Ref.124, the radial concentration gradient of MA of helium in the flux leaving a glow discharge was measured from the intensity of the luminescence (in the visible range) of different forms of helium MA. It was found that the He* atoms are not completely deactivated on the walls, and the deactivation coefficients on glass are 0.35 for He $2^1S$ and 0.11 for He $2^3S$. In Ref.125, an optical method was also used to determine the radial distribution of MA in a tube through which a stream of gas was passed after a discharge, and it was found that for Pyrex, $\gamma_{He^*} < 0.75$ and $0.12 < \gamma_{Ar^*} < 0.5$.

The reflection of a beam of inert gas MA from different surfaces has been studied.[126] The SEE was measured inside a metal cylinder when the MA struck the end face, which consisted of targets of different materials. The values of the reflection coefficients of the MA on glass and stainless steel were 0.01 for He*, 0.02 for Ne*, and 0.03 for Ar*, that is the values of $\gamma$ were close to 1. In Ref.155, the deactivation of excited argon ($^3P_2$) atoms in the gas phase was studied, and the deactivation coefficient on the walls of the quartz reactor estimated ($\gamma > 0.4$).

A new method was recently proposed[127,128,135] for measuring the coefficients of the heterogeneous deactivation $\gamma$ of metastable atoms, based on the use of semiconducting detectors of the active species.[129] A reversible change in the electrical conductivity of a film of ZnO activated by gold micro-crystals was detected on reaction with MAIG.[127] Comparison of the values of the initial rate of change in the electrical conductivity of the detector ($\nu$) and the emission current of the magnesium plate $I_m$ (the detector and the magnesium target were placed in the same vessel) under the conditions of the generation of MA of helium or krypton (a low-voltage discharge with an incandescent cathode, at $10^{-2}$ hPa and room temperature) showed that there is a linear relationship between $\nu$ and $I_m$. The emission current is proportional to the concentration of MAIG in the gas phase.[130] Thus a ZnO/Au film can be used as an MAIG proportional detector. In these experiments, the MAIG concentration was $10^7$–$10^8$ cm$^{-3}$. The range of concentrations measured can be extended considerably both into the range of lower MAIG concentrations (by increasing the sensitivity of the measuring scheme) and into the range of higher concentrations (by strobing the flux of MAIG reaching the ZnO/Au film).

This detector was used to determine the values of $\gamma$ on various surfaces.[127] The change in the concentration of MAIG was measured along a cylinder whose inner surface was covered with the substance being studied, with increase in the distance from the MAIG source. The coefficient $\gamma$ was calculated from the equation

$$\frac{2\gamma}{2-\gamma} = \frac{4Da}{c} \frac{I_1(ar)}{I_0(ar)}$$

where $D$ is the diffusion coefficient, $c$ the thermal velocity of the atoms, $r$ the radius of the vessel, $I_1$ and $I_0$ the Bessel functions of first and zeroth orders, $a$ the slope of the straight line ($n/n_0 - h$), $h$ the distance from the detector to the inlet into the cylinder, $n$ the MAIG concentration at a distance $h$, and $n_0$ the MAIG concentration at the inlet into the cylinder. To confirm that the constant obtained does in fact characterise the heterogeneous and not the homogeneous deactivation of the MA, the values of $\gamma$ in helium were determined at different pressures ($10^{-2}$–$10^{-3}$ hPa). It was found that in this range, $\gamma$ is independent of pressure, that is under the chosen conditions the homogeneous quenching of the excited atoms is not significant. The coefficients $\gamma$ on glass are $2.0 \times 10^{-3}$ (He*), $7.3 \times 10^{-3}$ (Kr*), $3.5 \times 10^{-3}$ (Xe*), and those on polycrystalline zinc oxide $3.4 \times 10^{-3}$, $4.1 \times 10^{-3}$, and $4.4 \times 10^{-3}$ respectively.

The authors cited[127] concluded that the method of detecting MA using semiconducting detectors is highly sensitive, produces little perturbation in the system being studied, and is most suitable for measuring $\gamma$ under diffusion conditions at low MA concentrations. The deactivation of inert gas MA on glass and ZnO is described by an equation of first order with respect to the MA concentration in the gas phase.

The same method was used to measure the values of $\gamma$ for discontinuous films of gold on glass and zinc oxide.[128] It was found that $\gamma$ depends on the gold concentration (the covering coefficient $f$) on the surface of the support. Thus for the Au/glass system, the value of $\gamma$ was 0.17 ($f$ = 0.13) or 0.37 ($f$ = 0.45), whereas for Au/ZnO the corresponding values of $\gamma$ were 0.11 and 0.38. The heterogeneous deactivation of the metastable atoms of inert gases on discontinuous films of gold apparently takes place on the surface of the metal particles, since the values of $\gamma$ and $f$ coincide. In this case the deactivation of the excited atoms takes place with an efficiency close to 1, whereas it is lower by a factor of 100 on the surface of the support, irrespective of the electronic structure of the carrier (dielectric, semiconductor).

Thus the results of the measurement of the coefficients of the heterogeneous deactivation of the metastable atoms of inert gases on non-metals are few and contradictory. For example, for glass the following values of $\gamma$ have been obtained: 0.35 and 0.11,[121] 0.75,[125] 1,[126] and $2 \times 10^{-3}$.[127] These marked differences are apparently related to the fact that in Refs.121, 125, and 126 the MA concentration was much higher than in Ref.127. In the deactivation of MA on non-metals, the excitation of the surface at sufficiently high concentrations of the excited species apparently facilitates the more effective loss of the energy of the excited atoms colliding with it.

Thus the deactivation of MA on non-metal surfaces takes place with a lower efficiency than on metal surfaces. In the last case the loss of the energy by the metastable atoms takes place chiefly in their reaction with the electronic system of the metal, leading to the emission of electrons. It is as yet difficult to say anything definite about the mechanism of the reaction of these species with non-metals.

The heterogeneous deactivation of electronically excited nitrogen molecules has been studied.[132,133] The longest-lived state was found to be $N_2(A^3\Sigma_u^+)$ with a radiative lifetime of 2 s. In Ref.133, the concentration of $N_2^*$ was measured from the photo-ionisation in a mass spectrometer, and also using a platinum calorimeter with a stream of nitrogen passed through a discharge ($p$ = 0.6–7 hPa). The coefficient of heterogeneous deactivation was found to be $3 \times 10^{-5}$, that is the efficiency of the deactivation of $N_2^*$ on the glass walls is very low. The dependence of the value of $\gamma$ on the concentration of excited nitrogen molecules was established;[132] the coefficient $\gamma$ is low ($7 \times 10^{-4}$) at low concentrations, and high (0.5) at high concentrations. Thus the concentration dependence of $\gamma$ obtained for metastable nitrogen molecules was the same as that for metastable inert gases on a glass surface.

There are practically no published data on the deactivation of excited metal atoms on solid surfaces. Only a few papers have dealt with the reaction of excited mercury atoms with semiconducting films of zinc oxide.[136–138] The change in the electrical conductivity ($\sigma$) of ZnO films under the influence of mercury atoms (Hg*), obtained by photo-excitation in the gas phase (non-excited Hg atoms have no influence on $\sigma$), was studied. At room temperature the reaction with Hg* atoms produces a marked increase in $\sigma$ for the ZnO films, and at "saturation" of the signal, $\sigma$ increases by 80%. The authors cited attributed the effect of "saturation" of the change in $\sigma$ to two processes taking place simultaneously on the ZnO surface: 1) the formation on the surface of zinc atoms, which bring about an increase in $\sigma$ for ZnO:[114]

$$ZnO + Hg^* \rightarrow (HgO)_s + Zn_s \qquad (6)$$

(s = surface); and 2) the formation of surface zinc mercurides, which, like metal molecules (for example $Ag_2$),[114] apparently have no influence on the electrical conductivity of semiconducting films

$$Zn_s + Hg^* \rightarrow (HgZn)_s \qquad (7)$$

The simultaneous processes (6) and (7) are responsible for the establishment of the stationary value of $\sigma$ for ZnO on bombardment of its surface.

The proposed scheme was verified by experiments in which zinc atoms were deposited on the ZnO surface, or oxygen was adsorbed on it. On the films activated by zinc atoms, the magnitude and the sign of the change in $\sigma$ depend on the concentration of Zn atoms; at high zinc concentrations, the value of $\sigma$ for ZnO decreases under the influence of Hg* atoms (process 7). On ZnO films treated with oxygen, the magnitude of the change in $\sigma$ for ZnO increases (process 6).

In Refs.136–138 it was established that at a definite concentration of previously deposited zinc atoms, the value of $\sigma$ for ZnO remains unchanged under the influence of Hg* atoms. From the change in the electrical conductivity of the adsorbate, the authors cited reached conclusions about the dissociation of the molecules adsorbed on ZnO in their reaction with excited mercury atoms. A marked increase in $\sigma$ took place after the adsorption of hydrogen on bombardment with Hg* atoms, indicating that $H_2$ is dissociated to atoms, since it was previously shown[114] that H atoms are electron donors on a ZnO surface. The same effect was detected for adsorbed isopropyl alcohol.

Thus the action of excited mercury atoms (and possibly other metal atoms) leads to a change in the chemical composition of the clean surface of oxide semiconductors, and also of the adsorbed layer.

# Zirconium Complexes in Synthesis and Catalysis

U.M.Dzhemilev, O.S.Vostrikova, and A.G.Ibragimov

Data on the use of organometallic complexes of zirconium as key intermediates in organic synthesis and the catalysis of the transformations of alkenes, dienes, and acetylenes have been systematised. The hydrozirconation of unsaturated compounds and the reactions of alkyl- and alkenylzirconium complexes with electrophilic reagents, $\alpha,\beta$-unsaturated ketones, aryl and vinyl halides, and salts of transition and non-transition metals have been examined. The use of zirconium complexes as catalysts in the homogeneous hydrogenation, isomerisation, linear dimerisation, and oligomerisation of alkenes and dienes, and the hydro- and carbometallation of the latter, have been considered. The mechanisms of these reactions have been discussed. The bibliography contains 147 references.

CONTENTS

I. Introduction 66
II. The synthesis and transformations of alkyl- and alkenylzirconium complexes 66
III. Catalysis by zirconium complexes 74

## I. INTRODUCTION

Many of the most important achievements in organic chemistry in the last 15–20 years have been associated in some way with the use of transition metal complexes. Among these complexes, an increasingly important place is occupied by zirconium compounds, which have a number of unique properties enabling them to be used as highly reactive reagents in organic synthesis, and also as effective catalysts for transformations of unsaturated hydrocarbons and organometallic compounds. The discovery of the reaction of organozirconium intermediates with transition metal complexes, involving the transfer of alkyl or alkenyl substituents from the zirconium atom to other metals, has made it possible to carry out the stereoselective synthesis of compounds with a definite structure, whose preparation by other methods is extremely complicated.

Extensive material on the use of zirconium complexes in synthesis and catalysis has now accumulated, and studies in this field are being carried out actively in the Soviet Union and abroad. Although some aspects of the use of zirconium derivatives in organic synthesis have been discussed in two reviews,[1,2] there is a large amount of material which did not appear in these reviews. A large amount of data on the use of zirconium compounds as homogeneous metal-complex catalysts (published mainly in the last five years) has not yet been discussed and systematised.

The present review gives the most important results of studies of the use of organozirconium compounds in organic synthesis and metal-complex catalysis, published chiefly in the last ten years. The polymerisation of unsaturated compounds on zirconium-containing catalysts is not examined.

## II. THE SYNTHESIS AND TRANSFORMATIONS OF ALKYL- AND ALKENYLZIRCONIUM COMPLEXES

### 1. The Hydrozirconation of Unsaturated Compounds

About ten years ago it was established[3,4] that bis(cyclopentadienyl)zirconium chloride hydride $Cp_2Zr(Cl)H$ (I) and bis(cyclopentadienyl)zirconium dihydride $Cp_2ZrH_2$ react readily with alkenes or acetylenes to give fairly stable alkyl and alkenyl complexes of zirconium. Subsequently, Schwartz and co-workers[1] developed a number of promising schemes for the use of hydrozirconation products as active intermediates in organic synthesis. In the last ten years, hydrozirconation has become popular in organic synthesis, chiefly as a result of these studies, as indicated by the fact that the hydride complex (I) is often referred to in the chemical literature as the "Schwartz reagent".[5]

The hydrozirconation of linear and cyclic alkenes by bis(cyclopentadienyl)zirconium chloride hydride (I) takes place under mild conditions and with high yields, giving alkyl complexes $Cp_2Zr(Cl)R$. The latter, unlike their lower homologues, are fairly stable.[6] The hydrozirconation of alkenes using $Cp_2Zr(Cl)H$ or $Cp_2ZrH_2$ takes place strictly as a 1,2-addition and is highly regioselective, reacting with both mono- and disubstituted alkenes to give only the primary alkylzirconium complexes, which are readily split by electrophiles (Table 1).

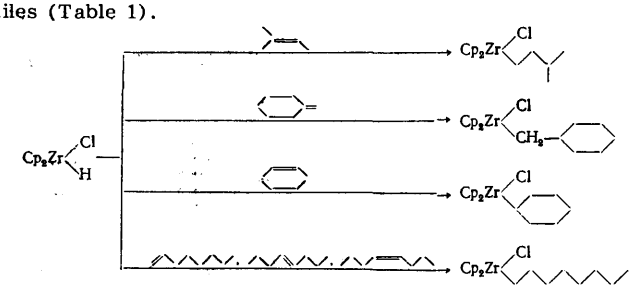

**Table 1.** Hydrozirconation of alkenes using compound (I).[6]

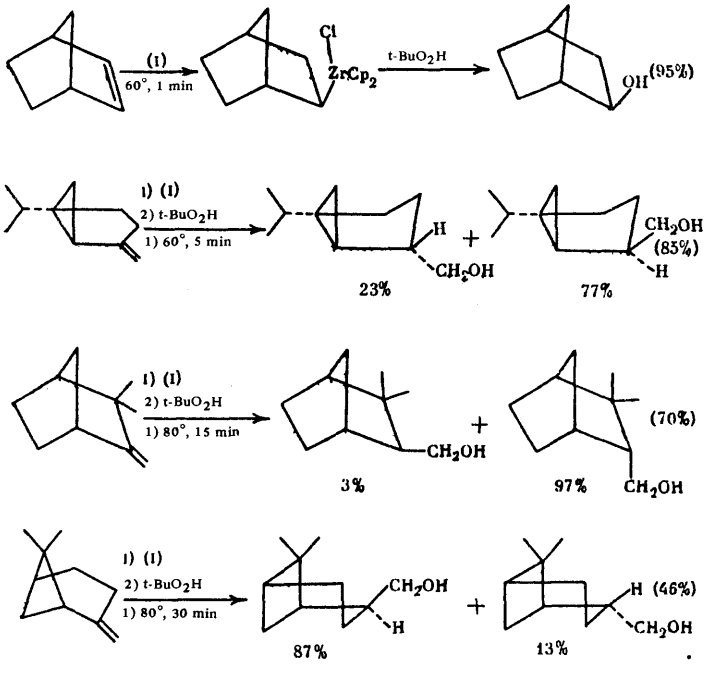
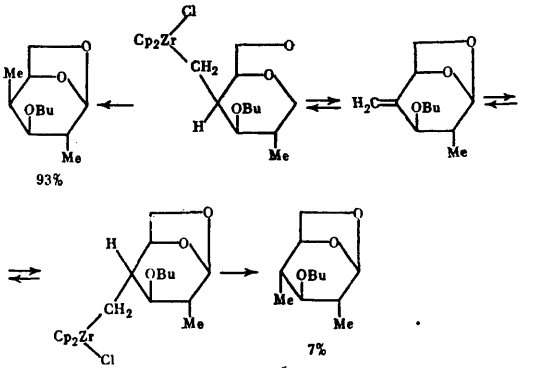
| Alkene | Electrophilic reagent | Reaction product | Yield, %* |
|---|---|---|---|
| Oct-1-ene or oct-4-ene | HCl (dil.)** | octane | 100 |
| Ditto | $Br_2$ | 1-bromo-octane | 96 |
| » | $I_2$ | 1-iodo-octane | 91 |
| » | $PhICl_2$ | 1-chloro-octane | 65 |
| » | $MeC(O)Cl$ | decan-2-one | 80 |
| 2-Methylbut-1-ene | $Br_2$ | 1-bromo-3-methylbutane | 100 |
| » | $MeC(O)Cl$ | 5-methylhexan-2-ol | 72 |
| Cyclohexene | $Br_2$ | bromocyclohexane | 95 |



*Calculated for $Cp_2ZrCl_2$.
**Temperature 0°.

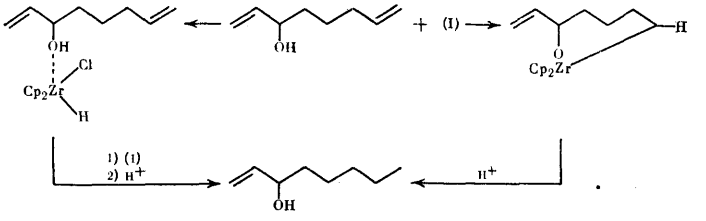
It is noteworthy that the hydride complexes of zirconium give exclusively primary alkylzirconium organic metallic compounds, irrespective of the position of the double bond

in the original alkene. Under hydrozirconation conditions, repeated addition and elimination of hydride complexes of zirconium probably take place, giving finally the thermodynamically most stable primary alkylzirconium complexes. These transformations take place fairly rapidly and under mild conditions, unlike the corresponding reactions of organoboron and organoaluminium compounds.[7,8] For example, the hydrozirconation of symmetrical disubstituted alkenes containing 24–42 carbon atoms gives only primary alkylzirconium complexes.[9] To obtain the optimum yields (50–80%) of the desired products in these experiments, however, the reaction must be carried out for 1–6 d at 40°.

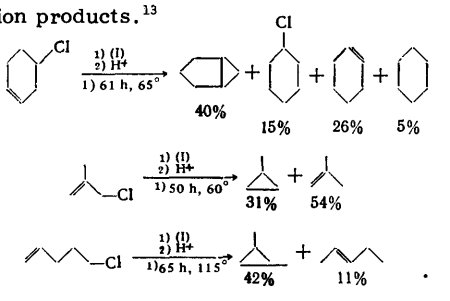


According to Schwartz's data, the relative rate of the hydrozirconation of alkenes decreases in the order: α-alkene > *cis*-alkene > *trans*-alkene > exocyclic alkene > cyclic alkene > trisubstituted alkene; the last three alkenes react with $Cp_2Zr(Cl)H$ at temperatures not lower than 40°.[1,6] Bulky groups in the substituted alkenes probably create steric hindrance to the approach of the zirconium hydrides, which have a "sandwich" structure, to the reaction centre. Thus tetrasubstituted alkenes and also methylcyclohexene and cyclo-octene do not react with $Cp_2Zr(Cl)H$ even when kept at 40° for a long time.[6]

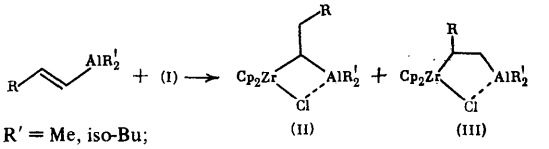
In a series of bicyclic hydrocarbons with double bonds shielded to different extents, the rate of hydrozirconation decreases sharply in the order: norbornene > sabinene > camphene > β-pinene,[10] and the addition of the hydride complex (I) takes place chiefly on the least shielded side. The highest stereoselectivity of the addition is observed for camphene.



The anomalously high yield of 10-isothujanol in the oxidation of the hydrozirconation products of sabinene was attributed[10] to electronic factors.

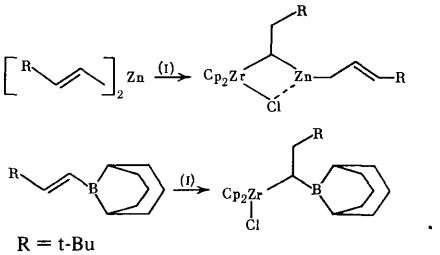


Hydrozirconation with subsequent protolysis made it possible to carry out the stereoregulated reduction of a methylene derivative of a monosaccharide in the synthesis of the C(9)–C(19) fragments of the antibiotics oleandonolide and erythronolide B.[11]

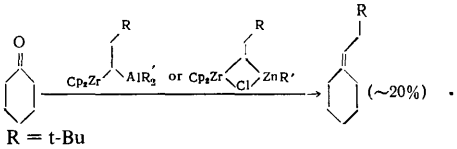


In this case the predominant formation of the thermodynamically more favourable galacto-isomer indicates that kinetic factors have a decisive influence. The hydrozirconation of unsaturated compounds is not only highly regiospecific but also highly selective. In particular, the hydrozirconation of non-conjugated dienols takes place exclusively at the double bond farthest from the hydroxyl group.[12] The high selectivity of this reaction is evidently due to the formation of a complex of the dienol with the hydride (I), which then reacts with a second $Cp_2Zr(Cl)H$ molecule at the sterically least hindered C(7)–C(8) vinyl group. It is not excluded that in these experiments, intramolecular hydrozirconation involves the formation of an alkoxyzirconium hydride according to the scheme:

In the reaction of $Cp_2Zr(Cl)H$ with various γ-halogenoalkenes, cyclopropane derivatives are formed in addition to the dehalogenation products.[13]

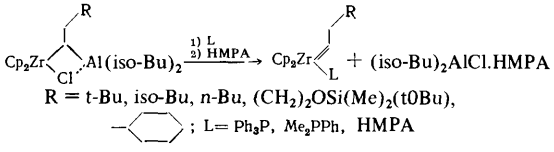


Complex (I) can hydrozirconate not only the simplest alkenes and dienes but also unsaturated organoaluminium, -zinc, and -boron compounds.[14] The hydrozirconation of alkenyldialkylalanes by $Cp_2Zr(Cl)H$ gives a bimetallic complex containing a bridging chloride ligand. The regioselectivity of the addition of the hydride (I) to the double bond depends on the size of the alkyl substituents on it.



R′ = Me, iso-Bu;
R = t-Bu, (II) : (III) = >20 : 1
R = n-Bu, (II) : (III) = 3 : 2
R = Me, (II) : (III) = 1 : 2 .

Dineohexenylzinc forms with $Cp_2Zr(Cl)H$ an analogous bimetallic cyclic complex, whereas the neohexenyl derivative of borane reacts with compound (I) according to the usual scheme.[14]



R = t-Bu

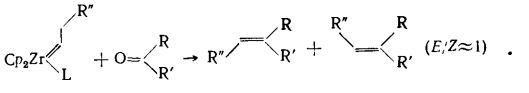
The zirconium complexes obtained are of interest as analogues of "Wittig's reagent" in carbonylalkenylation.[14]

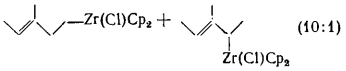
R = t-Bu

More active analogues of "Wittig's reagent" are the carbene complexes of zirconium formed by the reaction of the above zirconium–aluminium complexes with a mixture of hexamethylphosphamide (HMPA) and a stabilising ligand (for example $PhP_3$, $Me_2PPh$, or an excess of HMPA).[15]

R = t-Bu, iso-Bu, *n*-Bu, $(CH_2)_2OSi(Me)_2(t0Bu)$, ; L= $Ph_3P$, $Me_2PPh$, HMPA

The reagents obtained convert esters and ketones into the corresponding alkenes in 78–100% yield.





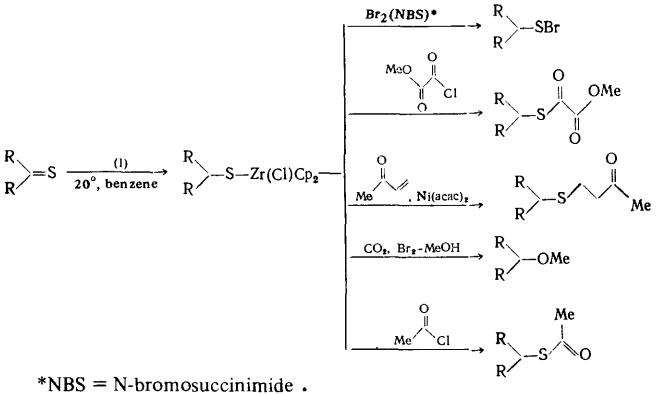


Table 2. Hydrozirconation of 1,3-dienes using compound (I).[1,18]

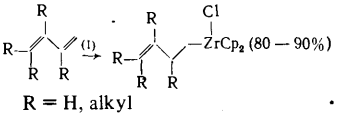
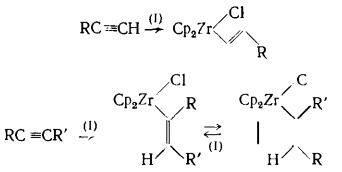


| 1,3-Diene | Product |
|---|---|
|  |  |
|  |  |
|  |  |
|  |  |
|  |  |
|  |  (10:1) |

An attempt has been made to hydrozirconate heteroalkenes, in particular Schiff bases, in order to subsequently transform them into amides.[16] It was found, however, that complex (I) does not add on to a C=N bond but transforms Schiff bases into enamides and imides, apparently via a Zr–enamide complex. At the same time, aromatic and aliphatic thioketones, including the α, β-unsaturated compounds, are smoothly hydrozirconated by $Cp_2Zr(Cl)H$ at room temperature to give compounds with a Zr–S bond, which can readily be converted into various sulphur-containing compounds under very mild conditions.[17]

*NBS = N-bromosuccinimide .

Unlike monoalkenes, 1,3-dienes undergo hydrozirconation much more slowly (by a factor of ~50) to give γ,δ-unsaturated zirconium complexes.[18] The reaction takes place mainly by the 1,2-addition of complex (I) at the sterically least hindered double bond of the diene (Table 2).

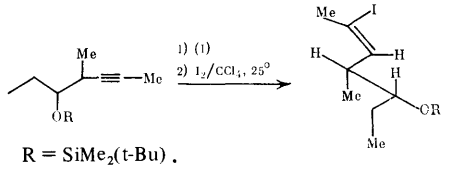


R = H, alkyl

Thus "Schwartz's reagent" as a hydrometallating agent is superior not only to the hydrides of boron and aluminium, which in the case of 1,3-dienes give a complex mixture of products,[19,20] but also to the hydrides of most transition metals, which react with conjugated dienes to form both 1,2- and 1,4-addition products.[21]

A review by Schwartz[1] contains the only mention of the possibility of carrying out the reaction between 2,4-dienes and three equivalents of $Cp_2Zr(Cl)H$, but no data on the structure of the products are given. There are no published data on the hydrozirconation of allenes.

The protonation of Vitamin $D_3$ and its 5*E*-isomer illustrates the possibility of hydrozirconating conjugated trienes.[22] The activity of the hydride complex (I) in this reaction is greater than that of 9-borabicyclononane. Irrespective of the structure of the original trienes, hydrolysis gave a mixture of the 5*E*- and 5*Z*-dihydrovitamins, indicating that the reaction is accompanied by 5*Z* ⇄ 5*E* isomerisation. Thus the sterically more hindered 5*Z*-isomer is hydrozirconated much more slowly. This reaction is apparently the only example of the hydrozirconation of 1,3-dienes containing functional substituents.[22]



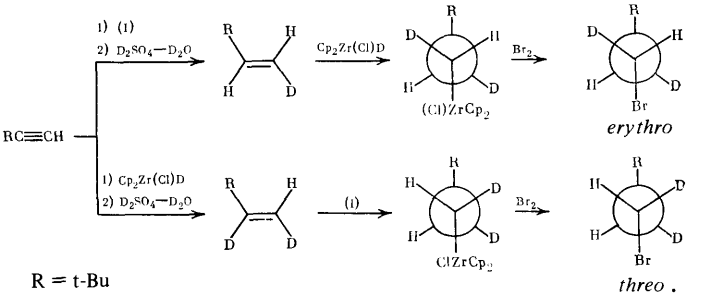
The addition of $Cp_2Zr(Cl)H$ to acetylenes is ~70–100 times more rapid than that to alkenes with analogous structures. Monosubstituted acetylenes form exclusively the 1*E*-alkenylzirconium complexes, and the disubstituted compounds give a mixture of the two possible isomers, the ratio of which depends on the structure of the alkyl substituents;[23,24] 1-alkenylzirconium complexes, unlike their alkyl analogues, do not undergo the above isomerisation, which takes place with the migration of the zirconium atom to the end of the carbon chain.

R = H, Me; R′ = Et, n-Pr, iso-Pr, n-Bu, iso-Bu, t-Bu.

In a number of cases, in the hydrozirconation of unsymmetrical disubstituted acetylenes with bulky substituents, the addition of complex (I) is highly regioselective.

Thus the hydrozirconation of 4-methyl-5-(dimethyl-t-butylsiloxy)-hept-2-one with one equivalent of compound (I) gave a single alkenylzirconium complex, which was readily converted into the corresponding halogenoalkene by treatment with $I_2$.[25]

R = $SiMe_2$(t-Bu).

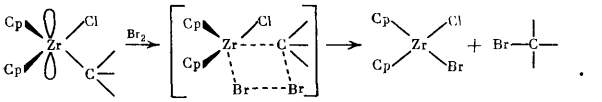


It should be noted that in the hydrozirconation of acetylenes with an excess of compound (I), stereo- and regioselective isomerisation of the resulting alkenyl complexes of zirconium is observed, giving organometallic compounds in which the zirconium atoms are situated predominantly on the least shielded side.[1,23]

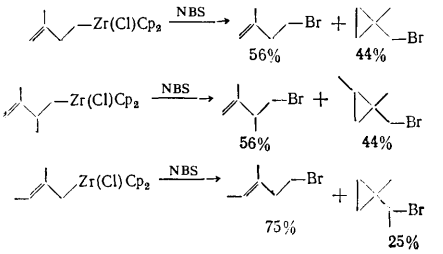
Published data on the hydrozirconation of acetylenes indicate that $Cp_2Zr(Cl)H$ is currently one of the most active and regioselective reagents, capable of hydrometallating acetylenes, including those containing such functional substituents as Cl, OH, OR, $CO_2H$, C≡N, $CO_2R$, and in the case of the last two groups no appreciable reduction is observed in the reaction.[26] Thus $Cp_2Zr(Cl)H$ acts as a universal, highly active, and selective hydrometallating agent for a wide range of unsaturated compounds.

It has recently been shown possible to use $Cp_2Zr(Cl)H$ and its derivatives as reducing agents. Thus for example "Schwartz's reagent" (I) reduces cyclic ketones stereoselectively to the corresponding axial alcohols.[27] The mixed zirconium hydride $Cp_2Zr(Cl)BH_4$ has been proposed[28] for the selective reduction of aldehydes and ketones in the presence of carboxylic acids, esters, nitriles, and nitroalkanes. This reducing agent is more selective than the known derivatives $LiAlH_4$, boranes, and trialkyl borohydrides, and does not require the use of an inert atmosphere.

## 2. Reactions of Alkyl- and Alkenylzirconium Complexes with Electrophilic Reagents



Alkyl- and more particularly alkenylzirconium complexes are convenient intermediates in the functionalisation of unsaturated compounds. One of the simplest ways of functionalising these compounds is by the stereospecific splitting of Zr–C bonds by electrophilic reagents. This process has been studied in considerable detail for a wide range of electrophilic reagents. Alkyl or alkenyl halides are readily formed by the reaction of the corresponding alkyl- and alkenylzirconium complexes with halogens and *N*-halogenosuccinimides. For the example of the reaction of bromine with the *erythro*- and *threo*-forms of the complex $Cp_2Zr(Cl)CHD–CHD–CMe_3$ it was shown that the formation of the alkyl halide molecules takes place with preservation of the configuration of the substituents on the carbon atom joined to Zr, indicating that the reaction involves a cyclic intermediate state.[2,29]

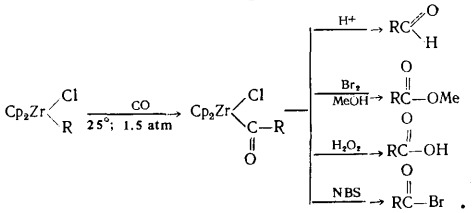


R = t-Bu

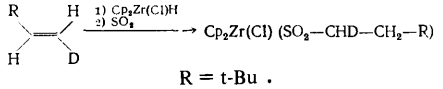
*threo*.

According to the proposed mechanism, the electrophilic reagent reacts with the substrate to form a cyclic intermediate complex using an unoccupied low-lying orbital of zirconium; this facilitates frontal attack at the Zr–C bond, and the subsequent polarisation of the coordinated electrophilic reagent leads to the rupture of this bond.

Similar reactions with $Br_2$ and N-bromosuccinimide (NBS) are undergone by alkyl- and alkenylzirconium complexes, the latter with preservation of the geometry of the double bond.[18,29] An exception is provided by 3-alkenylzirconium complexes containing, in addition to the double bond, alkenyl substituents on the C(3) atom. Under the influence of NBS, they are partly converted into cyclopropylalkyl bromides.[18]



According to Schwartz's data,[29,30] alkylzirconium complexes are oxidised at the Zr–C bond in satisfactory yields by $O_2$, $H_2O_2$, alkyl hydroperoxides, and peroxyacids. In the later paper,[31] however, it was noted that in the oxidation of $C_8$–$C_{30}$ alkylzirconium complexes, reproducible high (~70%) yields of primary alcohols can be obtained only using anhydrous t-butyl hydroperoxide. The use of a 70% solution of the hydroperoxide in water gives mainly hydrocarbons, and the yields of alcohols are low, and decrease with increase in the length of the hydrocarbon chain. The formation of appreciable quantities of unsaturated hydrocarbons was also observed in the oxidation of the products of the hydrozirconation of β-pinene and camphene by a 95% aqueous solution of t-butyl hydroperoxide.[10]

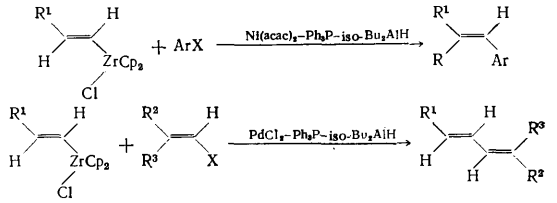


The presence, in the hydrocarbon group of the alkyl peroxide complexes, of double bonds separated by several carbon atoms from the metal atom has practically no influence on the oxidation, whereas the 1*E*-alkenylzirconium complexes cannot be oxidised smoothly.[1]

A convenient method for functionalising unsaturated compounds via the preparation of alkyl- and alkenylzirconium complexes is by the reaction of the latter with CO.[18,32] It is suggested that this reaction involves the rapid and reversible coordination of CO to the central metal atom to give a coordinatively unsaturated carbonyl complex $Cp_2Zr(Cl)(R)-CO$, in which the alkyl substituent migrates slowly to the active CO ligand.[2,32]

The relative ratio of formation of acyl complexes of zirconium depends markedly on the nature and structure of the alkyl substituent.[1] The acyl complexes can readily be selectively converted into aldehydes, carboxylic acids, esters, or acid halides, according to the scheme:

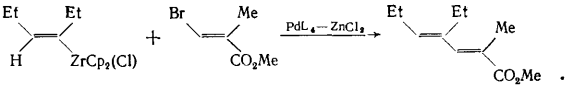
The analogous reaction of alkyl complexes of zirconium with $CO_2$ and $SO_3$ has not yet been carried out. Coordinatively saturated O,O'-sulphinate complexes of zirconium have been obtained using $SO_2$.[29]



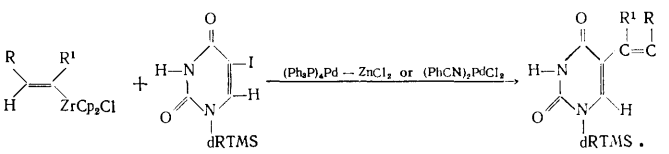
R = t-Bu .

In an excess of $SO_2$, this reaction is more complex.[33] $Cp_2Zr.(Cl)CH_3$ reacts similarly with $NO_2$ to give a zirconium complex of methylnitrosohydroxylamine.[34]

### 3. Alkenylzirconium Complexes in Cross-Coupling Reactions with Aryl and Vinyl Halides



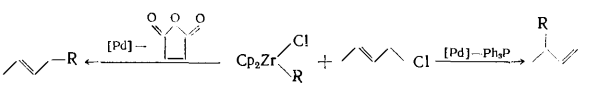
Negishi and co-workers were the first to establish that 1*E*-alkenylzirconium complexes in the presence of catalytic quantities of nickel or palladium compounds react readily with aryl[35] and vinyl[35-37] halides to give respectively derivatives of the arylethylene or dienes in 97–98% yield. The reaction is highly stereospecific (not less than 97%).



X = Cl, Br, I .

Attempts to extend the range of application of this reaction encountered serious difficulties. In particular, the formation of molecules of cross-coupled dienes, which takes place without complications in the case of β-monosubstituted alkenyl derivatives of zirconium, is extremely non-selective and gives low yields when the alkenyl substituents in the zirconium compounds are α, β- and β,β'-disubstituted. These difficulties were overcome by increasing the activity of the catalyst using promoting additives. The additives were salts of metals with electronegativities comparable with that of Zr, Ni, or Pd, but a much smaller atomic radius (Cu, Zn, Cd, Sn, In, Ti). Zn and Co salts were found to be most effective.

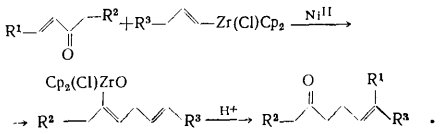
For example, the reaction between a 1*E*-alkenyl complex of zirconium and methyl β-bromomethacrylate in the presence of 5% $Pd(Ph_3P)_4$ after 6 h gives an ester of 2-methyl-4-ethyl-2*E*, 4*E*-heptadienoic acid in 22% yield, whereas with the "tandem" $(Ph_3P)_4Pd-ZnCl_2$ (1:1) the required product is formed in ~80% yield in 1 h.[38,39]



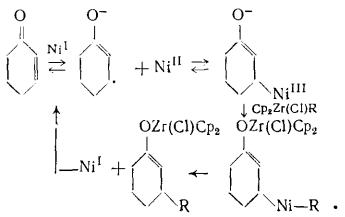
The same catalyst was used in the synthesis of 5*E*-alkenyl-substituted 2-deoxyuridines by cross-coupling 5-iodo-O-3',5'-bis(trimethylsilyl)deoxyuridine with α-substituted alkenylzirconium complexes obtained from disubstituted acetylenes. In the case of less hindered alkenylzirconium complexes, the most active cross-coupling catalyst was found to be the complex $(PhCN)_2PdCl_2$.[26]

where dTRMS represents O-3',5'-bis(trimethylsilyl)deoxyribose.

The influence of the nature of the ligands on the regioselectivity of the reaction has been demonstrated for the example of the cross-coupling of alkenylzirconium complexes with allyl halides and allyl acetates in the presence of bis-π-crotylpalladium chloride.[40] The introduction of phosphine ligands into the palladium catalyst promotes the coupling of the allyl fragment at the sterically more hindered end, whereas the addition of maleic anhydride favours the formation of the coupling products with the other structure.



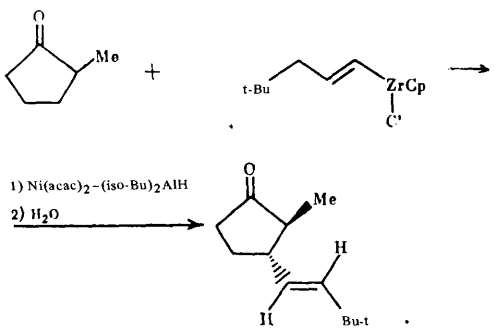
[Pd] = bis-π-allylpalladium chloride .



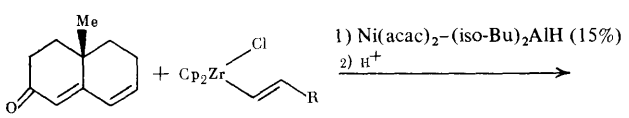
A similar influence of the ligands is observed in the coupling of alkenylzirconium compounds with stoichiometric quantities of π-allylpalladium chloride complexes. This made it possible to carry out an elegant regioselective synthesis of 20(S)-cholestan-3-one and 20(R)-cholestan-3-one.[41,42]

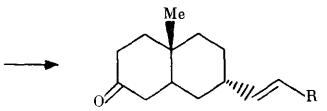
### 4. The Reactions of Alkenylzirconium Complexes with α,β-Unsaturated Ketones and the Transformations of Zirconium O-Enolates

Individual alkenyl complexes of zirconium react with α,β-unsaturated ketones even in the absence of catalysts, but the reaction is very slow, and the yields of required products are low.[43] Attempts to catalyse this reaction by transition metal complexes have been unsuccessful, probably because of the low activity of alkylzirconium complexes in *trans*-metallation. At the same time, the addition of 1*E*-alkenylzirconium complexes to enones is successfully catalysed by Ni compounds.[44,45] The corresponding β-alkenyl-substituted ketones are formed in high yield.



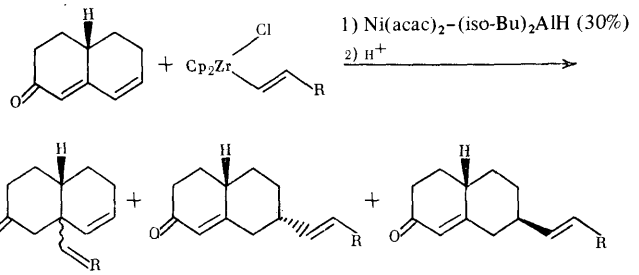
The catalytic systems obtained by reducing Ni compounds with $(iso\text{-}Bu)_2AlH$ are more active catalysts than nickel(II) salts. Moreover, an electrochemical study of the reaction of alkenylzirconium complexes with α,β-unsaturated ketones showed that this reaction, like the cross-coupling of vinyl complexes of zirconium with aryl and vinyl halides, is catalysed by nickel(I) complexes. On the basis of the results obtained, the following mechanism was proposed for the alkylation of enones.[46,47]





According to this scheme, the first stage involves the transfer of an electron from $Ni^I$ to the enone, followed by the oxidative addition of the ketyl to $Ni^{II}$, giving a σ-bonded complex of $Ni^{III}$ with the enone. The subsequent transformations of this complex as a result of *trans*-metallation and reductive elimination give the Zr enolate with the simultaneous regeneration of $Ni^I$.

The yield of the products of the 1,4-addition of 1*E*-alkenylzirconium complexes to enones is influenced considerably by the structure of the original ketone. The reaction gives good yields with most cyclic and acyclic ketones (Table 3), but in the case of $\Delta^{1(9)}$-octen-2-one and 10-methyl-$\Delta^{1(9)}$-octenone the yields of the products of the coupled addition do not exceed 33% and 70% respectively. Like the cuprate method, the addition of alkenylzirconium complexes to α-substituted cyclic enones gives the *trans*-disubstituted ketones with the same stereochemistry.[45]



The selectivity of the alkylation of dienones depends to a marked extent on their structure. For example, the addition of alkenylzirconium complexes to 10-methyl-1(9),7-hexalin-2-one takes place selectively to give a single isomer, whereas in the case of non-substituted 1(9),7-hexalin-2-one, a mixture of regio- and stereoisomers is obtained.[47]

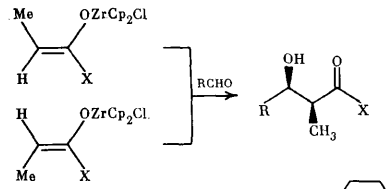
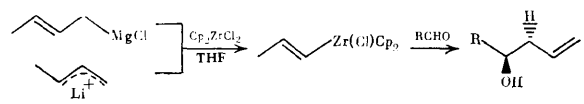
*R = t-Bu.

The highly reactive zirconium enolates formed have been made the basis of promising methods for obtaining β-keto- and homoallyl alochols of definite structure, used as synthones in the synthesis of natural compounds. Thus hydrozirconation and the coupled addition of alkenylzirconium complexes to cyclopentenone derivatives have been used to synthesise analogues of prostaglandins.[45,48]

Attempts to use alkyl and allyl halides to introduce a substituent into the α-position of β-substituted Zr enolates were unsuccessful, but Zr cyclopentenolate reacts readily with a solution of monomeric formaldehyde in ether, to give after hydrolysis α-hydroxymethylcyclopentenone in 70% yield. When formaldehyde is replaced by acetaldehyde, the yield of desired products decreases sharply,[48] evidently as a result of steric hindrance, since non-substituted Zr O-cycloalkenolates react readily with benzaldehyde.[49]



The reaction of zirconium O-enolates with selenium derivatives (PhSeBr, Ph–Se–Se–Ph) gives α-phenylselenylcyclopentanones, used as synthones in the preparation of analogues of prostaglandins.[50]



The use of zirconium O-enolates opens up an original approach to diastereoselective aldol condensation, which is generally carried out using prochirally pure enolates or enolates enriched in one of the isomers, which are difficult to obtain. Thus *Z*-enolates usually react with carbonyl compounds to give *erythro*-adducts, and *E*-enolates give *threo*-adducts. Since in the enolates of cyclic ketones the double bond has a fixed *E*-geometry, the preparation of *erythro*-aldols from these materials is complicated.

In 1980, almost simultaneously, two groups of workers reported that zirconium O-enolates, irrespective of their geometry and the nature of the substituents, react with aldehydes to give β-hydroxyketones, esters, and amides, with predominantly the ***erythro***-configuration.[49,51,52]

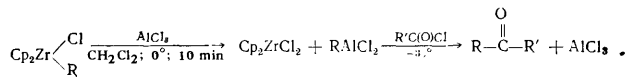
X = SBu-t, OMe, Ph, Et, OBu-t,  , N(iso-Pr)$_2$;
R = Ph, n-Pr, iso-Pr, C(CH$_3$) = CH$_2$ .

An interesting feature is that crotyl derivatives of zirconium, which can readily be obtained from crotylmagnesium chloride or crotyl-lithium and $Cp_2ZrCl_2$ in THF, react with aromatic and aliphatic aldehydes to give high yields of β-methylhomoallyl alcohols with predominantly the *threo*-configuration (yield 85–95%, selectivity 73–94%).[54]

## 5. Reactions of Alkyl- and Alkenylzirconium Complexes with Salts of Transition and Non-transition Metals

Considerable progress in the chemistry of organozirconium compounds was made with the discovery of the reaction involving the stereospecific transfer of a σ-bonded organic ligand from a zirconium atom to a metal atom which together with its ligand environment is more electronegative than the species $Cp_2Zr(Cl)^-$. The use of this reaction made it possible to overcome the difficulty of the low reactivity of alkyl- and alkenylzirconium complexes towards alkylating electrophilic reagents.

The first example of the use of these reagents to form a carbon–carbon bond was the reaction of alkyl- and alkenylzirconium complexes with $AlCl_3$, discovered in 1976.[54]



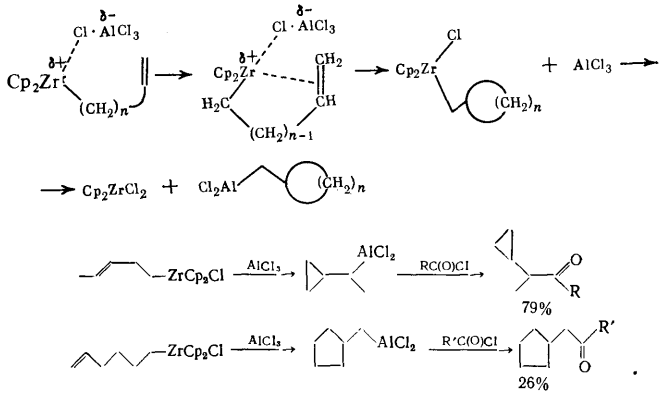


Table 4. Hydroalumination of cyclo-alkenes using (iso-Bu)$_2$.AlH (alkene : Al : $ZrCl_4$ : n-BuOH = 50 : 50 : 1 : 4; hexane).[107]

| Alkene | Yield*, % | T, °C | *t*, h |
|---|---|---|---|
| Cyclopentene | 100 | 20 | 6 |
| Cyclohexene | 99.5 | 20 | 8 |
| Cyclohexene | 100 | 40 | 2 |

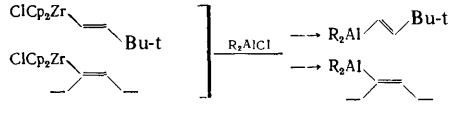
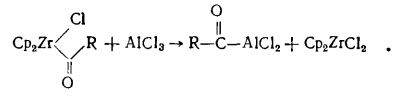
| Methylcyclododec-1-ene | 0 | 20 | 24 |



*Calculated for the cycloalkane.

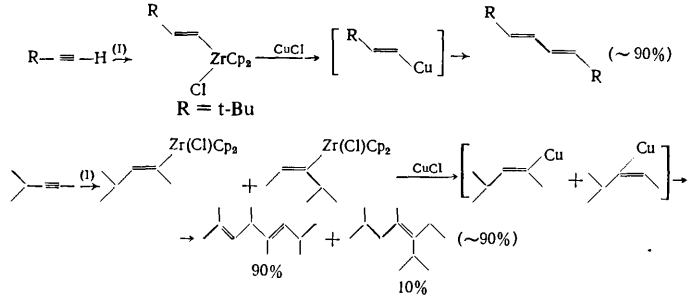
The alkyl- or alkenylaluminium chlorides formed were used as acylating agents to obtain ketones, including enones, which cannot be synthesised by the direct acylation of the corresponding alkenyl-zirconium complexes (Table 4).



As a rule, the configuration of the double bonds of the alkenyl complexes remains unchanged in *trans*-metallation and subsequent transformations. In a number of cases, however, the reaction with ω-alkenylzirconium complexes is more complicated, and is accompanied by intramolecular cyclisation. This method was used to obtain a number of ketones which are difficult to prepare.[43]

According to Ref. 43, the reaction of alkylzirconium complexes with $AlCl_3$ is much slower than that of the corresponding alkenyl derivatives. Moreover, alkyl complexes of zirconium react with an excess of $AlCl_3$ to form exclusively monoalkylaluminium chlorides, whereas the alkenyl complexes may give mono-, di-, and trialkenylalanes, depending on the Zr:Al ratio. This method has been used to obtain mixed dialkenylalanes with different structures.

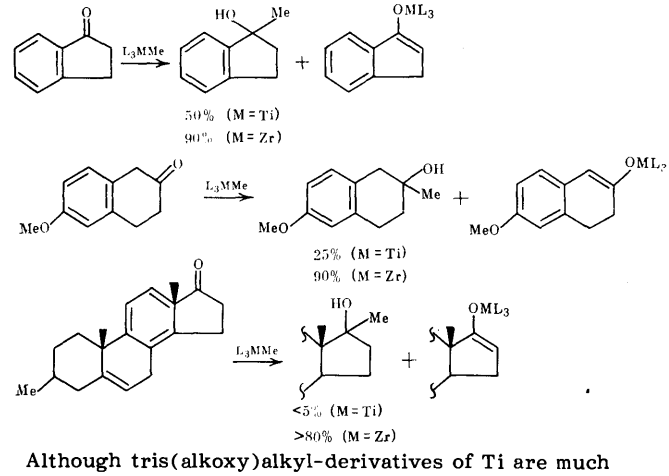
Acyl complexes of Zr react similarly with $AlCl_3$ to give acyldihalogenoalanes, which are of interest as potential equivalents of the acyl anion.[55]



Special experiments with deuteriated alkylzirconium complexes showed that *trans*-metallation takes place predominantly with preservation of the configuration of the substituents on the carbon atom joined to the metal. This indicates a similarity between the mechanisms of *trans*-metallation and the splitting of the Zr–C bond by heteroatomic electrophilic reagents, discussed above.[43] *trans*-Metallation has been used to prepare alkyl and alkenyl complexes of a number of transition and non-transition metals.

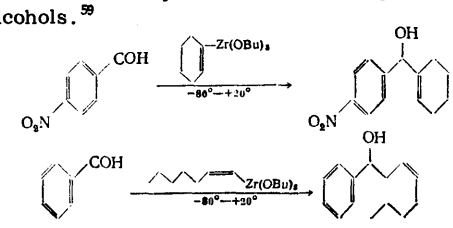
Thus partly deuteriated *threo*- and *erythro*-alkylzirconium complexes react with $HgCl_2$ to give alkylmercury chlorides in ~50% yield with a high degree of stereoisomeric purity (≥80%).[56]

Alkenyl complexes of zirconium undergo an analogous reaction with copper salts; the configuration of the double bonds in the alkenyl groups remains unchanged. The alkenyl compounds of copper formed are extremely unstable, and decompose even at 0° to give *E,E*-conjugated dienes.[57]



An analogous reaction is observed when copper salts are replaced by $PdCl_2$, but the yields of conjugated dienes in this case do not exceed 60%. Alkylzirconium complexes do not react with Cu and Pd salts under the conditions described.

According to Ref. 47, the reaction of alkenylzirconium complexes with $Ni(acac)_2$ also gives conjugated dienes, but no experimental details were given. A review by Schwartz[2] mentions (referring to unpublished results) that *trans*-metallation with $Sn^{IV}$ and $Zn^{II}$ compounds is possible in principle. *trans*-Metallation reactions using other transition and non-transition metals can undoubtedly be expected, and this will extend significantly the range of application of these methods in directed organic synthesis.

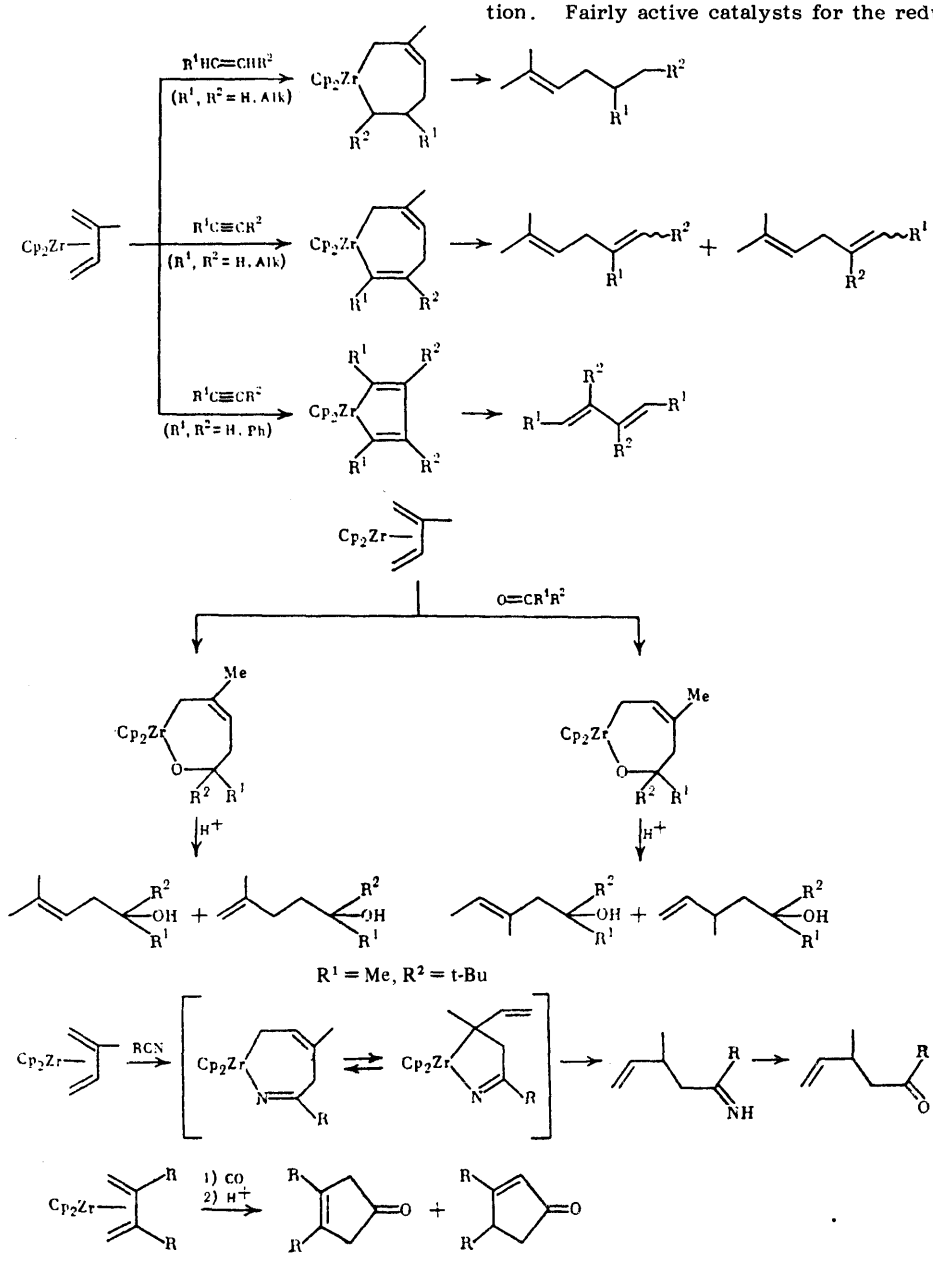


### 6. Alkoxyalkyl-complexes of Zirconium as Stable and Highly Selective Alkylating Agents

A new class of highly selective and stable alkylating agents for carbonyl compounds was recently proposed,[58–60] namely alkoxyalkyl-complexes of titanium and zirconium, obtained by the reaction of $(RO)_3MCl$ (where M = Ti, Zr) with lithium or magnesium alkyls. These reagents, particularly the Zr derivatives, are fairly stable, and differ from classical alkylating agents in their low basic strength and higher stereo- and regiospecificity, and also their selectivity, which makes it possible, for example, to alkylate aldehydes selectively in the presence of ketones with the same structure.[58,59]

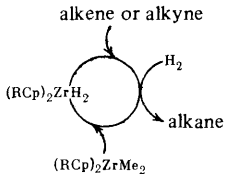
Although tris(alkoxy)alkyl-derivatives of Ti are much less basic than organolithium or organomagnesium compounds, they are insufficiently nucleophilic for the successful alkylation of ketones which are readily enolised. The zirconium compounds $(RO)_3ZrR'$ successfully combine an exceptionally low basic strength with highly nucleophilic properties, so that they can be used for the selective alkylation of ketones which are readily enolised, including those containing various additional substituents. Moreover, alkoxyalkyl-compounds of titanium containing vinyl or α-branched hydrocarbon

groups decompose under the conditions of the reaction with carbonyl compounds, leading to a decrease in the yield of alkylation products. At the same time, the corresponding zirconium derivatives are more stable, and can, for example, convert aromatic aldehydes into the corresponding unsaturated alcohols.[59]



Another class of promising organozirconium reagents, synthesised in the last 2–3 years from σ,π-complexes of zirconium, should be noted. These complexes have a unique reactivity, and are being studied intensively by several groups of workers.[60–70] The most interesting reactions are given below.

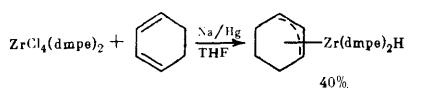
## III. CATALYSIS BY ZIRCONIUM COMPLEXES



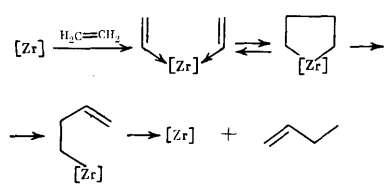
### 1. Transformations of Alkenes and Dienes, Catalysed by Zirconium Complexes

In spite of the fact that organozirconium compounds are firmly established in synthetic organic chemistry as active intermediates, their use as metal-complex catalysts in organic synthesis, apart from polymer chemistry, has only recently attracted extensive attention from research workers both in the Soviet Union and abroad.

The use of zirconium complexes as hydride-transfer catalysts has been studied in considerable detail. Thus a number of hydride complexes of zirconium(IV), fixed on activated silica gel, are highly active catalysts of the isomerisation of alkenes under mild conditions in thermodynamically equilibrium mixtures of the *cis*- and *trans*-isomers.[72] The hydrogenation of alkenes on these complexes is much slower than isomerisation. Fairly active catalysts for the reduction of alkenes

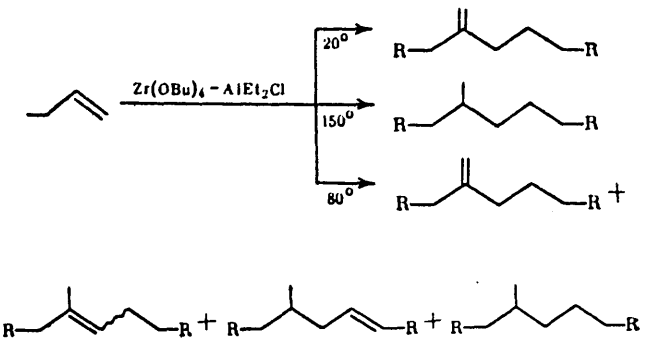


and acetylenes have been based on the zirconium complexes $RCp_2ZrR'_2$, where R' = H, Me; R = Me, $Me_2CH$, $Me_3C$.[73,74] The hydrogenation takes place by the following catalytic cycle:



Attempts to use the optically active complexes $(R^*Cp)_2ZrR'_2$ for the asymmetric hydrogenation of the prochiral alkenes α-ethylstyrene and 2-ethylhex-2-ene were not successful. The yield of optically active hydrocarbons in these experiments did not exceed 2%, evidently because of the large distance between the chiral and reactive centres of the catalyst.[74]

High catalytic activity in hydride transfer was shown by stable low-valent zirconium complexes obtained by reducing $ZrCl_4$ with sodium amalgam in the presence of bis(dimethylphosphino)ethane (dmpe), cyclohexa-1,3-diene, or butadiene in THF solution.[75] The complexes synthesised in this way are highly active catalysts of the disproportionation of cyclohexa-2,3-dienes to cyclohexene and benzene, and of the reduction of mono0 and disubstituted alkenes and acetylenes to the corresponding alkanes.[75]

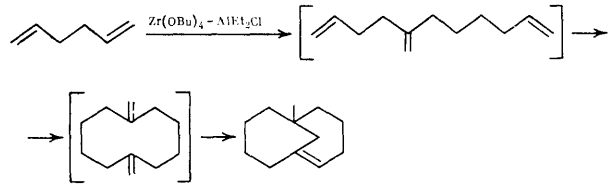


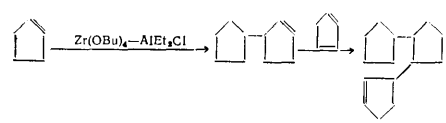
It is suggested that these processes involve the redox couples $Zr^{IV} \rightleftarrows Zr^{II}$; $Zr^{II} \rightleftarrows Zr^0$, which are the catalytically active centres in these reactions. The butadiene complex of zirconium $[Zr(C_4H_6)_2(dmpe)_2]$.dmpe catalyses the oligomerisation of various alkenes and dienes.[76]

From an an analysis of the structure of the oligomers obtained, and their distribution with respect to composition, a mechanism was proposed for the transformation of alkenes,[76] assuming the formation of five-membered metal-containing rings, which are responsible for the formation of the unsaturated hydrocarbon molecules:

The above zirconium complexes have not found extensive preparative applications, however, since they are difficult to obtain. More promising catalysts for these purposes were obtained by the reaction of accessible zirconium compounds (halides, alkoxides, acetylacetonates) with alkylhalogenoalanes. These catalysts were used to develop highly selective and effective methods for copolymerising ethylene with propylene, or converting ethylene into but-1-ene[77–79] or into higher alkenes, including α-alkenes with controlled molecular weight.[79,80]

The two-component catalytic system $Zr(OBu)_4$–$AlEt_2Cl$ brings about the highly selective transformation of higher α-alkenes into unsymmetrical methylene-alkanes in high yields.[81,82] The reaction is sensitive to the structure of the original alkene and the temperature of the process. Increase in the length of the hydrocarbon group ($C_6$–$C_{10}$) in the α-alkene decreases considerably the yield of corresponding methylene-alkanes. On the other hand, with increase in the reaction temperature (100–150°), the yield of dimers increases, but dimerisation is accompanied by simultaneous isomerisation and hydrogenation of the unsaturated hydrocarbons formed.

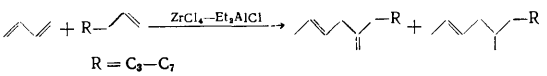




This catalytic system did not enable the authors cited to carry out the dimerisation of α-alkenes containing substituents in the α- or β-positions to the double bond. This catalyst selectively converts trimethylvinylsilane into 1,4-bis(trimethylsilyl)but-1-end.[81]

The dimerisation of hexa-1,5-diene is more complex, and gives a ~25% yield of a bicyclic hydrocarbon, identified as 6-methyl[4,4,1]bicycloundec-1-ene.[83,84]

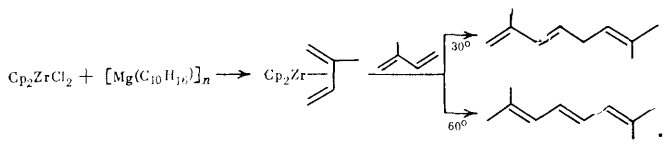
When $Et_2AlCl$ in the catalytic system is replaced by $EtAlCl_2$, it is possible to carry out the dimerisation and trimerisation of cyclic $C_5$–$C_{12}$ alkenes, whose activity in this reaction decreases in the order $C_5 > C_8 > C_7 > C_{12} > C_6$.[85]



Unlike the homodimerisation of α-alkenes, the codimerisation of the latter with butadiene in the presence of zirconium complex catalysts takes place at a high temperature. Butadiene, however, having a greater coordinating power than α-alkenes, reacts with the central atom of the catalyst to form fairly stable complexes, in which the dissociation of the diene molecules and the approach and activation of the monoalkenes can take place only at a high temperature. Evidence in support of this suggestion is provided by the fact that the homodimerisation of hex-1-ene under the influence of zirconium catalysts at 20–60° is readily inhibited by the addition of butadiene.[86]

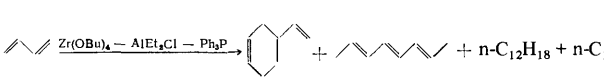
In particular, butadiene reacts with ethylene in the presence of the catalytic system $Cp_2ZrCl_2$–EtMgBr at 140–155° to give the single hydrocarbon hexa-1,4Z-diene in 20% yield.[87]

Higher α-alkenes do not react with butadiene on this catalyst, but the catalytic system $ZrCl_4$–$Et_2AlCl$ (1 : 10) makes it possible to carry out at 120° the codimerisation of butadiene with hex-1-ene, oct-1-ene, non-1-ene, and dec-1-ene to give the corresponding 2*E*,5-methylene alkenes.[80]

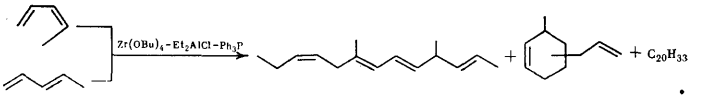


The codimerisation is accompanied by the homodimerisation of both original monomers, so that the yield of codimers does not exceed 15–20%. The mono-unsaturated codimers are evidently produced by the reaction of the initially formed 2,5-dienes with the organoaluminium component of the catalyst under the conditions of the reaction.[86]

In 1969, Japanese workers reported for the first time the possible use of the multicomponent catalytic systems $Zr(OBu)_4$–$Et_2AlCl$–$Ph_3P$ and $Zr(C_3H_5)_4$–$Et_3Al_2Cl_3$ as catalysts of the linear dimerisation of isoprene to give 2,6-dimethylocta-1,3*E*,6*E*-triene.[88,89] In addition to the latter, the reaction gave a mixture of trimers, in which the concentration of 3,6,10-trimethyldodeca-2,5,7,10-tetraene was ~90%.[90]

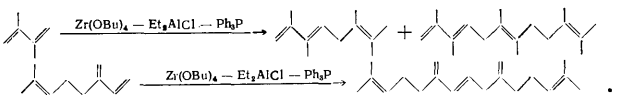


Later, more active catalysts were obtained, making it possible to increase the conversion of isoprene in this reaction to 90–95%.[91–93] The direction of the dimerisation of isoprene is changed completely by using the catalyst bis(cyclopentadienyl)isoprenylzirconium, which, depending on the reaction temperature, converts the original diene into 2,7-dimethylocta-1,3,6-triene or 2,7-dimethylocta-2,4,6-triene.[63]

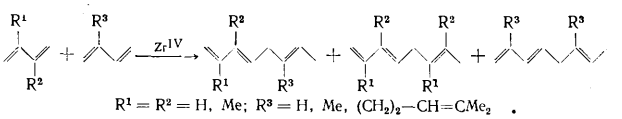


Subsequently, the authors of the present review established that three-component zirconium-containing catalysts can be used successfully for the dimerisation of other conjugated dienes with different structures.[94–97]

In the presence of the catalyst $Zr(OBu)_4$–$AlEt_2Cl$–$Ph_3P$, butadiene gives a mixture of linear and cyclic hydrocarbons consisting of 4-vinylcyclohexene, octa-2,4,6-triene, and isomeric tri- and tetramers of butadiene, differing in the positions of the double bonds.[94,95]



At the same time, the σ,π-complexes of zirconium formed by the reaction of $(C_8H_8)_2ZrCl_2$ with $C_3H_5MgCl$ convert butadiene with an exceptionally high selectivity into octa-1,3*E*,6*Z*-triene.[98,99]

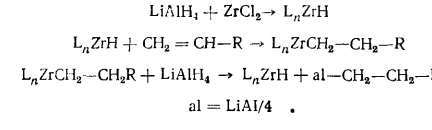


The reaction with *cis*- and *trans*-piperylenes gave 4,8-dimethyltrideca-2*E*,5*E*,7*E*,10*Z*-tetraene and a mixture of six-membered dimers and unidentified tetramers in the ratio 45 : 20 : 35.[95]

The oligomerisation of 2,3-dimethylbutadiene gives 2,3,6,7-tetramethylocta-1,3,6-triene and 2,3,6,7,10,11-hexamethyldodeca-1,3,6,10-tetraene. Myrcene is dimerised with a high selectivity to give the linear dimer 2,14-dimethyl-6-methylene-10 ethylidenepentadeca-2,7,13-triene.

The homodimerisation of farnesene gives a complex mixture of linear dimers and isomers of the original hydrocarbon.[94,95] Zirconium catalysts have made it possible to carry out the codimerisation of mono- and disubstituted conjugated dienes with different structures according to a "head-to-tail" scheme.

It is suggested[95] that the formation of linear dimers and codimers from 1,3-dienes takes place via the formation of bis-π-allyl and σ,π-allyl complexes of zirconium.



Thus of the catalysts known at present for the linear dimerisation and codimerisation of conjugated dienes, the zirconium complexes are the most universal, and can be used for the directed synthesis of polyenes with definite structures.

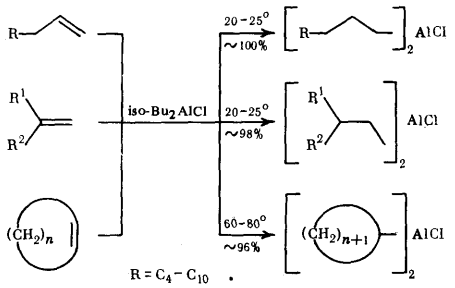
## 2. The Hydro- and Carbometallation of Alkenes, Dienes, and Acetylenes Under the Influence of Zirconium Catalysts

The first attempts to extend the range of application of hydroalumination using metal-complex catalysts were made by Asinger, who, in particular, used Ti and Zr compounds to convert a mixture of isomeric n-alkenes into primary alcohols by hydroalumination with tri-isobutylaluminium at 120° with subsequent oxidation of the higher organoaluminium compounds formed.[100]

The greatest progress in this field was made as a result of the discovery by Sato in the late nineteen-seventies[101,102] of the $ZrCl_4$-catalysed hydroalumination of alkenes by $LiAlH_4$ under mild conditions. Mono- and β,β'-disubstituted α-alkenes react selectively to give the corresponding lithium tetra-alkylalanates. Linear and cyclic α,β-disubstituted hydrocarbons, except cyclopentene, do not react with $LiAlH_4$ under these conditions.

According to Ref.103, the reaction takes place with the formation of intermediate hydride complexes of Zr, which hydrozirconate the alkenes, giving alkyl complexes of Zr, and subsequent *trans*-metallation leads to the regeneration of the original hydrides.

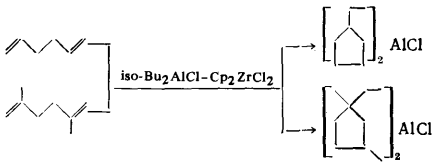
It was later established[101] that hydroalumination is catalysed not only by $ZrCl_4$ but also by $Cp_2ZrCl_2$, $VCl_4$, $Cp_2TiCl_2$, and $TiCl_4$, the last of these being the most effective catalyst. Its use made it possible to carry out the hydroalumination of alkenes with di- and trisubstituted double bonds under mild conditions, using not only $LiAlH_4$ but also $AlH_3$, $AlClH_2$, and $AlHCl_2$.



In a number of cases, however, the use of zirconium catalysts is still preferable. For example, allyl alcohols and their ethers react smoothly with $LiAlH_4$ only in the presence of Zr salts, $ZrCl_4$ is more effective for the hydroalumination of alcohols, and $Cp_2ZrCl_2$ is more effective for the hydroalumination of esters.[104,105]

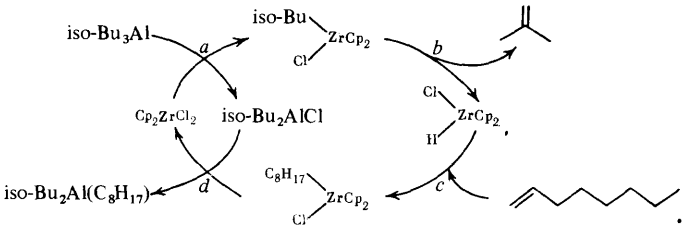
The authors of the present review established[106,107] that Zr salts catalyse the hydroalumination of linear and cyclic alkenes under the influence of $(iso\text{-}Bu)_2AlH$ under mild conditions. The most effective catalysts of this reaction were found to be the mixed zirconium chloride alkoxides formed *in situ* by the reaction of $ZrCl_4$ with aliphatic alcohols or of $ZrCl_4$ with $Zr(OR)_4$. The activity of the zirconium catalysts decreases in the order: $Zr(OR)_nCl_{4-n}$ > $ZrCl_4$ > $Zr(OR)_4 \geq Cp_2ZrCl_2$.[107] The rate of hydroalumination of cycloalkenes depends on the size of the ring, and decreases in the order: cyclopentene > cyclohexene > cycloheptene > cyclododecene > cyclo-octene (Table 4).

Almost simultaneously and independently, Negishi[108] and the authors of the present review,[79,109] found that $Cp_2ZrCl_2$ catalyses the hydroalumination of mono- and disubstituted linear and cyclic alkenes under the influence of $(iso\text{-}Bu)_3Al$, $(t\text{-}Bu)_3Al$, and $(iso\text{-}Bu)_2AlCl$. The yields of the products of the hydrometallation of the alkenes are 85–99%. When $Cp_2ZrCl_2$ is replaced by $ZrCl_4$, the yields are lowered to 50%.



This reaction has a number of advantages over hydroalumination using dialkylaluminium hydrides, described above; in particular, it takes place under exceptionally mild conditions (0–20°) and can be carried out using alkenes containing electron-donor substituents (OH, SPh, Br), whose hydroalumination by Al hydrides is difficult.[111]

The hydroalumination of alkenes by $(iso\text{-}Bu)_2AlCl$, catalysed by $Cp_2ZrCl_2$, opens up a route to higher dialkylhalogenoalanes difficult to obtain.[109–111]



β,β′-Disubstituted alkenes are also selectively hydroaluminated by di-(n-alkyl)halogenoalanes and trialkylalanes.[112] Di-isobutylaluminium chloride reacts comparatively readily with α-alkenes at 20–25°, and with disubstituted and cyclic alkenes at 60–80°.[79]

Linear 1,5-dienes react with $(iso\text{-}Bu)_2AlCl$ in two stages. Hydroalumination takes place initially at one of the double bonds of the diene, after which intramolecular carbometallation gives the corresponding mono- and bicyclic halogenoalanes.[79]

A mechanism has been proposed for the catalysed hydroalumination of alkenes by trialkylalanes,[109,110] involving alkylation (*a*), the elimination of isobutylene (*b*), hydrozirconation (*c*), and *trans*-metallation (*d*):

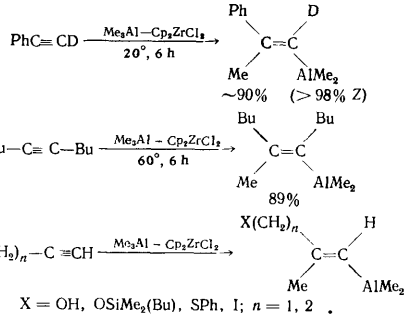
This mechanism does not appear correct, however, since the regeneration of $Cp_2ZrCl_2$ from $Cp_2Zr(Cl)R$ and $(iso\text{-}Bu)_2$. .AlCl seems unlikely, because the concentration of the latter in the system is low. Moreover, according to Schwartz's data,[43] dialkylhalogenoalanes are inactive in *trans*-metallation with alkyl complexes of Zr. In the reaction conditions, under the influence of catalytic quantities of zirconium salts, trialkylalanes are probably succively split to give aluminium hydrides $R_nAlH_{3-n}$, which then bring about the hydroalumination of the alkenes or acetylenes. Evidence in support of this suggestion is provided by the fact that $(iso\text{-}Bu)_3Al$ in the presence of catalytic quantities of $ZrCl_4$ under mild conditions gives up a molecule of isobutylene, forming $(iso\text{-}Bu)_2AlH$.[79] Since groups with a normal structure are not eliminated under these conditions, the authors of the present review developed a catalytic method for obtaining higher dialkylaluminium hydrides:

$$iso\text{-}Bu_3Al \xrightarrow[30-40^\circ]{ZrCl_4} iso\text{-}Bu_2AlH + \text{(cyclohexene)} \quad \sim 98\%$$

$$iso\text{-}Bu_3Al + 2R\text{-(cyclohexene)} \xrightarrow[20^\circ]{Cp_2ZrCl_2} (R\text{-(cyclohexyl)})_2Al(iso\text{-}Bu) \xrightarrow[30-40^\circ]{ZrCl_4} (R\text{-(cyclohexyl)})_2AlH \quad \sim 96\%$$

Papers published in the last 4–5 years indicate that zirconium-containing catalysts can be used for the hydrometallation of alkenes by hydrides and hydride complexes of Mg and Zn.[111,115–117]

In particular, the hydrometallation of linear and cyclic alkenes by $ZnH_2$ has been studied in detail. The reaction is carried out at 80° in a medium of aromatic or aliphatic hydrocarbons. The most active catalyst of this reaction is $Zr(OBu)_3Cl$, obtained by the reaction of $ZrCl_4$ with $Zr(OBu)_4$. In addition to zinc dialkyls, the reaction products include metallic zinc, hydrogen, and saturated hydrocarbons; this was attributed[117] to the instability of the intermediate alkylzinc hydrides under the reaction conditions:

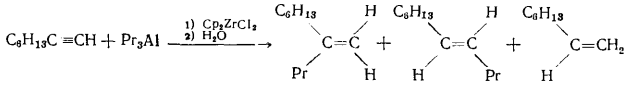


$$\text{alkene} + ZnH_2 \xrightarrow[PhMe,\ 80^\circ,\ 3\ h]{Zr(OBu)_3Cl} RZnH + R_2Zn \xrightarrow{1)\ O_2;\ 2)\ H^+} ROH \quad (D_2O \rightarrow RD)$$

$$RZnH + R_2Zn \rightarrow RZn_2H_3 + R_2Zn \xrightarrow{\Delta} RH + H_2 + Zn$$

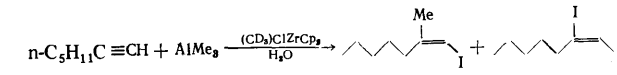
R = alkyl, cycloalkyl

An interesting feature is that oxidation of the reaction mass with oxygen gave not the expected alkyl hydroperoxides[118] but the corresponding primary alcohols, again evidently due to the influence of the zirconium catalysts.



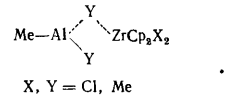
In 1978, Negishi and co-workers[110,119] carried out for the first time the $Cp_2ZrCl_2$-catalysed regio- and stereoselective *cis*-carboalumination of mono- and disubstituted acetylenes by trimethylaluminium. This reaction can be carried out with substituted acetylenes containing alkyl, alkenyl, and aromatic groups, including propargyl and homopropargyl derivatives. The carbometallation generally takes place with a high stereoselectivity, which reaches 95–100%.[110,119]

X = OH, $OSiMe_2(Bu)$, SPh, I; $n = 1, 2$ .



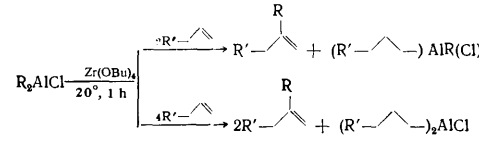
The carbometallation of monosubstituted acetylenes by $Me_3Al$, catalysed by $Cp_2ZrCl_2$, provides a simple and effective method of obtaining trisubstituted alkenes with the *cis*-configuration of the double bond, promising as synthones for the synthesis of natural products with the isoprene structure.[110]

The structure and nature of the carbometallating reagent have a much greater influence on the direction of the carboalumination of acetylene than the structure of the original acetylene. In particular, in the reaction of n-$Pr_3Al$ with oct-1-yne, the regioselectivity of the process does not exceed 70–80%, and the yield of the carbometallation products is lowered to 35–75% as a result of the simultaneous competing reaction of hydroalumination.[110]

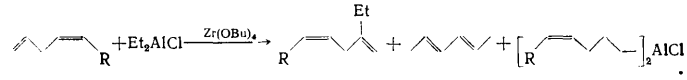


When $Pr_3Al$ is replaced by $(iso\text{-}Bu)_3Al$ or $(t\text{-}Bu)_3Al$, only hydrometallation of the acetylenes is observed. The hydrometallation of both mono- and disubstituted acetylenes can be excluded by using the $R_2AlCl$–$Cp_2ZrCl_2$ system as the carbometallating reagent.[120] The mechanism of this extremely promising reaction and the role of $Cp_2ZrCl_2$ in it are still not clear.

On the basis of recent results,[121] Negishi rejected his earlier suggestion[122] that carbometallation involves successive *trans*-metallation, carbozirconation, and *trans*-metallation. Moreover, halogen–alkyl exchange between the Al and Zr atoms, which was previously regarded as a necessary condition for carbometallation, not only is not the decisive stage, but also favours the competing reaction of hydroalumination.[121] Thus in the bimetallic system $Me_3Al$–$Cp_2$. .Zr(Cl)Me, in contrast to the reagent $Me_3Al$–$Cp_2ZrCl_2$, halogen–alkyl exchange is not observed, but the rate of the carbometallation of the acetylenes is the same in both cases. In the carbometallation of hept-1-yne by the reagent $Me_3Al$–$Cp_2Zr(CD_3)Cl$, treatment of the reaction products with $I_2$ gives a quantitative yield of a mixture of 1-iodo-2-methylhept-1*E*-ene and 3-iodohept-2*Z*-ene. The concentration of the deuteriated alkenes in these experiments did not exceed 4%.



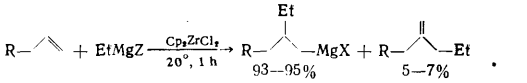
From these data, Negishi concludes that the zirconium-catalysed carboalumination of acetylenes by $Me_3Al$, at least in typical cases, involves direct carbometallation with the participation of zirconium complexes. It is suggested that the active intermediate is a bimetallic complex with the following structure:[121]



X, Y = Cl, Me

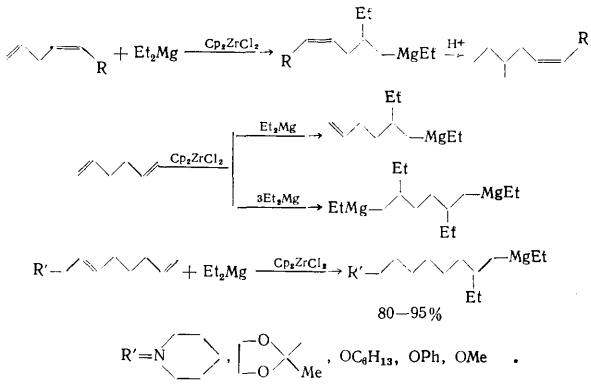
The authors of the present review were the first to establish that zirconium compounds also catalyse the carbometallation of α-alkenes by organoaluminium and organomagnesium compounds.[112 123–125] Thus the reaction of α-alkenes with dialkylaluminium halides in the presence of $Zr(OBu)_4$ leads to the selective formation of methylene-alkanes and the corresponding higher di-n-alkylaluminium halides; this can be attributed to successive carbo- and hydroalumination:[112]

The size of the hydrocarbon group, and the presence of a localised disubstituted bond in the molecule of the original α-alkene, have no influence on the direction of the reaction, but in the last case the yield of reaction products is lower, because of the partial isomerisation of the original 1,4-diene to the 2,4-isomer.[112]



Under the conditions of this reaction, conjugated dienes polymerise, and β,β′-disubstituted alkenes, as noted above, give exclusively the hydroalumination products. The reagents with the most selective action are the dialkylhalogenoalanes.

The highest yields of carboalumination products were obtained using diethylaluminium chloride, whereas with increase in the length of the hydrocarbon group on the aluminium atom their yield decreases slightly.[112] A higher catalytic activity and selectivity of action in this reaction are shown by $Zr(OBu)_4$. In the presence of $ZrCl_4$ and $(C_5H_5N)_2ZrCl_2$, and also $TiCl_4$ and $Ti(OBu)_4$, a mixture of the products of hydro- and carbometallation, and also oligomerisation of the original alkenes, is formed, whereas $Cp_2$. .$ZrCl_2$ and $Zr(acac)_4$ were found to be completely inactive in this reaction. In the presence of an equivalent quantity of $(iso\text{-}Bu)_3Al$ or $Et_2Mg$, however, $Cp_2ZrCl_2$ catalyses the selective carboalumination of α-alkenes not only by diethylmagnesium but also by triethylaluminium. An interesting feature is that in this case the process stops at the carboalumination stage.[126,79]

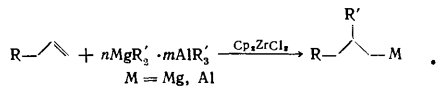


This reaction has been made the basis of a synthesis of 2-ethylhexanol from hex-1-ene and $AlEt_3$.[127]

The use of $Cp_2ZrCl_2$ made it possible to carry out under mild conditions the regioselective carbomagnesation of α-alkenes by $Et_2Mg$ or EtMgX (where X = Cl, Br, I).[125,128] Unlike the reaction of α-alkenes with $R_2AlCl$ described above, the process is not accompanied by subsequent hydrometallation. In this connection, the mechanism of formation of small quantities (5–7%) of β-alkylated alkenes under the conditions of the carbomagnesation is not yet clear. It should be noted that $ZrCl_4$ and $Zr(OBu)_4$ do not catalyse carbomagnesation; in their presence, the yield of hydromagnesation products is 3–5%. An interesting feature is that the action of $Cp_2ZrCl_2$ is completely blocked by the addition of equivalent quantities of hydrocarbons containing a triple bond or a conjugated system of double bonds.

The reaction with the α-alkenes involves one ethyl group of the $Et_2Mg$ molecule or half of the ethyl groups in EtMgX, and the latter reacts much more slowly than $Et_2Mg$. This suggested that under the reaction conditions, EtMgX disproportionates to $MgX_2$ and $MgEt_2$, which is then involved in the carbomagnesation.[128]

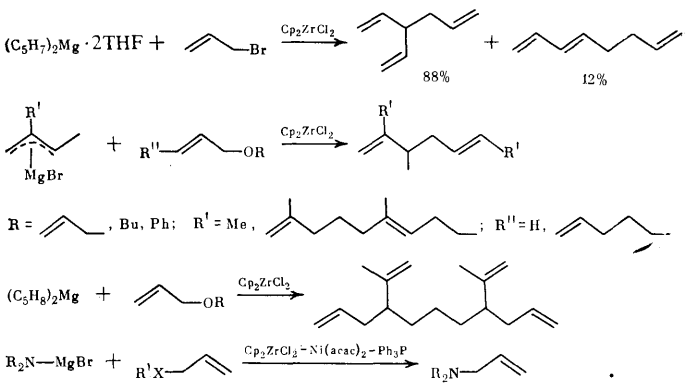
The method described is applicable to a wide range of α-alkenes containing internal double bonds and various functional substituents, and the regioselectivity of the process remains unchanged.



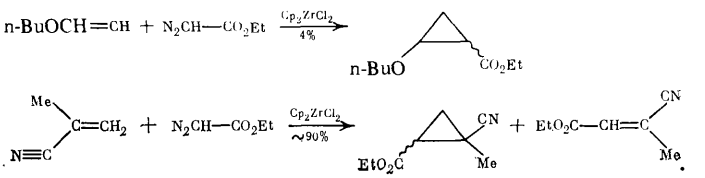
Electron-acceptor substituents on the allyl carbon atom lower considerably the activity of the double bond in carbomagnesation.

The complex $Cp_2ZrCl_2$ catalyses the carbomagnesation of α-alkenes under the influence of not only $Et_2Mg$ and EtMgX but also a number of other important Grignard reagents RMgZ, where the rate of carbomagnesation decreases in the Z order:

Compounds of the type R'OMgR, RMgSR, RMgF, and $RMgC{\equiv}CR'$ are completely inactive in carbomagnesation.[129,130] In the case of higher magnesium alkyls $R_2Mg$ (R = n-Pr, n-Bu, n-Oct), a considerable quantity of unsaturated organomagnesium compounds is formed in addition to the products of the direct carbometallation.[130]

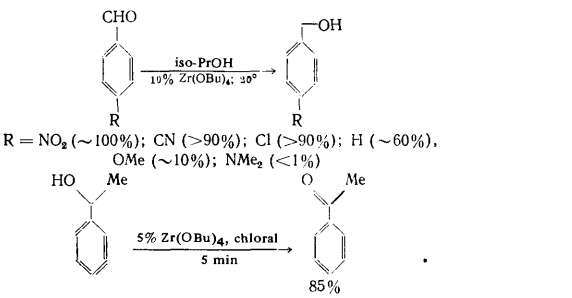


It was shown that the carbometallation of α-alkenes, catalysed by Zr salts, by bimetallic compounds in a hydrocarbon medium is possible in principle.[130]



This reaction opens up extensive possibilities for the development of new effective technological carbo- and hydrometallating agents.

### 3. Other Examples of the Use of Zirconium-containing Catalysts



The cross-coupling of diene–magnesium complexes[131–133] and of alkenylmagnesium bromides and magnesium amides with allyl and aryl halides, catalysed by $Cp_2ZrCl_2$ and bimetallic catalysts,[132] are of undoubted interest and practical importance.

Two recent papers[134,135] describe the use of $Cp_2ZrCl_2$ to catalyse the cyclopropanation by diazoacetic ester of alkenes containing an activated double bond.

The use of zirconium tetra-alkoxides as catalysts of the Meerwein–Ponndorf–Varley reduction of carbonyl compounds or the Oppenauer oxidation of aromatic alcohols in the presence of chloral has been reported.[59]

While the present review was being prepared for publication, a number of papers on the topics of its sections were published. Thus the hydrozirconation of aliphatic and aromatic nitriles has been carried out; a heteroallyl structure

has been proposed for the complexes formed.[136] The $Cp_2ZrCl_2$–t-BuMgCl system has been proposed for the hydrozirconation of unsaturated compounds, and has been used to carry out for the first time the carbozirconation of 1,3-dienes.[137] The condensation of crotylzirconium complexes with aldehydes in the presence of $BF_3$, giving β-methylhomoallyl alcohols with predominantly the *threo*-configuration, has been described.[138] It has been shown that hydride complexes of cyclopentadienyl-zirconium can reduce the trichloromethyl groups in polychloroalkanes.[139] Studies directed towards increasing the activity of akylidene-zirconium complexes in carbonylalkenisation are continuing.[140] Zirconium(II) complexes have been used to convert ω-vinyl-1-silylalk-1-ones into zirconabicyclanes, which after treatment with CO give the corresponding α-silylbicyclopentenones.[141]

Interesting results have been obtained on hydro- and carbometallation involving zirconium-containing catalysts.[142–147]

The above results show the promising possibilities provided by the use of zirconium compounds in synthesis, including their use for the regio- and stereoselective synthesis of complex organic molecules. It is to be hoped that further studies in this field will make it possible to develop new and highly effective reagents and catalysts for organic synthesis.

# $p\pi$-Conjugation in Aromatic Compounds of Group V and VI Elements

I.P.Romm and E.N.Gur'yanova

The results of experimental and theoretical studies of intramolecular electronic interactions in aromatic compounds of group V and VI elements have been reviewed. The principal characteristics of their electronic structure, their geometry, and their electron-donor properties have been discussed. The possibilities provided by various methods (UV spectroscopy, NMR, PES, thermochemistry) for detecting and estimating the degree of combination of the unshared pair of electrons of the heteroatom with the $\pi$-electron system of the aromatic fragment have been analysed in detail. Quantitative estimates of the energy of $p\pi$-conjugation have been given.
The bibliography contains 240 references.

CONTENTS

I. Introduction 83
II. The structure of $p\pi$-conjugated molecules and their complexes 83
III. The electron-donor properties of aromatic compounds of group V and VI elements 87
IV. Estimation of the degree of $p\pi$-conjugation 89

## I. INTRODUCTION

The concept of the unshared electron pair is one of the most fundamental and widely used concepts in organic chemistry. This concept is used to explain various phenomena in the chemistry of aromatic and unsaturated compounds containing heteroatoms. The idea that the unshared electron pair (UEP) of the heteroatom interacts with the $\pi$-electron system of a neighbouring aromatic or unsaturated fragment makes it possible to explain many physical and chemical properties of the corresponding compounds. Various symbols and varied terminology are used in the scientific literature to characterise this type of intramolecular interatomic interaction. In the present review, the most widely encountered term, namely $p\pi$-conjugation, will be used.

In recent years the problem of $p\pi$-conjugation has been studied intensively by various physical methods, including photoelectron spectroscopy (PES), X-ray electron spectroscopy (XES), nuclear magnetic resonance (NMR), electron spectroscopy, etc. Together with quantum-chemical calculations, this information makes possible a deeper understanding of the nature of this interaction and enables the degree of interaction to be related to the structure and properties of the molecules. The degree of combination of the UEP of the heteroatom with the $\pi$-system determines to a large extent the electron-donor properties of compounds. The study of the electron-donor properties of aromatic compounds containing a heteroatom gives extensive information on the structure of their molecular orbitals (MO) and makes it possible in a number of cases to obtain quantitative estimates of the degree of $p\pi$-conjugation.

The present review analyses the most characteristic indications of $p\pi$-conjugation, and discusses the regular features of and differences in its manifestation in compounds of different elements for examples of simple molecules with typical compositions and structures, containing elements of groups V and VI. Particular attention has been paid to the questions of the coordination and changes in the structure of $p\pi$-conjugated molecules on complex formation.

Because of the vast amount of material, the literature in which the use of various methods to study $p\pi$-conjugated molecules is discussed has been examined selectively. Only those papers which contain information making it possible to estimate to some extent the degree of $p\pi$-conjugation have been included. The literature on the reactivity of $p\pi$-conjugated molecules (apart from their complex-forming power) is not discussed. Because of the large number of literature sources, reference is sometimes made not to an original paper but to a later review which gives references to the original work.

## II. THE STRUCTURE OF $p\pi$-CONJUGATED MOLECULES AND THEIR COMPLEXES

### 1. The Electronic Structure and Conformations of $p\pi$-Conjugated Molecules

In the valence bond (VB) method, $p\pi$-conjugation is regarded as an intramolecular donor–acceptor interaction with charge transfer.[1,2] The donor fragment is the UEP of the heteroatom, and the acceptor fragment is the $\pi$-system of an aromatic group adjoining the heteroatom. The production of this interaction is determined to a large extent by the conditions of overlap of the orbital of the UEP of the heteroatom and the $p_\pi$-orbital of the carbon atom of the aromatic fragment joined to it.

In the molecular orbital method, the extent of the production of $p\pi$-conjugation is often related to the relative contributions of the atomic orbitals, including the orbital of the UEP of the heteroatom, to the highest occupied orbitals of the molecule. Mixing of the highest occupied $\pi$-orbital of the aromatic fragment with a UEP $p_\pi$-orbital of appropriate symmetry leads to the formation of two new orbitals, whose relative positions are represented schematically in the Figure (for the anisole molecule).[3] The Figure shows that the interaction of the UEP of the heteroatom with the aromatic fragment leads to an increase in the energy of the highest occupied MO of the molecule relative to the aromatic fragment.

The energy of the $\pi$-bond produced is determined by the value of the resonance integral (MO method) or the exchange integral (VB method), and depends on the degree of overlap of the corresponding orbitals of the fragments. The overlap of orbitals is usually estimated using the overlap integral, which depends on the angle between the axis of symmetry of the $p$-component of the UEP orbital and the axis of symmetry of the $p_\pi$-orbital of the neighbouring carbon atom of the aromatic fragment.[4] Thus both the MO method and the VB method make quite definite requirements of the state of the

interacting orbitals, both in relation to their energy and in relation to their relative orientation.

Both of these methods (VB and MO) are used to interpret the experimental data obtained by different physicochemical methods. In the study of properties related to the excitation of the molecules and one-electron transitions (electronic spectra, photoelectron spectra, etc.), the MO method is usually employed.

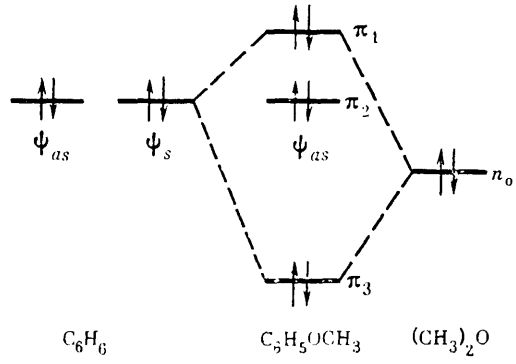

Diagram of the energy levels in the anisole molecule.[3]

The E atom in compounds of elements of group VI of the type ArER has two UEP. From the symmetry and energy of the atomic orbitals, it is assumed[3] that $p\pi$-interaction involves the UEP in the $p_z$-AO of the E atom. The extent of this interaction has been estimated[5] using the values of the resonance integrals $\beta_{E-C}$, which in compounds of the type $C_6H_5ECH_3$ decrease in the order O > S > Se > Te.

The heteroatom of tervalent compounds of group V elements has one UEP. The contribution of the $p_z$-orbital to the orbital of the UEP of compounds of group V elements can be estimated from the value θ of the C–E–C valence angle:[6]

$$p,\ \% = \frac{3\cos\theta}{\cos\theta - 1} \cdot 100$$

The average values of the valence angles θ in triaryl derivatives of group V elements, obtained by X-ray diffraction, are given below.

| Compound | N | P | As | Sb | Bi |
|---|---|---|---|---|---|
| $(C_6H_5)_3E$ | 119.6 (Ref.7) | 103.0 (Ref.8) | 100.1 (Ref.9) | — | 94 (Ref.10) |
| $(4\text{-}CH_3C_6H_4)_3E$ | 119.9 (Ref.11) | 101.7 (Ref.12) | 99.3 (Ref.13) | 97.3 (Ref.14) | 94.7 (Ref.15) |

The practically planar (θ ≅ 120°) structure of the central fragment of triarylamines indicates that the UEP of the nitrogen atom in these compounds is in the *p*-state. In the compounds of other elements, the contribution of the *p*-orbital to the orbital of the UEP is appreciably smaller, and, judging from the values of the valence angles, decreases in the order N > P > As > Sb > Bi. It may be noted that the contributions of the *p*-component to the orbital of the UEP, obtained for phosphines from the values of the valence angles, are appreciably lower than those found from the results of non-empirical calculations[16,17] or determined from an analysis of the PES by CNDO/2 calculations.[18]

Thus the orbital of the UEP in compounds of group V elements contains an appreciable contribution from the *p*-orbital, so that it is capable of reacting to some extent with a neighbouring π-system. The values of the overlap integrals of the Slater orbitals, calculated (as in Ref.19) with

Symbols: *R*(E–C) is the length of the E–C bond; θ the valence angle; τ the angle between the axis of the N–$C_{Ar}$ bond and the bisector of the angle RNR (R = H, $CH_3$); φ the angle between the plane of the ring and the plane of the C–E–C angle; and γ the angle between the plane of the ring and the plane passing through the E–$C_{Ar}$ bond and the axis of the UEP. Methods: MW = microwave spectroscopy, ED = electron diffraction, XRD = X-ray diffraction. The geometric parameters for identical atoms and groups, obtained by X-ray diffraction, have been averaged.

*Here and subsequently the superscript in brackets gives the number of the aromatic ring.

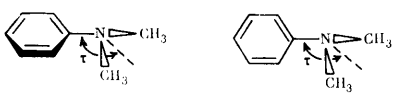
allowance for the values of the C–E–C angle in compounds of the type $(C_6H_5)_3E$, decrease in the order: N–C > P–C > As–C > Sb–C > Bi–C (0.185, 0.119, 0.093, 0.063, 0.040 respectively). The angles of rotation of the aryl fragments about the E–C bond were not taken into account, since they have similar values for all triphenyl and tri-*p*-tolyl derivatives of group V elements ($\gamma$ = 37–47°, Table 1).[7–15]

The conformation of molecules of the type $C_6H_5ER$ is determined to a large extent by the competition between two factors: $p\pi$-conjugation (which is a maximum for the planar conformation (A), $\phi$ = 0°) and steric hindrance (which is a minimum for the orthogonal conformation (B), $\phi$ = 90°).

(A) (B)

Depending on the contributions of these effects determining the barrier to the rotation of the ER group relative to the ring, an effective conformation with an angle of $0° \leq \phi \leq 90°$, and an equilibrium between planar and orthogonal conformers, may be produced. From data on the dipole moments (DM) and Kerr constants of anisole[20,21] and thioanisole[22] it was concluded that these compounds show conformational uniformity; the angles $\theta$ are 18°[20] and 23°[22] respectively.

At the same time, data obtained from an analysis of the temperature dependence of the Raman spectra of anisole indicate[23] that the system contains the conformers (A) and (B). The same conclusion was reached in a study of the PES of anisole;[24] the difference in the energies of the conformers (B) and (A) was estimated as 1.3 kcal mole$^{-1}$. From the observed splitting of the first band in the PES of a series of compounds of the type $C_6H_5SR$,[25] it was concluded that they show conformational non-uniformity in the gas phase. Estimation of the concentration of the conformers from the ratio of the intensities of the components of the complex PES band showed that the proportion of the planar conformer decreases with increase in the volume of the alkyl substituent R, and has the values 0.90, 0.40, 0.15, and 0.05 for R = $CH_3$, $C_2H_5$, iso-$C_3H_7$, and t-$C_4H_9$ respectively. Approximately the same ratio of conformers for the compounds $C_6H_5SR$ was obtained from UV and NMR spectroscopy.[26,27] At the same time, other authors[28] consider that the analysis of the PES of these compounds does not indicate unambiguously whether increase in the volume of the alkyl group leads to a gradual increase in the angle $\phi$ or displaces the conformational equilibrium (A) $\rightleftarrows$ (B).



New classes of conformationally non-uniform alkylaromatic and unsaturated compounds of group V and VI elements have been described in recent papers. These include alkylaromatic compounds of selenium and tellurium,[3,29,30] alkyl phenyl ethers and sulphides containing different substituents,[3,30,31] and compounds of the type $(C_6H_5)_nPR_{3-n}$.[26,31] The difference in the energies $\Delta E_{A-B}$ of the conformers (A) and (B) is generally small. Thus for the compounds $C_6H_5SR$, the values for R = $CH_3$, $C_2H_5$, iso-$C_4H_9$, and t-$C_4H_9$ are –3.1, –1.4, –1.0, and 4.6 kJ mole$^{-1}$.[31] The comparatively small difference in the energies of the planar and orthogonal conformers of these compounds is apparently one of the reasons why they cannot be distinguished by certain methods. The methods examined below for estimating the energy of the $p\pi$-conjugation of aromatic compounds relate to the averaged characteristics of the geometry, and are interpreted in terms of the average value of the angle $\phi$.

## 2. The Geometry of the Molecules of Aromatic Compounds of Group V and VI Elements

Intramolecular $p\pi$-interactions are reflected in the structural parameters of molecules. This question can be examined for the compounds of nitrogen and phosphorus (group V) and oxygen and sulphur (group VI).

Table 1 gives the bond lengths, valence angles, and various other structural parameters of the key fragments of molecules, obtained by microwave spectroscopy, gas-phase electron diffraction, and the X-ray diffraction study of crystals. The data for various aliphatic compounds are given for comparison. These are mainly the most reliable results obtained in recent years. Primary, secondary, and tertiary aliphatic amines ((I), (V), and (VII)) have a pyramidal configuration with an average value of the valence angle of the heteroatom ($\theta$) of 110–111°. The pyramidal character of aromatic amines ((II)–(IV), (VI), (VIII)–(XII)) is much less marked, and the average value of the valence angle of the heteroatom is greater and for a number of compounds reaches 120°, that is the amino-group has the planar conformation ($sp^2$ hybridisation of the nitrogen atom), most favourable for $p\pi$-conjugation with the appropriate orientation of the aryl fragment.

The values of the angle $\phi$ in Table 1 show that in compounds (IV) and (IX) the ring and the amino-group are almost coplanar. The pyramidal (in the gas phase) molecules of aniline, N-methylaniline, N,N-dimethylaniline, and anilines containing substituents in the ring have the conformation (C), favourable for $p\pi$-conjugation.[33,38,39,41,42,67,68] For the molecule $C_6H_5CH(CH_3)_2$, the conformation (D) predominates.[69]

(C); $\gamma$ = 90° (D); $\gamma$ = 0°

The influence of $p\pi$-conjugation is reflected not only in the valence angles and the conformation of the molecules but also in the E–C bond lengths. Thus the $N-C_{Ar}$ bond length in $p\pi$-conjugated molecules is appreciably shorter than $N-C_{Alk}$ (see Table 1). The bond length depends not only on the degree of double bond character but also on a number of other factors, such as the nature of the hybridisation of the orbitals and the electronegativities of the atoms forming the bond.[70] The increase in the $N-C_{Ar}$ bond length when there is steric inhibition of $p\pi$-conjugation or when aromatic amines are protonated (see below) shows, however, that the difference in the $N-C_{Ar}$ and $N-C_{Alk}$ bond lengths is determined chiefly by $p\pi$-conjugation.

In this connection, it is of interest to examine the structure of 2,6-dichloro-4-nitro-N,N-dimethylaniline (X).[44] In this molecule, for steric reasons, the $p\pi$-conjugation of the dimethylamino-group is prevented to a considerable extent; the angle between the plane of the amino-group and the ring is 60.5°. The $N_{am}-C_{Ar}$ bond length is 1.41 Å, which is much greater than in compound (IX) (1.36 Å) or in 3,5-dichloro-4-nitroaniline (1.37 Å).[44]

Gas-phase electron diffraction[45] has shown that the molecule of triphenylamine (XI) is slightly pyramidal ($\theta$ = 116°). X-Ray diffraction[7,11] has shown that the amine fragment of the crystalline amines (XI) and (XII) is planar ($\theta \cong 120°$). For steric reasons, however, triarylamines cannot have the conformation most favourable for $p\pi$-conjugation, with the ring and the amino-group coplanar. For triphenylamine, the values obtained for the angle $\gamma$ are 47° from electron diffraction,[45] 44° from X-ray diffraction,[7] and 62° from data on the Kerr effect.[71]

In the molecules of crystalline *ortho*- and *para*-phenylenediamine, the amino-group has a pyramidal structure.[72,73] The non-planar structure of *ortho*-phenylenediamine ($\theta$ = 112.7°) was attributed[72] to the mutual repulsion of the two closely situated UEP and the location of these UEP on different sides of the plane of the ring. The presence of intermolecular H-bonds of the type N–H...N in *ortho*- and *para*-phenylenediamine crystals may influence the geometry of the amino-group.

The degree of pyramidal character of the aromatic phosphines (XVI)–(XXI) is lower than that of the aliphatic phosphines (XIII) and (XV). The valence angle of the phosphorus atom is ~102–103° for the sterically non-overcrowded triarylphosphines (XVI)–(XVIII) and (XXI), which corresponds to approximately *sp* hybridisation of the UEP of the phosphorus atom and indicates that the UEP of the phosphorus atom can be involved in $p\pi$-conjugation.[19] The angles of rotation of the rings ($\gamma$) for the triarylphosphines (XVI)–(XXI) differ little from the corresponding angles of rotation for the triarylamines (XI) and (XII) and is ~40°. From data on the Kerr effect, the angle $\gamma$ for triphenylphosphine in solution is 59°.[71]

The steric effects of phosphorus-containing ligands in transition metal complexes have been analysed.[74] The steric effects of phosphines increase in the order: $(CH_3)_3P$ < $(C_2H_5)_3P$, $(C_3H_7)_3P$ < $(C_6H_5)_3P$, $(iso\text{-}C_4H_9)_3P$ < $(iso\text{-}C_3H_7)_3P$ < $(C_6H_{11})_3P$ < $(t\text{-}C_4H_9)_3P$ < $[2,4,6\text{-}(CH_3)_3C_6H_2]_3P$. The greatest steric effect is observed for trimesitylphosphine. The introduction of $CH_3$ groups in positions 2 and 6 of each ring of triphenylphosphine leads to a sharp increase (to 109.5°) in the valence angle of the phosphorus atom both in the crystalline phase (XIX) and (XX) (see Table 1) and in solution.[75] The average value of the angle $\gamma$ differs little from that for triphenylphosphine. An increase in the valence angle of the heteroatom is also observed when two $CH_3$ groups are introduced in the *ortho*-positions of each ring of triphenylarsenic,[76] triphenylantimony,[77] and triphenylbismuth.[78]

The conformation of phenylphosphines is not yet clear. According to electron diffraction data, the molecules of $C_6H_5PH_2$ and $C_6H_5PCl_2$ have the conformation (D) with angle $\gamma$ = 0°,[47,69,79] and the $C_6H_5PF_2$ molecule has a conformation with an angle $\gamma$ = 31°.[80] Data on the Kerr effect do not make it possible to reach definite conclusions about the conformation of dialkylarylphosphines in solution.[31,81–83] Recent data[26,31] indicate that an equilibrium between the conjugated (C) and non-conjugated (D) conformers is established in solution. The data in Table 1 show that the P–$C_{Ar}$ bond is shorter than P–$C_{Alk}$, but the difference is much smaller than in the case of amines; this question will be examined below.

The C–E–C valence angle in the sterically non-overcrowded aromatic ethers (XXIII)–(XXVI) and sulphides (XXX)–(XXXVI) is much larger than in the corresponding aliphatic compounds (XXII) and (XXIX).[69] The crystalline aromatic ethers (XXIII)–(XXVI) have the planar conformation (A) ($\phi$ = 0°) favourable for $p\pi$-conjugation. In the gas phase at a temperature of 325 K, anisole has an almost planar conformation; with increase in temperature to 523 K, the geometry of the anisole molecule changes considerably, and the angle $\phi$ increases to 40°.[84] The lower ability of sulphur and selenium atoms, compared with oxygen, to take part in $p\pi$-conjugation leads to much larger values of the angle $\phi$ in thioanisole (XXX) (45.3°) and selenoanisole (40°).[84] Data on the Kerr effect indicate that anisole,[20] thioanisole,[22] and selenoanisole[85] have non-planar structures, and that the angle $\phi$ increases in the order indicated. When electron-acceptor substituents (for example $NO_2$) are introduced into the *para*-position, the $p\pi$-conjugation of the O, S, and Se atoms with the ring increases, and the angle $\phi$ decreases.[20,22,85]

The coplanarity of the ring and the methoxy-group may be destroyed by steric factors. *para*-Dimethoxybenzene[86] and *para*-diethoxybenzene (XXVI) have planar structures. The introduction of four bulky substituents, $CH_3$ (XXVII), and also Cl and Br,[87] into the 2,3,5,6-positions of the ring displaces the methoxy-groups from the plane of the ring ($\phi$ = 84–88°); the valence angle of the oxygen atom decreases to 114.5°, and the $p\pi$-conjugation is destroyed.[88] The conformation of compounds containing two methoxy-groups in the *ortho*-position to one another apparently depends on the state of aggregation. In the crystalline state, the molecules are planar (XXV), but in the gas phase, one of the methoxy-groups is coplanar with the ring, but the second is not.[86] The conformation of these molecules in solution is not clear.[89,90]

A coplanar arrangement of the two phenyl rings and the plane of the CEC angle in diphenyl ether and diphenyl sulphide is impossible, for steric reasons. If one of the rings is coplanar with the plane of the CEC angle ($\phi$ = 0°), the second ring forms an angle $\phi$ = 70–90° with this plane, (XXVIII) and (XXXIII)–(XXXVI). The introduction of an electron-acceptor substituent into one of the rings of diphenyl sulphide (XXXIV) facilitates $p\pi$-conjugation of the substituted ring, as indicated by the value of the angle $\phi^{(1)}$ = 2.3°, whereas the angle $\phi^{(2)}$ for the non-substituted ring is 84.3°. On the other hand, the introduction of an electron-donor substituent into one of the rings (XXXV) leads to coplanarity of the CSC group and the non-substituted ring. In the diaryl sulphide (XXXVI), the CSC plane is coplanar with the ring containing the nitro-group ($\phi^{(2)}$ = 1.8°) and makes an angle of 68.9° with the ring containing the dimethylamino-group. If the substituents are identical, the angles $\phi^{(1)}$ and $\phi^{(2)}$ may be similar (XXXII) or different (XXXIII); this apparently depends on the packing conditions in the crystals. In this connection it should be noted that electron diffraction[62] did not make it possible to conclude that diphenyl sulphide has a definite conformation in the gas phase. This agrees with the idea that molecules of the type $Ar_2E$ are non-rigid. The two equivalent aryl rings can rotate relative to one another about the E–$C_{Ar}$ bonds. A non-rigid structure has been proposed for diphenyl ether.[91,92]

### 3. Changes in the Structure of Molecules on Complex Formation

The extent of the rearrangement of the molecules of electron donors on complex formation depends on the type of complex formed and the strength of the electron acceptor. Complexes with compounds of group III elements will be examined, since in the interaction with these acceptors, the geometry of aromatic compounds containing a heteroatom undergoes a rearrangement leading to breakdown of the $p\pi$-conjugation.[93] Breakdown of the $p\pi$-conjugation in aromatic amines and phosphines has also been observed when a H-bond is formed with strong carboxylic acids and on protonation.[19,94,95]

Gillespie's theory[96] predicts that when a complex is formed, the valence angle of the heteroatom of an acceptor should decrease, and the length of the bonds should increase. On the other hand, the valence angle of the heteroatom of a donor should increase, and the length of the bonds should decrease. The changes in the geometry of trimethylphosphine on complex formation with $BH_3$ (Table 2) agree with this prediction. The differences in the valence angles and bond lengths of the original trimethylphosphine and triphenylphosphine practically disappear when complexes are formed with $BH_3$ (Table 2). The geometry of the $R_3P$ frag-

ments of trimethylphosphine and triphenylphosphine in the complexes is close to that of the $R_3P$ fragments in phosphine oxides. All this indicates that the differences in the geometry of trimethylphosphine and triphenylphosphine are related to the $p\pi$-conjugation in the molecule of the latter. This applies particularly to the P–C bond length. In tetravalent phosphorus compounds there are no differences in the P–$C_{Ar}$ and P–$C_{Alk}$ bond lengths.[102]

**Table 2.** Geometric parameters of various phosphines, phosphine oxides, and complexes with $BH_3$.*

| Compound | θ, ° | $R$(P-C), Å | $R$(P-B) or $R$(P-O), Å | Method | Refs. |
|---|---|---|---|---|---|

| $(CH_3)_3PO$ | 104.1; 106.0 | 1.809; 1.81 | 1.476; 1.48 | ED | [99, 100] |
| $(C_6H_5)_3PO$ | 106.2 | 1.82 | 1.49 | XRD | [101] |

*For symbols see Table 1.

Aromatic phosphines, particularly triphenylphosphine, are widely used as ligands in transition metal complexes. Many of these complexes have been studied by X-ray diffraction. The value of the C–P–C angle of the phosphorus atoms in both aliphatic and aromatic phosphines in transition metal complexes varies over a wide range (100–108° in triphenylphosphine); here, an important role is played by the strength of the coordinate bond and steric effects.[74, 103]

Aliphatic amines undergo slight rearrangement on complex formation, and, in contrast to the case of aliphatic phosphines, the nature of the rearrangement does not agree with Gillespie's theory. Thus the C–N–C angle in the molecule of trimethylamine (110.9°) decreases in the complexes with compounds of group III elements to 108–111°, and the N–C bond length increases from 1.458 Å to 1.47–1.49 Å. The reasons for this anomaly are discussed, for example, in Refs. 104–106.

**Table 3.** N–C bond lengths in protonated ($R_1$) and non-protonated ($R_2$) aromatic amines.

| Compound | $R_1$, Å | $R_2$, Å |

*N–C bond length in the neutral amino-group of the complex.

**Note. Numbers in square brackets denote references (Ed. of Translation).**

There are no published data on the structure of complexes of aromatic amines with compounds of group III elements, but X-ray diffraction studies of transition metal complexes indicate that there is considerable rearrangement of aromatic amines on complex formation. As in the case of phosphines, the differences in the geometry of aliphatic and aromatic amines disappear on complex formation. The C–N–C valence angles decrease from 120° in the free aromatic amine to tetrahedral in a complex, and the N–$C_{Ar}$ bond length increases sharply, becoming equal to the N–$C_{Alk}$ bond length. Similar structural changes were observed for the molecule of N,N-dimethylaniline on complex formation with copper compounds,[107] for aniline and 4-toluidine in their complexes with nickel compounds,[108] and for 4-toluidine in its complex with $CdI_2$.[109]

Table 3 gives the N–$C_{Ar}$ bond lengths in protonated aromatic amines and the N–$C_{Ar}$ bond lengths for the corresponding neutral molecules. Protonation or methylation of the amino-group leads to a considerable increase in the N–$C_{Ar}$ bond length to 1.45–1.50 Å, that is to a value characteristic of N–$C_{Alk}$ bonds. The observed effect is evidently related to the breakdown of $p\pi$-conjugation on protonation of the aromatic amines.

## III. THE ELECTRON-DONOR PROPERTIES OF AROMATIC COMPOUNDS OF GROUP V AND VI ELEMENTS

### 1. π-Donor Properties

Donors having a heteroatom with an UEP and a system of π-bonds can be divided into two groups. A characteristic feature of the molecules of one group is that the UEP of the corresponding heteroatom is not joined directly to the π-system of the molecule (pyridine, aryl ketones, etc.). In the molecules of the second group, the UEP of the heteroatom is included in the conjugated system (furan, thiophene, anisole, etc.).

The donors of the two groups behave differently towards different acceptors. The first group of donors, in their reactions with σ-acceptors ($I_2$, ICl, etc.) and ν-acceptors ($BF_3$, $AlCl_3$, $SnCl_4$, etc.) show the properties of *n*-donors, that is the intermolecular bond involves the free UEP of the heteroatom.[93] In their reaction with π-acceptors, the donors of the first group show π-donor properties.[93] In compounds of the second group, the UEP of the heteroatom is not free, but is involved in $p\pi$-conjugation. These compounds are weaker *n*-donors than the corresponding aliphatic compounds (see below). This is illustrated by the compounds furan and thiophene, which do not show *n*-donor properties and which form π-complexes not only with π-acceptors but also with σ- and ν-acceptors.[115,116] The symmetry and energy of the MO of analogues of furan have been discussed.[117]

The electronic spectra of complexes of aromatic and heteroaromatic π-donors with π- and σ-acceptors may contain two (and sometimes more) charge-transfer bands, as a result of the participation in complex formation of not only the HOMO but also lower-lying orbitals of the π-donor. As shown in the Figure, transitions from the $\pi_1$ and $\pi_2$ orbitals of the donor molecule are most probable.[115,118–122] The relative arrangement of the energy levels of the π-donor (see Figure) is determined by a number of factors, and primarily by the energies of the UEP of the heteroatom and the π-system.[3] The structure of the MO in aromatic compounds of group VI elements, of the type $C_6H_5ECH_3$, $XC_6H_4ECH_3$, $XC_6H_4ER$, etc. (from the electronic spectra of charge-transfer complexes of tetracyanoethylene and iodine and quantum-chemical calculations) has been discussed in a number of papers (see Refs. 3 and 123–126 and references therein).

The complexes of aromatic compounds of group V elements with π-acceptors (except nitrogen compounds) have been less extensively studied, and the available data are somewhat contradictory. The question of whether the complexes of aromatic amines with nitrobenzenes are π-complexes, *n*-com-

plexes, or complexes with an H-bond has not yet been resolved.[127] It is not clear whether the $p\pi$-conjugation is destroyed when $I_2$ forms complexes with aromatic amines, that is whether the molecular compounds formed are $n,\sigma$- or $\pi,\sigma$-complexes.[93,128]

Complex formation by aromatic amines with various $\pi$-acceptors is accompanied by chemical reactions. The latter often depend on the conditions of the experiment. Low temperatures and inert solvents stabilise $\pi,\pi$-complexes.[129–132] Triarylphosphines react with tetracyanoethylene in dichloroethane in the same way as amines, that is $\pi,\pi$ complexes are formed first, after which reactions take place.[133] A similar study[134] of the complexes of $(C_6H_5)_3N$, $(C_6H_5)_3P$, and $(C_6H_5)_3$. .As with tetracyanoethylene in chloroform, however, led to the conclusion that the complexes formed are stable. As in the case of the complexes of tetracyanoethylene with aromatic ethers and sulphides, the spectra of these complexes contain two charge-transfer bands, which were assigned to transitions from the two highest MO of the donor to the LUMO of the acceptor.

Since the chief characteristics of the charge-transfer bands in the spectra of charge-transfer complexes are determined by the highest occupied orbitals of the donor molecule, it is natural to look for correlations between the energies of these bands ($h\nu$) and the ionisation potentials (IP) of the donors. For many classes of compound of group VI[3,115,119,128,131,135,136] and V [131,133,134] elements, a linear correlation has been observed between $h\nu$ and IP. This relationship has been widely used to determine IP from $h\nu$ data for charge-transfer complexes. The question of the range within which a linear correlation is observed between $h\nu$ and IP has been examined.[1,93,137]

The participation of several MO of a donor in electron transitions has been used[138–140] to explain the differences in the structures of the complexes formed, for example the "longitudinal" and "transverse" orientation of the tetracyanoethylene molecule relative to the phenyl ring in complexes with substituted benzenes. The relative orientation of the molecules of the donor and acceptor in $\pi,\pi$- and $\pi,\sigma$-complexes, as in complexes of other types, is determined to a large extent by the principle of maximum overlap of the interacting orbitals.[1,93] Of the two highest MO of aromatic compounds containing a heteroatom, only one contains a contribution from the UEP of the heteroatom (see Figure) and hence is localised in the region of the $E-C_{Ar}$ bond. The second orbital of $\pi$-symmetry is localised in the hydrocarbon fragment.[117,121] Different orientations of the acceptor molecule in the complex are possible, depending on which of these two orbitals overlaps the orbital of the acceptor. Evidence in support of this approach is provided, for example, by the results of an X-ray diffraction study of the charge-transfer complex of fluoranil with N,N-dimethylaniline.[141] In this case, two orientations of the fluoranil molecule were detected: in one of them, the ring of the acceptor is positioned directly above the phenyl ring of the donor, and in the other it is directly above the dimethylamino-group; judging from the distances between the donor and acceptor, the interaction in the latter case is stronger than in the former.

The energy of formation of $\pi,\pi$-complexes is generally low (~1–3 kcal mole$^{-1}$),[119,129,132] and the extent of charge transfar in the ground state of the complex does not exceed ~0.05;[119,120] complex formation in these systems is not accompanied by a significant rearrangement of the molecules of the donor and acceptor.[142–144] This makes it possible to use the electronic spectra of charge-transfer complexes to study intramolecular electronic interactions in organic and organometallic compounds.[145]

### 2. *n*-Donor Properties. The Determination of the Energy of $p\pi$-Conjugation by the Method of Complex Formation

On $\pi$-complex formation, aromatic compounds containing a heteroatom do not undergo appreciable rearrangement; the system of MO formed as a result of $p\pi$-conjugation is preserved. A fundamentally different picture is observed in the reaction of these compounds with strong electron acceptors (the halides of group III elements, strong carboxylic acids, etc.). The donor–acceptor bond is formed by the UEP of the heteroatom of the donor and an unoccupied orbital of the acceptor. The $p\pi$-conjugation is destroyed, the MO system of the original aromatic compound breaks down, and and an MO system characteristic of the aromatic fragment of the molecule is produced. A good illustration of this is provided by the changes in the electronic spectra of aromatic amines, ethers, phosphines, and sulphides on complex formation with strong acceptors (see below)

Some physicochemical properties and geometric characteristics (see above) of complexes of strong acceptors with aromatic and corresponding aliphatic *n*-donors are similar. These are the properties which are determined by the strength of the donor–acceptor bond ($-\Delta H_{DA}$) and the magnitude of the charge transferred from the donor to the acceptor. One such parameter is the dipole moment of the donor–acceptor bond ($\mu_{DA}$) and (other conditions being equal) the dipole moment of the complex as a whole ($\mu_c$), and also the extent of charge transfer from the donor to the acceptor $\mu_{DA}/er_{DA}$ ($r_{DA}$ is the length of the donor–acceptor bond), determined from the value of $\mu_{DA}$. Some examples are given in Table 4. The dipole moments of the complexes of the halides of boron, aluminium, and gallium with aliphatic and aromatic *n*-donors (amines, ethers, phosphines, sulphides) differ little from one another.[19,93,146]

Table 4. Dipole moments ($\mu_c$, D) and enthalpies of formation of the complexes $D.AlBr_3$($-\Delta H$, kcal mole$^{-1}$).[19,146] *

| D | $\mu_c$ | $-\Delta H$ | $\Delta\Delta H$** | D | $\mu_c$ | $-\Delta H$ | $\Delta\Delta H$** |
|---|---|---|---|---|---|---|---|
| $Alk_2O$ | 7.2 (av) | 23.3 (av) | — | $Alk_3N$ | 8.6 (av) | 32.3 (av) | — |
| $C_6H_5OCH_3$ | 7.00 | 15.9 | 7.4 | $C_6H_5N(CH_3)_2$ | 8.68 | 24.2 | 8.1 |
| $(C_6H_5)_2O$ | 7.29 | 12.0 | 11.3 | $(C_6H_5)_2NCH_3$ | 8.01 | 17.4 | 14.9 |
| $Alk_2S$ | 7.6 (av) | 17.5 (av) | — | $Alk_3P$ | 10.2 (av) | 32.2 (av) | — |
| $C_6H_5SCH_3$ | 7.00 | 13.1 | 4.4 | $C_6H_5P(C_3H_7)_2$ | — | 27.7 | 4.5 |
| $(C_6H_5)_2S$ | 7.55 | 10.2 | 7.3 | $(C_6H_5)_3P$ | 10.0 | 21.3 | 10.9 |

*Some of the $-\Delta H$ values have been refined by the present authors.
**See the text for the significance of $\Delta\Delta H$.

A characteristic feature of donor–acceptor complexes is the relationship between the magnitude of the transferred charge and the energy of the donor–acceptor bond.[93] This is revealed by the linear relationship between the enthalpy of formation of the complex ($-\Delta H_c$) and the extent of charge transfer from the donor to the acceptor. For the complexes of aluminium and gallium compounds with aliphatic *n*-donors, the relationship has the form:[147]

$$-\Delta H_c \text{ kcal mole}^{-1} = 69.2\,\mu_{DA}/er_{DA} - 1.6 \qquad (1)$$

For the complexes with carboxylic acids, a similar relationship is observed:[148]

$$-\Delta H_c \text{ kcal mole}^{-1} = 38.0\,\mu_{DA}/er_{DA} + 3.9 \qquad (2)$$

According to Eqns.(1) and (2), complexes with identical degrees of charge transfer should have identical enthalpies of formation. The values of $-\Delta H_c$ for complexes of aromatic and corresponding aliphatic *n*-donors with the same acceptor should therefore be similar. It can be seen from Table 4, however, that the values of $-\Delta H$ for complexes with aromatic compounds are much lower than those for aliphatic compounds. This has been established for a wide range of complexes of strong acceptors with amines,[93,94,146] ethers, sulphides,[93,146,147,150,151] and phosphines.[19,93,147,149] The observed difference ($\Delta\Delta H$) in the values of $-\Delta H$ are due to the expenditure of energy in the rearrangement of the aromatic *n*-donor on complex formation, that is in the breakdown of $p\pi$-conjugation.

Thus the study of complex formation opens up a route for determining the values of the energy of $p\pi$-conjugation ($E_c$). In the simplest and crudest version, the energy of $p\pi$-conjugation can be estimated as the difference ($\Delta\Delta H$) in the values of $-\Delta H$ for the complexes of a given acceptor with aliphatic and corresponding aromatic donors.[19,88,93,94,146,149,150] The values of $\Delta\Delta H$ for each aromatic donor, obtained by the method of complex formation with different acceptors, agree well with one another, although the acceptors used differ considerably in their strength and in the nature of the interaction; the halides of group III metals[19,93,146] and carboxylic acids[94,149] were studied.

An unsatisfactory feature of this approach is that inductive and steric effects are underestimated. More accurate values of the energy of $p\pi$-conjugation ($E_c$) can be obtained using correlation equations relating the values of $-\Delta H$ to the sum of the induction ($\Sigma\sigma^*$) and steric ($\Sigma E_s^0$) constants of the substituents on the heteroatom of the donor. An equation of this kind has been obtained[147] for complexes of gallium trichloride with a number of aliphatic ethers containing substituents with markedly different induction and steric constants. Using this equation, it is possible to calculate the value of $(-\Delta H)_{calc}$ for an aromatic ether in accordance with the values of $\Sigma\sigma^*$ and $\Sigma E_s^0$, and the energy of $p\pi$-conjugation for the ether can be determined as the difference $E_c = (-\Delta H)_{calc} - (-\Delta H)_{expt}$. This method of determining $E_c$ is independent of the linear relationship (1), and is essentially a second, independent method of determining $E_c$ from data on the heats of formation of the complexes.

In the determination of $E_c$ by this method it is important to estimate correctly the values of $\sigma^*$ and $E_s^0$ for the phenyl substituent. The induction constant of the phenyl substituent is +0.6,[152] but the choice of the steric constant is more complicated. Because of the marked difference in the dimensions of the phenyl group in the plane of the ring and at right angles to it, two steric constants are given for this substituent ($E_s^0 = -0.3$ and $-2.77$ [147,153]). In complexes in which the $p\pi$-conjugation is broken down, the ring occupies the most favourable position from the viewpoint of steric conditions. For example, in the complex $C_6H_5OCH_3.AlBr_3$, the plane of the ring is perpendicular to the COC plane.[150] The low value of the steric constant $E_s^0 = -0.3$ apparently reflects fairly objectively the steric influence of the phenyl substituent in this complex. The same value of $E_s^0$ for the phenyl substituent was used[147] to calculate the energy of the $p\pi$-conjugation of aromatic phosphines. This estimate of $E_s^0$ is confirmed by Tolman's data[74] on the steric effects of phosphine-containing ligands. The steric effects of trimethylphosphine and dimethylphenylphosphine practically coincide, and the steric properties of triphenylphosphine are similar to those of tertiary aliphatic phosphines containing alkyl groups not branched in the α-position.

Since the steric constants of the phenyl substituent and alkyl substituents with the normal structure are similar, steric effects have relatively little influence on the magnitude of $\Delta\Delta H$. The main contribution to the value of $\Delta\Delta H$, in addition to the energy of $p\pi$-conjugation, is made by the difference in the energies of the donor–acceptor bonds due to the difference in the inductive effects of the alkyl and phenyl substituents. This error can be taken into account by introducing into the value of $\Delta\Delta H$ a correction for the inductive effect of the phenyl substituent equal on the average to 1.2 kcal mole$^{-1}$ per ring.[147] The values of $E_c$ for aromatic ethers, sulphides, amines, and phosphines, obtained using the correlation equations, $E_c$(I), and from the values of $\Delta\Delta H$ with a correction for the inductive effect of the aryl fragments, $E_c$(II), are analysed below (see Tables 6 and 7).

The introduction of two *ortho*-substituents leads to the production of appreciable steric hindrance to intermolecular donor–acceptor interaction in $AlBr_3$ complexes. Thus the heat of the addition of $AlBr_3$ molecules to dimethoxydurene (21.2 kcal mole$^{-1}$)[88] is lower than that to aliphatic ethers (23.3 kcal mole$^{-1}$), although the $p\pi$-conjugation in dimethoxydurene is prevented by steric factors (see above). At the same time, in the complexes of aromatic phosphines with trifluoroacetic acid, the influence of *ortho*-substituents on the strength of the donor–acceptor bond is slight, because of the low sensitivity of the H-bond to steric effects. Thus the heats of formation of the complexes $Alk_3P.(CF_3COOH)_2$ in benzene are on the average 27.5 kcal mole$^{-1}$,[149] whereas that for the corresponding complex of diethylmesitylphosphine is 27.3 kcal mole$^{-1}$. Thus the energy of $p\pi$-conjugation in the diethylmesitylphosphine molecule is zero, in agreement with the electronic spectra (see below), which indicate that there is steric inhibition of $p\pi$-conjugation in this compound. The heats of formation of the complexes of trifluoroacetic acid with triphenylphosphine (18.4 kcal mole$^{-1}$) and diethylphenylphosphine (24.6 kcal mol$^{-1}$) are much lower, because of the expenditure of energy in the breakdown of $p\pi$-conjugation on complex formation.

## IV. THE ESTIMATION OF THE DEGREE OF $p\pi$-CONJUGATION

Many physicochemical properties of aromatic compounds of group V and VI elements can be interpreted in terms of the conjugation of the UEP of the heteroatom with the π-electron system of the aromatic fragment. At the present stage of development, some physicochemical methods for studying molecules make possible only comparative estimates of the degree of $p\pi$-conjugation in compounds with similar compositions and structures (UV, NMR, and Raman spectroscopy). Other methods, such as PES, make it possible to characterise quantitatively the degree of $p\pi$-conjugation in certain compounds. The most reliable information on the energy of $p\pi$-conjugation is given by methods involving the measurement of thermal effects such as heats of combustion and the calorimetric study of the electron-donor properties of the corresponding compounds. The results of the study of $p\pi$-conjugated systems by some of these methods can be considered.

### 1. Electronic Spectra

The interaction of the UEP of a heteroatom with a neighbouring π-system can be regarded as an intramolecular donor–acceptor interaction.[1,2] The electronic spectra of aromatic compounds containing a heteroatom should contain intense bands similar in character to the charge-transfer bands of intermolecular charge-transfer complexes. A necessary condition for the appearance of charge-transfer

bands is the overlap of the orbitals of the donor and acceptor in the ground state,[2] or, in the case of aromatic compounds, the overlap of the orbital of the UEP of the heteroatom and the π-system of the aromatic fragment. The conditions of orbital overlap and hence the spectral manifestation of $p\pi$-conjugation are determined to a large extent by the geometry of the molecules.

When there is steric inhibition of the $p\pi$-conjugation in aromatic amines[95] and ethers,[156,157] the spectra of the compounds, in which there is no conjugation, are similar to the spectra of the corresponding aromatic hydrocarbons. For example, in the case of benzoquinuclidine, the orbital of the UEP of the nitrogen atom is orthogonal to the orbitals of the π-system of the aromatic fragment, and the electronic absorption spectrum is similar to that of benzene.[158] The spectrum of dimethoxydurene, in the molecule of which the planes of the methoxy-groups are perpendicular to the plane of the ring (compound (XXVII) in Table 1), is similar to the spectrum of durene.[88] The influence of steric inhibition of $p\pi$-conjugation on the electronic spectra of aromatic sulphides has also been extensively studied,[26,27,157,159,160] but in contrast to the case of amines and ethers, even those aromatic sulphides showing the greatest degree of steric overcrowding absorb more strongly in the near ultraviolet than the corresponding aromatic hydrocarbons.

The nature of the electronic spectra of aromatic phosphines has been discussed for many years (see Refs. 6 and 161–164 and references therein). Recent studies[26,31,165,166] have shown that the electronic spectra of dialkylarylphosphines undergo considerable changes with increase in the volume of the alkyl group or on the introduction of bulky *ortho*-substituents (Table 5). Thus as in the case of aromatic amines, ethers, and sulphides, the nature of the electronic spectra of aromatic phosphines depends on the degree of overlap of the UEP of the phosphorus atom with the orbitals of the π-system, that is on the degree of $p\pi$-conjugation.

Table 5. Parameters of the long-wave band in the ultraviolet spectra of dialkylarylphosphines.

| Phosphine | $\lambda_{max}$, nm | $10^{-3}\varepsilon$ | $10^{3}f$ | Refs. |
|---|---|---|---|---|
| $C_6H_5P(CH_3)_2$ | 251 | 5.6 | 13.0 | [165] |
| $C_6H_5P(C_2H_5)_2$ | 255 | 3.3 | 7.5 | [163] |
| $C_6H_5P(C_4H_9)_2$ | 256 | 3.0 | 7.3 | [163] |
| $C_6H_5P(C_4H_9\text{-iso})_2$ | 257 | 2.4 | 5.9 | [163] |
| $C_6H_5P(C_8H_7\text{-iso})_2$ | 259 | 2.0 | 5.6 | [163] |
| $C_6H_5P(C_4H_9\text{-t})_2$ | 260 | 1.7 | 4.7 | [165] |
| $4\text{-}CH_3C_6H_4P(CH_3)_2$ | 253 | 3.6 | — | [166] |
| $2\text{-}CH_3C_6H_4P(CH_3)_2$ | 254 | 4.8 | — | [166] |
| $2,4,6\text{-}(CH_3)_3C_6H_2P(CH_3)_2$ | 265 | 2.3 | — | [166] |
| $2,4,6\text{-}(CH_3)_3C_6H_2P(C_2H_5)_2$ | 260 | 1.7 | — | [161] |

Symbols: ε is the molar absorptivity, and $f$ the oscillator strength.

The high sensitivity of the electronic spectra to $p\pi$-conjugation makes it possible to detect this effect not only in aromatic sulphides and phosphines but also in the compounds of the elements of later periods,[30,167,168] although the conditions of overlap of the orbital of the UEP with the π-system become less favourable with increase in the atomic number of the heteroatom. For example, it has been shown[30] that as in the case of the compounds of oxygen and sulphur, the intensity of absorption by aromatic compounds of selenium $C_6H_5SeR$ in the near ultraviolet decreases with increase in the volume of the aliphatic group R. The changes in the electronic spectra with change in temperature are characteristic not only of the aromatic sulphides and phosphines,[27,31,168] but also of the triaryl derivatives of arsenic, antimony, and bismuth.[168] This effect is usually attributed to the presence of conjugated and non-conjugated conformers in solution and to the displacement of the conformational equilibrium with change in temperature.

Thus the steric inhibition of $p\pi$-conjugation is clearly revealed in the electronic spectra, and this makes it possible to establish in narrow series of compounds the relationship between the spectral characteristics and the geometry of the molecules. Quantitative estimates of the degree of $p\pi$-conjugation cannot usually be obtained, however, from spectrophotometric data, particularly when the spectra of compounds with different heteroatoms are compared.[169,170]

One of the main reasons for these difficulties is apparently that for a fairly wide range of $p\pi$-conjugated molecules there is no unique dependence of the parameters of the intramolecular charge-transfer bands on the energy of $p\pi$-conjugation. To continue the parallel between $p\pi$-conjugation and intermolecular donor–acceptor interaction, it may be stated that the relationship between the position and intensity of the charge-transfer bands and the thermodynamic parameters of the complexes is extremely complicated.[1,93,171]

In the comparison of the electronic spectra of aromatic compounds of the elements of periods II and III, it is necessary to take into account not only the effect of $p\pi$-conjugation but also the possible contribution of the *d*-orbitals of the sulphur and phosphorus atoms to the MO of aromatic sulphides and phosphines. Although the concept of unoccupied *d*-orbitals has been criticised,[172,173] it is still widely used,[145,174] and provides a simple and natural explanation of the above differences in the spectral behaviour of the compounds of elements of periods II and III when there is steric inhibition of $p\pi$-conjugation.

It should also be noted that the electronic spectra are integral characteristics of the compounds, and result from the superposition of individual bands. Information on the number of bands and their parameters is necessary for a correct assignment of the bands and the correct comparison of experimental data with quantum-chemical calculations. The integral absorption curve can be described by a set of Gaussians.[154,155,175–177] Most frequently, however, the number of bands is estimated from the number of clearly defined maxima, and bands appearing as shoulders are taken into account or ignored arbitrarily. The problem of distinguishing the bands becomes particularly acute for systems in which there is an equilibrium between conjugated and non-conjugated conformers whose electronic spectra differ considerably.

The breakdown of $p\pi$-conjugation is clearly reflected in the nature of the change in the spectrum on going from an aromatic compound containing a heteroatom to a complex with a strong electron acceptor. The spectra of the complexes of aromatic amines and ethers with the halides of group III metals and strong carboxylic acids are similar to the spectra of the corresponding aromatic hydrocarbons.[93,94,146,178,179] Similar changes in the electronic spectra take place when aromatic amines are protonated.[95] Since the groups $OCH_3$, $MX_3$ and $N(CH_3)_2.MX_3$ have strong inductive ($-I$) effects,[150] the inductive effect of the substituent apparently does not influence the parameters of the long-wave band of the aromatic fragment.

The spectra of aromatic sulphides also change considerably when they form complexes with the halides of group III metals, but in contrast to the complexes of amines and ethers, the complexes of aromatic sulphides absorb much more strongly than the corresponding hydrocarbons. Thus the spectrum of the complex $(C_6H_5)_2S.GaCl_3$ is similar to the

spectrum of diphenyl sulphoxide, and not to the spectrum of benzene.[179] A similar picture is observed when aromatic phosphines form complexes with strong electron acceptors[19] or are protonated.[166] The spectra of these systems differ considerably from those of the corresponding hydrocarbons. The spectrum of a solution of triphenylphosphine in trifluoroacetic acid is similar to the spectrum of triphenylphosphine oxide.[19] These facts agree with the view that the 3*d*-orbitals of the phosphorus and sulphur atoms take part in the formation of the MO of aromatic sulphides and phosphines.

The analogous changes taking place in the electronic spectra of aromatic compounds containing a heteroatom when the UEP of the heteroatom forms an intermolecular donor–acceptor bond on the one hand and when bulky substituents are introduced on the other hand leaves no doubt that the intense absorption in the long-wave range of the electronic spectra of these compounds is related to the interaction of the UEP of the heteroatom with the neighbouring π-system, that is to $p\pi$-conjugation. The spectral manifestation of the breakdown of the $p\pi$-conjugation in aromatic compounds containing a heteroatom when complexes are formed has provided a basis for developing a method for estimating the energy of $p\pi$-conjugation.[93,146]

## 2. NMR Spectroscopy

The parameters of the NMR spectra, namely the chemical shifts (δ) and the spin–spin coupling constants (*J*), show a complex dependence on the structural characteristics of molecules and reflect the influence of various factors (inductive, resonance, steric) on the state of individual fragments of the molecules. Nevertheless, in spite of the fact that the parameters of the NMR spectra depend on many factors, they have been widely used to study the effects of $p\pi$-conjugation. Systematic studies of $p\pi$-conjugation by NMR in aromatic and unsaturated compounds of group VI elements have been described in Refs. 26, 31, 180–189 and references therein.

Comprehensive studies of alkyl phenyl ethers[181,185,187] and sulphides[181,186] showed that the most informative parameters for estimating the effects of $p\pi$-conjugation by NMR are those relating to the atom in position 4 of the phenyl ring. This position in the molecule is less influenced than other positions by the inductive and steric effects of the ER group. The values of $\delta(^{13}C_n)$ for compounds of the type $C_6H_5ER$ are (p.p.m.):

| R | O (Ref.187) | S (Ref.186) | Se (Ref.182) | $CH_2$ (Ref.181) |
|---|---|---|---|---|
| $CH_3$ | 120.92 | 125.06 | 125.55 | 125.67 |
| $C_2H_5$ | 120.57 | 125.74 | 126.24 | 125.67 |
| $C_3H_7$ | 120.25 | 125.68 | 126.16 | 125.58 |
| iso-$C_3H_7$ | 120.55 | 126.72 | 126.84 | 125.62 |
| t-$C_4H_9$ | 123.27 | 128.57 | 128.10 | 125.63 |

Since the value of $\delta(^{13}C)$ is directly related to the electron density on the carbon atom, it follows in accordance with the induction constants of the $ECH_3$ groups that a decrease in the shielding of the $C_n$ atom in the compounds studied should be expected, compared with benzene ($\delta(^{13}C)$ = 128.70 p.p.m.) or ethylbenzene ($\delta(^{13}C_n)$ = 125.67 p.p.m.). The increase in the degree of shielding of the $C_n$ atoms of the compounds studied is a consequence of the $p\pi$-conjugation of the UEP of the heteroatoms with the π-system. Comparison of the values of $\delta(^{13}C_n)$ for R = $CH_3$ indicates that the degree of $p\pi$-conjugation decreases in the order $C_6H_5OCH_3 > C_6H_5SCH_3 > C_6H_5SeCH_3$. The nature of the changes in $\delta(^{13}C_n)$ with increase in the size of R reflects the influence of steric effects on $p\pi$-conjugation. The chemical shifts $\delta(^{13}C_n)$ of alkylbenzenes are practically the same for all compounds. For the oxygen compounds there is a sharp decrease in the shielding only for R = $C(CH_3)_3$. For phenyl alkyl sulphides and selenides, the shielding decreases regularly in the order $C_3H_7$ > iso-$C_3H_7$ > t-$C_4H_9$.

The main reason for the observed regularities is the steric inhibition of $p\pi$-conjugation. This is indicated by the good correlation between the values of $\delta(^{13}C_n)$ and the steric constants $E_s^0(CH_2R)$ of the substituents for phenyl alkyl sulphides[181] and phenyl alkyl selenides.[182] Proof that the observed changes in $\delta(^{13}C_n)$ are due to steric factors is provided by the fact that, in contrast to the phenyl derivatives, in compounds of the mesityl series, for example in mesityl alkyl sulphides,[184] the value of $\delta(^{13}C_n)$ remains constant for all R ($CH_3$, $C_2H_5$, iso-$C_3H_7$, t-$C_4H_9$), since in these compounds the $p\pi$-conjugation is prevented by steric factors.

Thus according to the NMR data, the intensity of the $p\pi$-conjugation in alkyl phenyl compounds of group VI elements is determined to a large extent by the conformation of the molecules, which depends on the volume of the alkyl group. This conclusion is confirmed by the results of a study of the chemical shifts of the signal of the proton in position 4 and by the changes in $J(^1H-^1H)$ and $J(^{13}C-^1H)$ for phenyl alkyl ethers and sulphides.[185–187] A similar conclusion that there is steric inhibition of conjugation was reached on the basis of $^{13}C$ and $^1H$ NMR data for the β-atoms of the vinyl group in alkyl vinyl ethers and sulphides.[180,183,190]

The magnitude of the chemical shift of the $^{17}O$ signal is extremely sensitive to the effects of $p\pi$-conjugation in aromatic and unsaturated oxygen-containing compounds. The $^{17}O$ NMR data for these compounds[189] confirmed the conclusions reached from the $^{13}C$ and $^1H$ NMR data. It was shown that the $p\pi$-interaction between the UEP of the oxygen atom and the aromatic (unsaturated) fragment remains approximately the same for R = $CH_3$, $C_2H_5$, and iso-$C_3H_7$, and changes sharply on going to t-$C_4H_9$.

For aromatic compounds of the group V elements, the NMR studies of $p\pi$-conjugation have been less systematic, and the results are less unambiguous. It has been pointed out[191] that it is difficult to interpret the spectral data, since the NMR spectra of these compounds may be influenced by many different factors. From an analysis of the relationship between $\delta[^{13}C(R^{13}CH_3)]$ and $\delta[^{31}P(R^{31}PPh_2)]$ it was concluded that there is only slight overlap of the orbital of the UEP of the phosphorus atom and the π-system of aryl phosphines.[192] In Ref. 193 it was shown that triarylphosphines show a common correlation with alkylphosphines between $\delta(^{31}P)$ and θ (where θ is the valence angle of the phosphorus atom). Assuming that the inductive influence of the substituents on the magnitude of $\delta(^{13}C)$ in the *para*- and *meta*-positions of monosubstituted benzenes are approximately the same, the authors of a number of studies[192,194] took as a measure of the resonance effects the quantity $\Delta\delta = \delta(^{13}C_n) - \delta(^{13}C_m)$. Analysis of the values of $\Delta\delta$ for arylphosphines[192,194–196] led to the conclusion that there is little $p\pi$-conjugation. According to Ref. 192, the value of $\Delta\delta$ is 0.5 p.p.m. for arylphosphines and 12.5 p.p.m. for dimethylaniline. $^{13}C$ NMR data indicating a marked difference in the ability of N and P atoms to undergo $p\pi$-conjugation have been reported.[197]

At the same time, the results of a study of the anisotropy of the chemical shift of the $^{31}P$ NMR signal for trimethyl- and triphenylphosphines in the liquid-crystal phase have been interpreted[198] in terms of the delocalisation of the UEP of the phosphorus atom in triphenylphosphine. The same conclusion was reached from a study of $J(^{31}P-^1H)$ for phenylphosphines.[199] An analysis of the temperature dependence of the difference $\delta(^{31}C_n) - \delta(^{31}C_m)$ for aromatic phosphines $C_6H_5PR_2$ and sulphides $C_6H_5SR$ for R = $CH_3$, $C_2H_5$, iso-$C_3H_7$, and t-$C_4H_9$ indicates[26,31] that in solution there is an equi-

librium between conjugated and non-conjugated conformers; the concentration of the non-conjugated conformer increases in the R order given. In the case of the planar conformation, the maximum contribution of the UEP of the phosphorus atom to the $p\pi$-conjugation with the ring is ~50% of the contribution of the UEP of the nitrogen atom in dimethylaniline.

### 3. Photoelectron Spectroscopy

Photoelectron spectroscopy (PES) is an extremely promising method for studying intramolecular interactions.[200] When combined with quantum-chemical calculations, this method makes it possible to characterise quantitatively the energies of the MO of the molecules and to assign the bands in the PES. The application of this method to organic and heteroorganic compounds has been examined in general reviews[200,201] and also in special reviews on the PES of phosphorus compounds,[202,203] the PES of oxygen and sulphur compounds,[204] and the use of PES to study the conformations of molecules.[205]

The parametrisation of quantum-chemical calculations from PES data is widely used in the study of the regular features of the production of MO. In particular, for aromatic compounds of group VI elements of the type $C_6H_5ECH_3$, the contribution of the UEP of the heteroatom to the HOMO has been determined, and it has been shown that the energy of the HOMO calculated by the simple MO method agrees well with the experimentally determined value.[30,124] The regular features of the influence of the size of the aliphatic group R in series of compounds of the type $C_6H_5ER$ on the conformation of the molecules have been determined.[3,30] It has been shown that in disubstituted benzenes with two electron-donor substituents, the greater contribution to the HOMO is made by the substituent with the lower IP.[206] The conditions for steric inhibition of $p\pi$-conjugation in substituted benzenes have been determined.[207,208] It has been shown for the case of compounds of group VI elements that PES combined with quantum-chemical calculations makes it possible to reach conclusions about the three-dimensional structure of molecules.[209]

A number of papers[202,210-216] have described the geometry and $p\pi$-conjugation of compounds of phosphorus and other group V elements. It has been established that $IP_1$ is linearly dependent on the valence angle of the heteroatom in the phosphine series,[18] and also in more extensive series of compounds of group V elements.[210] In the estimation of the extent of $p\pi$-conjugation in aromatic phosphines, it was first concluded from the interpretation of the PES that there is practically no $p\pi$-conjugation or that it is negligible.[211-213] Later more detailed PES studies and quantum-chemical calculations led to the conclusion that the UEP of the phosphorus atom makes a significant contribution to the HOMO of phenylphosphine and other aromatic phosphines.[164,214,216]

There are a number of different approaches in the use of PES to estimate the extent to which the UEP of the heteroatom is combined with the $\pi$-system. In certain series of compounds, a relative characteristic of the extent of $p\pi$-interaction can be obtained by comparing the values of the resonance integrals $\beta_{E-C}$ calculated from PES data.[217] This parameter has been used to estimate the degree of binding of the UEP in compounds of the type $C_6H_5OR$ and in isologues of anisole,[3,5,218] and in a comparison of the effects of $p\pi$-conjugation in non-substituted and perfluorinated thiophenols, thioanisoles, and diphenyl sulphides.[219]

In accordance with the scheme given in the Figure, the relative efficiency of $p\pi$-interaction has been characterised[219-221] using the difference in the energies of the HOMO ($\pi_1$) and the levels $\pi_2$ or $\pi_3$: $\Delta_{1,2} = \pi_1 - \pi_2$ or $\Delta_{1,3} = \pi_1 - \pi_3$; both quantities can be estimated from the PES. The parameter $\Delta_{1,3}$ can also be obtained from the X-ray fluorescence spectra.[221] The numerical values of $\Delta_{1,2}$ and $\Delta_{1,3}$ have been used to estimate the degree of $p\pi$-interaction and the conformations of the molecules of diphenyl sulphide and other sulphur compounds,[220] aryl alkyl and diaryl sulphides and their perfluorinated analogues,[219,220] and various phosphines.[202]

The PES is influenced considerably, however, not only by $p\pi$-conjugation but also by other factors such as the inductive and steric influence of the substituents, hyperconjugation, $p_\pi$–$d_\pi$ conjugation, etc. Thus the approach described above is useful for comparing the effects of $p\pi$-conjugation in series of compounds with similar compositions and structures.

In addition to PES, X-ray electron spectroscopy (XES) is extremely promising for the analysis of $p\pi$-conjugation. It has been suggested[222] that a measure of the binding of the UEP in a compound being studied is provided by the quantity $\Delta = IP - IP_{stand} - 0.8(E_i - E_{i(stand)})$, where IP and $IP_{stand}$ are the ionisation potentials (determined from the PES), and $E_i$ and $E_{i(stand)}$ are the binding energies of the internal electrons of the heteroatom (determined from the PES) for the compound being studied and a compound taken as standard respectively. A positive value of $\Delta$ corresponds to bonding character for the UEP, and a negative value corresponds to antibonding character. The combined analysis of the ionisation potentials of the outer and inner electrons of the $p\pi$-conjugated molecule being studied and the molecule of the standard compound, in which the UEP of the heteroatom is not combined, makes it possible to eliminate the influence of differences in the charges of the atoms and other electronic effects.

The values of $\Delta$ have been determined for a number of $p\pi$-conjugated molecules. It has been shown that in aliphatic amines, the UEP of the nitrogen atom has antibonding character (for trimethylamine $\Delta = -0.9$ eV), and this has been attributed to the repulsion of the UEP by the electrons of the C–H bonds. On the other hand, for the aniline molecule, $\Delta = 1.3$ eV, indicating that the UEP of the nitrogen atom is combined to a considerable extent with the $\pi$-system. Similarly, the UEP of the oxygen atom of dimethyl ether ($\Delta = -1.8$ eV) is antibonding, whereas in the phenol molecule ($\Delta = 0.7$ eV) it is combined with the $\pi$-system of the ring.

Thus the combined use of PES and XES makes it possible to estimate quantitatively the effects of $p\pi$-conjugation.

### 4. The Energy of $p\pi$-Conjugation from Thermochemical Data

Like any interaction, $p\pi$-conjugation is characterised quantitatively by its energy. At the present time, the energy of $p\pi$-conjugation is determined by two thermochemical methods: a method based on the measurements of heats of combustion, and the recently developed method of complex formation. The first method has been known for a long time, but the data obtained by this method are extremely contradictory;[93,146,173] there have been no systematic studies of aromatic compounds containing a heteroatom, apart from work[223] on the measurement of the heats of combustion of a series of alkyl and aryl vinyl ethers $H_2C{=}CHOR$ and the determination (with a correction for the inductive effect) of the values of the energies of $p\pi$-conjugation $E_c$ (kcal mole$^{-1}$) of the following compounds:

| R | $C_2H_5$ | $C_3H_7$ | iso-$C_3H_7$ | $C_4H_9$ | $C_2H_4Cl$ | $C_6H_5$ | $H_2C{=}CH$ |
|---|---|---|---|---|---|---|---|
| $E_c$ | 6.8 | 6.8 | 6.5 | 7.3 | 7.3 | 6.6 | 10.1 |

In Refs. 223 and 224, the MINDO/2 method gave estimates of $E_c$ agreeing with experimental data. The method of determining $E_c$ from heats of combustion has much in common with the method of complex formation, the principles of which were described above; the values of $E_c$ obtained are given in Tables 6 and 7. Both methods are based on the comparison of the thermochemical properties of aromatic and corresponding aliphatic compounds with allowance (in recent studies) for the differences in the inductive effects of the corresponding groups on the heteroatom.

**Table 6.** Values of the energy of $p\pi$-conjugation (kcal mole$^{-1}$).*

| Compound | $E_c$ (I) | $E_c$ (II) |
|---|---|---|
| $C_6H_5OCH_3$ | 6.2 | 6.2 |
| $C_6H_5OC_2H_5$ | 4.8 | 5.5 |
| $(C_6H_5)_2O$ | 8.8 | 8.6 |
| $C_6H_5SCH_3$ | — | 3.7 |
| $C_6H_5SC_2H_5$ | — | 2.7 |
| $(C_6H_5)_2S$ | — | 5.5 |
| $C_6H_5N(CH_3)_2$ | — | 8.4 |
| $(C_6H_5)_2NCH_3$ | — | 14.6 |
| $C_6H_5P(C_2H_5)_2$ | 5.2 | 3.0 |
| $(C_6H_5)_2PC_2H_5$ | — | 4.9 |
| $(C_6H_5)_3P$ | 7.1 | 6.9 |
| $(4\text{-}CH_3C_6H_4)_3P$ | — | 4.9 |
| $2,4,6\text{-}(CH_3)_3C_6H_2P(C_2H_5)_2$ | — | ~0 |

*The values of $E_c$(I) were obtained using the correlation equations, with the acceptor $GaCl_3$;[147] the values of $E_c$(II) were obtained from the values of $\Delta\Delta H$ [19,94,146,149,150] with a correction for the inductive effect of the aryl ring, the acceptors were metal halides and carboxylic acids, and the average values are given.

**Table 7.** Values of the energy of $p\pi$-conjugation for aromatic ethers (kcal mole$^{-1}$).*

| Compound | $E_c$ (I) | $E_c$ (II) | Compound | $E_c$ (I) | $E_c$ (II) |
|---|---|---|---|---|---|
| $C_6H_5OCH_3$ | 6.2 | 6.2 | $1,4\text{-}(CH_3O)_2C_6(CH_3)_4$ | — | 0 |
| $3\text{-}CH_3C_6H_4OCH_3$ | 5.8 | 5.5 | $C_6H_5OC_2H_5$ | 4.8 | 5.3 |
| $4\text{-}CH_3C_6H_4OCH_3$ | 5.4 | 5.3 | $(C_6H_5)_2O$ | 8.8 | 8.9 |
| $3,5\text{-}(CH_3)_2C_6H_3OCH_3$ | — | 5.3 | $3\text{-}CH_3C_6H_4OC_6H_5$ | — | 8.9 |
| $2,6\text{-}(CH_3)_2C_6H_3OCH_3$ | — | 0.6 | $4\text{-}CH_3C_6H_4OC_6H_5$ | — | 8.9 |
| $3\text{-}BrC_6H_4OCH_3$ | 6.8 | 6.9 | $(4\text{-}CH_3C_6H_4)_2O$ | — | 8.3 |
| $4\text{-}BrC_6H_4OCH_3$ | 6.4 | 6.5 | $(4\text{-}BrC_6H_4OC_6H_5)$ | — | 9.4 |
| $1,2\text{-}(CH_3O)_2C_6H_4$ | — | 9.1 | $(4\text{-}BrC_6H_4)_2O$ | — | 10.5 |
| $1,3\text{-}(CH_3O)_2C_6H_4$ | — | 15.9 | $4\text{-}CH_3OC_6H_4OC_6H_5$ | — | 19.5 |
| $1,4\text{-}(CH_3O)_2C_6H_4$ | — | 12.8 | $4\text{-}CH_3OC_6H_4OC_6H_4Br\text{-}4$ | — | 19.6 |

*The values of $E_c$(I) were obtained by the method of complex formation using correlation equations, with $GaCl_3$ as the acceptor;[147] the values of $E_c$(II) were obtained from the values of $\Delta\Delta H$ [88,90,150,151] with a correction for the inductive effect of the aryl ring, with $AlBr_3$ and $GaCl_3$ as the acceptors.

The values of $E_c$(I) and $E_c$(II) (Tables 6 and 7), obtained by measuring the heats of complex formation by two independent methods (see section III), are similar to one another. The values of $E_c$ for the compounds studied vary over a wide range (0–20 kcal mole$^{-1}$), depending on the nature of the heteroatom and the substituents, the steric conditions, etc. In a series of analogous compounds (Table 6), the heteroatoms can be arranged in the following order of decreasing ability to take part in $p\pi$-conjugation: N > O > S ≅ P. The energy of $p\pi$-conjugation for aromatic amines is approximately three times that for the corresponding phosphines.

The effects of the steric inhibition of $p\pi$-conjugation in aromatic ethers, revealed in the UV, NMR, and PE spectra, are characterised quantitatively by the data in Table 7. The energy of $p\pi$-conjugation for anisole is fairly high (6.2 kcal mole$^{-1}$). The introduction of two $CH_3$ groups in the 2,6-positions of the phenyl ring removes the methoxy-group from the conjugation; $E_c$ for 2,6-dimethylanisole is only 0.6 kcal mole$^{-1}$. The effect of the steric inhibition of $p\pi$-conjugation is revealed by comparing the values of $E_c$ for 1,4-dimethoxybenzene (12.8 kcal mole$^{-1}$) and dimethoxydurene (~0). A similar picture is observed for aromatic phosphines (Table 6). In diethylmesitylphosphine, the $p\pi$-conjugation is destroyed for steric reasons, and accordingly $E_c \cong 0$, whereas $E_c$ for diethylphenylphosphine is 3–5 kcal mole$^{-1}$, and that for triphenylphosphine is ~7 kcal mole$^{-1}$.

The introduction of the electron-donor $CH_3$ group in the 2-, 3-, or 4-position or of two $CH_3$ groups in the 3,5-positions of the phenyl ring of anisole leads to a decrease in the energy of the $p\pi$-conjugation of the UEP of the oxygen atom with the ring. On the other hand, electron-acceptor substituents (the Br atom) lead to an increase in $E_c$ (Table 7).[88,150,151]

An interesting feature is that the introduction of a $CH_3$ group into the 3- or 4-position of one of the rings of diphenyl ether, in contrast to anisole) is not accompanied by a decrease in the energy of $p\pi$-conjugation (Table 7). In these compounds, a conformation ensuring $p\pi$-conjugation of the UEP of the oxygen atom with the $\pi$-system of the non-substituted ring is produced (see above). Electron-acceptor substituents (for example Br) lead to better overlap of the UEP of the oxygen atom with the $\pi$-system of the substituted ring and to less effective overlap with the non-substituted ring. In accordance with this, the value of $E_c$ for $4\text{-}BrC_6H_4OC_6H_5$ is greater than that for diphenyl ether. The question of the energy of $p\pi$-conjugation and the conformation of diphenyl ethers with different substituents ($CH_3$, Br, $OCH_3$, $OC_6H_5$) has been examined.[151]

The values of $E_c$ for *ortho*-, *meta*-, and *para*-dimethoxybenzene, given in Table 2, represent the total energy of conjugation of two methoxy-groups. The energy of the $p\pi$-conjugation of *para*-dimethoxybenzene is slightly less than that of *meta*-dimethoxybenzene, because of the "saturation" effect.[88,152] The energy of conjugation of *ortho*-dimethoxybenzene is even lower,[90] apparently because one of the methoxy-groups is not coplanar with the ring (see above).

Continuing the parallel between $p\pi$-conjugation and intermolecular donor–acceptor interaction, it should be noted that the significance of the value of $E_c$ determined by thermochemical methods corresponds to the enthalpy of formation of the complex ($-\Delta H_c$), which in addition to the energy of the donor–acceptor bond ($-\Delta H_{DA}$) also contains a contribution from the energy of the rearrangement of the molecules of the donor and the acceptor on complex formation. Similarly, the energy of $p\pi$-conjugation ($E_c$), in addition to the energy of the $\pi$-bond between the heteroatom and the $\pi$-system, contains a contribution associated with the differences in the geometries of the aromatic and aliphatic molecules, for example a contribution associated with the difference in the steric interactions.[225] On complex formation with strong electron acceptors, these differences in the geometries, which are most clearly defined in the case of amines, are levelled out. In the determination of the energy of the $p\pi$-conjugation of strained molecules by the method of complex formation, it must be borne in mind that complex formation may

lead to a change in the strain energy, and this will be reflected in the $\Delta\Delta H$ values. This situation has been described[90] for the complexes of cyclic alkylaromatic diethers. The energy of $p\pi$-conjugation of benzo-1,4-dioxan was found to be much too high, since the value of $\Delta\Delta H$ contains a contribution from the change in the strain energy and the conformational rearrangement of the heterocycle.

---o0o---

The above data indicate fairly reliably that there is intramolecular $p\pi$-interaction not only in aromatic compounds of nitrogen, oxygen, and sulphur, but also in compounds of the heavier elements of groups V and VI, and particularly in phosphorus compounds. The problem of $p\pi$-conjugation in phosphorus compounds has been widely discussed.[6,19,31,161-166,226,227] The use of accurate and sensitive methods will apparently make it possible to find new hetero-organic compounds in which $p\pi$-interaction with an aromatic system may take place.

While the present review was being prepared for publication, new reviews[228,229] and original papers on the geometry of $p\pi$-conjugated molecules[230-233] and the study of $p\pi$-conjugation by electron spectroscopy, NMR, PES, quantum-chemical methods, etc.[234-240] were published.

# The Reduction of Organic Compounds by Solvated Electrons Generated Electrochemically

N.M.Alpatova, S.E.Zabusova, and A.P.Tomilov

The present review deals with the reduction of organic compounds by solvated electrons generated at a cathode. The general conditions necessary for the electrochemical production of solvated electrons, and the systems in which this process is possible, have been examined. The characteristic features of the reactions of organic compounds with solvated electrons compared with other methods of reduction have been discussed.
Specific data on the reduction by solvated electrons of individual classes of substances difficult to reduce, aromatic and unsaturated compounds, ketones, and derivatives of carboxylic acids—amides, nitriles, and esters—have been examined.
The review will be useful for specialists in the physical chemistry of solvated electrons, theoretical electrochemistry, the electrochemistry of organic compounds, and organic synthesis.
The bibliography contains 92 references.

## I. INTRODUCTION

Among the varied methods for the electrochemical synthesis of organic compounds, reduction by solvated electrons generated at a cathode has found application in recent years.

Solvated electrons in the liquid phase can be obtained by various methods, chiefly radiation-chemical, photochemical, and photoelectrochemical methods, via atomic or molecular hydrogen, by dissolving alkali metals, and by cathodic generation. Not all of these methods, however, are suitable for the preparative reduction of organic compounds. The most universal method of obtaining solvated electrons is the radiation-chemical method. In systems based on the most varied solvents,[1] solvated electrons are obtained by the removal of electrons from molecules, ions, or atoms by the action of X-rays or gamma-radiation, and also fast electrons. In photochemical generation, solvated electrons are produced by the action of light on substances which are electron donors.

These two methods, however, in addition to solvated electrons, produce radicals and ions which react rapidly with electrons, and this makes it difficult to use these methods of generation for the preparative reduction of organic compounds. Unstable systems are also produced when the electrons are obtained by photoelectrochemical methods.[2]

When a mixture of molecular and atomic hydrogen is passed through aqueous alkali solutions with pH > 12, hydrated electrons ($e_h^-$) are formed:[3-5]

$$H + OH^- \rightarrow e_h^- \ .$$

In liquid ammonia, molecular hydrogen reacts with the amides anion:

$$^1/_2H_2 + NH_2^- \rightleftharpoons e_s^-$$

where $e_s^-$ is the solvated electron. The process takes place at high pressures of hydrogen and high concentrations of potassium amide.[5-8] The reactions with hydrogen have a restricted range of application, however, since they are known only for water and ammonia, and require complex apparatus.

For the reduction of organic compounds by solvated electrons, it is more convenient to use the solution of alkali metals and electrochemical generation. These methods make it possible to produce systems in which the solvated electrons are stable. In many cases, electrolysis makes it possible to control the concentration of electrons and to carry out a process repeatedly. The use of cathodic generation makes it possible to avoid dangerous operations with alkali metals. The main limitations of generation are associated firstly with the use of a conducting medium, that is the use of electrolytes and a solvent with a fairly high dissociating power, and secondly with the need to work in a medium stable to cathodic reduction.

## II. SYSTEMS FOR GENERATING SOLVATED ELECTRONS ELECTROCHEMICALLY

The electrochemical generation of solvated electrons takes place at very negative potentials. Table 1 compares the values of the standard equilibrium potential of the electron electrode with the corresponding values for other electrodes. The term "electron electrode" is used to describe an inert metallic electrode in which the electrons ($e_m^-$) are in equilibrium with solvated electrons in a solution.

**Table 1.** Standard equilibrium potentials ($\phi_0$, V).[9]

| $e_s^- \rightleftharpoons e_m^-$ | $Na \rightleftharpoons Na^+ + e_m^-$ | $K \rightleftharpoons e_m^- + K^+$ | $Rb \rightleftharpoons Rb^+ + e_m^-$ | $Cs \rightleftharpoons Cs^+ + e_m^-$ | $Li \rightleftharpoons Li^+ + e_m^-$ |
|---|---|---|---|---|---|
| Water (n.h.e. in water, 25 °C) | | | | | |
| −2.77—−2.88 | −2.714 | −2.924 | −2.925 | −2.923 | −3.045 |
| Ammonia (n.h.e. in ammonia, 25 °C) | | | | | |
| −1.95 | −1.89 | −2.04 | −2.06 | −2.08 | −2.34 |
| HMPA (s.c.e. in water, 5.5 °C) | | | | | |
| −3.02—−3.05 | −2.92 | −3.04 | −3.00 | −2.96 | −3.21 |

Note: n.h.e. = normal hydrogen electrode; s.c.e. = saturated calomel electrode.

The data in Table 1 show firstly that the potentials of the electron electrode are close to the potentials of the alkali metals, that is the reducing power of solvated electrons is comparable with that of the strongest reducing agents known at present.

In the case of liquid ammonia, the decrease in the difference in the standard potentials of the electron and hydrogen electrodes is due to the higher energy of formation of the ammonium ion from the hydrogen ion, compared with the energy of formation of the hydroxonium ion in water. Secondly, the cathodic generation of electrons can be carried out only in systems in which neither the solvent nor the background salts undergo direct reduction at very negative potentials. In spite of the severity of this requirement, the electrochemical generation of solvated electrons can be carried out in a whole range of systems, which are classified in Table 2.

Table 2. Classification of systems suitable for the cathodic generation of solvated electrons.[10]

| A Solvated electrons stable | | B Solvated electrons unstable | |
|---|---|---|---|
| A-2 | A-2 | B-1 | B-2 |
| Liquid ammonia, HMPA $Li^+$, $Na^+$, $K^+$, $Rb^+$, $Cs^+$ | methylamine, glyme*, diglyme**, ethylenediamine, $Li^+$, $Rb^+$, $Cs^+$ | HMPA, dimethyl, sulphoxide, diglyme, $NAlk_4^+$ | HMPA–water (alcohol), diglyme–water, $NAlk_4^+$ |

*Glyme = 1,2-dimethoxyethane; **diglyme = dimethyl ether of diethyleneglycol.

The cathodic generation of electrons is most frequently carried out using systems in which the solvated electrons are chemically stable. These are the systems in liquid ammonia, hexamethylphosphortriamide (HMPA), amines, and ethers (group A). The counter-ions in the systems of this group are generally alkali metal cations, although in liquid ammonia at low temperatures it is possible to use salts of aluminium, magnesium, the tetra-substituted ammonium ion, etc. In the systems of sub-group A-1, it is thermodynamically more favourable for the cathodic generation of solvated electrons to take place on solid electrodes, that is for an electron to be removed from the metal into the solution, $e_m^- \rightarrow e_s^-$, and not the deposition of the alkali metal, $M^+ + e_m^- \rightarrow M$. For the same reason, the reaction in the volume involving the reduction of the cations of the background by solvated electrons, $M^+ + e_s^- \rightarrow M$, does not take place. Table 1 shows that for liquid ammonia and HMPA, the standard equilibrium potential of the electron electrode is more positive than the potential of the lithium electrode, and is close to the potentials of the other alkali metals. Under real cathodic generation conditions, dilute ($10^{-5}$–$10^{-2}$ M) solutions of solvated electrons are formed, displacing the equilibrium potential of the electron electrode by 0.1–0.3 V to more positive values. In the case of HMPA, the binding of electrons by the cations of all alkali metals except lithium to form stable non-paramagentic associates $M^+..2e^-$ acts in the same direction.[10] The ratio of the potentials expected from this indicates that generation is thermodynamically preferred to the deposition of the alkali metal.

In the systems of sub-group A-2, the reactions involving reduction are not thermodynamically unfavourable for all alkali metal cations. Electrolytic deposition of the metal generally takes place in sodium salt solutions, and cathodic generation of electrons in solutions of lithium, rubidium, and caesium salts. Systems containing potassium salts occupy an intermediate position.

All the solvents of group A are thermodynamically unstable to the action of high cathodic potentials and solvated electrons. In these systems, however, the reduction of the solvent at the electrode and the chemical reaction of the solvent with solvated electrons in the volume are kinetically hindered (see below).

The systems of group B include solutions of tetra-alkylammonium salts (mainly tetrabutylammonium salts) in aprotic solvents (sub-group B-1) or mixtures of an aprotic and a protonic solvent (sub-group B-2). In these systems there is kinetic retardation of the cathodic reduction of the components of the solution at the electrode, whereas the chemical reaction of the electrochemically generated electrons with some component of the solution takes place relatively rapidly. The electrons disappear by reacting with the cations of the salt or the molecules of the solvent.

It can be seen from Table 2 that the question of the participation of solvated electrons in reduction processes can be raised not only when liquid ammonia and similar solvents are used, but also in systems with an appreciable concentration of proton donors.

Table 3. Physical properties of the solvents.[10]

| Solvent | M.p., °C | B.p., °C | $E$ (T, °C) | $\eta$, cP (T, °C) | DN | AN |
|---|---|---|---|---|---|---|
| Ammonia | −77.7 | −33.4 | 20.0 (−34) | 0.2558 (−34) | 59.0 | — |
| Methylamine | −92.5 | −6.7 | 12.7 (−22.8) | 0.353 (−22.8) | — | — |
| Ethylamine | −81.0 | 16.6 | 5.9 (20) | — | 55.5 | — |
| Ethylenediamine | 11.0 | 116.5 | 12.9 (25) | 1.54 (25) | 55.0 | — |
| Tetrahydrofuran | −65.0 | 64–65 | 7.4 (25) | 0.764 (25) | 20.0 | 8.0 |
| HMPA | 7.2 | 232 | 29.0 (25) | 3.1 (25) | 38.8 | 10.6 |
| Thiohexamethylphosphortriamide | 29.0 | 94 (130 Н/м²) | 39.5 (30) | 5.55 (30) | — | — |
| Glyme | −58.0 | 82–85 | 7.2 (25) | 0.455 (25) | 24.0 | 10.2 |
| Diglyme | — | 161–163 | 7.2 (25) | 2.0 (20) | — | 10.2 |
| Water | 0 | 100 | 78.5 (25) | 1.01 (20) | 18.0 (33) | 54.8 |
| Ethanol | −114.5 | 78.3 | 24.3 — | 1.08 — | — | 37.1 |
| Methanol | −97.5 | 64.5 | 32.6 — | 0.55 — | 19.0 | 41.3 |

Note: $E$ = dielectric constant; $\eta$ = viscosity; DN = donor number; AN = acceptor number.

The suitability of the systems given in Table 2 for the reduction of organic compounds by solvated electrons generated at a cathode is determined chiefly by the ratio of the rates of the reactions of the electrons with the organic compound and with the components of the solution. All the systems of group A are obviously suitable for this purpose. Table 3 gives various physicochemical characteristics of the solvents listed in Table 2. The combination of medium dielectric constant values with high donor numbers ensures that liquid ammonia and HMPA bring about effective dissociation of the background salts and hence effective conductivity of the solution (reaching $10^{-3}$–$10^{-2}$ $\Omega^{-1}cm^{-1}$). Another advantage of liquid ammonia is its ease of purification. The use of this solvent, however, requires increased pressure or reduced temperature. The high boiling point of HMPA makes it possible to use it under ordinary conditions, but the purification of HMPA is very laborious,[11] and the toxicity of this solvent makes it necessary to take special precautions when working with its solutions.[10,12,13]

Of the systems of sub-group B, only the solutions in dimethyl sulphoxide are unsuitable for electrosynthesis using solvated electrons, since dimethyl sulphoxide is an effective acceptor of solvated electrons.[1]

It is important to note that solvated electrons can be generated in mixtures containing considerable quantities of a proton donor, that is essentially in mixed solvents.[14] Solvation in these systems should be heteroselective in character; cations are solvated by the aprotic component, and anions by the protonic component. This ensures the solution and dissociation of the background salts. The solvating power of the protonic component also extends to the solvated electron. Clearly defined heteroselective solvation, for example in mixtures of HMPA with water or alcohol, should lead to an increase in the thermodynamic probability of the cathodic generation of electrons. The strong solvation of cations by HMPA hinders the reduction of the cation of the background salt competing with generation, and strong solvation of the electrons by the protonic solvent ensures the electrochemical generation of electrons.

The cathodic reduction of water and aliphatic alcohols in aprotic solvents is usually difficult, even on platinum. Fig.1 gives the cyclic voltammetric curves in a solution of lithium chloride in mixtures of HMPA and ethanol.[15] The increase in the current strength at higher absolute values of the negative potentials corresponds to the generation of solvated electrons. The peak corresponding to the cathodic reduction of alcohol appears only at a concentration of 50 mole %.

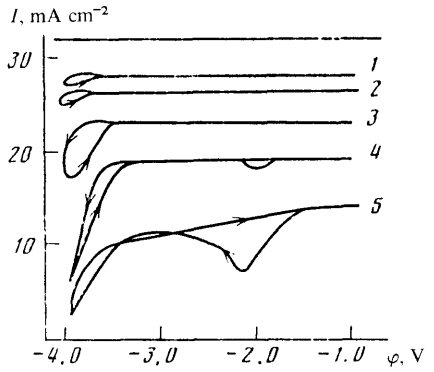

**Figure 1.** Cyclic voltammetric curve (3.3 mV $s^{-1}$) for a platinum electrode in a solution of lithium chloride (0.5 M) in a mixture of HMPA and ethanol; alcohol concentration (mole %): *1*) 0; *2*) 14; *3*) 35; *4*) 50; *5*) 67;[15] (Ag/0.1 M $Ag^+$).

To suppress more reliably the electrode reduction of the protonic component, it is necessary to use metals with a high hydrogen overvoltage (mercury, amalgams), and also to use a tetrabutylammonium salt as background. These salts not only are the most difficult to discharge with the formation of amalgams, but also decrease sharply the rate of the cathodic discharge of water. The retardation can be attributed to the ease of adsorption of the cation on mercury, leading to shielding of the surface, and to a decrease in the concentration of water in the layer next to the electrode as a result of the preferential solvation of the tetrabutylammonium cations by the organic component of the mixed solvent.

Fig.2 gives the cathodic polarisation curves recorded in mixtures of two parts by volume of HMPA with one part by volume of water or ethanol, corresponding to concentrations of the aprotic component of 17 mole % and 42 mole % respectively. According to spectral data,[16] this composition of the mixture with water still ensures the preferential solvation of the electron by water.

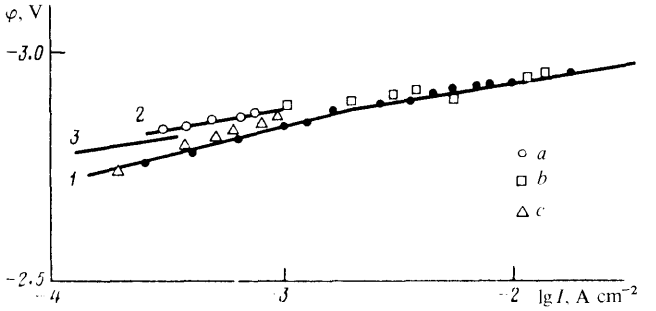

**Figure 2.** Dependence of the potential $\phi$, V (s.c.e.) on the current density ($I$, A $cm^{-2}$) in tetrabutylammonium tetrafluoroborate solutions (0.1 M) at 25 °C; *1*) amalgamated copper (*a*, *b*) in a mixture of HMPA with water (*a*) and with ethanol (*b*), and mercury in a mixture of HMPA with water (*c*); *2*) mercury in hexamethylphosphortriamide; *3*) copper in HMPA.[14]

Curve 1 in Fig.2 shows that the cathodic process in the mixtures takes place at very negative potentials. The potentials in all the systems were measured relative to the saturated calomel electrode in water. The ethanol/water and HMPA/water interphase potential jumps are 30 mV and 150 mV respectively.[17] The interphase potential jumps between water and the systems being studied probably do not exceed 100–150 mV, and this should not introduce qualitative changes in the observed picture. The cathodic process described by curve *1* may correspond to several reactions: the discharge of a proton donor, the discharge of the tetrabutylammonium cation with the formation of an amalgam, and the electrochemical generation of electrons. The first suggestion is not consistent with the similarity in the potentials for the mixtures with water and with alcohol (curves *1a* and *1b*). Moreover, the potentials of curve *2*, recorded in HMPA without water or alcohol, are close to the potentials in mixtures containing a proton donor. Curve *3*, which corresponds to the cathodic process at a copper electrode in HMPA, practically coincides with the curve for a mercury electrode, making it possible to reject the suggestion that the cation is discharged and to assume that the cathodic process is the electrochemical generation of solvated electrons.

The possibility of using protonic media for the reduction of organic compounds by solvated electrons is closely related to the high selectivity of the reactions of solvated electrons. In addition to the reduction of compounds difficult to reduce, solvated electrons liberate hydrogen only very slowly from a whole range of substances containing active hydrogen. It is the low rate of reduction of water and aliphatic alcohols by solvated electrons that makes it possible to use them as proton donors for the reduction of organic compounds. Water in solutions of sodium and lithium perchlorates in HMPA does not

react with solvated electrons up to a water concentration of 0.1 M.[18] Table 4 gives the rate constants for the reactions of solvated electrons with water and alcohols in various media.

Table 4. Rate constants ($k$) for the reactions of solvated electrons with water and alcohols.

| Solvent | Electron acceptor | $k$, litre mole$^{-1}$s$^{-1}$ | Refs. |
|---|---|---|---|
| Water | $H_2O$ | 16 | [1] |
| Ethanol | $C_2H_5OH$ | $4.7 \cdot 10^3$ | [19] |
| Ethylenediamine | $H_2O$ | 24.7 | [20] |

## III. THE REACTIONS OF SOLVATED ELECTRONS WITH THE SOLVENT

The reactions of solvated electrons with organic compounds take place in parallel with their reactions with the molecules of the solvent. All the systems in which solvated electrons are fairly stable are metastable, and gradually decompose as a result of the chemical reaction of the solvated electrons with the solvent. This reaction is generally catalytic, and its rate is increased by impurities, the walls of the apparatus, and reaction products, so that its quantitative study is difficult. There are few published data on this topic. The addition of two electrons to the HMPA molecule gives the dimethylamide anion and the diamidophosphite anion:[22]

$$[(CH_3)_2N]_3PO + 2e_s^- \rightarrow (CH_3)_2N^- + [(CH_3)_2N]_2PO^- \ .$$

In highly purified solutions, it is this reaction that determines the stability of the solvated electrons. The time taken for the disappearance of the colour of a $10^{-2}$ M solution of electrons in a background of sodium perchlorate in HMPA was 4 h at 25 °C and 24 h at 5 °C.[23]

In very pure solutions in liquid ammonia, the reaction is slow, particularly at temperatures of −33 °C and below.

$$NH_3 + e_s^- \rightarrow NH_2^- + {}^1/_2H_2 \ .$$

The rate of the reaction is increased with increase in temperature and under the influence of catalysts. The catalysts include platinum black, iron oxides, the walls of the cell, and the products of the reaction of the electrons with impurities. The reaction of solvated electons with liquid ammonia may be more closely related to the reduction of an organic compound. Thus in the reduction of ethylene oxide in liquid ammonia by solvated electrons obtained by dissolving alkaline earth metals, the amide alkoxide, for example $NH_2CaOC_2H_5$, is formed.[24]

The reduction of tetrahydrofuran by solvated electrons generated at a cathode in HMPA has been studied.[15] The ether is not reduced in the absence of a proton donor. At an ethanol concentration of 50 mole %, tetrahydrofuran is converted into a mixture of n-$C_4H_9OH$, n-$C_4H_9OC_2H_5$, and n-$C_4H_{10}$. In the reduction of ethers with one aromatic group, hydrogenation of the ring takes place first. Thus in a mixture of ethanol (67 mole %) with HMPA in a background of lithium chloride, anisole is reduced to methoxycyclohexane.[25]

The possibility that ethers may be reduced in the presence of impurities which are proton donors must be taken into account when they are used for the cathodic generation of electrons.

## IV. THE CHARACTERISTIC FEATURES OF THE REDUCTION OF ORGANIC SUBSTANCES BY SOLVATED ELECTRONS GENERATED AT A CATHODE

Solvated electrons have exceptionally powerful reducing properties. Their electrochemical generation requires high negative potentials, so that solvated electrons cannot be generated in the presence of substances which are easily reduced. It is therefore appropriate to use solvated electrons to reduce substances whose reduction requires fairly high potentials.

The reduction of organic compounds by solvated electrons generated at a cathode is usually carried out in systems in which the solvated electrons are stable. Substances which dissolve alkali metals to give solvated $M^+$ cations and electrons are used for this purpose:

$$M \underset{}{\overset{\text{solvent}}{\rightleftharpoons}} M^+ + e_s^- \ .$$

Table 5. The solubility of alkali metals and the possibility of the cathodic generation of solvated electrons in various media.[10]

| Solvent | Solubility of alkali metals | Cathodic processes in solutions of salts of the corresponding metals |
|---|---|---|
| Liquid ammonia | all alkali metals readily soluble (more than 10 mole per 1000 g solvent) | cathodic generation of electrons in solutions of all alkali metal salts |
| Methylamine | [Li] = 7.4 M*<br>[Na] = $4 \times 10^{-3}$ M<br>[K] = $10^{-2}$ M<br>Cs—soluble | salts:<br>Li—generation of electrons<br>Na—metal deposition<br>K—generation + deposition<br>Cs—generation of electrons |
| Ethylamine | Li—soluble | Li salts—generation of electrons |
| Glyme | Li, Na, K } insoluble<br>Rb, Cs } soluble | salts:<br>Li, Na, K, Rb, Cs } metal deposition<br>generation of electrons |
| HMPA | all alkali metals readily soluble | $NaClO_4$ + 18-crown-6 in solutions of salts of all alkali metals—cathodic generation of electrons |
| Thiohexamethylphosphortriamide | Na—insoluble | Na salts—metal deposition |

*−23 °C.

The relationship between the solubility of an alkali metal in a given solvent and the thermodynamic possibility of carrying out the cathodic generation of electrons in it is given by Makishima's equation:[26]

$$\varphi^0_{M/M^+} - \varphi^0_{e_s^-} = -\frac{RT}{F} \ln a_{M^+} a_{e_s^-}$$

where $\phi^0_{M/M^+}$ is the standard potential of the alkali metal; $\phi^0_{e_s^-}$ the standard potential of the electron electrode; and $a_{M^+}$ and $a_{e_s^-}$ the corresponding activities in a solution saturated with the alkali metal. Makishima's equation shows that the higher the solubility of the alkali metal, the greater the difference in the standard potentials, that is the more thermodynamically favourable the cathodic generation relative to the electrodeposition of the alkali metal, which is the main reaction competing with the generation of electrons. The quantitative application of the equation is difficult, since usually only the total solubilities of the alkali metals in different media are

known, but it provides a good qualitative explanation of the observed regularities illustrated in Table 5.

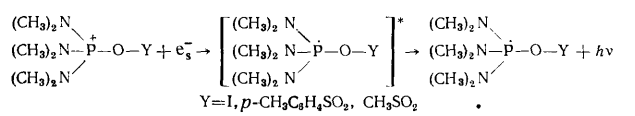
Comparison of the data in Tables 3 and 5 shows that there is no correlation between the physical properties of the solvents on the one hand and their ability to dissolve alkali metals and the possibility of electrochemical generation of solvated electrons on the other. Thus for example on going from HMPA to thiohexamethylphosphortriamide (on replacing oxygen by sulphur), the dielectric constant and the dipole moment increase. At the same time, however, the medium loses its ability to dissolve alkali metals and hence the possibility of the electrochemical generation of solvated electrons; this can be related to the decrease in the solvation of the alkali metal ions on going to the thio-derivative. Although the solvating power of the medium both with respect to the cation and with respect to the electron should have a decisive influence on the solution of alkali metals and the cathodic generation of electrons, the main influence is usually shown by the solvation of the cations. Tables 3 and 5 show that liquid ammonia and HMPA, which dissolve alkali metals most readily, have high donor numbers, which are combined with relatively high dielectric constant values. Increase in the energy of solvation of the cations displaces the equilibrium potential of an alkali metal in a solution of its own cations to more negative values, and hence increases the thermodynamic probability of the cathodic generation of solvated electrons. This is facilitated both by the use of solvents with high donor numbers and by binding the cations with special complex-forming reagents, cryptates and crown ethers. Complex formation in this way facilitates generation in systems in which the alkali metal is deposited in the absence of the additive (Table 5).

When an organic substance is added to a system in which cathodic generation of solvated electrons can take place, in the general case the stationary polarisation curves show the formation in this way facilitates generation in systems in which are not too negative, direct reduction of the organic compound at the electrode will take place. Under certain conditions, retardation of this process takes place, displacing the potential sharply towards negative values, due to the start of generation (see Fig. 6 below). The limiting current of the electrode reduction of an organic compound may be a diffusion current (supply of the organic substance) or a passivation current (change in the state of the electrode surface as a result of the formation of tarry products by the organic compounds or films of the hydroxides of the cations of the background salts). At the generation potentials, the additive is reduced by two parallel routes: directly at the electrode at a rate corresponding to the limiting current, and as a result of chemical reaction with the solvated electrons. The rate of the direct reduction in the generation range is independent of the potential. With increase in the generation current, the proportion of direct reduction decreases. For many organic compounds, the electrode reduction is hindered for kinetic reasons, and most of the substance is reduced by reaction with solvated electrons.

One of the advantages of the reduction of organic compounds by electrons obtained electrochemically is the possibility of using higher current densities than in direct cathodic reduction. This is due firstly to the high value of the diffusion coefficient of solvated electrons. The corresponding values for water, ammonia, and HMPA are given in Table 6. Solvated electrons are several times more mobile than common ions (the mechanism of the motion is similar to Grotthus' relay mobility). It should be noted that the Walden product (the product of the diffusion coefficient and the viscosity of the solvent) is approximately the same for the three solvents. This feature can be used to estimate the values for solvents with unknown solvated electron mobilities.

A second feature ensuring the rapid removal of solvated electrons from the electrode is intensive convection due to the decrease in the density of the solution at the cathode surface. This phenomenon is related to the increase in the volume of the solution when electrons are introduced into it. In contrast to the electrostriction accompanying the solvation of ordinary ions, the formation of solvated electrons gives an increase in volume of 65–95 ml mole$^{-1}$ for liquid ammonia[5] and ~80 ml mole$^{-1}$ for HMPA.[32] The current densities of the generation of solvated electrons may be 2500 or more time the diffusion currents of organic compounds to the electrode, as demonstrated[33] for the reduction of anthracene.

Table 6. Diffusion coefficients ($D$, cm$^2$s$^{-1}$) of solvated electrons in liquid ammonia, water, and HMPA.



| Solvent | $T$, °C | Method of determination | $10^4 D$, cm$^2$s$^{-1}$ | $10^5 D.\eta$, cm$^2$cP s$^{-1}$ | $D/D_{Na^+}$ | Refs. |
|---|---|---|---|---|---|---|
| Liquid ammonia | —36.0 | chronopotentiometric anodic oxidation of electrons | 1.45 | — | — | [27] |
| | | measurement of electrical conductivity and transport numbers | 1.74 | 4.45 | 6.7 | [28,29] |
| Water | room temp. | radiation-chemical method, measurement of electrical conductivity | 0.49 | 4.90 | 3.7 | [21] |
| Hexamethylphosphortriamide | room temp. | radiation-chemical method, current relaxation curves | 0.14 | 4.59 | 10.0 | [30,31] |

A characteristic feature of the reaction of solvated electrons with organic substances is chemiluminescence. The luminescence is produced simultaneously with the cathodic generation of the solvated electrons, and may be very intense.

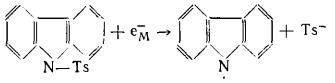
One group of reactions accompanied by chemiluminescence consists of the reactions of solvated electrons with organic cations and radical-cations to give neutral molecules or radicals.

Thus cyclic voltammetry with simultaneous recording of the luminescence spectra showed that N,N,N′,N′-tetramethyl-*para*-phenylenediamine does not undergo direct cathodic reduction in a solution of sodium perchlorate in HMPA, but can be oxidised reversibly to a radical-cation which reacts with solvated electrons to give an excited molecule of N,N,N′,N′-tetramethyl-*para*-phenylenediamine, which returns to the ground state with the emission of a quantum of light.[34,35] Similar results were obtained[36] with N,N,N′,N′-tetramethylbenzidine, N,N-dimethylanisidine, and other amine derivatives which form stable radical-cations.

Luminescence was also observed[37] when thoroughly purified solutions of salts of various alkali metals in HMPA were electrolysed under galvanostatic pulse conditions without separating the cathode and anode compartments. It was suggested that the chemiluminescence is due to the reaction of the solvated electrons with a pseudo-phosphonium cation, which gives a neutral radical in an excited state; this radical returns to the ground state with the emission of a quantum of light:

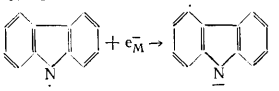
The iodine derivative was formed by the reaction between the solvent and elemental iodine liberated at the anode in potassium iodide solution, and the other two compounds were obtained

by adding tosyl chloride and mesyl chloride respectively to the solution.



The second group of processes accompanied by the emission of light consists of the reduction of neutral molecules with the simultaneous dissociation of the original molecule. In these processes the formation of the excited state often takes place at the stage of the addition of the second electron, after the dissociative one-electron reduction:[36]

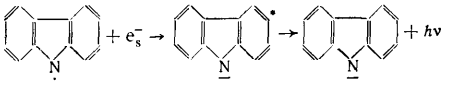
$$(C_6H_5)_3CCl + e_s^- \rightarrow (C_6H_5)_3C^{\cdot} + Cl^- \qquad (C_6H_5)_3C^{\cdot} + e_s^- \rightarrow (C_6H_5)_3C^{-}$$



Reactions of this type include the reduction of N-toluenesulphonylcarbazole, examined below, and the reduction of benzyl chloride and diphenylmethyl chloride.[35]

It is of interest to compare the direct cathodic reduction with the reduction of the same substance by solvated electrons. Thus the pseudo-phosphonium cations formed in solutions of iodine, tosyl chloride, and mesyl chloride in HMPA are reduced at potentials more than 2.5 V more positive than the potential of the generation of solvated electrons; this gives non-excited species.[37]

Similarly, N-tosylcarbazole is reduced at an electrode without luminescence at a potential which is 0.8 V more positive than the generation potential of solvated electrons:



(1)

(2)

As always, chemiluminescence appears when the generation potential of the solvated electrons is reached. It is due to the reaction

The process takes place similarly when HMPA is replaced by a mixture of ammonia and tetrahydrofuran in the volume ratio 2:1.[38]

This system is similar to that in pure ammonia. Tetrahydrofuran ensures the solution of the organic compounds. The reduction of α- and β-naphthol tosylates by solvated electrons in a mixture of ammonia and tetrahydrofuran leads to the emission of light:[38,39]

$$Naph{-}Ts + e_s^- \rightarrow Naph{-}Ts^{\cdot-} \rightarrow Naph^{\cdot} + Ts^-$$
$$Naph^{\cdot} + e_s^- \rightarrow Naph^-$$

Chemiluminescence was also observed when solvated electrons were generated in a solution of sodium perchlorate in HMPA containing 9-chlorofluorene derivatives.[34]

Thus the study of chemiluminescence provides a useful method of studying the mechanism of the reduction of compounds by solvated electrons.

## V. THE REDUCTION OF INDIVIDUAL CLASSES OF ORGANIC SUBSTANCES BY SOLVATED ELECTRONS

From the preparative viewpoint, the use of the electrochemical generation of solvated electrons is most effective for reducing substances which require high negative potentials for electron transfer or which are not reduced at all electrochemically. These compounds are aromatic hydrocarbons, alkenes, aliphatic ketones, amides. and nitriles.

### 1. Aromatic Compounds

The aromatic compound most difficult to reduce is benzene. It is polarographically inactive,[40] and does not undergo direct electrochemical reduction. Direct cathodic reduction of benzene does not take place in liquid ammonia in a background of potassium or methyltributylammonium iodide at silver or gold electrodes.[41]

Benzene does not react with solvated electrons obtained by dissolving alkali metals in liquid ammonia.[1] In the presence of proton donors, however, benzene ir hydrogenated under the influence of solvated electrons. Table 7 gives data obtained by different authors on the preparative electrochemical reduction of this compound, and shows that in some cases the process can be carried out fairly selectively and with a good current efficiency. Allowance must be made, however, for the fact that the data in Table 7 were generally obtained with incomplete transformation of the starting material. The high current efficiencies show that the proportion of side reactions is small. This agrees with the results of Schindewolf and Neumann,[49] which showed that solvated electrons obtained by laser photolysis in a mixture of ammonia and water (25 °C) containing benzene hydrogenate benzene and do not react with the components of the solvent (ammonia and water).

Table 7. Reduction of benzene in aprotic media.

| No. | Solvent | Background | Proton donor | $I$, A cm$^{-2}$ electrode | $T$, °C | Reduction | | Refs. |
|---|---|---|---|---|---|---|---|---|
| | | | | | | product (%) | overall current efficiency, % | |
| 1 | Liquid ammonia | NaCl | ethanol 1-4% | $2 \times 10^{-2}$ platinum | —33 | cyclohexa-1,4-diene (98) | 41* | [42] |
| 2 | HMPA | LiCl | methanol | platinum | — | cyclohexa-1,4-diene (53)<br>cyclohexa-1,3-diene (2)<br>hexene (21)<br>hexane (24) | — | [43] |
| 3 | Ditto | ditto | ethanol 67 mole % | $9.0 \times 10^{-2}$ aluminium | — | cyclohexadiene (23)<br>cyclohexene (10)<br>cyclohexane (67) | 95<br>—<br>— | [44] |
| 4 | Ditto | $LiClO_4$ 0.2 M | water 0.1 M | | — | cyclohexa-1,3-diene | — | [18] |
| 5 | Methyl-amine | LiCl | solvent | $10^{-1}$ platinum | —70 | cyclohexene (100)<br>cyclohexa-1,4-diene (95)<br>cyclohexene (4) | 49[2*]<br>49[3*]<br>— | [45,46] |
| 6 | Ethylene-diamine | LiCl 0.3M | ditto | $2 \times 10^{-2}$ platinum | +25—27 | cyclohexadiene (17)<br>cyclohexene (70)<br>cyclohexane (13) | 64<br>70 | [47][2*] |
| 7 | Ditto | LiCl, 0.3 M | | $7 \times 10^{-2}$ carbon | 33 | cyclohexa-1,4-diene (38)<br>cyclohexane (14.4) | 52,4<br>— | [48][3*] |

Note. 1*) excess of benzene; 2*) diaphragm; 3*) without diaphragm, excess of benzene; 4*) diaphragm, excess of benzene.

The data in Table 7 illustrate the reduction of benzene in media typical of the electrochemical generation of solvated electrons. The addition of proton donors, however, may lead to appreciable reduction of benzene in mixtures of water

with aprotic solvents such as diglyme and sulpholane (Table 8). In these solvents also, the reduction apparently involves the formation of solvated electrons. Thus for example in a diglyme–water mixture the process takes place at a potential of −3.3 V (s.c.e.), which is sufficient for the generation of solvated electrons, and the potential is the same in the presence and in the absence of benzene.

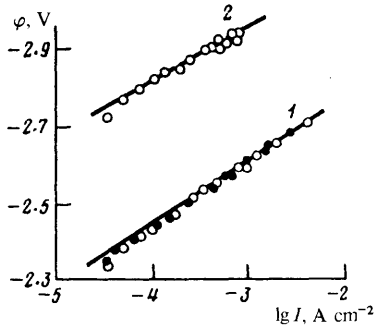


**Figure 3.** Dependence of the potential $\phi$, V (s.c.e.) on the current density at a dropping mercury electrode in aqueous solutions ($c$ = 0.1 M) at 20 °C; *1*) in solutions of tetramethylammonium hydroxide and iodide; *2*) in a solution of tetrabutylammonium hydroxide.[58]

The increase in the proportion of products with a high degree of hydrogenation with increase in the concentration of proton donors is noteworthy (Table 9).

**Table 9.** Reduction of benzene in HMPA–ethanol mixture.[44]

| Cathode | Donor, mole % | $T$, °C | $I$, A cm$^{-2}$ | Reduction product, % | | |
|---|---|---|---|---|---|---|
| | | | | cyclohexadiene | cyclohexene | cyclohexane |
| Al | 66.6 | 28 | $9.1\cdot10^{-2}$ | 20.2 | 8.5 | 71.3 |
| Al | 5 | 28 | $9.1\cdot10^{-2}$ | 81.2 | 16.4 | 2.3 |
| Al | 66.6 | 28 | $3.6\cdot10^{-3}$ | 53.1 | 10.1 | 36.8 |
| Al | 66.6 | −2 | $3.6\cdot10^{-3}$ | 93.0 | 5.8 | 1.2 |
| Pt | 5 | 28 | $9.1\cdot10^{-2}$ | 85.7 | 12.9 | 1.4 |

The favourable influence of a high concentration of proton donors on reductive hydrogenation is also observed in other cases. For example, aromatic sulphides and ethers are also reduced with the participation of solvated electrons generated at a cathode.[15] The cyclic voltammetric curves at a platinum electrode in solutions of lithium chloride in HMPA and its mixtures with ethanol (up to 50 mole %) in the presence of diphenyl sulphide coincided with the curves obtained without adding the organic substance. Table 10 gives the composition of the reduction products for different concentrations of alcohol in the solution, and shows that solvated electrons break the bond between sulphur and the carbon atom of the aromatic ring, with subsequent addition of a proton. In the absence of alcohol, the main reduction product is benzene,

**Table 8.** Reduction of benzene in protonic media.

* Electrolysis at a controlled potential of −3.3 V (s.c.e.); the potential is the same in the presence and in the absence of benzene.

[2*] Or other amine containing 1–8 carbon atoms.

[3*] Or a lower aliphatic (alicyclic) alcohol.

[4*] Mole %.

[5*] Or sulphoxide.

[6*] $\{(C_4H_9)_4N\}_2SO_4 : (C_4H_9)_4NOH : H_2O : C_6H_6 = 20 : 1 : 71 : 8$ (by weight).

[7*] Can be replaced by $(C_4H_9)_3C_2H_5NOH$ or $(C_3H_7)_4NOH$.

[8*] At high pH values there is a decrease in the liberation of hydrogen and an increase in the stability of the steel anode.

[9*] In a background of $(C_4H_9)_3CH_3NOH$ the yield decreases, and in a background of $(C_2H_5)_4NOH$ and $(CH_3)_4NOH$ reduction does not take place.

for the reduction of which the protons of impurities are sufficient. Without alcohol, benzene is stable to the action of solvated electrons, but in the presence of alcohol, benzene undergoes reductive hydrogenation, which is greater, the higher the concentration of alcohol in the solution.

**Table 10.** The reduction of diphenyl sulphide in solutions of lithium chloride (0.5 M) in mixtures of HMPA and ethanol, 15 °C.[15]

| Alcohol, mole % | Yield of products, % | | | | | | Transformation, % | Current efficiency, % |
|---|---|---|---|---|---|---|---|---|
| | benzene | cyclohexa-1,4-diene | cyclohexa-1,3-diene | cyclohexene | biphenyl | other substances | | |
| 50 | 32.7 | 10.3 | 1.6 | 1.3 | traces | 0.8 | 46.4 | 67.2 |
| 35 | 42.1 | 8.2 | 1.1 | 1.3 | traces | 3.2 | 54.3 | 69.6 |
| 14 | 65.1 | 0 | 0 | 0 | 1.8 | 0 | 66.9 | 61.4 |
| 0 | 84.8 | 0 | 0 | 0 | 1.8 | 2.4 | 88.9 | 79.4 |

An interesting feature is that benzene can be reduced not only in a mixture of an aprotic and a protonic solvent but also in purely protonic media. Thus dihydric and monohydric alcohols, and also water, have proved suitable for this purpose (Table 8).

In aqueous tetrabutylammonium hydroxide solution, the potential of a mercury cathode is displaced to between − 2.5 V and −2.8 V (Fig.3),[58] which is sufficient for the generation of solvated electrons (see Table 1). Tetrabutylammonium cations are adsorbed on the electrode surface, displacing water molecules and hindering their discharge at the electrode.

When purely aqueous solutions are used, a complication not encountered in organic systems arises, due to the low solubility of benzene and many other organic compounds in water (20 °C, M):[59–61]

| | |
|---|---|
| Benzene | $2\cdot10^{-2}$; $2.4\cdot10^{-2}$ (25°C) |
| Toluene | $6\cdot10^{-3}$ |
| *o*-, *m*-, and *p*-Xylenes | $1.6—1.8\cdot10^{-3}$ |
| Phenol | $9\cdot10^{-1}$ |
| α-Naphthol | $3\cdot10^{-4}$ |

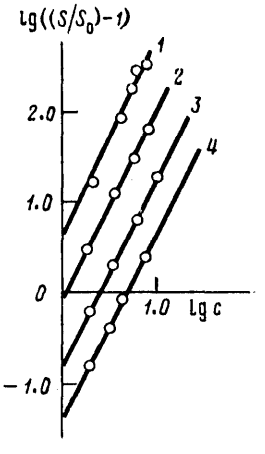

**Figure 4.** Solubility of benzene at 25 °C in solutions of the bromides: *1*) tetrabutylammonium; *2*) tetrapropylammonium; *3*) tetraethylammonium; *4*) tetramethylammonium; *S* is the solubility in the solution; $S_0$ is the solubility in water.[60]

The solubility decreases in the order benzene–toluene–ethylbenzene–mesitylene (1.6–0.6–0.2–0.05 g litre$^{-1}$).[60]

It should be noted, however, that in the presence of tetraalkylammonium cations the solubility of organic compounds increases[61–64] (the "salting-in" effect). The solubility is higher, the higher the concentration of the salt and the longer its alkyl group (Fig.4),[60,61] and also on going from chlorides to bromides and iodides.[64]

The reduction of benzene can also be carried out in a heterogeneous system (emulsion) with vigorous stirring (Table 8). The movement of benzene to the electrode is apparently facilitated by the presence on the elrctrode surface of the electrical double layer of tetrabutylammonium cations, which should help to bring benzene on to the electrode surface.

An examination of different mechanisms of mass transfer and charge transfer in the electrolysis of an emulsion (organic substance–water) showed that an important positive role is played by the hydrophobic tetra-alkylammonium cations.[59]

The behaviour of toluene is analogous to that of benzene. Toluene is also polarographically inert, and does not react with solvated electrons obtained by dissolving alkali metals in liquid ammonia,[1] but it can be reduced by solvated electrons in aprotic, mixed, and protonic media (see Table 11).

**Table 11.** The reduction of toluene.

| Solvent | Background | Proton donor | Electrode | Product (%) | Refs. |
|---|---|---|---|---|---|
| HMPA | $LiClO_4$ $NaClO_4$ | $H_2O \leqslant 0.1$ M | Pt | 1-methylcyclohexa-1,4-diene | [18] |
| HMPA | LiCl | $C_2H_5OH$ 67 mole % | Al | methylcyclohexane (45.4) | [25] |
| Methylamine | LiCl | solvent | Pt | methylcyclohexadiene (94)[1*] | [45[1*], 46[2*]] |
| Ditto | LiCl | ditto | Pt | methylcyclohexene (5)[1*] methylcyclohexane (86)[2*] toluene (14)[2*] | |

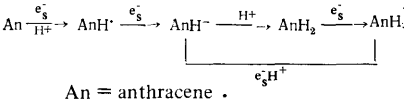
| Isobutyl alcohol | $(C_4H_9)_4NBr$ | ditto | Hg | 1-methylcyclohexa-1,4-diene | [54] |
| Water | $(C_4H_9)_4NOH$ | » | Hg | reduction | [56] |

Note. 1*) without diaphragm, current efficiency 64%; 2*) with diaphragm, current efficiency 44%; 3*) electrolysis at a potential of −3.3 V (s.c.e.), which is the same in the presence and in the absence of toluene; 4*) current efficiency 61%.

As in the case of benzene, it is possible to select conditions under which the process is fairly selective. The maximum degree of reduction is obtained in a mixed solvent at a high concentration of the protonic component (Table 11).

Table 12 compares the results of the reduction of other aromatic compounds: naphthalene, tetralin (tetrahydronaphthalene), anthracene, and dihydroanthracene, in media in which the cathodic generation of electrons is possible. Like benzene and toluene, tetralin is not reduced at an electrode, for example at mercury in ethylenediamine,[48] but is effectively hydrogenated with the participation of solvated electrons (Tables 12 and 13).

Unlike benzene, toluene, and tetralin, naphthalene and anthracene can be reduced directly at an electrode. Thus in anhydrous ethylenediamine, naphthalene is active at mercury and platinum electrodes.[47,48] The product of the reduction of naphthalene in protonic media is 1,4-dihydronaphthalene.[67] For example, the preparative direct electrode



reduction of naphthalene in a mixtpre of acetonitrile and water gives 98% 1,4-dihydronaphthalene mixed with small quantities of 1,2-dihydronaphthalene and tetralin with an overall current efficiency of 86%.[68]

Table 12. The reduction of naphthalene, anthracene, and their derivatives by electrolysis in HMPA and ethylenediamine.

| Medium | Proton donor | Electrode | $I$, A cm$^{-2}$ | Substance | Reduction products (%) | Current efficiency, % | $E_{1/2}$* | Refs. |

Note: *) half-wave potentials (s.c.e.) for the reduction of the substances in a mixture of 75% dioxan + 25% water in a background of tetraethylammonium or tetrabutylammonium iodide;[40] 2*) potential relative to a silver wire in the same solution, which is the same for benzene, naphthalene, and tetralin; 3*) with a diaphragm; 4*) there is practically no reduction in the absence of a proton donor; 5*) polarographically inactive; 6*) with diaphragm; 7*) see Table 13; 8*) without diaphragm; 9*) generation of electrons does not take place at this current density; 10*) traces of the last compound.

In a solution of lithium chloride in HMPA, anthracene gives two cathodic peaks: a peak due to the reversible formation of a radical-anion (+1.23 V)† and a peak due to the irreversible formation of the dianion (+0.33 V)#.[66] As a proton donor is added, a second peak gradually appears beside the first, that is as in the case of naphthalene, hydrogenation of one bond takes place. Tables 12 and 13 show that more extensive hydrogenation takes place under the influence of solvated electrons. Analysis of the preparative electrolysis data shows that, irrespective of the electrode material, the reduction gives a mixture of dihydro-, tetrahydro-, and hexahydroanthracenes. The change in the concentration of these products as electrolysis proceeds (see Fig.5) shows that the reduction takes place in stages, and a more detailed study of the kinetics of the process indicates that the formation of tetrahydroanthracene takes place partly without the stage of dihydroanthracene formation:

An = anthracene .

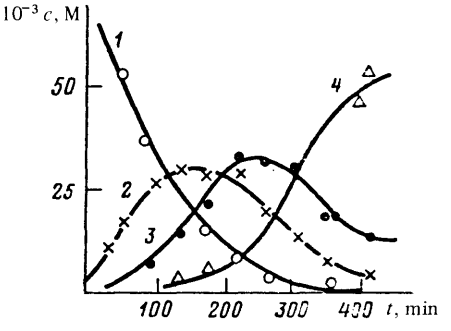

Figure 5. Change in the concentration of anthracene ($c$) and its reduction products at a current density of $1.25 \times 10^{-1}$ A cm$^{-2}$; initial anthracene concentration 0.070 M; *1*) anthracene; *2*) dihydroanthracene; *3*) tetrahydroanthracene; *4*) hexahydroanthracene.[66]

Table 13. Reduction of tetralin by electrolysis in ethylenediamine.[48]

| Background | $T$, °C | Electrode* | Current efficiency, %2* | Products3* | |
|---|---|---|---|---|---|

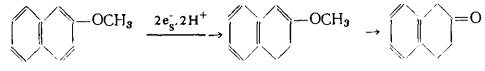
| Lithium chloride | 33.0 | platinum | 57.9 | 41.6 | 7.5 |
| | | graphite | 70.5 | 55.4 | 11.6 |
| | | carbon | 80.3 | 67.3 | 9.5 |
| Tetrabutylammonium iodide | 28.0 | ditto | 17.0 | 13.0 | 1.8 |
| Ammonium chloride | 20.0 | ditto | 0 | 0 | 0 |

Note: *) current density $7 \times 10^{-2}$ A cm$^{-2}$; 2*) a small fraction of the current is used for the reduction of dihydronaphthalene (impurity in tetralin); 3*) fraction of the current.

Interesting data were obtained[69] on the reduction of naphthalene on platinum in mixtures of alcohols (methanol, ethanol, propan-1-ol, and propan-2-ol) with HMPA in a background of lithium chloride at a high concentration of the protonic component. Naphthalene is not reduced in pure ethanol§. When 10–50 vol.% HMPA is added at a potential which is 1 V more negative than the potential of the electrode reduction of naphthalene, the latter is converted into a mixture of dihydronaphthalene, tetralin, hexalin, and decalin. The value of

†The potentials are given relative to a lithium reference electrode; on this scale, the potential at which the generation of electrons starts is +0.16 V.



#The direct reduction of anthracene can also be carried out in ethylenediamine.[47]

§ Tetralin also could not be reduced in ethanol containing lithium chloride.[65]

the potential and the nature of the products indicate that the reaction involves solvated electrons, in spite of the high concentration (up to 90 vol.%) of alcohol in the solution.

The example of aromatic compounds illustrates a characteristic feature of reduction by solvated electrons: the rate of the process is independent of the nature of the organic substance. Thus in HMPA, the reduction potentials of benzene, naphthalene, and tetralin coincide.[65] There are very few published data on the reduction of an aromatic ring in compounds containing functional groups. In the HMPA–ethanol system at an aluminium cathode, phenol and anisole are reduced to cyclohexanol and methoxycyclohexane respectively in yields of 51.7% and 45.8%.[25]

2-Naphthyl ethers are reduced selectively to dihydro-compounds, whose hydrolysis gives tetralones which are the starting materials for the synthesis of medicinal products.

This process has been carried out on a large scale.[70]

## 2. Unsaturated Compounds

Table 14 gives data on the reduction of alkenes in systems in which the cathodic generation of electrons is possible. It cannot be concluded, however, that the reaction involves the formation of solvated electrons in all cases. In solutions of lithium chloride and tetrabutylammonium tetrafluoroborate in HMPA, 1,1-diphenylethylene and tetraphenylethylene are reduced directly at a mercury electrode.[74]

**Table 14.** The reduction of alkenes by electrolysis in HMPA and methylamine.

| Medium | Proton donor | Alkene | Reduction product | Refs. |
|---|---|---|---|---|
| LiBr, HMPA | without donor | $(C_6H_5)_2C{=}CH_2$ | $[(C_6H_5)_2C(CH_2)_2C(C_6H_5)_2]^{2-*}$ | [71] |
| NaI, HMPA | without donor | $(C_6H_5)_2C{=}C(C_6H_5)_2$ | $[(C_6H_5)_2C{-}C(C_6H_5)_2]^{2-}$ | [71] |
| LiCl, HMPA | $C_2H_5OH$ 67 mole % | $(CH_3)_2C{=}C(CH_3)_2^{2*}$ | $(CH_3)_2CHCH(CH_3)_2$ | [44] |
| LiCl, methylamine | without donor | 1-octene | octane 51%$^{3*}$ | [72] |
| LiCl, HMPA | $C_2H_5OH$ 5–50 vol.% $C_3H_7OH$ 10–50 vol.% | cyclo-octa-1,5-diene | cyclo-octane, cyclo-octene$^{4*}$ | [73] |

Note: *) hydrolysis gave a high yield of tetraphenylbutane; 2*) the alkene $(CH_3)_2C = C(CH_3)_2$, which shows steric hindrance, is reduced in 30% yield at practically the same rate as hex-1-ene and hex-2-ene; 3*) the rest is the starting material (2% in unchanged form, 47% in the isomerised form); 4*) the proportion of cyclo-octene increases on going from ethanol to propanol and with decrease in the concentration of alcohol and increase in the current density.

It is of interest to compare the reactivities of alkene and aromatic bonds towards solvated electrons. Table 14 shows that in a number of cases only alkene bonds are reduced. This is characteristic of short alkene bonds¶. Thus the main product of the reduction of styrene in a solution of lithium chloride in methylamine (proton donor–solvent) is ethylbenzene (~70%),[72] and allylbenzene gives n-propylbenzene. If a stronger proton donor (ethanol) is added, the aromatic ring begins to be hydrogenated instead of the alkene bond, and the main product of the reduction of allylbenzene is 2,5-dihydroallylbenzene. The highest selectivity in methylamine in the presence of ethanol was achieved[72] for 5-phenylpent-2-ene, which gave 83% 2,5-dihydro-5-phenylpent-2-ene.

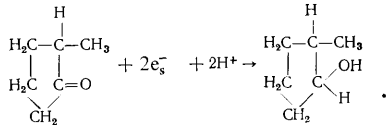
## 3. Ketones

Other compounds difficult to reduce are aliphatic ketones, which are reduced at potentials more negative than −2.0 V (s.c.e.).

A number of ketones illustrate another characteristic feature of the reduction of organic compounds by solvated electrons, namely the high stereospecificity of the process. In particular, the products of the reduction of alkylcyclohexanones and alkylcyclopentanones are alcohols in two stereoisomeric forms. Preparative data for these compounds are given in Table 15. The proton donor in all cases was ethanol.

**Table 15.** Reduction of alkylcyclopentanones and alkylcyclohexanones by solvated electrons generated in HMPA.

| No. | Ketone, mass% in the catholyte | Ketone : Donor | Electrode | Current efficiency, % | *trans*-Isomer, % | Method of reduction* | Refs. |
|---|---|---|---|---|---|---|---|
| 1 | 2-Methylcyclopentanone, 2 | 1:2 | copper | 83.5 | 90.2 | 2 | |
| 2 | 2-Methylcyclopentanone, 2 | 1:2 | copper | 88 | 90.6 | 1 | |
| 3 | 2-Methylcyclopentanone, 0.5 | 1:4,5 | platinum | 56.2 | 86.4 | 2 | [76] |
| 4 | 2-Methylcyclopentanone, 1 | 1:4,5 | copper | 78.5 | 93.7 | 2 | |
| 5 | 2-Ethylcyclopentanone, 2 | 1:2 | copper | 71.7 | 93.4 | 2 | |
| 6 | 2-Ethylcyclopentanone, 2 | 1:2 | copper | 84.8 | 89.3 | 1 | |
| 7 | 2-Methylcyclopentanone | 1:1 | copper | polymer | | 2 | |
| 8 | 4-t-Butylcyclohexanone | 4 mole % alcohol | platinum | 87 | 95 | 1 | [77] |
| 9 | 3,3,5-Trimethylcyclohexanone | 10 mole % alcohol | $5.9 \times 10^{-2}$ A cm$^{-2}$ | 50 | 91 | 1 | |



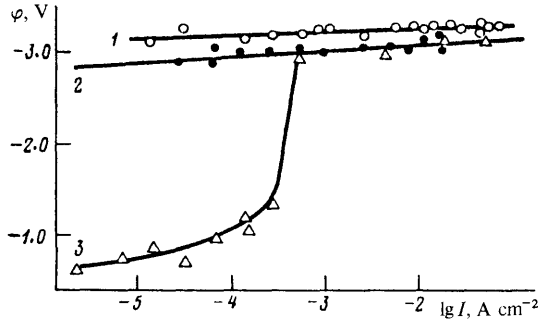
*1) The total quantity of substance to be reduced (and the proton donor) was added to the catholyte, and electrolysis was carried out until the stable colour of solvated electrons appeared; 2) the starting material (and the proton donor) was added to the catholyte containing previously generated electrons; the quantity of starting material added left a slight excess of solvated electrons; the whole procedure was repeated many times; Nos.1–7—sodium bromide; Nos.8 and 9—lithium chloride.

Table 15 shows that the cathode material and the method of reduction have no influence on the isomeric composition of the alcohol (the *trans*-form predominates†), whereas the electrode reduction gives a mixture of *trans*- and *cis*-carbinols, the ratio of which depends on the electrolysis conditions.[76] This indicated that in all cases the ketones are reduced by solvated electrons generated at the cathode, and this is confirmed by

¶ This agrees with data[75] which show that α-alkenes from pentene to decene are more difficult to reduce by metallic sodium in liquid ammonia than a longer alkene.

†High stereospecificity was also observed in the reduction of stilbenes in monoglyme by solvated electrons obtained by dissolving potassium; *trans*- and *cis*-stilbenes $C_6H_5CH = CHC_6H_5$ give the same radical-anion with the *trans*-configuration.[78]

the polarisation curves(Fig.6). Curve *1*, recorded in the presence of methylcyclopentanone and ethanol, lies in the range of generation potentials of solvated electrons (curve *2*). The slight displacement of the curve towards negative potential values in the presence of the ketone is due to the passivation of the surface as a result of the polymerisation of reduction products. Fig.6 gives for comparison curve *3*, corresponding to the case where the generation of electrons is accompanied by a second cathodic process, namely the cathodic liberation of hydrogen. Thus the reduction of cyclic ketones takes place according to the scheme



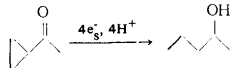


**Figure 6.** Dependence of the potential $\phi$, V (s.c.e.) on the current density at a stationary copper electrode in HMPA at 25 °C: *1*) lithium chloride 0.2 M + methylcyclopentanone $1.8 \times 10^{-2}$ M + ethanol $3.1 \times 10^{-2}$ M; *2*) lithium chloride 0.2 M; *3*) lithium chloride 0.1 M + sulphuric acid $2.2 \times 10^{-2}$ M.[76]

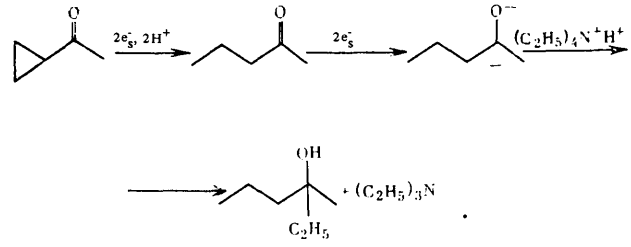

Similarly, solvated electrons generated at a cathode in a solution of lithium chloride in methylamine have been used[79] to reduce a number of ketones to the corresponding alcohols, namely heptan-2-one, pentan-3-one, cyclohexanone, and cyclopentanone. Electrons obtained by dissolving lithium, sodium, and potassium in HMPA have been used to reduce the ketone $C_6H_{13}COCH_3$, with t-butyl alcohol as proton donor.[80]

Alkali metals in liquid ammonia have been used[81] to reduce various substituted bicyclohexanones (bicyclo[3,1,0]hexa-3-en-2-ones).

The behaviour of acetylcyclopropanes deserves special examination. The reduction by an active metal in liquid ammonia takes place with opening of the ring:[82,83]

If the same reaction is carried out with electrochemically generated solvated electrons at a mercury or platinum cathode in liquid ammonia using tetraethylammonium tetrafluoroborate as background electrolyte, the chief electrolysis product is 3-methylhexan-3-ol. It is suggested that in this process the tetraethylammonium cations can act as an alkylating agent.

## 4. Carboxylic Acid Derivatives—Amides, Nitriles, and Esters

Electrochemically generated solvated electrons have been used to reduce various other organic compounds.

The data for aliphatic amides are given in Table 16.

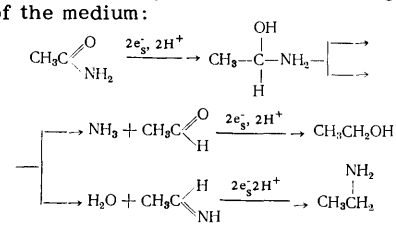

Table 16. The reduction of aliphatic amides by solvated electrons generated at a cathode.

| Medium | Proton donor | Amide | Reduction product, % | Refs. |
|---|---|---|---|---|
| LiCl + HMPA | acetic, oxalic, hydrochloric acids | $CH_3CONH_2$ | ethanol, ethylamine* | [84] |
| LiCl + methylamine | solvent | $CH_3(CH_2)_4CONH_2$ | alcohol, 58 | |
| | | $CH_3(CH_2)_6CONH_2$ | ditto, 59 | |
| | | $CH_3(CH_2)_{12}CONH_2$ | » 92 | |
| | | $CH_3(CH_2)_{11}CONH_2$ | » 86 | |
| | | $CH_3(CH_2)_{16}CONH_2$ | » 79 | |
| | | $CH_3(CH_2)_4CONHCH_3$ | » 51 | [79, 85] |
| | | $CH_3(CH_2)_6CONHCH_3$ | » 81 | |
| | | $CH_3(CH_2)_6CON(CH_3)_2$ | » 93 | |

*Decrease in temperature and the current density, and increase in the acidity, increase the proportion of amine.

Table 16 shows that solvated electrons can reduce aliphatic amides to alchols in good yield. In a medium of methylamine, the alcohol is formed if the solvent itself acts as proton donor. When ethanol, which is a stronger proton donor, is added to methylamine, the yield of alcohol decreases sharply, and the aldehyde becomes the main reaction product.[79,85]

In the reduction of acetamide in HMPA, the reduction products are ethylamine and ethanol. When the process is carried out at room temperature, the main reduction product is ethanol, but at a lower temperature (~11 °C), the two products are formed in approximately equal quantities. A low current density and more acidic proton donors (for example hydrogen chloride) also favour the formation of the amine. To explain the observed regularities, it was suggested that the first stage of the reduction is the formation of an unstable aminoalcohol, which undergoes decomposition depending on the acidity of the medium:

Ethanol is formed in basic catalysis, whereas another route, giving the amine, is followed preferentially in an acidic medium.

Published data on the reduction of nitriles and dinitriles are summarised in Table 17#.

**Table 17.** Reduction of nitriles and dinitriles by solvated electrons.[86–89]

| Method of generating electrons | Nitrile | Product (%) |
|---|---|---|

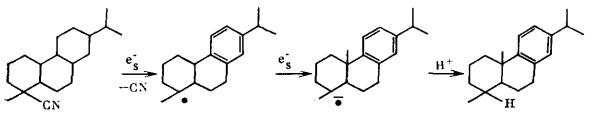
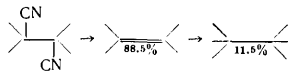
Note. *) Sufficient nitrile and ethanol (proton donor) was added by means of a micro-burette to a solution in which solvated electrons had previously been generated, to leave a slight excess of electrons; the procedure was repeated many time; 2*) the co-solvent t-butyl alcohol was used as proton donor, although in the authors' opinion the role of donor may be played by HMPA; 3*) the alkali metal was dissolved in ammonia, the nitrile was added, the ammonia was removed, and hydrolysis was carried out.

#The reduction of nitriles to amines also takes place by direct electrode reduction in solutions of hydrochloric and sulphuric acids in ethanol at palladium or nickel black cathodes (benzonitrile to benzylamine, and benzyl cyanide to β-phenylethylamine).[90]



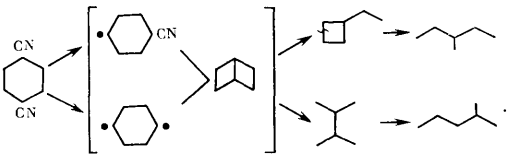
Solvated electrons, generated at a cathode or obtained by dissolving an alkali metal, have been used to reduce nitriles. Table 17 shows that in general, two reactions may take place: decyanation to give the hydrocarbon

$$RCN + 2e_s^- + 2H^+ \rightarrow RH + HCN$$



and reduction to the amine

$$RCN + 4e_s^- + 4H^+ \rightarrow RCH_2NH_2 \ .$$



The amine group formed is inert towards solvated electrons. Judging from available data on reduction by solvated electrons, the more characteristic reaction is the removal of the nitrile group (decyanation), which probably takes place via a radical-anion stage. Thus the following scheme has been proposed[91] for the reduction of dehydroabietonitrile by sodium in liquid ammonia:

Nitrile groups on neighbouring carbon atoms are removed with the preferential formation of carbon–carbon multiple bonds, for example:

Interesting transformations are undergone by 1,4-dicyanocyclohexane under the influence of solvated electrons:[88]

The final reaction products are 3-methylpentane and 2-methylpentane.

The nitrile group is apparently more reactive towards solvated electrons than the alkene bond or the bonds of the benzene ring, but the latter may be partly hydrogenated after the nitrile group has been reduced (Table 17).

Solvated electrons also reduce esters.[92] In particular, dimethyl adipate gives hexane:

$$CH_3OC(=O)(CH_2)_4C(=O)OCH_3 \xrightarrow[-2H_2O]{12H^+,\ 12e_s^-} C_6H_{14} + 2CH_3OH$$

that is the reduction takes place with rupture of the C–O bond. There are no published quantitative data on this reaction.

---o0o---

The material of the present review shows that electrochemically generated solvated electrons can be used successfully to reduce various organic compounds, many of which are electrochemically inactive, that is at the potentials attainable in polar solvents (between −2.5 V and −2.8 V, s.c.e.) there is practically no electron exchange between an electrode and the molecules of these organic substances. Thus the electrochemical generation of solvated electrons extends the possibilities in preparative electrochemical synthesis.

Another advantage of this method is that the actual generation of the solvated electrons can be carried out with high current densities, irrespective of the concentration of organic substance in the solution. This feature is important when it is necessary to carry out the exhaustive reduction of a substance present in solution at a low concentration. Thus the use of solvated electrons can be regarded as one possible way of intensifying electrochemical processes.

The first work on the generation of solvated electrons was carried out in liquid ammonia, and slightly later, HMPA began to be used as solvent. Both of these solvents are inconvenient to use. Ammonia can be used only at low temperatures of about −30 °C, and HMPA has a high boiling point, so that the separation of pure reduction products from it is difficult. In this connection it is worth noting recently published data on the possibility of generating electrons in solutions containing a large quantity of protogenic solvents, or even in aqueous solutions, containing 25–40% tetrabutylammonium salts. The change to these media simplifies considerably the procedure for generating solvated electrons, making it comparable with the ordinary electrochemical process. This version of electroreduction by solvated electrons should apparently find preparative application in laboratory practice and in various industrial processes.

The reduction of organic substances with the participation of solvated electrons can be regarded as a particular case of reactions involving electron carriers, which may be either organic or inorganic compounds. The use of solvated electrons, however, has at least two advantages: it is not necessary to introduce additional reagents into the reaction mass, and in preparative electrolysis this facilitates the separation of the reaction products; and there are processes such as, for example, the reduction of amides or certain aromatic compounds, which can be carried out only using solvated electrons. From these viewpoints alone, the use of solvated electrons in the electrosynthesis of organic substances appears promising and worthy of further study.

# Ferrocenyl Carbonium Ions and Related Cationic Complexes. Structure and Stabilisation Mechanism

A.A.Koridze

The review presents data on the structure and mechanism of the stabilisation of ferrocenyl carbonium ions and related cationic complexes with different types of hydrocarbon ligands. The results obtained in the study of complex carbonium ions by X-ray diffraction, $^{57}$Fe Mössbauer spectroscopy, and $^{1}$H, $^{13}$C, $^{19}$F, $^{57}$Fe, and $^{187}$Os NMR are compared. It is shown that the ability of the metal atom to interact directly with the carbonium ion centre generated in the β-position relative to it is a general property of transition metal complexes.
The bibliography includes 132 references.

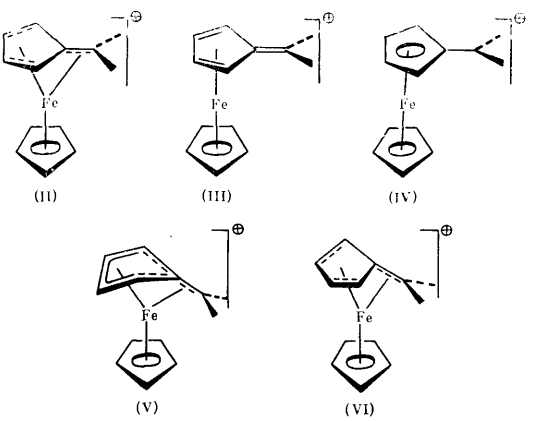
IV. Conclusion 123

## I. INTRODUCTION

Over a quarter of a century has elapsed since the discovery of the unusually high stability of α-ferrocenylcarbonium ions.[1] It was found subsequently that the enhanced stability is a characteristic property of complex carbonium ions in which the transition metal is present in the β-position relative to the carbonium ion centre. α-Ferrocenylcarbonium ions remain the most thoroughly investigated among complex carbonium ions because of their comparatively high stability, the ready availability of ferrocene, and the wide variety of its chemical behaviour.

Throughout all these years, a lively controversy has continued concerning the structure and mechanism of the stabilisation of the α-ferrocenylcarbonium ions (see the earlier reviews[2-6]). In the explanations put forward for the stability of these ions, one can see two main concepts differing in the role which the transition metal atom plays in the stabilisation. According to one of them, the high stability of the carbonium ions (I) is achieved by the overlap of the *d* orbitals of the metal atom with the unoccupied *p* orbitals of the α-carbon atom. On the other hand, it has been claimed that the delocalisation of the positive charge of the ferrocenyl group takes place via a system of carbon–carbon bonds without the direct involvement of the iron atom in the stabilisation of the carbonium ion centre.

(I)



A wide range of physicochemical methods have been used to solve the problem of the structure and mechanism of the stabilisation of α-ferrocenylcarbonium ions. The data obtained recently have led to a considerable advance in our understanding of the causes of the enhanced stability of these cationic complexes. However, there are no reviews in the literature in which the experimental data obtained by different methods have been examined critically.

We therefore thought it useful to discuss the available data on the structure and mechanism of the stabilisation of ferrocenylcarbonium ions and also, bearing in mind the general nature of the problem, the corresponding information about related complex cations.

## II. FERROCENYLCARBONIUM IONS

### 1. Structural Models of α-Ferrocenylcarbonium Ions

The unusually high ability of the ferrocenyl group to stabilise the neighbouring carbonium ion centre was demonstrated at an early stage in ferrocene chemistry. In particular, this was manifested by the high rate of solvolysis of α-acetoxyalkylferrocenes (comparable to that of trityl acetate)[1,7,8] and the ease of addition of weak acids to α-vinylmetallocenes.[9] Hill and Richards[7] suggested that structure (II) can reasonably explain the high stability of α-ferrocenylcarbonium ions. In this structure the $FeC_5H_5$ fragment is displaced towards the exocyclic carbon atom and the *d* orbitals of the metal atom overlap the *p* orbital of the $C_\alpha$ atom.

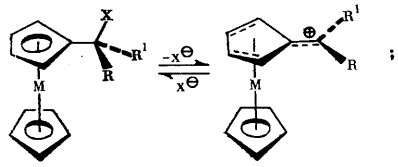
(II) (III) (IV) (V) (VI)

According to Traylor,[10,11] there is no need to postulate the direct participation of the iron atom in stabilisation to account for the experimental data and the best description of the structure of α-ferrocenylcarbonium ions is provided by the

resonance hybrid (III) ↔ (IV) with the predominant contribution by the canonical fulvene structure (III). Subsequently this concept was invoked to account for the mechanism of the stabilisation of other complex carbonium ions.

Both models have been frequently criticised. The criticism of model (II) is based on data obtained in a comparative $^1$H NMR study of various α-ferrocenylcarbonium ions—of the kind for which a shift of the $FeC_5H_5$ fragment is possible and others where such a shift is prevented by the presence of a heteroannular bridge.[12] Traylor's model[10,11] has been criticised because the metal atom in structure (III) [which makes a dominant contribution to the (III) ↔ (IV) resonance hybrid] has a 16-electron configuration unusual for such an atom. Furthermore, structure (III) was proposed as a model for α-ferrocenylcarbonium ions on the basis of a comparison of $^1$H NMR data for these cations and related tricarbonyliron(η-cyclobutadienyl)-substituted carbonium ions for which $\eta^3$-binding of the cyclic ligand has been erroneously postulated.[13] However, this structure was rejected after an X-ray diffraction study of the $BF_4^-$ salt of the bis[tricarbonyliron-(η-cyclobutadienyl)]benzyl cation.[14]

A further two structural models of α-ferrocenylcarbonium ions, in which there is a direct Fe–$C_\alpha$ interaction, have been proposed. These are Cais's structure (V) with a non-planar cyclic ligand [bent at the C(II) and C(V) atoms][2,3] and structure (VI) in which the exocyclic bond is displaced from the plane of the five-membered ring and inclines towards the metal atom.[15] According to Cais, model (V) explains satisfactorily both the data on the solvolysis of ferrocene derivatives and the $^1$H NMR data for α-ferrocenylcarbonium ions. However, a distortion of the cyclic ligand of this kind has not been observed in any of the X-ray diffraction studies of both cationic and uncharged cyclopentadienyl or fulvene metal complexes.



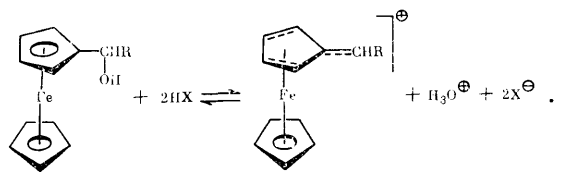
Model (VI) has been proposed on the basis of a calculation for $[FcCH_2]^\oplus$ (Fc = ferrocenyl) by the extended Hückel method.[15] According to the calculation, a 40° inclination of the C(I)–$C_\alpha$ bond in the direction of the iron atom corresponds to the minimum energy and the five-membered rings deviate from a parallel arrangement by 10°. The distortion of the fulvene ligand (the substituted ligand in α-metallocenylcarbonium cations is frequently regarded as a fulvene ligand[7,16]) is a consequence of the interaction of the unoccupied π* molecular orbital of the fulvene ligand with the $d_{z^2}$ orbital of iron, which is non-bonding in ferrocene. According to the calculation, in contrast to model (VI), the model with a planar fulvene ligand should have a triplet ground state.

Model (VI) is consistent with many experimental data. However, one should note that a subsequent calculation[17] for $[FcCH_2]^\oplus$ by an analogous method led to a structure in which the angle of inclination of the C(I)–$C_\alpha$ bond is only 6°.

## 2. Kinetics and Stereochemistry of Solvolytic Reactions

After the first communications about the hydrolysis of the carbinols of the ferrocene series via the $S_N1$ mechanism, demonstrating the high stability of α-ferrocenylcarbonium ions,[1,8] several groups of investigators measured the rate of solvolysis in order to elucidate the role of the metallocenyl group in the acceleration of these reactions.[7,10,11,18–23]

Together with a high rate of the reactions of the metallocenyl-substituted substrates in solvolysis, the preferential *exo*-elimination of the leaving group was then demonstrated (the attack by the nucleophile on the carbonium ion also takes place in the *exo*-position).[8,18]



M = Fe, Ru, Os.

The increase of the solvolytic reaction in the series of iron, ruthenium, and osmium derivatives is regarded as evidence for the direct nucleophilic cooperation of the metal atom in these reactions. The stereochemical result of these reactions is also explained by the direct involvement of the metal atom.[8,18] On the other hand, the high rate of these reactions has been attributed to the effect of σ,π-conjugation (vertical stabilisation) and the stereochemical result has been attributed to steric causes.[10,11,21,22]

In considering the kinetic data it has usually been assumed that the α-ferrocenylcarbonium ion is closely related to the transition state in the heterolytic process. However, a very interesting observation has been made: the thermodynamic stability of α-ferrocenylcarbonium ions is much higher than would follow from the rate of their formation in solvolytic reactions.[24]

The thermodynamic stabilities of a series of α-ferrocenylcarbonium ions have been determined in a quantitative study of the ionisation equilibria involving ferrocenylcarbonium ions in aqueous solutions of inorganic acids:

The equilibrium constants of the above reaction have been determined in $H_2SO_4(HClO_4)$–$H_2O$ systems. The $pK_{R^+}$ were obtained from linear plots of lg $[R^+]/[ROH]$ against the acidity function $H_{R^+}$.

The discrepancy between the data for the stability of ferrocenylcarbonium ions obtained from measurements of the equilibrium constants and the reaction rates suggests that a significant electronic and evidently a structural rearrangement of the ferrocenyl group takes place in the pathway from the transition state to the α-ferrocenylcarbonium ions in the heterolytic process.[24]

## 3. X-RAY DIFFRACTION STUDY OF THE SALTS OF COMPLEX CARBONIUM IONS

It was to be expected that X-ray diffraction study of the salts of α-ferrocenylcarbonium ions or related cationic complexes would provide a final unambiguous answer to the question whether there is a direct interaction of the metal atom with the carbonium ion centre. However, the problem was not found to be quite so simple.

No significant interaction of any kind between the iron atoms and the carbonium ion centre has been observed in the structure of the $BF_4^-$ salt of bis[tricarbonyliron(η-cyclobutadienyl)]benzyl cation,[14] where the Fe...$C_\alpha$ distances amounted to 2.85 and 2.94 Å. The $C_\alpha$ atom is coplanar with the cyclobutadiene rings, which have been somewhat rotated (by 5° and 8°) relative to the molecular plane; the benzene ring has undergone a rotation by 43°. This shows that the organometallic groups make a larger contribution to stabilisation than the benzene ring.

Nor has a significant Fe...$C_\alpha$ interaction been observed in the $BF_4^-$ salt of the ferrocenyldiphenylcyclopropenyl cation.[25] The Fe...$C_\alpha$ distance is 2.96 Å and the angle of inclination of the C(I)–$C_\alpha$ atom in the direction of the iron atom is 6.3°. The deviation of the $C_\alpha$ atom relative to the plane of the ligand by 0.16 Å exceeds only slightly the value (~0.1 Å) observed in certain uncharged ferrocene derivatives. One cannot therefore agree with the authors' claim[25] that the Fe–$C_\alpha$ interaction takes place in this complex. Furthermore, bearing in mind the aromatic character of the cyclopropenyl cation, one can hardly expect any significant Fe–$C_\alpha$ interaction, leading to the delocalisation of the positive charge.

In the study of the structure of the $BF_4^-$ salt of the diferrocenylmethyl cation it was observed[26,27] that the $C_\alpha$ atom has deviated from the plane of the five-membered rings but the Fe...$C_\alpha$ distances have been reduced to 2.69 and 2.81 Å, which corresponds to inclinations of the exocyclic bonds towards the iron atoms by 19.9° and 17.9° respectively. The authors suggest that the observed deviations may be the result of the interaction of the *d* electrons of the iron atom with the fulvene system, although the Fe...$C_\alpha$ distances are too large to permit the presence of a strong bond.

Yet another dinuclear complex with unequal Fe...$\overset{\oplus}{C}$H distances (2.59 and 2.72 Å) is $\{[Fe(\eta\text{-}C_5H_5)(CO)_2CH_2]_2CH\}.[BF_4]$.[28] In the precursor of this complex $[Fe(\eta\text{-}C_5H_5).(CO)_2CH_2]_2CH_2$ (the complex is generated from the latter by the abstraction of a hydride ion) the Fe...$C_\beta H_2$ distances are 3.07 Å.[29] It has been suggested that the difference between the Fe...$\overset{\oplus}{C}$H distances in the cationic complex are due to forces associated with the crystal packing.

The results of a study of the structure of the $BF_4^-$ salt of the ferrocenyldiphenylmethyl cation were published in 1979.[30] The angle of inclination of the C(I)–$C_\alpha$ bond in this complex is 20.7° and the Fe...$C_\alpha$ distance is 2.715 Å.† The metal atom occupies an asymmetric position under the substituted ring, being displaced somewhat (by 0.008 Å) in the direction of the exocyclic $C_\alpha$ atom. As a result, the Fe–C(1) distance is somewhat shorter (2.009 Å) and the Fe–C(4) and Fe–C(5) distances are somewhat longer (2.095 and 2.085 Å) than the average length of the bond between the iron atom and the carbon atoms of the unsubstituted ring (2.056 Å). The planes of the five-membered rings are at an angle of 9.3°. The length of the exocyclic C(1)–$C_\alpha$ bond (1.416 Å) is significantly smaller than would be expected for a single bond between $sp^2$-hybridised carbon atoms (1.48 Å) indicating an appreciable proportion of double bond character. According to Behrens,[30] the structure can be fully regarded as one corresponding to the diphenylfulvenylcyclopentadienyliron cation.

Here it is appropriate to recall that the possibility of an appreciable deviation of the exocyclic bond of the fulvene ligand had been demonstrated earlier in a study of diphenylfulvenechromium tircarbonyl;[32] a similar deviation of the *exo*-bond has been observed recently for the complex $C_5H_5FeC_2B_9H_{10}CHC_6H_5$.[33]

Compared with the complex $(OC)_3CrC_5H_4C(C_6H_5)_2$, in which the angle of inclination of the *exo*-bond is 31°, in the zwitter-ionic chromium complex $(OC)_3\overset{\ominus}{C}rC_5H_4CH{=}\overset{\oplus}{N}(CH_3)_2$ with a planar imine group the corresponding angle of inclination is only 10°.[34] The decrease of the degree of deviation of the fulvene ligand from planarity with increasing ability of the substituent to delocalise the positive charge on the $C_\alpha$ atom also follows from data obtained for the complex $FcCH{=}\overset{\oplus}{N}(CH_3)_2$ where the "distortion is minimal".[35] The influence of complex formation with the metal and of the nature of the substituent at the $C_\alpha$ atom on the distortion of the fulvene ligand and on the barrier to rotation about the *exo*-bond has been examined.[35]

Thus structural studies on salts of α-ferrocenylcarbonium ions and related complexes have provided much valuable information about the structure of these interesting systems in the crystal state and the results of Cais et al.[26] and Behrens[30] can be regarded as evidence for the direct Fe–$C_\alpha$ interaction. However, it remains obscure to what extent the Fe...$C^\oplus$ distances found for the complex cations, which occur in the wide range from 2.59 to 2.96 Å, should be regarded as "bonding" and what the situation is in this respect on passing from the crystal to the solution. It would be desirable to answer this question also in connection with the fact that hitherto there have been no structural data for the carbonium ion $[FcCH_2]^\oplus$ in which the strongest Fe–$C_\alpha$ bond is to be expected.

## 4. $^{57}$Fe Mössbauer Spectroscopy

The study of frozen solutions (137 K) of the carbonium ion $[FcCH_2]^\oplus$ in concentrated sulphuric acid and of the carbinol $FcCH_2OH$ in benzene by $^{57}$Fe Mössbauer spectroscopy[36,37] showed that the isomer shifts δ of the complexes differ little and are close to that for ferrocene (0.56, 0.57, 0.53 mm $s^{-1}$ respectively). According to the author's data, another parameter, namely the quadrupole splitting Δ, for the carbinol $FcCH_2OH$ is the same as for ferrocene, whereas Δ for the carbonium ion is greater by 15% than for the carbinol—1.99 and 2.29 mm $s^{-1}$ have been quoted for $FcCH_2OH$ and $[FcCH_2]^\oplus$. It is known that the chemical shifts for the ferrocene derivatives vary little and are observed in the range 0.48–0.60 mm $s^{-1}$ at 80 K; the quadrupole splittings are somewhat more sensitive to the influence of the substituent (2.05–2.55 mm $s^{-1}$) and diminish as the electron-accepting properties of the substituent are enhanced.[38,39] Accordingly, the substituent in model (IV) of α-ferrocenylcarbonium ions should manifest pronounced electron-accepting properties, which would diminish Δ. Model (II) with participation of the iron atom, in which one of the cyclopentadienyl ligands has been substituted by the fulvene ligand, linked to the metal atom the six carbon atoms, is consistent with experimental data according to Dannenberg and co-workers.[36,37]

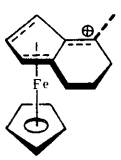
A series of studies have been published recently (see Roberts and Silver[40] and the references quoted therein) concerning the application of Mössbauer spectroscopy to the study of derivatives of ferrocene and α-ferrocenylcarbonium ions. Neshvad et al.[41] studied the carbonium ion $[FcCH_2]^\oplus$ and $[FcCHCH_3]^\oplus$ and criticised the earlier investigations.[36,37] It was found that Δ for $FcCH_2OH$ and $[FcCH_2]^\oplus$ are not 1.99 and 2.29 mm $s^{-1}$ but 2.40 and 2.70 mm $s^{-1}$ respectively.[41] Furthermore, in discussing their own data, Dannenberg and Richards[36] used an erroneous, unduly low, value of Δ for ferrocene.

Overall, the reasoning the conclusions arrived at by both groups of investigators were analogous. A new factor in the study of Neshvad et al.[41] is that, in contrast to $[FcCH_2]^\oplus$, for which the Fe–$C_\alpha$ interaction has been postulated, in the tertiary carbonium ion $[FcC(CH_3)_2]^\oplus$ the possibility of this interaction is ruled out on the grounds of the similarity of the values of δ and Δ for this complex (0.51 and 2.41 mm $s^{-1}$ respectively) and for ferrocene (0.53 and 2.42 mm $s^{-1}$). It has been suggested that the stabilisation in the complex

†It is remarkable that the Fe...$C^\oplus$ distances found in a number of studies,[26–28,30] are close to that between the bridging μ-CO ligand and the most remote iron atom in the cluster $[Fe_3(CO)_9(\mu\text{-}CO)(\mu_3\text{-}CO)]^{2\ominus}$; the distance 2.72(1) Å is believed to correspond to the presence of a bond between them.[31]

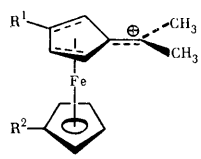
$[FcC(CH_3)_2]^{\oplus}$ is achieved through the inductive and hyperconjugation influences of the two methyl groups and also the resonance influence of the cyclopentadienyl ligand (see, however, Section II).

### 5. $^1$H NMR Spectroscopy



$^1$H NMR spectroscopy makes it possible to detect readily the formation of α-ferrocenylcarbonium ions when the traditional precursors of these ions, namely α-ferrocenylcarbinols[42-45] and α-vinylferrocenes[46] are treated with acids, usually $CF_3COOH$ or $H_2SO_4$.

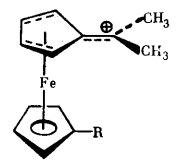
The formation of α-ferrocenylcarbonium ions is accompanied by a downfield shift of the signals due to the cyclopentadienyl protons. The greatest shift is then undergone by the signals of the H(3,4) protons of the substituted ring, while the H(2,5) protons are less deshielded [in contrast to acylferrocenes and other ferrocene derivatives with substituents exhibiting the $-R$ effect, in which the H(2,5) protons are more deshielded than the H(3,4) protons]. Thus, signals at $\delta$ = 5.45 ($CH_2$), 4.72 [H(2,5)], 6.32 [H(3,4)], and 5.27 ($C_5H_5$) p.p.m. have been observed[45] in the spectrum of a solution of the cation $[FcCH_2]^{\oplus}$ in $CF_3COOH$ ($\delta$ = 4.04 p.p.m. for ferrocene in $CCl_4$).



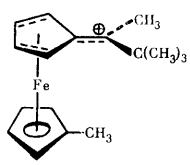
The difference between the relative shieldings of the H(2,5) and H(3,4) protons depends on the character of the substituent at the carbonium ion centre $C_\alpha$ and diminishes with increase of the ability of the substituent to delocalise the charge. For non-identical substituents at the $C_\alpha$ atom, four protons of the substituted ligand in the spectrum of α-ferrocenylcarbonium ions give separate signals, indicating that the rotation about the exocyclic $C(1)-C_\alpha$ bond is hindered.

The fact that the H(2,5) protons of the substituted ligand are more shielded in α-ferrocenylcarbonium ions (in contrast to, for example, acylferrocenes) has been regarded as evidence in support of model (II): when the $FeC_5H_5$ group shifts towards the $C_\alpha$ atom, its anisotropic effects leads to a greater shielding of the H(2,5) protons.[37]

To test the possibility of the displacement of the $FeC_5H_5$ fragment along the fulvene ligand, the carbonium ions (VII)–(X) have been investigated[12] assuming that such a shift is possible in the complexes (VII)–(IX) but not in the complex (X), where this is prevented by the heteroannular bridge consisting of three methylene units.



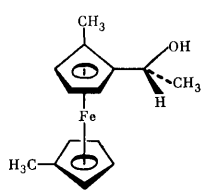
(VII)



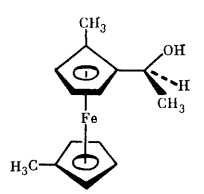
(VIII): $R^1 = R^2 = H$
(IX): $R^1 = R^2 = CH_3$
(X): $R^1, R^2 = (CH_2)_3$

The average difference $\Delta\nu$ between the shieldings of the H(2,5) and H(3,4) protons in the complexes (VII)–(X) is 72, 80, 86 and 65 Hz respectively, which is believed to be inconsistent with model (II) [a greater difference $\Delta\nu$ is expected if the model is applied to the complexes (IX) and (X)]. One can therefore assume that α-ferrocenylcarbonium ions undergo a deformation which is different from that postulated by the above model; otherwise one would have to assume that the metal–ring interaction and the character of the charge distribution in α-ferrocenylcarbonium ions and ferrocene differ significantly.

Data consistent with the distortion from planarity of the fulvene ligand have been published.[47] The protons of the alkyl-substituted ring in the carbonium ion (XI) are manifested in the $^1$H NMR spectrum by a single narrow signal, which indicates the ease of the relative rotation of the rings. However, the H(2,5) and H(3,4) protons of the methylcyclopentadienyl ligand give rise to two multiplets at $\delta$ = 4.78 and 5.15 p.p.m. in the spectrum of the cation (XII), which is believed to be due to the restriction of the rotation of the cyclic ligands as a consequence of the contact between the t-butyl group at the $C_\alpha$ atom and the methyl group of the $C_5H_4CH_3$ ligand.

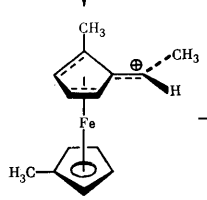


(XI): R = $CH_3$, $C_2H_5$, $CH(CH_3)_2$, $C(CH_3)_3$

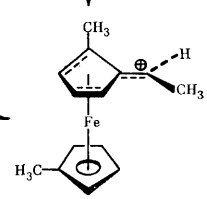


(XII)

Such a difference between the relative rotations of the ring in the isomeric complexes (XI, R = t-butyl) and (XII) was not to be expected for planar fulvene ligands. The spectroscopic differences between the isomeric cations noted above are therefore explained by the distortion of the fulvene ligand similar to that postulated in models (V) and (VI).

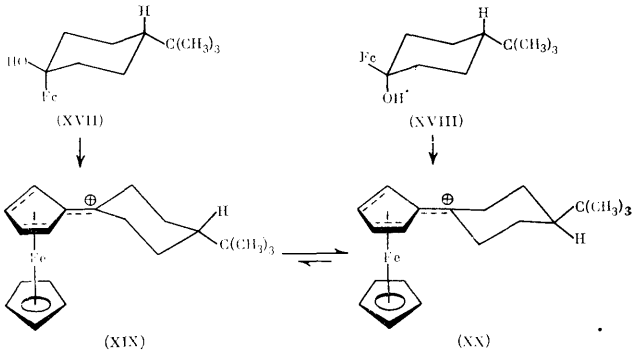


$^1$H NMR has been used to study the barrier to rotation about the exocyclic bond in α-ferrocenylcarbonium ions.[48] When the diastereoisomeric carbinols (XIII) and (XIV) are dissolved in acid, the isomeric carbonium ions (XV) and (XVI) are generated respectively and it is possible to follow the slow transformation of the carbonium ion (XV) into the sterically less strained isomer (XVI).



(XIII)

(XIV)



(XV)

(XVI)

The barrier to rotation about the $C(1)-C_\alpha$ bond is sufficiently large to detect the optically active carbonium ions generated from the enantiomeric carbinols *R*-(−)-$FcCH(OH).CH_3$ and *S*-(+)-$FcCH(OH)CH_3$; the racemisation of these ions has been investigated by the polarimetric method.[48]

The carbonium ions (XIX) and (XX) are formed from the tertiary carbinols (XVII) and (XVIII) respectively; the complexes isomerise slowly, giving rise to an equilibrium mixture consisting mainly (approximately 90%) of the carbonium ion (XX).

(XVII) (XVIII)

(XIX) (XX)

The lower stability of the carbonium ion (XIX) compared with (XX) has been explained by the more marked steric repulsion between the conformationally rigid t-butylcyclohexyl ring and the unsubstituted cyclopentadienyl ligand.[48]

The torsional barrier in the equilibrium (XIX) ⇌ (XX) between the tertiary carbonium ions is appreciably lower than in the equilibrium (XV) ⇌ (XVI) between the secondary carbonium ions (69.4 ± 2 and 88.7 ± 2.0 kJ mol$^{-1}$ respectively). Consequently the difference between the energy barriers to rotation about the C(1)–$C_\alpha$ bond is not determined by steric causes due to contacts between the substituents at the $C_\alpha$ atom and the unsubstituted ring in the transition state. It is believed that these differences reflect the role of the electronic factors characteristic of the substituents at the $C_\alpha$ atom.[48]

The estimated torsional barriers (~100 kJ mol$^{-1}$) in the α-ferrocenylcarbonium ions show that the exocyclic bond of the fulvene ligand does not have an appreciable double bond character and this is inconsistent not only with model (III) but also with the appreciable contribution of the canonical structure (III) to the (III) ↔ (IV) resonance hybrid.[48]

## 6. $^{13}$C NMR Spectroscopy

The study of α-ferrocenylcarbonium ions by $^{13}$C NMR showed that the signals of all the carbon atoms in the cyclic ligand have undergone a downfield shift compared with the neutral precursors, which indicates the delocalisation of the charge over the entire ferrocenyl unit.[49–56] The deshielding of the carbon nuclei in the ferrocenyl group is relatively insensitive to the nature of the substituents at the $C_\alpha$ atom, so that the ferrocenyl group makes the main contribution to the stabilisation of the carbonium ion.

The relative shielding of the C(2,5) and C(3,4) atoms in the $^{13}$C NMR spectra of α-ferrocenylcarbonium ions is the same as that of the H(2,5) and H(3,4) atoms: the signals of the nuclei in the 3,4-positions are less shielded. Thus signals at δ = 87.7 ($CH_2$), 110.6 [C(1)], 84.6 [C(2,5)], 94.4 [C(3,4)], and 82.3 ($C_5H_5$) p.p.m. have been observed in the spectrum of the cation $[FcCH_2]^\oplus$ (δ = 67.7 p.p.m. for ferrocene in dichloroethane). Similar relative shielding of the carbon atoms of the substituted ligand has been observed in the ferrocene derivatives FcR, where R = CHO, $COCH_3$, CN, or other substituents with a $-R$ effect.[57]

The cause of the smaller shielding of the C(3,4) atoms compared with C(2,5) may be the known sensitivity of the former to the $-R$ effect of the substituents in ferrocene derivatives.[57] Another factor which also favours the observed spectral picture may be the shift of the $FeC_5H_5$ fragment to the exocyclic $C_\alpha$ atom. Such a shift would weaken the bond between the metal atom and the C(3,4) carbon atoms and hence should entail a smaller shielding of the latter as a consequence of the diminution of the effect of the "coordination shift"#. At the same time the displacement of $FeC_5H_5$ towards the $C_\alpha$ atom should favour a greater shielding of the C(2,5) atoms as a consequence of the effect of the magnetic anisotropy of the $FeC_5H_5$ fragment.[37]

In the discussion of the $^{13}$C NMR spectra of α-ferrocenylcarbonium ions, attention was drawn to the relatively small downfield shift of the $C_\alpha$ signal on passing from carbinols to carbonium ions.[51] For example, on formation of the $[FcCH_2]^\oplus$, $[FcCHCH_3]^\oplus$, and $[FcCHC_6H_5]^\oplus$ carbonium ions from the corresponding carbinols, the quantities $\Delta\delta(^{13}C_\alpha)$ are 26.2, 52.1, and 49.9 p.p.m. respectively. On the other hand, they are much greater for organic systems, $\Delta\delta(^{13}C_\alpha)$ amounting to 127.4 p.p.m. in the case of the 3,5-$(F_3C)_2C_6H_3$·.$CH(OH)CH_3$/3,5-$(F_3C)_2C_6H_3\overset{\oplus}{C}HCH_3$ pair for example.[58] This difference between the $\Delta\delta(^{13}C_\alpha)$ for organometallic and organic systems may be the result of the more effective delocalisation of the positive charge in the organometallic carbonium ions and the occurrence of the metal–$C_\alpha$ interaction.

The $^{13}$C–$^1$H spin–spin interaction constants (SSIC) for α-ferrocenylcarbonium ions, which are in the range 160–165 Hz, are consistent with the $sp^2$ hybridisation of the $C_\alpha$ atom but not with the formation of the Fe–$C_\alpha$ σ-bond.[49,51–53,55]

## 7. The $^{57}$Fe NMR Chemical Shifts and the $^{13}$C–$^{57}$Fe Spin–Spin Interaction Constants for α-Ferrocenylcarbonium Ions

Since it is impossible to resolve the question of the mechanism of the stabilisation of α-ferrocenylcarbonium ions within the framework of traditional methods for the investigation of carbonium ions, it became necessary to seek a new approach. Such an approach, consisting in the study by the $^{13}C\{^1H\}$ and $^{13}C\{^1H, ^{57}Fe\}$ methods of organoiron compounds enriched in the $^{57}$Fe isotope (natural abundance 2.2%, nuclear spin 1/2), has been used in an investigation carried out at the Institute of Organoelemental Compounds of the USSR Academy of Sciences.[59,60] It was found that the $^{13}$C–$^{57}$Fe SSIC for ferrocene derivatives is relatively insensitive to the nature of the substituent and usually occurs in the range 4.2–5.2 Hz; the signal of the exocyclic $C_\alpha$ carbon atom in the $^{13}C\{^1H\}$ NMR spectrum is manifested by a narrow singlet.[59,61]

In contrast to ferrocene derivatives, the $^{13}$C–$^{57}$Fe SSIC for α-ferrocenyl carbonium ions are clearly not the same for different carbon atoms, being greatly reduced for C(3,4), while the signal of the $C_\alpha$ atom is either broadened or (when the resolution is sufficiently good) is observed as a doublet with a $^{13}C_\alpha$–$^{57}$Fe constant up to 2.7 Hz.[59,60]

The assignment of the observed broadening (splitting) of the signal of the $^{13}C_\alpha$ atom to interaction via only one bond ($^{13}C_\alpha$–$^{57}$Fe) and not via two bonds [$^{13}C_\alpha$–C(1)–$^{57}$Fe] has been justified[60] on the basis of the $^{13}$C–$^{57}$Fe SSIC obtained for $^{57}$Fe complexes with a wide variety of hydrocarbon ligands.

The broadening (splitting) of the $^{13}C_\alpha$ signal in the spectra of α-ferrocenylcarbonium ions is accompanied by a decrease of the $^{13}$C(3,4)–$^{57}$Fe SSIC, which suggests that the "non-bonding" hybrid *d* orbitals of iron undergo a rehybridisation, which promotes the Fe–$C_\alpha$ interaction.

The data on the shielding of $^{57}$Fe in the α-ferrocenylcarbonium ions $[FcCH_2]^\oplus$ (XXI) and $[FcCHCH_3]^\oplus$ (XXII) published in 1978 [59] confirmed this hypothesis. It has been

#The term "coordination shift" denotes the upfield shift of the NMR signals of the hydrocarbon ligand on coordination to the transition metal.

shown beforehand that the $^{57}$Fe chemical shift for ferrocenes is very sensitive to the nature of the substituent, electron-accepting substituents of the *-R* type leading to a marked deshielding of iron. Thus the $\delta(^{57}Fe)$ are 215.5 and 425.6 p.p.m. for acetyl- and 1,1'-diacetyl-ferrocenes respectively (relative to ferrocene as the standard).[59]

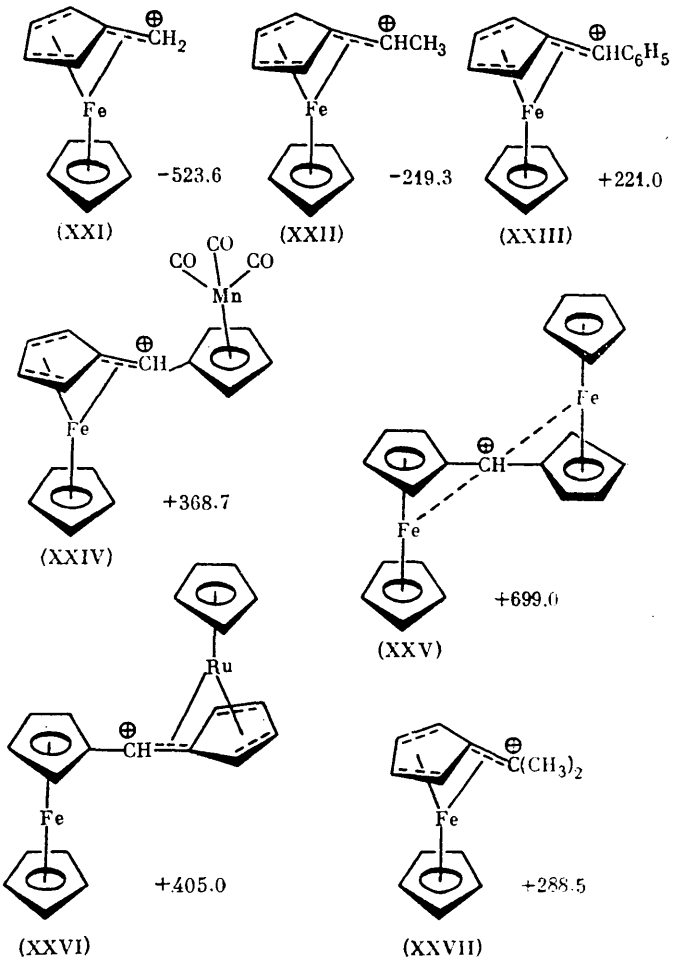


**Figure 1.** The $^{57}$Fe NMR chemical shifts (p.p.m.) of α-metallocenylcarbonium ions.[60]

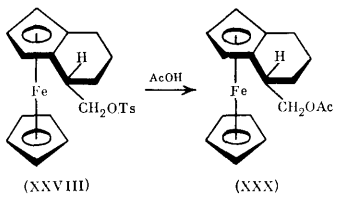
However, despite the "electron-accepting" character of the substituent, the $^{57}$Fe signals of the carbonium ions (XXI) and (XXII) are observed in strong fields—at -523.6 and -219.3 p.p.m. respectively. The conclusion that the *d* orbitals are rehybridised in α-ferrocenylcarbonium ions has been supported by the following observations. The shift of the iron signal to a very strong field (-1098.8 p.p.m.) has also bee noted[61] for the protonated ferrocene $[HFe(C_5H_5)_2]^{\oplus}$, where the above rehybridisation is known to take place.[62,63] In addition an upfield shift has been observed also for those "uncharged" ferrocenophanes in which the rehybridisation of the "non-bonding" *d* orbitals is induced by the breakdown of the parallel arrangement of the rings as a consequence of the inadequate lengths of the hydrocarbon bridge.

It has been found that the $^{57}$Fe NMR signal undergoes consecutive upfield shifts with increase of the degree of deviation of the cyclopentadienyl rings of ferrocene from the parallel arrangement: the $\delta(^{57}Fe)$ chemical shifts for 1,1'-diethylferrocene, [4]ferrocenophane, and [3]ferrocenophane are +72.5, -56.5, and -272.5 p.p.m. respectively. In ferrocene derivatives containing a heteroannular bridge made up of three or four carbon atoms, the five-membered rings are known to deviate from the parallel arrangement by approximately 9° and approximately 4° respectively as a consequence of the tightening (in the former case) and expanding (pushing apart) (in the latter case) effects respctively. Thus the $^{57}$Fe signal of [3]ferrocenophane has undergone an upfield shift of approximately 350 p.p.m. compared with 1,1'-diethylferrocene containing parallel ligands.[60,64]

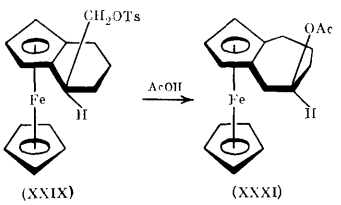
The study of the carbonium ions (XXI)–(XXVII) showed that their $^{57}$Fe chemical shifts cover a range of 1200 p.p.m. and constitute a sensitive measure of the direct involvement of the iron atom in the stabilisation of the carbonium ion centre (Fig.1). The relative shielding of the $^{57}$Fe nucleus in carbonium ions is determined by the sum of two opposed effects: the rehybridisation of the "non-bonding" *d* orbitals of iron promotes shielding, while the electron-accepting influence of the substituent promotes the deshielding of the $^{57}$Fe nucleus.

Thus the $^{57}$Fe chemical shifts for the series (XXI)–(XXVI) undergoes a consecutive [with the exception of the complex (XXV)] downfield displacement with increasing ability of the substituent R to delocalise the positive charge in the carbonium ions $[FcFHR]^{\oplus}$. The explanation is that, with increase in the ability of the group R to delocalise the charge, the contribution of the direct involvement of the metal to the stabilisation (i.e. the factor promoting the rehybridisation of its *d* orbitals, the $^{57}$Fe shielding factor) diminishes.[60,65]



In the symmetrical complex $[(Fc)_2CH]^{\oplus}$(XXV) both ferrocenyl units make equal contributions to the delocalisation of the charge and the orbitals of each of the iron atoms are therefore less rehybridised [compared, for example, with the complex (XXIV)]; there is a simultaneous increase of the fraction of the charge delocalised via the system of carbon–carbon bonds of the cyclopentadienyl ligands. As a result, the complex (XXV) exhibits the most marked "carbenium ion" character among all the complexes (XXI)–(XXVII) investigated, which explains the marked deshielding of the iron nucleus in it (+699.0 p.p.m.). Data on the shielding of the $C_\alpha$ nuclei in the dinuclear complexes (XXIV), (XXV), and (XXVI) (122.4, 147.2, and 116.9 p.p.m. respectively) also agree with this finding.[60,65]

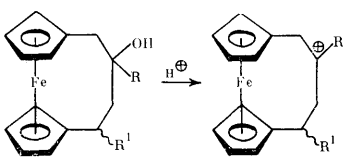
On the basis of the $^{13}C-^{57}Fe$ SSIC data for the shielding of the $^{57}$Fe nucleus in the cationic complexes (XXI)–(XXVII), one may assume that the strongest $Fe-C_\alpha$ bond obtains in the primary carbonium ion (XXI), although in this case too the strength of the $Fe-C_\alpha$ bond should be smaller than that of the bond with the carbon atoms of the five-membered ring. The greatest $^{13}C_\alpha-^{57}Fe$ shielding, amounting to 2.7 Hz, has been noted for the [3]ferrocenophan-7-yl cation,[60] which may be accounted for by the distortion of the fulvene ligand as a consequence of the additional tightening influence of the heteroannular bridge. The minimum $Fe-C_\alpha$ interaction evidently takes place in $[(Fc)_2CH]^{\oplus}$, whereas the results obtained indicate the occurrence of the $Fe-C_\alpha$ interaction in the tertiary carbonium ion $[FcC(CH_3)_2]^{\oplus}$[in contrast to the claim based on the Mössbauer spectra of this complex:[41] being highly sensitive, $^{57}$Fe NMR spectroscopy should indicate the occurrence of a weak $Fe-C_\alpha$ interaction in those cases where Mössbauer spectroscopy fails to record a change in the ligand environment of the metal on passing from the tertiary carbinol to the ion (XXVII)].



### 8. β-Ferrocenylcarbonium Ions

In view of the unusually high stability of α-ferrocenylcarbonium ions, it was of interest to discover how the ferrocenyl group influences the stabilisation of the carbonium centre in the β-position relative to it.

It has been observed[66] that *endo*-α-tosyloxymethyl-1,2-tetramethyleneferrocene (XXVIII) undergoes acetolysis 2780 times faster than its *exo*-isomer (XXIX). The corresponding acetate (XXX) is then formed from the *endo*-isomer, while the *exo*-isomer gives rise to the rearrangement product (XXXI), with a seven-membered ring:



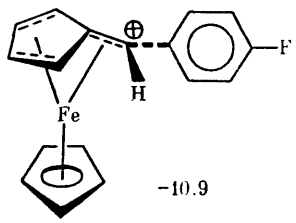
(XXVIII) (XXX)

(XXIX) (XXXI)

The difference between the rates of solvolysis of the complexes (XXVIII) and (XXIX) and also between the structures of the resulting products can be accounted for by the effective involvement of interannular electrons (in essence, the electrons of the iron atom) in the stabilisation of the β-ferrocenylcarbonium ion. The retention of configuration in the solvolysis of the optically active 1-ferrocenyl-2-propyl tosylate is consistent with the involvement of iron.[67]

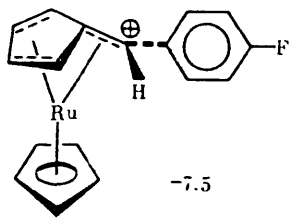
The stability of β-ferrocenylcarbonium ions has been demonstrated in a $^1$H NMR study of the cationic complexes (XXXIII) generated from carbinols of the [4]ferrocenophane series (XXXII):[68–70]

(XXXII) (XXXIII)



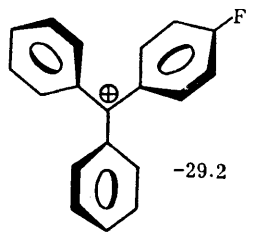
The effect of conjugation with the metallocenyl group is ruled out in the carbonium ions (XXXIII) where the electron-deficient centre is separated from the ferrocenyl group by the methylene unit. It is therefore natural to suppose that the stabilisation is achieved by the direct involvement of the iron atom.[69] The comparatively strong field of the C(7) hydrogen atom signal in complexes (XXXIII) (5.36–5.55 p.p.m.) agrees with this assumption.

## III. RELATED COMPLEX CARBONIUM IONS

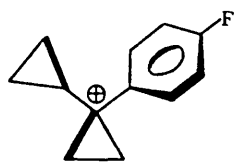


This Section does not deal with heteroatomic systems (for example, those generated by the protonation of acylferrocenes). These were partly considered in a previous review.[5] The presence of a heteroatom next to the carbonium ion centre can significantly reduce the role of the metallocenyl group in its stabilisation. Although these systems have been considered as models of α-ferrocenylcarbonium ions, this study has made little contribution towards the elucidation of the role of the transition metal atom in stabilisation.

### 1. Ruthenocenyl- and Osmocenyl-carbonium Ions



The rates of the $S_N1$ acetolysis of α-acetoxyethylmetallocenes[7] and of the non-catalysed addition of acetic acid to vinylmetallocenes[9] indicate an increase of carbonium ion stability in the sequence $[FcCHCH_3]^{\oplus} < [RucCHCH_3]^{\oplus} < [OscCHCH_3]^{\oplus}$ (where Ruc and Osc denote ruthenocenyl and osmocenyl). This stability series can be accounted for by the improvement of the overlap of the metal atom orbitals and the π orbitals of the fulvene ligand as the volume and polarisability of the valence shell of the metal increase.[2,3,7,71] The $pK_{R^+}$ for $[RucCHCH_3]^{\oplus}$ and $[FcCHCH_3]^{\oplus}$ are 1.20 and −0.65 respectively.[71]



(XXXIV)

(XXXV)

(XXXVI)

(XXXVII)

Figure 2. The $^{19}$F NMR chemical shifts (p.p.m.) of the p-fluorophenyl-substituted carbonium ions.[75,76]

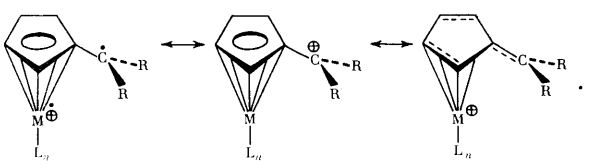
It has been shown for the optically active carbonium ions $[RucCHCH_3]^{\oplus}$ that the torsional barrier is so high that racemisation does not take place even when the solution in $CF_3COOH$ is heated at 70 °C for several days.[48]

The signals of the protons at $C_\alpha$ in the $^1$H NMR spectra of the carbonium ions $[McCHCHC(CH_3)_2]^{\oplus}$ (Mc = Fc, Ruc, Osc) as well as $[McCHCH_3]^{\oplus}$ (Mc = Fe or Ruc) undergo successive upfield shifts, which can be accounted for by the decrease of the positive charge on the $C_\alpha$ atom in the isostructural series of metallocenylcarbonium ions.[54,72]

According to $^{13}$C NMR data, the positive charge in the complex $[FeCHRuc]^{\oplus}$ (XXVI) is largely delocalised over the ruthenocenyl unit. The spectrum exhibits a temperature dependence due to the rotation about the Fe–$C_\alpha$ bond.[60,65] It is of interest to compare these results with data concerning the electronic influence of the corresponding metallocenyl

groups. It has been shown that, according to $^{19}F$ NMR data for the complexes *m*- and *p*-$Fc_6H_4Mc$, characterising the influence of the metallocenyl groups in the ground state of the uncharged substrates, the metallocenyl groups Fc, Ruc, and Osc show insignificant differences in their electronic influences, which are close to those of the alkyl substituents in the benzene ring.[73] Furthermore, estimation of the effective charges in metallocenes (also on the basis of the shielding of the $^{19}F$ nucleus) yielded the following values for the cyclopentadienyl ligand in ferrocene, ruthenocene, and osmocene: −0.26, −0.25, and −0.25 a.u. respectively.[74] In the light of these data, it is reasonable to postulate that the results obtained for the complex $[FcCHRuc]^{\oplus}$ agree with the direct involvement of the ruthenium atom in stabilisation.[60]

The $^{19}F$ NMR signals of the carbonium ions (XXXIV) and (XXXV) are observed at −10.9 and −7.5 p.p.m. respectively (in a weak field relative to fluorobenzene). Thus the ruthenocenyl group is more effective in delocalising the charge than the ferrocenyl group[75] (Fig.2).

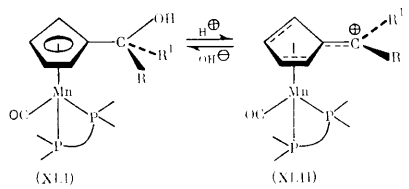


Comparison of the shielding of $^{19}F$ in the complexes (XXXIV) and (XXXV) and in the carbenium ions (XXXVI) and (XXXVII) [76] demonstrates to what extent the metallocenyl groups are superior to the phenyl and cyclopropyl groups as regards the delocalisation of the positive charge. The similarity of the $^{19}F$ chemical shifts for the complexes (XXXIV) and (XXXV) to those for *p*-fluoronitrobenzene and *p*-cyanofluorobenzene (−11.1 and −9.2 p.p.m. respectively) has also been noted.[75] Hence it follows that the treatment of the $C_\alpha$ atom as a "carbonium ion" centre is to a considerable extent arbitrary.

## 2. Cymantrenylcarbonium Ions

The cymantrenyl group is less effective in stabilising the cationic centre than the ferrocenyl group, but it is superior to the phenyl group in this respect.[77–80]

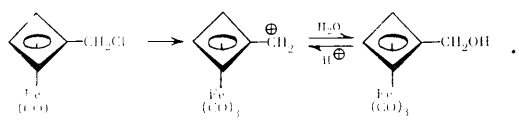
The substitution of the CO ligands by phosphine ligands increases the stabilisation of the corresponding ions, as might have been expected on the basis of the donor–acceptor properties of CO and $PR_3$ groups.[81]



The similarity of the ultraviolet[80] and $^1H$ NMR [80,82,83] spectra of α-cymantrenyl- and α-ferrocenyl-carbonium ions suggested the similarity of the mechanisms of their stabilisation. A distinctive feature of the $^{13}C$ NMR spectra of cymantrenylcarbonium ions is that the signal due to the C(1) atom exhibits the greatest degree of shielding. According to Loim et al.,[84] the structure of α-metallocenyl carbonium ions (including cymantrenyl ions) may be described by the resonance of the structures (XXXVIII), (XXXIX), and (XL), in which the exocyclic bond is inclinded in the direction of the metal atom.

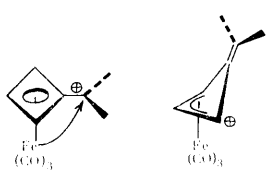
(XXXVIII) (singlet state) (XXXIX) (XL)

The contribution of each structure depends on the nature of the metal, its lipand environment, and the substituents at the $C_\alpha$ atom. With increase of the number of electron-donating substituents at this atom the stabilisation due to the $M-C_\alpha$ interaction diminishes owing to steric hindrance. The "approach of the cationic centre" to the plane of the five-membered ring diminishes the contribution of the structure (XXXVIII) with the direct involvement of the metal atom and correspondingly increases the contribution of the structures (XXXIX) and (XL). Overall, these considerations agree with those presented previously[37] for α-ferrocenylcarbonium ions and are not open to objection. However, it has not been explained why the exocyclic bond in the structures (XXXIX) and (XL), where a direct involvement of the metal atom in stabilisation is not implied, should nevertheless be inclined towards the metal atom.



Two $^{31}P$ signals are sometimes observed when the cationic complexes (XLII), generated from the diphosphine derivatives of the cymantrenyl carbinols (XLI), are investigated by $^{31}P$ NMR, which is explained by hindrance to free rotation of the $Mn(CO)P_2$ group about the metal–ring axis, possibly owing to the inclination of the exocyclic bond.[85]

(XLI) (XLII)

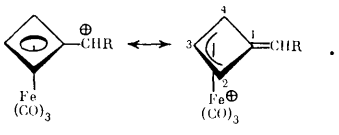


## 3. Tricarbonyliron(η-cyclobutadienyl)carbonium Ions

It has been shown that tricarbonyliron(α-chloromethylcyclobutadiene) (XLIII) undergoes rapid solvolysis in water or methanol, giving rise to the carbinol (XLV) or the corresponding methyl ether. These reactions have been explained by the intermediate involvement of the stable carbonium ion (XLIV). The latter has been isolated in the form of the $SbCl_6^-$ salt on treatment of the complex (XLIII) with antimony pentachloride.

(XLIII) (XLIV) (XLV)

In order to account for the pronounced shielding of the exocyclic protons in the $^1H$ NMR spectrum of the carbonium ion (XLIV) (signals at δ = 6.68, 5.91, and 5.09 p.p.m. with the relative intensities 1:2:2) and also of the secondary carbonium ion generated from tricarbonyliron(η-α-hydroxyethylcyclo butadiene), the structures (XLVI) and (XLVII) were examined and preference was given to the π-allyl structure (XLVII).[13]



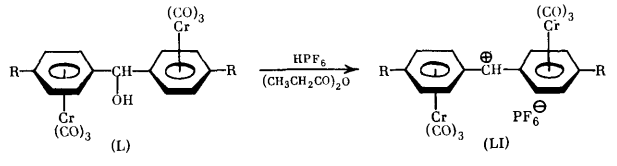
(XLVI) (XLVII)

On the basis of the results of X-ray diffraction analysis of the tetrafluoroborate salt of the cation $\{[(OC)_3Fe(\eta\text{-}C_4H_3)]_2.CC_6H_5\}$, the authors later concluded[14] that the main contribution to stabilisation comes from the interaction between the occupied orbitals of the metal atom and the four carbon

atoms of the cyclobutadiene ring with subsequent electron transfer to the electron-deficient centre via π,π interaction.

In the study of the cationic complexes $[(OC)_3Fe(\eta\text{-}C_4H_3).CHR]^{\oplus}$(R = H, $CH_3$, or $C_6H_5$) by $^{13}C$ NMR, it was noted[86] that $\Delta\delta(^{13}C_\alpha)$ is comparatively small for the transition from the carbinol to the carbonium ion (in contrast to organic systems). Furthermore, an appreciable downfield shift of the signal of the C(3) carbon atom (42–46 p.p.m.), compared with 3–13 p.p.m. for the C(2) and C(4) atoms, has been observed. These data can be accounted for in terms of hyperconjugation with participation of the metal–carbon bond.[11,87] It is believed[87] that the hyperconjugation effect weakens the bond between the metal and the C(1) atom, which increases the contribution of the π-allyl structure to the resonance hybrid (XLVIII)↔(XLIX):

(XLVIII) (XLIX)



However, the above spectroscopic features may be a result of the rehybridisation of the iron atom, which ensures the Fe–$C_\alpha$ direct interaction.

## 4. Benchrotrenylcarbonium Ions

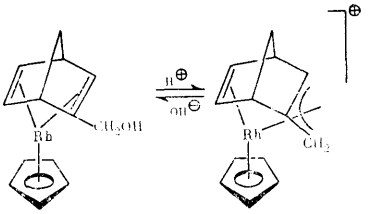
The study of tricarbonylarenechromium-substituted systems has the advantage that it makes possible a direct comparison with the corresponding non-coordinated arenes. The solvolysis of $(OC)_3Cr(\eta\text{-}C_6H_5CH_2Cl)$ is approximately $10^5$ times faster than that of benzyl chloride, while the solvolysis of η-chlorodiphenylmethanechromium tricarbonyl is approximately $10^3$ times faster than that of diphenylmethyl chloride.[88] A slight increase (only by a factor of 28) of the rate of solvolysis of α-chlorocumene on coordination to the $Cr(CO)_3$ group can be explained by the influence of steric factors.[89]

Data obtained from measurements of the $pK_{R^+}$ for benchrotrenylcarbonium ions also indicate the ability of the $Cr(CO)_3$ group to delocalise the charge.[90,91]

The attempts to obtain stable salts of carbonium ions from $(OC)_3Cr(\eta\text{-}C_6H_5CH_2X)$ (X = Cl or $CH_2OH$) were unsuccessful.[88] The stable $PF_6^-$ salts of the carbonium ions (LI, R = H or $CH_3$) have been synthesised only from the dimetallic carbinols (L):[92]

(L) (LI)

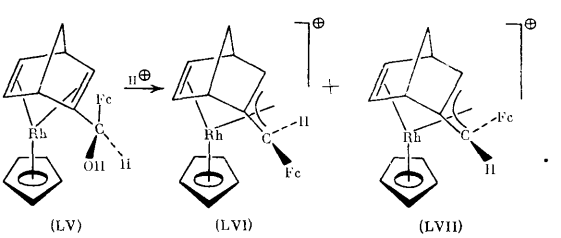
The 1-(tricarbonyl-*p*-tolylchromium)ethyl and bis(tricarbonyl-*p*-tolylchromium)methyl cations, generated from the corresponding carbinols in $HSO_3F$ at −50 °C, have been identified by $^1H$ NMR.[93] $^{13}C$ NMR data for the same carbonium ions were published later.[92,94] Although the results presented did not enable the authors[94] to make a choice between the resonance-stabilised structure and the structure involving the direct participation of the metal atom, preference was given to the latter.



In a study of the $^{13}C$ NMR spectrum of the tricarbonylcumenylchromium cation (LII), it was noted[95] that, whereas the *ortho*- and *para*-carbon atoms in benchrotrenes and non-coordinated monosubstituted benzenes are usually more sensitive to the influence of substituents than the *meta*-carbon atoms, in the carbonium ion (LII) the opposite situation is observed: the *meta*-carbon atoms proved to be the most deshielded. On this basis, the authors regard the direct involvement of the metal atom and delocalisation via the overlap of the π,π type as unlikely; a significant role of the σ,π conjugation is also rejected (the appearance of a signal due to $C_i$ in a very weak field would be expected in such a case). The authors merely state that the charge is delocalised over the $Cr(CO)_3$ group, although the mechanism of the delocalisation remains obscure.

According to a calculation by the LCAO-MO SCF method, the stability of the $[(OC)_3Cr(\eta\text{-}C_6H_5CH_2)]^{\oplus}$ ion is the result of the supply of the electrons from the $d_{x^2-y^2}$ orbital of chromium to the non-bonding π orbital of the benzyl ligand.[96] The mechanism corresponds to the direct participation of the metal atom but not via the formation of a specific Cr–$C_\alpha$ bond but as a result of the interaction with the π-benzyl ligand as a whole. The angle of inclination of the exocyclic bond towards the metal is 40°.

## 5. Carbonium Ions Stabilised by Olefins and Dienes Bound in Complexes

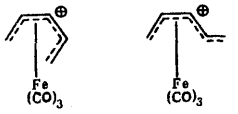


In the chemistry of transition metal π-complexes, it is well known that the generation of a carbonium ion centre next to a coordinated π-olefinic linkage transforms the olefin complex into a cationic π-allyl complex.

The stereochemistry of similar reactions and the influence of the character of the substituents at the exocyclic carbinol carbon atom has been investigated in detail in relation to norbornadiene carbinols.[97–100] Treatment of the carbinol (LIII) with acid results in the formation of the cationic complex (LIV) in which the bicyclic ligand is linked to the metal via π-ethylenic and π-allyl bonds.[98] The structure of this complex, proposed on the basis of $^1H$ and $^{13}C$ $^1H$ NMR data, has been confirmed by X-ray diffraction.[97]

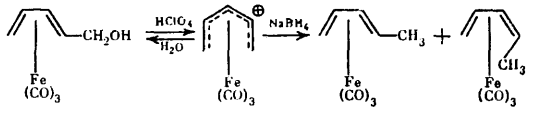
(LIII) (LIV)

It has been shown for the diastereoisomeric 2-(α-hydroxyethyl)norbornadienecyclopentadienylrhodium complexes with the ψ-*exo*- and ψ-*endo*-configurations of the OH group that the elimination of the hydroxy-group is highly stereospecific and leads to the *syn*- and *anti*-allyl cationic complexes respectively.[97–100] The stereospecificity is retained also in the reaction of the phenyl-substituted ψ-*endo*-carbinol, while a mixture of the *syn*- and *anti*-isometric complexes (LVI) and (LVII) is obtained from the ferrocenyl-substituted ψ-*endo*-carbinol (LV) in proportions of 4:1, i.e. the complex having the expected configuration is obtained in a lower yield:



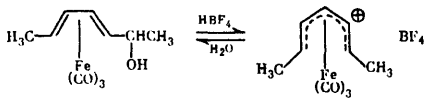
(LV) (LVI) (LVII)

The breakdown of stereospecificity in the reaction involving the elimination of the hydroxy-group from the carbinol (LV) can be accounted for by the competition between the iron and rhodium atoms in the stabilisation of the carbonium ion centre in the transition state of the reaction.[97]



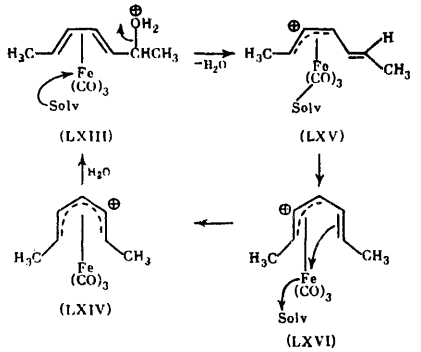
Considerable efforts have been devoted to the elucidation of the structure and mechanism of the stabilisation of the carbonium ions generated from dieneiron tricarbonyl complexes.[101]

The cationic pentadienyl complexes can exist in both the *cis*-form (LVIII) and the *trans*-form (LIX):



(LVIII) (LIX)

Although the formation of complexes of type (LIX) has been postulated in many reactions, for a long time they could not be detected owing to the ease of their rearrangement to the more stable *cis*-isomers (LVIII). Thus treatment of the complex (LX) with perchloric acid yielded the salt of the *cis*-cation (LVIII):[102]

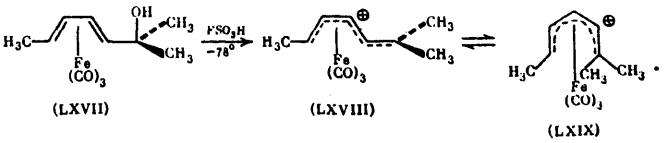


(LX) (LVIII) (LXI) (LXII)

The carbonium ion (LVIII) reacts with water, regenerating the *trans*-pentadienecarbinol (LX).[102] Such stereoselectivity does not always obtain in the reaction of the cation (LVIII) with nucleophiles. Treatment of salts of the carbonium ion (LVIII) with sodium tetrahydroborate yielded a mixture of the isomers (LXI) and (LXII) in proportions of 1:4.[102] The tricarbonyl-*syn*,*syn*-1,5-dimethylpentadienyliron cation (LXIV) has been regenerated from the diastereoisomeric carbinols (LXIII) by treatment with acids. Its hydrolysis is stereospecific and involves the formation of one of the isomeric carbinols:

(LXIII) (LXIV)

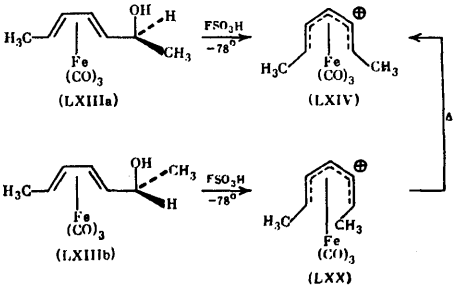
The following mechanism has been postulated to account for the stereochemistry of these reactions:[102]



(LXIII) (LXV) (LXIV) (LXVI)

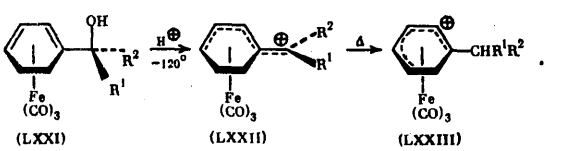
In the first stage both diastereoisomeric carbinols are converted (albeit at different rates) to the hydrated vinylallyl complex (LXV). Rotation about the single bond in compound (LXV) affords compound (LXVI) and subsequent displacement of the solvent molecule and coordination to the vinyl bond leads to compound (LXIV). The *exo*-attack on the cation (LXIV) by the $OH^{\ominus}$ion regenerates one of the carbinols (LXIII).

The study of the solvolysis of the 3,5-dinitrobenzoates of the diastereoisomeric carbinols of the butadieneiron tricarbonyl series showed that the solvolysis proceeds via the $S_N1$ mechanism with retention of configuration.[103] The study of the reaction products by spectroscopic methods indicates the retention of the initial carbon skeleton in the carbinols formed: thus the intermediate species in these reactions are tricarbonyl-*trans*-η-pentadienyliron cations.



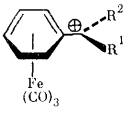
According to the authors,[103] the solvolytic data agree both with the direct nucleophilic involvement of the metal atom and with the hyperconjugation of the metal–carbon bond.

The direct detection of the *trans*-pentadienyl cations by $^1$H NMR was achieved after many attempts[104–107] by employing appropriately substituted dienol complexes.[105,106] After dissolving the carbinol (LXVII) in cooled fluorosulphonic acid, the formation of the *trans*-cation (LXVIII), in equilibrium with its *cis*-isomer (LXIX), was observed:[105]



(LXVII) (LXVIII) (LXIX)

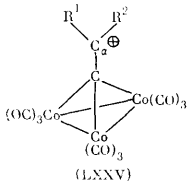
In the same study[105] it was shown that, when the reaction of the diastereoisomeric carbinols (LXIII) is carried out at a low temperature, a stereospecific conversion into the *cis*-ions (LXIV) and (LXX) takes place [in contrast to the data of Mahler and Pettit[102] who isolated only the cation (LXIV) from both carbinols]. The *trans*-cations could not be detected in this case. It was therefore assumed that the structure of the carbonium ions generated is determined not only by steric but also by electronic factors.[105]



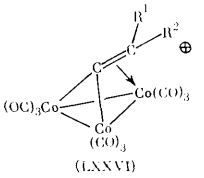
(LXIIIa) (LXIV) (LXIIIb) (LXX)

Cyclic *trans*-cations (LXXII), generated at −120 °C in solution in the $FSO_3H$–$SO_2ClF$ mixture from the carbinols (LXXI), have been detected by $^1$H NMR.[108] On raising the temperature of the solution, the complexes (LXXII) rearrange to the more stable cyclohexadienyl cations (LXXIII):

(LXXI) (LXXII) (LXXIII)



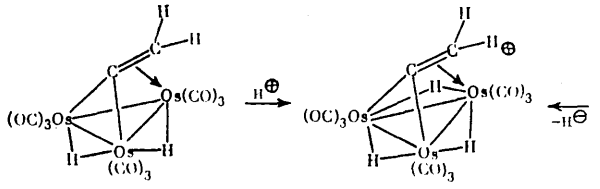
The rate of the rearrangement of the secondary ion (LXXII, $R^1 = H$, $R^2 = CH_3$) is much higher than that of the tertiary ion (LXXII, $R^1 = R^2 = CH_3$). On this basis, it has been suggested that the positive charge is localised on the exocyclic carbon atom. The authors therefore believe that the tetrahapto-structure (LXXIV) makes an important contribution to the overall structure of the complex and the stability of these cationic complexes should be a result of the delocalisation of the charge via a conjugation mechanism.[108]



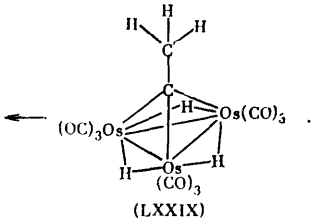
(LXXIV)

## 6. Carbonium Ions Stabilised by the $Co_3(CO)_9C$ and $Os_3H_3(CO)_9C$ Clusters

Seyferth and co-workers[109] investigated thoroughly the cationic complexes stabilised by the nonacarbonyltricobalt-methinyl group. The cationic complexes $[Co_3(CO)_9CCR^1R^2]^{\oplus}$ were isolated in the form of stable salts with the $PF_6^{\ominus}$ anion. The structure of the carbenium ion (LXXV) with the $Co_3C-C_\alpha$ bond directed at right angles to the plane of the $Co_3$ triangle was postulated for them. The high stability of the cationic complex was accounted for by the $\sigma,\pi$ conjugation mechanism.[110–112]



(LXXV)



(LXXVI)

An alternative structure (LXXVI) with an inclined $\mu_3$-$\eta^2$-hydrocarbon ligand has been suggested on the basis of $^1H$ NMR data for the related osmium complex $[Os_3H_3(CO)_{10}\cdot(\mu_3\text{-}\eta^2\text{-}C{=}CH_2)^{\oplus}]$ (LXXVII), generated by protonating the dihydride complex (LXXVIII) or by eliminating a hydride ion from the methyl group of the complex (LXXIX).[113]

(LXXVIII) (LXXVII)

(LXXIX)

The spectrum of the complex (LXXVII) in the $CF_3COOH$–$CDCl_3$ mixture at −10 °C contains two hydride signals with relative intensities in proportions of 2 : 1 at −18.36 and −20.58 p.p.m. When the solution is heated, the hydride signals are broadened and merge into a singlet at 70 °C. It has been suggested[113] that the temperature dependence of the spectrum can be a consequence of either the migration of the hydride ligands relative to the $Os_3$ triangle or of the formation of a carbenium ion at an elevated temperature, as in the case of the complex (LXXV). Yet another explanation of the stereochemical non-rigidity of the complex (LXXVII) in relation to its cobalt analogue has been proposed. It consists of the rearrangement of the $\mu_3$-$\eta^2$-hydrocarbon ligand. This process has been examined theoretically by Schilling and Hoffmann,[114,115] who state that the inclined structure (LXXVI) corresponds to the ground state of the complex $[Co_3(CO)_9CCH_2]^{\oplus}$. The experimental data obtained in a $^{13}C$ NMR study of the complex $[Co_3(CO)_9CCHCH(CH_3)_2]^{\oplus}$ are consistent with this finding. The signals of the methyl carbon atoms are anisochronic at −65 °C, in conformity with the structure (LXXVI), where they are diastereotopic. With increase of temperature, the signals of the methyl carbon atoms in the isopropyl substituent coalesce, possibly as a consequence of the correlated rotation about the $Co_3(CO)_9$–C and C–$CHCH(CH_3)_2$ axes. However, spectroscopic data do not rule out a non-correlated rotation [i.e. the rotation of the $CHCH(CH_3)_2$ fragment without the simultaneous rotation of the $Co_3(CO)_9$ unit] or the formation of the carbenium ion structure (LXXV) at elevated temperatures.

The observation of satellites due to the $^{187}Os-^1H$ spin–spin interaction (natural abundance of the $^{187}Os$ isotope 1.64%, nuclear spin 1/2) in the $^1H$ NMR spectra of the cationic complexes $[Os_3H_3(CO)_9CR^1R^2]^{\oplus}$ established that the temperature variation of the spectrum is due to the migration of the hydrocarbon and not the hydride ligands.[117,118] One hydride signal at $\delta$ = 19.63 p.p.m. has been observed in the $^1H$ NMR spectrum of the complex $[Os_3H_3(CO)_9C\overline{C(CH_2)_2CH_2}]^{\oplus}$ at 30 °C. Two pairs of satellites (with 28.8 and 32.0 Hz splittings) have been noted on either side of the signal. It has been demonstrated by the method of double homonuclear resonance that the $^{187}Os-^1H$ SSIC is 30.4 Hz and the double set of satellites in the spectrum is explained by the further splitting of the satellite signal as a consequence of the spin–spin interaction with the third hydrogen atom which is not linked to the $^{187}Os$ isotope. The $^{187}Os-^1H$ SSIC, amounting to 30.4 Hz, lies in the range 27–35 Hz characteristic of saturated osmium complexes with stereochemically rigid (bridging) hydride ligands.

## IV. CONCLUSION

Examination of the literature data presented above permits the conclusion that the structure of some of the cationic complexes and the role of the transition metal atom in their stabilisation have now been reliably established. This applies in the first place to the α-metallocenylcarbonium ions and also to cationic complexes of the type $[Co_3(CO)_9CCR_2]^{\oplus}$ and $[Os_3H_3(CO)_9CCR_2]^{\oplus}$. Although the available data for other related complexes are not quite so unambiguous, they are in overall agreement with the direct involvement of the metal atoms in the stabilisation of the carbonium ion centre.

One can therefore assume that the *ability (tendency) of the transition metal atom to enter into a direct interaction with the carbonium ion centre generated in the β-position relative to its is a general property of transition metal complexes.* Exceptions are possible in those cases where the need for the direct interaction with the metal atom does not arise because of the presence of heteroatomic substituents at the carbonium ion centre.

The validity of this generalisation can be confirmed by studying cationic complexes whose structure and the mechanism of the stabilisation of which have not yet been established. For example, stable complexes having the compositions $[(RC{\equiv}CCR^1R^2)Co_2(CO)_6][BF_4]$ [119,120] and $[(HC{\equiv}CCR^1.R^2)M_2(CO)_4(C_5H_5)_2][BF_4]$ (M = Mo or W) [121] and obtained from the corresponding complex ethynylcarbinols[121-123] are now known; they are usually regarded as carbenium ions. However, the spectroscopic characteristics and the set of available data for the related cationc complexes suggest that in these complexes too the metal atom interacts directly with the "carbonium ion centre".

In connection with the structure and the stabilisation mechanism mention should be made of the "redox tautomerism" of ferrocenylcarbonium ions.[124,125] It has been suggested[125] that ferrocenylcarbonium ions can readily undergo an intraionic oxidation-reduction reaction in which an electron is transferred from the metal atom to the "carbonium ion centre" $C_\alpha$ with formation of the ferricenium biradical cation. Calculation by the MO method[15] predicted that this type of reaction should be accompanied by a change in the geometry of the fulvene ligand—the latter should be planar in the triplet ferricenium cation.

Experiments with a spin trapping agent seemingly confirmed the hypothesis of the possible redox tautomerism,[125] but subsequently it was noted[126] that the formation of nitroxyradicals following the addition of nitrosobenzene to the ferrocenylcarbonium ion can also proceed via other pathways not involving the biradical redox tautomer.

Nevertheless one can assume that, in the presence of a suitable ligand environment, it is possible to achieve an intraionic oxidation-reduction reaction of the metallocenylcarbonium ion. Studies on these lines are being prosecuted by Rybinskaya and co-workers.[127]

The general assessment of the long controversy concerning the structure and mechanism of the stabilisation of α-ferrocenylcarbonium ions is that it has been extremely useful. Numerous studies of the factors influencing the stability of organic carbonium ions (the involvement of neighbouring groups in solvolytic reactions, the "problem of non-classical ions",[128] the σ- and π-donation of electron density by heteroatomic substituents,[129] the possibility of the donation of π electrons by the electron-accepting substituents CN, CHO, $CF_3$, and $\overset{\oplus}{N}H_3$,[130] and other problems) are being continued. It is therefore evident that the understanding of the mechanism of the delocalisation of the positive charge in the α-ferrocenylcarbonium ions and related cationic complexes extends our overall ideas about carbonium ions—these most important species in organic chemistry.

Furthermore, the elucidation of the way in which the transition metal atom influences the delocalisation of the positive charge (reactivity) of the organic ligand bound to it is now particularly timely, an increasing number of cationic complexes finding applications in the synthesis of organic compounds.[131,132]

In conclusion, we have to consider the names of the cationic complexes $[FcCR^1R^2]^{\oplus}$. The following notation has been adopted for them in the literature: α-ferrocenylcarbenium ion, α-ferrocenylcarbonium ion, and fulvenecyclopentadienyliron cation.

According to $^{57}Fe$ NMR and X-ray diffraction data, the exocyclic $C_\alpha$ atom in these complexes usually interacts with the metal atom. Consequently it is not tervalent and the term "carbenium ion" is not applicable to these systems.

Judging from the $^{19}F$ NMR chemical shifts, the fraction of the positive charge localised on the $C_\alpha$ atom in the complex $[FcCHC_6H_4F\text{-}p]^{\oplus}$ is so small that the term "fulvenecyclopentadienyliron cation" must be recognised as adequately justified, being particularly valid for the complex $[FcCH_2]^{\oplus}$. However, the $^{13}C$ and $^{57}Fe$ NMR studies of the complex enriched in the $^{57}Fe$ isotope have shown that the $Fe{-}C_\alpha$ interaction weakens with increasing capacity of the groups $R^1$ and $R^2$ to delocalise the charge and the fraction of the charge delocalised via the system of carbon–carbon bonds increases. In this case the term "α-ferrocenylcarbonium ion" appears more suitable. Although the latter term cannot be regarded as adequate, it has the advantage that it reflects the genesis of these complexes.

# Dinuclear Metallocenes

D.A.Lemenovskii and V.P.Fedin

Data on the methods of synthesis and chemical reactions of bismetallocene complexes of Group IV-VI transition elements are analysed. Attention is concentrated on the determination of the general characteristics of the structure and reactions of dinuclear metallocenes and also on the analysis of the discrepancies frequently arising in studies of these compounds. The bibliography includes 117 references.

## I. INTRODUCTION

Since the discovery of ferrocene and the synthesis of its closest analogues, the modern stage of the development of the organic chemistry of transition and non-transition elements has begun. The synthesis of new unusual structures has sharply stimulated research into the theory of the chemical bond, studies on the synthesis of a wide variety of skeletal structures, regardless of the elements constituting them, and a vigorous development of virtually all the physical research methods, for which these new compounds have been an extremely rewarding object of study.

Among the entire wide variety of transition metal complexes with organic ligands obtained at the present time, the carbonyl and biscyclopentadienyl compounds continue to retain their leading position. This is caused mainly by the strength of the binding of the ligands in these complexes to the transition metal atoms, which makes it possible to carry out a wide range of reactions of these complexes in most cases without risk of a complete and unpredictable rearrangement of the entire ligand sphere of the metal. The wide variety of the chemical properties and the high stability of the metallocene $(Cp_2M)$† analogues of ferrocene in terms of the Group and Period permitted the hypothesis, put forward in the early stage of these studies, that the sandwich structure (I) with a parallel arrangement of the Cp rings is universally applicable to the complexes of all transition metals.

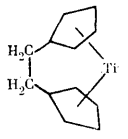
(I) (II)

Numerous attempts have therefore been made to obtain such compounds for all transition metals. However, it was found that the synthesis of mononuclear homoligand metallocenes (I) is not easy for transition elements located at the beginning and end of the long Periods; this is manifested particularly strikingly in the second and third transition series. The phenomenon is caused by the inconsistency, as regards these elements, between the coordinating capacity of the Cp ligand and the coordination requirements of the metal atom and also by the very markedly unfavourable character of the filling of the bonding and antibonding orbitals of the metal–ring bond. This results in a decrease of the overall metal–ring bond order, which facilitates the distortion of the sandwich and its conversion into wedge-shaped derivatives of the type $Cp_2ML_{1-3}$ or into the monocyclopentadienyl complexes $CpML_n$.

This review deals with compounds of the Group IV, V, and VI elements at the beginning of the large Periods. Such differentiation of the objects of study is natural and easily attainable, since the majority of the transition metals in these Groups form compounds having similar structures; in addition, the methods of synthesis (of the complexes) and the reactions undergone by these derivatives are also similar. The very first and most general structural feature which it is appropriate to identify already at this stage is the tendency of these elements to form heteroligand wedge-shaped derivatives $Cp_2M(L)_{1-3}$ (II) in which the additional groups L are located in the bisector plane of the wedge-shaped sandwich.

Among all the nine elements of the above Groups, stable compounds, whose molecules consist of regular sandwiches of type (I), have been isolated only for vanadium and chromium (vanadocene and chromocene).[1,2] The relatively small size of the vanadium and chromium atoms enables the cyclopentadienyl ligands to exhaust to a large extent the coordinating capacity of the metal atoms in the regular sandwich structures, virtually isolating them from the possibility of attack by external reagents. Although the instances of the expansion of the coordination sphere of these elements above the formal hexacoordinate sphere in $Cp_2M$ are feasible and known,[1,2] nevertheless the $Cp_2V$ and $Cp_2Cr$ molecules are kinetically fairly inert in many reaction mixtures, which makes it possible to isolate these complexes as individual crystalline products. As regards the remaining seven elements (Ti, Zr, Hf, Nb, Ta, Mo, and W), the structure of their biscyclopentadienyl complexes proved to be much more complex and the problem has not been yet fully elucidated. None of the early mentions of the synthesis of monomeric metallocenes of these elements were subsequently confirmed. The history of the development of the research into titanocene, the representation of the formula of which by $(C_5H_5)_2Ti$ can be encountered in the early communications by very many investigators together with claims that all operations have been carried out with an individual compound having precisely this structure, is most interesting and instructive.

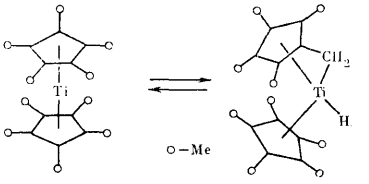
Only in the very recent years has direct experimental confirmation been obtained for the existence of the extremely



†Here and henceforth the symbol Cp has been adopted for the $\eta^5$-cyclopentadienyl ligand.

reactive mononuclear complexes of niobium ($Cp_2Nb$) [3] and molybdenum and tungsten ($Cp_2Mo$ and $Cp_2W$) [4] with structure (I) analogous to that of ferrocene, as well as the titanium compound $(Me_5C_5)_2Ti$. [5,6] However, the experimental details quoted in the above studies[3–6] show that there is virtually no hope of isolating pure crystalline specimens of these complexes, since at room temperature they undergo either rapid dimerisation (the Nb, Mo, and W complexes) or the sandwich structures isomerise (the Ti complex). We may predict with a considerable degree of confidence that in the case of the mononuclear metallocenes of other Group IV–VI elements the situation will be entirely analogous, i.e. that direct experimental confirmation of their existence also will be obtained in the next few years. On the other hand, the set of data available at present allows virtually no doubt as to the formation of mononuclear compounds of type (I) as intermediate species in various chemical reactions of derivatives of these elements.

A series of theoretical studies have been made on the stereochemical and electronic structures of mononuclear metallocenes as a function of the position of the central metal atom in the transition series; the complete list of references can be found in a series of communications.[7–10] Analysis of the variation of the energies of three frontier molecular orbitals (MO) of the sandwich systems as a function of the angle θ characterising the distortion of the metallocene fragments has led to the conclusion that the regular sandwich structure ($\theta = 180°$) and not the wedge-shaped sandwich is preferable for the monomeric homoligand species.



(III)

(IV)

The energies of these frontier MO, which are located in the bisector plane of the wedge-shaped sandwich and are predominantly the *d* orbitals (70–80%) of the metal, increase appreciably with decrease of θ. The energies of the deeper Cp–M bonding MO should also increase appreciably with decrease of θ. Consequently the distortion of the sandwiches requires a definite energy expenditure. The structures of all the known monomeric transition metal metallocenes, including the complexes $Cp_2Mo$, $Cp_2W$, and $Cp_2Nb$ which have been detected only at a low temperature, are consistent with this conclusion.

On the other hand, the mononuclear metallocenes of Group IV–VI elements should remain distinctly carbene-like (carbenoid) complexes, since the frontier MO (in the regular sandwich these are two degenerate $e_2$ orbitals and the $a_1$ orbital having a similar energy) are only partly filled by electrons. The carbenoid character of many metallocene derivatives of these elements has been confirmed chemically by the ease of oxidative addition and ligand addition reactions. In conformity with the Jahn–Teller theorem, a distortion of the regular sandwich structure may be expected only for the elements of the titanium subgroup, but this would not alter the carbenoid character of the molecules, while an increase of the accessibility of the metallic centre, which occurs because the angle θ ceases to be 180°, increases still further the likelihood of the formation of wedge-shaped derivatives having the composition $Cp_2MX_{1-2}$. Experimental data permitting at least approximate inferences about the stereochemical configuration of the mononuclear metallocenes in the titanium subgroup are at present lacking. The greatest hopes are with further studies of decamethyltitanocene,[5,6,11,12] whose existence as a homoligand complex has been demonstrated but only in equilibrium with the isomeric cyclopentadienylfulvenetitanium hydride compound:

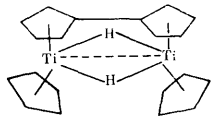
The search for methods of synthesis of titanocenophane (IV) with a fairly short bridge is also promising. The first study[13] on these lines demonstrated that the reactions which proceed readily for unsubstituted titanocene derivatives and which proceed preferentially via the homoligand complex $(C_5H_5)_2Ti^{II}$ cannot be achieved for the complex with a bridging ligand. The first stage of the reaction, namely the reduction of titanium (IV) or titanium (III) to titanium (II) with formation of the complex (IV) as a kinetically independent species, is then unsuccessful.

The carbenoid character and coordination accessibility of the central metal atom to attack by external reagents are the main causes responsible for the vanishingly low stability of the homoligand monomeric metallocenes of type (I) formed by Group IV–VI metals. The complexes $Cp_2V$ and $Cp_2Cr$ (see above), containing metals with the smallest atomic radii, are an exception. However, these complexes too are highly reactive and are readily converted into the wedge-shaped structures $Cp_2ML_n$ and are unstable when acted upon by atmospheric oxygen and moisture. For all the remaining metals of these Groups, the complexes $Cp_2ML_n$ are virtually the only form of the compounds in which the metallocene fragment is present.

The spontaneous formation of dinuclear compounds in reactions where the formation of monomeric metallocenes of type (I) would be expected constitutes perhaps the most striking confirmation of the preferred formation of wedge-shaped structures where metal atoms are bound not only to the $\eta^5$-cyclopentadienyl ligands but also to other groups. The vast majority of bismetallocene structures obtained at the present time for the Group IV–VI elements are formed as a result of the insertion of one carbene-like metallocene fragment in the C–H bonds of the ligands of a second analogous fragment.

The first hypothesis that the metallocenes of Ti, Zr, Hf, Nb, Ta, Mo, and W are associated was put forward a fairly long time ago, almost immediately after the first attempts to synthesise these compounds in the middle 1950's. However, it was not until more than 15 years had elapsed that the first studies demonstrating the structure of the bismetallocene molecules have been published. The fact that studies in this field using unusually sophisticated experimental techniques began has played a decisive role. Low-valence metallocene complexes of the above elements are extremely sensitive to atmospheric oxygen and moisture and sometimes to molecular nitrogen. In view of the high M–O bond energy, the range of organic solvents which can be used in experiments with these compounds is extremely narrow. It is virtually necessary to confine oneself to saturated and aromatic hydrocarbons and solvents of the ether type. The employment of chromatographic methods of purification with carriers such as alumina, silica gel, and similar substances is not permissible.

The composition of the bismetallocenes obtained at the present time, derivatives of Group IV–VI elements, as a rule corresponds to the formula $(C_{10}H_{10}M)_2$ or differs from it by one, two, or more hydrogen atoms. The data concerning



bismetallocenes presented below are arranged in terms of Groups of elements.

## II. BISMETALLOCENE COMPLEXES OF GROUP IV ELEMENTS

### 1. Titanium Compounds

The development of the chemistry of titanocene has been extremely non-uniform and has been distinguished by the publication of a large number of inconsistent results obtained by different investigators. The isolation of the dark-green diamagnetic titanocene $(C_5H_5)_2Ti$ was first reported by Fischer and Wilkinson[14] in 1956. Somewhat later, other investigators[15] who attempted to reproduce this synthesis were unable to isolate the complex of this composition and they therefore raised serious doubts concerning the existence of titanocene. The attempts to synthesise this metallocene were frequently resumed, but the monomeric complex was never obtained. At the present time at least five different bistitanocenes have been described. With serious stipulations, an attempt may be made to regard some of them as identical but the number of undoubtedly different bistitanocenes is even then reduced only to as many as three.

The most thermally stable form of titanocene is the fulvalenetitanium hydride complex $\mu$-($\eta^5$:$\eta^5$-$C_{10}H_8$)-$\mu$-$(H_2)$-($\eta^5$-$C_5H_5)_2Ti_2$:

(V)

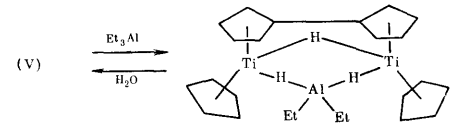
The possibility of the formation of this structure was first suggested in 1970.[16] Analysis of the mass spectra[16,17] and infrared spectra[17,18] has played an important role in demonstrating its existence. The infrared spectrum of the complex is characterised by an intense absorption at 1230 $cm^{-1}$ due to the metal–hydride vibration. Important information has also been obtained from an X-ray diffraction study of certain products of the chemical transformation of the stable bistitanocene. However, a study of the $^{13}C$ NMR spectra in 1974 was of decisive importance.[19]

Thus more than 15 years elapsed between the first publication about the synthesis of titanocene and the elucidation of its structure. Approximately the same period was required to determine the necessary experimental conditions for its successful synthesis. In particular, prolonged heating of the reaction mixture or, better, sublimation of the reaction product at temperatures of ~200–220 °C is essential. When this requirement is met, bistitanocene (V) can be synthesised by reducing titanocene dichloride by various reducing agents and also by the thermal decomposition of titanium hydride complexes.

The bistitanocene (V) has been obtained on reducing $Cp_2TiCl_2$ with sodium in toluene with the system heated to 50 °C; the completion of the reaction requires 4 days.[18] Titanocene dichloride is rapidly reduced by sodium in the presence of catalytic[20] or equimolar[21] amounts of naphthalene. Studies have recently been published[17,22] in which $LiAlH_4$ was used as the reducing agent. The stable bistitanocene is formed when the reaction is carried out above 100 °C in cyclo-olefins or aromatic solvents:

$$Cp_2TiCl_2 \xrightarrow{Na,\ or\ Na\text{-}C_{10}H_8,\ or\ LiAlH_4} (V)$$

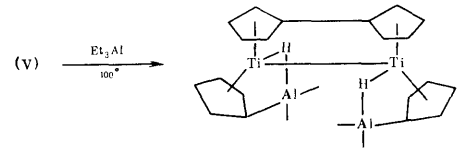
The stable bistitanocene is also obtained on heating the titanocene hydride $(Cp_2TiH)_2$ [28] above 170 °C or on hydrogenating the dimethyl derivative of titanocene in solution:[24]



$$(Cp_2TiH)_2 \rightarrow H_2 + Cp_2Ti_2(H)_2\ (\eta^5\text{:}\ \eta^5\text{-}C_{10}H_8);$$

$$Cp_2Ti(Me)_2 + H_2 \rightarrow Cp_2Ti_2(H)_2\ (\eta^5\text{:}\ \eta^5\text{-}C_{10}H_8).$$

The second reaction apparently proceeds via the intermediate formation of the hydride complex $(Cp_2TiH)_2$, which decomposes under the reaction conditions to form the stable bistitanocene; however, the result depends greatly on the reaction conditions (see below).



The chemical properties of the bistitanocene (V) have been studied in fair detail. The structures of the products of its reactions with HCl, $H_2O$, and $Et_3Al$ have been established by X-ray diffraction. In all these reactions the dinuclear fulvalene structure is retained.

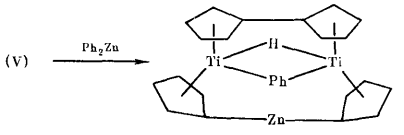
The interaction of the stable bistitanocene with triethylaluminium under mild conditions (25 °C) yielded the fulvalenetitanium hydride complex,[25] whose hydrolysis under mild conditions regenerates the bistitanocene (V):

(A) $R(Ti\text{–}Ti) = 3.374$ Å

When the reaction was carried out under more severe conditions (100 °C), another fulvalene complex was obtained:[25–27]

(B) $R(Ti\text{–}Ti) = 2.910$ Å

The large difference between the Ti–Ti distances in the structures of compounds (A) and (B) obtained, which are derived from the same initial complex (V), is somewhat unexpected. However, the difference is almost wholly a consequence of the fact that the stereochemical requirements of the Ti–H–Al–$C_{Cp}$ and Ti–H–Al–H–Ti bridging groups are different in the two complexes. The presence of the bridging hydride hydrogen atom in the first structure (A) does not imply the absence of direct Ti–Ti bonding. The three AO in the three-atom system M–H–M (one for each atom) form a single strongly bonding three-centre orbital or two antibonding combinations.[28,29]



When the system contains only two electrons, only the bonding orbital is filled. In this case the two metal atoms and hydrogen should be located at the corners of a non-equilateral triangle. The addition of a pair of electrons fills one of the antibonding orbitals, i.e. leads formally to the formation of a four-electron three-centre bond. Either the linear configuration (M–H–M) or dissociation of the system with formation of M–H and M is preferable in such a situation. The presence of the direct M–M overlap in the bridging metal hydride complexes has been frequently emphasised in the literature.[28–31]

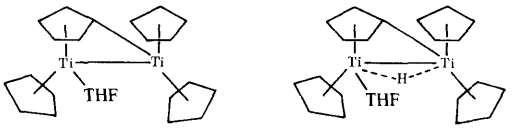
As already stated, the stable bistitanocene reacts with water[14,21,32] and hydrogen chloride.[14,17,18,21] The products of these reactions, namely $Cp_2Ti_2(\mu\text{-}OH)_2(\eta^5\text{:}\eta^5\text{-}C_{10}H_8)$ [32] and $Cp_2Ti_2(\mu\text{-}Cl)_2(\eta^5\text{:}\eta^5\text{-}C_{10}H_8)$,[33] have the structure of dinuclear fulvalene complexes with bridging hydroxy-groups or with bridging chlorine atoms; the structure has been established by X-ray diffraction. It has been noted that,

on interaction of the stable bistitanocene with HCl, the replacement of bridging hydrogen atoms by bridging chlorine atoms takes place consecutively.[17] The reactions of the fulvalene bistitanocene with HCl and $H_2O$, in which the fulvalene structure is retained and only the bridging hydrogen atoms are replaced by the μ-Cl or μ-OH ligands, are as a whole analogous to the thoroughly investigated reactions of the mononuclear complexes $Cp_2TiX_2$ and $Cp_2TiX$ with nucleophiles.[34]

When the bistitanocene (V) reacts with HCl, the mononuclear complex $Cp_2TiCl_2$ is not formed. This conclusion is important: the metastable titanocene dimers, which are frequently obtained together with the stable isomer, give rise to a high yield of $Cp_2TiCl_2$ in their reactions with HCl, in contrast to the stable isomer. The reaction with hydrogen chloride is therefore a qualitative test for the absence of an admixture of metastable titanocenes in the stable bistitanocene.

Together with the reactions of the stable bistitanocenes examined above, in which the structure of the products has been reliably established, studies have been made where the structure of the products of the reactions of compound (V) cannot be regarded as established. The interaction of the bistitanocene (V) with diphenylzinc yielded the unusual compound [μ-($\eta^5$:$\eta^5$-$C_{10}H_8$)-μ-($\eta^5$-$C_5H_4$Zn-$\eta^5$-$C_5H_4$)(μ-H)(μ-Ph)$Ti_2$], whose structure has been proposed on the basis of the study of the products of its decomposition by heating or by treatment with various chemical reagents.[35] There is no doubt that the proposed structure should be very strained.

When the stable bistitanocene reacts with nitrogen (at a nitrogen pressure of 4 atm) in benzene at room temperature, a nitrogen complex having the composition $C_{20}H_{20}Ti_2(N_2)_2$, whose structure has also not been established, is formed slowly (over a period of three weeks).[36] On reduction with sodionaphthalene and subsequent hydrolysis, the nitrogen complex gives rise to ammonia.[36]



Doubts as to whether the complex is really formed from the molecule of the stable bistitanocene have been raised.[37] One must note that in the first communication concerning the fixation of nitrogen under mild conditions it was already noted that the $Cp_2TiCl_2$–reductant system combined with molecular nitrogen.[38] Later such nitrogen-fixing systems were investigated in many studies (see, for example, Refs. 36–41). In these systems nitrogen is fixed rapidly even at low temperatures and atmospheric nitrogen pressure, while the formation of a complex of the stable bistitanocene and nitrogen is very slow (if it occurs at all).[37] The stable isomer of bistitanocene is chemically fairly inert in the reaction with nitrogen and is apparently not the compound responsible for the effective activation of nitrogen in the $Cp_2TiCl_2$–reductant system.

The stable fulvalene bistitanocene, the synthesis and chemical properties of which were examined above, is the least reactive form of titanocenes. Together with the stable bistitanocene, there exist several highly reactive, so-called "metastable" bistitanocenes. The metastable forms of titanocenes exist at temperatures not exceeding 90 °C; on heating to 100–110 °C, the metastable titanocenes are converted into the stable isomer (V). The properties of the metastable titanocenes are similar but not identical. Nor can one rule out the possibility that in the future, after appropriate checks of the data obtained previously, the number of compounds treated as individual will be reduced.

At least four different metastable isomers of bistitanocene are known: (1) the "low-temperature titanocene" $(C_5H_5)_3$.$(\mu\text{-}C_5H_4)Ti_2$; (2) the "active titanocene" $[(C_5H_5)_2Ti]_{1-2}$; (3) the metastable titanocene" $[(C_5H_5)_2Ti]_2$; (4) the "black titanocene" $(C_{10}H_{10}Ti)_n$ or $(C_{10}H_{9-10}Ti)_n$. Rigorous evidence for the structure is available only for the first of these compounds, obtained in 1976 by the low-temperature reduction of $Cp_2TiCl_2$.[42] Henceforth we shall refer to this form of titanocene as "low-temperature titanocene".

$$Cp_2TiCl_2 + C_{10}H_8\cdot K \xrightarrow{-80^\circ} Cp_3Ti_2\,(\eta^5{:}\ \eta^1\text{-}C_5H_4)\,.$$

The complex obtained is stable in an atmosphere of argon at 20 °C for several days but decomposes in solution, the decomposition being particularly rapid in tetrahydrofuran (THF). The structure of the complex with a THF solvate molecule has been established by X-ray diffraction:[42]

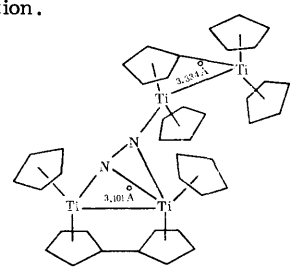
(VIa) $R(Ti\text{-}Ti) = 3.336$ Å (VIb)

In the molecule of compound (VIa) there are two types of titanium atoms—bivalent and tervalent titanium. The $Cp_2Ti^{II}$ species is stabilised by the formation of a Ti–Ti bond and by coordination to the THF molecule. A characteristic feature of this molecule is a high degree of electron unsaturation (a 31-electron complex) and the accessibility of the $Ti^{II}$ atom and the Ti–Ti bond to attack by various reagents. These factors are responsible for the high reactivity of the low-temperature titanocene (VIa) compared with the fulvalene titanocene (V).

The chemical properties of the low-temperature titanocene have been investigated in fair detail. In the majority of reactions the structure of the low-temperature titanocene decomposes with formation of mononuclear biscyclopentadienyltitanium complexes or fulvalene complexes. The THF solvate molecule can be removed by evacuating solutions of the complex in octane. On the basis of infrared spectroscopic data, it is believed that the structure of the complex is then retained. According to Pez,[42] the ease of formation of the non-solvated complex is one of the causes which can explain its high reactivity in relation to compounds such as CO, $N_2$, $H_2$, olefins, etc.

On heating to 110 °C, the low-temperature titanocene is slowly converted into the fulvalene complex (V) in 40% yield:[43]

$$(VI) \xrightarrow[\Delta]{} (V)\,.$$



The reactions of compound (VI) with hydrogen chloride, carbon monoxide, ammonia, and hydrogen take place readily and with high yields:[43,44]

$$(VI) \begin{cases} \xrightarrow{HCl} Cp_2TiCl_2 + Cp_2TiCl\,; \\ \xrightarrow{CO} Cp_2Ti(CO)_2\,; \\ \xrightarrow{NH_3} (Cp_2TiNH)_2H\,; \\ \xrightarrow{H_2} (Cp_2TiH)_n\,. \end{cases}$$

In contrast to the stable bistitanocene (V), the low-temperature titanocene (VI) is active in the hydrogenation and isomerisation reactions of unsaturated compounds. Thus compound (VI) catalyses the conversion of ethylene into ethane and buta-1,3-diene.[45]

The high reactivity of the low-temperature titanocene compared with the stable bistitanocene is manifested particularly strikingly in the reaction with molecular nitrogen.

The low-temperature titanocene (VI) reacts with nitrogen even at −80 °C to form a tetranuclear complex with a bridging $N_2$ molecule;[46] its structure has been established by X-ray diffraction.

It is striking that two different bistitanocene fragments are linked by the nitrogen bridge in this molecule: one resembles the low-temperature dimer, while the other is analogous to the molecule of the stable bistitanocene. In discussing the infrared spectrum of this complex and in comparing it with data for other complexes with molecular nitrogen, the authors[46] put forward the interesting idea that the unusually pronounced decrease of the vibration frequency of the N–N bond in some of these complexes, including the compound considered, where $\nu(^{14}N^{14}N) = 1282\ cm^{-1}$ or $\nu(^{15}N^{15}N) = 1240\ cm^{-1}$, is due to the coordination of a nitrogen molecule in these complexes to three metal atoms simultaneously.

It is essential to note a further two significant facts. Firstly, when the N–N bonding [$R$(N–N) = 1.302 Å] is retained in the dinuclear fulvalene fragment of the molecule, the Ti–N and Ti–Ti bonds are unable to be located in a single plane close to the bisector plane of the wedge-shaped sandwiches, as required by the theory and the stereochemical features of the structure of the wedge-shaped sandwiches. Thus the above molecular fragment must be greatly strained. Secondly, the exceptional ease of the transformation of the structure of the low-temperature titanocene with the bridging $\mu$-($\eta^5:\eta^1$-$C_5H_4$) ligand into a structure of the fulvalene type is significantly non-trivial, particularly in view of the fact, mentioned above, that the $Ti(N_2)Ti$ fragment is strained and also the fact that, in the absence of the $N_2$ molecule, the conversion of the low-temperature titanocene (VI) into the fulvalene isomer (V) requires much more severe conditions (temperature ~100 °C) and proceeds at a much lower rate.

The phenomenon of the preferential transformation of the dinuclear metallocene structures with the bridging $\mu$-($\eta^5:\eta^1$-$C_5H_4$) ligands into dinuclear structures with the $\mu$-($\eta^5:\eta^5$-$C_{10}H_8$) bridging fulvalene ligand has been studied in detail in relation to niobocene systems (see below). Regardless of the mechanism of these reactions, the above structural transformations of the dinuclear complexes are always accompanied by the substitution of the metal hydride atoms by other elements capable of playing a much more effective role as bridging ligands; in the first place these are halogen, sulphur, oxygen, nitrogen, etc. atoms. One of the driving forces of these reactions is undoubtedly the energy gain associated with the formation of the M–E–M bridge bonds (where E = halogen, O, S, N, etc.).

In conclusion of the discussion of the available data concerning the structure and properties of the low-temperature titanocene, we shall consider a few more facts. Although for a number of reasons the proposed structure (VIa) is preferable, it is not possible to reject fully the possible presence in the molecule of yet another bridging atom–the hydride hydrogen atom (the location of the hydrogen atoms was not established in the X-ray diffraction study), i.e. the formation of the structure (VIb).

It was established that the interaction of the low-temperature titanocene with HD yields a mixture of gases ($H_2$ + HD + $D_2$), while the reaction with methyl iodide affords methane.[43] In addition there are discrepancies between various spectroscopic properties of the low-temperature titanocene. The hypothesis of the existence of the bridging hydrogen atom agrees with the finding that the infrared spectra of even very pure specimens of the low-temperature dimer always contain an intense absorption at 1230 $cm^{-1}$. The presence of this band cannot be explained (as suggested by Pez[42]) by the presence of an admixture of stable bistitanocene, since according to other estimates its amount cannot exceed several per cent. It may be that the bridging hydrogen atom is present in the molecule of compound (VI) itself. On the other hand, the paramagnetism of the low-temperature bistitanocene agrees well with the structure without a bridging hydrogen atom. However, the conclusion that the complex is paramagnetic is not based on the study of the EPR spectra or a direct measurement of the magnetic moment and was reached only from the change in the positions of the signals of the cyclopentadienyl rings in the $^1H$ NMR spectra as the temperature was altered.[42]

We shall proceed to the consideration of other metastable bistitanocenes. In contrast to compound (VI), obtained by Pez,[42] attempts to establish their exact structure has not been reported.

Van Tamelen et al.[47] investigated the multistage reduction of $Cp_2TiCl_2$ by sodium in toluene, the process being followed by visible and infrared spectroscopy. It was established that different products, which can be isolated, are formed in succession; one of these the authors regard as the "active titanocene":[47] #

$$Cp_2TiCl_2 + 2Na \xrightarrow{20^\circ} [Cp_2Ti]_{1-2}.$$

The results of elemental analysis are not available for this complex, the criteria of its purity and individuality have not been specified, and reactions, sufficiently refined to help in the elucidation of its structure, have not been found. Nevertheless, it has been demonstrated that the complex $[Cp_2Ti]_{1-2}$ is metastable and is converted into the stable bistitanocene on prolonged stirring in solutions with sodium or on heating to 100 °C. Its properties have been described extremely briefly.[47] Thus it has been reported that the reaction with HCl leads to $Cp_2TiCl_2$, while the reaction with CO yields $Cp_2Ti(CO)_2$. The complex catalyses the hydrogenation of olefins at atmospheric hydrogen pressure and is capable of forming a complex with nitrogen having the tentative composition $Cp_2Ti{-}N{=}N{-}TiCp_2$.

A highly reactive titanocene complex, called "metastable titanocene", was obtained in 1971 as a result of the slow spontaneous decomposition of a suspension of the grey-green polymeric hydride $(Cp_2TiH)_x$ § in toluene.[11,23] The process proceeds with evolution of hydrogen:

$$Cp_2Ti(Me)_2 \xrightarrow[0^\circ]{H_2} (Cp_2TiH)_n \rightarrow (C_5H_5Ti)_2 + H_2.$$

The complex has an intense dark colour with a greenish tint; measurement of its molecular weight showed that it is dimeric and has the tentative composition $C_{20}H_{20}Ti_2$. Measurement

---

#The reduction of $Cp_2TiCl_2$ by sodium amalgam and the Na/K alloy has been mentioned;[48–51] the structures of the products of these reactions have not been established.

§The polymeric hydride $(Cp_2TiH)_x$ is characterised by an intense Ti–H absorption at 1140 $cm^{-1}$, in contrast to the dimeric hydride $(Cp_2TiH)_2$, in the spectrum of which the Ti–H absorption band is at 1450 $cm^{-1}$.[12,23]

of its magnetic susceptibility demonstrated that it is paramagnetic. The complex could not be isolated from solution in the crystalline state and its elemental composition was not therefore analysed; it is not known whether one or several compounds are present in solution. We may note that conclusive evidence concerning the structure and individuality of the polymeric hydride $(Cp_2TiH)_n$ is not available either.

The chemical properties of this bistitanocene have been investigated in fair detail; all the reactions quoted below take place readily and with high yields:[11,23,52]

$$\begin{array}{l} (Cp_2Ti)_2O \xleftarrow{N_2O} \\ (Cp_2TiH)_n \xleftrightarrow{H_2} \\ Cp_2Ti(CO)_2 \xleftarrow{CO} \end{array} \Bigg| \longrightarrow [(C_5H_5)_2Ti]_2 \longrightarrow \begin{array}{l} \xrightleftharpoons{N_2} (Cp_2Ti)_2N_2; \\ \xrightarrow{HCl} Cp_2TiCl_2; \\ \xrightarrow{PPh_3} C_{10}H_{10}TiPPh_3. \end{array}$$

It is striking that the reactions of all the metastable titanocenes described above with HCl and CO proceed in the same way. The so-called "black titanocene", obtained by the photolysis of dimethyltitanocene,[53] i.e.

$$Cp_2Ti(Me)_2 \xrightarrow[\text{solvent}]{h\nu} (C_{10}H_{10}Ti)_n + CH_4^{\cdot},$$

also reacts analogously with the above reagents.

The authors themselves[53] initially suggested that the "black titanocene" which they obtained is analogous to the metastable titanocene synthesised previously.[11,23] However, in contrast to the latter the "black titanocene" is diamagnetic and the $^1H$ NMR spectra of its solutions contain signals due to the Cp protons (albeit broadened). The structure of the complex has not been discussed in detail and there is also uncertainty as regards its composition: $[C_{10}H_{10}Ti]_2$ or $[C_{10}H_{9-10}Ti]_2$. The complex is much less volatile than the stable bistitanocene. It was found unexpectedly that its interaction with molecular nitrogen leads to the formation of a dark-red compound. In a later investigation[54] the same workers reported the isolation of a very similar but not identical compound on photochemical decomposition of $Cp_2TiPh_2$.[54] However, it was suggested almost simultaneously[55] that the "black titanocene" is in essence the polymeric compound $[Cp_2TiH]_n$.

All four metastable titanocenes described above are reactive towards molecular nitrogen. Complexes of different compositions have been described and it has been established that treatment of these complexes with reducing agents and subsequent hydrolysis lead to the evolution of ammonia or hydrazine. These investigations have been analysed in detail in a communication[37] whose authors have been actively engaged in this field recently.¶ Only those data are important to us which make it possible to compare the metastable titanocenes with one another. In particular the "metastable titanocene"[11,23] has properties resembling those of the "low-temperature titanocene".[42] Their reactions with $H_2$, $N_2$, HCl, and CO are also similar; their infrared spectra and the spectra of the products of their reactions with $H_2$ and $N_2$ are likewise similar but not identical. Both compounds form adducts with THF.[12,42,43] One can also assume that the "active titanocene" is identical with the "low-temperature titanocene".[47] The infrared and ultraviolet spectroscopic characteristics of both the initial complex and of its compounds with nitrogen are similar. On the other hand, in terms of a series of other characteristics discussed above, these compounds are not identical or cannot be compared. The greatest uncertainty concerns the "black titanocene".[53] All its reported characteristics differ from those of the other isomers of bistitanocene.

In conclusion, it is appropriate to mention yet again that the metastable bistitanocenes are highly reactive compounds and that in many cases this might have led to methodological errors in the formulation of the experiments and hence to an incorrect interpretation of some of the results.

Titanocenes whose nature is close to that of the metastable complexes discussed above have also been obtained in studies of the thermal decomposition of titanocene derivatives of the type $Cp_2TiR_2$, where R is an organic or organoelemental group. Depending on the substituents, the decomposition of the complexes $Cp_2TiR_2$ is carried out at room temperature (R = $CH_2Ph$,[56] $SnEt_3$, $GeEt_3$, or $SiEt_3$ [57]) or on heating to 70–90 °C (R = Me or Ph [58,59]). It was assumed that initially the thermolysis proceeds in the same way in all cases:

$$Cp_2TiR_2 \rightarrow (C_{10}H_{10}Ti)_n + R^{\cdot},$$

The reactions result in the formation of highly reactive titanocenes sometimes containing THF solvate molecules. The possible structures of the complexes have not been discussed and the formulae of the compounds ($Cp_2Ti$ and $Cp_2Ti$. .THF) were proposed mainly on the basis of the microanalytical determination of their metal content.

The following reactions have been achieved for the titanocenes obtained in this way:[58–62]

$$(C_{10}H_{10}Ti)_n \Bigg| \begin{array}{ll} \xrightarrow{PhCH_2Cl} & Cp_2TiCl_2; \ \text{(Ref.58)} \\ \xrightarrow{HCl} & Cp_2TiCl_2; \ \text{(Ref.59)} \\ \xrightarrow{RCCl_3} & Cp_2TiCl_2; \ \text{(Ref.59)} \\ \xrightarrow{(PhCOO)_2} & Cp_2Ti(OCOPh)_2; \ \text{(Ref.60)} \\ \xrightarrow{H_2C_2Cl_2} & Cp_2TiCl_2; \ \text{(Ref.61)} \\ \xrightarrow{Ph_3CCl} & Cp_2TiCl_2 + CpTi(Cl)CPh_3. \ \text{(Ref.62)} \end{array}$$

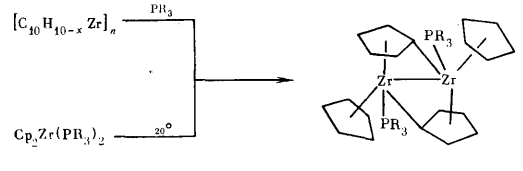
All these reactions with reagents tending to interact via the oxidative addition mechanism proceed readily; they all result in the formation of isotypical mononuclear titanocene derivatives and the yields of the products are frequently high.

Later investigations of the thermal decomposition reactions of the titanocene derivatives $Cp_2TiR_2$ showed, however, that the abstraction of the groups R from the $Cp_2TiR_2$ molecules is followed by a hydride shift from the cyclopentadienyl ring to the titanium atom;[63] thus, the structure of the reaction products is undoubtedly more complex than $Cp_2Ti$ or $Cp_2Ti$. .THF, although it has not yet been established.

The reactions of titanocenes obtained by reducing $Cp_2TiCl_2$ with boron disulphides, diselenides,[64] and halides[65] have also been achieved:

$$(C_{10}H_{10}Ti)_n \Bigg| \begin{array}{ll} \xrightarrow{RS-SR} & Cp_2Ti(SR)_2, \\ \xrightarrow{YBX_2} & Cp_2Ti(Y)BX_2. \end{array}$$

Unfortunately the relevant communications contain no information which would make it possible to determine the type and quality of the titanocenes with which the authors worked; one cannot rule out the possibility that they dealt with a mixture of isomers.

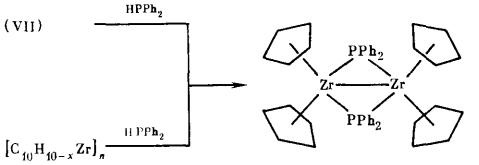


¶ We may point out that the majority of the nitrogen-containing complexes of titanocene and their derivatives, whose structure has been established fairly reliably in one way or another, are dinuclear compounds. However, the dinuclear nature of the structures arises precisely and solely as a result of the 1,2-bidentate nature of the $N_2$ ligand, which entails the formation of the long Ti–N–N–Ti bridge. Examination of this mode of formation of the dinuclear structures is outside the framework of this review, but the synthesis is nevertheless almost always based on mononuclear titanium compounds. Such structures differ little from other bridged structures with long bidentate or polydentate ligands of the type M–L–L–M.

## 2. Compounds of Zirconium and Hafnium

Zirconium and hafnium bismetallocenes have been investigated to a much lesser extent than the corresponding titanium derivatives. The increase of the atomic radius on passing from titanium (1.45 Å) to zirconium and hafnium (~1.60 Å), while the structures of the outer electronic levels are the same ($d^2s^2$ or $d^4$), leads to an increase of coordinating capacity on passing from Ti to Zr and Hf; the ionisation potentials of the atoms diminish in the same sequence. Accordingly, compounds of the type $Cp_2MX_2$ are more stable for the heavy elements. It has also been noted that the dialkyl and diaryl derivatives of zirconocene and hafnocene $Cp_2MR_2$, where R = alkyl or aryl, are thermally more stable than the corresponding titanium compounds.[66]

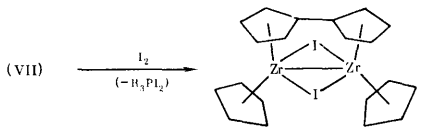
The methods used to synthesise the zirconium and hafnium metallocenes are on the whole analogous to those employed for the synthesis of bistitanocenes. The reduction reactions of the dihalides $Cp_2MCl_2$,[20,25,67,68] the thermal decomposition reactions of the dialkyl compounds $Cp_2M(Alk)_2$ and the alkyl hydride complexes,[53,69,70] as well as the reduction reactions involving the cleavage of the dimethylmetallocenes $Cp_2M(Me)_2$ by triethyltin and triethylgermanium hydrides[71] have been investigated. All the reactions led to similar but not identical compounds. The attempts to obtain crystals suitable for X-ray diffraction studies were unsuccessful. The hypothesis that the zirconocene and hafnocene structures are identical with the structure of the stable bistitanocene has not received serious confirmation.



The majority of the investigations have been carried out with zirconium derivatives. However, the data available at present are insufficient to attribute a specific structure to these compounds with adequate confidence. There are also no reliable grounds for the assumption that these compounds are chemically individual (although it is quite natural that, in the analysis of their reactions, the discussion is conducted from the standpoint of their individuality). The presence of an intense absorption band in the infrared spectra of the zirconocenes isolated in the range 1250–1300 $cm^{-1}$, which disappears after only brief contact of the compounds with air, has been noted. The band occurs in the region characteristic of the Zr–H–Zr bridging fragments.[70,72] Its great width is most probably due to the indeterminate oligomeric character of the structures, which leads to the non-equivalence of the crystal-chemical environments of the hydride atoms. In solution, the zirconium compounds are unstable and give rise slowly to insoluble polymers. It has been found[70,73,74] that the zirconocenes obtained by different methods react with phosphines ($PMe_2Ph$ and $PPh_2Me$) at 50–60 °C to form the dinuclear zirconocene complexes $[Cp_2.(\mu\text{-}C_5H_4)_2Zr(PR_3)_2]$ in 30–50% yields; the processes are accompanied by the evolution of hydrogen. This readily occurring reaction constitutes in fact the main objection to the hypothesis that the zirconocene has a structure analogous to that of the stable bistitanocene (V).

(VII)

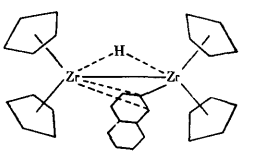
The thermal decomposition of the mononuclear zirconocene-phosphine complexes $Cp_2Zr(PR_3)_2$ leads to the same biszirconocene–bisphosphine product in a high yield.[73,74] The structure of the complex (VII) has been postulated on the basis of the study of its NMR spectra. It is shown below that this complex can be regarded as a kind of structural and electronic analogue of the bisniobocene (XIV).



Treatment of compound (VII) with diphenylphosphine ($Ph_2PH$), which contains a mobile hydrogen atom, results in a very ready cleavage of the Zr–C σ-bonds and the formation of the dinuclear phosphide complex (VIII), whose cyclopentadienyl ligands contain only hydrogen atoms as substituents.[74] However, this reaction is not unambiguous, since the complex $[(C_5H_4)_2Cp_2Zr_2(PHPh_2)_2]_n$ is formed in addition to compound (VIII).

(VIII)

The complex (VIII)† is also formed when oligomeric zirconocenes are treated with $Ph_2PH$.



The only example of a dinuclear fulvalene derivative of zirconocene is compound (IX) obtained by treating compound (VII) with iodine at a temperature below −50 °C. The complex (VIII) is diamagnetic, is weakly associated in solution, and, according to $^1H$ and $^{13}C$ NMR spectra, has a structure analogous to the fulvalene bistitanocene (V):[74]

(IX)

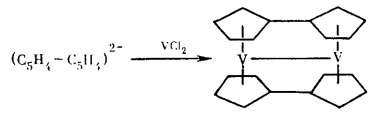
It must be assumed that, as in compound (V), a direct metal–metal bond should be present in the complex (IX).

In conclusion of this Section, we may mention a recently published study[76] in which an attempt was made to synthesize monomeric zirconocene by the low-temperature reduction of $Cp_2ZrCl_2$ with potassionaphthalene in THF at −80 °C. The reaction led to the unexpected dinuclear complex (X) with a bridging β-naphthyl group and hydride hydrogen:

(X) $R(Zr\text{-}Zr) = 3.307$ Å

The presence of hydride hydrogen was demonstrated by $^1H$ NMR and by chemical methods. At room temperature the complex (X) decomposes slowly, giving rise to unknown products. Treatment of the complex with HCl produces $Cp_2ZrCl_2$ and a mixture of hydrogenated naphthalenes ($C_{10}H_{10}$, $C_{10}H_{12}$, and $C_{10}H_8$). Comparison of the properties of compound (X) and the "low-temperature" bistitanocene as hydrogenation catalysts showed that the effectiveness of compound (X) in this reaction is incomparably lower.[76]

As regards the chemistry of the bismetallocene complexes of Group IV elements, one should also note than an increasing number of studies of the reactions of compounds contain-

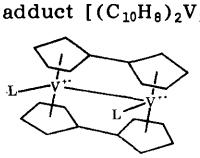


†Such complexes had been obtained earlier from $Cp_2ZrCl_2$ and $LiPR_2$.[75]

ing the $\eta$-$C_5Me_5$ ligands instead of the $\eta$-$C_5H_5$ ligands have been published in recent years. It has been established that the hydrogen atoms of the methyl groups are directly involved in many reactions of these metallocene derivatives, but the compounds formed are as a rule mononuclear and their structures have nothing in common with those discussed above. For this reason, we have in fact not considered these data; most of such studies have been surveyed in another review.[37]

## III. BISMETALLOCENE COMPLEXES OF GROUP V ELEMENTS

Numerous dinuclear metallocene derivatives can be obtained comparatively readily for heavy Group V elements—niobium and tantalum. On the other hand, the formation of bismetallocene complexes, resulting from the combination of mononuclear molecules, has not so far been observed for vanadium. Simple vanadium compounds such as $Cp_2V$,[1,77] $Cp_2VR$,[1,78,79] $Cp_2VX$,[1,80] and $Cp_2VR_2$[1,81] are monomeric both in solution and in the crystalline state and are not converted into dinuclear structures even under severe conditions. One of the most important causes of this is the marked coordination shielding of the small vanadium atom. All reactions whose mechanisms involve a stage in which there is a significant expansion of the coordination sphere of the metal are apparently extremely energetically unfavourable. Reactions which do not incorporate such a stage proceed readily and lead to complexes with coordination numbers typical for vanadium.

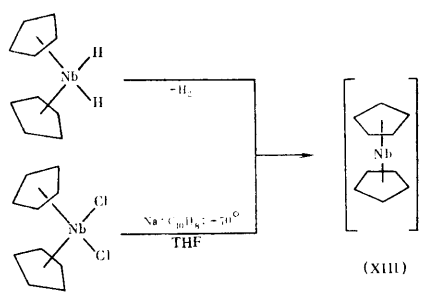


There has been only one study devoted to the synthesis of bismetallocene derivatives of vanadium.[82,83] The key compound in this investigation was difulvalenedivanadium, which has been synthesised in a high yield from the vanadium salt $VCl_2$ and the fulvalene dianion $(C_5H_4-C_5H_4)^{2-}$:

(XI)

As for the monovanadocene complexes, the coordinating capacity of the metal atom in this compound has been to a significant extent exhausted. Accordingly, the chemical properties of the complex (XI) have nothing in common with those observed for compounds of the Ti, Zr, and Hf series.

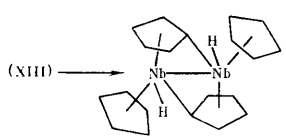
Difulvalenedivanadium (XI) and its dicarbonyl derivative $(C_{10}H_8)_2V_2(CO)_2$ are diamagnetic,[83] and in contrast to the related complexes of monomeric vanadocene. The mono- and di-cationic compounds $[(C_{10}H_8)_2V_2]^{n+}$, where $n = 1$ or 2, and $[(C_{10}H_8)_2V_2L_2]^{n+}$, where $n = 1$ or 2 and L = CO or $NCCH_3$, obtained from them are also either diamagnetic or their magnetic susceptibility is low, which distinguishes them sharply from the related derivatives of mononuclear vanadocene. The dicationic adduct $[(C_{10}H_8)_2V_2(NCCH_3)_2]^{2+}(PF_6^-)_2$,[82] i.e.



(XII) $R(V-V)=3.329$ Å

has been studied by X-ray diffraction. Crystallographic data for compound (XII) as well as analysis[83] of the electronic absorption spectra and the magnetic behaviour of other dinuclear complexes are consistent with the occurrence of a direct bonding interaction between the vanadium atoms.

Analogous difulvalene compounds of the elements in the second and third transition series are unknown for both Group V and Group IV elements examined above.



A different picture has been observed for niobium derivatives (there are very few data on the tantalum compounds[84]). There are numerous elements of similarity in the structure and characteristic features of the reactions of the bismetallocene compounds of Ti, Zr, Hf, Nb, and Ta (and, as will be shown below, also Mo and W). However, the first characteristic which draws attention is the fact that the dinuclear compounds are readily formed when attempts are made to synthesise the mononuclear metallocenes. The observed structural and chemical differences between the isoligand dinuclear complexes of different metals are fairly simply and unambiguously related to the electronic configuration of the atoms of these metals, which have different numbers of intrinsic valence electrons depending on the Group.

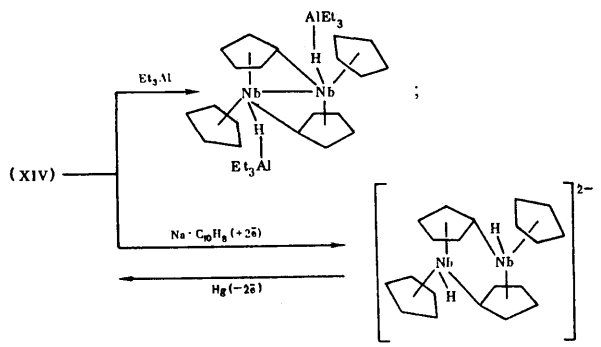
Like the Group IV elements, niobium and tantalum do not form homoligand mononuclear metallocenes of the type $Cp_2M$ which are stable at room temperature. However, at low temperatures a niobium complex having this particular composition can in fact be detected in solution by EPR.[85-87] It may be that this fact manifests objectively the lower reactivity of the mononuclear metallocenes of the Group V metals caused by their lower electron deficiency.

(XIII)

The monomeric niobocene (XIII) is comparatively stable at temperatures below −60 °C; an increase of temperature entails its rapid and easy conversion into the bisniobocene (XIV):[85,86]

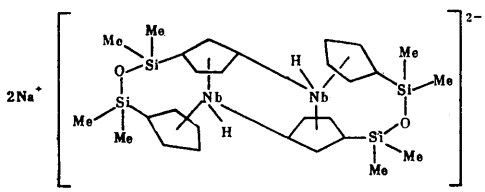
(XIV) $R(Nb-Nb)=3.105$ Å

This reaction is of second order with respect to the monomeric complex and is so far the only known example confirming directly the possibility of the formation of bismetallocenes considered via the dimerisation of the monomeric homoligand metallocenes $(\eta\text{-Cp})_2M$.[86] In essence this is an oxidative addition reaction involving the C–H bonds of another niobocene fragment.# Furthermore the Nb–Nb bond is formed in compound (XIV) despite the fact that the resulting structure is sterically very strained. Overall, the effective atomic number rule holds for the niobium atoms in compound (XIV) and these atoms thus make use of their coordinating and valence capacities in bonding.



#We may note that other oxidative addition reactions are also known for compound (XII), which, however, have no bearing on the subject of this review.[3]

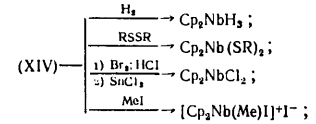
We may note that the bisniobocene (XIV) was the first compound among the dinuclear metallocene complexes of Group IV–VI elements whose structure and dinuclear nature have been established by direct investigation.[88,89] It was in fact after these publications that all the early studies where the formation of coordination- and electron-deficient mononuclear complexes had been unjustifiably postulated for Group IV–VI elements were re-examined and retested.



The structure of the bisniobocene (XIV) has different elements of similarity with the "low-temperature" bistitanocene (VI). However, in contrast to the latter, the bisniobocene (XIV) is thermally entirely stable and does not isomerise to a complex with the fulvalene ligand analogous to compound (V) even after prolonged heating to 200–250 °C. The explanation of this difference in the behaviour of compounds (VI) and (XIV) is that the direct thermal rearrangement to the fulvalene dimer $[(Cp)_2(C_5H_4{-}C_5H_4)Nb_2(H)_2]$ is unfavourable for the bisniobocene (XIV) as a consequence of the overall loss of bonding energy. However, we showed in our later studies (see the appendix at the end of the review) that the indirect two-stage conversion of compound (XIV) into a fulvalene complex of this kind takes place readily; it entails the intermediate synthesis of a dinuclear halogeno-derivative.

The majority of the reactions of the bisniobocene (XIV), like those of the titanium subgroup derivatives, are many-centre processes and involve the entire system of σ-bonds (i.e. the M–M, M–C, and M–H σ-bonds) in the central fragment of this compound. On the whole, this is not surprising, since such molecular fragments are none other than heteronuclear clusters in which the simultaneous rearrangement of a large number of chemical bonds constitutes a common phenomenon. The local transformations involving one atom or one bond are not then ruled out, but the range of reagents capable of effecting such reactions is sharply reduced.

It has been noted for only two reactions of the bisniobocene (XIV) that the nature of the ligand groups does not change. Thus the interaction of compound (XIV) with $Et_3Al$ involves only the Nb–H hydride atoms and converts them into the Nb–H–Al bridge group.[90] On the other hand, treatment of compound (XIV) with strong electron donors leads to the formation of dianionic complexes.[91] In the latter case the reverse reaction also takes place quantitatively.

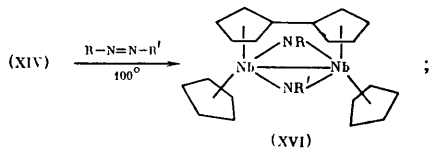


The disodium salt of silylbisniobocene has been investigated by X-ray diffraction.[91]

(XV) $R(Nb{-}Nb) = 3.932$ Å

Compared with the neutral bisniobocene, the corresponding dianionic complexes (XV) are characterised by significantly greater interatomic distances M...M, which can no longer be regarded as metal–metal bonds. As a consequence, there is virtually no steric strain in the structure of the dianions. The additional electrons are thus transferred to the antibonding $\sigma^*_{MM}$ molecular orbital. This conclusion has been confirmed unambiguously by a study of the electronic spectra of the neutral and anionic complexes.[91]

One of the most characteristic many-centre reactions of the bisniobocene (XIV) is its ready decomposition to the mononuclear derivatives $Cp_2NbX_2$. These reactions are rapid and smooth and the yields of the final products are extremely high.[3,84]



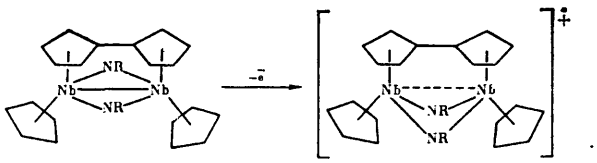
$Cp_2NbH_3$; $Cp_2Nb(SR)_2$; $Cp_2NbCl_2$; $[Cp_2Nb(Me)I]^+I^-$;

R = aryl or ferrocenyl.

It should be specially noted that the products of these reactions contain no substituents in the cyclopentadienyl rings other than hydrogen. We have already encountered a similar fact in relation to the individual reactions of the complexes (VI) and (VII), but, in view of the small number of available observations and the low yields of the final products, great importance could not be attributed to such reactions. The results obtained for bisniobocene show that these reactions occur consistently, but their mechanism is at present unknown. The main feature which must be established is whether individual stages of these processes can be discovered and then carried out as independent reactions (see the appendix below).

Another type of many-centre reactions of bisniobocene comprises those which lead to dinuclear complexes with the fulvalene ligand. As noted above in the discussion of the complexes of titanocenes with molecular nitrogen, such rearrangements are very strongly promoted by the presence in the coordination sphere of the metal of atoms capable of acting as effective bridging ligands; these are usually halogen, oxygen, sulphur, and nitrogen atoms. This approach has been specifically and widely used in the synthesis of fulvalene derivatives of niobium. Thus the interaction of compound (XIV) with aromatic azo-compounds led to fulvalene complexes with two bridging nitrene ligands:[92]

(XVI)

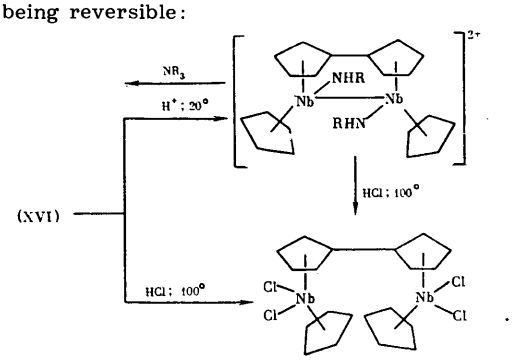


(a) $R = R' = Ph, C_6H_4Me, C_6H_4OMe$;

(b) $R = Ph$, $R' = C_6H_4NMe_2$.

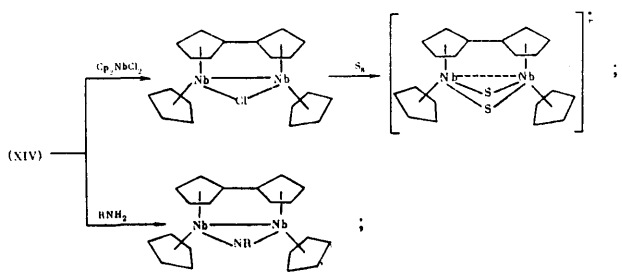
The use of an asymmetric azo-derivative made it possible to obtain a compound with two different nitrene ligands.

The complexes (XVI) proved to be very interesting subjects for spectroscopic, structural, and chemical studies.[93,94] The presence of the direct metal–metal bond and the stereochemical and electronic saturation of the coordination spheres of the metal atoms determine all the characteristic features of their structure and behaviour. Among all the dinuclear metallocene complexes examined in the present review, these are the only compounds which are entirely stable in air even at elevated temperatures (250 °C). They withstand chromatographic purification on $Al_2O_3$ and readily sublime *in vacuo*.



The one-electron oxidation of the fulvalenenitreneniobium complexes (XVI) by ferrocenium salts, mercury and silver salts, and atmospheric oxygen in an acid medium takes place quantitatively.[94] This has led to the synthesis of a whole series of salts of the complex radical-cations (XVII) which are stable in air.

(XVIa) $R(Nb-Nb)=2.834$ Å (XVII) $R(Nb-Nb)=2.921$ Å



Comparison of the structures and the electronic spectra of the complexes (XVI) and (XVII) established that the electron is eliminated from the metal–metal bond.[94]

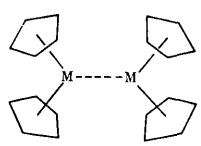
Protonation of compound (XVI) by dilute solutions of strong acids under mild conditions converts them into dicationic complexes with terminal nitrogen-containing ligands, the process being reversible:

Under severe conditions (~100 °C) in the presence of an excess of acid and anions which are powerful nucleophiles the nitrene ligands are split off irreversibly.[93]

Another series of dinuclear fulvalene complexes have been obtained from the bisniobocene (XIV), namely compounds with a single bridging heteroligand. Two types of such compounds have been obtained: diamagnetic with a single bridging nitrene two-electron-donating ligand[95] and paramagnetic with a bridging halogen atom—a three-electron-donating ligand:[96,97]

R = Ph, $C_6H_4Me$, $C_6H_4N_2Ph$.

The chlorine-containing single-bridge complex is converted by elemental sulphur into a disulphide radical-cation complex, which is an analogue of the radical-cation dinitrene compound (XVII).[98]



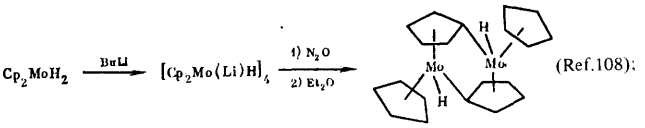
Comparison of the overall data on the bismetallocenes of Group IV and V elements shows that throughout the period of the development of the research into the Group IV elements, most effort has been directed to the determination of the structures of the key compounds. In the case of the Group V compounds the situation is different; the structure of the compounds was established comparatively rapidly and investigations were concentrated mainly on the characteristic features of their chemical reactions.

## IV. BISMETALLOCENE COMPLEXES OF GROUP VI ELEMENTS

The first bismetallocene compounds of Group VI metals were synthesised approximately 10 years ago and the most intense research has been prosecuted during the last five years. As for the Group V compounds, among the derivatives of the Group VI elements dinuclear complexes with a wide variety of structures are formed readily only by the heavy elements—molybdenum and tungsten. On the other hand, as in the case of vanadium,[1] the formation of bismetallocene compounds is altogether uncharacteristic of chromium.[2] The only exception is difulvalenedichromium,[99] which is discussed below after the monofulvalene derivatives; data on the difulvalenedimolybdenum compounds are also presented.[100]

The monomeric homoligand molybdenocene and tungstocene were obtained in 1979 by the low-temperature photolysis of $Cp_2MH_2$ and $Cp_2M(CO)$ and have been detected spectroscopically (on the basis of infrared spectroscopic data) in an argon matrix at 10 K.[4] The claims concerning the formation of derivatives having the composition $C_{10}H_{10}M$ prior to the above study refer, as is now clear, to compounds having a more complex structure; the monomeric compounds $C_{10}H_{10}M$ are indeed formed but only as extremely labile intermediates which cannot be detected by physical methods. It has been found that, on raising the temperature, the monomeric molybdenocene and tungstocene undergo irreversible association to form complexes $(Cp_2M)_x$ of unknown structure—tentatively dimers.[101,102] It may be that these compounds are identical with complexes having the same composition and obtained previously by the reduction of $Cp_2MCl_2$ with sodium amalgam.[103,104] In the mass spectra of the complexes $(Cp_2M)_x$, obtained by reducing metallocene dihalides, the $C_{20}H_{20}M_2^+$ ion is heaviest, while the $^1H$ NMR spectra of solutions of these compounds exhibit only one signal due to the protons of the unsubstituted cyclopentadienyl rings.[104]

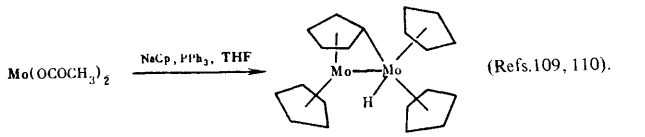
For a long time, the above derivatives were the only bismetallocene complexes whose association was tentatively assumed to occur only as a result of metal–metal bonding. Analogous evidence has now been obtained also for rheniocene (see the appendix below).



(XVIII)

The chemical behaviour of the complexes (XVIII) is characterised by an extremely ready conversion into mononuclear derivatives on interaction with a wide variety of compounds in which they behave as carbene-like species.[103–107] The reaction products are complexes of the type $Cp_2M(L)_n$ ($n$ = 1 when L is a two-electron-donating ligand and $n$ = 2 when L is a one-electron-donating group).

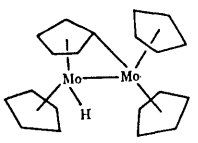
Attention has been drawn to the fact[105,107] that the rearrangement of these associated species to other bismetallocenes, whose structures include bridging $\eta^5:\eta^1$-$C_5H_4$ and $\eta^5:\eta^5$-$C_5H_4$-$C_5H_4$ ligands, does not take place. This is surprising because many compounds with such bridging groups are known for both molybdenum and tungsten and the latter complexes readily undergo interconversions.



The bismetallocenes of molybdenum and tungsten with the $\eta^5:\eta^1$-$C_5H_4$ and $\eta^5:\eta^5$-$C_5H_4$–$C_5H_4$ ligands have now been investigated in fair detail. Their structure and interconversions follow the same rules, as regards their most fundamental aspects, which were manifested in the behaviour of the isoligand complexes of Group IV and V metals.

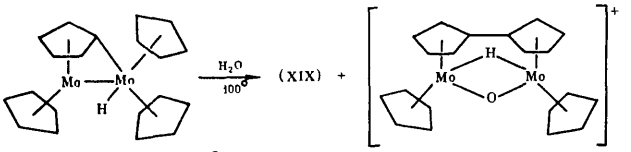
Two reactions, which make it possible to obtain dinuclear compounds with bridging $\eta^5:\eta^1$-$C_5H_4$ ligands, are known for molybdenocene derivatives:

(Ref.108);



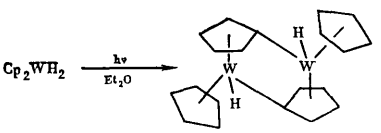
(XIX)

(Refs.109, 110).



(XXa)

The bismolybdenum complex (XIX) resembles the bisniobocene (XIV), while the other compound (XXa) is similar to the "low-temperature" isomer of the bistitanocene (V). Compound (XXa) has also been converted into the complex (XIX) by heating a suspension of compound (XX) in water at 100 °C.[110]

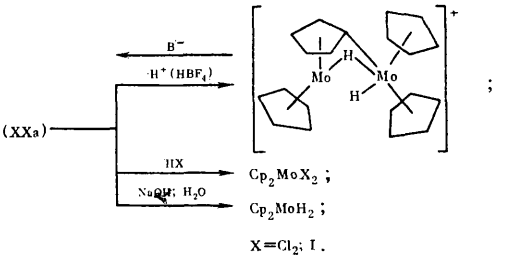


(XXb)

As shown below, the process leads to a mixture of two products. Compound (XXa) is apparently converted into compound (XIX) directly in the crystal phase, while the second compound is formed on interaction of compound (XX) with water. The structures of the complexes were determined from infrared spectroscopic, NMR, and mass spectrometric data and for compound (XXa) an X-ray diffraction study was carried out in addition.[109,110] However, the locations of the hydrogen atoms could not be determined in the course of the structural study. The association of the hydride hydrogen with the molybdenum atom can therefore be regarded merely as being most probable on the basis of a set of spectroscopic and stereochemical considerations but has been by no means finally demonstrated. The structure (XXb) is possible as an alternative.

(XXa) $R$(Mo–Mo)=3.189 Å

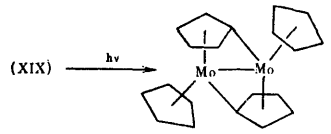
The bistungstocene (XXI) has been obtained by the photolysis of tungstocene dihydride in ether and also by its thermolysis in cyclohexane.[111,112] The structure of the product has been demonstrated by X-ray diffraction:[101]



(XXI) $R$(W–W)=3.81 Å

Its photolysis or thermolysis in the presence of tetramethylsilane led to the synthesis of the related *cis*- and *trans*-isomeric products $(C_5H_5)(Me_3SiCH_2)W(\mu\text{-}\eta^5:\eta^1\text{-}C_5H_4)_2W(H).(C_5H_5)$.[101,111] The methyl analogue $(C_5H_5)MeW(\mu\text{-}\eta^5:\eta^1\text{-}C_5H_4)_2W(C_2H_5)(H)$ has also been obtained by the thermolysis of $Cp_2WH(Me)$.[112]

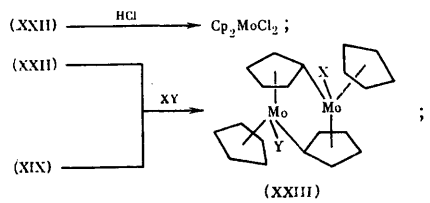
In discussing the mechanisms of these reactions, it has been suggested[111,112] that they all include a stage involving the formation of the free metallocenes $(\eta^5\text{-}C_5H_5)_2M$, because otherwise the complexes (XIX), (XX), and (XXI) should have been readily obtained from the monomeric molybdenocene and tungstocene, whose existence has been demonstrated. It has been postulated[101,108–112] that the dimers (XIX)–(XXI) listed above arise not from the free mononuclear metallocenes but from their highly reactive adducts (having a wedge-shaped structure) with molecular nitrogen [in the synthesis of compound (XIX)], with triphenylphosphine [in the formation of compound (XXI)], or, finally, with solvent molecules [in the formation of compound (XXI)]. However, there is no reliable experimental confirmation of these hypotheses.



Further chemical reactions of the dinuclear compounds with bridging $\eta^5$-$C_5H_4$ ligands resemble the familiar reactions of the corresponding bistitanocene and bisniobocene complexes. The differences observed in these reactions are due to the increase of the number of intrinsic electrons in each metal atom in the series of derivatives of Group IV, V, and VI elements or, in other words, to the decrease of the electron deficiency of the metallic centre. In the molybdenum and tungsten compounds this is responsible for the resulting decrease of the maximum number of possible chemical bonds. Such a decrease entails a smaller steric strain in virtually all the dinuclear derivatives of molybdenum and tungsten compared with the analogous isoligand complexes of Group IV and V metals. A second characteristic feature, an overall appreciable decrease of the reactivity of the bismetallocene compounds on passing to derivatives of Group VI elements and also a significant decrease of the proportion of many-centre reactions of such compounds, is directly related to the first feature described above. Thus molybdenum and tungsten complexes are as a rule fairly resistant to reaction with water and acids (even at elevated temperatures), while the decomposition of the titanium, zirconium, hafnium, niobium, and tantalum compounds proceeds very readily and is frequently accompanied by the loss of cyclopentadienyl ligands. Reactions involving individual bonds, in the first place M–M and M–H bonds, can be achieved much more readily having molybdenum and tungsten complexes.

The complex (XXa) is readily and reversibly protonated. On the other hand, when acids whose anions are powerful nucleophiles are used for the protonation, the dinuclear structure is completely cleaved:[109,110]

Treatment of compound (XXa) with aqueous alkali unexpectedly led to the formation of the mononuclear molybdenocene dihydride.[110] In relation to the metal atoms, this is in essence a disproportionation reaction, although the nature of the metal-containing products has not been established.



The structures of the complexes (XIX) and (XXI) are analogous to that of the dianionic bisniobocene derivative (XV). This is not surprising, since all these compounds contain identical ligand groups and are isoelectronic. On the other hand, the oxidised dicationic derivatives of the bismolybdenocene (XIX) and the bistungstocene (XXI) should apparently be isoelectronic and apparently isostructural with the neutral bisniobocenes (XIV). However, the oxidation reactions of molybdenocene and tungstocene have not been investigated. At the same time, the photochemical dehydrogenation of compound (XIX) has been achieved.[102,110,113]

(XXII) $R(Mo-Mo)=2.886$ Å

The structure of compound (XXII) isolated in this reaction, which the authors called "dehydromolybdenocene", has been established by X-ray diffraction. This structure does indeed resemble that of the bisniobocene (XIV) and differs from it by the absence of two hydride hydrogen atoms, whose place in the molecule of compound (XXII) is taken by three electron pairs. The same compound has been obtained also from other isomeric bismolybdenocenes by their photochemical dehydrogenation.[111,113] It was found that all the reactions leading to compound (XXII) are extremely sensitive to a series of factors and their successful occurrence is strongly influenced by the temperature, the nature of the solvent, and the presence of specific nucleophilic additives (organic phosphines, etc.).

Two types of reactions have been carried out for the dehydromolybdenocene (XXII)—the complete cleavage of the dinuclear structure and oxidative degradation of the Mo–Mo σ-bond.[112-113] The latter reaction leads to the dinuclear complexes (XXIII), which are analogues of bismolybdenocene (XIX). It has been shown that the same compounds (XXIII) can be obtained directly from the molybdenocene (XIX) by treatment with the appropriate reagents under mild conditions:[108]

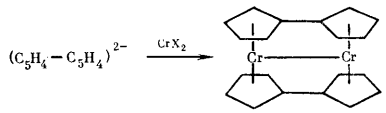
(XXIII)

XY=MeBr; MeI; $I_2$.

The complex (XXIII), in which the neopentyl substituents $CH_2CMe_3$ are σ-bound by the Mo–X and Mo–Y groups, was unexpectedly obtained by the reaction of $Cp_2MoCl_2$ with $LiCH_2CMe_3$.[114]

We shall now consider data on the dinuclear fulvalene complexes. As happens for the derivatives of Group IV and V metals, the bismolybdenocenes (XIX) and (XX) with the bridging $\eta^5:\eta^1$-$C_5H_4$ ligands enter comparatively readily into thermal reactions, rearranging under these conditions into bimetallic fulvalene derivatives. The simultaneous replacement of hydride hydrogen atoms by other more electronegative atoms accelerates these reactions significantly, enabling many of them to take place rapidly even at room temperature.

It has been noted that two types of bismolybdenocene complexes are formed.[101,106,108,110-112,115,116] Compounds of the first type [(X)(Y)CpMo($\eta^5$-$C_5H_4$-$\eta^5$-$C_5H_4$)MoCp(Y)(X)] (XXIV) are usually produced. The corresponding monometallocene analogues $Cp_2Mo$ (X)(Y) are known and have been thoroughly investigated for all the complexes (XXIV) synthesised. The chemical and physical properties of the mononuclear and dinuclear complexes are extremely similar owing to the absence of the mutual influence of the two metallic centres in compound (XXIV). In view of the foregoing, there is no point in considering in detail the reactions of compound (XXV). Another situation arises as regards the fulvalene bismolybdenocene complexes of the second type—compounds (XXV). These complexes have no direct analogues among the mononuclear derivatives. A distinctive structural characteristic of the molecule of compound (XXV) is the presence of the direct metal–metal bond, as a consequence of which the number of σ-bound groups is reduced by two in these compounds compared with compound (XXIV). The schematic formula (X)CpMo($\eta^5$-$C_5H_4$-$\eta^5$-$C_5H_4$)MoCp(X) corresponds to compounds (XXV); the groups X always occupy the terminal positions and cannot pass to the bridging positions owing to the electronic and coordination saturation of the metallic centres.



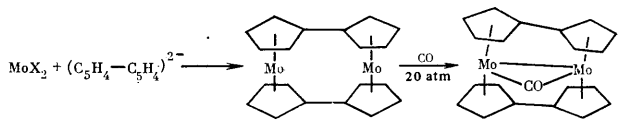
Certain reactions involving the Mo–Mo σ-bonds in the complexes (XXV) have been investigated and it has been shown that these reactions do not differ essentially from those which occur normally for different dinuclear complexes of other transition metals of the type $L_nM-ML_n$ without bridging groups. All the reactions in which compounds (XIX) and (XX) are converted into the fulvalene derivatives (XXIV) (XXV) and the principal reactions of the latter are indicated in the Scheme below.

The photochemical reactions of the fulvalenebismolybdenocenes, which permit the reverse conversion of the fulvalene complexes into compounds with bridging $\eta^5:\eta^1$-$C_5H_4$ ligands, are much more important and interesting. Such reactions have not been investigated at all for other dinuclear metallocene compounds.

It has been established that the photolysis of the fulvalene derivative (XXV) takes place rapidly in toluene in the presence of small amounts of added tri-n-propylphosphine, which results in a mixture of the *cis*- and *trans*-isomeric complexes (XIX).[113] It has also been observed that, in the presence of free phosphine, compounds (XXV) and (XIX) are virtually unable to be converted into the "dehydromolybdenocene" (XXII). At the same time the complex (XXII) is readily formed from both compound (XXV) and compound (XIX) by their photolysis in the absence of phosphine in the reaction mixture.[112] The mechanisms of these reactions are at present obscure. It has been suggested that intermediates containing both hydride hydrogen atoms at one metal atom, i.e. incorporating the $MoH_2$ fragment, lead to the "dehydromolybdenocene" (XXII). On the other hand, the role of phosphine in this process reduces to the fact that, by occupying coordination sites at the Mo atoms (and possibly also by converting some of the $\eta^5$-Cp ligands into $\eta^3$-bound ligands), it prevents the transfer of hydride atoms and the formation of intermediates with $MoH_2$ fragments.[112,113]

In conclusion we shall consider the very small amount of data on compounds containing two fulvalene ligands. As for vanadium (see above), the presence of two rigid polydentate ligands sharply restricts the capacity of such compounds for chemical reactions. The only bismetallocene complex of chromium, namely difulvalenedichromium, has been obtained by direct synthesis from the fulvalene ligand and a chromium

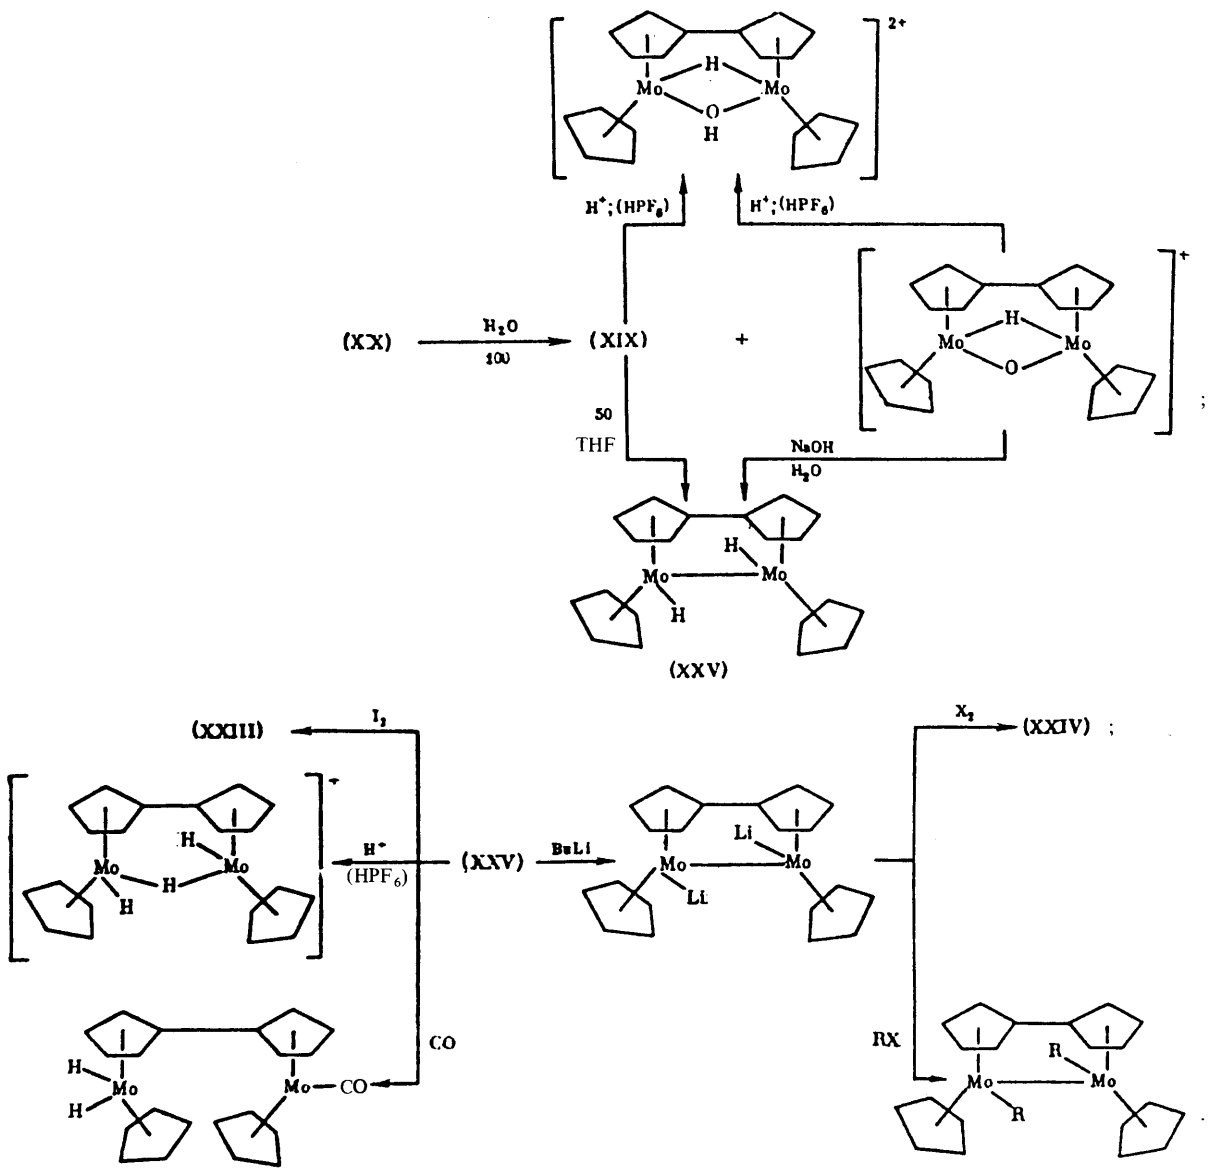
salt:[99]



(XXVI)

Only one reaction of the complex (XXVI) has been achieved, namely oxidation leading to the formation of the corresponding monocation and dication.

The magnetic and spectroscopic characteristics of compound (XXVI) agree with the hypothesis of the direct overlap of the AO of the metal atoms, which results in the complete pairing of the electron spins in the ground state (even at temperatures below −50 °C). On the other hand, with increase of temperature, the excited paramagnetic states of the molecule are populated.[99]



An analogous difulvalene complex has been synthesised for molybdenum [compound (XXVII)]; this is so far the only difulvalene derivative obtained for metals of the second transition series:[100]

(XXVII) (XXVIII)

The ready addition of carbon monoxide to compound (XXVII), which results in the formation of compound (XXVIII), can be easily explained by taking into account the coordination capacity of molybdenum and the entire data presented above. The question of metal–metal interaction in compounds (XXVII) and (XXVIII) has not been analysed in detail, but one cannot rule out the possibility that a multiple

Scheme

metal–metal bond exists in the molecule of compound (XXVII), since in the related complex tetraallyldimolybdenum a quadruple metal–metal bond is believed to be produced.[117]

---o0o---

During the preparation of the manuscript for the press, one of the authors of this review obtained new data on the structure and reactions of the bisniobocene and bistitanocene complexes.[118–121] It was established that the replacement of one of the terminal hydride atoms in the bisniobocene (XIV) under mild conditions by a halogen atom entails the formation of thermally extremely unstable derivatives having apparently the structure $Cp(H)Nb(\mu\text{-}C_5H_4)_2NbCp(Hal)$. These intermediates rapidly rearrange to the thermally stable fulvalene hydride halide complexes $\mu\text{-}(\eta^5:\eta^5\text{-}C_{10}H_8)Cp_2Nb_2(\mu\text{-}H)(\mu\text{-}Hal)$ (XXIX), such rearrangements being both thermodynamically and kinetically allowed.[118,119] The bridging halogen atom in compound (XXIX) can be readily substituted by nucleophiles. The alkoxide hydride complexes $\mu\text{-}(\eta^5:\eta^5\text{-}C_{10}H_8)Cp_2Nb_2.(\mu\text{-}H)(\mu\text{-}OR)$ (XXX), where R = Me or Et, and the dihydride complex $\mu\text{-}(\eta^5:\eta^5\text{-}C_{10}H_8)Cp_2Nb_2(\mu\text{-}H)_2$ (XXXI) have been obtained in this way. The latter is an isomer of the bisniobocene (XIV). One cannot rule out the possibility that the majority of the syntheses of the stable isomer bistitanocene (V) described in the literature also proceed via the hydride halide fulvalene complex $\mu\text{-}(\eta^5:\eta^5\text{-}C_{10}H_8)Cp_2Ti_2(\mu\text{-}H)(\mu\text{-}Hal)$ (XXXII), by-passing the stage involving the formation of the metastable bistitanocenes. This conclusion agrees with the finding that the metastable bistitanocenes are converted into compound (V) usually under more severe conditions and that the yields of compound (V) are far from quantitative.

Compounds (XXX, R = Et) and (XXXII) have been studied by X-ray diffraction. Despite the different electronic configurations of the metal atoms, the structures of the two complexes are almost identical; the metal–metal distances are respectively $R$(Nb–Nb) = 3.136 Å and $R$(Ti–Ti) = 3.126 Å.[120]

The temperature variation of the $^1$H NMR spectra of compounds (V) and (XXXI) have been investigated.[121] The complex (XXXI) is diamagnetic, while the complex (V) is also diamagnetic at a low temperature (–60 °C) but at higher temperatures its excited triplet state is appreciably populated, which is manifested by the corresponding shift of the signals and broadening of the lines.

Mention should also be made of the study[122] of the rheniocene dimers. $(Cp_2Re)_2$ was obtained by oxidising $Cp_2ReLi$ with benzaldehyde. This complex gives rise to a single signal in the $^1$H NMR spectrum and is apparently associated only via a direct metal–metal bond. A disproportionation reaction is induced when it is heated in acetonitrile, which entails the formation of a mixture of $Cp_2ReH$ and $\mu\text{-}(\eta^5:\eta^1\text{-}C_5H_4)_2Cp_2Re_2$. The photolysis of $(Cp_2Re)_2$ leads to the formation of $\mu\text{-}(\eta^5:\eta^1\text{-}C_5H_4)CpRe(\eta^4\text{-}C_5H_6)ReCp$.

In conclusion of the review, we may say that the studies of recent years have led to the discovery of a large new field of bismetallocene complexes of the elements at the beginning of the transition series, the complexes having specific structures. Interesting many-centre rearrangements and certain unusual reactions have been observed for these complexes. The very fact of the formation of bismetallocenes demonstrates that the labile intermediates arising in the course of the reactions activate the C–H bonds of the organic ligands very effectively. On the other hand, the determination of the characteristic features of the electronic structures of the bismetallocenes already makes it possible not only to explain the experimental results but also to plan specific syntheses of quite definite new compounds.

However, it is evident that the point on which research is concentrated is beginning to shift. In the next few years there will probably be an appreciable expansion of research into the chemical properties of bismetallocenes and among them compounds of interest for practical applications will be found. The synthesis of mixed metallic complexes, whose chemistry is richer still, is also in the pipeline.

# Sterols as Complex-forming Species

D.V.Ioffe

The formation of complexes of sterols with different compounds determines the biological properties of both sterols and various natural substances such as saponins and polyene antibiotics. Complex formation by sterols with phospholipids, steroid saponins, and polyene antibiotics is determined by the same characteristic features of the structure of the sterol molecule. The principal role in complex formation is played by the hydrophobic reaction of the cyclopentanoperhydrophenanthrene ring. The formation of a hydrogen bond between the hydroxyl group of the sterol and a proton acceptor, which is assumed in most complexes, has been proved only in the complexes of sterols with water and acids.
The bibliography contains 122 references.

## I. INTRODUCTION

The ability of sterols in general and cholesterol in particular to form complexes† with steroid saponins was detected much earlier than the determination of the structural formula of cholesterol.[2] Since then, a large number of studies have shown that sterols form complexes with a number of organic compounds: alcohols, phenols, acids and their derivatives, amines, carbohydrates, various heterocyclic compounds, and recently proteins, and also with inorganic acids and salts. Complex formation with saponins has found extensive practical application in the preparative and analytical chemistry of sterols,[3,4] and complex formation with salts and alcohols is used to separate and purify sterols.[5,6] The formation of complexes of sterols with saponins forms the basis of the use of the latter as hypocholesterolemic agents,[7,8] and in recent years it has been used to develop sorbents which selectively extract the cholesterol of blood plasma.[9-11] However, it is not so much these applied aspects that are attracting interest in the complexes of sterols as the fact that complex formation determines a large part of the biological functions of sterols. Thus it was established at an early date that the biological action of polyene antibiotics is determined by the fact that they form complexes with membrane sterols. The same or a similar reaction explains the action of various toxins, for example tetrodotoxin and saxitoxin,[12] and also the membranotropic action of triterpene glycosides.[13] The incorporation of sterols into biological membranes takes place as a result of the formation of complexes with other components of the membranes, primarily phospholipids. Finally, in recent years there has been considerable interest in the reaction of sterols with proteins in lipoproteins, lipid–protein complexes which brind about the transport of lipids in living organisms.

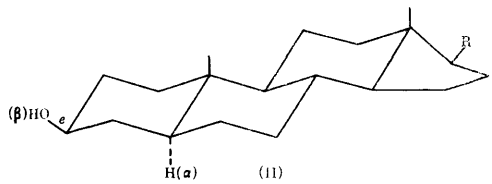
The aim of the present work was to systematise individual scattered data on complex formation by sterols with various compounds, and to try to determine which intermolecular interactions are responsible for the high complex-forming power of sterols and which structural functions of their molecules are involved in these interactions. It should be stated at once that there are few published data on the quantitative study of sterol complexes. The published papers generally give no information on the stability constants of the complexes, their energies of formation, etc. Thus the present review is also based chiefly on qualitative relationships between the structure of sterols and their ability to form complexes.

## II. COMPLEXES WITH STEROID SAPONINS

In 1909, Windaus[2] found that cholesterol forms a sparingly soluble complex with digitonin, a steroid saponin (Ia). Complexes of this kind, which are called digitonides and which contain equimolar quantities of digitonin and a sterol, have been obtained for a whole series of sterols, and the solubility of the digitonides of different sterols depends on the nature of the latter These differences in the stability of the complexes have been widely used to separate sterols with similar structures, particularly epimers.

a) R = Xyl—Glc—Gal—
Gal—Glc

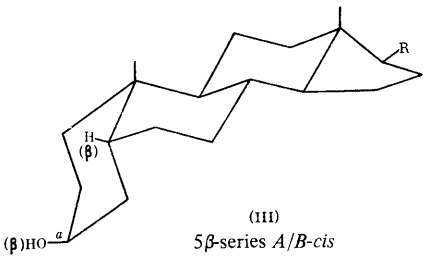
b) R = Xyl—Glc—Gal—
Gal



c) R = Glc—Gal—

Xyl = xylose, Glc = glucose, Gal = galactose

In the course of these studies, data were accumulated, relating the structure of a sterol to its ability to form a complex with digitonin. It should be emphasised, however,



†According to Ref.1, the term "complex" signifies a molecular unit formed by the association of two compounds without change in the nature of the bonds within each part.

that the classification into sterols precipitated by digitonin and sterols not precipitated, frequently encountered in the literature, is extremely relative. The formation of a complex with digitonin is not determined entirely by the structure of the sterol; the dissociation of the complex is determined to a large extent by the reaction conditions, and in particular by the solvent and temperature. Thus digitonides have the minimum solubility in ethanol, in which they are prepared, but dissociate completely in such solvents as pyridine, dimethylformamide, and dimethyl sulphoxide.[14] The complexes dissociate when studied by chromatography on silica gel[15] and with increase in temperature; when cholesterol digitonide is heated in a vacuum to 240°, the cholesterol distils off practically completely.[16] Thus generalisations relating the stability of digitonides to the structure of sterols must be based on experiments carried out under rigorously comparable conditions, and there have been few such studies; the aim of most published work has been the preparative separation of isomers. Only a few authors[17–19] have determined quantitative characteristics of the stability of the digitonides of different sterols, namely the solubility product $S$. It is suggested that the lower the solubility and the value of $S$, the greater the ability of the sterol to form a complex. The data in Table 1 show that the lowest solubilities correspond to the digitonides of 3β-hydroxyl derivatives of the 5α-gonane series (II), that is compounds with *trans*-connection of the *A* and *B* rings, and also the corresponding $\Delta^5$-derivatives. All these compounds have a more planar molecule, compared with the 5β-conformers (III) and the 3β-configuration of the hydroxyl group:

(II)

5α-series *A/B-trans*

(III)

5β-series *A/B-cis*

| | |
|---|---|
| R=H | androstane |
| R=$C_nH_5$ | pregnane |
| R=CH $(CH_3)$ $(CH_2)_2CH_3$ | cholane |
| R=CH $(CH_3)$ $(CH_2)_3CH$ $(CH_3)_2$ | cholestane |

*a*—OH-group in the axial position, *e*—OH-group in the equatorial position.

The 3β-hydroxyl group plays a decisive role in the formation of the complexes; its acylation leads to a sharp increase in the dissociation of the complex, and this forms the basis of one method for separating sterols from digitonides. Not only acylation, elimination (separation or reduction), or oxidation at the keto-group, however, but even epimerisation of the 3β-hydroxyl group has a marked influence on the stability of the complexes. All 3α-hydroxy-derivatives of the 5α-series form complexes with S > 1100 × $10^{-8}$ mole$^2$ litre$^{-2}$, that is they are much more soluble than the 3β-derivatives.

**Table 1.** Influence of the structure of the sterol on the solubility of the digitonide.[17–19]

| Compound | Configuration of the 3-OH-group | | $10^8$ *S*, mole$^2$litre$^{-2}$ |
|---|---|---|---|
| 5α-Cholestan-3β-ol | β | *e* | 4 |
| 5α-Cholestan-3α-ol (epicholestanol) | α | *a* | 2200 (900) |
| 3β-Acetoxy-5α-cholestane | β | *e* | 1100 |
| Cholest-5-en-3β-ol (cholesterol) | β | *e* | 4 |
| 3β-Acetoxycholest-5-ene | β | *e* | >1100 |
| 5β-Cholestan-3β-ol (coprostanol) | β | *a* | 70 |
| 5β-Cholestan-3α-ol (epicoprostanol) | α | *e* | 2200 |
| Stigmasta-7,22-dien-3β-ol (stigmasterol) | β | *e* | 4 |
| 5α-Ergost-7,22-dien-3β-ol (ergosterol) | β | *e* | 4 |

| 5β, 22-Spirostan-3β-ol (sarsapogenin) | β | *a* | 280 (970) |
| Cholest-4-en-3-one | | | >2200 |

The difference in the reactivities of epimers of sterols with different conformations of the 3-hydroxyl group is well known. Equatorial hydroxyl groups are less shielded than axial groups, so that they undergo certain reactions more readily. For example, they are more readily acylated, and the corresponding esters are more readily hydrolysed. Epimers with an equatorial hydroxyl group are more strongly sorbed on various carriers, indicating that they form more stable complexes,[20,21] possibly by hydrogen bonding.[22] It is logical to assume that the differences in the ability of epimeric sterols to form digitonides is also related to the equatorial or axial arrangement of the 3-hydroxyl groups. It has been suggested, however, that in complex formation with digitonin, the decisive role is played not by the equatorial or axial arrangement of the 3-hydroxyl groups but by their α- or β-arrangement relative to the cyclic system.[3,23] This generalisation appears unjustified. It can be seen from Table 1 that among epimeric compounds, the lower solubility is shown by the equatorial 3-isomer, irrespective of the position, α or β, occupied by the 3-hydroxyl group in the axial epimer#. An exception is provided by coprostanol and epicoprostanol, for which the opposite relationship is observed. It was on the basis of this pair of compounds that the suggestion that the α- or β-arrangement of the hydroxyl group plays a decisive role in the formation of digitonides was first put forward, and it was subsequently repeated in the literature, in spite of the large number of exceptions. It should be emphasised that for most of these exceptions, that is when the compound with the 3β-hydroxyl group does not form a digitonide, the hydroxyl group occupies the axial position (lumisterol, the methyl esters of 3β,5β,14β-trihydroxyandrostan-17β-carboxylic acid and its 17α-epimer, methyl 3β-hydroxy-11α-acetoxy-

#In the 5α-gonane series, the 3β-hydroxyl group is equatorial, and the 3α-group is axial, whereas in the 5β-gonane series, the 3β-hydroxyl group is axial, and the 3α-group is equatorial.

5β-androstan-17β-carboxylate, and the cardenolide aglycones gitoxigenin, digitoxigenin, sarmentogenin, and strophanthidin).[4,24] Moreover, in individual cases it has been shown that the corresponding 3α-epimer, whose hydroxyl group is equatorial, forms a digitonide, in contrast to the 3β-axial epimer (epilumisterol).[25] All this indicates that the influence of the 3-hydroxyl group in the formation of complexes with digitonin is determined not by its α- or β-arrangement but by its equatorial or axial arrangement, and is related to the same steric factors as the above differences in reactivity. This suggestion naturally requires confirmation using a larger amount of experimental material than is available at present.

The lower complex-forming power of the axial epimers is not the only feature illustrating the influence of steric factors on the formation of digitonides. Thus the introduction of an additional methyl group into a sterol in position 3 makes the formation of the digitonide more difficult, while the relationship between the stabilities of the equatorial and axial epimers is preserved (see Table 1). The introduction of additional methyl groups in position 4 of the molecule on going from cholesterol to lanosterol also leads to higher solubility of the digitonide.[26] Esters of 3β-hydroxyandrostan-17-carboxylic acid, containing the bulky diphenylmethane group in the alcohol fraction of the molecule, also do not form digitonides, in contrast to the esters with simple alcohols (methanol, ethanol).[24]

The role of the aliphatic chain on the C(17) atom in the formation of sterol digitonides has been less extensively studied than the role of the hydroxyl group. The data in Table 1 show that the double bonds in the aliphatic chain of ergosterol and stigmasterol have no influence on the stability of the complex, whereas in the series of identical derivatives of cholestane, cholane, pregnane, and androstane, decrease in the length of the chain leads to a slight but regular decrease in the stability of the digitonide. The competitive formation of digitonides by cholesterol and its synthetic analogues containing unbranched aliphatic chains of different length on the C(17) atom has been studied.[27] Gradual increase in the length of the chain increases the stability of the complex, which became equal to the stability of cholesterol digitonide for the compounds containing 8–10 carbon atoms in the side chain. Further increase in the length of the aliphatic chain to $C_{11}$–$C_{13}$ gave digitonides with an even higher stability, but at $C_{15}$ the stability of the complex decreased sharply.

In addition to the dependence of complex formation on the structure of the sterol, some data have been published on the influence of the structure of the second component of the complex, that is the saponin, on this process. Complexes with sterols are formed not only by digitonin but also by a whole series of steroid saponins, and also various steroid alkaloids[20,28] and triterpene glycosides.[13] Comparison of the stability of the complex with the saponin aglycone structure indicates that spirostanol saponins containing six rings form less soluble complexes than furostanol saponins, which contain one fewer ring.[9,29,30] The structure of the glucoside residue of the saponin has a marked influence on complex formation. The optimum number of monose residues for complex formation is 4–5, and decrease in this number leads to an increase in the solubility of the complexes.[9,10,30] A quantitative study has shown that desglucosodigitonin (*Ib*), which contains four monose residues, has practically the same complex-forming power as digitonin (*Ia*), whereas glucosogalactosodigitonin (*Ic*), obtained by removing three monoses from natural digitonin, does not form a complex with cholesterol under the conditions studied.[27]

The above regular features relating the stability of the complex to the structures of both the sterol and the saponin have made it possible to put forward suggestions about the structure of the complex itself.[27] It is suggested that the digitonide is a clathrate, in which the saponin is the host, and the sterol the guest. The digitonin molecules are oriented to form a hydrophobic cabity capable of accommodating a guest molecule. This model assumes that the aglycone fraction of the saponin undergoes a hydrophobic interaction with the sterol molecule. The rigid cyclic systems of the two components ensure that the interaction is equimolar. A mobile aliphatic side chain on the C(17) atom of the guest molecule, capable of changing its position in space and undergoing an additional hydrophobic interaction with the host molecule, should, for a definite length, ensure stability of the complex. In a development of this hypothesis it may be assumed that the part of the host cavity which is formed by the glucoside residue and which is hydrophilic in character leads to stabilisation of the complex as a result of the formation of hydrogen bonds between the hydroxyl groups of the sugars and the 3-hydroxyl group of the sterol. This last suggestion agrees with the stability of the digitonides of steroids which contain in position 3 not a hydroxyl group but certain other groups capable of acting as proton donors or acceptors in hydrogen bond formation, such as amino- or dimethylamino-groups,[4,31] but not the thiol group,[32] which is a less effective partner in hydrogen bond formation. The hypothesis is supported by other factors. The ability of cholic acids to act as the host in clathrates with various compounds, including cholesterol, is well known.[33] The common features of the structures of saponins and cholic acids include not only the common hydrophobic cyclopentanoperhydrophenanthrene framework, but also the necessary presence of hydrophilic groups—the carboxyl group in cholic acid, and the hydroxyl groups of the sugars in the saponins. The blocking or elimination of these groups by esterification of the acid or the removal of monoses makes the compounds unable to form complexes.

Steroid saponins have a marked haemolytic and antimycosal action. The dependence of these properties on the chemical structure of the saponins shows regular features analogous to those of the above relationships between the complex-forming power and the structure. For example, the maximum haemolytic activity is shown by spirostanol saponins containing 4–5 monose residues.[34,35] This parallel suggests that the haemolytic action of saponins and other glycosides is due to complex formation with membrane sterols.[36,37,38] and this increases the interest in the complexes of sterols with saponins.

## III. STEROL CRYSTALLINE SOLVATES

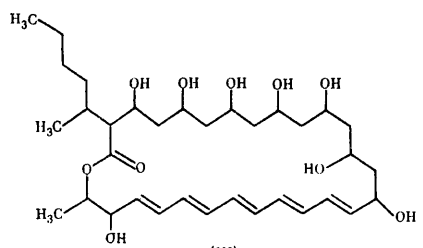
Only a few papers have been published on these sterol complexes. The crystalline hydrates of cholesterol, formed by crystallising the latter from aqueous solvents (alcohol, acetone), gradually lose water of crystallisation at ordinary temperatures, and are completely dehydrated at 80°.[39,40] The crystalline hydrates of other sterols such as β-sitosterol and ergosterol behave similarly. Sterols also form complexes with alcohols[41] and inorganic and organic acids, the highest stability being shown by the complexes with the strong acids perchloric,[42] trichloroacetic,[43] and oxalic.[44]

It is logical to assume that in complex formation by a sterol with small polar molecules, the hydrophobic inter-

action between them plays an insignificant role, and that the principal contribution is made by forces associated with the hydroxyl group. Thus only sterols with a free 3β-hydroxyl group, and not sterol esters, form both crystalline hydrates and complexes with acids. Similarly, the corresponding complexes are not formed by compounds which do not contain hydroxyl groups, such as cholestenes and cholestadienes. It has been shown qualitatively that, as in the formation of digitonides, a decisive role in complex formation with perchloric and oxalic acids is played by not only the presence but also the configuration of the 3-hydroxyl group. Thus unlike 5α-cholestan-3β-ol and cholesterol, the corresponding 3α-epimers do not form oxalates or perchlorates.[42,44]

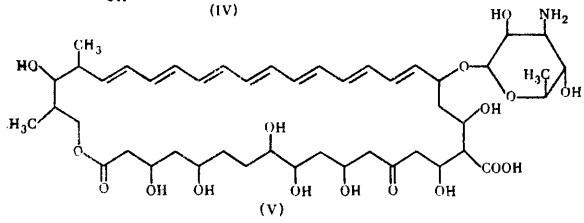
In contrast to digitonides, where hydrogen bonding has only been assumed, in the case of the crystalline solvates various data have been published on the nature of the hydrogen bond between the hydroxyl group of the sterol and the second component of the complex.

In the crystal of cholesterol[45] and its esters containing a polar group in position 3, such as the hydrogen sulphate[46] and phosphate,[47] the molecules are packed in structures in which the rigid system of rings, the substituent on the C(3) atom, and the aliphatic side chain are arranged in different positions in the molecular layer. Within the layer, the molecules are arranged in two series with their planar rear α-sides turned towards one another, favouring the maximum hydrophobic interaction. On the other hand, neighbouring double bonds make contact through their frontal β-sides. The double layers are displaced slightly (~0.85 Å) relative to one another in such a way that the angular methyl groups projecting above the surface are entangled. The maximum hydrophobic interaction is achieved when the long axes of the molecules are parallel, but at the same time this parallel arrangement leads to an increase in the distance between the oxygen atoms of the two hydroxyl groups of two molecules of the bilayer, to a value >3.0 Å, preventing the formation of a hydrogen bond between them. On the other hand, when the two hydroxyl groups approach one another to a distance <2.5 Å to give a strong hydrogen bond, the parallel arrangement of the molecules breaks down, and the hydrophobic interaction decreases. Thus in the cholesterol crystal there is a compromise between these two requirements: the parallel arrangement of the axes of the molecules is slightly disturbed, and the O...O distance is 2.87 Å, which is at the upper limit for possible hydrogen bond formation. In cholesterol monohydrate, however, hydrogen bond formation takes place not between two cholesterol hydroxyl groups but through water molecules acting as bridges.[48,49] This makes it possible for two cholesterol molecules to be joined by a hydrogen bond while preserving the parallel arrangement of the axes of the molecules. Thus in the crystal of cholesterol monohydrate there is a greater interaction between the individual parts of the two molecules than in the crystal of the anhydrous substance, that is the inclusion of water in the polar fraction of the molecules also increases the strength of the hydrophobic interaction.



Complex formation by cholesterol with other ligands, for example acids, apparently takes place similarly. Infrared spectroscopy has shown that the reaction of cholesterol with trichloroacetic acid in carbon tetrachloride solution involves the formation between them of a hydrogen bond, in which the acid acts as proton donor, and cholesterol as proton acceptor.[50] Increase in the concentration of both components leads to aggregation of the binary particles as a result of the formation of new hydrogen bonds between them. In these aggregates, the hydroxyl group of cholesterol acts simultaneously not only as a proton acceptor, but also as a proton donor, which accepts either the hydroxyl group or the carbonyl group of the acid. In the solid complex, the role of acceptor is apparently played only by the carbonyl group of the acid; in this case the bridge formed is longer, and creates more favourable conditions for the interaction of two sterol molecules in the crystal.

The proposed model requires that not only cholesterol but also the second component of the complex should be not only a proton acceptor but also a proton donor in hydrogen bond formation. Thus cholesterol forms solid complexes with alcohols, but not with esters, and only with those amides which contain $NH_2$ or NHR groups.[50]



Cholesterol and other sterols form complexes with various salts, for example chlorides.[6,51] Published data on these complexes are few and often contradictory, but the hydroxyl group plays an important role in their formation. Thus only compounds with a free 3β-hydroxyl group, and not sterol esters or 3α-epicholesterol, form complexes with calcium chloride.[52] The rate of acetylation of the hydroxyl group of cholesterol in its complexes with calcium and magnesium chlorides is higher than the rate of acetylation of the sterol itself.[53] The complexes with salts also apparently contain water molecules, as confirmed in a number of cases by analysis.[6,52] The conditions of preparation of other complexes with salts also indicate that they contain water molecules, but unfortunately, no analytical data are available.

## IV. COMPLEXES WITH POLYENE ANTIBIOTICS

The biological action of polyene antibiotics is due to their complex formation with the sterols of cell membranes. The proof of this mechanism and the investigation of the relationship between the structure and action of antibiotics have been the subject of a large number of publications, including a number of reviews,[54-58] so that the present review will only list briefly the characteristic features of the structure of polyene antibiotics, for example filipin (IV) and amphotericin B (V). Polyene antibiotics are characterised by the presence of a macrolide ring, formed by the closure of a lactone ring. One side of the ring consists of a system of 4–7 conjugated double bonds. The total number of carbon atoms in the ring is $4n + 4$, where $n$ is the number of double bonds of the polyene chain. A second characteristic feature is the large number of hydroxyl groups, from 6 to 14, situated on the opposite side of the ring. Finally, most polyene antibiotics contain a mycosamine residue.

(IV)

(V)

The simultaneous presence in the molecule of a polar region, formed by a number of hydroxyl groups, and a rigid hydrophobic system of conjugated double bonds is responsible for the amphipathic properties of polyene antibiotics, for example their ability to form micellar solutions. It follows from the above material that this amphipathic character may be responsible for the ability to form complexes with sterols. Unlike the crystalline complexes described above, the complexes of sterols with antibiotics have not been isolated in the crystalline state, and their formation has been demonstrated by various physicochemical methods, primarily spectroscopic methods. The addition of sterols to solutions of polyene antibiotics produces a characteristic change in the ultraviolet spectra of the latter, namely a change in the ratio of the absorptivities of different maxima, indicating that the antibiotic reacts with the sterol. Complex formation is reversible, and depends on the solvent and temperature. The change in the spectra of the antibiotics, measured by the ratio of the absorption at 320 nm and 356 nm (the so-called 1:3 peak ratio), takes place only in the reaction with the sterol. The data in Table 2 show that the addition of other compounds such as cetyl alcohol or lecithin to a filipin solution produces no change in the spectrum; the changes brought about by secosteroids are also very slight. The ability to form a complex with an antibiotic is also influenced by the presence of a 5α-gonane system, an aliphatic chain on the C(17) atom, and a 3-hydroxyl group on the C(3) atom, although there are also unexplained exceptions, namely the 3-ketoderivatives. More definite information can be obtained by comparing the changes produced in the spectrum of filipin by its reaction with not a free sterol but a sterol in a sterol–lecithin liposome. In the case of liposomes containing 16–50% sterol, the optimum interaction is observed for sterols containing a 5α-gonane or $\Delta^5$-gonene ring and a aliphatic chain on C(17). In this case, complex formation depends on the substituent on C(3). The maximum interaction is shown by compounds with a free 3β-hydroxyl group, and its acetylation, oxidation, or epimerisation leads to a sharp decrease in the stability of the complex. According to Ref.61, the dissociation constant of the epicholesterol–filipin complex is 15 times the corresponding constant of the cholesterol–filipin complex. Similar regular features are observed for sterols in not liposomes but natural membranes. A culture of Acholeplasma Laidlawii does not contain sterols in the cell membranes, but is capable of including them in the membrane when grown in sterol-containing media. This is widely used in the study of the influence of sterols on the properties of biological membranes.[62] It follows from the data in Table 2 that the reaction of filipin with this membrane also leads to characteristic changes in its ultraviolet spectrum. Maximum complex formation takes place in the case of membranes containing sterols of the 5α- or $\Delta^5$-series with a 3β-hydroxyl group; the spectral changes are much less marked on going to the 5β-series (coprosterol) and to the 3α-epimers (epicholesterol).

The dependence of complex formation with an antibiotic on the structure of the sterol is confirmed by not only ultraviolet but also fluorescence spectroscopy.[63] The formation of complexes with sterols leads to quenching of the fluorescence of the antibiotics. Data on the quenching of the fluorescence of antibiotics brought about by the formation of complexes with sterols show that complex formation with filipin, amphotericin, and pimaricin is a maximum for sterols containing a 3β-hydroxyl group, and that practically no complex formation takes place when this group is acylated or epimerised.[64] Similar results have been obtained in spectroscopic studies of the reactions of sterols with other polyene antibiotics. All these data indicate that the stability of the complexes of sterols with antibiotics is determined by the same characteristic features of the sterol structure as the stability of the complexes with saponins. The following model of the complex of an antibiotic with a sterol has been proposed by a number of authors.[65,66] When the antibiotic enters the membrane its hydrophobic polyene chain reacts with the hydrophobic cyclic system of the sterol to form a 1:1 complex. Several such complexes (eight in the case of amphotericin B) join together to form a so-called semi-pore, whose inner part, containing a large number of hydroxyl groups, acts as a hydrophilic canal. Two semi-pores form a pore penetrating the membrane. The hydroxyl group of the sterol and the polar amino- and carboxyl groups of amphotericin B are on the membrane surface facing water. It is assumed that hydrogen bond formation between these groups is possible.

Table 2. Influence of the structure of the sterol on complex formation with philipine (3:7 peak ratio in the ultraviolet spectrum).

| Compound | In aqueous solution (Ref.59) | In liposomes (Ref.59)* | In natural membranes (Ref.60) |
|---|---|---|---|
| Original solution | 0.72 | — — | — |
| 5α-Cholestan-3β-ol | 2.17 | 1.35; 1.94 | 2.99 |
| 5α-Cholestan-3α-ol | — | — — | 1.16 |
| Cholest-5-en-3β-ol | 2.12 | 1.40; 1.95 | 2.18 |
| Cholest-5-en-3α-ol | 1.63 | 0.85; 1.04 | 1.47 |
| 3β-Palmitoylcholest-5-ene | 1.78 | — — | — |
| 5β-Cholestan-3β-ol | 1.56 | 0.88 — | 1.35 |
| Stigmasterol | 1.70 | 1.71; 2.23 | 1.56 |
| Ergosterol | 1.88 | 1.48; 1.70 | 2.01 |
| 5α-Androstan-3β-ol | 1.52 | 0.94; — | — |
| 5α-Androstan-3α-ol | 1.50 | — — | — |
| Cholest-5-en-3-one | 2.50 | — — | — |
| 5α-Cholestan-3-one | 2.27 | 0.90; 0.96 | — |
| Dihydrotachysterol | 0.92 | — — | — |
| Vitamin $D_2$ | 0.84 | — — | — |
| Lecithin | 0.88 | — — | — |
| Cetyl alcohol | 0.78 | 0.87; — | — |

*First figure—16% sterol, second figure—50% sterol.

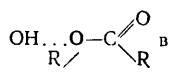
The change in the penetrability of natural membranes brought about by the addition of antibiotics is determined by the nature of the sterol present in the membrane.[54] The maximum change is observed when cholestanol and cholesterol are present, whereas their epimers undergo practically no reaction with antibiotics. The need for the presence of a 3β-hydroxyl group for the reaction with an antibiotic was also proved in a study of the conductivity of bimolecular lipid membranes; the addition of levorin increased the conductivity of membranes containing cholesterol by a factor of $10^5$, but increased the conductivity of membranes containing esterified cholesterol and cholest-5-en-4-one by a factor of only 10.[67]

The proposed model of the sterol–antibiotic complex explains satisfactorily the role of the sterol framework. The planar polyene chain of the antibiotic molecule complements to a maximum extent the planar cyclic system of the sterol. Breakdown of the planarity of the polyene chain by the introduction of one simple bond (nystatin) or by the complete reduction of all the double bonds (hydrogenated amphotericin) reduces the complementarity of the interacting molecules.[68] An even greater influence on the

stability of the complex is shown by breakdown of the planarity of the cyclic system in secosteroids (see Table 2) or by the steric hindrance produced by geminal methyl groups in such sterols as tetrahymanol,[64] eburicol, and lichesterol.[69] On the other hand, an increase in the planarity of the sterol molecule facilitates complex formation (Table 2). This has been confirmed by studies of the conductivity of bilayer lipid membranes; the increase in the conductivity brought about by the addition of levorin is proportional to the number of double bonds in the sterol framework.[70,71] According to Ref.72, the complete aromatisation of the ring *A* of the sterol also favours complex formation with antibiotics.

Although it explains the role of the sterol framework in the hydrophobic interaction, the proposed model does not explain the importance of the aliphatic chain on C(17). The data in Table 2 show that androstane derivatives have a much lower complex-forming power than cholestane derivatives. A gradual decrease in the length of the side chain in synthetic homologues of chlolesterol also leads to a decrease in their ability to form complexes with antibiotics.[73] Another factor is the degree of branching of the side chain, as can be seen by comparing cholesterol, β-cytosterol, and stigmasterol. The introduction of double bonds not only into the rings but also into the aliphatic chain favours complex formation with antibiotics.[70,71] It should be noted, however, that the role of double bonds is different for complex formation with different antibiotics. Thus filipin forms a more stable complex with cholesterol than with ergosterol, but amphotericin, pimaricin, and nystatin form more stable complexes with ergosterol than with cholesterol.[74,78] The authors cited relate this difference to the presence of mycosamine in the structure of the last three antibiotics, but they leave open the question of how mycosamine can react with the additional double bonds in the ergosterol molecule. At the same time, this question is of not only theoretical but also applied importance; its solution facilitates the choice of particular antibiotics for treating different illnesses. The role of the 3β-hydroxyl group also remains unexplained. Although the formation of a hydrogen bond between the hydroxyl group of a sterol and the functional groups of antibiotics has been postulated repeatedly on the basis of the observed dependence of complex formation on the sterol structure, the existence of this bond has not been proved. A leading role in the formation of the sterol–antibiotic complex is apparently played by the hydrophobic interaction, particularly in solutions, where the solvent prevents hydrogen bond formation. The decisive role of the hydrophobic interaction in solutions is confirmed by the fact that complex formation is influenced by the presence of detergents and organic solvents, and is not influenced by the addition of salts and organic compounds.[78,79] In the reaction with a sterol in a membrane, the possibilities for hydrogen bond formation are greater, and this is revealed by the clearly defined influence of the nature and the sterochemistry of the substituent on C(3) on complex formation. Even in a membrane, however, the sterol–antibiotic interaction is weaker than the sterol–saponin interaction, as proved by the fact that digitonin blocks the action of antibiotics on membranes.[54] On the other hand, the fact that the antibiotic enters the membrane indicates that the interaction of the sterol with the antibiotic is stronger than the interaction of the sterol with other components of the membrane. It may also be noted that the reaction of cholesterol with levorin and amphotericin B inhibits the enzymatic esterification of cholesterol by lecithin–cholesterol–acetyltransferase.[80]

## V. STEROLS IN MEMBRANES



The role of cholesterol and other sterols in the structure of natural membranes and their models has been examined in detail in a number of reviews and monographs (see for example Refs.81–83). The sterol molecules are introduced between the hydrocarbon chains of phospholipids, and the intermolecular interaction between the sterol and the phospholipid is greater than the interaction between identical molecules of both phospholipids and sterols. The main structural function of cholesterol in the membrane is to stabilise the hydrophobic part of the bilayer by decreasing the mobility of the hydrocarbon chains at temperatures above the phase transformation and increasing their mobility at temperatures below the phase transformation. Both the condensing and the decondensing ("liquefying") effects of sterols have been proved by various physical methods in natural and model membranes. This influence is determined to a large extent by the structure of the sterol.

Only compounds containing a 3β-hydroxyl group influence the properties of lecithin monolayers.[84,85] The 3-keto-steroids cholestan-3-one and its $\Delta^4$-, $\Delta^5$-, and $\Delta^{4,6}$-derivatives have a much weaker condensing effect and have practically no influence on the permeability of liposomes for glucose, glycerol, and the $Rb^+$ cation. The influence of the 3-hydroxyl group is determined by its conformation; the presence of 3α-epicholesterol has no influence on the permeability of the membranes of Acholeplasma Laidlawii for glycerol and erythritol or on the energy of the phase transformation in these membranes.[86] As in the case of the complexes of sterols with saponins and antibiotics, the specific role of the 3β-hydroxyl group has been explained by assuming that a hydrogen bond is formed between this group and some acceptor group of the phospholipid. It was first suggested that the phosphate group acts as proton acceptor, but this suggestion was rejected on the basis of $^{31}P$ NMR data.[87,88] At almost the same time it was shown that the sterol is arranged in the lipid bilayer in such a way that its hydroxyl group is located close to the glycerol residue of the phospholipid.[89,90]§ This led to the appearance of several models of the hydrogen bond between the hydroxyl group of the sterol and the carbonyl group of the aliphatic acid of the phospholipid. The first of these postulates the existence of "hydrogen belts" in the membrane, including hydrogen bonds between hydrated cholesterol and the carbonyl group.[92] An examination of models of cholesterol and the phospholipid showed that the formation of a bond of this kind should lead to a stronger hydrophobic interaction with the hydrocarbon chain not only of the planar α-surface of the sterol but also of its β-surface, where the projecting angular methyl groups on C(10) and C(13) are inserted into a hydrophobic "loop" formed by the unsaturated aliphatic acid.[93] Although some studies by the authors of these hypotheses[94] indicated an OH...O=C bond, more detailed studies did not confirm its existence. It was shown that the influence of epicholesterol on the chemical shift of the signals in the NMR spectrum of dipalmitoyl-lecithin containing a $^{13}CO$-group is much greater than the corresponding influence of cholesterol.[95] At the same time it was suggested that it is cholesterol, and not its epimer, that forms a hydrogen bond with the carbonyl group. An infrared and Raman spectroscopic study of the carbonyl

§To counterbalance this, it has recently been shown[91] that the hydroxyl group of cholesterol is situated close to the phosphate group of lecithin.

absorption of the same phosphatidylcholine in the presence of cholesterol showed that there is no hydrogen bond between the hydroxyl and carbonyl groups, at least in the anhydrous specimens.[96] Some spectral changes in the carbonyl region of hydrated dipalmitoylphosphatidylcholine are observed, however, when cholesterol is added.[97] The Raman spectrum of anhydrous crystalline dipalmitoylphosphatidylcholine shows a carbonyl group doublet, corresponding to two different acyl groups in different conformations. Hydration of dipalmitoylphosphatidylcholine, which converts it into a gel phase, transforms this doublet into a single band, as a result of the formation of the conformationally uniform phospholipid. The addition of cholesterol to the hydrated phospholipid, however, splits the carbonyl band again, and it becomes similar to the doublet in the spectrum of the crystalline specimen. The two conformations of the acyl chains of phosphatidylcholine in the gel phase in the presence of cholesterol were also demonstrated by $^{2}H$ and $^{13}C$ NMR spectroscopy.[98,99] Compounds which cannot act as proton donors, such as the methyl ester of cholesterol, do not influence the conformation of the aliphatic acid chains. Thus the influence of cholesterol on the conformation of the acyl chains of the phospholipid indicates indirectly that a hydrogen bond is formed, but cannot prove the existence of the OH...O=C bond.

An attempt was recently made to resolve this contradiction. From a detailed examination of molecular models, it was suggested[100] that a hydrogen bond is formed between the hydroxyl group of cholesterol and the ester oxygen and not the carbonyl oxygen, of the alkoxycarbonyl group. Although the ester oxygen is a weaker proton acceptor than the carbonyl oxygen, it can fulfil this role when the steric arrangement is favourable.[101,102] Examination of molecular models shows that for the maximum hydrophobic interaction between the α-side of the sterol ring and the hydrocarbon chain of lecithin, the hydroxyl group of cholesterol is arranged in such a way that it can form a linear hydrogen bond with the ester oxygen, but not with the carbonyl oxygen. In the case of the α-conformation of the hydroxyl group (epicholesterol), however, this bond is impossible. The proposed hypothesis makes it possible to explain both the difference in the conformations of the two acyl chains in the presence of cholesterol and the difference in the influences of the cholesterol epimers on the properties of the lipid layers. It should be noted, however, that no experimental proof of the formation of an

bond was obtained in this case.

The question of hydrogen bond formation was investigated by another method, by studying the influence of cholesterol on the properties of model membranes constructed from different lipids. In one case the membranes consisted of lipids containing ester or ether groups capable of acting as proton acceptors in hydrogen bonding, and in the other case these groups were replaced by hydrocarbon chains incapable of acting as proton acceptors.[103-107] It was found that the addition of cholesterol to the last membranes, where hydrogen bond formation is impossible in principle, brings about the same condensing effect as in membranes containing ester and ether groups. It is true that it was shown for the first time that there is a slight difference in the changes in the permeability of membranes of different types under the influence of cholesterol,[104] but this difference was not confirmed in subsequent studies.[105-107]

Irrespective of whether a hydrogen bond is present or absent, the localisation of the hydroxyl group close to the glycerol residue of the phospholipid, confirmed by recent studies,[108,109] is responsible for the definite arrangement of cholesterol in the membrane. The gonane ring is fixed between the C(2) and C(8) atoms of the aliphatic acid, and it is the interaction in this section that determines the stability of the complex. As in the complexes with saponins and polyene antibiotics, the stability is determined primarily by the planar α-surface of the sterol. It was shown in Refs.84 and 85 that cholestanol, which is a planar sterol of the α-gonane series, has a more marked condensing effect and a stronger influence on the permeability of membranes, compared with coprostanol. An increase in the planarity of the cyclic system by the introduction of double bonds into the *B* ring (cholesterol, dehydrocholesterol) or by the replacement of the six-membered ring by a five-membered ring (*B*-norcholesterol) increases this influence. On the other hand, the introduction of methyl groups, which break down the planarity of the α-surface of the sterol, decreases its influence on the properties of membranes. The decrease is proportional to the number of these groups: cholesterol < 4α-methylcholesterol < 4,4-dimethylcholesterol < 4,4-diethylcholesterol ≪ 4,4,14α-trimethylcholesterol (lanosterol).[110] The influence of the three-dimensional structure of the sterol on other properties of the membrane, for example the micro-viscosity, is completely analogous.[111,112] An interesting feature is that the above sequence corresponds to the step wise demethylation of the precursors of cholesterol during its biosynthesis. The biological demethylation is highly selective, and only the α-surface of the sterol is affected. This creates a planar surface, capable of maximum interaction with the aliphatic chain of the phospholipid. At the same time, practically all natural sterols contain β-methyl groups on the C(18) and C(19) atoms. Apparently, elimination of these groups does not take place because this would not lead to an increase in the strength of the contact between the sterol and the phospholipid. Moreover, according to the hypothesis of Ref.93, the β-methyl groups are necessary for more complete contact with the unsaturated aliphatic chain.

The interaction between the aliphatic chain of the phospholipid and various sterols differing in the planarity of the α-surface was recently studied by the spin probe method, using stearic acid containing nitroxyl groups on the C(5), C(7), C(12), and C(17) carbon atoms.[113] As suggested, methyl groups situated on the α-surface bring about considerable perturbation of the EPR spectrum, and this perturbation is determined by the relative arrangement of the methyl groups of the sterol and the nitroxyl groups of the probe. The methyl group of 3α-methylcholesterol brings about considerable perturbation in the region of the C(5) atom of stearic acid and less perturbation in the region of C(7) and C(12). Lanosterol, on the other hand, brings about perturbation chiefly in the region of C(12), from its C(14) methyl group, and brings about less perturbation in the region of C(5) and C(7). All this indicates that there is considerable contact between the sterol molecules and the section of the aliphatic acid from C(2) to C(9), which is broken down by the projecting axial methyl groups. The compounds studied bring about practically no perturbation of the signal in the region of the C(17) carbon atom, indicating that there is little interaction between the isooctyl chain of the sterol and the aliphatic chain of the acid.

The side chain of the sterol plays a lesser role in complex formation with a phospholipid, compared with the polycyclic system. The aliphatic chain promotes the solubility of the sterol in the membrane. Decrease in the length of the chain, and the introduction of double bonds into it,

decrease this solubility. At low sterol concentrations (up to 20%), the ordering action of different analogues of cholesterol with shortened chains is practically identical, but increase in the sterol concentration increases this effect only for cholesterol and its closest analogue with an isoheptyl chain, and compounds with a shorter chain at high concentrations no longer dissolve in the bilayer, but form a separate phase.[114,115] At the same time, increase in the length of the side chain to ten carbon atoms alters sharply the properties of the bilayer. This compound, penetrating into the membrane with its long aliphatic "tail", apparently breaks down the neighbouring layer of the bilayer.

Thus the suggestion, put forward as early as 1967,[116] that the sterol in a membrane acts as a "filler" of the space between the hydrocarbon chains of the phospholipid has now been supplemented by a number of requirements which must be satisfied by the sterol structure if it is to be the optimum structure from the viewpoint of the formation of the sterol–phospholipid complex.

In complex formation by sterols with the various groups of chemical substances examined in the present review, a decisive role is played by the planar tetracyclic system. This system, produced in the course of biochemical evolution, is the most favourable for hydrophobic interaction with the aliphatic chains of phospholipids, required for the fulfilment of the normal function of sterols in biological membranes. The two other important structural units of the sterol molecule, namely the 3-hydroxyl group and the iso-octyl chain on C(17), play a lesser role in complex formation. Only complete elimination of the aliphatic chain destroys the ability of the molecule to dissolve in a membrane, but the formation of a hydrogen bond involving the hydroxyl group has not yet been proved. The same polycyclic system interacts even more effectively with the more planar, compared with the chain of the aliphatic acid, rigid alkene system of polyene antibiotics and the planar polycyclic system of saponins. Although the formation of a hydrogen bond with the hydroxyl group of the sterol has not been proved in these cases either, the undoubted requirement of a hydrophilic region in the second component of the complex makes it more probable. Finally, in complexes with simple molecules such as water and acids, the existence of a hydrogen bond has been proved. Here also, however, the hydrogen bond plays a secondary role, orienting the molecules to give the maximum interaction of the gonane rings. The hydrophobic interaction determines complex formation in all the cases examined. This should apparently be taken into account in the study of those sterol complexes about whose structure little is as yet known, in particular lipoproteins.

As already noted, the synthesis of compounds which sorb cholesterol selectively by forming complexes with it is now an important practical problem. Up to the present, success in the preparation of these compounds has been achieved by using derivatives of the natural complex-forming saponins.[10] Synthetic compounds forming complexes of the host–guest type with hydrophobic molecules have proved to be ineffective in the case of cholesterol.[117] These compounds, however, were designed to include as guest molecules small molecules such as benzene, and molecules not containing polar groups.

The material of the present review shows that the possibility of complex formation with sterols is determined by the definite structure of the second component of the complex, in particular its amphipathic nature. This property should apparently be made the basis of the synthesis of compounds capable of forming stable complexes with sterols.

---o0o---

While the present review was being prepared for publication, several new papers dealing with the formation of hydrogen bonds by sterols appeared. In Refs.118 and 119 it was shown that this bond in carbon tetrachloride solution is identical to the hydrogen bond formed by other alcohols. Papers by the authors of the model of "hydrogen belts" in membranes give some indirect evidence in support of this model.[120,121] The most important paper[122] described the influence of cholesterol ethers (3β-alkoxycholest-5-enes) on the properties of the membranes. The methyl ether of cholesterol alters the permeability of model membranes to almost the same extent as cholesterol, disproving the suggestion that cholesterol acts as a proton donor in hydrogen bond formation with phospholipids. At the same time, the authors cited showed that the influence of cholesterol derivatives on the properties of membranes is due to the presence of the oxygen-containing substituent in position 3 of the sterol, and is determined by the size of this substituent. It was suggested that oxygen may play a role as hydrogen bond acceptor, and that a bond is formed between the oxygen of the sterol and the carbonyl group of the phospholipid via a water molecule.

# Quantum-chemical Methods in Catalysis

G.M.Zhidomirov and N.D.Chuvylkin

The methods and various approximations used in quantum-chemical studies of chemisorption and heterogeneous catalysis have been examined, and the principal directions and aims of these studies characterised. Particular attention has been paid to the concept of local centres in heterogeneous catalysis and its realisation in model quantum-chemical calculations. Various types of active centre on the surface of metals and oxides have been examined, and the questions of their quantum-chemical description discussed. Quantum-chemical calculations of the chemisorption and catalytic properties of the Bronsted and Lewis acidic centres of aluminosilicates and related systems have been reviewed.
The bibliography contains 90 references.

## I. INTRODUCTION

The theory of chemical catalysis is one of the most difficult fields of chemical science. Many problems of organic, inorganic, and metal-complex chemistry essentially converge here. In the case of heterogeneous catalysis, additional problems arise, since it is necessary to take account of the properties of the solid surface. It is possibly only in the last ten years that the extent of the structural complexity and the lability of the properties of the structure of solids has been fully appreciated. It is not surprising that the detailed experimental study of the mechanisms of heterogeneous catalytic reactions encounter considerable difficulties; the complex structure and variety of the active centres (even within a given system) controlling the reaction, their possible modification during the reaction, the variety of intermediate structures produced in the system, the superposition of different reaction channels, changes in reaction mechanisms, etc. all complicate the overall kinetic scheme and make it difficult to understand catalytic processes at the molecular level, so that their interpretation is usually not unambiguous.

The mechanisms of catalytic reactions are mainly studied by direct kinetic experiments (the study of non-stationary kinetic conditions is of particular interest). At the same time, the use of various physical methods to study catalytic systems is raising high hopes. Here, quantum-chemical calculations have been called upon to provide definite assistance.

The aim of the present review is not to provide a complete and systematic picture of the state of affairs in the application of quantum chemistry in catalysis. It is now impossible to do this in a single article, because of the large volume of published calculations. It is necessary to point out, however, that quantum-chemical calculations on individual systems are still fragmentary in character; different authors sometimes reach different conclusions, depending on the models of the active centres and the quantum-chemical methods used.

This feature is still a serious obstacle to the complete systematisation of the results of published studies. Subsequently, therefore, the present review will be restricted to a brief general characterisation of the principal aims and the methods used, and more attention will be paid to the concept of active centres. The review will make practically no reference to such important problems as the calculation of surface states and the rearrangement of the structure of the surface, chemisorption on elemental semiconductors, and lateral interactions of adsorbed molecules. The problems of calculations on chemisorption and reactions on metals will be dealt with to only a limited extent.

It should be emphasised that in the general theory of catalysis, in addition to quantum-chemical methods, whose role is extremely limited, use is made of the methods of statistics and thermodynamics, and physical and chemical kinetics. In addition, formal structural description, etc. is of considerable importance.

It is possible to distinguish three aspects of the application of the methods of quantum chemistry to catalytic systems. Firstly, quantum chemistry provides the most systematic language for describing the structure of catalytic systems and the processes taking place in them, at the electronic level. It is hardly possible at the present time to discuss the individual stages of a catalytic process without the concepts of reactions in $\sigma$- and $\pi$-electronic systems, covalent, ionic, and donor–acceptor bond types, etc. All this provides a basis for understanding the nature of the interactions in catalytic systems at a qualitative level of rigour, and this role of quantum chemistry cannot be underestimated, although it is often masked by specific applications. The possibilities provided by quantum chemistry in this area have not yet been exhausted.

It is possible to take as an example several approaches which in a number of cases may be useful and make it possible to reach simple qualitative conclusions comparatively easily. One of these can be described as the "modified" molecule method. In this case, the changes in the electronic structure of a molecule (the changes in the charges, the energies of individual bonds, etc.) brought about by contact with the catalyst are analysed. This method is used fairly widely in many studies, for example in a series of studies of acid–base reactions on oxides, carried out by the authors of the present review.[1-5]

This approach was developed further in studies[6,7] aimed at analysing the change in the vibronic interactions in molecules when they are coordinated to a catalyst. This approach gives a picture of the intramolecular forces acting on individual atoms and produced on coordination, so that it gives information on the possible deformations of the molecule and the tendency for changes to take place in various chemical properties. In studies of this type, the role of the catalyst reduces either to the transfer of an electron to the molecule or to the capture of an electron from the molecule; alternatively, a model functional group of the catalyst, for example $H^+$, $OH^-$, etc., is taken into account in explicit form in the calculation. In those cases where the influence of the adsorbent on the adsorbate is mainly electrostatic in character (for example a strongly heteropolar support or an individual charged centre), this influence can be estimated using simple electrostatic models.[8] For cubic ionic crystals it is possible to obtain explicit expressions for the electrostatic potential on a regular surface,[9] and in the more general case it is possible to use a system of point Coulombic charges.[10]

Another method of describing the influence of a catalyst on chemical transformations is based on the concept of boundary molecular orbitals. In this case, perturbation theory is usually employed. The application of this method to catalytic problems was developed in Refs.11 and 12.

Metal-complex systems have an important place in both homogeneous and heterogeneous catalysis. Thus in the qualitative quantum-chemical theory of catalysis, particular attention is paid to the analysis of coordinate bonding[13] and to a deeper understanding of the nature of such chemical bonds as the metal–carbene (or carbyne) bond, or M...H–C interactions, which are of considerable importance in catalysis. Here, various aspects of the coordinate bonding of hydrogen in metal complexes are acquiring particular importance.[14]

Secondly, specific applications of the methods of quantum chemistry to catalysis are associated primarily with the study of the elementary act of a given stage of the catalytic reaction, including the chemisorption (coordination) stage. The structural problems which arise in this case can be divided into the following three groups.

a) Calculations of the electronic structure of the assumed active centres (AC), which are generally various structural and impurity defects and surface functional groups. These include calculations of the change in the electronic structure of these active centres as a result of the chemical modification of the catalyst surface in various ways.

b) Estimation of the positions at which the chemisorption of atoms and molecules takes place, the geometry and energetics of chemisorption, comparison of the preference for different chemisorption states, and estimation of the magnitude of the energy barriers to transitions between these states. The investigation of the nature of chemisorption (molecular or dissociative, with or without activation), the determination of the degree of covalent and ionic character in chemisorption bonding, and analysis of the modification of these characteristics with change in the degree of coverage of the surface, etc., solution of the problem of the possible formation during chemisorption of structures with the transfer of ions or charged molecular fragments (carbonium ions, carbanions, etc.).

c) Direct analysis of different paths in the reactions of adsorbed molecules on a surface or in the reactions of adsorbed molecules with surface structures. Comparison of the Eley–Rideal and Langmuir–Hinshelwood mechanisms. Examination of the separate and combined mechanisms of a reaction and the study of the dependence of these channels on different forms of the catalysts, and the use of the results of the calculations for the planning of experiments.

Finally, a third important aspect of the application of the methods of quantum chemistry in catalysis is the calculation of the physical characteristics of surface centres. It was noted above that an important role is played by physical methods for studying catalysts, in particular spectroscopic methods: NMR, EPR, infrared, ultraviolet, photoelectron, X-ray electron spectroscopy, etc. The structural information provided by these studies is increased considerably when parallel quantum-chemical calculations are carried out. Extremely varied structural formations, which as yet have no direct analogues among traditional molecular structures, may be produced on a surface. The only approach, therefore, is to use the results of sufficiently correct quantum-chemical calculations.

Quantum-chemical calculations of chemisorption encounter a fundamental methodological difficulty associated with the need to take account of the interaction of a molecule with the unbounded surface of a solid. The initial stage of the development of the theory of chemisorption was characterised by increased attention to the purely solid-state characteristics of the system, and to the analysis of the types, symmetry, and properties of the zone surface states. This gave many important results; in particular, the conditions for the appearance of Tamm and Shockley surface states were determined. In this approach, ordered chemisorption was

regarded as a change in the structure of the surface states, and the adsorption of isolated molecules was regarded as the appearance of point defects on the surface with a tendency for the capture on this defect of an electron (or hole) from the band states of the solid. A detailed critical analysis of this problem has been carried out,[15] and it will not be dealt with further in the present review.

The development of experimental and theoretical studies of chemisorption led to the conclusion that chemisorption should be regarded rather as the formation of chemical surface compounds. In the theory of heterogeneous catalysis, this was reflected in the chemical concept of catalysis.[16] The determination of the local character of the electronic rearrangements taking place on chemisorption also influenced the quantum-chemical theory of chemisorption phenomena. The effort to obtain a correct description of local chemical bonds and the neglect of the effects of long-range order led to the development of the cluster approach, which involves the separation of a finite (usually small) fragment of the surface (cluster). This method makes it possible to use the methods of quantum chemistry directly.

The cluster approximation is very convenient in quantum-chemical calculations of surface structures. It makes it possible, without difficulty, to construct molecular models of all structural and impurity defects on a surface and models of surface functional groups, and to describe the surface of amorphous solids and alloys. The cluster approximation is also attractive in that it concentrates attention on the chemical nature of chemisorption and catalysis. This approach is now used in most studies involving the calculation of chemisorption. Different versions of the cluster approximation, its unsatisfactory features, and methods for improving its efficiency will be examined below. Various questions related to the choice of the "minimum" clusters for modelling active centres in heterogeneous catalysis have been discussed.[17]

## II. QUANTUM-CHEMICAL METHODS

At the present time, practically the entire range of methods of quantum chemistry, from the simplest semi-empirical methods to fairly complete versions of the non-empirical approach, are used in quantum-chemical studies of chemisorption and surface structures. This situation appears justified, and should be preserved for a fairly long time. This is related, firstly, to the characteristic features of the systems studied: the cluster structures modelling the real surface are extremely extended molecular structures. Moreover, cluster modelling is always indeterminate. It is therefore usually appropriate to analyse a number of versions and to estimate the stability of the results of the calculations when the cluster is expanded; this makes it necessary to carry out a large number of individual calculations. All this requires the use of semi-empirical methods which are as economical as possible.

At the same time, situations often arise in which it is necessary to reach a sufficiently reliable conclusion. Such a situation arises, for example, in the analysis of the possibility of dissociative adsorption or when resolving the question of the reality of certain chemisorption structures. Although experimental methods are constantly improving, it is nevertheless the case that in such a complex and labile system as a surface, the investigation of a number of structural problems still cannot be carried out by experimental methods, and it is here that sufficiently reliable quantum-chemical calculations, carried out using non-empirical methods, may be useful. Moreover, the results of non-empirical calculations for small molecular systems can be used to select and improve the parametrisation of semi-empirical methods. This approach is finding increasing application in problems related to a surface.

Calculation schemes in quantum chemistry are traditionally based either on the method of molecular orbitals (MO) or on the valence bond method.[18] A molecular orbital $\phi_i$ is defined as a one-electron wavefunction describing the movement of an electron in the effective electric field of the nuclei and the other electrons. Usually, $\phi_i$ are represented as a linear combination (LCAO) of atomic orbitals (AO) $\chi_k$

$$\varphi_i = \sum_k c_{ik}\chi_k \,, \qquad (1)$$

The many-electron wavefunction $\Psi$ of a molecular system is expressed as the antisymmetrised product of the spin orbitals, and for closed levels it is conveniently represented as a Slater determinant. This approach is called the restricted Hartree–Fock (RHF) method. The analogous approach, in which the condition that the spatial parts of the spin orbitals $\phi_i^{\alpha}$ and $\phi_i^{\beta}$ for electrons with spin $\alpha$ and $\beta$ be equal is not imposed, is called the unrestricted Hartree–Fock method, and is often used in calculations for systems with open levels (free radicals, triplet and other states, etc.).

A fundamental shortcoming of the Hartree–Fock method is that it neglects the Coulombic correlation of the movement of the electrons. The calculation can be refined by the method of configuration interaction (CI), in which the complete wavefunction $\Phi$ is represented as the superposition of the Slater determinants $\Psi$ for different configurations. With a sufficiently broad basis set in the expansion of Eqn.(1) and allowance for a large number of configurations, it is possible to carry out calculations with a high accuracy, and the accuracy of present-day calculations for small molecules already competes with that of experimental studies.

It is not the purpose of the present review to give details of quantum-chemical calculation schemes; see for example Ref.19. The treatment will therefore be restricted to a formal systematisation with particular attention to those methods which are fairly widely used in calculations on chemisorption and catalysis.

The group of simple semi-empirical MO LCAO methods includes the extended Hückel method (EHM),[20] and its modified form[21] in which additional allowance is made for core repulsion. In Ref.21, an attempt was made to obtain more justified values for the total energy, compared with the ordinary EHM method, in order to optimise the geometry of the molecular systems. This approach (the ASED method) was specially developed for problems of chemisorption and surface reactions, and has been used successfully in a whole series of subsequent studies (calculations of chemisorption and catalysis on metals). The application of the above form of the EHM to oxide systems, which have fairly high ionic character, is formally less justified, however.

The nex group of semi-empirical MO LCAO methods consists of the methods of so-called zero differential overlap. Here it is possible to distinguish two sub-groups, provisionally described as physical and chemical. The first consists of the CNDO/2 and INDO methods, and some of their modified forms.[19] These methods are oriented towards the calculation of electronic characteristics: charge distribution, dipole moments, polarisabilities, spin density, electronic spectra, etc.; that is mainly physical properties. The characteristic features of the parametrisation scheme in these methods make it possible, without particular difficulty, to extend it to the compounds of heavy elements, including 3*d*, 4*d*, and 5*d* transition elements (see for example Ref.22).

The second sub-group consists of the CNDO/BW and MINDO/3 methods, which are oriented towards the calculation of the total energy, heats of atomisation, barriers to conformational transformations, and the geometry of molecular systems. It is these characteristics that are particularly important and interesting in problems of chemisorption and catalysis, but the development of the parametrisation in this case involves much greater difficulties than in the first case. A parametrisation has now been described for the compounds of the elements of the second period (as far as fluorine). A simplified procedure has been proposed[23] for estimating the parameters in the CNDO/BW method, based on correlations with the parameters of the CNDO/2 method.

A parametrisation of the CNDO/BW method has been developed within the framework of the general scheme[24] for calculations on the chemisorption of compounds containing H, C, N, and O atoms on aluminosilicates. The CNDO/BW method gives good results in the calculation of chemisorption on oxides, mainly because this method provides a satisfactory description of hydrogen bonds. One significant shortcoming of the CNDO/BW method, however, is the unsatisfactory description of conjugated organic compounds, which makes it necessary to introduce special corrections. This shortcoming, generally speaking, is not shown by the MINDO/3 method, but the application of this method in chemisorption calculations requires expansion of the parametrisation to the elements of the third and subsequent periods. This problem has been solved for the Si and Al atoms in chemisorption on aluminosilicates.[25]

The problem of expanding the parametrisation of the MINDO/3 method to the 3*d* transition elements is now being studied by several research groups. Thus parameters have been proposed for calculating the chemisorption of hydrogen on iron[26] and on nickel.[27] The MINDO/3 method, however, provides an insufficiently good description of donor–acceptor bonds, particularly hydrogen bonds. In view of the above limitations of the CNDO/BW and MINDO/3 methods, it is appropriate, to control the reliability of the results, by carrying out parallel calculations by these methods.[25] Here, various control calculations carried out by non-empirical methods, and also by MNDO methods, may be of considerable assistance.

The next group of methods consists of calculation schemes in which use is made of a local approximation of the exchange potential: the $X_\alpha$–SW and $X_\alpha$–DV methods.[19] According to the formal classification, these methods occupy a unique intermediate position between semi-empirical and non-empirical methods. The $X_\alpha$–SW method has proved to be extremely effective in calculations of ionisation potentials and electronic spectra, and it is now widely used for these purposes in the cluster analysis of the photoelectron and X-ray electron spectra of chemisorption structures. Certain characteristics of this method make it unsuitable, for example, for calculating the total energy and geometry of these structures. These same characteristic features, however, bring it closer to the methods used in most zone calculations in crystals. The $X_\alpha$–DV method also gives fairly reliable results in the calculation of electronic spectra (although it is less economical than the $X_\alpha$–SW method). The chief advantage of the $X_\alpha$–DV method is that it is possible to carry out fairly good calculations of the energies and the geometry. Very powerful computers are required, however, to realise these possibilities. Nevertheless, the $X_\alpha$–DV method is beginning to be more widely used in the calculation of surface structures and chemisorption.

Non-empirical (*ab initio*) methods form the apex of this quantum-chemical pyramid. Since with catalysis the main interest is in adsorbents containing many-electron atoms (for example transition metals and their oxides), it is appropriate, for the effective utilisation of non-empirical quantum-chemical calculations, to develop the pseudo-potential approximation for the electrons of the core. Most non-empirical calculations of chemisorption on metals are now carried out using this approach. The results of the first calculations using a pseudo-potential for aluminosilicates have now been published.[28] Another important task in non-empirical calculations is to take account of the correlation of the movement of the electrons. In addition to the traditional CI scheme, mention may be made of methods in which partial allowance is made for electron correlation. Among these methods, the generalised valence bond (GVB) scheme,[29] which is oriented towards the solution of problems related to surfaces and chemisorption, has found comparatively wide application in chemisorption calculations.

## III. THE CLUSTER APPROXIMATION

The chief disadvantage of the cluster approach is the rupture of the chemical bonds between the bopndary atoms of the cluster and the rest of the lattice. This results in the production of artificial "surface states", situated partly in the band gap; distortion of the charge distribution; etc. Too many "surface" atome are obtained in the cluster. Unfortunately, to obtain a more correct surface/volume ratio, it is necessary to examine such large clusters that the approach loses its significance. The calculated characteristics of the electronic structure, in which the collective properties of the solid are important, converge slowly with increase in the size of the clusters. This applies to the energy of the Fermi level, the ionisation potentials, the electron affinity, and the atomisation energy.

The cluster approach is completely satisfactory, however, in the calculation of chemisorption, where a decisive role is played by local interactions. Thus even in the case of metals, which is particularly difficult for the cluster approach and where a band gap appears in the cluster calculation, chemisorption calculations for comparatively small clusters give good results. The preferred positions for the chemisorption of molecules, and the geometry, energy, and frequency characteristics of the chemisorption structures, are predicted fairly satisfactorily. Thus for example, in comparative calculations of the chemisorption of atomic hydrogen on Be, going from the $Be_{22}$ cluster to $Be_{36}$, the changes in the equilibrium Be–H distance and the frequency of the stretching vibration of this bond are 4%, and the change in the energy of chemisorption ~20%. The relative stability of the chemisorption states is estimated correctly even for the $Be_{13}$ cluster.[30]

To improve the results of the calculations, in addition to the obvious recommendation that the cluster be expanded, allowance for the influence of its environment, that is the rest of the lattice of the solid, can be proposed. A large number of recommendations of this kind have now been proposed and tested in the literature. This topic has also been reviewed.[31–33] The resulting hierarchy of versions of the cluster approximation makes it possible in principle to construct a bridge to band calculations.[32] At the same time, in the literature, particularly that dealing with chemical problems, use is generally made of simple model methods for taking account of the environment of the cluster; only these will be examined subsequently.

One of the first methods for taking account of the environment of a cluster was based on the introduction of boundary atoms, which were used to saturate the broken outer valence bonds of the cluster ("pendent valencies"). This method

was first used to calculate point defects in homoatomic crystals of diamond and silicon, and H atoms were used as the saturating atoms. The same approach was used successfully to calculate the chemisorption of atomic hydrogen on a graphite surface.[34] In Ref.23, an approach was developed in which the boundary valencies were saturated using univalent atoms whose quantum-chemical parameters (the form of the AO, electronegativity, etc.) were selected to give the best reproduction of various characteristics of the electronic structure of the solid (the stoichiometric charge distribution, the widths of the band gap and the valence band, the orbital composition of the top of the valence band and the bottom of the conductivity band, and various experimentally determined properties of the surface groups). These atoms bounding the cluster were called pseudo-atoms. Corresponding calculation schemes have been developed within the framework of the CNDO/BW[23] and MINDO/3[25] methods, and also the non-empirical method.[28]

This calculation scheme was first used[23] to describe the surface hydroxide groups of silica gel. The parameters of the pseudo-atoms A were selected to give the stoichiometric distribution of charge in a cluster imitating the "volume" of $Si(OA)_4$. The logical consistency of the scheme was verified by analysing the stability of the calculated electronic characteristics (charge distribution, position of the one-electron levels) with respect to expansion of the cluster, that is with successive replacement of the pseudo-atoms A in $Si(OA)_3$.[35] The results of the calculation of the infrared spectroscopic characteristics of the stretching vibrations of the OH bond in the cluster $(HO)Si(OA)_3$ show good agreement with experimental data in the range of both the fundamental $\nu_{OH}$ vibrational band and the overtones, and describe familiar trends in the properties of the OH groups of oxides, namely the comparatively weak dependence of $\nu_{OH}$ on the acidity of the surface OH group, and the marked increase in this dependence when basic molecules are adsorbed.[36]

Different versions of the scheme with boundary pseudo-atoms can be realised. Thus the orbitally stoichiometric cluster method[37] uses a boundary atom with one 3*s* or 3*p* or $sp^3$ orbital of the silicon atom with the AO oriented along the direction of the chemical bond.

Certain difficulties arise when attempts are made to extend the above scheme involving the introduction of boundary atoms into the cluster (which can be called the covalent cluster scheme) to lattices with high coordination numbers ($Al_2O_3$, MgO, ZnO, transition metal oxides). In this case it is more convenient to distinguish an ionic cluster, corrresponding to the ionic model of the lattice. In essence, excess (relative to the neutral cluster) electrons (or an electron deficit) are used to compensate the "pendent valencies", although in this case this terminology is of course fairly arbitrary. The resulting excess of electronic charge can be compensated, to obtain an overall neutral cluster, by an appropriate choice of the charge on the core of the boundary ions.[38]

For the discussion of these two methods of selecting the clusters (covalent and ionic), it is of interest to compare the results of calculations for a given system. This comparison has been carried out for the hydroxide group on an $SiO_2$ surface,[39] the magnetic resonance parameters of paramagnetic surface structures,[40] and a number of models of chemisorption.[41] In spite of certain differences, the two schemes on the whole give similar results. For more definite conclusions, it is necessary to carry out more extensive comparative studies. For close-packed oxide structures, in a number of cases, stoichiometric clusters (for example $Mg_{2n}O_{2n}$) will apparently be preferable, although in these cases also it is appropriate to take account of the Madelung field from the nearest part of the rest of the lattice.

Another method for selecting the cluster is based on the saturation of the "pendent valencies" within the cluster. This approach is convenient when comparing the chemisorption and catalytic activity of active centres of the same kind in different systems; it has been used successfully to compare the acidic centres in aluminosilicates and aluminium phosphates.[24]

## IV. QUANTUM-CHEMICAL STUDIES OF CHEMISORPTION AND CATALYSIS ON METALS

The very first steps are now being taken in the quantum chemistry of catalysis on metals. This is revealed by the fact that the great majority of calculations deal with problems of chemisorption, and the problems of chemical transformations and catalytic reactions are as yet discussed only in a very few papers. From certain trends in the theoretical literature, however, a definite change towards chemical topics may be expected in the near future.

Various metals have been examined in the cluster approximation in quantum-chemical studies. The largest number of published theoretical studies deal with Li, Be, Al, Ni, Cu, and Pt, and to a lesser extent with Na, Fe, Ti, and Ag. The studies have for the most part dealt with the chemisorption of atoms (H, C, O, and various others), diatomic molecules ($H_2$, $O_2$, CO, $N_2$, NO) and simple organic molecules such as acetylene, ethylene, etc. Chemisorption at different positions on various faces of single crystals has been examined; for example, for the (100) face, atomic adsorption on an atom, on a bond, and in a four-coordinate $C_{4\nu}$ position has been studied.

In a number of cases the question of the possibility of surface atomic adsorption and the estimation of the magnitude of the barrier to the transition from the state of an atom above the surface into the surface state has been discussed. An example is the non-empirical calculation of the adsorption of Li, O, and Na atoms on the (111) face of an Al crystal, which was modelled by a three-layer cluster $Al_{19}$ with the (12, 6, 1) structure; the figures give the numbers of Al atoms in the individual layers.[42] The calculation was carried out using a pseudo-potential for the core electrons, so that each Al atom was modelled by a three-electron system (such an extended cluster could be examined only in this approximation). The calculations for $Al_{19}O$ were carried out for a system with $C_{3\nu}$ symmetry with localisation of the O atom on the *z* symmetry axis perpendicular to the surface face of the cluster. Two local energy minima were found, corresponding to one chemisorption state situated above the surface and another situated under it, with octahedral coordination of oxygen. The two states have similar bond energies. The theoretical estimate of the energy of the transition below the surface for the oxygen atom (~2.4 eV), however, was much greater than the experimental estimate of this quantity (~1 eV). The discrepancy is apparently due to the fact that no allowance was made for electron correlation. In the case of Li and Na atoms, no chemisorption bound states were found below the surface. Another example of studies of this kind is provided by Ref.43, where the $X_\alpha$–DV method was used to calculate the adsorption of S, Se, and Te atoms on Ni clusters modelling the (100), (110), and (111) faces.

In calculations of the adsorption of diatomic (and polyatomic) molecules on metals, the question of the dissociative adsorption and fragmentation of the molecules is of particular interest for catalysis. These topics for the most part have been examined using semi-empirical methods of calculation. An illustration is provided by Ref.44, where the CNDO/2 method was used in cluster calculations of the dissociative

chemisorption of $H_2$ on Ni, and also Ref.45, where the dissociative chemisorption of $O_2$ on Ni was examined by the EHM. In those cases where there is a good pseudo-potential approximation for the core electrons, however, it is also possible to carry out non-empirical calculations of this type. For example, the decomposition of methanol on Ni(100) has been examined,[46] and the calculation was carried out by the GVB method for an $Ni_{20}$ cluster. The results of quantum-chemical calculations have also been used[47] to study the role of the *d*-orbitals of metal atoms in the dissociative adsorption of hydrogen on metal surfaces.

Of the published papers on the theoretical study of the fragmentation of organic molecules on metal surfaces, mention may be made of work[48] in which the original form of the EHM was used to examine the localisation of different hydrocarbon fragments ($CH_n$ and $C-CH_n$, where $n = 1, 2, 3$) on the (111) face of a Pt single crystal. The calculation was carried out in the cluster and band versions; it was concluded that allowance for band effects has no significant influence on the results of the calculations. From a comparison of the energies of different chemisorption states for these fragments, the authors cited[48] arrived at the so-called covalent model of chemisorption bonding, in which the most favourable structures are those with complete saturation of the valence of the hydrocarbon fragments; thus for example for CH, $CH_2$, and $CH_3$, three-, two-, and one-coordinate states with respect to the platinum atoms are produced.

The quantum-chemical study of the electronic structure and chemical properties of adsorbed atoms and other structural defects such as steps and vacancies is of particular interest for the discussion of the catalytic properties of metal surfaces. It is widely held that these structures play a unique role as active centres in catalysis. Thus cluster quantum-chemical calculations have shown that certain characteristic features of the electronic structure of the adsorbent, which favour the reactions, can be related to the presence of adsorbed atoms. Thus in a cluster calculation by the $X_\alpha$–DV method it was found[49] that an adsorbed Fe atom on the Fe(111) surface leads to the appearance of new occupied states of *e* symmetry close to the Fermi level, and this may facilitate the dissociation of the CO molecule; this effect was not detected for the adsorption of a Cu atom on Cu(111).

The increased chemical activity of step defects on a Pt surface has been discussed in work[50] where the $X_\alpha$–SW method was used. The calculation shows clearly that these defect structures are coordinatively unsaturated; in the electronic spectrum, a number of orbital states are identified, which lie close to the top of the valence zone and which are directed "away from the surface". The increased chemisorption and catalytic activity of step defects on a surface can also be related to the appearance of these unsaturated valences.

The production of centres with increased activity on metal surfaces may be related not only to structural defects but also to chemical impurities. The influence on the chemisorption of $O_2$ of atomic oxygen in the surface region of Ni(111) has been examined.[45] It was found that in this case there should be a change in the order of preference of adsorbed states, and the most favourable state is one-point adsorption with perpendicular orientation of the molecule. This example of course indicates only that this influence exists, but it may also appear in catalysis.

A cluster calculation (ASED method) of the dissociative adsorption of CO in Ni(111) has been carried out[51] to determine how the dissociation is influenced by the modification of the surface by electron-donor (K, Na) and electron-acceptor (Cl, S) additives. It is known from experiments that the former activate and the latter inhibit the process. The authors cited examined Ni clusters into which a K or Cl atom was introduced, leading to qualitatively different changes in the energy profile along the reaction path; the effect was significant only when the modifying atom entered the immediate environment of the active centre, that is it is fairly local in character. From the qualitative viewpoint, the presence of, for example, the K atom leads to greater population of the MO of the nickel cluster from which, during the chemisorption of CO, partial transfer of electron density takes place to the antibonding $2\pi^*$ orbital of the CO moelcule, facilitating its dissociation. Thus the calculation predicts the production of a negative charge on the CO molecule and an increase in its bond length in this adsorption.

The role of modifying additives may be played by adsorbed reagents, intermediate complexes, and reaction products. This is probably one way of influencing the composition of a reaction mixture during a catalytic reaction on a surface. This provides extensive possibilities for the application of the methods of quantum chemistry. Thus quantum-chemical calculations can be used to look for chemisorption states with an increased chemical activity; an example is provided by a study[52] where a cluster calculation (GVB method) was used to find a quasi-radical adsorption state of an O atom on an Ni surface.

As noted above, there are only a few published papers on the quantum-chemical examination of surface reactions on metals. A typical example is provided by a study[53] where the ASED method was used to calculate the adsorption of CO and O on Pt(111); the calculation was carried out for $Pt_4$ and $Pt_9$ clusters. The Langmuir–Hinshelwood and Eley–Rideal mechanisms for the reaction $CO + O \rightarrow CO_2$ were compared. It was concluded that the energy characteristics of the two reaction channels are similar; the estimated magnitude of the activation energy for the formation of $CO_2$ from adsorbed CO and O was ~1.6 eV, which is close to the experimental value (~1 eV). The chemisorption of Cl, $Cl_2$, and HCl on Fe(100) and the reaction $HCl + O(s) \rightarrow OH(s) + Cl$, where (s) represents the surface form, has also been discussed;[54] the surface was modelled using $Fe_n$ clusters, where $n = 4-21$.

In conclusion it may be noted that the published results of quantum-chemical calculations, together with the results of experimental studies, are sometimes used for a general analysis of important classes of catalytic reaction. An illustration is provided by the discussion of the catalytic hydrogenation of CO on transition metals.[55]

## V. QUANTUM-CHEMICAL STUDIES OF CHEMISORPTION AND CATALYSIS ON OXIDES

In this section, particular attention will be paid to chemisorption and catalytically active centres on the surface of silica and aluminosilicates. Other oxides will be discussed only briefly. This to some extent reflects the thematic distribution of quantum-chemical studies in this field.[56] A series of studies involving quantum-chemical calculations of adsorption on $SiO_2$ can be considered first. Fig.1 shows different possible forms of the adsorption of an $H_2O$ molecule on $SiO_2$. The relative stability of the two forms of $H_2O$ adsorption on a terminal OH group in silica gel has been debated in the literature. A semi-empirical calculation by the CNDO/BW method using a cluster scheme with boundary pseudo-atoms[23] led to the conclusion that form (I) is preferred, in qualitative agreement with experimental data which show that there is only slight perturbation of the frequency characteristics of the hydroxide group when water is adsorbed. A different result was subsequently obtained by

a non-empirical STO-3G calculation.[57] It should be noted, however, that H atoms were used as boundary atoms in the cluster.

The development of a scheme for including pseudo-atoms in non-empirical calculations[28] made it possible to carry out an improved version of this study. This confirmed the conclusion reached in the semi-empirical calculation. The same conclusion was reached in calculations of the adsorption of $H_2O$ on a terminal hydroxide group in $SiO_2$.[58] In this case, the CNDO/2 method with gradual increase in the size of the clusters was used.

Systematic calculations of the adsorption of $H_2O$ on geminal and vicinal pairs of OH groups in silica gel have been undertaken.[59] The energy of the chemisorption of an $H_2O$ molecule on a hydroxide group in silica was estimated as ~10 kcal mole$^{-1}$. The question arose of whether the adsorption of $H_2O$ on a silicon atom is energetically more favourable (form (IV) in Fig.1). Non-empirical calculations[28,60] do not indicate that chemisorption of $H_2O$ and $NH_3$ at an Si atom is possible (as is sometimes assumed). This chemisorption becomes favourable only when there is appreciable deformation of the geometry of the silicon–oxygen tetrahedron (increase in the length of the Si–O bonds, increase in the O–Si–O valence angle), that is only on highly defect structures or on specially prepared surfaces. This apparently provides the answer to the question, discussed in the literature (in the interpretation of experiments and the results of different quantum-chemical calculations), of the production, stability, and prevalence of this form of coordination bonding of $H_2O$ on silica. The details of this discussion cannot be examined in the present review, but references to this topic can be found in Refs.28 and 60.

The CNDO/BW calculation scheme described above has been used[61] to calculate the chemisorption of $NH_3$ at a hydroxide group in $SiO_2$. In this case the most favourable form of adsorption corresponds to the production of a hydrogen bond between the nitrogen atom of ammonia and the hydrogen atom of the surface hydroxide group. The calculation on the whole shows good agreement with the results of infrared spectroscopic studies of the adsorption of $NH_3$ on silica. The adsorption of the molecules of thiophene and thiophane on silica has been calculated[62] by the CNDO/2 method.

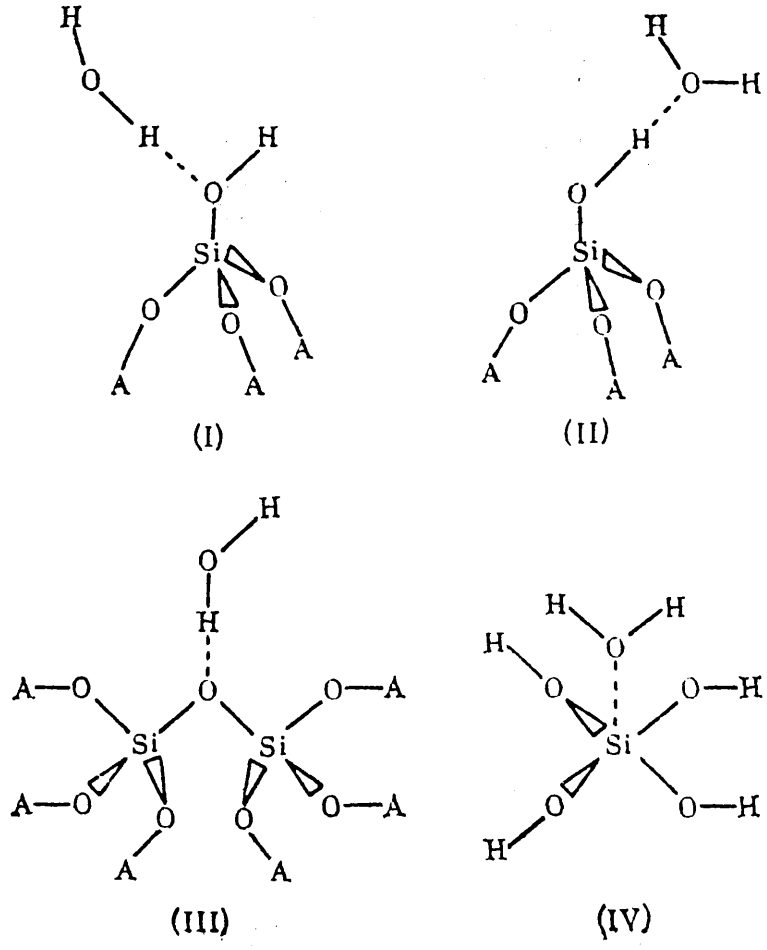

**Figure 1.** Cluster models of the possible forms of adsorption of $H_2O$ on an $SiO_2$ surface; here and subsequently, A represents a univalent pseudo-atom.

Quantum-chemical calculations of the synchronous mechanism of the surface reactions of isotopic H/D exchange between a terminal OH group in $SiO_2$ and molecules of water and hydrogen have been carried out.[23] A systematic study of the influence of change in the acidity of the hydroxide group on the reaction of isotopic H/D exchange with water has been carried out.[63] The most important conclusion from these studies was that the energy barriers of these mechanisms are comparatively low, so that these processes can take place at low temperatures. It was found that the lowest energy corresponds to a transition state with $C_{2v}$ symmetry (compared with $C_{3v}$ symmetry). The extension of this conclusion to other systems indicated, for example, that isotropic exchange between the hydroxide group and an acetylene molecule (where the formation of a $C_{2v}$ transition state is possible) should take place more readily than the corresponding reaction with an ethylene molecule (where only a $C_{3v}$ transition state can exist); this conclusion was subsequently confirmed by direct calculation.[64] The qualitative dependence of these mechanisms on the acidity of the surface group and on the properties of the molecule, obtained in these quantum-chemical calculations, may indicate directions for experimental studies.[63]

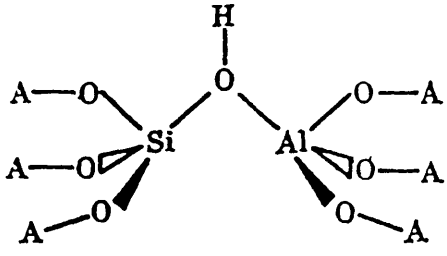

Figure 2. Cluster model of a Bronsted acidic centre in an aluminosilicate.

Quantum-chemical studies of the Bronsted acidic centres (BAC) and Lewis acidic centres (LAC) in aluminosilicates can now be considered. The simplest cluster that can be used to describe a bridging hydroxide group in aluminosilicates is shown in Fig. 2. The results of the calculation show that this group should have much stronger acidic properties than a terminal OH group in $SiO_2$ (estimated from the energy of removal of a proton). In the cluster calculation it was shown that change in the chemical composition of the second sphere (relative to the OH group; for example, by replacing Si by Al + H) leads to an appreciable decrease in the acidity of the OH group; this calculation naturally requires expansion of the cluster shown in Fig. 2. Systematic calculations of this kind, together with allowance for Loewenstein's rule, made it possible to interpret the change in the Bronsted acidity in a series of zeolites with different Si/Al ratios.[65]

Cluster calculations (CNDO/BW method) of the chemisorption of $H_2O$ [59] and $NH_3$ [61] on bridging OH groups in aluminosilicates have been carried out. A non-empirical method has been used[66] to calculate the chemisorption of $H_2O$ on the bridging groups in aluminosilicates. It may be noted that even in the case of the adsorption of the strong base $NH_3$ on an acidic bridging hydroxide group, the calculation does not indicate that the formation of an isolated $NH_4^+$ ion (that is transfer of a proton to $NH_3$) is possible. Preliminary results indicate that this form can be stabilised only by the two-point adsorption of $NH_4^+$ on basic centres of the surface. This indicates the possibility of the easy formation of carbonium ions in these systems, often postulated in the discussion of the mechanisms of acid catalysis. At low degrees of covering, when the effects of solvation in the adsorption layer can be neglected, proton transfer to organic molecules (alcohols, alkenes) should apparently require appreciable expenditure of energy. This in turn raises the question of the possible competition from a synchronous mechanism in these reactions, particularly at lower temperatures.

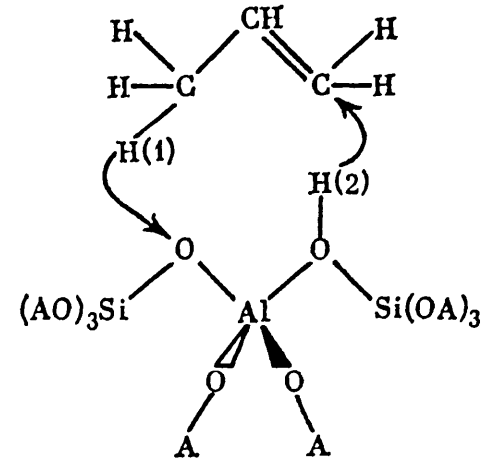

Figure 3. Cluster model of the mechanisms of the isomerisation of propylene on an aluminosilicate surface.

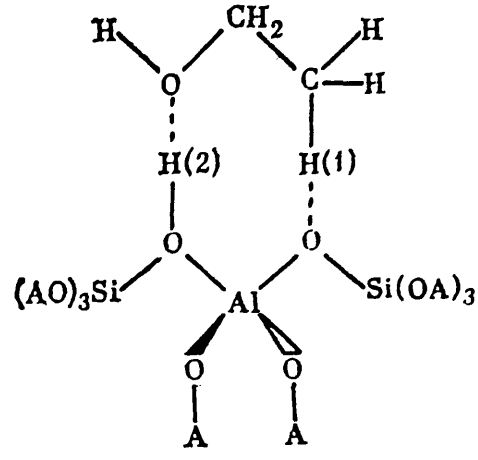

Figure 4. Cluster model of the synchronous mechanism of the dehydration of $C_2H_5OH$ on an aluminosilicate surface.

The carbocation, carbanion, and synchronous mechanisms of the displacement of the double bond in alkenes, catalysed by a birdging hydroxide group in aluminosilicates, have been compared.[67] The cluster examined is shown in Fig. 3; the carbocation mechanism corresponds to the initial displacement of the atom H(2), the carbanion mechanism to the initial

displacement of the atom H(1), and the synchronous mechanism to their simultaneous displacement. The synchronous mechanism of the dehydration of ethanol on the same BAC (Fig.4) has been examined.[68]

As noted above, the most interesting conclusions from these studies are those on the possibility (or difficulty) of the synchronous mechanisms, the factors favouring them (for example the appropriate geometry of the adsorption centre), and the prediction of various qualitative relationships. The latter include, for example, the conclusion that these mechanisms depend comparatively little on the acidity of the hydroxide group; this can be understood qualitatively if account is taken of the fact that the synchronous mechanism involves an acid–base pair, and that a change in acidity in one direction produces changes in the opposite direction in the characteristics of the basic centre, so that there is effective compensation.

The theoretical estimation of the relative specific catalytic activity (within a given system) of different active centres of the same kind, for example BAC, having different structures, is of undoubted interest for catalysis. In addition to a comparison of the strengths of different active centres, this also requires the estimation of their relative concentrations, and definite information on the mechanism of the reaction. The first attempt of this kind at a semi-quantitative level was made[69] in a comparison of BAC of three types in aluminosilicates: a bridging hydroxide group, a water molecule coordinated to an Al atom, and an adsorbed hydroxonium ion. A cluster scheme was used for this calculation. It was concluded that the first two BAC have comparable activities, whereas the concentration of hydroxonium ions is too low. All the studies were carried out for the dehydration of butanols. A quantum-chemical study of different possible BAC in aluminium phosphates, with analogous formulation of the problem,[70] led to the conclusion that the formation of bridging hydroxide groups in these systems is unlikely. In agreement with experiment, the calculation predicts the formation of terminal P–OH groups in these systems. The cluster approach was used to compare the strengths of the BAC in aluminosilicates and aluminium phosphates, and it was concluded that the bridging OH group in aluminosilicates is more acidic than the P–OH group in aluminium phosphates.

A separate series of studies deal with the cluster modelling of the LAC in aluminosilicates.[71–73] It was shown that the exposed three-coordinate Al(1) atom in the pyramidal configuration (see Fig.5) shows all the characteristic properties of an LAC;[72] It has a low-lying unoccupied orbital, localised mainly on Al, and it shows qualitatively the chemisorption properties characteristic of LAC. Estimation of the energies of both molecular and dissociative adsorption on this centre (for $H_2O$, $NH_3$, and $CH_3OH$ molecules), however, gave an unexpectedly high value (several hundred kJ $mole^{-1}$). The calculation was carried out by the CNDO/BW method. Non-empirical estimates led to essentially the same conclusion.

As noted subsequently,[73] however, the chemisorption properties of Al in an oxide lattice may change considerably as a result of the structural coordination of anions. It is possible to have a situation in which only activated adsorption is realised. This last case is illustrated in Fig.5; the localisation of Al in position 2 is energetically more favourable, due to the structural coordination of Al in the lattice. An adsorbed molecule can stabilise the Al atom in position 1, but the change Al(2) → Al(1) generally requires passage over an energy barrier.

It is thus possible to reach the general conclusion that the types of LAC depend markedly on the rigidity of the lattice, and that there is probably extensive dispersion of the properties of the LAC even within a given system; the conclusion that activated adsorption is possible may be the subject of directed experimental studies. A comparison of the strengths of the structural coordination of Al in aluminosilicates and aluminium phosphates[70] indicated that the LAC are stronger in aluminosilicates.

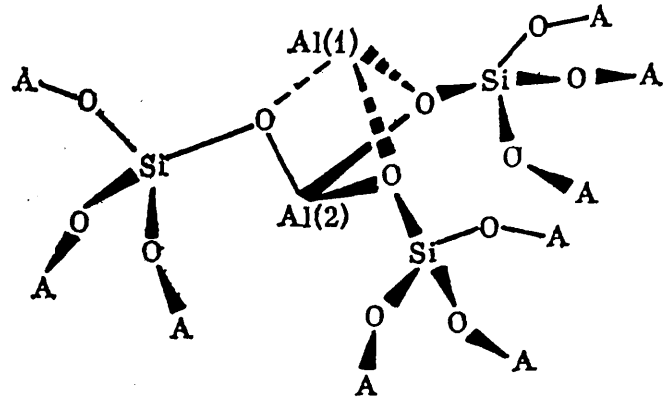

**Figure 5.** Cluster model of a Lewis acidic centre in an aluminosilicate.

The development of the concepts of structural non-rigidity in the systems being considered made it possible to approach in slightly non-traditional fashion the question of the quantum-chemical estimation of the thermal stability of zeolites.[74] Here, the usual approach involves the isolation of the weakest element of the structure. In zeolites, this element is the donor–acceptor bond Al...O. In quantum-chemical calculations, the difference in the strengths of the Si–O and Al–O bonds is revealed, for example, in the difference in the Wiberg indices $P$ of these bonds. By calculating the change in the Wiberg indices $P_{AlO}$ for different forms of zeolite structure, it should be possible to follow the nature of the change in the stability of the zeolite structure. This approach was widely used, for example, in a series of studies[75–78] on the cluster modelling of the structural rings in zeolites, where the influence of the chemical character of the central cation and its effective charge were examined. Although this approach undoubtedly has advantages, it essentially ignores the fact that the stability of a given structure is determined not only by its strength but also by the presence (or absence) of other structural conformations with similar energies.

The examination of the problem of the thermal stability of zeolites by comparing the energies of competing structures opens up new possibilities;[74] in particular, it leads immediately to the conclusion that boralites are less stable than zeolites.

Another type of active centre in zeolites may be cations in cation positions (zeolite windows of different types). These centres have been the subject of an extensive series of studies by Beran and co-workers.[76–78] The calculations were carried out by the CNDO/2 method, and clusters modelling the four- and six-membered "windows" in zeolites and the cations inside them were examined. It is not possible to analyse this entire cycle of studies in the present review; some references to these studies have been given above, and they are examined in more detail in Ref.33.

Finally, brief mention may be made of quantum-chemical calculations on active centres, chemisorption, and reactions in other oxides. As already noted, the cluster modelling of the surface centres of oxide lattices with high coordination numbers encounters certain difficulties. (This feature apparently explains the comparatively small number of calculations of this kind.) An example of this type is the $Al_2O_3$ surface. In this case, quantum-chemical methods have been used to study the properties of the surface hydroxide groups, and also LAC, associated with surface oxygen vacancies. An orbitally stoichiometric cluster, combining Al atoms in octahedral and tetrahedral positions, was used[79-81] to study various surface defects and their chemisorption properties. It was established that the formation of oxygen vacancies leads to the appearance of LAC. The adsorption of $H_2O$, HF, KOH, and $NH_3$ was examined. The calculation showed that fluorination increases the strength of the Lewis activity, whereas the addition of alkali and ammonia weakens it, in agreement with the experimental data. The same approrch was used[81] to examine the dependence of the Lewis acidity on the degree of dehydroxylation of $\gamma$-$Al_2O_3$.

Different defect centres in $Al_2O_3$ have been discussed[82,83] using simple ionic clusters and the EHM and the $X_\alpha$–SW method. Cluster calculations (CNDO/2 method) and a simple qualitative quantum-chemical scheme have been used[24] to carry out a systematic examination of the dependence of the frequency of the $\nu_{OH}$ stretching vibrations of the surface hydroxide groups on $Al_2O_3$ on their immediate environment. The cluster approach (CNDO/2 method) has been used[84] to calculate the chemisorption of ethanol on $\gamma$-$Al_2O_3$; molecular adsorption and two forms of dissociative adsorption were examined.

The possibility of the dissociative adsorption of $H_2$ on an MgO(001) surface has been discussed;[85] the calculations were carried out by a non-empirical method using a minimum ionic cluster. Account was taken of the Madelung field. It was concluded that the dissociation of $H_2$ on a defect-free MgO surface is impossible.

Transition metal oxides form a large and important class of catalysts. Quantum-chemical calculations of the surface centres and reactions on these systems are only beginning. Examples include the examination of clusters modelling the $V^{5+}$ ion in a tetrahedral and octahedral environment of oxygen ions.[86,87] In these studies, the nature of the electron rearrangements taking place on excitation into the singlet and triplet states was analysed. This problem was formulated in relation to various problems in photocatalysis.

An attempt has been made[88] to use the cluster approach to study the reaction of NO with $NH_3$ on a vanadium oxide surface; the CNDO/2 method was used. Different chemisorption structures and a successive series of states along the reaction path were examined; it was concluded that the Eley–Rideal mechanism applies. An unsatisfactory feature of the calculation is that the "pendent valencies" of the cluster were saturated using H atoms, which can hardly be justified for this system. The fact that the results did not change significantly on going to a larger cluster, however, indicates that the qualitative conclusions are correct.

Deposited systems may provide an extensive field of application for quantum-chemical methods, but few studies have as yet been carried out.[89,90]

---o0o---

To summarise, it can be stated that the application of the methods of quantum chemistry in the theory of surface phenomena and catalysis has now developed into a separate branch of science with its own methodology, experience, success, and failure. This field is now being very actively developed. It is faced with severe methodological problems, associated with the need to improve the calculation schemes (in particular the cluster approximation) and to increase the efficiency of the programs (primarily for non-empirical calculations and calculationd by the $X_\alpha$–DV method). Considerable effort is also required to determine the optimum directions for these studies in catalysis. The latter to a large extent depends on progress in the experimental study of the mechanisms of catalytic reactions, and should be carried out in close contact with experiment.

An increase in the mutual influence of quantum-chemical and kinetic studies can be expected. The greatest problems and the greatest progress in the application of quantum-chemical methods in the study of chemisorption and catalysis are undoubtedly still in the future.

# Physical Methods for the Investigation of Catalysis *in situ*

O.V.Krylov and A.D.Berman

The principal problems and certain examples of the application of physical methods for investigations in the course of catalysis are examined. The methods for the investigation of the role of phase transformations in heterogeneous catalysis and the application of infrared spectroscopy to the study of surface compounds are considered in greatest detail.
The bibliography includes 65 references.

III. Application of infrared spectroscopy in kinetic studies 169

## I. INTRODUCTION

The state of both the active catalyst surface and of the structure of its bulk phase differs under the conditions of catalysis from the corresponding state before and after catalysis. The chemical and phase compositions of the catalyst can change during catalysis. The study of the structure of the surface layer and of the bulk-phase and surface phase transformations of the catalyst is essential for the understanding of the nature of selectivity in complex catalytic processes and for the elucidation of the causes of the non-stationary phenomena in heterogeneous catalysis. Hence the necessity for the application of physical (spectroscopic, structural, etc.) methods to direct investigations during the course of the catalytic reaction is evident.

It is possible to distinguish two main problems for the solution of which one employs physical methods in investigations *in situ*, i.e. directly under the conditions of the catalytic process.

1. The elucidation of the structure of the active centre and of the phase composition of the catalyst and also of the changes undergone by them during catalysis.

2. The elucidation of the structure of the surface compounds formed by the reactants and of their role in the catalytic reaction.

X-Ray diffraction analysis, Mössbauer spectroscopy, EPR and other methods are used for the solution of the first problem, while the second problem is solved most successfully by infrared spectroscopy.

In terms of the specific features of their application, the physical methods can be divided into stationary and non-stationary. In the former measurements are performed at a constant temperature and constant reactant concentrations under conditions where there are no changes whatever in the measured quantities as a function of time. In this case the decisive factor is the sensitivity of the method and (a less fundamental factor) the duration of the measurement. For this reason, a method such as, for example, Mössbauer spectroscopy, which requires a long time for the measurement of the spectrum is employed mainly under stationary conditions. The stationary methods make it possible to characterise the chemical or phase composition of the catalyst and the state of its surface in the course of the catalytic reaction. In principle, it is possible to identify also the surface compounds formed under stationary conditions.

By studying the dependence of the rate of the catalytic reaction on the concentrations of the surface compounds measured by physical methods under stationary conditions, it is possible to formulate certain hypotheses about the process mechanism. However, the stationary methods do not permit direct measurements of the rates of the processes occurring on the surface or in the bulk phase of the catalyst, without which it is frequently difficult to assess also their role in heterogeneous catalysis (for example, the involvement of the surface compounds in the reaction). The test of hypotheses about the mechanisms of catalytic processes frequently requires measurements or comparison of the rates of individual stages.

Non-stationary methods are used to solve problems of this kind†. In this case measurements are made of the rate of the catalytic reaction and of the concentrations of various structures in the bulk phase and on the surface of the catalyst under the non-steady-state conditions arising when several parameters are altered: reactant concentrations, temperature, etc. Together with sensitivity, the speed of the response of the apparatus is important in non-stationary measurements. The shorter the time constant of the apparatus the faster the stages susceptible to measurement and the greater the amount of information which can be derived, in principle, about the mechanism of heterogeneous catalysis. We shall consider certain examples of the application of physical methods in the course of catalysis.

This review covers studies where physical methods have been used to investigate the phase transformations of the catalyst and also the surface compounds formed directly under the conditions of the catalysis. The methods most widely used for such purposes are considered: X-ray diffraction analysis, Mössbauer spectroscopy, electron paramagnetic resonance, and infrared spectroscopy. The examples are selected in order to demonstrate specific features and the scope of the application of the physical methods *in situ* and also to reflect the most interesting, in our view, results obtained recently by these methods. More detailed information about the application of physical methods in catalysis can be found in other reviews, references to which are given in the text below.

## II. THE STUDY OF PHASE TRANSFORMATIONS IN HETEROGENEOUS SYSTEMS

### 1. X-Ray Diffraction Analysis

Studies of the changes in the phase composition of the catalyst under the conditions of catalysis present considerable difficulties. The standard high-temperature X-ray cameras are relatively unsuitable for this purpose. With

†The non-stationary methods are also referred to as response or transient methods.

such cameras, it is not always possible to heat the gas phase whose composition is to be monitored. Furthermore, the volume of the cameras is usually too great and precludes the rapid determination of the change in the composition of the gaseous medium as the phase composition of the catalyst is altered.

A differential flow reactor with a small volume (1 $cm^3$) has been developed for the study of the changes in the structure of catalysts during the reaction.[1] The X-ray reactor-camera can be charged with 0.5 g of the catalyst. The reactor has a beryllium window which is transparent to X-rays; at the outlet of the reactor-camera a gas chromatograph is mounted for the measurement of the composition of the reaction products. By recording the changes in the intensities of the individual lines in the X-ray spectrum of the catalyst in the reaction medium, it is possible to measure directly the kinetic parameters of the phase transformation under the conditions of the catalysis.

The study of complex catalysts of selective oxidation have shown that their phase composition, determined on rapid cooling to room temperature, differs from that under the conditions of the catalytic process.[1,2] This result, obtained for nickel molybdates, emphasises the need to investigate the phase composition of the catalyst in the course of the reaction.

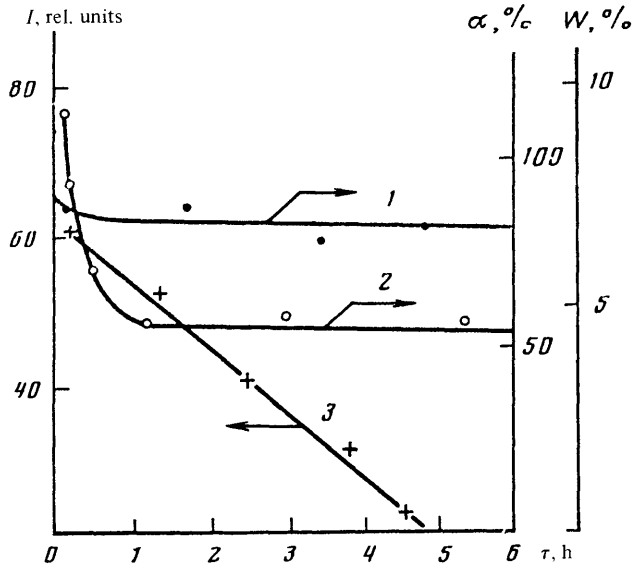

Figure 1. Variation of the degree of conversion α of propene (curve *1*), of the yield of $CO_2$ *W* (curve *2*), and of the intensity *I* of the principal line due to iron(III) molybdate (curve *3*) for the complex Co–Mo–Bi–Fe–O catalyst in the oxidation of propene to acrolein (according to the data of Shiryaev et al.[3]).

The method developed has been used[3] to investigate the phase transformations and rearrangements of the crystal structures of complex oxide catalysts ($Co_6Mo_{12}Bi_{1.0}$, $Fe_{1.5}O_x$, $Mg_6Mo_{12}Bi_{0.75}Fe_{0.35}K_{0.25}O_x$, $Co_6Mo_{12}Bi_{0.75}P_{0.25}O_x$, and $Mo_{12}Bi_{1.0}Fe_{1.5}O_x$) for the oxidation of propene to acrolein. Experiment showed that the iron(III) molybdate present in the complex multicomponent catalysts is reduced during the oxidation of propene at 623 K in a reaction mixture whose composition is stoichiometric for the mild oxidation of propene to acrolein ($C_3H_6:O_2:He = 1:1:8$). It is of interest that no reduction was observed in the experiments with pure $Fe_2(MoO_4)_3$ and mechanical mixtures of $Fe_2(MoO_4)_3$ and $Bi_2(MoO_4)_3$. Fig. 1 illustrates the variation of the contents of different phases in the complex catalyst under the conditions of the catalysis. The content of $Bi_2(MoO_4)_3$ hardly changes. The increase of the intensities of the lines due to cobalt molybdate β-$CoMoO_4$, which is isostructural with β-$FeMoO_4$, accompanied by the simultaneous decrease of the intensities of the $Fe_2(MoO_4)_3$ line indicates the reduction of ferric ions to the bivalent state. The virtually identical parameters of the unit cells of cobalt and iron molybdates lead to the superposition of their lines on the diffractometer traces. Fig. 1 shows that the time taken for the catalytic activity to reach a stationary level is 1–2 h under these conditions. After this, the catalytic activity does not change although the amount of iron molybdate continues to vary. The active centres on the catalyst surface are apparently formed before the rearrangement of the bulk-phase structure of the catalyst is completed.

The phase composition of the deposited $V_2O_5$–$SiO_2$ catalusts has been investigated in the oxidation of tetrahydrofuran (THF).[4] It was shown that the reduction with hydrogen or THF at 200 °C leads to the formation of the $V_4O_9$ phase. After exposure to a mixture of THF and oxygen at 200 °C for 16 h, $V_4O_9$ was also detected together with a small amount of the initial $V_2O_5$ phase.

A phase transition in the orthorhombic molybdenum oxide $MoO_3$ has been observed[5] when a mixture of methanol and helium was passed through the specimen. It was shown that this entails the formation of bronzes having the composition $H_xMoO_3$; dimethyl ether is formed from ethanol. The oxidation of methanol was observed in the $CH_3OH$–$O_2$–He mixture, but the content of the $MoO_3$ phase did not change.

## 2. Mössbauer Spectroscopy

It is possible to distinguish two ways in which Mössbauer spectroscopy can be applied in heterogeneous catalysis: (1) absorption spectroscopy based on the fact that the radiation emitted by a standard radioactive source is absorbed by the "Mössbauer" isotope in the specimen; (2) emission spectroscopy based on the fact that a radioactive isotope, which is in fact used as the source of radiation, is added to the specimen. In this case the radiation is emitted from the specimen itself and is then absorbed by a standard adsorbent containing the "Mössbauer" isotope. We shall examine certain examples of the application of Mössbauer spectroscopy *in situ*.

*(a) Absorption spectroscopy.* Mössbauer spectra were obtained for the first time in the course of a catalytic reaction in a study[6] of the oxidation of propene to acrolein in the presence of complex Co–Mo–Fe catalysts (the composition of the catalysts was indicated above in the description of X-ray diffraction analysis). The Mössbauer spectra were recorded *in situ* in a specially designed small cell (60 ml) which served at the same time as a flow-circulation reactor.[7] The design of the cells for the measurement of Mössbauer spectra *in situ* has also been described.[8,9] Fig. 2, illustrating typical spectra of the Co–Mo–Bi–Fe–O catalysts,[7] shows that under the conditions of the catalysis the singlet line characteristic of the crystalline garnet-like $Fe_2(MoO_4)_3$ is transformed into a four-line spectrum arising from two structurally non-equivalent positions of the iron atoms, Fe(1) and Fe(2), of iron(II) molybdate β-$FeMoO_4$ having the

scheelite structure. However, tervalent iron is also retained in the system, probably in a highly dispersed state, which is not detectable by X-ray methods.

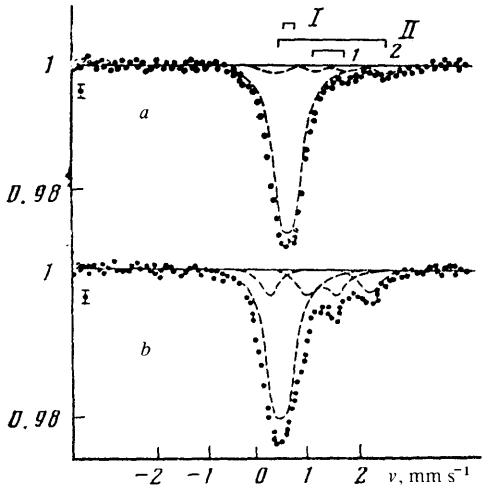

**Figure 2.** The Mössbauer spectra of the Co–Mo–Bi–Fe–O catalyst obtained at 623 K in a stream of $O_2$ (*a*) and in the $C_3H_6 + O_2$ mixture (*b*): I) $Fe_2(MoO_4)_3$ signal; II) β-$FeMoO_4$ signal [1) Fe(1) position; 2) Fe(2) position].

Fig.3 presents the temperature variation of the isomer shift (i.s.) in the Mössbauer spectrum of iron(III) molybdate and of the overall rate of oxidation of propene *w* in the presence of the same catalyst.[7] The continuous line represents the theoretical dependence of the isomer shift on temperature in terms of the classical Debye approximation. The arrows denote the boundary temperatures between the selective and extensive oxidation of propene, which are 680 ± 20 K: the mild oxidation of $C_3H_6$ to acrolein predominates at the lower temperature, while extensive oxidation predominates at the higher temperature. Fig.3 also indicates the values of the relative concentrations *r* of bivalent iron determined from the ratio of the area under the $Fe^{2+}$ spectrum to the overall area of the spectrum.

Fig.3 shows that, in measurements in air (curve *1*), the temperature dependence of the isomer shift is described satisfactorily by the theoretical curve. This can be said also of the experiments *in situ* at 300–520 K. However, at $T \geq 520$ K the isomer shift exhibits a striking anomaly, deviating from theoretical values and reaching a constant value of 0.52 ± 0.02 mm $s^{-1}$ in the region of selective catalysis. In the temperature range 520–680 K the variation of the isomer shift along the dashed curve in Fig.3 is reversible. At 680 K (the onset of extensive oxidation) significant changes take place in the catalyst. The fraction of β-$FeMoO_4$ increases abruptly (*r* rises from 10 to 35%). The temperature variation of the isomer shift is then described by another straight line whose slope differs sharply from the theoretical value. The latter dependence persists in the temperature range 300–750 K both in experiments *in situ* (under the conditions of the catalysis) and in air. The irreversible changes occurring at $T \geq 680$ K in iron(III) molybdate are confirmed also by X-ray data, indicating a change in its structure.

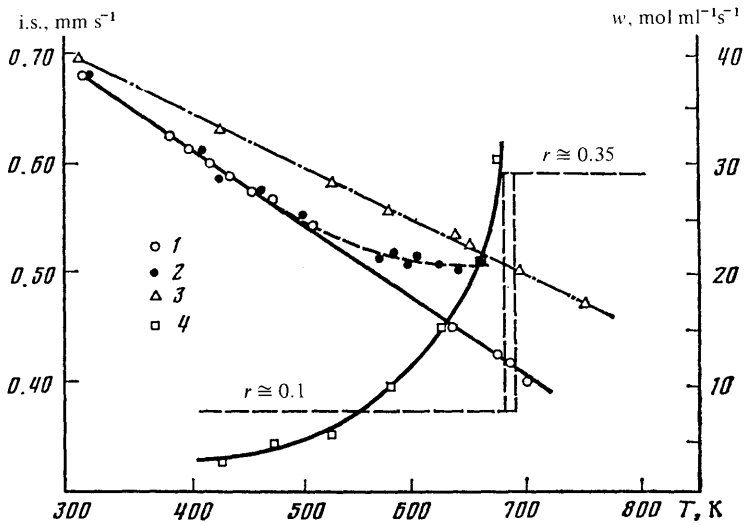

**Figure 3.** Temperature variation of the isomer shifts in the spectra of iron(III) molybdate obtained under static conditions in air (1), *in situ* in the selective oxidation region (2), and *in situ* after experiments at 680 K (3) and the temperature variation of the overall rate of oxidation of propene *w* (4) on the CoMo–Bi–Fe–O catalyst. The dashed band denotes the boundary temperatures between the mild and extensive oxidation processes; *r* = fraction of β-$FeMoO_4$ below and above the boundary temperatures (according to the data of Maksimov et al.[7]).

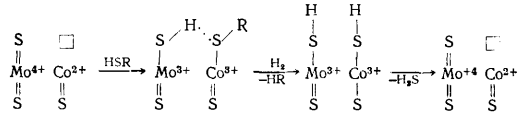
The results obtained[7] can be accounted for as follows. At the boundary of the iron molybdate crystal anionic vacancies are formed in the course of selective oxidation owing to the removal of oxygen from the $O_L$ lattice in accordance with the following scheme:

$$Fe_2Mo_3O_{12} \rightleftarrows [Fe_2Mo_3O_{12-x}\square_x]^* + xO_L ,$$

where $\square$ is an anionic vacancy. Thermally activated ionisation of the vacancies leads to the appearance of an excess negative charge, which influences the electronic state of the iron ions in the molybdate. In these experiments a change in the spectrum of the entire iron molybdate crystal is observed, indicating a rapid (over a period of $10^{-7}$–$10^{-8}$ s) shift of electron density in the excited $[Fe_2Mo_3O_{12-x}\square_x]^*$ crystal. The iron passes from the $3d^5$ state in the initial crystal to the $3d^{5+\Delta}$ state. The latter is intermediate between the state of iron in the oxidised and reduced iron(III) and iron(II) molybdates respectively.[7] At the iron molybdate–cobalt molybdate interface $Fe_2(MoO_4)_3$ is reduced to $FeMoO_4$, the structural correspondence of $\beta$-$FeMoO_4$ and $\beta$-$CoMoO_4$ promoting the formation of the nuclei of the $\beta$-$FeMoO_4$ phase. A concentration of vacancies $\square_x$ in excess of the equilibrium value is generated at the interface between the iron(II) and iron(III) molybdates in the course of the catalysis. The vacancies, diffusing towards the surface, can serve as centres for the dissociative adsorption of oxygen from the gas phase with formation of $O_L$. Oxygen is apparently absorbed on the $\beta$-$FeMoO_4$ phase. The non-equilibrium polarised $[Fe_2Mo_3O_{12-x}\square_x]^*$ structure constitutes an "arterial highway" supplying the necessary amount of $O_L$ to the active centres for the oxidation of propene to acrolein, which are located, according to the model proposed.[10,11] at the interfaces. In the region of extensive oxidation irreversible changes take place in the $Fe_2(MoO_4)_3$ phases. There is a sharp increase in the amount of $\beta$-$FeMoO_4$, which cannot be fully reoxidised. $C_3H_6$ is oxidised mainly by surface, possibly molecular, oxygen and not $O_L$, with formation of CO and $CO_2$.

The phase transformations in the reduction and reoxidation of the Fe–Mo–O catalyst with the ratio Mo/Fe = 2.4 have been investigated.[12] The reduction of the catalyst with methanol at $T$ < 553 K results in the formation of $\alpha$-$FeMoO_4$. If the specimen is then reoxidised at 600 K, a metastable phase appears, in which $Fe^{3+}$ in a high spin state is located in a distorted octahedron.



The variation of the composition of the $Fe/Al_2O_3$ catalyst for the Fischer–Tropsch synthesis has been studied.[13] The measurements were made in a steel cell with a beryllium window.[8] The apparatus made possible the mass-spectrometric analysis of the reaction products. It was shown that the rate of reaction in the reduced catalyst reaches a maximum during the first hour of the experiment and then falls. The Mössbauer method has been used to test the hypothesis that the activation of the catalyst is associated with the formation of carbides. Experiment showed that a mixture of the carbides $Fe_{2.5}C$ and $Fe_{2.2}C$ is formed in the presence of CO and $H_2$.

*(b) Emission spectroscpy.* Emission Mössbauer spectroscopy is frequently used to study cobalt-containing catalysts. Such catalysts do not contain an isotope which would permit the employment of the absorption spectroscopy. However, by adding the $^{57}Co$ isotope, it is possible to use it subsequently as a source of radiation in Mössbauer experiments. Information about the cobalt atoms is obtained by studying the signal of the $^{57}Fe$ isotope formed on decomposition of $^{57}Co$. The observed valence and spin states of $^{57}Fe$ can, however, differ from the states of the initial $^{57}Co$ isotope. One of the causes of this difference is that the Co and Fe atoms have different chemical and electronic properties. Furthermore, the decomposition itself can induce unstable but fairly long-lived ($10^{-7}$ s) changes in the environment of the Mössbauer nuclei.[9] A general consideration of the "after-effect" has been described.[14] In conducting materials it can be neglected but the "after-effect" is important in the case of insulators. For example, the $Fe^{2+}$ and $Fe^{3+}$ signals are observed[15] in the emission spectra of CoO, although only $Co^{2+}$ had been detected before decomposition.

However, the "after-effect" is unable to induce a significant displacement of the nuclei, for example, to cause the removal of $^{57}Fe$ from the lattice sites previously occupied by $^{57}Co$. The environment of the $^{57}Fe$ atom is almost identical with that of the $^{57}Co$ atom before decomposition, which makes it possible to employ the emission spectroscopy for the investigation of the catalyst structure. It has been established by this method that cobalt chromite $CoCr_2O_4$ has a direct spinel structure in which the $Co^{2+}$ ions occupy tetrahedral vacancies in the anionic sub-lattice, while the $Cr^{3+}$ ions occupy octahedral vacancies.[16]

In certain cases cobalt-containing phases can be identified by comparing the spectra of the catalysts with those of model compounds. As an example, we shall consider the study of Co–Mo sulphide catalysts for hydrodesulphurisation. It has been shown[9] that in the course of catalysis the Co–Mo–S phase is formed both in the catalysts deposited on the $Al_2O_3$ and in the non-deposited catalysts and has the $MoS_2$ structure. This conclusion is based on the analysis of the spectra of the catalyst obtained *in situ* and on the study of the spectra of a whole series of model compounds ($Co/Al_2O_3$, $CoMoS_4$, $Co_9S_8$, $Co_3S_4$).

A series of $Co–Mo/Al_2O_3$ catalysts with different Co/Mo ratios at a constant molybdenum content have been investigated.[17] The study of the Mössbauer spectra showed that cobalt can enter into three different phases: into the $Al_2O_3$, $Co_9S_8$, and Co–Mo–S lattices. A linear correlation has been obtained between the catalytic activity and the amount of cobalt in the Co–Mo–S phase. According to Topse and co-workers,[9,17] the mechanism of the hydrodesulphurisation is as follows:

Mössbauer spectroscopy is also used in the study of bimetallic catalysts.[18] In cases where one or both metals are active in the Mössbauer effect, it is possible to obtain information about the interactions of the metals with one another or with the carrier. Mössbauer spectroscopy is useful for the elucidation of the positions of the iron ions in the skeletons of zeolite catalysts and their migrations on dehydration of the zeolite. Information about these and other applications of Mössbauer spectroscopy in catalysis can be found in other reviews.[19,20]

### 3. The Method of Electron Paramagnetic Resonance

The EPR method is widely used in catalytic studies because of its sensitivity and the large amount of information which it yields. For example, the method makes it possible to investigate the interaction of oxygen radical-ions with hydrocarbons or the interaction of transition metal ions with the components of oxidation reactions.[21–23]

The difficulties in the employment of the method for the study of catalytic reactions *in situ* at a fairly high pressure, particularly for oxidation reactions, are associated with the broadening of the signal due to the surface ions and radicals after the physical adsorption of $O_2$, $H_2O$, and other molecules on the catalyst surface owing to dipole–dipole interaction. Surface ions or radicals have therefore hardly ever been observed by EPR under the conditions of stationary catalysis.

The EPR method can be used successfully in the study of exchange processes between the surface and bulk of the oxide. Thus it has been shown[24] that the appearance of active centres for the isomerisation of olefins on the $MoO_3$ catalyst is associated with the formation of anionic vacancies on the $MoO_3$ surface and the deactivation of the catalyst is associated with the diffusion of the vacancies into the bulk phase. The diffusion of the vacancies was followed from the EPR signal of the $Mo^{5+}$ ion stabilised in the vicinity of the vacancy.

The EPR method has been used[25] to investigate the phase transformations in $BaTiO_3$, which undergoes a transition from the tetragonal to the cubic phase at 120 °C. This transition could be observed by using impurity $Mn^{2+}$ or $Fe^{3+}$ ions as labels. Owing to local structural distortions in the tetragonal ferroelectric phase, the EPR spectral lines due to $Mn^{2+}$ are broadened, the signal intensity increasing almost by an order of magnitude after the removal of the distortions (on transition to the cubic paraelectric phase). The adsorption of various gases influences the phase transition temperature $T_C$. Only the cubic phase is catalytically active in relation to the oxidation of CO. At low temperatures (130–170 °C) the adsorption and catalytic properties of $BaTiO_3$ are fully determined by the impurity manganese ions. Following the adsorption of CO, the intensity of the EPR signal of the impurity $Mn^{2+}$ ion increases and the amount of $Mn^{2+}$ ions which have appeared is equivalent to the number of CO molecules removed in conformity with the equation:

$$CO + Mn^{4+} + O^{2-}_{surf} \rightarrow CO_2 + Mn^{2+}.$$

On the other hand, $Mn^{2+}$ ions disappear when $O_2$ is adsorbed:

$$2Mn^{2+} + O_2 \rightarrow 2Mn^{4+} + 2O^{2-}_{surf}.$$

A specific feature of the model proposed[25] is that the active centres are present not only on the surface but also in the bulk of barium titanate. The catalytic oxidation of CO takes place via an oxidation-reduction mechanism at a certain constant stationary concentration of $Mn^{2+}$ in $BaTiO_3$, which is determined by the depth of diffusion of the electrons from the $Mn^{2+}$ ions near the surface to the surface. The influence of the phase transition on the catalytic properties of $BaTiO_3$ is associated with the fact that electron transfer from the surface to the bulk phase is possible only in the paraelectric phase.

Another example of phase transformations in the course of the catalysis has been observed in the study of the oxidation of $SO_2$ to $SO_3$ in the presence of vanadium catalysts.[26] The change of the state of the vanadium ions on passing from the melt to the solid state has been followed by EPR. The deactivation of the catalysts and the long relaxation times of the rate of reaction are associated with this process. Studies of the application of EPR *in situ* have also been described in another review.[27]

### 4. Video-LEED—A New Method for the Investigation of Surface Phase Transformations

The methods examined above make it possible to investigate the changes in the bulk-phase structure of the catalyst. A new Video-LEED method (direct observations of the structure from the diffraction of slow electrons) has been developed recently[28,29] and has been used successfully to investigate the rearrangement of the (100) phase of platinum during the adsorption of CO and in the course of the oxidation of CO by oxygen. The method makes it possible to record simulcaneously the intensities of the signals from several two-dimensional structures. At coverages $\theta_{CO} < 0.5$, the $(5 \times 20)$ structure is stable, while at higher coverages the $(1 \times 1)$ structure is stable. The phase transition proceeds via a mechanism involving the formation and growth of nuclei. The transformations of these structures, which take place as the degree of surface coverage is altered, lead to auto-oscillations in the rate of oxidation of CO. A possible relation between the two-dimensional phase transformations and the non-stationary phenomena in heterogeneous catalysis has been indicated.[30] This relation was demonstrated experimentally for the first time by Thiel et al.[28]

We may note that the direct observation of the structure of the surface phase by the Video-LEED method under the conditions of the catalysis is possible only at fairly low pressures ($\sim 10^{-3}$ Pa), where the electrons probing the surface are not scattered by the gas. This applies also to other electronic methods for the study of the properties of the surface (X-ray and photoelectron spectroscopy, Auger spectroscopy, and energy loss spectroscopy with slow electrons), whose application to the study of adsorption and catalysis is still in the initial stage but is developing rapidly.

## III. APPLICATION OF INFRARED SPECTROSCOPY IN KINETIC STUDIES

In order to understand the mechanism of catalysis, it is extremely important to have information about the structure and properties of the surface compounds. It is also important that such data should be obtained directly in the course of the catalysis. Such a possibility is provided, in principle, by infrared spectroscopy. The method yields most information in cases where it is possible to determine quantitatively the concentration of the surface compounds to measure the rate of their formation and consumption, and to compare it with the rate of the catalytic reaction.

In this section we shall consider mainly studies in which infrared spectroscopy was used in kinetic investigations. We shall deal with problems associated with the limitations as regards sensitivity and deviations from the Bouguer–Lambert–Beer law. Other reviews[31–34] have been devoted to other aspects of the application of infrared spectroscopy in catalysis.

In the study of the kinetics of heterogeneous processes, it is essential that the cells used as reactors should make it possible to obtain spectra under the conditions of the catalytic process and should permit a reliable determination of its rate. The present cell designs enable us to carry out catalytic reactions in cells at high temperatures[35] and pressures.[36,37] The flow cells operate under the conditions of a differential reactor for low degrees of conversion. A design for a gradient-free reactor with circulation of the reaction mixture has also been proposed. Since discs containing 20–100 mg of the catalyst are normally used in

infrared spectroscopy, the sensitivity of the detectors usually used for the gas phase may prove inadequate for the detection of the reaction products. In this case an additional amount of the catalyst can be included in the circulation system.[38]

The question of the sensitivity of the method is important. The extinction coefficients in the absorption bands of different functional groups or bonds in a molecule vary within the limits of 2–3 orders of magnitude. Approximate estimates have shown that, under most favourable conditions, concentrations of adsorbed substances of the order of $10^{12}$–$10^{13}$ molecules $cm^{-2}$ can be measured with the aid of conventional spectrometers (without Fourier transformation). In general, one may say that the method is applicable to catalysts with a high specific surface (10–100 $m^2\ g^{-1}$) when conventional spectrometers are employed. Fourier spectrometers, whose sensitivity is higher by two orders of magnitude, make it possible to investigate surface compounds also on industrial catalysts.

## 1. The Bouguer–Lambert–Beer Law

Quantitative measurements by the infrared spectroscopic methods are based on the Bouguer–Lambert–Beer law, from which it follows that the optical density $D$ is proportional to the concentration of the surface compound:

$$D=\varepsilon c l, \qquad (1)$$

where $l$ is the thickness of the disc (cm), $c$ the concentration of the surface compound expressed in terms of the number of molecules per unit volume of the specimen, and $\varepsilon$ the extinction coefficient (molecules$^{-1}$ cm$^2$). The extinction coefficient data for surface compounds are extremely limited; some can be found in Refs. 39–41.

We shall only note that the Bouguer–Lambert–Beer law does not always hold. For example, it is known that interactions between adsorbed molecules can lead to deviations from this law.[42] We shall consider certain experimental data concerning the validity of Eqn. (1) for surface compounds.

Intermolecular interactions are not apparently manifested for low coverages of zeolite catalysts. Thus it has been shown[43] that the Bouguer–Lambert–Beer law holds satisfactorily for formate and acetate complexes formed on interaction of formaldehyde, acetic acid, and acetaldehyde, with NaX zeolite (the concentration of the complexes did not exceed one molecule per cavity). Linear relations have been obtained[39] between the intensity of the absorption band at 1630 $cm^{-1}$ (of the C=C bond) and the concentration of butenes absorbed by NaY zeolite up to the concentrations corresponding to three molecules per large zeolite cavity. However, at high coverages the optical density is almost independent of the amount of butenes absorbed by the zeolite. The Bouguer–Lambert–Beer law holds also for formate complexes on $\gamma$-$Al_2O_3$ [40] at coverages of the order of $10^{13}$ molecules $cm^{-2}$, in the adsorption of CO on platinum deposited on aerosil,[44] and in the adsorption of CO on a number of oxides and zeolites.[45]

At the same time, it has been shown[46] that, for the methoxide ions (absorption band at 2830 $cm^{-1}$) on zinc oxide, the Bouguer–Lambert–Beer law holds only at low optical densities ($D < 0.25$). The interactions in the surface layer can also be manifested by a shift of the corresponding absorption bands as the surface coverage is altered. It has been shown[47,48] that the character of the interaction in the layer following the adsorption of CO on deposited platinum catalysts and in the oxidation of CO on the same catalyst is different. The authors[47,48] attribute this to the formation of "islands" of molecules adsorbed on the catalyst surface in the oxidation of CO. Inspection of literature data has shown that in most cases it is possible to distinguish a linear section on the relation between the optical density and the concentration of certain compounds. However, when quantitative measurements are made, the validity of the Bouguer–Lambert–Beer law must be tested.

We shall now examine certain experimental data obtained in the study of the formation of surface compounds during catalysis.

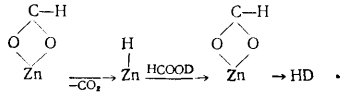
## 2. Stationary Measurements

Surface compounds have been detected by infrared spectroscopy in a whole series of studies under the conditions of stationary catalysis (see, for example, Bell[37]). However, it is difficult to reach a conclusion about the role of a particular surface compound in catalysis on the basis of stationary measurements, because dead end forms are possible.[37] Under stationary conditions, one can attempt, in principle, to establish correlations between the rate of reaction and the concentration of surface compounds at different reactant concentrations in the gas phase and at different temperatures. Such data might be employed to test kinetic equations. However, hitherto there have been few examples of studies of this kind. In an investigation of the Fischer–Tropsch synthesis on $Ru/Al_2O_3$, $Rh/SiO_2$, $Pt/SiO_2$, and $Pt/TiO_2$ deposited catalysts, no correlations whatever were found between the activity of the catalyst and the concentrations of the surface compounds detected.[49] We may note a study[50] in which it was shown that the rate of hydrogenation of ethylene on the $Pt/Al_2O_3$ catalyst is proportional to the product of the degrees of surface coverage by ethylene ($\theta_e$) and hydrogen ($\theta_H$). It was also found that $\theta_H$ and $\theta_e$ are functions of the ratio of the partial pressures $p_{H_2}/p_e$. In the synthesis of methanol from $CO_2$ and $H_2$ in the presence of catalysts containing CuO, ZnO, and $Al_2O_3$ a clear-cut dependence of the rate on the concentration of the surface formate complexes has been obtained.[51]

One may conclude that the study of the infrared spectra of the surface compounds under stationary conditions is undoubtedly useful. However, in the general case it does not permit a solution of the problem of their role in the catalytic reaction.

## 3. Non-stationary Measurements

Reliable conclusions about the involvement of surface compounds in a catalytic reaction can be reached when data are available for the rates of formation and consumption of these compounds relative to the rate of the catalytic reaction. An effective approach to the problem of identifying the real reaction intermediates involves the study of their dynamic behaviour under the reaction conditions.[52] In this case the experiment consists of the measurement of the concentration of the chemisorbed species under conditions involving sharp changes in the composition of the reactants (for example, when one of them is replaced by its isotopic analogue) and changes in the reaction temperature or the pressure of one of the reactants.



As stated above, a rapid response of the apparatus is important for non-stationary measurements. In the widely used infrared spectrometers without Fourier transform the usual rate of scanning employed to obtain a qualitative

spectrum does not exceed 100 $cm^{-1}$ $min^{-1}$ and the time taken to measure the spectrum in the frequency range 600–4000 $cm^{-1}$ is therefore 30–40 min. When the instrument is tuned to the maximum in a fixed absorption band, it is possible to record processes lasting ~1 s. The rate at which Fourier spectrometers respond can be altered within wide limits—from fractions of a second to several hours depending on the number of scans, which is determined by the required sensitivity of the apparatus. Reports concerning the development of an instrument specially designed for the study of rapid processes have appeared recently; the time taken to traverse half the scale is 0.02 s.[53] A modern apparatus for the study of non-stationary processes by infrared spectroscopy, consisting of an infrared spectrometer, a mass spectrometer and a computer, has been described.[53]

The infrared spectroscopic method is used under non-stationary conditions for the following purposes: (1) for the qualitative test of hypotheses concerning the process mechanisms; (2) for the determination of the kinetic parameters of individual stages occurring with the participation of surface compounds; (3) for a detailed investigation of the kinetics of heterogeneous reactions and for the construction of non-stationary kinetic models.

The decomposition of formic acid on alumina and on silica has been investigated.[52,54,55] It is known that the decomposition of formic acid on various metals and oxides leads to the formation of formate ions and it was assumed that formic acid decomposes via these compounds. However, it was shown with the aid of infrared spectroscopy that the rate of decomposition of formate ions on $Al_2O_3$ is lower by approximately two orders of magnitude than the rate of decomposition of formic acid at the same temperatures and for the same coverages.[52] Experiments were also performed on isotope exchange. After the attainment of the steady state, the formic acid having the composition DCOOD (used as the initial reactant) in the gas phase was rapidly replaced by HCOOH and the variation of the concentrations of the chemisorbed species was followed from the absorption bands at 2915 $cm^{-1}$ ($HCOO^-$) and 2220 $cm^{-1}$ ($DCOO^-$). If the formate ions are intermediates in the decomposition reaction of formic acid, then the $DCOO^-$ ions should be replaced by $HCOO^-$ at a rate equal to that of the catalytic reaction. However, this was not observed experimentally and it was therefore concluded that the decomposition of formic acid does not proceed via formate ions.

In the study of the decomposition of formic acid on zinc oxide at 448–493 K [54] surface formate ions were also detected. Experiments showed that the rate of decomposition is independent of the formic acid pressure and that the ratio of products $CO_2/H_2$ is unity when formic acid is present in the gas phase. On the other hand, when formic acid is removed (frozen out) from the system, the evolution of hydrogen ceases, while the evolution of carbon dioxide proceeds at the previous rate. HD was evolved in the decomposition of HCOOD on zinc formate. It was concluded that the formate ions on the surface of zinc oxide are intermediate species and the following mechanism was proposed for the decomposition of formic acid on ZnO:[55]

Non-stationary measurements have been used[36] to test the hypotheses of the adsorption or impact mechanisms of the oxidation of CO on the $Pt/SiO_2$ deposited catalysts. The surface concentration of CO was deduced from the absorption band at 2074–2080 $cm^{-1}$ (linear form). Fig.4 presents results obtained in experiments where a stream of oxygen was passed through the reactor after the preliminary adsorption of carbon monoxide. The curves describing the time variation of the degree of surface coverage $\theta_{CO}$ show an induction period, which depends on the flow rate. These data suggest that the reaction proceeds via an adsorption mechanism and the presence of the induction period is attributed to the liberation of sites for the dissociative adsorption of oxygen in the course of the desorption of carbon monoxide. The induction period shortens when the temperature is raised as a consequence of the desorption of CO. With increased flow rate, the induction period is also reduced, because the concentration of CO in the gas phase is diminished and the readsorption of carbon monoxide is retarded. Fig.5 presents the results obtained when a stream of CO is passed through the system after the preliminary adsorption of oxygen. Evidently, there is no induction period. The authors[36] explained these results by the establishment of a preadsorption state in the interaction of CO with the platinum surface. Carbon monoxide in this state can react with the adsorbed oxygen (modified impact mechanism) or can pass to a chemisorbed state. Afterwards there is also a possibility of reaction with the adsorbed oxygen (the adsorption mechanism).

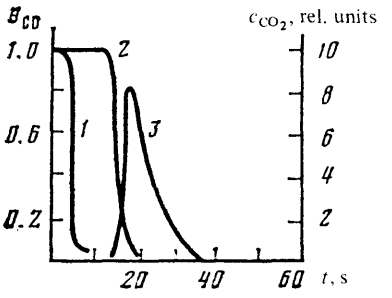


**Figure 4.** Interaction of oxygen with preadsorbed carbon monoxide on the $Pt/SiO_2$ catalyst at 160 °C: 1) and 2) variation of the degrees of surface coverage by CO at flow rates of 133 and 9.5 $cm^3$ $min^{-1}$; 3) variation of the concentration of $CO_2$ in the gas phase (according to Dwyer and Bennet's data[36]).

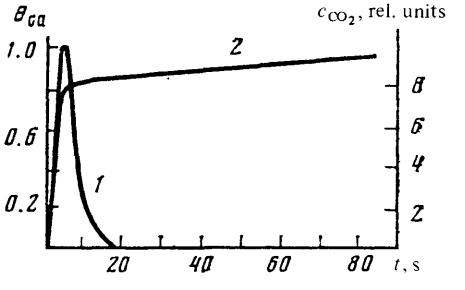

**Figure 5.** The interaction of carbon monoxide with preadsorbed oxygen on $Pt/SiO_2$ catalyst at 160 °C: 1) variation of the $CO_2$ concentration in the gas phase; 2) variation of the surface coverage by carbon monoxide (according to Dwyer and Bennet's data[36]).

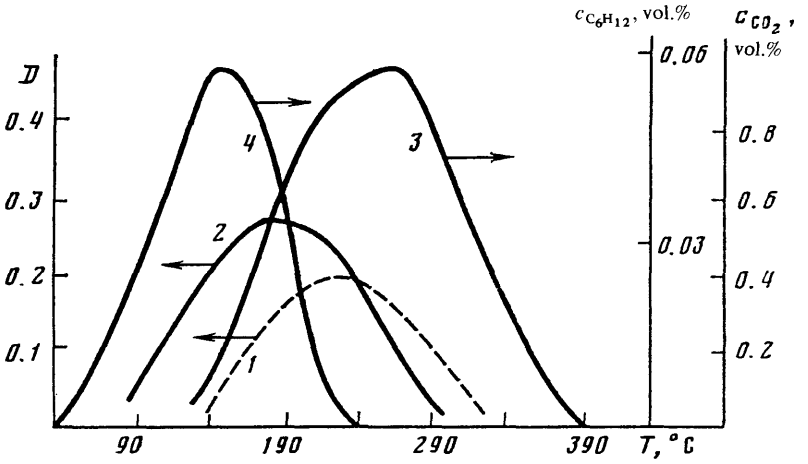

**Figure 6.** The oxidation of cyclohexane on NaX zeolite during programmed heating:[56] 1) and 2) variation of the optical densities in the absorption bands at 1620 and 1710 $cm^{-1}$ respectively; 3) and 4) variation of the $CO_2$ and $C_6H_{12}$ concentrations in the gas phase.

Interesting information can be obtained by combining the infrared spectroscopic and thermal desorption methods. As an example, we shall consider a study[56] of the oxidation of cyclohexane on NaX zeolite. In the course of the extensive oxidation of cyclohexane, carbonyl, formate, and acetate complexes were detected (bands at 1710, 1620, and 1580 $cm^{-1}$ respectively). Fig.6 illustrates the variation of the optical densities of the absorption bands of the surface compounds and the $CO_2$ concentration in the gas phase during programmed heated.[56] Evidently, the carbonyl and carboxylic complexes are formed and decompose at temperatures where $CO_2$ is evolved into the gas phase. These data agree with the hypothesis that the reaction proceeds via the complexes indicated.

The response method combined with infrared spectroscopy makes it possible in many instances to elucidate the mechanism of the reactions of the surface compounds. In particular, an attempt may be made to find the answer to the question whether the surface compounds are formed via a parallel or a consecutive mechanism. For this purpose, the concentrations of the starting materials in the gas phase are reduced sharply (almost to zero) under the conditions of the catalytic reaction. If the concentrations of some surface compounds then increase, while those of others decrease, we have evidence in support of the consecutive mechanism. On the other hand, if the concentrations of the surface compounds do not vary with time, one may use this as an argument in support of the parallel mechanism. It has been shown by this procedure[57] that carbonyl and carboxylate complexes are formed on NaX zeolite from adsorbed cyclohexane via a parallel mechanism. Similarly, it has been possible to demonstrate[58] that the oxidation of propene on the $Bi_2O_3$.MgO and $Bi_2O_3$.$MoO_3$.MgO model oxide catalysts leads to the formation of surface compounds (allyl, polyene, and carboxylate) also via a parallel mechanism.

The question whether the surface compounds detected by infrared spectroscopy are formed on the same or different centres is important for the construction of a kinetic model. If one of these compounds can be obtained on the surface in preliminary experiments, it is then possible to compare the rates of formation of the second compound on the initial catalyst specimen and on the specimen containing the first surface compound. Such data have led to the conclusion that the carbonyl and carboxylate complexes are formed on different centres in the oxidation of cyclohexane on NaX zeolite (Fig.7).[57]

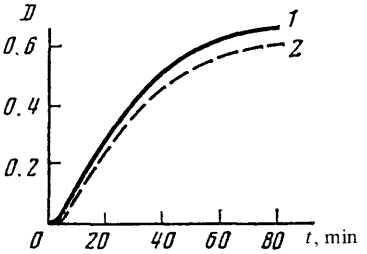

**Figure 7.** Time variation of the optical density in the 1710 $cm^{-1}$ absorption band at 368 K: 1) stream of cyclohexane directed to a conditioned NaX zeolite specimen; 2) stream of cyclohexane directed to the NaX zeolite after the preliminary formation of carboxylate complexes on the latter.[57]

In a whole series of studies the infrared spectroscopic method has been used to determine the rate constants and activation energies for individual stages of heterogeneous reactions. The effective activation energy has been found[59] for the overall process involving the hydrogenation and desorption of surface compounds formed in the hydrocracking of n-hexene on nickel and platinum. The activation energies for the oxidation of the carboxylate complexes formed in the oxidation of propene on $Cr_2O_3$ and NiO have been determined.[60] The results proved close to the activation energies for the oxidation of propene obtained in a gradient-free reactor. On this basis, it was concluded that the carboxylates are intermediates in the oxidation of propene on $Cr_2O_3$ and NiO and that the rate-limiting stage is the oxidation of the carboxylate. We may note that, generally speaking, comparison of the activation energies is insufficient to reach this type of conclusion.

The effective activation energies for the oxidation of the surface forms of CO adsorbed on CoO–MgO solid solutions and MgO have been obtained.[51,62]

The kinetics of the reactions of a series of surface compounds, namely π-allyl (1510 $cm^{-1}$), a polyene (1605 $cm^{-1}$), a carboxylate (1580 and 1430 $cm^{-1}$), and a propene degradation product (1340 $cm^{-1}$), formed in the oxidation of propene on the $Bi_2O_3$.MgO and $Bi_2O_3$.$MoO_3$.MgO model oxide catalysts, have been investigated[58] by infrared spectroscopy in the temperature range 200–400 °C. The introduction of molybdenum ions into the $Bi_2O_3$.MgO catalyst sharply reduces the activation energies for the formation and decomposition of the π-allyl complex.

Despite the comparatively large number of studies in which infrared spectroscopy was used directly in the course of catalysis, there have been almost no investigations in which the kinetics were studied in detail and a kinetic model constructed on the basis of the study of the surface compounds. One of the few examples of this kind involves the investigation of the oxidation of cyclohexane on NaX zeolite.[63,64] The authors of the review[63] studied the kinetics of the oxidation of the oxygen-containing complexes formed in the oxidation of cyclohexane under isothermal conditions and during programmed heating; the results are presented in Table 1. They made it possible to compare the rate of oxidation of the complexes with the rate of the catalytic reaction. The rate of oxidation of the complexes was calculated from the formula

$$w = \epsilon D_{st} k, \qquad (2)$$

where $D_{st}$ is the stationary optical density in the catalytic experiments, $k$ the rate constant for the oxidation of the corresponding complexes, and ε an experimental coefficient.

Table 1. The activation energies $E$ and the pre-exponential factors for the oxidation of the surface complexes.

| Complexes (spectral band) | $E$, kJ $mol^{-1}$ | | $k_0$, $s^{-1}$ | |
|---|---|---|---|---|
| | thermal desorption | isothermal experiments | thermal desorption | isothermal experiments |
| Carbonyl (1710 $cm^{-1}$) | 92 | 92 | $1.1 \cdot 10^7$ | $6.1 \cdot 10^6$ |
| Formate (1620 $cm^{-1}$) | 75 | 75 | $5.3 \cdot 10^4$ | $5.3 \cdot 10^4$ |
| Acetate (1580 $cm^{-1}$) | 63 | 63 | $3.4 \cdot 10^2$ | $2.2 \cdot 10^2$ |

For low degrees of conversion, the flow cell can be regarded as a differential reactor and the rate of extensive oxidation was therefore calculated from the equation

$$W = F c_{CO_2}, \qquad (3)$$

where $F$ is the flow rate and $c_{CO_2}$ the concentration of carbon dioxide in the gas phase.

The results of the comparison of the rates of the catalytic reaction ($w_{CO_2}$) and of the oxidation of the surface compounds—the carbonyls ($w_{1710}$), the formates ($w_{1620}$), and the acetates ($w_{1570}$)—are presented in Table 2. Their comparison shows that the overall rate of oxidation of the surface compounds $w_\Sigma$ is close to the rate of the catalytic reaction. One may conclude that the extensive oxidation of cyclohexane proceeds via the formation and oxidation of the carbonyl and carboxylate complexes and that the carbonyl complexes make the greatest contribution. A kinetic model, all stages of which have been demonstrated directly, has been proposed[64] on the basis of the results. The model reproduces correctly the changes in the concentrations of the surface compounds and the $CO_2$ concentration under non-stationary conditions; the stationary rates of reaction and the concentrations of the surface compounds also agree satisfactorily with the experimental values. The kinetic parameters of all the stages have been determined.

Table 2. Comparison of the rates of the catalytic reaction and of the oxidation of the surface compounds ($cm^3$ $min^{-1}$).

| $T$, K | $w_{1700}$ | $w_{1620}$ | $w_{1570}$ | $w_\Sigma$ | $w_{CO_2}$ |
|---|---|---|---|---|---|
| 493 | 0.07 | 0.02 | 0.007 | 0.09 | 0.13 |
| 513 | 0.13 | 0.03 | 0.08 | 0.17 | 0.13 |
| 533 | 0.22 | 0.04 | 0.01 | 0.27 | 0.27 |
| 568 | 0.32 | 0.06 | 0.013 | 0.4 | 0.34 |

---o0o---

In conclusion we may note that new vibrational spectroscopic methods are developing rapidly, including the characteristic slow electron loss spectroscopy (EELS), the inelastic electron tunnelling spectroscopy (IETS), and Raman spectroscopy with a laser source (laser-Raman), which is widely used in the study of surface compounds. However, the number of examples involving the use of these types of spectroscopy in studies directly under the conditions of catalysis is as yet small. Studies of catalysis *in situ* by infrared-Fourier spectroscopy have begun to be published recently.[53,65]

The experimental techniques for the investigation of catalysis by spectroscopic methods are developing rapidly. It is to be expected that the role of spectroscopic methods in the investigation of catalysis *in situ* will increase sharply as the sensitivity and rapidity of the response of the apparatus are improved.

# The Study of Heterogeneous Catalysis by Nuclear Magnetic Resonance

V.M.Mastikhin and K.I.Zamaraev

The use of modern NMR Fourier spectrometers to study heterogeneous catalysts and molecules adsorbed on their surface has been examined. Data obtained in the study of vanadium catalysts for the oxidation of sulphur dioxide; the state of aluminium and silicon in aluminium and silicon oxides and in zeolites; hydroxide groups; and platinum in deposited platinum catalysts, and also the first data on the $^{17}O$ NMR of oxide catalysts, have been summarised. The results of the study of adsorbed molecules, including the use of the high-resolution NMR spectroscopy of solids, have been discussed.
The bibliography contains 158 references.

## I. INTRODUCTION

Nuclear magnetic resonance (NMR) is one of the basic modern physical methods of study in chemistry. The high sensitivity to changes in the structure of molecules and to intermolecular interactions, the possibility of quantitative analysis, and the simplicity and reliability of the interpretation of the spectra have made NMR an important instrument in the study of the structure and reactivity of substances in solution.

In homogeneous catalysis, NMR has for a long time been widely used to establish the structure of catalytically active complexes, and to study ligand exchange, intramolecular rearrangements, inner-sphere and outer-sphere coordination of solvent molecules to molecules of the catalyst, the formation of intermediate complexes between the catalyst and the substrate, etc. (see the earlier review[1] and references therein). In heterogeneous catalysis, however, NMR has until recently been much less frequently used, since the study of solid catalysts and adsorbed molecules by this method is complicated by the much larger (by a factor of approximately $10^3$–$10^4$) NMR line width in the case of solids, compared with liquids. The marked broadening of the lines, firstly, decreases sharply the sensitivity of the method and, secondly, generally leads to a loss of information on the most important characteristics of the NMR spectra, namely the chemical shifts and spin–spin coupling constants. The decrease in sensitivity is particularly marked, since heterogeneous catalysts often consist of elements for which the nuclei of the magnetic isotopes either have low natural concentrations (for example 0.037% for $^{17}O$, 8.6% for $^{119}Sn$, etc.) or have a small magnetic moment ($^{27}Al$, $^{51}V$, $^{63}Cu$, $^{65}Cu$, $^{11}B$, $^{9}Be$, $^{71}Ga$, etc.). On the other hand, the study of adsorbed molecules is often made difficult by the small quantity of the substance being studied in the specimen.

At the same time, in principle, the NMR spectra of solids carry much more information on the structure of a substance than the spectra of liquids. This is related to the fact that many interactions which are averaged in liquids as a result of the thermal motion of the molecules are fully revealed in the spectra of solids; this makes it possible to obtain valuable information on the structure of crystals and the chemical bonding in them. For example, dipole–dipole interaction is not revealed in the spectra of liquids; in the case of solids, it carries information on the relative arrangement of atoms. Analysis of the temperature dependence of the dipole contribution to the line width makes it possible to study nuclear movements of different kinds in solids. Quadrupole interactions are also averaged in liquids, but their study in solids makes it possible to obtain information on the distribution of charges around a nucleus. In the spectra of liquids, the chemical shift is described by a single parameter, namely the isotropic magnetic shielding constant, whereas in the spectra of solids it is characterised by the three components of the magnetic shielding tensor, that is it contains much more information on the chemical bond than can be obtained from the NMR spectra of liquids.

A characteristic feature of NMR spectra is that in solids the interactions of different types often have similar orders of magnitude. Thus to obtain the required information it is necessary to separate from the spectrum the parameters characterising the interactions of a definite type. This makes it necessary to carry out additional experiments involving measurements at different frequencies and over a range of temperatures, the computer calculation of spectra, etc. The development of a new generation of NMR spectrometers which make it possible to carry out measurements in strong magnetic fields (~7 T) with Fourier transformation of the NMR signal, and also the use of different methods for decreasing the line width (the high-resolution NMR spectroscopy of solids), have led to qualitative changes in the possibilities provided by NMR in the study of heterogeneous catalysts and adsorbed molecules.

Most importantly, the use of strong magnetic fields and the rapid accumulation of signals by Fourier transformation, together with the marked increase in the volume of the specimen, has led to a sharp increase in the sensitivity of the method, making it possible to proceed to systematic studies of NMR involving the nuclei of various elements present in catalysts and adsorbed molecules. Fundamentally new possibilities for the study of catalysts appeared as a result of the application of the methods of the high-resolution NMR spectroscopy of solids, such as rotation of the specimens with a high frequency at the magic angle to the external field (MAS, or VMU in Russian) and the use of pulse sequences, which lead to a decrease in the line width in the spectra of solids. The use of these methods makes it possible to average some interactions, leaving others unchanged, and hence to analyse separately interactions of different types. In a number of cases these methods make it possible to obtain spectra with a resolution comparable with that of the spectra of liquids.

This considerable expansion of the possibilities provided by the method has led to the appearance in recent years of a large number of studies of adsorption and heterogeneous catalysis by NMR spectroscopy. The present review examines the principal results of studies in this field carried out in the period 1976–1983. Earlier studies were examined in earlier reviews.[2–4] The possibilities provided at present by NMR spectroscopy in this field are demonstrated, and new data on the structure of a number of important catalysts and on the mechanisms of adsorption and catalysis, obtained by this method, are also discussed.

## II. THE HIGH-RESOLUTION NMR SPECTROSCOPY OF SOLIDS

This rapidly developing branch of NMR spectroscopy[4–10] is extending considerably the possibilities provided by the method in the study of catalysts and adsorbed molecules.

The principles of the methods of high-resolution NMR spectroscopy of solids, most frequently used in the study of catalysts and adsorbed molecules, are described below.

### 1. The Principal Interactions in NMR Spectroscopy

The Hamiltonian $\mathcal{H}$ describing the NMR effect in solids consists of several terms:[11,12]

$$\mathcal{H} = \mathcal{H}_z + \mathcal{H}_Q + \mathcal{H}_D + \mathcal{H}_\sigma + \mathcal{H}_E + \mathcal{H}_{rf} \qquad (1)$$

Here, $\mathcal{H}_z$ is the Zeeman term characterising the interaction of the magnetic moment of the nucleus with the external magnetic field; $\mathcal{H}_Q$ the Hamiltonian of the quadrupole interaction, significant for nuclei with $I > 1/2$; the spectroscopic parameters determined by this term carry information on the electric field gradient at the point where the nucleus is situated; $\mathcal{H}_D$ the Hamiltonian of the dipole–dipole interaction; the parameters determined by it carry information on the relative positions of the nuclei; $\mathcal{H}_\sigma$ the Hamiltonian of the chemical shift characterising the shielding of the nuclei by electrons; measurement of the parameters determined by this term makes it possible to identify the chemical state of the atom; $\mathcal{H}_E$ the Hamiltonian describing the interaction of the magnetic moments of the nuclei with the magnetic moments of unpaired electrons; it is important for paramagnetic materials; the parameters determined by this term contain information on the relative positions of the nuclei and the unpaired electrons and on the nature of the chemical bond; and $\mathcal{H}_{rf}$ the Hamiltonian of the radiofrequency field used to observe the NMR (and to change the average values of the other terms in Eqn.(1)).

Since the terms of the Hamiltonian (1) depend on the angular coordinates in different ways, they change in different ways under the influence of molecular motion, as a result of rotation of the specimen, or under the influence of radiofrequency pulses. These changes depend on the frequency and anisotropy of the averaging action. The main idea in the high-resolution NMR spectroscopy of solids is to apply to the system of nuclear spins a strong perturbation organised in such a way as to suppress (average) some of the interactions, and hence to make it possible to study other interactions in purer form. If different perturbations are used, it is possible in principle to obtain detailed information on each interaction separately.

Before the methods of high-resolution NMR spectroscopy are described, the principal interactions of importance for the description of the NMR spectra of solids will be examined in slightly more detail; for simplicity, the treatment will be restricted to the case of diamagnetic crystals.

#### *a) Dipole–Dipole interaction*

The Hamiltonian of the direct dipole–dipole interaction in a strong magnetic field between nuclei having magnetic moments has the form:[11]

$$\mathcal{H}_D = \sum_{i<j} \frac{1}{2} \gamma_i \gamma_j \hbar^2 r_{ij}^{-3} (1 - 3\cos^2\theta_{ij}) [\vec{\mu}_i \vec{\mu}_j - 3(\mu_z)_i (\mu_z)_j] \qquad (2)$$

Here, $\gamma_i$ and $\gamma_j$ are the gyromagnetic ratios of the nuclei $i$ and $j$; $r_{ij}$ the distance between the nuclei; $\theta_{ij}$ the angle between the direction of the external magnetic field and the vector joining the nuclei $i$ and $j$; $\vec{\mu}_i$ and $(\mu_z)_i$ the vector of the magnetic moment of the nucleus $i$ and its projection on the direction of the external magnetic field; and $\hbar$ Planck's constant. The Hamiltonian of the dipole–dipole interaction depends markedly on the relative positions of the nuclei, so that the spectroscopic parameters characterising this interaction carry information on the relative positions of the nuclei in the solid. Movement of the nuclei leads to a change in $\mathcal{H}_D$ with time, and may change the NMR spectrum (if the frequency of the motion is sufficiently high). Thus the dipole–dipole interaction is also used to study dynamic processes in solids (diffusion, restricted rotation, etc.).

Studies using direct dipole–dipole interaction to obtain information on the positions of nuclei and on their motion in solids until recently made up the greater part of studies on the NMR spectroscopy of solids. In practice, however, the data obtained can be interpreted quantitatively in terms of interatomic distances usually only for solids with a simple structure or in those cases where the solid contains isolated groups consisting of a small number of nuclei, for which the Hamiltonian has a comparatively simple form. With increase in the number of interacting nuclei, the form of the spectrum becomes much more complicated, and its width increases. As a result of the strong orientational dependence of the Hamiltonian $\mathcal{H}_D$, the broadening of the spectra is particularly marked for polycrystalline specimens; in these cases the NMR spectrum is most frequently characterised by only a single parameter, the second moment of the spectrum. This field of study of usually called low-resolution NMR spectroscopy or broad line NMR spectroscopy.

#### *b) Chemical shielding*

The movement of the electrons surrounding the nucleus produces an additional magnetic field, which, combined with the external magnetic field $H_0$, creates an effective field $H_{\text{eff}}$ at the point where the nucleus is situated.[11] To take account of this fact, the magnetic shielding tensor $\hat{\sigma}$ is introduced into the expression for the Hamiltonian of the chemical shift:

$$\mathcal{H}_\sigma = -\mu(1 - \hat{\sigma}) H_0 \qquad (3)$$

The magnetic shielding tensor is a tensor of second rank; it is often also called the chemical shift tensor. It contains information on the electronic environment of the nucleus and on the chemical bonding in the crystal. The chemical shift tensor is described by six independent parameters—the three principal values of the tensor and the three angles which characterise the positions of the principal axes of the tensor relative to the axes of the crystal. It is possible to obtain all of these quantities only from the NMR spectra of single crystals. The spectra of polycrystalline specimens can give only three parameters—the principal values of the tensor $\hat{\sigma}$.

Systematic measurements of chemical shift tensors for solids became possible only after the development of the methods of high-resolution spectroscopy, since the chemical shifts are usually smaller than the dipole broadening, and therefore do not appear when ordinary methods are used to record the NMR spectra of solid specimens. In liquids, where the rapid molecular motion averages the dipole interactions, there are no obstacles to the measurement of the chemical shifts. The molecular motion averages the chemical shift tensor in such a way that only its average value is measured; even the average value of the tensor, however, is exceptionally informative.

The methods of the NMR spectroscopy of solids make it possible to measure all three principal values of the tensor $\hat{\sigma}$, so that more information is obtained. For example, the deviation of the electron density distribution round the nucleus from spherical symmetry is reflected in the difference between the principal values of $\hat{\sigma}$, whereas the average value of the chemical shift carries only indirect information on this deviation. In addition, measurements of the temperature dependence of the anisotropy of $\hat{\sigma}$ make it possible to detect and study various movements within solids, in particular anisotropic movements.

*c) Quadrupole interaction*

The Hamiltonian of the quadrupole interaction carries information on the electric field gradient $V$ at the point at which the nucleus with $I > 1/2$ is situated:[11]

$$\mathcal{H}_Q = \frac{e^2qQ}{4I(2I-1)}[3\hat{I}_z^2 - \hat{I}^2 + \eta(\hat{I}_x^2 - \hat{I}_y^2)] \qquad (4)$$

Here, $eq = V_{zz}$, $\eta = (V_{xx} - V_{yy})/V_{zz}$, and $eQ$ the quadrupole moment of the nucleus; the $z$ axis is directed along the external magnetic field $I_+ = I_x + iI_y$. The energy of the quadrupole interaction is usually much lower than the energy of the Zeeman interaction, and the influence of the quadrupole interaction on the spectra is revealed in first- and second-order perturbation theory. In first-order perturbation theory, the Zeeman levels are displaced by an amount which depends on the projection of the magnetic moment of the nucleus on the direction of the external field. This leads to the appearance of $2I$ lines in the NMR spectrum. For nuclei with half-integral spins, the central transition ($-1/2 \leftrightarrow 1/2$) remains unchanged in first-order perturbation theory. In second-order perturbation theory, the central transition is split, and its centre of gravity is displaced; the values of the splitting and the shift are inversely proportional to the magnitude of the external magnetic field.

The Hamiltonian of the quadrupole interaction may be so large that the displacements of second order will be close to (or greater than) the values of the chemical shift and the dipole contribution to the line width, particularly for measurements at low frequencies. The main difficulty in the recording of the NMR spectra when there are large quadrupole contributions is due to the marked broadening of the lines as a result of the non-uniformity of the electric field at different points in the specimen, and also as a result of the angular dependence of the energy of the quadrupole interaction (in the case of polycrystalline specimens). In these cases, for nuclei with half-integral spins, information can be obtained from measurements of second-order effects for the central transition.

## 2. Methods for Decreasing the Line Widths in the Spectra of Solids

*a) Rotation of the specimen at the magic angle*

Rapid rotation of the specimen about an axis directed at the so-called "magic" angle of 54°44', to the external magnetic field may lead to a considerable decrease in the line widths in the NMR spectra.[9,13-17] This follows from an examination of the expressions describing the Hamiltonians $\mathcal{H}_D$, $\mathcal{H}_\sigma$, and $\mathcal{H}_Q$ in Eqn.(1).

The Hamiltonian of the dipole–dipole interaction (2) can be considered first. When the specimen is rotated, the angle $\theta_{ij}$ between the external magnetic field and the vector $\vec{r}_{ij}$ depends on time, and the difference $(1 - 3\cos^2\theta_{ij})$ takes both positive and negative values. Analysis of expression (2) shows that rotation of the specimen about an axis coinciding with the direction of the field has no influence on the spectrum; rotation about an axis perpendicular to the field decreases the line width by a factor of 2; and rotation about an axis making an angle of 54°44' with the direction of the field ($\cos^2 54°44' = 1/3$) averages the dipole–dipole interaction to zero. The physical significance of this phenomenon is that when the rotation is sufficiently rapid, so that $h\nu$ (where $\nu$ is the frequency of the rotation, and $h$ is Planck's constant) is greater than the energy of the dipole–dipole interaction, the nuclei "feel" only the average value of the energy of the dipole–dipole interaction, which is equal to zero when the specimen is rotated at the magic angle. This leads to a marked decrease in the line width. On the other hand, as shown in Ref.13, the second moment of the spectrum remains unchanged when the specimen is rotated at the magic angle. As a result, the spectrum consists of a narrow central line and a system of side bands separated from it by distances which are multiples of the frequency of rotation.

Similarly, rapid rotation at the magic angle also averages the anisotropy of the chemical shift, giving an isotropic spectrum with an average value $\sigma = 1/3(\sigma_{zz} + \sigma_{yy} + \sigma_{xx})$.

The first-order quadrupole interaction is also effectively averaged when the specimen is rotated at the magic angle.[15] In contrast to this, the second-order quadrupole interaction is not completely averaged when the specimen is rotated in this way. In a number of cases this makes it difficult to obtain well resolved spectra.

The influence of molecular motion on the efficiency of the decrease in the line width as a result of rotation of the specimen at the magic angle has been studied.[17] The possibility of decreasing the line width depends on the type of molecular motion. If there is rapid restricted motion, for example random reorientation of the molecules or individual functional groups about a single axis, there is a partial decrease in the line width, and rapid rotation at the magic angle averages the remaining broadening. If however the molecular motion is completely random, but its rate is not sufficient to give narrow lines with widths close to the line widths in the spectra of liquids, then rotation of the specimen with a frequency of several kilohertz does not lead to a decrease in the line width. A decrease in width takes place if the frequency of the rotation is higher than the frequency of the molecular motion, which in most cases cannot be achieved in practice. This limitation in the production of high-resolution spectra also applies to other methods for decreasing the line widths in the spectra of solids.[2-5]

*b) Multi-pulse sequences*

In the case of very strong dipole interactions, when rotation of the specimen at the magic angle at attainable rates gives no result, the line width can be decreased using multi-pulse sequences.[2-5] In a multi-phase experiment, a four-pulse cycle is usually employed.[5] As a result, the average values of the Hamiltonians of the dipole and quadrupole interactions become zero. When a sequence of radiofrequency pulses is applied to a spin system, the nuclear spins begin to rotate about an axis making the magic angle with the direction of the field, and in the rotating system of coordinates the vector of the magnetisation of the system is oriented at this angle to the external field. As a result, the dipole–dipole interactions disappear. The Hamiltonian of the dipole interaction (2) can be represented as:

$$\mathcal{H}_D = \sum_{i<j} \gamma_i\gamma_j\hbar^2 r_{ij}^{-5}(\vec{r}_{ij}\vec{r}_{ij} - 3z_{ij}z_{ij})\,[\vec{\mu}_i\vec{\mu}_j - 3\,(\mu_z)_i\,(\mu_z)_j] \qquad (5)$$

In expression (5) the dependence of $\mathcal{H}_D$ on the coordinates of the vector $\vec{r}_{ij}$ and its dependence on the orientation of the spin moments are identical, so that rotation of the specimen and rotation of the nuclear spins at the same angle to the direction of the field lead to the same result.

The application of an appropriately selected sequence of radiofrequency pulses can reduce to zero not only the dipole–dipole interaction but also the first-order quadrupole interaction.[5] The effects of the chemical shift are preserved, although they are decreased by a factor of $3^{1/2}$, since the projection of the magnetisation vector on the direction of the external field is reduced by this factor. The spin–spin interaction via the chemical bond, which is independent of the magnitude of the angle, remains unchanged. Thus a sequence of radiofrequency pulses can be used to obtain high-resolution NMR spectra for solid specimens.

The efficiency of the decrease in the line width in multi-pulse experiments depends to a marked extent on the accuracy of the tuning of the pulses. Such factors as the finite length of the pulses, the non-uniformity of the radiofrequency field, the inaccuracy of the tuning of the phases, and the distortion of the form of the pulses have a marked influence on the width of the spectra obtained. These difficulties can be partly overcome by using complex sequences.[18,19] Almost all more complex pulse sequences are based on the four-pulse sequence in such a way that the experimental errors do not accumulate from one cycle to another.

The influence of various factors on the effective line width in multi-pulse experiments has been analysed;[18,19] it has been shown that the form of the high-resolution spectrum depends to a marked extent on the conditions of the experiment and even on the actual magnitude of the chemical shift. This may make it difficult to interpret the spectra and to determine the components of the shielding tensor. Another problem is that multi-pulse experiments do not completely eliminate heteronuclear dipole interactions, that is interactions between nuclei of different types. Like the anisotropy of the chemical shift, the heteronuclear dipole interaction decreases by a factor of $3^{1/2}$ in a four-pulse experiment. To suppress this interaction, it is necessary to use methods based on double resonance, for example cross polarisation.

*c) Cross polarisation*

Cross polarisation[20] is most widely used to obtain high-resolution spectra for $^{13}C$ nuclei. The method not only suppresses dipole interactions but also increases the intensity of the $^{13}C$ NMR signals by a factor of ~4 as a result of the transfer of polarisation from protons to carbon nuclei.

The first experiments to record NMR spectra using cross polarisation were described in Refs. 21 and 22. The method was subsequently improved considerably,[20] when it was shown experimentally that it is possible to suppress the scalar spin–spin and dipole interactions between spins of two kinds ($I_1$ and $I_2$) by recording the NMR spectrum of the spins $I_1$ under conditions in which the spins $I_2$ are irradiated by a strong electromagnetic field whose frequency is equal to their Larmor frequency. Under these conditions, not only are the scalar and dipole interactions between the spins $I_1$ and $I_2$ suppressed, but the relaxation time for the nuclear spins $I_1$ may also be decreased as a result of the exchange of energy between them. The recording time of the spectrum of the nuclei $I_1$ is preserved, so that the sensitivity of the method is increased as a result of accumulation of the signal.

In cross polarisation experiments, the scalar spin–spin and dipole interactions are completely suppressed, whereas the anisotropy of the chemical shift remains unchanged, so that it can be studied in pure form. As a rule, for $^{13}C$ nuclei the difference between the components of the chemical shift tensor reaches several hundred p.p.m. As a result, the spectrum is extended considerably over a wide frequency range. In this case it is possible to use a combination of cross polarisation and rotation of the specimen at the magic angle. This method often makes it possible to obtain for solid specimens spectra whose resolution is comparable with that of the spectra of liquids.

Thus special methods (rotation of the specimen at the magic angle, multi-pulse sequences, and cross polarisation) can suppress the interactions leading to line broadening and hence give high-resolution spectra for solids. The suppression of second-order quadrupole interactions presents the greatest difficulties. Here, the principal method involves increasing the resonance frequency by using stronger magnetic fields. It is also possible to use a method based on the recording of many-quantum transitions between levels which are not influenced by first-order quadrupole effects.[23-27] Dipole–dipole interactions can be suppressed fairly frequently by the above methods involving rotation at the magic angle, multi-pulse sequences, and cross polarisation.

## III. THE STUDY OF HETEROGENEOUS CATALYSTS

This section examines the results of the study of the structure of heterogeneous catalysts and their active centres by NMR involving the nuclei of different elements and the methods for decreasing the line width described in the previous section.

### 1. The $^{51}V$, $^{17}O$, and $^{23}Na$ NMR Study of Vanadium Catalysts for the Oxidation of Sulphur Dioxide

Oxygen-containing compounds of vanadium form part of many industrially important oxidation catalysts. The structure of the active centres and the mechanisms of the action of these catalysts have been insufficiently studied, however. The present section demonstrates for the example of catalysts for the oxidation of sulphur dioxide the possibilities provided by NMR using the nuclei of $^{51}V$ (natural abundance ~100%) and various other elements in the study of the structure and mechanisms of the production of vanadium catalysts.

The catalysts used to oxidise sulphur dioxide are sulphate and pyrosulphate compounds of vanadium and alkali metals, deposited on a porous carrier, usually silica gel or an aluminosilicate. X-Ray diffraction has shown that in these compounds, vanadium is surrounded by oxygen atoms forming a regular or distorted tetrahedron or a distorted octahedron.

$^{51}V$ NMR spectra recorded at low frequencies usually have a very complex form, because of the simultaneous influence of dipole and quadrupole interactions and chemical shift effects, which may be of the same order of magnitude.[28] On going to high resonance frequences $\nu_0 \cong 79$ MHz, achieved by using magnets with a field $H_0 \cong 7$ T, however, the influence of second-order quadrupole effects becomes insignificant, the spectra become much simpler, and it becomes possible to measure the anisotropy of the chemical shift.

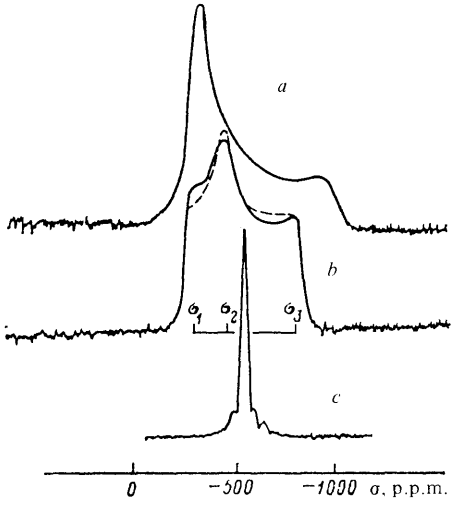

Figure 1. $^{51}V$ NMR spectra of vanadium compounds with different oxygen environments; the chemical shifts are given relative to $VOCl_3$;[29] *a*) $V_2O_5$ (distorted octahedron), *b*) $KVO_3$ (distorted tetrahedron), *c*) $K_3VO_4$ (regular tetrahedron).

The spectra of a number of individual vanadium compounds with known structures were studied first,[29] and it was shown for a large number of these model compounds that the anisotropy of the chemical shift can be taken as a characteristic of the structure of the oxygen environment of the vanadium atoms. Fig.1 shows typical $^{51}V$ NMR spectra for vanadium atoms in a regular tetrahedral environment (orthovanadates and pyrovanadates), in a distorted tetrahedral environment (metavanadates), and in a bipyramidal (distorted octahedral) environment (vanadium pentoxide, sulphate vanadates). For ortho- and pyrovanadates, the spectrum is almost isotropic. The spectrum of metavanadates indicates triaxial anisotropy of the chemical shift tensor (the corresponding spectrum, obtained by calculation using the optimally selected values of $\sigma_1$, $\sigma_2$, and $\sigma_3$, is given by the broken line in Fig.1). Vanadium in a bipyramidal environment gives spectra with almost axial symmetry of the tensor $\sigma$. For alkali metal metavanadates, a correlation is observed between the anisotropy of the chemical shift and the degree of distortion of the tetrahedron.[29]

The $^{51}V$ NMR spectra of different industrial catalysts for the oxidation of $SO_2$ (KS, BAV, and IK-1 grades) before the catalytic reaction differ considerably and depend on the method used to prepare the catalyst. Treatment of the catalysts under the conditions of the catalytic reaction, however, smooths out these differences to a considerable extent.[30] Thus in all the catalysts studied, the active component is produced in the course of the actual catalytic reaction. Although the chemical character of the compounds responsible for the catalytic properties of vanadium catalysts has not yet been finally determined, some preliminary conclusions can be reached. Thus comparison of the $^{51}V$ NMR spectra of the catalysts with the spectra of sulphate vanadates (see Fig.2) shows that one of the principal components of the industrial catalysts is the sulphate vanadate $K_3VO_2SO_4S_2O_7$.

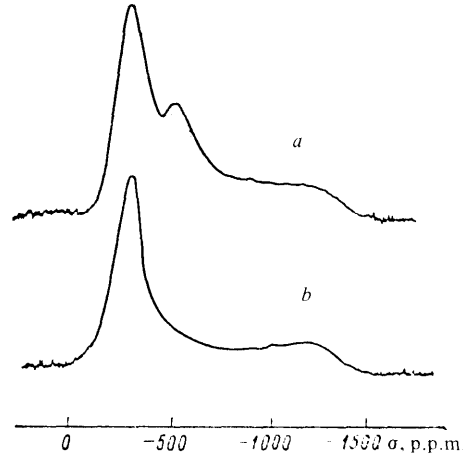

Figure 2. Comparison of the spectrum of the IK-1 catalyst for the oxidation of sulphur dioxide (*a*) with that of the potassium sulphate vanadate $K_3VO_2SO_4S_2O_7$ (*b*); the chemical shifts are given relative to $VOCl_3$.[31]

In addition to the lines from potassium sulphate vanadate, the spectra of the industrial catalysts usually show a line with $\sigma \cong -500$ p.p.m. relative to $VOCl_3$, characteristic of vanadium atoms in a regular tetrahedral environment (see Fig.2). This line has been assigned to vanadium atoms interacting with the carrier, silica gel or an aluminosilicate.[31] Thus vanadium pentoxide deposited on silica gel gave the same line;[31] its intensity increased with increase in the surface area of the silica gel for a constant quantity of vanadium pentoxide. Thus the carrier reacts chemically with the active component. Reactions of this type may be responsible for the fact that the catalytic activity depends on the type of carrier.

The spectra in Figs.1 and 2 were recorded at room temperature, at which the active component of the catalysts and the model compounds are solid. Under the conditions of the oxidation of sulphur dioxide (400–500 °C), however, the active component of the catalysts is in the molten state, and forms a very thin liquid film on the solid carrier. The chemical composition of the catalysts cooled to room temperature may differ from the composition at a high temperature. The spectra of the vanadium catalysts were therefore studied at 500 °C in an atmosphere of the reaction medium.[32]

The $^{51}V$ NMR spectra could not be observed at this temperature, because of the large width, apparently due to the short spin–lattice relaxation time of the vanadium nuclei. The melts were therefore studied by $^{17}O$ and $^{23}Na$ NMR. Fig. 3 gives the concentration dependence of the chemical shift and the line width for the $^{17}O$ NMR spectrum of vanadium pentoxide–potassium pyrosulphate melts, kept for a long time at 500 °C in an atmosphere of the equilibrium mixture $SO_3 \rightleftarrows SO_2 + \frac{1}{2}O_2$ at an $SO_3$ pressure of 400 mmHg.[32] The chemical shift and the line width depend markedly on the concentration of vanadium in the melt. This shows that a coordinate bond is formed between the pyrosulphate or sulphate anions and the vanadium cations. The nature of the relationships in Fig. 3 can be explained if it is assumed that in the melt there is exchange between sulphate and pyrosulphate anions not combined with vanadium and anions forming a coordinate bond with vanadium. The change in the slope of the lines in Fig. 3 at a vanadium concentration of ~1 M reflects a change in the state of the vanadium complexes, possibly as a result of their dimerisation.

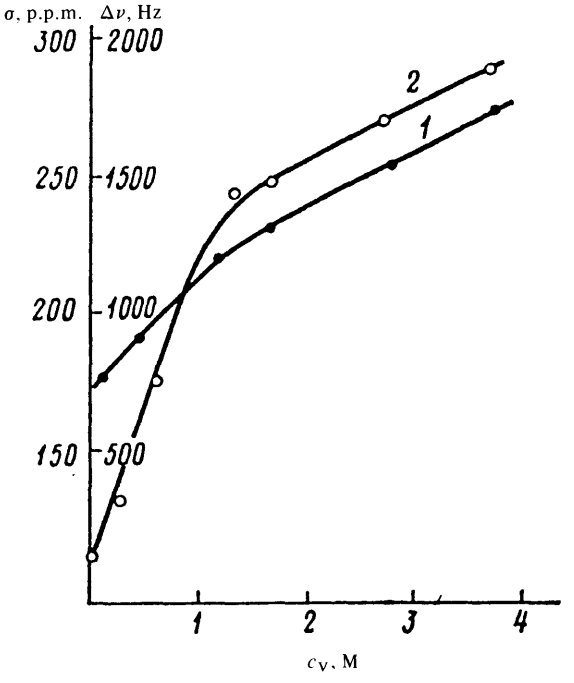

**Figure 3.** Dependence of the chemical shift σ (*1*) and the line width Δν (*2*) of the $^{17}O$ NMR spectra of the $K_2S_2O_7$–$V_2O_5$ system (500 °C, $SO_3$, $SO_2$, $O_2$ atmosphere) on the vanadium concentration; the chemical shift was measured relative to $H_2O$ at 25 °C.[32]

The replacement of potassium by sodium makes it possible to study the $^{23}Na$ NMR spectra of these melts.[32] Fig. 4 gives as a typical example the dependence of the $^{23}Na$ chemical shift on the ratio of the concentrations of sodium and vanadium, obtained for vanadium pentoxide–sodium pyrosulphate melts at 500 °C. These data indicate that sulphate (or pyrosulphate) compounds of vanadium are coordinated to some of the sodium cations. The relatively small changes in σ and the small line width (~300 Hz) agree satisfactorily with the model of outer-sphere coordination of the sodium ions.

Thus the study of vanadium catalysts for the oxidation of $SO_2$ shows that $^{51}V$ NMR can be used successfully to identify the vanadium compounds in heterogeneous catalysts and to detect chemical interaction between the active component and the carrier. $^{17}O$ NMR, even at the natural concentration of this isotope (0.037%), makes it possible to study melts of the active component of the catalyst directly under the conditions of the catalytic reaction.

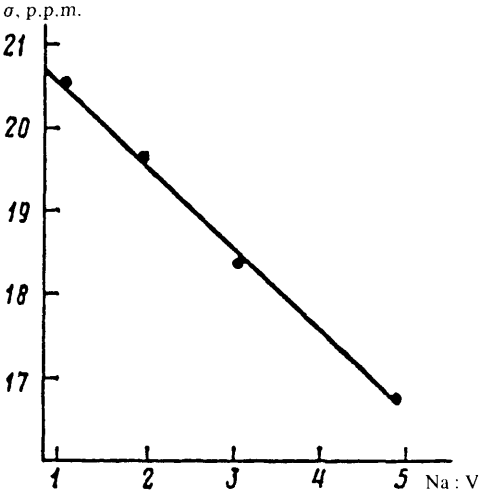

**Figure 4.** Dependence of σ on the ratio Na : V for an $Na_2S_2O_7$–$V_2O_5$ melt at 500 °C; the chemical shift was measured relative to NaCl.[32]

### 2. $^{27}Al$ NMR Studies of the State of Aluminium in Aluminium Oxides and Zeolites

Aluminium in an oxygen atom environment is present in many industrial catalysts. There is good evidence that it is often present in their active centres. The study of the state of aluminium in catalysts from the $^{27}Al$ (natural abundance 100%) NMR spectra is therefore of undoubted interest.

The spin of the $^{27}Al$ nucleus is 5/2. The $^{27}Al$ NMR spectra of powders usually show only the line from the central transition ($1/2 \leftrightarrow -1/2$), whose position is determined by the chemical shift and the second-order quadrupole effect. With increase in the working frequency ($\nu_0$), the chemical shifts increase in direct proportion to $\nu_0$, and the second-order quadrupole shifts decrease in inverse proportion to $\nu_0$. For example, for powdered zeolites and crystalline aluminium oxides even at $\nu_0 \cong 78$ MHz (magnetic field 7 T), the second-order shifts are much smaller than the line widths and the typical chemical shifts produced as a result of a change in the symmetry of the oxygen environment of the aluminium ions. The chemical shifts of aluminium in tetrahedral and octahedral oxygen environments in solution differ by 80 p.p.m.[33] For solids, the magnitude of σ also characterises the coordination state of aluminium, whereas the quadrupole coupling constant depends little on the aluminium coordination (oxygen tetrahedra or octahedra).[34] When the specimens are rotated at the magic angle, it is possible to obtain high-resolution $^{27}Al$

NMR spectra and to observe separately in these spectra the lines from aluminium in tetrahedral and octahedral oxygen environments. Methods for analysing the high-resolution NMR spectra for nuclei with a quadrupole moment have been developed,[35-38] and the principal methods for extracting the spectral parameters from the spectra of nuclei with a spin $I > 1/2$ have been described.

The review of the results of the study of the state of aluminium in heterogeneous catalysts by $^{27}Al$ NMR can begin with an examination of aluminium oxides.[39] Fig. 5 gives the spectra of powdered specimens of different crystalline aluminium oxides, and shows that rotation of the specimens at the magic angle leads to a marked decrease in the line width. For example, for $\gamma$-alumina the line width decreases by a factor of 6, and the two lines corresponding to tetrahedral and octahedral coordination of the aluminium atoms are resolved. Comparison of their positions with those of the lines for model oxygen-containing compounds of aluminium makes it possible to assign the weak-field line to aluminium atoms in a tetrahedral oxygen environment, and the strong-field line to atoms in an octahedral environment. This assignment is confirmed by the spectrum of $\alpha$-alumina, which, as expected from the known structure of this compound, consists of a single line whose chemical shift corresponds to that of aluminium atoms in octahedral coordination. The comparatively good resolution of the spectra makes it possible in principle to determine the relative concentrations of aluminium in octahedral and tetrahedral oxygen environments. Accurate quantitative measurements are difficult, however, since the rotation of the specimens leads to the appearance of side bands which partly overlap the line from the "tetrahedral" aluminium atoms. The side bands are marked with asterisks in Fig. 5.

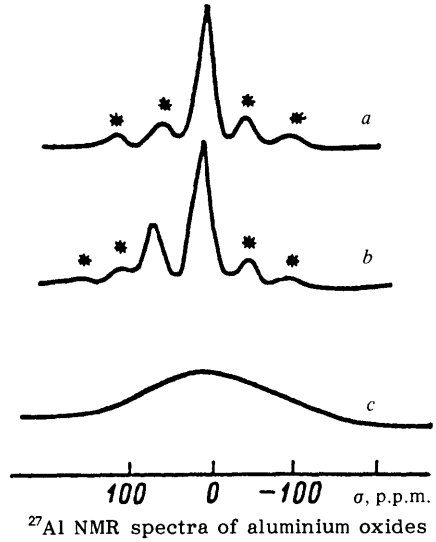

**Figure 5.** $^{27}Al$ NMR spectra of aluminium oxides with rotation of the specimen at the magic angle: *a*) $\alpha$-$Al_2O_3$, *b*) $\gamma$-$Al_2O_3$; *c*) $\gamma$-$Al_2O_3$ without rotation; the chemical shift was measured relative to $Al(H_2O)_6^{3+}$.[39]

In the case of zeolites, the lines from aluminium atoms in tetrahedral and octahedral oxygen environments can be resolved even without rotating the specimens at the magic angle.[30] The $^{27}Al$ NMR spectra[30] show that on hydrothermal treatment of $NH_4Y$ zeolite, which gives HY zeolite, some of the aluminium ions leave their tetrahedral positions in the zeolite lattice and move into cavities where they acquire octahedral coordination. Treatment of the specimens at a high temperature leads to breakdown of the zeolite structure, and a broad line appears in the spectrum.

Measurements of the integral intensity of the $^{27}Al$ NMR spectra have made it possible to determine the relative numbers of aluminium atoms remaining in the lattices of zeolites of types A and Y and displaced into cavities as a result of different forms of hydrothermal treatment and subsequent dehydration of the zeolites.[40,41] The zeolite specimens were placed in a solution of acetylacetone in ethanol, and the intensity of the broad signal from the aluminium atoms remaining in the lattice was compared with that of the narrow signal from the mobile aluminium atoms in the cavities. It was found that only a small proportion of the aluminium atoms (~10%) is displaced from the lattice when the specimens are treated in a shallow bed. When the specimens are treated in a deep bed, the number of aluminium atoms displaced from the lattice increases with increase in temperature. Thus after treatment of the specimens at 400 °C in a deep bed, ~50% of the aluminium atoms were displaced from the lattice. The high-resolution $^{27}Al$ spectra of zeolites which had been rehydrated after hydrothermal treatment and dehydration contained an additional line from the atoms of mobile hydrated aluminium displaced from the lattice. The proportion of this form of aluminium amounted to 70% of the total aluminium displaced from the zeolite framework after treatment at 300 °C. Increase in the temperature of treatment to 700 °C lowered this fraction to 3%. Comparison of the intensity of the $^{27}Al$ NMR lines with that of the $^{1}H$ NMR signals from the OH groups after treatment of the catalysts at different temperatures shows that the zeolite dehydroxylation scheme[42] which assumes that three-coordinate aluminium is formed is incorrect. In fact, dehydroxylation in water vapour takes place at the same time as the removal of aluminium.[40]

Comparison of the $^{27}Al$ NMR spectra of A, X, and Y zeolites established that the A zeolite does not contain Al–O–Al bonds; this confirmed that A zeolite obeys Loewenstein's rule.[43]

Thus the study of the high-resolution $^{27}Al$ spectra makes it possible to determine the coordination state of aluminium in oxides and zeolites and to follow the process of the removal of aluminium from zeolites. Further increase in the working frequency of the spectrometers should make it possible to use the $^{27}Al$ NMR spectra to distinguish tetrahedral aluminium atoms occupying different positions in a zeolite structure.

### 3. $^{29}Si$ NMR Studies of the State of Silicon in Silicate Systems

Silicon oxides, like aluminium oxides, are widely used in heterogeneous catalysis. The $^{29}Si$ isotope (natural abundance 4.7%) has a nuclear spin $I = 1/2$. There are therefore no quadrupole effects in $^{29}Si$ NMR spectra, so that it is usually simpler to obtain high-resolution NMR spectra of solid specimens for $^{29}Si$ nuclei, than for $^{27}Al$ nuclei.

One of the first applications of $^{29}Si$ NMR to the study of catalysts was an investigation of the surface of silica gel using cross polarisation and rotation of the specimen at the magic angle.[44] The use of these methods made it possible to observe in the spectra of silica gel lines with chemical shifts of −109.3, −99.8, and −90.6 p.p.m. relative to tetramethylsilane (TMS), whose intensities changed to different extents

with the transfer of polarisation from the protons to the silicon nuclei. From a comparison of these spectra with the spectra of silicate solutions, the lines with chemical shifts of −99.8 p.p.m. and −90.6 p.p.m. were assigned to the structures $HOSi(SiO_4)_3$ and $(HO)_2Si(SiO_4)_2$, and the line at −109.3 p.p.m. to $Si(SiO_4)_4$ groups. The first two structures correspond to surface silicon atoms joined to one or two hydroxide groups, and the third corresponds to silicon atoms in the volume. These results show that NMR can be used to distinguish chemically non-equivalent silicon atoms, and also surface and volume silicon atoms, in catalysts.

This approach was subsequently used to study the dehydration and rehydration of silica gel.[45] These processes depend markedly on the relative arrangement of the OH groups; $^{29}Si$ NMR was used to determine the quantity of geminal groups, that is structures of the type $(HO)_2Si(SiO_4)_2$. The results[45] showed that none of the previously proposed models explains all the regular features of the change in the structure of the surface during dehydration and rehydration. It was found that the silica gel surface is non-uniform, and may contain regions with structures resembling the (111) and (100) faces of cristobalite. It was concluded[45] that on regions of both types, the rehydration process is determined by kinetic rather than thermodynamic factors.

The possibilities provided by high-resolution $^{29}Si$ NMR spectroscopy for the determination of the ordering of silicon in silicates with different compositions have been demonstrated.[46] The $^{29}Si$ NMR spectra of the solutions and solids are similar, and depend on the condensation of the $SiO_4^{4-}$ tetrahedra. In aluminosilicates, the chemical shifts change regularly with change in the degree of replacement of silicon by aluminium in the tetrahedra closest to the $SiO_4^{4-}$ tetrahedron being considered. The spectra obtained for zeolites of type A showed that each $SiO_4^{4-}$ tetrahedron is surrounded by three $AlO_4^{5-}$ tetrahedra and one $SiO_4^{4-}$ tetrahedron, and that each $AlO_4^{5-}$ tetrahedron is surrounded by three $SiO_4^{4-}$ tetrahedra and one $AlO_4^{5-}$ tetrahedron (3 : 1 ordering). This arrangement of the tetrahedra does not obey the rule of alternation of aluminium–oxygen and silicon–oxygen tetrahedra (Lowenstein's rule,[43] noted above). It was therefore suggested[47] that the previously adopted model of the structure of the A zeolite is incorrect, and neutron diffraction and high-resolution electron microscope data were used to propose a new model for the structure of the A zeolite, containing Al–O–Al bonds.[47] This raised the question of the extent to which Loewenstein's rule can be used to analyse the distribution of aluminium in other zeolites.[48] Suggestions have been put forward on the possible reasons for the breakdown of this rule.

Subsequently, a more detailed study of the NMR spectra of ZK-4 zeolites, in which the aluminium atoms, as in the A zeolite, are present in double four-membered rings, showed that the $^{29}Si$ NMR spectrum depends not only on the number of neighbouring $AlO_4^{5-}$ groups but also on the Si–O–Si or Si–O–Al angle.[49] It was found that the strain of the bonds in structures with four-membered rings, which contain almost linear Si–O–Al bonds, leads to a displacement of the resonance compared with other structures with the same chemical composition. As a result, the signals which were previously assigned to Si atoms having three Al atoms in the second coordination sphere were found to belong to an Si atom joined to four Al atoms in neighbouring tetrahedra, as should be the case for a zeolite A structure obeying Loewenstein's rule.

The distribution of aluminium in X and Y zeolites has been studied in detail,[50,51] and it has been shown that the regular features of the change in the intensities of the lines in the $^{29}Si$ NMR spectra with change in the aluminium concentration obey Loewenstein's rule.

$^{29}Si$ NMR spectroscopy has been used[30,52] to study the displacement of aluminium atoms from the framework of zeolites of type Y on hydrothermal treatment. The high-resolution spectra of specimens from which aluminium ions have been displaced consist of four lines with $\sigma$ from −85 p.p.m. to −105 p.p.m. relative to TMS.[30] According to Ref.46, these lines correspond to Si atoms having 3, 2, 1, and 0 Al atoms in the second coordination sphere. Removal of ammonium ions from the zeolite leads to an increase in the intensity of the lines corresponding to the Si atoms with a smaller number of Al atoms in the second coordination sphere, and to a decrease in the intensity of the lines corresponding to a larger number of Al atoms in the second coordination sphere. This behaviour of the $^{29}Si$ NMR spectra confirms the displacement of the aluminium atoms from the zeolite lattice, detected from the $^{27}Al$ NMR spectra (see previous section).[30,52]

The $^{29}Si$ NMR spectra of Y zeolites from which aluminium ions had been displaced by thermochemical treatment in the presence of water vapour have been studied.[53] The spectra were used to calculate the concentration of $Si(O_4Si)_{4-n} \cdot (O_4Al)_n$ groups. The results show that the rate of the removal of aluminium increases with increase in the degree of replacement of $Na^+$ by $NH_4^+$ in the original specimens, and also with increase in the temperature of treatment and the partial pressure of water vapour.

The distribution of aluminium and silicon in the lattices of zeolites from which aluminium has been displaced influences their catalytic activity, adsorbing power, acidity, stability, etc. If the displacement of aluminium takes place at a sufficiently high temperature, the distribution of silicon and aluminium depends chiefly on the final ratio of the numbers of Si and Al atoms in the lattice, and not on the conditions and type of process involved in the displacement of aluminium.[54] For a given Si/Al ratio, the aluminium distribution was the same in zeolites obtained by direct synthesis and in specimens obtained by displacing aluminium, which had a higher initial aluminium concentration. Thus the final distribution of silicon and aluminium is not sensitive to the conditions of preparation of the specimen, and is determined by the minimum energy of the entire lattice. This indicates that there is a redistribution of the Si and Al atoms in the zeolite during the displacement of aluminium. If however the displacement of aluminium is carried out at relatively low temperatures, the lattice vacancies formed by the displacement of Al atoms are not occupied by Si atoms, and close to these vacancies there are four hydroxide groups (apparently one OH group next to each of the four neighbouring Si atoms). This follows from cross-polarisation experiments which showed an increase in the strength of the signals from Si atoms having one neighbouring OH group.[55]

The $^{29}Si$ NMR spectra have been used[56] to study the state of silicon in the lattices of ZSM-5 and ZSM-11 zeolites with different aluminium concentrations (the Si/Al ratio was varied from 30 to 1000). The line with $\sigma = -105$ p.p.m. was assigned to Si atoms joined to one Al atom in the second coordination sphere, since the intensity of this line decreased with decrease in the quantity of aluminium in the zeolites. The intensity of the line with $\sigma = -115$ p.p.m. in the spectra of the ZSM-11 zeolites was double that for the ZSM-5 zeolites. This made it possible to assign this line to Si atoms in four-membered rings, since the unit cell of the ZSM-5 zeolite contains four four-membered rings, and the unit cell of the ZSM-11 zeolite contains eight four-membered rings. The line with $\sigma = -103$ p.p.m. in the spectra of the ZSM-11 zeolites was assigned to silanol groups Si–OH. It was suggested[56] that the replacement of silicon by aluminium in these zeolites takes place in five-membered rings.

Thus high-resolution $^{29}Si$ NMR spectroscopy makes it possible to distinguish and identify different states of silicon in silicate structures, to obtain data on the distribution of silicon in zeolites, and to study surface Si atoms in silica gel and zeolites.

### 4. $^{195}Pt$ NMR Studies of Deposited Platinum

Since catalysts based on platinum are widely used in many industrial processes, the first papers on the use of $^{195}Pt$ NMR to study highly dispersed platinum deposited on aluminium oxide[57–59] are of considerable interest.

The $^{195}Pt$ nucleus (natural abundance 33%, spin 1/2) has the greatest Knight shift (3.37%) among metals, and this makes it possible to observe separately the signals from surface platinum atoms bonded to the carrier or to adsorbed molecules and from metallic platinum atoms in the volume. The very wide range of values of $\sigma$, the appreciable anisotropy of the chemical shift tensor, and the existence of platinum in a number of states on the surface are responsible for the appearance in the spectrum of a broad line from surface platinum atoms (~0.45 T). This is approximately $10^3$ times the typical line width in the spectra of solids. These exceptionally broad and therefore low-intensity lines have been recorded by accumulating the spin echo signals at a constant frequency with a gradual change in the magnetic field. Specimens with a platinum concentration of ~10% containing platinum particles with different dimensions were studied.[57] It was found that the form of the NMR line depends markedly on the average size of the particles and is sensitive to chemical treatment of the platinum surface. The spin–spin and spin–lattice relaxation times $T_1$ and $T_2$ changed on going from one region of the spectrum to another, but were the same for a given value of the magnetic field and for a given type of treatment of the surface, irrespective of the degree of dispersion of the specimens. The specimen with the largest platinum particles gave a narrow peak from metallic platinum.[57,58] After the specimens were treated with hydrogen or air, the spectra showed an intense peak with a chemical shift characteristic of diamagnetic platinum compounds. This peak was assigned to surface Pt atoms chemically combined with hydrogen or oxygen. Evidence in support of this assignment was provided by the long (~0.1 s) relaxation time $T_1$, whose dependence on temperature and on the field was different from that for metals.

For specimens of highly dispersed platinum on aluminium oxide after the chemisorption of carbon monoxide, the use of $^{13}C$ and $^{195}Pt$ double resonance made it possible to distinguish the signals from the Pt atoms in the surface layer and in the volume.[59] This is possible since irradiation of the specimen at the $^{13}C$ resonance frequency influences only the spectrum of those Pt atoms which are in direct proximity to C atoms. It was found that the magnitude of the spin–spin coupling constant between the carbon and platinum nuclei is similar to that of the corresponding constant for diamagnetic platinum carbonyl molecules. Thus carbon monoxide is bonded to deposited platinum through the carbon atom, as in platinum carbonyls.

### 5. $^{17}O$ NMR Studies of Oxides

Since oxide compounds are widely used as catalysts, the possibility of studying them by $^{17}O$ NMR is of considerable interest. The only oxygen isotope with a non-zero magnetic moment, $^{17}O$, has a very low natural abundance (0.037%). Until recently, therefore, $^{17}O$ NMR spectroscopic studies were carried out only for solutions and mainly using enriched specimens, and there were no published data on the $^{17}O$ NMR of crystalline specimens. Increase in the sensitivity of the method has made it possible to carry out routine measurements of the $^{17}O$ NMR spectra of solutions and to begin the $^{17}O$ NMR study of solid oxides.

The $^{17}O$ NMR spectra of MgO and $Ni_xMg_{1-x}O$ solid solutions with the natural concentration of the $^{17}O$ isotope were first reported in Ref.60. The chemical shift for oxygen in MgO was measured, and it was shown that the NMR parameters (line width, spin–lattice relaxation time) can be used to analyse the distribution of the paramagnetic $Ni^{2+}$ ions in the MgO lattice. In the analysis of enriched (enrichment in $^{17}O$ up to 20%) specimens of MgO, $SiO_2$, $\alpha$-$Al_2O_3$, and $CaMg.Si_2O_6$ [61] it was possible, using rotation at the magic angle, to resolve lines from structurally non-equivalent O atoms in the NMR spectra. Thus the spectrum of $CaMgSi_2O_6$ showed three lines from non-equivalent O atoms, whereas the $^{29}Si$ spectrum consisted of only a single line. The fact that the $^{17}O$ nucleus has a quadrupole moment makes it possible to obtain additional information on the symmetry of the environment of oxygen in the lattice by studying the quadrupole effects in the NMR spectra.

Thus the first studies of the $^{17}O$ NMR spectra of solid oxides demonstrate the possibilities provided by the method for structural studies based on the measurement of both the chemical shifts and the parameters of the quadrupole interaction.

### 6. $^{1}H$ NMR Studies of Surface OH Groups

The structure of the hydroxide covering of catalyst surfaces plays an important role in heterogeneous catalytic processes, so that it has been studied intensively by many methods, chiefly infrared spectroscopy.[62] A large number of studies have also been carried out by the traditional versions of NMR.[2] The use of the methods for decreasing the NMR line width makes it possible to observe separate lines from hydroxide protons of different chemical character, and this opens up the possibility of finding the relationship between the proton-donor properties of hydroxide groups and the nature of their chemical bond with the surface.

Thus the first papers[63,64] on the use of multi-phase sequences to study the OH groups of silica gel and aluminosilicates showed that this technique makes it possible to decrease the width and to measure the components of the tensor of the chemical shift for OH groups. For aluminosilicates, the free induction signal consisted of two components, one of which decreased more rapidly, and the other more slowly; the first component was assigned to OH groups bonded to aluminium, and the second to Si–OH groups. This made it possible to determine quantitatively the concentrations of OH groups of different types.

The proton resonance spectra of A-300 Aerosil dehydrated in a vacuum, with rotation at the magic angle, showed two lines with $\sigma$ = 2.0 p.p.m. and 2.9 p.p.m., corresponding to Si–OH and $Si(OH)_2$ groups respectively.[65] This made it possible to determine the concentrations of both types of group. When the specimen was kept in moist air, the spectrum showed new lines of two types, assigned[65] to water in hexagonal pores (signal with $\sigma$ = 1.1 p.p.m.) and water forming hydrogen bonds (signal with $\sigma$ in the range 4.2–4.4 p.p.m.).

For hygroscopic adsorbents and catalysts, the spectra of the OH groups are usually recorded in sealed ampoules, since atmospheric moisture adsorbed on the catalyst surface may distort the results considerably. The first studies of the NMR spectra of OH groups with rotation of the specimens

at the magic angle in sealed ampoules were described in Ref. 66. For silica gel it was possible to obtain a line width of 170 Hz, but the width was greater for the other specimens (~900 Hz for zeolites).

In the NMR spectra of the OH groups of HZSM-5 zeolites with different Si/Al ratios[68] without rotation of the specimen, the line width was ~4 kHz. With rotation of the specimen, the line width decreased by a factor of 6; this made it possible to resolve in the spectrum two lines with $\sigma = 1.4$ p.p.m. and 4.3 p.p.m. Since the intensity of the signal with $\sigma = 4.3$ p.p.m. increased with increase in the concentration of aluminium in the zeolite, this line was assigned to OH groups chemically combined with aluminium. The line with $\sigma = 1.4$ p.p.m. was assigned to Si–OH groups; this conclusion was confirmed by the fact that in the spectrum of silica gel the OH groups gave almost the same value of $\sigma$ (1.7 p.p.m.).[68] The spectra of amorphous aluminosilicates, including those of specimens with the same aluminium concentration as the HZSM-5 zeolites, did not show a line with $\sigma = 4.3$ p.p.m., corresponding to hydroxide groups joined to aluminium. This indicates that the concentration of these OH groups in zeolites is much higher than in amorphous aluminosilicates with the same composition. Phosphate catalysts contain several hydroxide groups of different types: P–OH and E–OH, where E is the second element in the phosphate. The lines with $\sigma$ in the range 3.1–4.4 p.p.m. are assigned to P–OH groups; the spectra of some specimens show lines due to P–OH groups forming a hydrogen bond, which displaces the signal of the OH groups to weak fields (the lines with $\sigma =$ 5.7 p.p.m. and 8 p.p.m. for $BPO_4$ and 5.8 p.p.m. for tin phosphate). The greatest shielding of the protons ($\sigma = -0.3$ p.p.m.) is observed for calcium phosphate; this possibly reflects the highly basic nature of the Ca–OH groups.

Comparison of the chemical shifts of the OH groups and the charges on the protons.

| OH group | $\sigma$, p.p.m. | $q$, e (Ref.68) | OH group | $\sigma$, p.p.m. | $q$, e (Ref.68) |
|---|---|---|---|---|---|
| $H^+$ ion in the gas phase | 31 (Ref.67) | 0.0 | Si–OH | 1.7 | 0.72 |
| P–OH | 3.1 | 0.7 | Al–OH | 1.2 | 0.76 |
| Al–O(H)–Si | 4.3 | 0.71 | B–OH | 1.1 | 0.76 |

Notation: $\sigma$ is the chemical shift relative to TMS, and $q$ the relative density of the charge on the proton.

The chemical shift in $^1$H NMR spectra is the sum of three components, produced by the effects of the shielding of the protons by the electron cloud (the so-called electronic component), the magnetic anisotropy of the chemical bonds, and the polarisation of the electron clouds by the charges of neighbouring ions. The values of $\sigma$ for OH groups of different kinds have been compared[68] with the values of the charges on the protons of the surface OH groups, calculated by the MINDO/3 method, which usually gives an accurate description of the charge distribution; the results of the comparison are given in the Table. The Table shows that the signal tends to be displaced to a strong field with increase in the negative charge on the proton. This may indicate that the change in the chemical shift is determined to a large extent by the change in the electronic component.

The $^1$H NMR spectra of ZSM-5 zeolites after thermal vacuum treatment at 200 °C and 350 °C have been studied.[69] These specimens contain hydroxide groups of two types; the weak-field signal was assigned to the protons of the Si–O(H)–Al group, and the strong-field signal to the protons of the Si–OH group.

The state of the protons in zeolite cavities has been studied.[70] The proton resonance signal after a $\pi/2$ pulse in hydrated NaA, NaX, and NaY zeolites at room temperature consists of rapidly ($\lesssim 100$ μs) and slowly ($> 1$ ms) damped components. The first component is assigned to the protons in β-cavities (cubo-octahedra); it was not clear whether the protons in these cavities belonged to water molecules or to OH groups. To investigate this question, sodalites, which contain only β-cavities, were studied. For these specimens, the signal contained only the rapidly damped component, and this made possible a more detailed study of the state of the protons in the β-cavities. It was found that the concentration of OH groups was only 0.5 per cubo-octahedron, and that they appear in the initial stage of the hydration of the zeolite after its activation at 400 °C. The number of OH groups does not increase with increase in the degree of filling of the zeolite cavities by water molecules, and is independent of temperature in the range between −150 °C and +150 °C. All the other protons belong to water molecules in the cubo-octahedra (~4 molecules per cubo-octahedron). The study of the temperature dependence of the spectra made it possible to follow the mobility of the water molecules.[70] In the comparatively short temperature range between −150 °C and 0 °C, the molecules undergo rapid anisotropic rotation; at a temperature above 0 °C the rotation becomes isotropic; and above 80–130 °C, translational movement of the water molecules between different cubo-octahedra takes place.

## IV. THE STUDY OF ADSORBED MOLECULES AND THEIR TRANSFORMATIONS

The high-resolution NMR spectra of adsorbed molecules can be obtained using the same methods of decreasing the line width as in the study of catalysts. The use of these methods is often made difficult, however, by the comparatively low concentration of adsorbed molecules. For this reason, in a number of cases, the NMR characteristics of chemisorbed species are obtained by recording the spectra under the conditions of the rapid exchange of molecules between the chemisorption centres and physical adsorption. A similar rapid-exchange procedure is widely used to study the complexes of reagents with metal-complex catalysts.[1] It makes it possible to determine the parameters of the low-intensity NMR spectra of chemisorbed species from the concentration dependence of the parameters of the overall averaged NMR spectrum of chemisorbed and physically adsorbed species. The intensity of this overall spectrum may be increased considerably by the high concentration of physically adsorbed species.

Rapid (on the NMR time scale) exchange between the chemisorbed and physically adsorbed states of molecules is encountered fairly frequently. The characteristic features of the analysis of NMR spectra under these conditions will be examined first, followed by an analysis of the results of NMR studies of specific adsorption and catalytic processes.

### 1. NMR Spectra with the Exchange of Molecules in the Adsorbed Layer

The principles of the analysis of NMR spectra with exchange in the adsorbed layer were developed in Refs.71–76. It is assumed that on a catalyst surface, molecules are present either in the chemisorbed state, which is characterised by a chemical shift $\sigma_A$ and a lifetime $\tau_A$, or in a state of weak physical adsorption with a chemical shift $\sigma_0$ and a lifetime $\tau_0$. It is also assumed that exchange takes place between these two states as a result of thermal motion. For long lifetimes, that is when $\nu_0(\sigma_A - \sigma_0) \gg \tau_A^{-1}$ and $\nu_0(\sigma_A - \sigma_0) \gg \tau_0^{-1}$, where $\nu_0$ is the resonance frequency of the nucleus, the NMR spectrum consists of the superposition of the signals from the two states. For short lifetimes, if the conditions $\nu_0(\sigma_A - \sigma_0) \ll \tau_A^{-1}$ and $\nu_0(\sigma_A - \sigma_0) \ll \tau_0^{-1}$ are fulfilled, an averaged spectrum will be observed, in which the chemical shift is the average for the molecules in the two states.

If the surface has only one type of chemisorption centre and if the number of adsorption centres $N_A$ is much smaller than the total number of molecules on the surface $N$, the expression for the chemical shift $\sigma$ has the form

$$\sigma = \sigma_A \frac{KN_A}{1 + KN} \qquad (6)$$

where $K$ is the complex-formation constant. The measured dependence of $\sigma$ on $N$ can be used to determine $K$ and the product $\sigma_A N_A$.

The chemical shift for a molecule in an adsorbed layer is often measured relative to the position of the line of the same molecule in the gas. In this situation, the interpretation of the results of the measurements is influenced considerably by the choice of the value of the chemical shift $\sigma_0$ in the "free" state. The chemical shifts of the same molecules in liquids and gases differ considerably as a result of intermolecular van der Waals interactions and self-association.[77,78] In the general case, the greatest differences (5 p.p.m.) are observed for the nuclei situated at the periphery of the molecule. The values of the shifts for the gas phase in the $^{13}C$ NMR spectra in the great majority of cases are displaced to a strong field compared with liquids. In the study of the chemisorption of molecules, the value taken for $\sigma_A$ is often the value of the chemical shift for the same molecules on inert carriers (that is carriers with practically no chemisorption centres), for example silica gel. With this choice of the value of $\sigma_0$, it is possible simultaneously to compensate to a considerable extent the influence of the magnetic susceptibility of the catalyst on the magnitude of the chemical shift of the signal of the adsorbed molecules relative to the molecules in the gas. Experiments have shown that the differences in the chemical shifts as a result of the differences in the magnetic susceptibilities of silica gel and the catalyst (if it is diamagnetic) are usually small (~0.5 p.p.m.).

### 2. $^{13}C$ NMR Studies of the Adsorption of Hydrocarbons and CO

The use of the resonance of the $^{13}C$ nucleus (spin 1/2, natural abundance 1.1%) has a number of advantages over proton resonance. $^{13}C$ NMR spectra have a much greater (by a factor of 20–30) range of chemical shift values, that is they are much more sensitive to a change in the electronic state of the molecule. This often makes it possible to observe a change in chemical shifts in $^{13}C$ NMR spectra in cases where a displacement of the lines in the proton resonance spectrum cannot be detected. On the other hand, the magnetic moment of the $^{13}C$ nucleus is smaller by a factor of ~4 than that of the proton. As a result, there is a decrease in the contribution of dipole interaction to the line width. At the same time the dipole interaction between the $^{13}C$ nuclei is small, because of their low natural abundance, and the dipole interaction of these nuclei with protons can be decreased considerably by broad-band suppression of the spin–spin interaction. Thus the $^{13}C$ NMR spectra of adsorbed molecules have a much higher resolution than the $^{1}H$ NMR spectra. This feature has led to the extensive use of $^{13}C$ NMR spectroscopy to study adsorption, in spite of the fact that, because of the low natural abundance, the intensity of the signal from the $^{13}C$ nuclei is smaller by a factor of approximately $1.8 \times 10^{-4}$ than that from the protons, and the relaxation times, which are much greater than those for protons, require long times for the accumulation and recording of the spectra.

The present section describes the results of the study of the adsorption of hydrocarbon and CO molecules by NMR without rotation at the magic angle. This method makes it possible to study comparatively weak forms of adsorption, when the adsorbed molecules are still able to move (movement over the surface or rotation), so that they have comparatively narrow NMR lines.

The first $^{13}C$ NMR spectra of adsorbed molecules were reported in Refs.79 and 80. The $^{13}C$ NMR spectra of adsorbed butenes and various other hydrocarbons have been studied.[79–84] A change in the chemical shifts and relaxation times was observed when butene isomers were adsorbed on zeolites.[80] The direction and magnitude of the shifts indicate that the electrons of the double bond take part in the interaction of the butenes with the surface active centres of the zeolites.

The spectra of toluene adsorbed on zeolites have been obtained.[82] The data on the chemical shifts of toluene and butenes adsorbed on zeolites were compared with the results of CNDO calculations. In the calculations it was assumed that the hydrocarbons interact with the sodium ions or OH groups of the zeolites. Agreement with experiment was not obtained, however, possibly because the quantum-chemical calculations were insufficiently accurate. The interaction of butenes with AgNaX and AgNaY zeolites has been studied,[83] and it was found that the chemical shifts are the same as those for the alkenes in aqueous solutions of silver salts. It was therefore concluded[83] that the butene molecules are adsorbed on the silver cation to form $\pi$-complexes. In Ref. 84, the $^{13}C$ NMR spectra were used for the first time to follow the isomerisation of but-1-ene into but-2-ene. Almost simultaneously, Gay[86] observed the spectra of carbon dioxide, ethylene, dichloroethane, ethanol, acetone, butenes, dimethyl ether, and hexane adsorbed on silica gel. In all cases the resolution of the $^{13}C$ NMR spectra was much better than that of the $^{1}H$ NMR spectra. For some molecules, changes in the chemical shifts (up to several p.p.m.) relative to the gas phase were observed.

$^{13}C$ NMR spectroscopy has been used[87] to study the adsorption of methane, carbon monoxide, acetylene, ethylene, propene, propyne, carbon oxide sulphide, propane, cyclopropane, and isobutane on NaA, NaX, NaY, and AgY zeolites and on silica gel. The influence of traces of iron in the catalysts on the line width of the adsorbed molecules was studied. At an iron concentration of $\sim 10^{-4}$ at.% it was possible to obtain very narrow lines (width ~10 Hz), and this made it possible to determine the changes in the chemical shifts (± 0.05 p.p.m.) and the spin–spin coupling constants (± 0.2 Hz) with a high accuracy. The magnitude of $\sigma$ was independent of the degree of covering. The shifts of the lines on adsorption on zeolites were attributed to interaction with surface centres—alkali metal cations and OH groups.

One of the main reasons for the change in the values of $\sigma$ for molecules in the adsorbed state is considered to be the influence of the electric field of the surface.[87] The decrease in the spin–spin coupling constant indicates an increase in the length of the C–H bonds in ethylene and propene when they are adsorbed on zeolites. Measurement of the temperature dependence of the line width and the spin–lattice relaxation time led to the conclusion that the mobility of the molecules in the adsorbed state is lower on HY zeolites than on NaY zeolites.

The spectra of a number of linear and cyclic alkenes adsorbed on zinc oxides have been studied.[88] For alkenes in whose molecules the double bond is readily accessible for interaction with surface atoms, the magnitude of $\sigma$ indicated that weak $\pi$-complexes are formed. In substituted alkenes there is steric hindrance to the formation of this bond. In Ref.88, as in most early work, the dependence of the chemical shifts on coverage was not studied, so that the conclusions reached about the relative strength of the bonds formed by different alkenes with the active surface centres of zinc oxide (assumed to be $Zn^{2+}$ ions on the surface) require verification.

The adsorption of butenes on silicon and aluminium oxides has been studied;[89] a correlation was observed between the values of $\sigma$ and the quantity of OH groups on the catalyst surface. On the other hand, spectroscopic studies of the adsorption of butenes on silica gel modified with alkali showed that the alkenes interact not only with the OH groups and sodium ions but also with other centres of the silica gel surface, possibly oxygen anions.[90]

The adsorption of formic acid on titanium dioxide has been studied by $^{13}C$ and $^{1}H$ NMR.[91] Appreciable strong-field shifts of the $^{1}H$ NMR lines and weak-field shifts of the $^{13}C$ lines were observed, due to interaction with the surface paramagnetic $Ti^{3+}$ ions. The dependence of the values of $\sigma$ on the degree of covering of the surface, and EPR data on the number of adsorption centres, were used to determine the values of $\sigma_A$ and the spin densities at the protons and carbon nuclei of the surface complex. Quantum-chemical calculations of the transfer of spin density from the $Ti^{3+}$ ion to the $\pi$-orbitals of the adsorbed molecule[91] show that the experimental values of the spin densities are best explained by an adsorption model in which the structure of the formic acid molecule is distorted relative to its state in the gas phase—it loses its planar structure.

The possibility of observing the change in the concentration of each of the reaction products from the $^{13}C$ NMR spectra enables this method to be used to study the kinetics of the transformation of hydrocarbons on catalyst surfaces and to study the intermediate products of the catalytic reactions. It has been possible to follow the kinetics of the isomerisation of but-1-ene on tin–antimony catalysts from the change with time in the intensity of the lines in the $^{13}C$ NMR spectra from all the reaction products.[92] The kinetic data were used to propose a cyclic model of the surface complex whose geometry ensures the transformation of but-1-ene into but-2-ene and the *cis–trans* isomerisation of but-2-ene.

$^{13}C$ NMR has been used[93] to study the mechanism of the conversion of methanol and ethanol into hydrocarbons on ZSM-5 zeolite. Analysis of the $^{13}C$ NMR spectra made it possible to follow the sequence of transformations of the alcohols into hydrocarbons. All intermediate products were identified (ethers, alkenes, aromatic hydrocarbons, cyclic and saturated hydrocarbons) and a reaction scheme was proposed.

Because of the increase in interest in the study of the Fischer–Tropsch synthesis, an increasing number of studies of the mechanism of this reaction by $^{13}C$ NMR are being reported. The forms in which CO is adsorbed, and the nature of the intermediate products of the reaction of CO and $H_2$, have been investigated.

By using carbon monoxide enriched in the $^{13}C$ isotope (~90%), it has been possible to establish the nature of the species formed when CO or a CO + $H_2$ mixture is adsorbed on an $Rh/La_2O_3$ catalyst.[94]

The magnitude of the shift observed for CO adsorbed on $La_2O_3$ (180–250 p.p.m.) is typical of carbon atoms in metal carbonyls or in aldehyde groups; this indicates that carbonyl-like structures are formed. The $^{13}C$ NMR spectra of carbon monoxide adsorbed on $Rh/La_2O_3$ at 20 °C and 150 °C are also typical of carbonyl structures.[94] Heating these specimens to 200 °C leads to the formation of saturated hydrocarbons as a result of the reaction of the carbonyl species with the OH groups of the surface. In a similar experiment with $Rh/SiO_2$, the chief product was ethylene, and the degree of transformation of the carbonyls to the hydrocarbon was much lower than on $Rh/La_2O_3$.

For mixtures with $CO:H_2 = 1:3$ on an $Rh/La_2O_3$ catalyst, the reaction of CO with $H_2$ begins with the formation of carbonyl species with $\sigma$ = 180–150 p.p.m. Up to 80 °C, no other species were detected. Heating at 200 °C leads to the formation of alcohols. At 240 °C, the alcohols are dehydrated to give hydrocarbons (lines at 10–30 p.p.m.), which in turn are converted into methane at 260 °C.[94] At lower partial pressures of hydrogen ($CO:H_2 = 1:1$) and a temperature of 230 °C, large quantities of oxygen-containing compounds with carbonyl groups (lines with $\sigma \cong$ 180–220 p.p.m.) and compounds of the formate type (lines with $\sigma \cong$ 150–180 p.p.m.) are formed. With increase in temperature, saturated hydrocarbons predominate in the reaction products. These examples show that $^{13}C$ NMR can be used to study the intermediate products of the heterogeneous catalytic reactions between CO and $H_2$.

A study of the $^{13}C$ NMR spectra of CO and $CO_2$ adsorbed on zeolites[95] detected unusually large weak-field shifts of the signals (by ~30–80 p.p.m.) compared with gaseous CO. The shifts were observed after zeolite treatment leading to the displacement of aluminium (heating at a high temperature in a deep bed of the specimen); it was therefore concluded that the CO molecules interact with Lewis centres, that is with the aluminium atoms displaced from the zeolite lattice. These effects were not observed for $CO_2$. A model *ab initio* calculation of the interaction of CO with an isolated $Al^{3+}$ ion[96] showed that the potential energy on the surface has two minima, which correspond to the attachment of a CO to an $Al^{3+}$ ion via the carbon atom or via the O atom, with approximately equal stabilisation energies. Comparison of the results of the calculation of the chemical shift tensors with the experimental data led to the conclusion that in the decationated zeolites the addition of CO to $Al^{3+}$ takes place preferentially via the O atom.

A study of the state of CO adsorbed on $Rh/Al_2O_3$[97,98] detected species of two types, which give overlapping $^{13}C$ NMR spectra; these spectra differ, however, in their spin–lattice relaxation times. In this case, NMR supplements the results obtained by infrared spectroscopy (which does not detect two forms of adsorbed CO).

The methods of the high-resolution $^{13}C$ NMR spectroscopy of solids, involving suppression of the dipole interaction with protons, cross polarisation, and rotation of the specimens at the magic angle, are now beginning to be used increasingly to study strongly adsorbed molecules.

$^{13}C$ NMR with cross polarisation and suppression of the dipole and scalar interactions with protons has been used[99] to study the interactions of methanol, toluene, and ethylbenzene with modified zeolites of type X, used as catalysts for the synthesis of styrene. The results[99] show that the

introduction of alkali metal cations (NaX and CsX) leads to a change in the geometry of the zeolite cavities and the composition of the intermediate reaction products. The change in the size of the "windows" in the zeolites with change in the nature of the alkali metal influences the mobility of the adsorbed molecules (revealed by a change in the NMR line width) and the geometry of the intermediate state (revealed by the formation of different intermediate reaction products, detected from the characteristic shifts in the NMR spectra). Thus on NaX zeolite the dehydration of methanol predominates, whereas on CsX zeolite, dehydrogenation predominates. Formaldehyde is converted into dimethyl ether on NaX, and into methanol on CsX.

The chemisorption of methanol on magnesium oxide has been studied by cross polarisation.[100] The $^{13}C$ NMR spectra of adsorbed methanol had axial symmetry. Comparison with the spectra of potassium, calcium, and magnesium methoxides made it possible to assign the lines obtained after the adsorption of 6 μmole $m^{-2}$ methanol to surface magnesium methoxides, firmly bound to the catalyst surface. At high degrees of coverage, mobile methanol molecules joined to OH groups by hydrogen bonds are formed on the surface.

$^{13}C$ NMR has been used[101] to study the conversion of methanol on NaGeX-300 zeolite, which has a structure similar to that of faujasite. The formation of dimethyl ether and partial methoxylation of the surface were detected at 300 °C. In the presence of water, the surface methoxy groups are readily converted into methanol at 25 °C.

Important information can also be obtained by analysing the form of the lines in the $^{13}C$ NMR spectra. In the adsorption of benzene on NaY zeolite, the line width reaches a maximum after the adsorption of four benzene molecules for every large cavity.[102] This was taken[102] as indicating that benzene reacts with four sodium ions in a large cavity.

An analysis of the form of the lines in the spectra of CO, $CO_2$, $CS_2$, and COS adsorbed on zeolites has been used to identify the probable centres on which these molecules are adsorbed in mordenites.[103] This identification can be carried out by studying (from the form of the NMR line) the characteristic features of the movement of the molecules in the zeolites. The molecules have a low mobility if their dimensions and the dimensions of the adsorption sites coincide, and are extremely mobile if the dimensions of the cavities in which adsorption takes place are much greater than the dimensions of the molecules. For example, the data obtained[103] for $CO_2$ adsorbed on Na-mordenite indicate that the zeolite contains molecules of three types: stationary, rotating anisotropically, and rotating isotropically. These results can be attributed to the adsorption of $CO_2$ molecules in three different positions: inside channels formed by large rings, inside channels formed by small rings, and on the external surface respectively. For K-, Cs-, and $NH_4$-mordenites, adsorption of gases in the small channels is not observed. These cations apparently themselves occupy the positions in the small channels, preventing the adsorption of other molecules in them.

### 3. The Use of Rotation at the Magic Angle to Study Adsorbed Molecules

The chief problem arising when rotation at the magic angle is used to study adsorbed molecules is associated with the need to rotate sealed glass ampoules. The strong centrifugal forces produced by rotation at a frequency of 2–4 kHz often lead to rupture of the ampoules. An ampoule and a rotor have been designed[104,105] for carrying out measurements with sealed ampoules at a rotation frequency of 2–2.5 kHz.

The efficiency of rotation of the specimen at the magic angle is illustrated in Fig.6, which gives the $^1H$ NMR spectra of propene adsorbed on $\gamma$-$Al_2O_3$.[104] In experiments without rotation of the specimen, the line width is ~500 Hz, which makes it impossible to resolve the lines from the protons of the CH and $CH_2$ groups. On rotation at the magic angle, the line width decreases by a factor of ~20, all the lines of propene are resolved, and the accuracy of the measurement of $\sigma$ is increased (to ±0.02 p.p.m.). For this system, all the resonance lines of both the $^1H$ NMR spectrum and the $^{13}C$ NMR spectrum are displaced to a weak field, compared with the spectrum of gaseous propene; the largest shift was observed for the CH group.

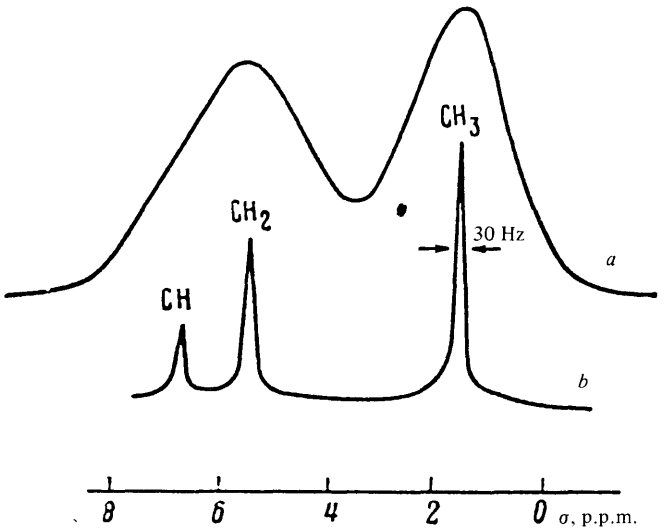

Figure 6. Influence of rotation at the magic angle on the $^1H$ NMR spectra of propene adsorbed on $\gamma$-$Al_2O_3$; the spectra were obtained: *a*) without rotation, *b*) with rotation at a frequency of 2 kHz.[104]

The dependence of the chemical shift on the degree of covering of the $\gamma$-$Al_2O_3$ surface by propene from the $^1H$ and $^{13}C$ NMR spectra is typical of rapid exchange between physically and chemically adsorbed alkene molecules. The dependence is effectively described by Eqn.(6), which corresponds to the chemisorption of propene on an active centre to give a 1:1 complex. Fig.7 gives the dependence of the chemical shift on the quantity of adsorbed propene.[105] The dependence of $\sigma$ on the degree of covering was used to find the complex-formation constant, whose value, as expected, was the same for all six lines in the $^1H$ and $^{13}C$ spectra. The values of the product of the chemical shift of the signal of the molecules in the adsorbed state and the number of chemisorption centres were also calculated. It was found that the complex-formation constant is independent of the temperature of preliminary vacuum treatment, whereas the product $\sigma_A N_A$ for all the lines increases with increase in the temperature of treatment (see Fig.7). This indicates that the propene chemisorption centres are most probably coordinatively unsaturated aluminium ions, the number of which increases with increase in the treatment temperature. A marked decrease in the values of the spin–spin coupling constants

$J(^{13}C-^{1}H)$ for all groups of chemisorbed propene compared with gaseous propene was also observed. For hydrocarbons, a decrease in the value of the constant $J(^{13}C-^{1}H)$ reflects a decrease in the strength of the C–H bond.[106] A comparison of the experimental values of σ and $J(^{13}C-^{1}H)$ with the results of MINDO/3 calculations for different forms of adsorption was used to obtain the most probable model of the chemisorption of propene on $\gamma$-$Al_2O_3$.[105] According to this model, the propene molecules are bonded to the surface by interactions of two types: between the π-electrons of the double bond of propene and the surface Al atom, and between the protons of the methyl group and the surface O atoms.

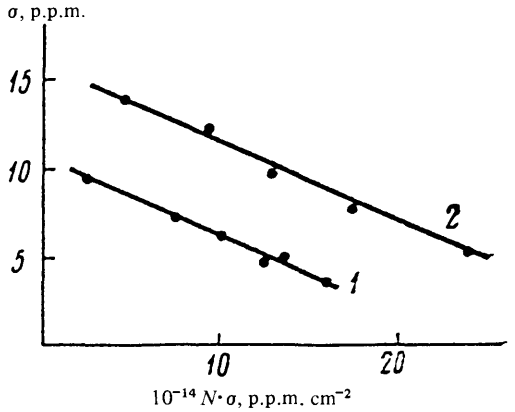

Figure 7. Plot of the chemical shift of propene adsorbed on $\gamma$-$Al_2O_3$ against $N.\sigma$ for different temperatures of treatment: *1*) 400 °C, *2*) 600 °C.[105]

Another example of the effective use of rotation at the magic angle to decrease the line widths for adsorbed molecules is provided by a study[107] of the $^{13}C$ NMR spectra of methane adsorbed on HZSM-5 zeolite. Rotation decreased the line widths considerably, making it possible to measure the change in not only the chemical shift but also the spin–spin coupling constant.[107] The signal from adsorbed methane is displaced to a weak field relative to methane in the gas phase. The spin–spin coupling constant decreases by ~10 Hz on adsorption. This indicates that a bond is formed between methane and surface centres, possibly leading to an increase in the length of the C–H bonds in the adsorbed molecule.

$^{13}C$ NMR with suppression of the spin–spin interaction with the protons has been used[108–110] to study the adsorption of ethylene enriched in the $^{13}C$ isotope on HZSM-5 zeolite at room temperature. The characteristic signal from ethylene (σ = 122 p.p.m.) was first observed. The intensity of this signal gradually decreased, and finally disappeared completely, indicating that ethylene is transformed into products which cannot be detected by NMR. The $^{13}C$ NMR spectra obtained with rotation of the specimens at the magic angle, immediately after the disappearance of the signal from ethylene, showed two lines at 28.8 p.p.m. and 13.5 p.p.m., assigned to aliphatic $CH_2$ and $CH_3$ groups respectively.[111] Both signals were broadened by dipole–dipole interaction between the carbon nuclei, but in spite of this, they showed a fine structure due to the presence of non-equivalent carbon atoms in the reaction products. Calculation of the relative intensity of the signals from the $CH_2$ and $CH_3$ groups[111] indicated that ethylene is converted into linear aliphatic hydrocarbons with 9–10 carbon atoms in the chain. The marked broadening of the lines and the fact that they cannot be observed without rotating the specimen at the magic angle indicate that the molecules of the reaction products form strong bonds with the zeolite.

$^{13}C$ NMR with rotation of the specimens at the magic angle and cross polarisation has also been used[112] to study the oligomerisation of alkenes on HZSM-5 zeolite. The chief products are linear oligomers at room temperature, and branched oligomers at high temperatures (~100 °C). This follows from a comparison of the values of σ with data for polymers with different structures. In contrast to this, on HY zeolites and H-mordenite, the alkenes are converted chiefly into branched oligomers at room temperature also. These differences are apparently due to the characteristic features of the structure of the HZSM zeolites, which have pores of smaller diameter.

## 4. The Study of the Adsorption on the Acidic Centres of Catalysts

Because of the important role of surface acidic centres in catalytic reactions, the adsorption of various molecules on these centres has been intensively studied for a long time by various physicochemical methods, mainly infrared spectroscopy.[113,114] Since $^{13}C$ NMR spectroscopy makes it possible to distinguish molecules in the free and adsorbed states, it has also been used to study surface acidic centres.[115–117]

The NMR spectra of a number of amines, including pyridine, aniline, and some of their derivatives, adsorbed on $SiO_2$, $Al_2O_3$, and an aluminosilicate, have been obtained.[115] On $SiO_2$, only a slight change in σ for the nuclei of the amines was observed, except for N,N-diethylaniline, for which an unusually large shift (–9 p.p.m.) of the signal of the C(4) carbon atom was observed; this may be due to a change in the geometry of the molecule on adsorption. The adsorption of amines on $Al_2O_3$ was accompanied by a much stronger interaction, but the spectra did not show the large chemical shifts usually observed when the corresponding amines are protonated in acidic solutions. This may be due to blocking of the strong acidic centres on the aluminium oxide surface. For the aluminosilicate, the values of σ were smaller than for the corresponding protonated amines in solution, and increased with decrease in the degree of covering of the surface. This last feature indicates that there is rapid exchange between the chemisorbed (protonated) and "free" (physically adsorbed) states of the amines. The rapid-exchange procedure was used[116] to study the adsorption of pyridine on silica gel treated with hydrochloric acid; the value of σ for chemisorbed pyridine was found to be close to the value for the pyridinium ion in aqueous solution.

In the simplest case, when there is exchange of an amine between two states, it is possible to write:[116]

$$\sigma = f_A\sigma_A + (1-f_A)\sigma_0 \qquad (7)$$

where σ is the observed chemical shift; $\sigma_0$ and $\sigma_A$ the chemical shifts for the free amine and for the amine combined with an acidic centre; and $f_A = N_A/N$ the proportion of amine molecules combined with acidic centres. If the amine can be combined with both Lewis and Bronsted acidic centres, generalisation of Eqn.(7) gives the expression

$$\sigma = f_H\sigma_H + f_L\sigma_L + (1-f_H-f_L)\sigma_0 \qquad (8)$$

where the subscripts "H" and "L" refer to Bronsted and Lewis centres respectively.

For the description of the dependence of $\sigma_H$ on the degree of covering of the surface in Ref.116 the value taken for $\sigma_H$ was that measured for the same amine in an acidic aqueous solution, the value taken for $\sigma_L$ was the value of the chemical shift for the complex of the amine with the Lewis acid $BF_3$, and the value taken for $\sigma_0$ was the value of the chemical shift for the amine adsorbed on $SiO_2$, which was assumed to have no surface acidic centres capable of protonating amines. Analysis (using Eqn.(8)) of the dependence of $\sigma$ on the degree of coverage for the adsorption of 4-ethylpyridine on the aluminosilicate showed good agreement between the values for the total number of acidic centres of the aluminosilicate obtained from the NMR spectra and from the adsorption of ammonia.

$^{13}C$ NMR has been used[118] to study the reaction of acetone with dehydroxylated and partly methylated silica gel specimens. An appreciable shift of the lines from the C=O group on the partly dehydroxylated specimens (by ~9 p.p.m. to a weak field) as a result of the formation of a hydrogen bond with OH groups was detected. The shifts for the methylated specimens were much smaller. The number of centres reacting with acetone was determined, and good agreement with the infrared spectroscopic data was obtained.

These studies were carried out using the standard high-resolution NMR procedure, which makes it possible to obtain well resolved spectra only when there is rapid movement of the adsorbed molecules on the surface. To obtain well resolved spectra for strongly adsorbed species, it is necessary to carry out the measurements at a fairly high temperature. This creates certain experimental difficulties, which can be overcome by using rotation of the specimens at the magic angle and cross polarisation to decrease the line widths. In Refs.119 and 120 these methods were used for the first time to study the adsorption of n-butylamine and pyridine on $\gamma$-$Al_2O_3$. The well resolved NMR spectra of n-butylamine showed the presence on the $\gamma$-$Al_2O_3$ surface of chemisorbed species of at least two types, due to the existence on the $\gamma$-$Al_2O_3$ surface of centres of two types interacting with the amine. Comparison with the spectra of the solid adducts of n-butylamine with HCl and $BCl_3$ made it possible to identify these centres as Bronsted and Lewis surface acidic centres. The separate observation of the lines from the amine adsorbed on these centres makes it possible in principle to use this method for the quantitative measurement of the numbers of acidic centres of different types.

The same procedure was used to study the spectra of pyridine adsorbed on $\gamma$-$Al_2O_3$. When the usual method of recording the spectra is used, pyridine gives broad poorly resolved lines even at increased temperatures and relatively high degrees of coverage. The use of rotation of the specimen at the magic angle combined with cross polarisation makes it possible to observe for pyridine adsorbed on $\gamma$-$Al_2O_3$ a completely resolved spectrum for all three non-equivalent carbon atoms. The values of $\sigma$ coincide with the corresponding values for liquid pyridine, indicating that the adsorbed pyridine molecules are weakly bound to the surface. When cross polarisation was used, lines of anomalous intensity were observed, and this can be attributed to the characteristic features of the dynamics of cross polarisation when the movement of the pyridine molecules in the adsorbed state is anisotropic. The results of the experiments agree with a model in which the pyridine molecule reacts with the surface via the nitrogen atom and rotates chiefly about the $C_2$ axis.

Extensive possibilities for the investigation of acidic centres are opened up by the study of the $^{15}N$ NMR spectra of adsorbed bases. Although the $^{13}C$ NMR spectra can be obtained at the natural concentration of the isotope, however, the much lower intensity of the signal from $^{15}N$ nuclei makes it necessary to use enriched specimens. The study of the $^{15}N$ NMR spectra of adsorbed bases is of particular interest, since both the protonation of these substances and their formation of a hydrogen bond with surface OH groups often take place directly via the nitrogen atom. As a result, the differences in the chemical shifts of the $^{15}N$ signals for the protonated and non-protonated molecules are greater than those for $^{13}C$ and $^{1}H$ nuclei. Few papers have yet been published, however, on the use of $^{15}N$ NMR to characterise surface acidic centres.

The $^{15}N$ NMR spectra of ammonia, trimethylamine, pyridine, and acetonitrile adsorbed on zeolites have been studied.[121] The spectra of pyridine on Y zeolite showed shifts (of ~90 p.p.m.) relative to the signal of pyridine adsorbed on $SiO_2$, indicating that pyridinium ions are formed. The number of OH groups interacting with pyridine was determined. The unusually large shifts obtained for a number of specimens were attributed to the formation of complexes with Lewis acid centres on the surface.

When pyridine was adsorbed on modified silica gels, the values of $\sigma$ in the $^{13}C$ NMR spectra remained practically unchanged, whereas the $^{15}N$ NMR spectra showed shifts of ~20 p.p.m. as a result of the formation of a hydrogen bond between pyridine and the OH groups of silica gel.[122] In the case of silica gel modified with phosphorus, the formation of pyridinium ions was observed, apparently as a result of the reaction with P–OH groups.

In a study of the $^{13}C$ and $^{15}N$ NMR spectra of acetonitrile adsorbed on zeolites containing $Li^+$, $Na^+$, $Rb^+$, $Cs^+$, and $Ag^+$ cations,[123] it was found that the exchange cations act as adsorption centres, leading to shifts of the signals in the $^{15}N$ NMR spectra. The $^{13}C$ and $^{15}N$ NMR spectra of pyridine adsorbed on an aluminosilicate have been studied[124] using cross polarisation and rotation at the magic angle. The reaction of pyridine with the surface centres of the aluminosilicate leads to a decrease in the difference in the chemical shifts in the $^{13}C$ NMR spectra for the $\alpha$- and $\beta$- and for the $\alpha$- and $\gamma$-carbon atoms of pyridine. Comparison of these values with the corresponding values for pyridine forming a hydrogen bond (a solution of pyridine in water) and for pyridine forming a coordinate bond with aluminium (the compound $C_5H_5NAl(C_2H_5)_3$) indicated that at low degrees of covering, pyridine is adsorbed chiefly on Lewis centres; the comparison also made it possible to calculate the proportion of pyridine combined with these centres, and to determine their absolute concentration. At high degrees of covering, most of the pyridine molecules form hydrogen bonds with OH groups.

An analysis of the $^{15}N$ NMR line widths indicated that there is movement of the adsorbed pyridine molecules on the surface.[124] Experiments on cross polarisation of the $^{13}C$ nuclei with different times of thermal contact between the spin systems showed that this movement is anisotropic. It apparently involves rotation of the pyridine molecule about the two-fold axis.

### 5. The Study of the Adsorption of Hydrogen

NMR is convenient for the study of adsorbed hydrogen, since it is highly sensitive to the electronic state and mobility of the adsorbed molecule. A large number of studies have been carried out by broad-line NMR or by nuclear magnetic relaxation to determine the correlation time of the movement of the molecules on the catalyst surface; these studies have been reviewed.[2,3] Recently, as a result of the development of spectrometers operating with high fields, it has become

possible to use NMR spectroscopy to measure the chemical shifts of adsorbed hydrogen.

A study of the spectra of hydrogen adsorbed on an $Rh/TiO_2$ catalyst detected two forms of hydrogen.[125] For the first, the value of $\sigma$ was close to that for TMS; this hydrogen is bound to rhodium. The second form of hydrogen has a very high mobility; this hydrogen reacts for a short time with surface paramagnetic $Ti^{3+}$ ions, leading to a strong-field shift of the signal. The mobile form is possibly produced by the dissociation of hydrogen molecules on rhodium with subsequent transfer of active hydrogen to the catalyst surface. After the combined adsorption of CO and $H_2$, the signal from the mobile hydrogen disappears, and the total absorption of hydrogen by the catalyst increases as a result of the formation of new species containing protons.[126]

A study of the $^1H$ NMR spectra of reduced copper–chromium catalysts for the partial hydrogenation of unsaturated hydrocarbons[127,128] indicated that the structure of the reduced catalysts contains an atomic form of hydrogen which brings about the selective hydrogenation of the hydrocarbons. The hydrogen species in these catalysts, which have the spinel structure, are situated close to the paramagnetic ions and have a low mobility, leading to marked broadening of their lines.

The adsorption of hydrogen on platinum has been studied.[129] Hydrogen may be present on platinum in two states: strongly (irreversibly) bound and weakly (reversibly) bound. On the basis of the first results, obtained in Ref.130 at high hydrogen pressures, it was possible in Ref.129 to detect two signals for platinum deposited on silica gel. The high-field signal with $\sigma \cong -50$ p.p.m. is due to irreversibly adsorbed hydrogen. This high value of $\sigma$ indicates a strong interaction between hydrogen and platinum. It is suggested that the atoms of this form of hydrogen are situated in the interstices of the surface platinum species. The signal close to that of TMS was assigned to hydrogen reversibly adsorbed on isolated platinum atoms.

A more detailed study[131] showed that for pure monodisperse platinum specimens deposited on $SiO_2$, the spectrum shows only the high-field signal, and the signal close to that of TMS is due to the presence of impurities in the specimens. It was also found that hydrogen in the presence of deposited platinum influences the spin–lattice relaxation of the Si–OH groups of the carrier. This effect is not observed for $SiO_2$ without platinum. It was suggested that the rate of the relaxation of the OH groups is increased by paramagnetic hydrogen atoms "flowing" from the platinum to the carrier. Further studies are required, however, for a more reliable explanation of the reasons for this effect.

Large strong-field shifts of the hydrogen signal, apparently due to the formation of hydride-like structures, have also been observed for other metals of the platinum group: Ru, Rh, Pd, Os, and Ir.[132] In the case of palladium, an averaged signal from chemisorbed hydrogen and hydrogen dissolved in palladium was observed. In the case of Ru and Os, the chemical shift for hydrogen was independent of the covering, but in the case of Rh it even increased with increase in the degree of covering of the surface by hydrogen. These effects have not yet been satisfactorily explained.

The adsorption of hydrogen on $Rh/Al_2O_3$ has been studied.[133] The $^1H$ NMR spectrum obtained consists of three lines: a line with $\sigma = -(10-15)$ p.p.m. from a surface hydride, a Pake doublet with a splitting of ~44 kHz from water molecules formed during the adsorption of hydrogen, and a narrow line from physically adsorbed hydrogen. Analysis of the spectrum shows that on the $Rh/La_2O_3$ catalyst, the activation of hydrogen involves hydride formation. The subsequent "flow" of activated hydrogen to the carrier may lead to partial reduction of the carrier surface. The water molecules formed in this process are firmly bound to metallic rhodium. Thus NMR spectroscopy makes it possible to observe the activation of hydrogen on metallic rhodium and its subsequent migration to the carrier.

The spectra of hydrogen adsorbed on $\gamma$-$Al_2O_3$ have been studied.[134] A single line was observed, due to rapid exchange between different forms of adsorbed hydrogen.

In a study of the adsorption of hydrogen on zinc oxide,[135] it was suggested that on the surface there is a weakly bound form $H_3^+$, produced by the reaction of hydrogen with a hydroxide group. This suggestion was based on the fact that the $^1H$ NMR spectrum showed a weak line with $\sigma \cong 15$ p.p.m. from the overall spectrum of the OH groups and physically adsorbed hydrogen; it requires verification.

While the present review was being prepared for publication, additional data appeared on the study of the local environment of silicon from the $^{29}Si$ NMR spectra[136–147] and the study of the acidic properties of the surface from the $^{31}P$ NMR spectra of phosphorus containing bases in HY zeolites.[148] High-resolution proton magnetic resonance has been used[149–151] to study the Bronsted acidic centres of amorphous aluminosilicates and zeolites. The high-resolution $^{17}O$ NMR spectra of solid oxides and zeolites have been studied.[152,153] Hydrocarbon complexes on catalyst surfaces have been studied.[154,155] There has recently been considerable interest in the high-resolution $^{27}Al$ and $^{31}P$ NMR study of aluminium phosphate catalysts with zeolitic structures.[156,157] Studies of heterogeneous catalysts and the processes taking place on their surfaces, carried out in the Soviet Union using the methods of the high-resolution NMR spectroscopy of solids, have been reviewed.[158]

---o0o---

The data given in the present review show that the production of a new generation of highly sensitive multi-nuclei NMR spectrometers and the development of various procedures for obtaining high-resolution NMR spectra for solid specimens have led to qualitative changes in the possibilities provided by NMR for the study of heterogeneous catalysis. This method can be used to carry out systematic studies of catalyst structures, the forms of adsorption of reagents, and their transformations in catalytic reactions.

The important role in the development of organic and inorganic chemistry, including homogeneous organic and metal-complex catalysis, now being played by the study of substances and processes in solution by the traditional method of high-resolution NMR is well known. The data presented in the present review indicate that in the near future, modern versions of the NMR method will begin to play a similar role in the development of heterogeneous catalysis.

# The Study of Heterogeneous Catalysts by the EXAFS Method

D.I.Kochubei

The principles of the EXAFS method, which makes it possible to determine the structure of the local environment of a chemical element being studied within a radius of 4 Å, are described. Information on the experimental apparatus, the fields of application, and the accuracy of the determination of the structural parameters (interatomic distances, coordination numbers, Debye-Waller factors) are given. Examples of the use of the method to study catalysts are described.
The bibliography contains 44 references.

## I. INTRODUCTION

In the last ten years, a fundamentally new method has been developed for determining the local structure of the environment of a given chemical element in any state of aggregation, namely the EXAFS method. (EXAFS is an abbreviation for Extended X-Ray Absorption Fine Structure, or DTSRSP in Russian). Unlike traditional diffraction methods, which make use of the phenomenon of the elastic scattering of the probing radiation (X-rays, electrons, neutrons) on a crystal lattice, the EXAFS method makes use of the characteristic absorption of X-rays by the chemical element being studied, which is independent of the existence of a crystal lattice. Thus the EXAFS method can be used to study materials amorphous towards X-rays, such as, for example, highly dispersed deposited catalysts. The present review describes the principles of the EXAFS method and describes its possible applications in the study of catalysts.

## II. PRINCIPLES OF THE METHOD

In X-ray absorption spectroscopy, use is made of processes involving the transfer of an electron from an inner level, usually 1*s*, 2*s*, and 2*p*, to higher unoccupied levels or to the free state, that is ionisation. Fig.1 shows the hypothetical X-ray absorption spectrum of an isolated atom. When the X-ray quantum reaches an energy $E_0$ sufficient to ionise the electrons of one of the inner levels, a sudden jump is observed. Before this point, absorption involves higher-lying levels and is described by an expression of the form $A.E^{-3} + B.E^{-4}$ (where $E$ is the energy of the X-ray quantum, and $A$ and $B$ are parameters specific for each chemical element). When the energies of the quanta are greater than the ionisation potential of this level, a regular decrease in the absorption coefficient according to the same law should be observed.

For a real specimen, where there are other atoms in the local environment of the absorbing atom, the absorption spectrum has a different appearance. Fig.2 gives the X-ray absorption spectrum of metallic platinum with ionisation of the $2p_{3/2}$ level; the spectrum shows a complex structure close to the absorption edge and oscillation over a very wide range, from 50 eV to ~1000 eV. These oscillations have been called the extended X-ray absorption fine structure.

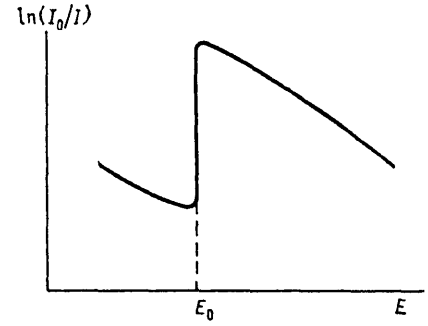

Figure 1. Assumed X-ray spectrum of an isolated atom: $I_0$ is the intensity of the incident radiation, $I$ the intensity of the radiation passed through the specimen, $E$ the energy of the X-ray quantum, and $E_0$ the ionisation potential of one of the inner levels of the atom.

The phenomenon was discovered[1] in the nineteen-thirties. In the nineteen-fifties, the following model was developed[2,3] to explain the nature of the phenomenon; for an isolated atom, a photoelectron ejected by an X-ray quantum is described by a spherically symmetrical divergent wave-function. When there are other atoms close to the absorbing atom, the photoelectron will be partly scattered backward

on these atoms, and its state will be described by the superposition of the emitted and scattered wavefunctions. This leads to a change in the absorption coefficient. The absorption coefficient will increase or decrease, depending on the phase in which the wave front of the scattered photoelectron returns to the absorbing atom. If the wavelength of the ejected photoelectron is changed by changing the energy of the incident quantum, sinusoidal fluctuations will be observed in the absorption spectrum, with a period equal to twice the distance between the absorbing and scattering atoms.

The total spectrum will contain oscillations of this kind from all surrounding atoms. By determining the period of the oscillations in the absorption spectrum, it is possible in principle to measure the distance from the absorbing atom to the scattering atom, and, by determining the amplitude of the oscillations, to measure the number of scattering atoms. The determination of interatomic distances by this method has an important advantage, since it is possible to measure the distances around the atom of one chemical element. The atoms of other chemical elements, which are present, for example, in multicomponent systems such as catalysts, do not interfere in these measurements, since as a result of the large energy range over which the absorption edges of the inner levels of the atoms of different chemical elements are distributed, the superposition of the absorption edges of different elements is fairly infrequent.

The first attempts to determine interatomic distances by this method were unsuccessful,[4] however, because in the emission and scattering of photoelectrons, additional displacements of the phase of their wavefunction may occur, and it became possible to calculate these displacements, and also the amplitudes of the probability of the scattering process, only in the mid nineteen-seventies.

With the development of computing techniques, the model was refined, the forms of the interatomic potentials were selected, and numerical calculations were carried out to determine the amplitudes of the probability of the scattering of the photoelectron and the magnitude of the phase displacements in the emission and scattering of the photoelectron.[5-9] Experimental verification showed that the model chosen for the phenomenon is correct, and confirmed that the accuracy attained in the calculations and the fact that the phase displacements are independent of the chemical state of the scattering and absorbing atoms make it possible to determine interatomic distances by means of a Fourier analysis of the fine structure of the X-ray absorption spectrum.[10] The limitations of the model lead mainly to uncertainty in the determination of the coordination numbers and the amplitudes of the thermal vibrations of the atoms, and have little influence on the accuracy of the determination of interatomic distances. Nevertheless, the complexity of the experiment (the recording of a single spectrum on a laboratory instrument even at the present time can take days) would have prevented EXAFS spectroscopy from developing into an analytical method if the synchrotron emission from electron storage rings had not begun to be more widely used in X-ray spectral studies.

## III. APPARATUS AND FIELDS OF APPLICATION

Synchroton emission (SE) is the emission by relativistic electrons in their movement along the annular orbit of the storage ring. The spectral range of SE extends from the infrared to the X-ray region. The intensity of SE is hundreds of times that of the emission of the resonance lines of the X-ray tubes usually employed for structural analysis; SE is continuous throughout its spectral range. This makes it possible to carry out experiments over a wide range of energies, to change easily from one element to another, and to work with lower concentrations of absorbing elements. Moreover, the SE beam has a very low angle of divergence ($10^{-3}$ rad) and a high degree of polarisation.[11,12]

Because of these advantages of SE, and in spite of the need to construct special apparatus, an increasing proportion of X-ray spectral studies are being carried out using it. The first studies were carried out in parallel with experiments on high-energy physics, but many countries, such as the USA, Britain, France, West Germany, Italy, and Japan, now have electron storage rings that are used only to generate SE as

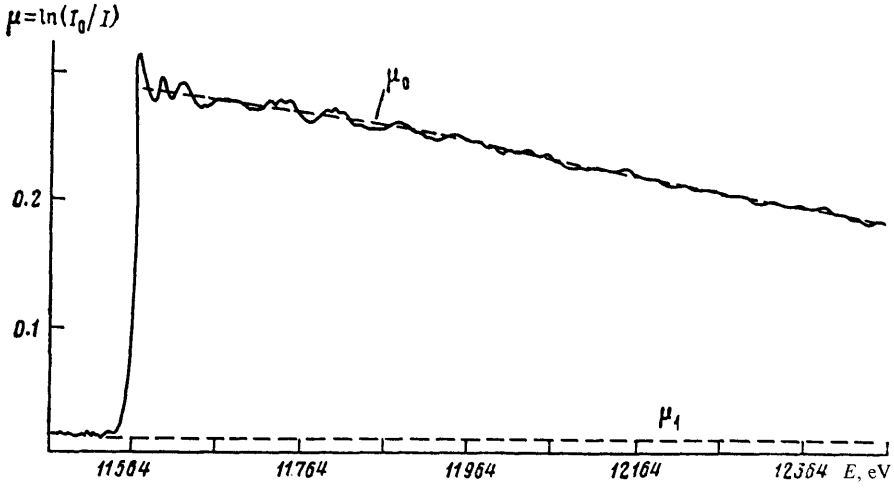

Figure 2. X-Ray absorption spectrum of the $L_{III}$ level of metallic platinum: $\mu$ is the absorption coefficient, $\mu_0$ the smooth part of the absorption coefficient, and $\mu_1$ the absorption of other electron levels in the atom.

a source for X-ray studies. The use of SE for EXAFS spectroscopy has made it possible to decrease the time taken to record the spectrum from days to 10–20 minutes and to work at concentrations of the element being studied reaching 0.1 M in a weakly absorbing matrix.

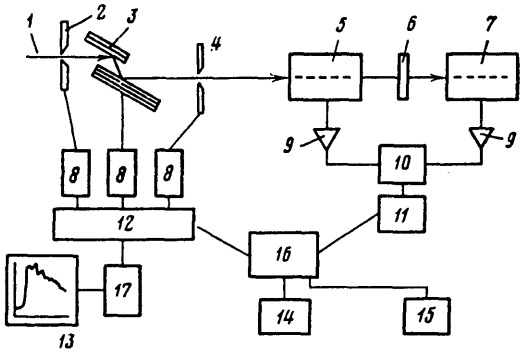

**Figure 3.** Block diagram of an EXAFS spectrometer: *1*) beam of synchrotron radiation, *2*) inlet slit of the monochromator, *3*) single-block crystal double monochromator, *4*) outlet slit of the monochromator, *5*) flow-through ionisation chamber, *6*) specimen, *7*) total absorption ionisation chamber, *8*) stepped motor control blocks, *9*) pre-amplifier, *10*) commutator, *11*) digital voltmeters, *12*) KAMAK box, *13*) display, *14*) video terminal, *15*) digital printer, *16*) ODRA-1305 computer, *17*) display control block.

In the USSR, EXAFS spectroscopic studies are being carried out using the electron storage rings of the Institute of Nuclear Physics of the Siberian Branch of the Academy of Sciences of the USSR in the Siberian Collective Centre for the Use of Synchrotron Emission. An EXAFS spectrometer (Fig.3) has been constructed for this purpose, and is in regular operation.[13] A general description of the principles of the construction of spectrometers for use with SE can be found in Ref.12. It should be noted only that when the generally employed two-crystal monochromator scheme (with Ge(111) and Si(220) crystal monochromators) is used to record the spectrum, no change takes place in the direction of the propagation of the X-ray beam after passing through the monochromator. Only a lateral displacement of the X-ray beam takes place, leading to a displacement of the beam along the specimen when the spectrum is recorded (by ~0.02 mm).

The recording system should ensure the measurement of the intensity of the quantum flux with an uncertainty of not more than $10^{-4}$ and the measurement of the absorption coefficient with an uncertainty of not more than 0.1% for an intensity of the incident radiation of $10^{13}$ photon $rad^{-1}\,s^{-1}$ with $\Delta\lambda/\lambda \cong 3 \times 10^{-4}$.

EXAFS spectrometers of different types have now been developed. They differ in the construction of the monochromator system and mainly in the recording system. Changes in the monochromator system are made to give a "purer" signal at the outlet by decreasing the scattered background and the contribution from higher harmonics. The choice of the method of recording the spectrum depends on the problem being studied. A whole set of procedures has now been developed. The most widely encountered scheme for operating the instrument "in transmission" makes it possible to record the EXAFS spectra from an element in a matrix whose absorption is slight compared with that by the element being studied in the range of quanta energies used, for example the spectra of $Pt/SiO_2$ and $Pd/TiO_2$ catalysts. The concentration of the element being studied may reach 1 mass %.

When the absorption by the matrix is strong compared with that of the element being studied close to its ionisation potential ($Ti/SiO_2$, $Pt/TiO_2$), the EXAFS spectra cannot be obtained by this method, since the strong absorption by the carrier leads to a decrease in the accuracy of the measurement of the absorption coefficient. For the study of these materials or for the study of surfaces, other methods are employed, which make use of the fact that the primary process in the absorption of X-rays is accompanied by secondary processes of X-ray and optical fluorescence or the emission of Auger electrons. The system of recording X-ray fluorescence[14] makes it possible to increase the sensitivity with respect to the element being studied by factors of 10–100 and to work with strongly absorbing matrices.

The recording of Auger electrons,[15,16] the total electron photocurrent,[17,18] or the X-ray-induced desorption of ions[19] makes it possible to study the structure of a surface and the coordination of molecules adsorbed on a surface. The thickness of the surface layer that can be studied reaches 100 Å for the total-photocurrent method, and 2–10 Å for methods using the recording of Auger electrons or the X-ray-induced desorption of ions.

Other methods are now being developed, which make it possible to study the structure of the surface of a catalyst not in a vacuum but in the presence of a reaction medium (the total external reflectance method[20]) or to carry out a selective study of the structure of the environment of the atoms of an element in states which luminesce in the optical range of the spectrum under the influence of X-rays.[21]

## IV. METHODS OF EXTRACTING STRUCTURAL DATA

In the model described above, the extended X-ray absorption fine structure is described by the function[10]

$$\chi(k) = \frac{1}{k}\sum_i \frac{N_i}{R_i^2} f_i(k)\, e^{-\sigma_i^2 k^2} e^{-R_i/\lambda} \sin(2kR_i + \varphi_i(k)) \qquad (1)$$

where $k$ is the modulus of the wave vector of the photoelectron, $k = [2m_e \times (E_0 - E)/\hbar^2]^{1/2}$, $E_0$ the ionisation potential of the absorbing electron level, $N_i$ the number of atoms in the $i^{th}$ coordination sphere, $R_i$ the radius of the $i^{th}$ sphere, $\sigma_i^2$ the Debye–Waller factor, $\lambda$ the free path of the photoelectron, $f_i(k)$ the amplitude of the probability of the scattering "backward" and $\phi_i(k)$ the change in phase during emission and scattering. The summation is carried out over all coordination spheres.

$\chi(k)$ is determined from the experimentally measured absorption spectrum using the equation

$$\chi(k) = (\mu - \mu_0)/(\mu_0 - \mu_1)$$

where $\mu$ is the absorption coefficient of the atom being studied in the specimen, $\mu_0$ the absorption coefficient of the same atom in the isolated state, and $\mu_1$ the absorption coefficient of the atoms of other elements present in the specimen, and of other levels of the atom being studied (see Fig.2).

There are several methods for analysing $\chi(k)$. The simplest is the Fourier transformation of $\chi(k)$, which gives a series of maxima displaced relative to the origin of coordinates by an amount $2R_i + \delta_i$, where $\delta_i$ is the linear part of

$\phi_i(k)$.[10] If the summation with respect to $i$ in Eqn.(1) is replaced by integration with respect to the distribution function $\rho(R)$,[22] it is possible to find a direct solution of the integral equation obtained. In addition, extensive use is made of modelling, where the parameters to be determined are varied to give best agreement between the experimental and model spectra.[23]

All these methods have advantages and disadvantages, and preference cannot yet be given to any one of them. The direct solution of the integral equation is possible only for one-component systems, and the results depend markedly on the uncertainty in the determination of the experimental data. This method therefore finds only limited application, and is unsuitable for the study of catalysts.

The methods of Fourier analysis and modelling are most widely used. Fourier analysis is applicable to all systems, does not require the introduction of additional assumptions, and gives reliable information. Its main unsatisfactory feature is that the analysis is carried out over a limited range of wavenumbers, 12–15 Å$^{-1}$. The narrowness of the range leads to a large apparatus width in the Fourier transformation for the atom radial distribution function being sought, and this makes it difficult to analyse complex systems, because of the overlap of the peaks. The necessary restriction of the range of integration at low wavenumbers to 3–4 Å$^{-1}$, below which the photo-ionisation model used is inapplicable, leads to the appearance of additional interference distortion on the atom radial distribution curve, as a result of which additional splitting and displacement of the peaks are possible. Moreover, Fourier analysis does not make it possible to determine the nature of the scattering atoms, and it is necessary to seek a correction for the phase displacement $\delta_i$, by making assumptions about the nature of the scattering element on the basis of additional information about the material being studied.

In the modelling method, the nature of the scattering atom and, usually, the functions $f_i(k)$ and $\phi_i(k)$ for this atom are given. The experimental spectrum and the Fourier filtration procedure are then used to separate the oscillations corresponding to the distance being analysed. The parameters $R_i$, $N_i$, $\sigma_i^2$, $E_0$, and, in individual cases, $\lambda$ are varied. This method gives a higher accuracy of the determination of the interatomic distances, compared with Fourier analysis, and makes it possible to find the atomic number of the element to within ±5. The parameters being varied are correlated ($E_0$ and $R_i$, $N_i$ and $\sigma_i^2$), however, because of the internal characteristics of the approximation used and the narrowness of the wavenumber range for which it is possible to obtain experimental data. The existence of this correlation may lead to errors in the determination of the parameters. The most reliable results are therefore obtained by a combination of both methods, where the primary analysis is carried out by the Fourier method, after which the results obtained are refined by modelling.

Fig.4 gives the results of a Fourier analysis of the function $\chi(k)$ for the absorption spectrum of the $L_{III}$ level ($2p_{3/2}$ level) of metallic platinum, given in Fig.2. Fig.4 shows that, in accordance with Eqn.(1) with increase in $R$ the intensity of the peaks decreases rapidly (as $R^2$). This feature, and also the damping of the function $\chi(k)$ as a result of the loss of energy by the photoelectrons with long free paths in inelastic scattering processes, restricts the range of interatomic distances that can be measured to 1.5–4.0 Å. The lower limit is determined by the need to have several oscillation periods on the experimental curve. The positions of the peaks in Fig.2 also do not correspond to the true distances between the atoms in metallic platinum. This difference is determined by the change in phase $\phi(k)$. Special studies have shown[24,25] that the observed displacement $\delta_i$ depends only on the nature of the absorbing and scattering elements, and not on their chemical state. The fact that $\phi_i(k)$ is independent of the chemical state makes it possible to determine interatomic distances with a high accuracy (from 0.04 Å to 0.01 Å for different methods). Tables of functions $f_i(k)$ and $\phi_i(k)$ for the ionisation of the $K$ and $L$ levels have now been published[9] for practically all chemical elements.

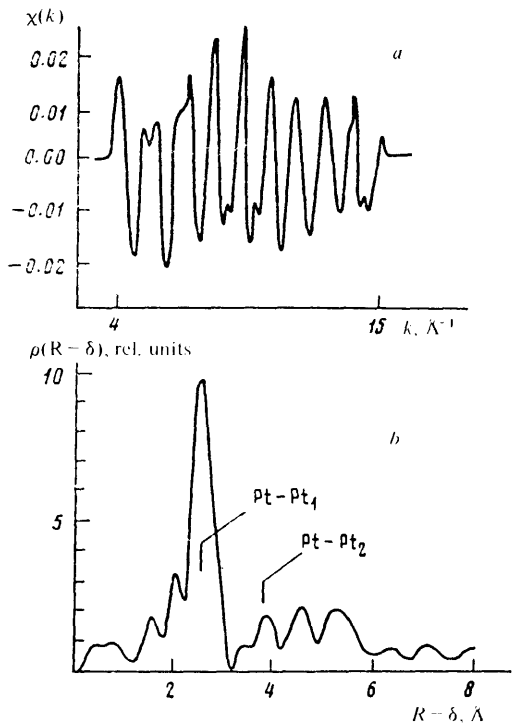

**Figure 4.** Extended X-ray absorption fine structure of the $L_{III}$ level of metallic platinum (*a*) and the radial distribution function of the atoms obtained from it (*b*).

The accuracy of the determination of coordination numbers is much lower than that for distances. There are several reasons for this. Firstly, the amplitude of a peak on the experimental curve is determined by the integral magnitude of $f_i(k)$ in the range in which the experimental data are analysed. A large contribution to the amplitude is therefore made by the scattering of low-energy photoelectrons, and the amplitude for a given coordination number depends markedly on the chemical state of the scattering atom.[25,26] Secondly, all the effects which are present in photo-ionisation and scattering processes and which are not taken into account in the model used also influence primarily the amplitudes of the peaks. Processes such as inelastic scattering give a value of the coordination number being determined which is too low,[27] whereas multiple scattering may give a value of the coordination number which is too low or too high[28] and may even lead to the appearance of spurious peaks.[29] At the present time it is considered that the EXAFS method can be

used to determine coordination numbers of the first coordination sphere to within 20%; for subsequent spheres the uncertainty may reach 100%.[23]

A systematic analysis of the accuracy of the determination of the Debye–Waller factor by the EXAFS method has not been carried out, although the method is used for this purpose.[23] It has been shown that the possibility of using the EXAFS method to determine interatomic distances and coordination numbers depends markedly on the magnitude of $\sigma_i^2$.[30] For values of $\sigma_i^2 > 0.04$ Å$^2$, oscillations are not observed in the EXAFS spectrum. In some cases this leads to a situation in which any changes in the environment of the ligand atom being studied are not reflected in the spectrum.[31]

The treatment of the spectra is now being carried out everywhere by practically identical methods using similar computer programs. Work is being carried out to extend the possibilities provided by the programs. Thus an attempt has been made,[28,29] by estimating the influence of double scattering on the amplitude of the peaks in the EXAFS spectrum, to determine the angular distribution of the atoms in the second and higher coordination spheres.

## V. APPLICATIONS IN THE STUDY OF CATALYSTS

The number of publications devoted to the study of catalysts by the EXAFS method has now reached several hundreds. The first reviews of these studies have been published.[23,32] The present section will examine mainly studies of deposited metallic catalysts, which make up a large proportion of the work carried out. This is related both to their extensive practical application and to their relative simplicity. These catalysts are distinguished by the ease of selecting model compounds, for which metals are used. In view of the practical importance of deposited platinum catalysts, most studies deal with these materials. Most studies have dealt with the effect on the structure of small metal particles of the adsorption of various molecules and of the interaction of the deposited metal with the support.

For platinum particles with dimensions of 20 Å or less, a significant change in the radius of the first coordinations sphere, normally a decrease, has been observed. The effect is observed on different supports, such as $SiO_2$, $Al_2O_3$, and HY zeolite.[33–36] The decrease in the metal–metal interatomic distances compared with metal foil reaches 0.2 Å. The reason for this effect is not yet clear. It is suggested that it is due to a change in the electron density in the metal as a result of surface effects, for example chemisorption. In contrast to this, in a study[37] of the dependence of the structure of platinum deposited on $\gamma$-$Al_2O_3$ on its degree of dispersion, an increase in the length of the Pt–Pt bond by 0.14 Å compared with platinum foil was observed in the most highly dispersed particles reduced at 470 K (see Fig.5). Estimation of the coordination numbers by comparing the intensities of the peaks in the catalyst and in Pt foil made it possible to establish with an uncertainty of 20% that the coordination number for the Pt–Pt distance is 3. This indicated that in this system, nuclei of metallic clusters are produced in the form of tetrahedra of platinum ions, stabilised in aluminium atom vacancies in the $\gamma$-$Al_2O_3$ lattice.

It should be noted, however, that the coordination number determined by the EXAFS method is averaged over all atoms of the element being studied. It is not excluded, therefore, that some of the platinum atoms are in the monoatomic form (coordination number for the Pt–Pt distance equal to zero), while the rest are present as large particles (coordination number 9–12). This apparently explains the fact that increasing the temperature of treatment to 670 K leads to the appearance of particles in which the Pt–Pt distance is the same as in the massive metal, while the coordination number is very small and equal to 3 (Fig.5*b*).

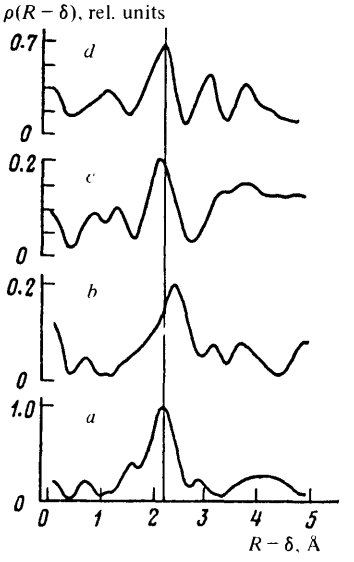

Figure 5. Radial distribution function of the atoms of metallic platinum (*a*) and catalysts with the composition 2.5 mass % $Pt/Al_2O_3$, reduced at 470 (*b*), 670 (*c*), and 870 (*d*) K.

A number of authors have studied the influence of the adsorption of various gases on the structure of the platinum particles. The adsorption of oxygen on highly dispersed catalysts at room temperature leads to a decrease in the Pt–Pt distance.[34–36] For catalysts deposited on $\gamma$-$Al_2O_3$ (particle size ~20 Å)[36] and on HY zeolite (particles 12 Å),[35] the decrease is 0.2 Å, and for catalysts deposited on $SiO_2$ (20 Å) it is 0.12 Å.[34] The adsorption of hydrogen leads to an increase in the length of the Pt–Pt bond to the value characteristic of the massive metal.[34] The adsorption of CO does not lead to a change in the interatomic distances.[35]

The possibility of following the phase composition of deposited catalysts by the EXAFS method has been demonstrated for deposited platinum catalysts treated with oxygen at high temperatures. In addition to metallic platinum, the phases PtO,[36] $\beta$-$PtO_2$,[38,39] and $Pt_3O_4$ [40] were observed. The change in the ratio of the intensities of the peaks corresponding to the Pt–O distances in the oxide and the Pt–Pt distances in the metal was used to determine the dependence of the ratio between the phases on the method of treatment of the specimen. Reaction with oxygen gives a range of oxides whose structure is perturbed by the interaction with the carrier, and which are very difficult to reduce.

The advantages of the EXAFS method are most clearly revealed in the study of multicomponent catalysts, if it is possible to study separately the environment of the atoms of each of the chemical elements making up the active fraction of the catalyst. An analysis of the environment of the Pt and Re atoms in platinum–rhenium reforming catalysts has been carried out.[41] The study of the absorption spectra of the $L_{III}$ level of the rhenium atoms established that when

platinum is deposited on rhenium catalysts obtained by reducing $[Re(OC_2H_5)_3]_3$ with hydrogen at 870 K, the platinum (at ratios Pt/Re = 1/3 and 2/3) is adsorbed on $Re_3^{n+}$ trimers, reoxidizing them. This is revealed by a decrease in the Re–Re distance. On subsequent reduction of Pt, the Re–Re distance increases, but comparison of the EXAFS spectra for Re and Pt indicates that the length of the Re–Pt bond remains unchanged and that platinum is stabilised not on $SiO_2$ but on rhenium ions. This effect is not observed with an excess of platinum relative to rhenium.[42]

Among non-metal systems, the EXAFS method has begun to be used to study oxide[32] and sulphide W and Mo hydrodesulphurization catalysts.[43,44] When W and Mo are deposited on $SiO_2$ and then treated with sulphur, surface oxide sulphides are formed, leading to a marked change in the nature of the metal–metal bond.[44] The metal ions are separated into pairs, within which the distance between the atoms is shorter than in tungsten and molybdenum disulphides, and the pairs themselves are separated from one another by larger distances. The position of the promoter (nickel) in W–Ni catalysts relative to the atom of the main element, which forms W–S–Ni bonds, has also been determined.

Thus the EXAFS method has now passed through the stage of methodological development, and is beginning to produce its first results. Its further application, particularly in the study of catalyst surfaces, will undoubtedly provide fundamentally new information.

# Application of Electron Paramagnetic Resonance and Ultraviolet Spectroscopy to the Study of Coordination-unsaturated Transition Metal Ions on the Surfaces of Catalysts

V.A.Shvets

The methodological characteristics of the application of the EPR and ultraviolet spectroscopic methods to the study of heterogeneous catalysts and reactions on their surfaces are briefly described. The concept of the coordination-unsaturated ions and the causes hindering their identification on catalyst surfaces by spectroscopic methods are discussed. Studies where the coordination and valence states of the surface coordination-unsaturated transition metal ions and their properties have been investigated with the aid of EPR and diffuse scattered light ultraviolet spectroscopy are examined. Data concerning the formation of surface complexes by the coordination-unsaturated ions with adsorbed molecules are analysed.
The bibliography includes 190 references.

## INTRODUCTION

The electron paramagnetic resonance (EPR) and ultraviolet and visible spectroscopic methods have come to be widely used in chemistry because of the large amount of information which they can yield. They have been widely employed also in heterogeneous catalysis for the investigation of the structures and properties of catalysts, adsorption, and reaction mechanisms. The majority of heterogeneous catalysts are known to contain transition metal ions and such catalysts will be in fact be considered in this review.

The ideas of the chemistry of coordination compounds and of the ligand and crystal field theories, according to which the central ion of the complex or the transition metal ion of the catalyst are in an electric field generated by the ligands in their immediate vicinity, proved applicable to the description of the structures of the surfaces of heterogeneous catalysts, the properties of the transition metal ions in their composition, and the nature of the surface compounds. Within the framework of these theories, it is possible to describe fairly adequately the dependence of the optical and EPR spectra of the transition metal ions in the catalysts on the symmetry of the first coordination sphere and on the nature of the chemical bonds between the ion and the ligand. This leads to the possibility of determining from spectroscopic data the electronic and geometrical structures of the active centres of the catalysts containing transition metal ions and the changes undergone by them following the adsorption of various molecules.

The so-called coordination-unsaturated (CU) ions are considered in the majority of investigations as the active centres of the catalysts containing transition metal ions. The concept of the existence of CU ions follows naturally from the development of our knowledge of the structures of the lattices of solids and conditions in their activation necessary for the appearance of catalytic activity. In fact, heterogeneous catalysts become active as a rule after treatment at fairly high temperatures, i.e. under conditions where the surface hydroxy-groups and adsorbed water molecules are at least partly removed. It might have been supposed that vacant sites appear as a result of these processes in the coordination spheres of the surface cations. This concept is so natural that it led to a wide-scale employment of the concept of CU ions in heterogeneous catalysis.[1-4] However, the study of the electronic structures of these ions and of their coordination and valence states (the term valence state is used in this review rather than "oxidation state" because it is more common in the literature devoted to heterogeous catalysts) has become possible only in the last two decades as a result of the application for this purpose of spectroscopic methods, in the first place the EPR and ultraviolet spectroscopic methods. Fairly reliable methodological procedures have now been developed for the detection of surface CU ions and for the investigation of their electronic and geometrical structures. Many detailed investigations of their properties have been made. This review is devoted to a systematic account and a survey of studies on these lines.

The first investigations of heterogeneous catalysts containing transition metal ions by the EPR and optical spectroscopic methods date back to 1950's. The application of these methods showed that, with their aid, it is possible to obtain sufficiently reliable information about the coordination, valence, and phase states of the transition metal ions in the bulk of the catalysts. On the other hand, the study of surface ions has encountered appreciable difficulties due mainly to the following two factors. Firstly, the number of surface ions is frequently much smaller than the total number of ions in the catalyst. It is therefore almost impossible to study them by the above spectroscopic methods owing to the background of the ions in the bulk of the catalysts. Secondly, since the coordination sphere of the surface CU ions is greatly distorted as a result of the removal of one or several ligands, the spectra are more difficult to interpret than those of ions in a more symmetrical environment. Even when a distinct spectrum is obtained the question whether a surface or a bulk phase ion is responsible for its appearance is likewise not always trivial. The simplest and most reliable experimental criterion for the assignment of ions to surface CU ions is their accessibility at low

temperatures to adsorbable molecules which behave as typical ligands, for example water, carbon monoxide, ammonia, etc. When these molecules are adsorbed, they enter the first coordination sphere of the CU ions, altering their coordination environment, which is reflected by a change in the parameters of the optical and EPR spectra. However, in this case the assignment of an ion to surface ions is not always evident, because such changes may be induced by other processes, for example, by the hydrolysis of the layer of catalyst near the surface, or by a change in the oxidation state of the ion due to the outer-sphere electron transfer to a molecule adsorbed at a fairly long distance from the given ion. As a rule, only a combined study of the properties of the catalyst surface therefore makes it possible to solve the problem of the assignment of a particular spectrum to surface CU ions.

The interaction of adsorbed molecules on CU ions with formation of surface complexes can proceed without change in the valence state of the CU ions and also with a change in this state. Complexes of the first type are formed as a rule when molecules which are typical ligands in homogeneous complexes and have no oxidation-reduction properties under the adsorption conditions are adsorbed. The complexes of the second type, involving a change in the oxidation state of the CU ions, are particularly characteristic of oxidant molecules ($O_2$, $N_2O$, $SO_2$, etc.). Electron transfer from the ion to the adsorbed molecule with formation of radical-anions, stabilised in the coordination sphere of the CU ions, takes place fairly frequently in this case. The structure and properties of such radical species have been studied vigorously by EPR,[5–9] because they play a significant role in many catalytic processes. Examination of studies of the radical-anions requires a special review and here we shall therefore consider them only to demonstrate the ability of the CU ions to form such charge-transfer complexes and attention will be concentrated on complexes of CU ions of the first type.

Deposited catalysts, i.e. catalysts prepared by depositing in one way or another transition metal compounds onto a support, in which the concentration of the CU ions is relatively high, are most convenient for investigation. However, in this case too the deposited ions can form either a solid solution in the carrier lattice or they can give rise to microcrystals of the deposited substance, i.e. they may exist in the bulk of the solid and not on the surface. During the last decade, zeolite catalysts into which transition metal ions have been introduced by ion exchange have come to be widely used. The study of such catalytic systems, as well as deposited catalysts, can yield rich information about the properties of the CU ions. The EPR and ultraviolet spectroscopic studies of CU ions in zeolites have been reviewed.[10,11]

## II. METHODOLOGICAL CHARACTERISTICS OF THE APPLICATION OF THE EPR AND ULTRAVIOLET SPECTROSCOPIC METHODS FOR THE STUDY OF HETEROGENEOUS CATALYSTS

The application of the ultraviolet spectroscopic method to the investigation of solid catalysts has a number of characteristic features which distinguish it from its application to liquids. This is due to the fact that, for catalysts which are usually finely dispersed systems, light is appreciably scattered and reflected which hinders and in many cases virtually precludes the observation of their transmission spectra. In order to diminish light scattering, one can place the disperse solid in a medium, for example, liquid paraffin, with the same refractive index, and then measure the absorption spectra. However, it is much more convenient to deduce the absorption spectrum from the information carried by the light scattered by the specimen. For this purpose, it is necessary to measure the diffuse reflectance spectra. The method of measurement of such spectra is relatively simple and has therefore come to be widely used nowadays.[12–17]

The reflectance spectrum of the specimen is usually obtained from measurements of the relative diffuse reflectance coefficient $R_{diff}$ as a function of the wavelength. The quantity $R_{diff}$ is defined as the ratio of the intensities of the light subjected to diffuse reflectance by the specimen and a standard. Strongly reflecting white powders, for example MgO, $SiO_2$, $MgSO_4$, $Al_2O_3$, and NaCl are used as standards. Kubelka and Munk and, independently of them, Gurevich, Girin, and Stepanov proposed an equation for the dependence of $R_{diff}$ on the concentration of the absorbing centres in the specimen $c$ and on their extinction coefficient $\varepsilon$:

$$(1-R_{diff})^2/2R_{diff} = S\varepsilon c,$$

where $S$ characterises the properties of the medium and is independent of the light wavelength.[12–15] Since the quantity $S$ is usually unknown, it is impossible to determine $\varepsilon c$ exactly. However, the position of the absorption maximum (the maximum value of $\varepsilon$) can be determined from measurements of $R_{diff}$, i.e. it is possible to obtain the same information about the energy of the optical transitions as in the measurements of absorption spectra.

The application of the EPR method to the study of catalysts does not entail any special methodological difficulties, because it is suitable for the study of substances in any state of aggregation. The spectra are usually measured in quartz bulbs, which makes it possible to subject the specimen to different types of treatment, including a high-temperature treatment, and to carry out adsorption and other operations in the absence of air or in a controlled atmosphere. The interpretation of the EPR spectra is sometimes difficult because polycrystalline or amorphous specimens have more complex spectra than single crystals and their elucidation requires special procedures.[18–20] The theoretical principles of the EPR method have been sufficiently fully described in various monographs, for example Refs.19–22.

## III. IONS OF METALS IN THE FIRST TRANSITION SERIES

We shall describe the available data in order of increasing atomic number of the transition element forming part of the catalyst. This method of exposition constitutes in our view the most rational way of giving a systematic account of the literature data.

### 1. Titanium Ions

The EPR and optical spectroscopic studies on surface titanium CU ions published hitherto refer mainly to $Ti^{3+}$ with the electronic configuration $(A)\ (3d)^1$, where $(A)$ is a completed electron shell. Titanium dioxide in two modifications (anatase and rutile) and deposited catalysts have been studied.

At the beginning of the 1960's it was shown that the adsorption of oxygen at room temperature on partly reduced anatase specimens leads to the appearance of a signal due to adsorbed oxygen radical-anions in the EPR spectrum.[23,24] The observation of this phenomenon led to a whole series of studies by different investigators[25–30] of the coordination

and valence states of the titanium ions on the surface of partly reduced $TiO_2$ and of their role in the formation of radical-anions. In a detailed investigation of specimens of partly reduced anatase, Kazanskii and co-workers observed in the EPR spectra, measured at the temperature of liquid nitrogen, a broad absorption line, whose form depended on the degree of reduction of the specimens.[25] In the spectra of specimens subjected to a vacuum heat treatment in the range 300–500 °C, the form of this line is determined by the anisotropy of the $g$-factor ($g_\perp = 1.97$ and $g_\parallel = 1.90$). On the basis of the values of the $g$-factors for the line and its disappearance when oxygen is adsorbed, the authors concluded that the line is due to surface tetrahedrally coordinated $Ti^{3+}$ ions.

A broad line has been frequently observed in the EPR spectra of partly reduced anatase at the temperature of liquid nitrogen also in other investigations.[26–28] The authors likewise attributed this to surface $Ti^{3+}$ ions. However, some workers[26,27] believe that the $Ti^{3+}$ ions responsible for its appearance exist in a tetragonal ligand field, i.e. are surrounded by five or four lattice oxygen ions forming a square pyramid or a square respectively. These coordinations arise from the initial octahedral environment of titanium ions when one or two lattice oxygen ions are removed in the reduction process. A specific type of coordination of the surface $Ti^{3+}$ ions of anatase was not discussed by Cornaz et al.,[28] but they noted that there are three sites in the coordination sphere of titanium ions.

Partly reduced specimens of another modification of $TiO_2$ (rutile) have also been investigated by EPR.[29,30]. A signal with $g_\perp = 1.959$ and $g_\parallel = 1.946$ appeared in the spectra of specimens subjected to a vacuum heat treatment at 500 °C (measurements at 77, 4.2, and 1.6 K). Analysis of the $g$-factors and spin–lattice relaxation times at the temperature of liquid helium and also the disappearance of the signal following the adsorption of oxygen showed that the signal is due to surface CU $Ti^{3+}$ ions tetragonally coordinated. Such coordination arises as a result of the abstraction of one or two oxygen ions located at a distance of 1.988 Å from the titanium ion (the remaining four oxygen ions are at a distance of 1.944 Å). The authors suggest that the width of the signal at 4.2 K is determined by the spin–lattice relaxation time and not by the dipole–dipole interaction and on this basis they concluded that the distance between the $Ti^{3+}$ ions should be not less than 6 Å.

In later studies[31–33] it was concluded from the analysis of the EPR signal parameters that the CU $Ti^{3+}$ ions on the rutile surface are most probably formed when one oxygen ion is removed from the first coordination sphere of the initially octahedrally coordinated titanium ions. Fluorinated rutile specimens have also been studied[31–33] and it has been shown that CU $Ti^{3+}$ ions involved in a square-pyramidal coordination, in the coordination spheres of which the oxygen ions have been partly replaced by fluoride ions, are present on the surface of such specimens. In these studies the EPR signal was assigned to surface CU ions not only from the analysis of the magnetic resonance parameters but also on the basis of the study of the formation of complexes by the CU ions with water and ammonia molecules. When the molecules of these substances were adsorbed at room temperature, they entered the first coordination sphere of the CU $Ti^{3+}$ ions, altering their coordination to octahedral, which changed the corresponding EPR parameters. After the vacuum heat treatment at 400 °C of specimens with adsorbed water molecules, the initial form of the spectrum due to the $Ti^{3+}$ ions and its intensity were restored, and the changes in the signal in repeated adsorption–desorption cycles were found to be fully reversible.

The conditions in the formation of the CU $Ti^{3+}$ ions on the surface of deposited titanium silicate catalysts and their properties were investigated for the first time by Shvets and Kazanskii,[34] who showed that the reduction and subsequent vacuum heat treatment at 500 °C lead to the formation of CU $Ti^{3+}$ ions. In the presence of a high titanium content in the specimens (≥2 wt.%) the ions exist mainly in square-pyramidal coordination, while in the presence of low titanium content (~0.2 wt.%) they exist in tetrahedral coordination. Both these and other ions serve as centres for the adsorption of the molecules of typical ligands, for example, water.

The surface $Ti^{3+}$ ions of silica gel have been obtained[35] by the reaction of $Ti(CH_2C_6H_5)_4$ with hydroxy-groups. It has been shown by EPR that this involves the formation of $(-O-)_2TiR$ and $(-O-)TiR_2$ complexes, in which titanium ions can apparently be regarded as coordination unsaturated. The adsorption of $H_2$ and $C_2H_4$ entails the formation of complexes with a Ti–H bond.

The method of optical spectroscopy in diffusely scattered light has been used[36] to study the coordination state of surface quadrivalent titanium ions deposited on the surface of silica gel by the reaction of $TiCl_4$ with OH groups. Analysis of the position of the absorption band enabled the author to attribute it to octahedrally coordinated $Ti^{4+}$ ions formed as a result of the interaction of the initial CU tetrahedrally coordinated $Ti^{4+}$ ions with water molecules.

### 2. Vanadium Ions

Hitherto the most detailed studies have been made of the Cu $V^{4+}$ ions [electronic configuration $(A)\ (3d)^1$]. $V_2O_5$ has been studied widely by EPR. However, it was not possible to observe effects associated with the formation of surface CU ions. Only recently it has been shown[37] that tetrahedrally coordinated $V^{4+}$ ions, whose EPR spectrum is not observed at room temperature, are formed on the surface of $V_2O_5$ subjected to a vacuum heat treatment at temperatures up to 200 °C. At the same time $V_2O_5$ contains also $V^{4+}$ ions in square-pyramidal coordination, although it is not clear whether they are present in the bulk phase or on the surface of the catalyst. It has been concluded that the tetrahedrally coordinated ions serve as centres for the adsorption of formic acid molecules. Following adsorption, the tetrahedral coordination of the $V^{4+}$ ions changes to square-pyramidal and their spectrum is observed at room temperature.

The CU ions on the surface of different deposited catalysts have been studied in greater detail. It has been shown[38] that the surface of vanadium silicate catalysts reduced *in vacuo* at 500 °C contains tetrahedrally coordinated $V^{4+}$ ions. The authors arrived at this conclusion by comparing the EPR spectra of the reduced catalysts measured at 20 K and of $VCl_4$ in which the $V^{4+}$ ion is tetrahedrally coordinated to chloride ions. The EPR spectrum of the tetrahedrally coordinated $V^{4+}$ ions, measured at room temperature, is greatly broadened and can hardly be observed. It has been shown[38] from the change in the spectrum after the adsorption of water at room temperature that these ions serve as centres for the adsorption of water molecules. After adsorption, the EPR spectrum of the tetrahedrally coordinated $V^{4+}$ ions disappears and is replaced by the vanadyl ion spectrum. This spectrum can be observed both at low and room temperatures. After the adsorption of water molecules, the $V^{4+}$ ions are in square-pyramidal or distorted octahedral coordination where one

of the bonds is shortened, which in fact results in the formation of the vanadyl bond.

Detailed EPR studies[39–42] of the properties of tetrahedrally coordinated CU $V^{4+}$ ions on the surface of $V/SiO_2$ catalysts showed that they adsorb not only $H_2O$ but also $NH_3$, $CH_3OH$, $C_2H_5OH$, $SO_2$, $N_2O$, and CO. Even complexes with the molecules of $N_2$,[39] olefins (for example, propene[43]), and aromatic compounds (for example o-xylene, toluene, and benzene[44,45]) have been observed. The parameters of the EPR spectra of the complexes with hydrocarbons are close to those of the vanadyl complexes.

It has been shown[9,46,47] that the adsorption of $O_2$ on the reduced $V/SiO_2$ catalysts in the temperature range 77–300 K leads to the appearance of two new EPR signals with $g_1 = g_1 = 2.023$, $g_2 = 2.011$, $g_3 = 2.004$, and $g_\perp = 2.026$ ($g_\parallel < g_\perp$), which are due to the adsorbed $O_2^-$ and $O^-$ radical-anions. The $O_2^-$ radical-anions are formed as a result of electron transfer from the CU $V^{4+}$ ions to adsorbed water molecules. The $O^-$ radical-anions are formed on dissociation of $O_2^-$. A hyperfine structure due to one vanadium nucleus is observed in the EPR spectra, which indicates the stabilisation of the radical-anions in the first coordination sphere of the CU vanadium ions. A calculation has been carried out[48] for a model of the adsorption complex formed under these conditions, while in other investigations the reactivity of complexes with charge transfer from the CU ion to oxygen was studied in detail by EPR.[49–52]

Tetrahedrally coordinated $V^{4+}$ ions are formed on the surface of $V/SiO_2$ catalysts not only on thermal reduction but also on photoreduction at 77 K in an atmosphere of $H_2$.[53,54] Two absorption bands, at 13 100 and 19 500 $cm^{-1}$, correspond to these ions in the diffuse electronic spectra, which indicates an appreciable distortion of their tetrahedral coordination. It is of interest that the photoreduction in an atmosphere of CO leads to the formation of CU $V^{3+}$ and not $V^{4+}$ ions. These ions cannot be detected by EPR at 77 K and above, but they have been reliably identified from the optical spectra (absorption bands at 11 800, 17 000, and 23 000 $cm^{-1}$). The $H_2O$, $NH_3$, CO, and $C_2H_4$ molecules can enter the first coordination sphere of the $V^{3+}$ ions with formation of surface complexes.

The coordination states of the ions in the $V/Al_2O_3$ and $V/SiO_2$ catalysts are different. The characteristic vanadyl ion signal has been observed in the EPR spectra of alumino-vanadium specimens.[38] The adsorption of water molecules does not alter its form. It was concluded that the ions are present in a layer of $\gamma$-$Al_2O_3$ near the surface and have square pyramidal coordination. Other workers[39,55,57] arrived at an analogous conclusion. However, one should note that, since the EPR parameters of the $V^{4+}$ ions in "vanadyl" coordination are determined mainly by the presence of a shortened metal–oxygen bond, it is difficult to reach a conclusion from the data obtained whether such square pyramidal ions, even if they are located on the surface, can serve as centres for the adsorption of polar molecules. Some increase in the intensity of the signal due to vanadyl ions has been observed after the adsorption of water and certain other substances. This can be explained by the fact that, before adsorption, CU $V^{4+}$ ions were present on the surface in a non-vanadyl type of coordination. The results of a study[57] where bands corresponding to vanadyl ions and tetrahedrally coordinated $V^{4+}$ ions were found in the EPR spectra of deposited aluminovanadium and vanadium–magnesium catalysts are of interest.

The coordination state of quadrivalent vanadium ions deposited on the surfaces of cabosil, $\gamma$-$Al_2O_3$, gibbsite, and boehmite [modifications of $Al_2O_3$] has also been investigated by allowing the surface OH groups to react with $VCl_4$.[58] When it is adsorbed on cabosil heated to 700 °C, $VCl_4$ reacts with only one OH group, forming tetrahedrally coordinated $V^{4+}$ ions. $V^{4+}$ ions which are both tetrahedrally coordinated and having the vanadyl coordination are formed on rehydrated cabosil. The ions on the $\gamma$-$Al_2O_3$ surface always have the vanadyl coordination, while on boehmite the authors observed a complex spectrum with three $g$-factors, apparently indicating the formation of ions involved in a strongly distorted octahedral coordination.

CU $V^{4+}$ ions have been observed and investigated on the surface of vanadium–zirconium catalysts.[59] A distinctive feature of these systems is that both CU ions and surface complexes with adsorbed water, methanol, and ammonium molecules have EPR spectra characteristic of the vanadyl coordination. The formation of complexes is manifested by a change in the magnetic resonance parameters, in the first place in $A_\perp$. Thus the CU $V^{4+}$ ions of the vanadium–zirconium catalysts are apparently involved in a square-pyramidal coordination.

Data concerning the existence of surface CU $V^{3+}$ ions on vanadium–phosphorus catalysts deposited on silica gel have been published.[60] These ions form surface complexes with water molecules. The subsequent adsorption of oxygen at room temperature leads to their oxidation to $V^{4+}$, which is manifested by a sharp increase of the EPR signal intensity.

The $V^{5+}$ ions, having the electronic configuration $(A)(3d)^0$, are non-paramagnetic and cannot be detected by EPR. The optical reflection and luminescence spectroscopic methods have therefore been used to detect the CU ions and to investigate their properties.[61–63] It has been shown that the CU $V^{5+}$ ions on the surfaces of vanadium silicate catalysts have distorted tetrahedral coordination (one of the vanadium–oxygen bonds is appreciably shortened and constitutes the vanadyl bond) and are capable of adsorbing various molecules ($H_2O$, $NH_3$, alcohols, etc.). Tetrahedrally coordinated CU $V^{5+}$ ions have been detected by reflection spectroscopy also on the surfaces of vanadium silicate catalysts prepared by molecular layer-by-layer deposition.[64–66] It has been suggested[67] that the presence of tetrahedrally coordinated CU vanadium ions on the surface of silica gel is responsible for the selectivity of the oxidation of propene to acrolein.

### 3. Chromium Ions

The extensive application of chromium-containing catalysts in various industrial processes (polymerisation of ethylene, dehydrocyclisation, dehydrogenation etc.) led to the publication of a large number of studies on such catalysts by EPR and optical spectroscopic methods. Although the coordination state of the chromium ions on the catalyst surface has been discussed in many communications, much less attention has been devoted to the direct investigation of the formation and properties of CU ions. We shall examine them in order of decreasing oxidation state of the chromium ions.

The $Cr^{6+}$ ions have no unpaired electrons and therefore do not give rise to an EPR signal. However, they have an intense absorption band in the near ultraviolet due to a ligand-to-cation charge-transfer transition. When $Cr^{6+}$ ions are deposited on silica gel and aluminosilicate, dichromate ions are formed,[68] while their deposition on $\gamma$-$Al_2O_3$ leads to chromate ions.[68,69] It has been shown[70–72] that chromate ions are present together with dichromate ions on the surface of silica gel.

When deposited chromium catalysts are heated in air or *in vacuo*, $Cr^{5+}$ ions are formed, which were first observed by EPR.[73–76] The amount of $Cr^{5+}$ ions in catalysts subjected to a high-temperature treatment *in vacuo* or in oxygen is

usually several per cent relative to the total deposited chromium.[73,75–79] The remaining chromium ions exist mainly in the hexavalent state. There is also several per cent of ions in the tervalent state.

The EPR spectrum of the $Cr^{5+}$ ions in aluminochromium catalysts consists of an almost isotropic line with a width of approximately 40–50 G and $g = 1.96$. When the spectrum is measured in the 8 mm range, the line becomes anisotropic.[76] On the basis of the broadening of the line after the adsorption of oxygen, it has been concluded[77] that it is due to surface ions. It has been shown[38] that the $Cr^{5+}$ ions in the aluminochromium catalysts subjected to a vacuum heat treatment at 500 °C are stabilised in the form of chromyl ions $(Cr{=}O)^{3+}$ in truncated square pyramidal coordination.

The reflection spectra of the aluminochromium catalyst activated at 300 °C consist of three bands with absorption maxima at 14 000, 18 200, and 22 700 $cm^{-1}$.[80,81] These spectra are close to those of various complexes containing the chromyl ion $(Cr{=}O)^{3+}$. In view of this finding and also from the comparison of the experimental $g$-factors of the EPR signal ($g_\perp = 1.97$ and $g_\parallel = 1.95$), measured in the 8 mm range, with the values calculated theoretically the authors concluded that the $Cr^{5+}$ ions on the surface of the aluminochromium catalysts are stabilised in square-pyramidal coordination. The optical and EPR spectra of the catalysts activated at 300° and 500 °C are different. It was concluded that the $Cr^{5+}$ ions can exist on the surfaces of the aluminochromium catalyst in two coordinations—tetrahedral and square-pyramidal. The number of centres of each type depends on the temperature of the heat treatment of the specimens.

EPR studies on chromium(V) ions in catalysts on other carriers have shown that the absorption line form for these ions depends on the nature of the carrier, indicating different types of coordination of the $Cr^{5+}$ ions on the surfaces of different carriers. A theoretical calculation led Aleksandrov et al.[82] to conclude that the ions in a deposited chromium silicate catalyst are stabilised on the surface of silica gel in oxygen tetrahedra. The tetrahedra are distorted, leading to anisotropy of the $g$-factor of the EPR signal. By measuring the EPR spectra in the range from room temperature to 20 K, it was possible to confirm this conclusion and also to show that only less than 1% of the $Cr^{5+}$ ions have square-pyramidal coordination.[38] Measurements of the integral intensities of the spectra have shown that both at room temperature and at the temperature of liquid nitrogen only a proportion of the ions are manifested. The explanation is that the catalyst surfaces contain tetrahedrally coordinated $Cr^{5+}$ ions distorted in different ways. The distortions of the tetrahedra lead to differences in the spin–lattice relaxation times of the $Cr^{5+}$ ions, which entails in its turn a different dependence of the width of the signals on the temperature of measurement of the EPR spectra. As a result, some of the $Cr^{5+}$ ions give rise to absorption lines in the measurement at room temperature and even at the temperature of liquid nitrogen which are so broad that they cannot be observed by EPR. Thus measurements of the concentration of chromium ions in chromium silicate catalysts from the intensities of the EPR spectra must be carried out at least at the temperature of liquid hydrogen.

Measurements of the optical spectra of deposited chromium silicate catalysts have also confirmed that the $Cr^{5+}$ ions are stabilised on the surface in oxygen tetrahedra. These investigations were first made by Pecherskaya and Kazanskii.[80,81] They observed that the optical spectra of the catalyst and the compound $Sr_5(CrO_4)_3OH$, in which the $Cr^{5+}$ ions are tetrahedrally coordinated, are identical. Later these conclusions were confirmed in other investigations.[71,72]

Studies on chromium oxide catalysts where aluminosilicates are used as carriers have shown that $Cr^{5+}$ ions in both tetrahedral and square-pyramidal coordination are formed on the surface, i.e. ions characteristic of chromium silicate and aluminochromium catalysts.[83,84]

We shall now consider the results of EPR and optical spectroscopic studies of the interaction of adsorbed molecules with surface $Cr^{5+}$ ions. Detailed EPR investigations of the character of the interaction of water and ammonia molecules with tetrahedrally coordinated CU $Cr^{5+}$ ions on the $SiO_2$ surface have been carried out.[38] Analysis of the EPR spectra at 20 K has shown that the adsorption of $H_2O$ and $NH_3$ at room temperature leads to the formation of $Cr^{5+}$ ions in square pyramidal coordination. For specimens activated at 500 °C, the ratio of the $(CrO_4)^{3-}$ (tetrahedron) and $(Cr{=}O)^{3+}$ (square pyramid) signal intensities was 100; after the adsorption of $H_2O$ and $NH_3$ for 1 h at room temperature, the $(CrO_4)^{3-}$ signal intensities were negligibly small, while the $(Cr{=}O)^{3+}$ signal intensities were 4 and 140 respectively. Thus the adsorption of $H_2O$ molecules at room temperature leads to the disappearance of most of the $Cr^{5+}$ ions. The phenomenon is caused by the disproportionation of the $Cr^{5+}$ ions to $Cr^{6+}$ and $Cr^{4+}$ ions when water is adsorbed.

The adsorption of water also leads to a fourfold increase of the concentration (compared with the initial value) of $Cr^{5+}$ ions having square-pyramidal coordination. After $NH_3$ adsorption the concentration of the $Cr^{5+}$ ions exceeds the initial value, which is apparently associated with the partial reduction of the $Cr^{5+}$ [$Cr^{6+}$?] ions by ammonia. Thus the tetrahedrally coordinated $Cr^{5+}$ ions on the $SiO_2$ surface serve as centres for the adsorption of polar molecules, i.e. they are CU ions. The adsorbed molecules enter the first coordination sphere of the CU ions and form surface complexes.

Changes in the coordination state of $Cr^{5+}$ ions on the $\gamma$-$Al_2O_3$ surface, occurring on adsorption of various molecules, are much more difficult to observe. However, in this case too it has been possible to establish[38] that the adsorption of $H_2O$ molecules decreases the anisotropy of the absorption line due to ions with a square-pyramidal coordination. Measurement of the intensities of these spectra in the range from room temperature to 20 K showed that Curie's law holds in both cases. It was therefore concluded that both before and after the adsorption of $H_2O$, the $Cr^{5+}$ ions forms a chromyl bond with one of the oxygen ions in the catalyst lattice.

The formation of complexes by the adsorbed molecules of water, ammonia, alcohols, and aldehydes with the CU $Cr^{5+}$ ions has also been observed in other studies.[85–87] The EPR spectra of the complexes are characteristic of $Cr^{5+}$ ions with a shortened chromyl bond. Thus in all cases the chromium ions in such complexes have a distorted octahedral or square-pyramidal coordination.

The reduction of the deposited chromium oxide catalysts in $H_2$ or CO leads to the disappearance of the absorption lines from the optical spectra and of the EPR signals characteristic of the $Cr^{6+}$ [sic] and $Cr^{5+}$ ions. The EPR spectrum of the reduced deposited aluminochromium catalysts consists of a superposition of a very broad asymmetric line in the range 1500–1800 G ($\delta$-phase) and a symmetrical line with $g \cong 2$ ($\beta$-phase).[76] The $\delta$-phase consists of magnetically isolated $Cr^{3+}$ ions in an axial electric field (apparently in the field of a distorted octahedron). The broad symmetrical line is due to the $Cr^{3+}$ ions forming a magnetically concentrated system. The $Cr^{3+}$ ions of the $\beta$-phase apparently form clusters in which there is a fairly intense exchange and dipole–dipole interaction between the ions. However, the structure of the $\beta$-phase differs from that of $Cr_2O_3$ and is

closer to the chromium oxide gel, which is paramagnetic at room temperature.

When oxygen is admitted at room temperature, the intensity of the EPR line due to the δ-phase diminishes and the EPR signal characteristic of the $Cr^{5+}$ ions appears.[76,88,89] The intensity of the δ-phase signal does not change under these conditions, which shows that some of the $Cr^{3+}$ ions of the β-phase are present on the catalyst surface.

The properties of surface CU ions in reduced aluminochromium catalysts have been studied in greater detail in other investigations.[90–92] It follows from the analysis of the optical spectra of the reduced specimens containing adsorbed water that all the $Cr^{3+}$ ions are involved in octahedral coordination. The desorption of water at 500 °C alters both the optical and EPR spectra. The width of the β-phase line in the EPR spectra increases from 750 to 1070 G. After the adsorption of water at room temperature, the line width diminished and returned to the initial level. The adsorption of methanol at room temperature likewise entails an analogous effect. In contrast to this, the adsorption of ammonia does not induce narrowing of the β-phase absorption line. The broadening of the line on desorption of water was accounted for by the diminution of the indirect exchange interaction via the $O_2$ ions as a consequence of the formation of CU $Cr^{3+}$ ions in a coordination sphere of which one or several oxygen atoms are missing. On adsorption, polar molecules enter the coordination spheres of all the ions and, when the adsorbed molecule contains oxygen atoms, the exchange interaction intensifies and the EPR line becomes narrower.

Measurements of the optical spectra of the aluminochromium catalysts agree well with EPR data.[91,92] After the desorption of water, maxima at 10500, 28800, and 31200 $cm^{-1}$, corresponding to $Cr^{3+}$ ions with square-pyramidal coordination, appear together with the signals of octahedrally coordinated $Cr^{3+}$ ions. The adsorption of ammonia and methanol shifts the absorption maxima of the CU $Cr^{3+}$ ions with square-pyramidal coordination to the short-wavelength region. These effects are caused by the formation of surface complexes with a distorted octahedral coordination. It is of interest to note that the CU $Cr^{3+}$ ions with square-pyramidal coordination form complexes with ethylene and benzene on the surface of aluminochromium catalysts at room temperature.[92]

It has been observed[88] that, after the reduction with hydrogen and subsequent vacuum heat treatment of the deposited aluminochromium catalysts containing 2 wt.% of chromium, the β-phase band virtually disappears from the EPR spectra, reappearing after the adsorption of water at room temperature. The authors assume that the disappearance of the line is associated with the reduction of the $Cr^{3+}$ ions to $Cr^{2+}$ and its appearance after the adsorption of water is due to the oxidation of the $Cr^{2+}$ ions to $Cr^{3+}$. Although there is no doubt about the formation of $Cr^{2+}$ ions in the reduced aluminochromium catalysts,[93–95] nevertheless the increase of the intensity of the EPR band due to the β-phase of the $Cr^{3+}$ ions, observed also in the adsorption of methanol,[90–92] is undoubtedly caused, in our view, by its narrowing and the increase of the amplitude as a consequence of the formation of surface complexes, as stated in the discussion just completed, and not by the oxidation of the $Cr^{2+}$ ions by water molecules, which hardly occurs at room temperature.

The complexes of $Cr^{3+}$ ions, deposited on the carrier surface by different methods, as well as the CU ions formed on their decomposition, have been investigated by EPR and optical spectroscopy in several studies. It was shown that the vacuum heat treatment of the complexes $Cr(NH_3)_6^{3+}$, $Cr(H_2O)_6^{3+}$, and several others at 500 °C leads to the formation of CU $Cr^{3+}$ ions, characterised by a structureless absorption in a broad region of the optical spectrum.[96,97] Such CU ions are centres for the adsorption of polar molecules. In the adsorption of water molecules, their coordination returns to the initial octahedral coordination. The study of the adsorption of ethylene on CU $Cr^{3+}$ ions, stabilised on the silica gel surface, has shown that these ions serve as polymerisation centres.[96,97]

Chromium(III) complexes grafted or deposited on the surface have been investigated by optical spectroscopic and EPR methods.[98–100] The high-temperature dehydration of the specimens caused the same broadening of the EPR line as for the aluminochromium catalyst.[90–92] It is caused by the formation of CU ions.[100]

The reduction of deposited chromium silicate catalysts in an atmosphere of CO or $H_2$ leads to the formation mainly of $Cr^{2+}$ ions, in contrast to the aluminochromium systems.[40,93,95,101] The chromium silicate catalyst reduced in CO at 500 °C assumes a blue colour. Its optical spectrum consists of one band with an absorption maximum at 13000 $cm^{-1}$. Absorption bands have not been observed in the EPR spectrum of such a specimen either at room temperature or at the temperature of liquid nitrogen. The adsorption of polar molecules (water or ammonia) at room temperature does not entail the appearance of absorption lines in the EPR spectra, but it does induce a change in the optical spectrum: after the adsorption of water, the absorption maximum undergoes a hypsochromic shift and is observed as 15500 $cm^{-1}$, while after the adsorption of ammonia it occurs at 16400 $cm^{-1}$. The presence of a single absorption maximum in the optical spectra of reduced chromium silicate specimens both before and after the adsorption of polar molecules and the hypsochromic shift of this maximum after adsorption indicate the tetrahedral coordination of the $Cr^{2+}$ ions in the reduced chromium silicate specimen.[40,95] After adsorption at room temperature, the water and ammonia molecules enter the first coordination sphere of the tetrahedrally coordinated CU $Cr^{2+}$ ions without altering their oxidation state and their coordination is built up to the octahedral coordination. It has also been shown that the concentration of $Cr^{2+}$ ions depends on the nature of the reductant and the amount of deposited $Cr^{6+}$ ions.

The CU $Cr^{2+}$ ions on the $SiO_2$ surface are also capable of forming complexes with CO molecules without change in the oxidational state.[101–103] Depending on the pressure and temperature, the adsorption of CO can lead to complexes containing both two molecules and one molecule. The interaction of CU ions with oxygen induces their rapid oxidation, which makes it possible to employ reduced chromium silicate systems for the elimination of traces of oxygen from various gases.[93] Chromium silicate catalysts for the polymerisation of ethylene also contain CU $Cr^{2+}$ ions, which are believed to be the active centres for this reaction.[93,101,104] However, doubts have been cast on this conclusion[96,97] and it has been shown that the active catalyst contains CU $Cr^{3+}$ ions. It has been recently established that both these valence states of chromium ions are active in the polymerisation of ethylene.[105]

CU $Cr^{2+}$ ions on the $SiO_2$ surface can be obtained not only by thermal reduction at high temperatures but also by photochemical reduction in CO at 20 °C.[106] These ions have a tetrahedral coordination and are characterised by the absorption band at 11800 $cm^{-1}$. Photochemical reduction leads to the formation of CU ions which are more uniform as regards coordination than those obtained by thermal reduction. A very interesting property of CU $Cr^{2+}$ ions obtained by photochemical reduction has been noted, namely their ability to undergo a rearrangement of their coordination environment at temperatures above 150 °C, which alters

their optical spectrum and properties. The reduction of the $Cr/SiO_2$ catalyst in CO at the temperature of liquid nitrogen leads to the formation of CU $Cr^{4+}$ ions and not $Cr^{2+}$ ions. Absorption bands due to the *d–d* transitions at 9400 and 17 000 $cm^{-1}$ correspond to these ions. Apparently the existence of $Cr^{4+}$ ions on the catalyst surfaces was demonstrated fairly reliably for the first time by Pershin et al.[106] It has also been shown that the CU $Cr^{4+}$ ions form the complexes $Cr^{6+}.NO^{2-}$ with NO molecules, transferring two electrons to the adsorbed molecule, which leads to the appearance of an EPR signal with $g_{\parallel} = 2.046$, $g_{\perp} = 1.99$, $A_{\parallel}^{N} = 0$ G, and $A_{\perp}^{N} = 10$ G.

The formation of CU $Cr^{2+}$ ions on the surfaces of reduced aluminochromium catalysts has been observed by EPR from the interaction with the adsorbed NO molecules.[107] The adsorption of NO at room temperature led to the formation of the surface complexes $Cr^{+}.NO^{+}$ in a low-spin state as a result of electron transfer from the adsorbed molecules to the CU $Cr^{2+}$ ions.

The formation of CU ions in the vacuum heat treatment of mononuclear and dinuclear complexes of $Cr^{2+}$ ions deposited by ion exchange or grafted on to $SiO_2$, $\gamma$-$Al_2O_3$, and MgO has been investigated.[96,108] The vacuum heat treatment of such complexes on $SiO_2$ leads to the formation of tetrahedrally coordinated $Cr^{2+}$ ions, while on MgO and $\gamma$-$Al_2O_3$ a considerable proportion of the ions are oxidised to $Cr^{3+}$.

In conclusion of this Section, one should note that, in connection with the extensive application of chromium-containing systems as catalysts, the formation and properties of the CU chromium ions in a wide variety of oxidation states has been studied in greatest detail compared with other transition metal ions.

### 4. Manganese Ions

In the EPR study of manganese oxides, both pure and deposited on MgO,[109–112] it was not possible to separate the spectra of the bulk-phase and surface ions, although an increase of the width of the lines due to the $Mn^{2+}$ ions with increase of the specific surface of MgO, caused by the formation of surface ions, has been noted, for example, by Cordishchi et al.[110] Yamamura et al.[111] assumed that they were able to observe surface octahedrally coordinated $Mn^{2+}$ ions in MgO, but later[112] this conclusion was subjected to a fairly convincing criticism.

The $Mn^{2+}$ ions deposited on silica gel surface have been investigated[113,114] by EPR. At a manganese concentration up to several per cent, a broad line due to a magnetically concentrated phase or clusters of $Mn^{2+}$ ions was observed. At low concentrations it was possible to observe a spectrum which was attributed to individual $Mn^{2+}$ ions. The change of their symmetry and coordination compared with a solution has been noted,[114] but in the above studies the formation of CU manganese ions was not investigated under conditions of high-temperature hydration, although their existence on the $SiO_2$ surface can be demonstrated with the aid of the interaction of manganese silicate specimens with oxygen: the presence of such ions permits the use of these systems as sorbents for trace amounts of oxygen in olefins.[115] Yamamura et al.[111] showed only that, in the high-temperature dehydration of octahedral complexes of $Mn^{2+}$ ions deposited on silica gel, their EPR signal disappears, apparently owing to the great band width for the highly distorted surface complexes.

### 5. Iron Ions

The conditions in the formation and properties of CU $Fe^{2+}$ ions on $SiO_2$ have been investigated[116] by diffuse reflectance optical spectroscopy. The formation of CU ions of two types was established: tetracoordinated at activation temperatures *in vacuo* up to 700 °C and bicoordinated at 1000 °C. The former adsorb $H_2O$, NO, and $O_2$ at room temperature, while the latter also adsorb CO, $C_2H_4$, and $N_2$ molecules. It has been noted that the complexes with CO, $O_2$, and $N_2$ are unstable and are readily decomposed after the adsorption of water. The catalytic reactivity of such CU $Fe^{2+}$ ions on $SiO_2$ in the reactions involving the decomposition of NO and its reduction by CO has been studied.[117]

The formation of surface compounds of $Fe^{3+}$ ions in the $Fe_2O_3$–$SiO_2$ and $Fe_2O_3$–$SiO_2$–$Al_2O_3$ catalysts in the high-temperature heat treatment in air have been investigated by EPR and diffuse reflection spectroscopy.[118] It has been observed that water molecules and hydroxy-groups enter the coordination sphere of the surface $Fe^{3+}$ ions.

### 6. Cobalt Ions

The study of deposited cobalt silicate catalysts by the joint application of the EPR and optical spectroscopic methods has shown that the vacuum heat treatment at 700 °C leads to the formation of surface CU $Co^{2+}$ ions in a tetrahedral coordination and that tetrahedra compressed along the trigonal axis are produced.[119] The optical spectra change after the adsorption of $H_2O$ and $NH_3$ molecules at 20 °C, which indicates the formation of complexes with a square-pyramidal or highly distorted octahedral coordination.

The optical spectra of specimens obtained by impregnating silica gel with aqueous $CoCl_2$ and $Co(NO_3)_2$ solutions and by ion exchange have been compared.[99] It was found that the properties of the surface complexes depend both on the methods of their deposition on the surface and on the nature of the cobalt compound. Thus, whereas the octahedral coordination of the $Co^{2+}$ ion on the catalyst surface, obtained by impregnation with a $Co(NO_3)_2$ solution, does not change after drying at room temperature, nevertheless under the same conditions the octahedral coordination of the $Co^{2+}$ ions obtained from $CoCl_2$ changes to the tetrahedral coordination. The introduction of $Co^{2+}$ ions by ion exchange immediately leads to tetrahedrally coordinated ions. After specimens prepared by impregnation had been heat treated in air at 500 °C, cobalt ions with a tetrahedral coordination are also formed.

Much attention has been devoted to the investigation of the state of the cobalt ions deposited on $Al_2O_3$ and MgO.[120–122] Changes have been observed in the optical spectra of tetrahedrally coordinated $Co^{3+}$ ions on the $Al_2O_3$ surface after the adsorption of propene.[120] On the MgO surface, some of the $Co^{2+}$ ions are in square-pyramidal coordination, which changes to distorted octahedral coordination on adsorption of $NH_3$.[122]

The surface CU $Co^{2+}$ ions have been detected by optical spectroscopy also in mixed Co–Mo–$Al_2O_3$ catalysts.[123] The changes in the spectra after the adsorption of CO, $H_2O$, thiophen, and pyridine indicate the localisation of the main bulk of the ions in the oxygen tetrahedra. A small proportion of the $Co^{2+}$ ions are present on the surface in a trigonal coordination. Analysis of the optical spectra showed that the presence of the $MoO_3$ phases is essential for the formation of such CU trigonally coordinated ions.

### 7. Nickel Ions

In one of the first studies of nickel ions in catalysts by optical spectroscopy,[124] it was shown that the spectrum of dispersed NiO, obtained *in vacuo*, resembles the spectrum of the complex $Ni(H_2O)_6^{2+}$. The absorption of $O_2$ leads to the same changes in the spectra of the specimens as the introduction of $Li^+$ ions. On this basis, it has been suggested that the effect of $O_2$ is associated with the conversion of some of the $Ni^{2+}$ ions into $Ni^{3+}$. The adsorption of $H_2$ and CO leads to the partial reduction of the oxide and the formation of $Ni^+$ ions. Klier[124] was unable to establish whether the $Ni^+$ and $Ni^{3+}$ ions formed on adsorption are present on the surface layer of NiO or in its layer next to the surface.

Much attention has been devoted in the literature to nickel silicate catalysts. In one of the first studies of these catalysts it was shown[125] that the initial distorted octahedral coordination of the ions in specimens prepared by impregnation with aqueous $NiCl_2$ solutions persists on heating in air up to 500 °C. It was noted that the adsorption of ammonia influences the optical spectra of such specimens albeit fairly weakly. The coordination of the $Ni^{2+}$ ions remains octahedral after adsorption. Conditions for the formation of CU $Ni^{2+}$ ions on the $SiO_2$ surface were found in subsequent investigations.[126] It was shown that the ions are most likely to have distorted tetrahedral coordination and serve as centres for the adsorption of polar molecules.

Measurements of optical reflectance spectra somewhat later[127] led to the conclusion that the $Ni^{2+}$ ions on the $SiO_2$ surface after evacuation at 1000 °C have a coordination number of two and their coordination sphere can therefore include up to four adsorbed molecules. The formation of surface complexes with CO, $C_2H_4$, NO, and $NO_2$ molecules have been observed. One should note that the possibility of such low coordination of surface ions (with a coordination number of two) requires, in our view, more rigorous evidence, although the existence of CU $Ni^{2+}$ ions and their complexes on the $SiO_2$ surface is not in fact open to doubt.

Using the EPR method, the interaction of surface $Ni^{2+}$ ions with anthracene and diphenylpicrylhydrazine to form charge-transfer complexes has been investigated by EPR.[128–130] It has been suggested that anthracene is adsorbed on $Ni^{2+}$ ions with tetrahedral coordination.

Together with the traditional method for the preparation of deposited catalysts by impregnation with inorganic nickel salts, the catalysts have been prepared by the interaction of bis-π-allylnickel with $SiO_2$.[131] It has been established that, when the specimens are heated in $O_2$ above 300 °C, the organic ligand is fully oxidised and CU $Ni^{2+}$ ions in a state with a low symmetry are formed. The exact coordination state could not be established.

The formation of CU nickel ions on MgO has also been investigated by EPR and optical spectroscopy,[132,133]. It has been observed that the intensity of the EPR signal due to the $Ni^{2+}$ ions involved in an octahedral coordination increases after the adsorption of $H_2O$, $NH_3$, and HBr molecules at 20 °C. This was caused by the presence on the surface of CU $Ni^{2+}$ ions involved in a square-pyramidal or tetrahedral coordination, which were undetectable by the EPR method before the adsorption. Analysis of the optical spectra led the authors to give preference to the square-pyramidal coordination.[133]

On reduction of the $Ni/SiO_2$ catalyst by ultraviolet light in $H_2$ at 77 K, the formation of CU $Ni^+$ ions with distorted tetrahedral coordination, containing an $H_2$ molecule in the coordination sphere, was observed.[134] Their EPR spectrum is characterised by the $g$-factors: $g_1 = 2.015$, $g_2 = 2.30$, and $g_3 = 2.64$. After vacuum heat treatment at 520 K, the coordination environment of these ions changes, as shown by the change in the $g$-factor. The CU $Ni^+$ ions form complexes with the adsorbed $O_2$, $H_2O$, $NH_3$, and CO molecules, complexes with one, two, and three CO molecules being present in the last case. At a low temperature, even $N_2$ molecules can enter the coordination spheres of the CU $Ni^+$ ions.

The nickel ions deposited on the silica gel surface can be reduced to the metallic state. Examination of studies on such catalysts is outside the framework of the present review. Nevertheless we would wish to note an interesting study[135] in which the poisoning of a nickel silicate catalyst in the course of the hydrogenation of butene was investigated by ultraviolet spectroscopy and it was shown that this entails the formation of surface complexes of nickel with hydrogen sulphide and the hydrocarbon. These complexes can be extracted from the catalyst and the spectra of the solution and the surface complex are analogous.

### 8. Copper Ions

The EPR study of $Cu^{2+}$ ions deposited on $SiO_2$ by impregnation with an aqueous $Cu(NO_3)_2$ solution showed that CU $Cu^{2+}$ ions in different coordination environments, particularly in distorted tetrahedral coordination, are formed on vacuum heat treatment at 500 °C.[136] Some of the CU $Cu^{2+}$ ions cannot be detected at all by EPR at 77 K apparently owing to the short spin–spin lattice relaxation time. The $H_2O$, $NH_3$, $C_5H_5N$, $C_2H_5OH$, and $SO_2$ molecules adsorbed at 20 °C enter the coordination spheres of the CU $Cu^{2+}$ ions and form surface complexes having distorted octahedral coordination. Reactions involving substitution in the coordination spheres of the surface complexes of one set of adsorbed molecules by another have been observed.

The adsorption properties of the CU $Cu^{2+}$ ions on the $SiO_2$ surface after the introduction of copper ions by ion exchange in the form of the $Cu(NH_3)_4^{2+}$ and $Cu(H_2O)_6^{2+}$ complexes have been investigated.[137,138] It was shown that the initial copper complexes lose the coordinated ligand molecules on vacuum heat treatment and form CU $Cu^{2+}$ ions. In the case of specimens prepared by exchange with $Cu(NH_3)_4^{2+}$, tetrahedrally coordinated ions are formed, as in the study of Bogdanov et al.[136] The coordination of the ions in catalysts prepared by exchange with $Cu(H_2O)_6^{2+}$ could not be determined owing to the poor resolution of the EPR spectrum. The adsorption of $NH_3$ and $C_5H_5N$ molecules leads to the formation of tetragonally distorted octahedral complexes of the CU ions. In the adsorption of $H_2O$ two different EPR spectra were observed, which indicates the existence of two types of complexes with different coordination sphere symmetries.

The formation of exchange-linked ion pairs, which possess the properties of CU ions, i.e. are able to stabilise the different molecules in their coordination spheres, has been observed[139] for deposited copper silicate specimens heated *in vacuo* at 650–950 °C. After the adsorption of polar and non-polar molecules, the ion pairs decomposed and the signals due to the isolated $Cu^{2+}$ involved in different types of coordination were observed in the EPR spectra. Thus octahedral complexes were formed after the adsorption of $NH_3$ and $H_2O$ and complexes involved in coordination corresponding to a truncated octahedron or a tetrahedron compressed along the threefold axis (the EPR spectra have $g_\perp > g_\parallel$) were noted after the adsorption of $C_2H_4$ and CO. The copper ions forming part of the composition of the ion pairs are also capable of forming covalently bound complexes with $O_2$ molecules.

Much attention has been devoted in the literature to aluminocopper catalysts.[140–143] Although it has now been fairly reliably established that the bulk-phase copper ions

in such catalysts have both octahedral and tetrahedral coordination,[144] the coordination state of the surface $Cu^{2+}$ ions has not been determined quite so reliably. On the basis of the analysis of EPR spectra, it has been suggested[145] that the $Cu^{2+}$ ions on the surfaces of oxidised specimens are involved mainly in square-pyramidal coordination. On reduction, some of the $Cu^{2+}$ ions are converted into $Cu^0$ atoms, which form diamagnetic clusters.

In an EPR study of the state of copper in copper-magnesium oxide catalysts,[146] four types of signals were observed, one of which was due to the $Cu^{2+}$ ions in an axial field ($g_\parallel = 2.34$, $g_\perp = 2.058$, $A \cong 150$ G, $B = 28$ G) and was attributed to surface copper complexes with $CO_2$ molecules. This finding indicates the formation of CU $Cu^{2+}$ ions, but their coordination state could not be determined. The appearance of the characteristic EPR spectra after the adsorption of molecules revealed the presence of CU $Cu^{2+}$ ions also on the CuO surface.[147,148] It has been shown that the adsorption of various amines at room temperature entails the appearance of broad signals ($\Delta H \cong 700$–$900$ G), which has been attributed to surface copper complexes. Following the adsorption of $NH_3$, a fairly narrow signal arose with $g$-factors of 2.211, 2.122, and 2.071. The $Cu^{2+}$–$NH_3$ complexes responsible for this signal are stable up to 130 °C. The coordination state of the $Cu^{2+}$ ions before the adsorption was not investigated.

## IV. THE IONS OF METALS IN THE SECOND AND THIRD TRANSITION PERIODS

### 1. Molybdenum Ions

There have been very many fewer studies by EPR and optical spectroscopy of the CU ions of metals in the second and third transition Periods than for the metal ions of the first transition Period. Only molybdenum ions have been studied in fair detail.

In oxidised molybdenum silicate specimens molybdenum exists in a hexavalent state and forms tetrahedral and octahedral complexes according to reflectance spectroscopic data.[149–153] An analogous conclusion was also reached from measurements of luminescence spectra.[62] The surface acidity of the carrier influences significantly the position of the charge transfer band for the $Mo^{6+}$ ions, which is due to the formation of polymeric species incorporating both tetrahedral and octahedral molybdenum ions.[149] It has been suggested that these species are the anions of molybdosilicic heteropolyacid.[154,155]

The reduction of molybdenum silicate catalysts leads to the appearance of an intense EPR signal due to the $Mo^{5+}$ ions with the $A(4d^1)$ electronic configuration.[154–158] Analysis of the spectrum showed that these ions have molybdenyl coordination ($g_\perp = 1.940$; $g_\parallel = 1.882$; $B = 44$ G, $A = 98$ G).[154, 156,157] Furthermore, a considerable proportion of the CU ions on the surface have apparently distorted tetrahedral coordination.[156] At room temperature these ions were not detected in the EPR spectra and at 77 K their signal was superimposed on that due to the molybdenyl ions. On adsorption of $H_2O$, $NH_3$, CO, and other molecules, surface complexes of the CU ions are produced. The EPR spectra indicate their distorted (compressed) octahedral structure. The EPR spectrum of the CU $Mo^{5+}$ ions involved in a low coordination could be observed in a "pure" form on the $Mo/SiO_2$ surface on reduction of the catalyst by exposure to light in an atmosphere of $H_2$ and not thermally.[159] The EPR parameters are as follows: $g_1 = 1.811$, $g_2 = 1.929$, $g_3 = 1.952$, $A_1 = 82$ G, $A_2 = A_3 = 29$ G. The photochemical reduction of the same catalysts in a CO atmosphere leads to the formation of the CU $Mo^{4+}$ ions.[160,161] After the adsorption of NO at 77 K an EPR signal is generated ($g_\parallel = 2.075$, $g_\perp = 1.996$, and $A_\perp^N = 15$ G); it is due to the $Mo^{6+}.NO^{2-}$ complexes, formed as a result of the transfer of two electrons from the CU $Mo^{4+}$ ion to the orbitals of the NO molecule. The unusually strong reductive properties of the CU $Mo^{4+}$ ions, caused by the anomalous coordination, have been observed. For example, the interaction of $Mo^{4+}$ with $CO_2$ at 100 °C entails their oxidation to $Mo^{6+}$ and the liberation of CO molecules to the gas phase. After the reduction of molybdenum silicate catalysts with trimethylaluminium in suspension in toluene, an EPR signal with $g = 1.989$ and seven hyperfine lines having a splitting of 4.9 G, attributed to a surface complex of $Mo^+$ with two toluene molecules, was observed.[162]

The CU $Mo^{5+}$ ions formed on the $SiO_2$ surface on reduction also serve as centres for the adsorption of $O_2$ and $N_2O$ molecules. The adsorption results in the formation of the $O_2^-$ and $O^-$ radical-anions respectively in the coordination spheres of the CU ions.[9,156,163] The $O_2^-$ and particularly $O^-$ radical-ions are highly reactive and can participate in various reactions.[9,50,52,156] Thus $O_2$ and $N_2O$ molecules are activated in the coordination spheres of the CU $Mo^{5+}$ ions, which makes it possible to regard them as active centres for catalytic oxidation reactions.

Oxidised aluminomolybdenum catalysts contain both $Mo^{6+}$ [164, 165] and $Mo^{5+}$ [166] ions. At low concentrations the $Mo^{6+}$ ions have tetrahedral coordination, but, with increase of the molybdenum content, octahedrally coordinated ions are also formed.[164] The reduction of the aluminomolybdenum catalysts leads to the formation of appreciable amounts of $Mo^{5+}$ ions. According to the majority of investigators,[165,167–170] the EPR spectrum indicates their square-pyramidal or compressed octahedral coordination. Some workers[171,172] assume, however, that the $Mo^{5+}$ ions have a distorted tetrahedral coordination. Nevertheless in the majority of studies it has not been possible to observe clear-cut effects indicating the possibility of the stabilisation of polar molecules in the coordination sphere of the $Mo^{5+}$ ions on the $Al_2O_3$ surface and hence to confirm the formation of CU ions. It is noteworthy that the formation of CU molybdenum ions on the surfaces of aluminomolybdenum catalysts has been demonstrated reliably by EPR on the basis of the stabilisation of the $O_2^-$ radical-anions in their coordination sphere.[6,173]

Surface $Mo^{5+}$ ions have been detected by EPR in molybdenum–magnesium systems[173–175] from the broadening of the lines after the adsorption of molecular oxygen at low temperatures. The question of their coordination state has not been ultimately elucidated. Both distorted octahedral and tetrahedral coordinations have been suggested,[173,174] while other workers[175] believe that the ions exist only in distorted octahedral coordination. It has been observed[175] that the adsorption of CO, $C_3H_6$, $N_2O$, $H_2O$, and $NH_3$ molecules increases the anisotropy of the EPR signals by altering $g_\perp$ ($g_\parallel$ is almost constant), which indicates, according to the investigators, a lengthening of the $Mo^{5+} = O$ bond owing to the interaction of the adsorbed molecules with oxygen.

Surface $Mo^{5+}$ ions with square-pyramidal coordination as well as the bulk-phase ions have also been detected in the EPR study of bismuth–molybdenum and zinc–molybdenum catalysts.[176–178] A decrease of the intensity of their EPR signal following the adsorption of water and its increase after the adsorption of propane have been observed.[177] It has been suggested that these changes are caused by the decrease and increase respectively of the spin–lattice relaxation time of the ions as a consequence of the increased degree of symmetry of their environment in the case of $H_2O$ and its decrease in the case of $C_3H_8$.

CU $Mo^{6+}$ and $Mo^{5+}$ ions formed on the surface of carriers in the decomposition of grafted organic or carbonyl complexes of molybdenum have also been studied by EPR and ultraviolet spectroscopy[179,180] and it has been shown that, on the $SiO_2$ and $Al_2O_3$ surfaces, these ions have distorted tetrahedral coordination and the nature of the active centres in catalysts of this type has been discussed.

### 2. Rhodium Ions

It has been shown by EPR that evaluation in the temperature range 200–500 °C of $Rh/SiO_2$ specimens containing $Rh^{3+}$ ions in the initial state leads to the formation of CU $Rh^{2+}$ ions with the $A(4d)^9$ electronic configuration and distorted tetrahedral coordination ($g_1 = 2.68$, $g_2 = 2.22$, $g_3 = 2.00$) as well as octahedrally coordinated $Rh^{2+}$ ions ($g_\parallel = 2.00$, $g_\perp = 2.43$).[181] The fraction of the CU ions increase with increase of the evacuation temperatures and in the specimens heated at 500 °C there are virtually no octahedrally coordinated $Rh^{2+}$ ions. The adsorption of $H_2O$, $NH_3$, $CH_3OH$, and $C_2H_4$ molecules entails the expansion of the coordination sphere of the CU ions and the formation of octahedral complexes of $Rh^{2+}$ ions ($g_\perp = 2.43$, $g_\parallel = 2.00$).

Tetrahedrally coordinated $Rh^{2+}$ ions, formed as a result of the disproportionation of the $Rh^{3+}$ ions *in vacuo* at 500–700 °C, have been observed on the $\gamma$-$Al_2O_3$ surface.[182] CO and $O_2$ molecules can enter their coordination sphere on adsorption, forming paramagnetic surface complexes. The EPR spectra of $Rh/Al_2O_3$ specimens reduced in $H_2$ also show a signal due to the surface complexes of $O_2$ ($g_\parallel = 2.043$, $g_\perp = 2.004$) and CO ($g_\parallel = 2.038$, $g_\perp = 2.003$) with a CU $Rh^0$ atom.[182]

### 3. Palladium Ions

The application of the EPR method to the study of deposited $Pd/Al_2O_3$ [183] and Pd/MgO [184] catalysts made it possible to detect CU $Pd^+$ and $Pd^{3+}$ ions on the surface with the $A(4d)^9$ and $A(4d)^7$ configurations respectively. The CU $Pd^+$ ions are formed on high-temperature activation (reduction, evacuation, partial oxidation, and re-evacuation) of $Pd/Al_2O_3$. Their concentration is several per cent relative to the total palladium content in the specimen. These ions behave as centres for the adsorption of $H_2O$, $NH_3$, CO, and $O_2$ molecules. The EPR spectra of the complexes with CO molecules labelled with the $^{13}C$ isotope show that the complexes contain different numbers of molecules. The adsorption of $O_2$ leads to the formation of the $O_2^-$ radical-anions stabilised in the coordination spheres of the CU palladium ions. The CU $Pd^{3+}$ ions are formed on the Pd/MgO surface under severe oxidation conditions (800 °C). At room temperature *in vacuo* or in an atmosphere of $O_2$ they disproportionate together with the $Pd^+$ ions, present simultaneously in the catalyst, to form $Pd^{2+}$ ions: the CU $Pd^{3+}$ ions are readily reduced in $H_2$ and CO.

### 4. Tungsten Ions

The reduction of deposited $W/SiO_2$ catalysts does not lead to the appearance of any signals in the EPR spectra measured at 77 and 300 K.[185] However, after the adsorption of CO or $NH_3$ on the reduced specimens, intense EPR signals are generated. Their parameters (CO: $g_\perp = 1.901$ and $g_\parallel = 1.784$, $NH_3$: $g = 1.800$ and $g = 1.674$) indicate the formation of surface distorted octahedral complexes of the $W^{5+}$ ions. Consequently, before adsorption, CU $W^{5+}$ ions, undetectable by EPR at 77–300 K owing to their short spin–lattice relaxation time, are present on the surfaces of these catalysts. The adsorption of $O_2$ stabilises the $O_2^-$ radical-anions in the coordination spheres of the CU ions.[179,185]

### 5. Platinum Ions

The EPR method has been used to identify the paramagnetic centres in deposited $Pl/Al_2O_3$ and $Pt/SiO_2$ catalysts.[186] It has been shown that heat treatment of the $Pt/Al_2O_3$ specimens in $O_2$ at 623 K induces the appearance of an intense EPR signal with $g_\perp = 2.222$ and $g_\parallel = 2.046$, which has been attributed to the $Pt^{3+}$ ions with the electronic configuration $A(5d)^7$. The adsorption of $O_2$ entails a decrease of the intensity of this signal and the appearance of signals due to oxygen radicals. It has been concluded that the $Pt^{3+}$ ions are present on the catalyst surface, but their coordination state has not been established. In contrast to $Pt/Al_2O_3$, the formation of paramagnetic platinum ions could not be observed on the $Pt/SiO_2$ catalyst. When $Pt/Al_2O_3$ and $Pt–Ir/Al_2O_3$ catalysts containing chlorine were heated, the formation of paramagnetic CU $Pt^+$ ions, stabilised in the form of the surface $[PtCl_2]^-$ complex, was observed.[187] It has been suggested that the $Pt^+$ ion in this complex is an active centre for the dehydrocyclisation of paraffinic hydrocarbons.

## V. CONCLUSION

The data presented show that electron paramagnetic resonance and optical spectroscopy of diffusely scattered light permit a reliable identification of the formation of CU transition metal ions on the surfaces of catalysts and an investigation of their properties.

It is possible to demonstrate, fairly reliably, tetrahedral coordination of the CU transition metal ions, distorted in different ways, on the silica gel surface. When alumina was used as the carrier, the formation of CU ions in square-pyramidal and tetrahedral coordinations was observed. Thus the coordination state is determined to a large extent by the nature of the carrier. The methods of deposition of the transition elements, their concentration, and the conditions in their activation also play an important role.[60,65,66,127,136,139,153,188,189] The literature data show that the coordination state of the surface ions influences significantly the selectivity and rate of catalytic reactions.[153,158,188–190] The stabilisation of transition metal ions on the catalyst surfaces in an oxidation state atypical for the bulk phase ($Cr^{5+}$, $Cr^{2+}$, $Mo^{5+}$, $Rh^{2+}$, $W^{5+}$, etc.) is also associated with their unusual coordination.

The CU transition metal ions are able to interact with various adsorbed molecules to form surface complexes, which in the case of molecules behaving as typical ligands in solutions, have as a rule a distorted octahedral coordination. There is a possibility of the formation of complexes having a more involved structure, for example, those with olefinic hydrocarbons, $SO_2$, $O_2$, and $N_2O$. It is noteworthy that the stabilisation of polar molecules in the coordination spheres of CU ions in many cases does not apparently reduce solely to the filling of the vacant sites by adsorbed molecules. The coordination environment of the ions also undergoes a rearrangement under these conditions.

The formation of complexes between the adsorbed molecule and the CU ions can lead to an increase of its reactivity. Thus the adsorption of $O_2$ molecules entails in many cases the formation of $O_2^-$ radical-anions stabilised in the coordination sphere of the CU ion. Their reactivity is much higher than that of $O_2$ molecules. On raising the temperature, the

molecules adsorbed in the coordination spheres of the surface CU ions can be both desorbed and can undergo chemical changes as a result of their interaction with the CU ions, as has been demonstrated, for example, in the case of $H_2O$ molecules in the coordination spheres of the $Cr^{3+}$ ions[95] or $N_2O$ molecules in the coordination sphere of the $V^{4+}$ ions.[39,46] There is also a possibility of the substitution of one set of molecules adsorbed in the coordination sphere by another, for example, in the case of the surface copper complexes on $SiO_2$ when ammonia and methanol are adsorbed.[136]

The adsorption of carbon monoxide molecules frequently leads to the formation of surface paramagnetic complexes of the carbonyl type. A weak bond between the CO molecule and the ion, which is ruptured even on evacuation at room temperature, is characteristic of these complexes. On the other hand, the changes in the optical and EPR spectra occurring in such complex formation indicate that, although this type of weak adsorption of CO corresponds to physical adsorption as regards bonding energy, it nevertheless entails significant changes in the electronic state of the adsorption centre—the CU transition metal ion. Consequently it occurs with participation of the electrons of the adsorption centre and constitutes chemical adsorption.

The anomalous, compared with the bulk phase, coordination of the surface CU transition metal ions also leads to a difference in the oxidation-reduction properties [compared with the bulk-phase]. Thus the interaction of the CU $Cr^{2+}$ ions in tetrahedral coordination on the $SiO_2$ surface with oxygen leads to their oxidation to the quinquevalent and hexavalent states even at room temperature, whereas the octahedrally coordinated $Cr^{2+}$ ions are oxidised under these conditions to the tervalent state.[95]

# Reactions on Catalyst Surfaces under Programmed-heating Conditions

A.V.Sklyarov

The temperature-programmed reaction method and the principles of the calculation of the kinetic parameters of the surface stages of a catalytic process have been described. The influence of surface non-uniformity and the limiting stage on the parameters obtained has been examined. The possibility of detecting intermediate products of surface reactions has been analysed.
The bibliography contains 37 references.

## I. INTRODUCTION

The large number of studies of catalytic processes, including the stages of adsorption, the surface reaction, and desorption, indicate the complexity of the reactions of gases with solid surfaces. Even when catalysts with well characterised surfaces, for example metal single crystals, are used, the interpretation of the data obtained under stationary reaction conditions is extremely difficult. It is therefore natural to study the kinetics and mechanism of these processes by non-stationary methods, in particular the familiar thermal desorption (TD) method, which has been widely used to study the energy parameters of the reaction of simple gases with pure metal surfaces.[1,2] One of the first studies of the use of this method in catalysis was carried out in the 1960's,[3] and since then the number of studies carried out by the TD method has increased continuously.[4-6] The present review examined chiefly work carried out in the 1970's and 1980's, and deals with the problems of the reactions of gases with surfaces of interest for catalysis.

## II. PRINCIPLES OF THE METHOD AND THE CALCULATIONS

### 1. The Temperature-programmed Reaction Method

The temperature-programmed reaction (TPR) or temperature-programmed surface reaction (TPSR) method involves the adsorption of the substance being studied on a catalyst surface under given conditions, the removal of molecules of the original substance from the gas phase, and subsequent heating of the catalyst (usually at a constant rate) with simultaneous analysis of the products liberated at definite time intervals or at different catalyst temperatures. TPSR differs from thermal desorption in that in the first case the adsorbed substances undergo various transformations on the catalyst, that is a surface reaction takes place and the products of the transformation are liberated into the gas phase, whereas in the second case the adsorbed and desorbed species have the same composition. The main experimental approaches can be divided into two groups, depending on the methods used to remove and analyse the products from the gas phase: the chromatographic version,[3] in which the removal of the reaction products and the chromatographic analysis are carried out using an inert carrier gas, and the vacuum version, which originates from the first studies of the thermal desorption of simple gases from metal surfaces,[1,2] and which involves the vacuum treatment of the specimen after adsorption and mass-spectrometric analysis of the desorbed products. In the last case, the experiments can be carried out in closed systems or in flow systems.

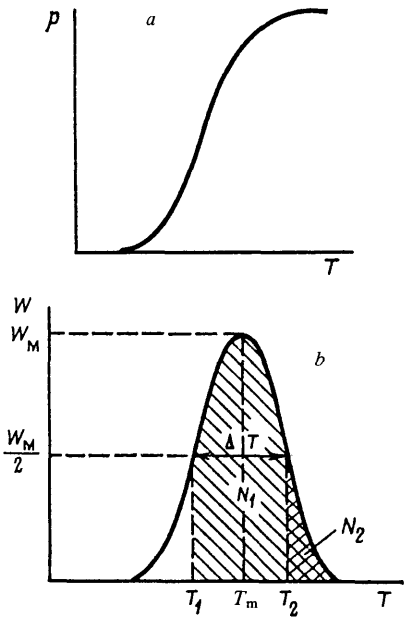

Figure 1. Schematic representation of the desorption curves in closed (*a*) and flow (*b*) systems. The hatched areas correspond to the concentrations of the molecules on the surface at temperatures $T_1$ and $T_2$; $T_m$ is the temperature of the peak maximum.

Fig. 1*a* gives a schematic representation of the temperature dependence of the pressure of the desorbed substances ($p$) in a closed system. Differentiation of the curve in Fig. 1*a* makes it possible to find the dependence of the rate of liberation of the product into the gas phase on time (that is the catalyst temperature). The same dependence (of $W$ on $T$)

can be obtained by carrying out TD and TPSR in a flow system (Fig. 1*b*) at sufficiently high rates of evacuation. Although carrying out the experiments in a flow system lowers the sensitivity of the method, it makes it possible to avoid graphical differentiation, that is to increase the accuracy of the determination of the kinetic parameters; moreover, as a consequence of the decrease in the pressure in the system, it is possible to neglect the re-adsorption of the desorbed gases. For a flow system, the equation for the material balance of the product liberated in the gas phase can be written as follows:

$$V\frac{dp}{dt} = W - ps \qquad (1)$$

where $V$ is the reactor volume, $W$ the rate of desorption, $p$ the pressure of the given component of the gas mixture, and $s$ the rate of evaucation. Each term of Eqn.(1) is usually expressed in litre.mmHg $s^{-1}$, from which values of the rate of desorption expressed in molecule $s^{-1}$ can readily be obtained. If $V(dp/dt) \ll ps$, it follows that

$$W = ps \qquad (2)$$

In the chromatographic version of TD and TPSR, the material-balance equation in the absence of re-adsorption has the form:

$$W = Fc \qquad (3)$$

where $F$ is the velocity of the stream of carrier gas, and $c$ the concentration of the desorbed substance in the carrier gas. Eqns.(2) and (3) have similar forms, and make it possible, by measuring the pressure of the gas above the specimen or the concentration of the desorbed substance in the carrier-gas stream during the TPSR, to determine directly the time (temperature) dependence of the rate of removal of substance from catalyst surfaces into the gas phase.

A term describing the rate of re-adsorption is often included in Eqns.(2) and (3). In a number of cases, allowance for the rate of re-adsorption is necessary,[7] but this complicates the kinetic equations considerably and makes it necessary to study the adsorption separately, so that it is practically impossible to analyse the equations obtained. It is therefore usually preferred to create experimental conditions under which re-adsorption can be neglected, and the rate of desorption can be determined from Eqns.(2) and (3). A sufficiently correct analysis of the influence of re-adsorption on the form of the TD curves has been published.[3,5,8]

As already noted, the products can be analysed chromatographically or mass-spectrometrically. In the first case the desorption products are directed together with the stream of carrier gas into a thermal-conductivity or flame-ionisation detector, and the time (temperature) dependence of the concentration of the product is recorded, that is the TD peak is obtained directly. This method is simple and sufficiently reliable if only one reaction product is liberated. Otherwise, the chromatographic analysis of each substance is necessary, and a series of several peaks, or, as it is usually described, a TPSR spectrum, is obtained. When peaks overlap (when different substances are liberated simultaneously), the problem is complicated, and it is very difficult to obtain TD peaks for each substance separately, even by successive sampling of the products, for example by freezing before chromatographic analysis.

Continuous mass-spectrometric analysis of the gas phase makes it possible to avoid these difficulties, since the change in the concentration of each substance can be followed. The mass spectrometers used for this purpose must satisfy a number of requirements, however. Firstly, the range of masses recorded should cover all the substances studied, including that with the highest molecular mass. It is also necessary to be able to vary the ionising voltage, in order, for example, to reduce as far as possible the extent of the fragmentation of the molecules in the mass spectrometer and hence facilitate the interpretation of the mass spectra obtained. Secondly, the time taken to record the entire mass spectrum should be so short (usually 0.1–1 s) that it is possible to obtain the complete spectrum at the same catalyst temperature. Experience has shown that these requirements are most fully satisfied by quadrupole, monopolar, and time-of-flight mass spectrometers (of the instruments produced in the USSR, the MKh-7304 and MSKh mass spectrometers). It is particularly convenient to use mass spectrometers in which it is possible to record continuously several fixed masses in the computer memory, so that the TD curves for each substance can subsequently be constructed separately.

No special requirements have to be satisfied by the reaction cell in which the catalyst specimen is placed. It is necessary only to note that the volume of the cell should be such that the quantity of catalyst, on the one hand, corresponds to the sensitivity of the recording system, and on the other hand is the minimum quantity, to avoid re-adsorption. The temperature of the specimen is usually measured by a thermocouple placed in the layer of catalyst. It is first necessary to be sure that there are no radial and axial temperature gradients; at the heating rates usually employed ($b$ = 0.01–1 K $s^{-1}$), these effects are insignificant.

## 2. Methods for Determining the Kinetic Parameters of TD and TPSR

One of the problems in TD and TPSR is the determination of the kinetic parameters of the processes of desorption and the surface reaction respectively. In spite of the variety of methods for determining these parameters, they are all based on the Polanyi–Wigner equation

$$W = -dN/dt = kN^n \exp(-E/RT) \qquad (4)$$

where $W$ is the rate of desorption (or of the surface reaction accompanying desorption), $k$ the pre-exponential factor, $N$ the concentration of adsorbed substance, $n$ the kinetic order of the process, $E$ the activation energy, and $T$ the temperature of the catalyst surface.

One method for determining $k$ and $E$ is the so-called linearisation of the thermal desorption curve. In this case, Eqn.(4) and the experimental data (see Fig. 1*b*) are used to construct the plot of $\ln(W/N)$ against $1/T$ or of $\ln(W/N^2)$ against $1/T$ (for processes of first or second order respectively). The concentration ($N$) of the substance remaining on the surface at each temperature is determined as the fraction of the area under the TD curve bounded on the left-hand side by the corresponding temperature (as an example, Fig. 1*b* gives $N_1$ and $N_2$ for temperatures $T_1$ and $T_2$). The slope of the straight line on Arrhenius coordinates gives the activation energy of the process. For this it is sufficient to know the relative values of the rates of liberation of the substance into the gas phase and the degrees of covering ($N$). To determine the pre-exponential factors by this method, however, it is necessary to have data on the absolute values of the rates.

Since in TD and TPSR experiments both the temperature and the degree of covering change continuously, the usual methods for determining the order of the reaction, for example from the dependence of the rate of the process on concentration (in this case the degree of covering) are not applicable, and the order is found from the best agreement

with experimental data from the $\ln(W/N)-1/T$ or $\ln(W/N^2)-1/T$ plots.

If the catalyst is heated by a linear programme ($T = a + bt$) and account is taken of the fact that at the maximum of the TD peak at $T_m$ (see Fig.1*b*) $dW/dT = 0$, then Eqn.(4) gives:

$$E/RT_m = \ln\frac{knN^{n-1}T_m}{b} - \ln(E/RT_m) \qquad (5)$$

or, in slightly modified form, for a process taking place, for example, according to first order kinetics:

$$2\ln T_m - \ln b = E/RT_m + \ln(E/kR) \qquad (6)$$

Eqn.(6) was first proposed by Amenomiya and Cvetanovic.[3] It can be seen from Eqns.(5) and (6) that $T_m$ for the TPSR peak depends on the heating rate. If the dependence of $(2\ln T_m - \ln b)$ on $1/T_m$ is determined experimentally, Eqn.(6) can be used to find the parameters $k$ and $E$ being sought. This method has been called the "displacement of the temperature of the maximum with change in the heating rate" method or the method of Amenomiya and Cvetanovic. Here it should be noted that the experiments must be carried out at constant original degrees of covering of the surface, since otherwise $T_m$ may change even for a constant heating rate. Thus Eqn.(5) and Fig.2 show that it is only for a first-order process that $T_m$ is independent of the degree of covering of the surface, and that for a second-order reaction, $T_m$ decreases, and for a zeroth-order reaction $T_m$ increases, with increase in the original concentration of the adsorbate. For second-order processes, the form of the TD peak is symmetrical.

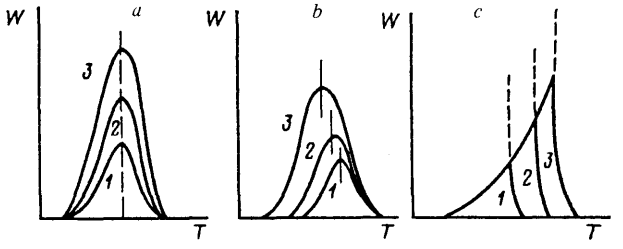

Figure 2. Schematic representation of the TD curves for processes of first (*a*), second (*b*), and zeroth (*c*) orders; the original coverage increases from (*1*) to (*3*).

To determine the kinetic parameters of desorption and surface reactions, extensive use has been made of a method based on the measurement of the so-called half-width of the TD peak $\Delta T = T_2 - T_1$, that is the difference between the temperatures at which the rate of the process is equal to half the maximum rate (see Fig.1*b*).[9,10] According to Eqn. (4), the expressions for the rates of the process at $T_1$ and $T_2$ can be written in the form:

$$\frac{W_m}{2} = kN_1^n \exp(-E/RT_1); \quad \frac{W_m}{2} = kN_2^n \exp(-E/RT_2) \qquad (7)$$

which gives:

$$E = \frac{R\ln(N_1/N_2)^n T_1T_2}{\Delta T} . \qquad (8)$$

Eqn.(8) shows that the factor $T_1T_2/\Delta T$ is independent of the heating rate. It is therefore possible to determine the activation energy from one experiment. Computer calculations by the present author showed that the first-order processes, $\ln(N_1/N_2)$ is constant, and that for second-order processes, $\ln(N_1/N_2)^2$ changes little, even with change in the concentration by a factor of 10. Using the calculated values of these parameters, the expressions for the activation energies of the first- and second-order processes can be written in the form:

$$E = 4.6T_1T_2/\Delta T \text{ for } n = 1;\ E = 6.2T_1T_2/\Delta T \text{ for } n = 2. \qquad (9)$$

The order of the reaction can be estimated from the form of the peak (see Fig.2). A more accurate equation for calculating $E$ for second-order processes using the half-widths of the TD peaks has been proposed.[11] The pre-exponential factors can be calculated (if the value of $E$ is known) using Eqns.(4) and (5) or a simplified form of Eqn.(5).[9]

The method in which $E$ is determined using the parameter $\Delta T$ and hence Eqn.(9) or the published equations[11] is much less sensitive to various experimental errors than the method based on the measurement of the dependence of $T_m$ on the heating rate.

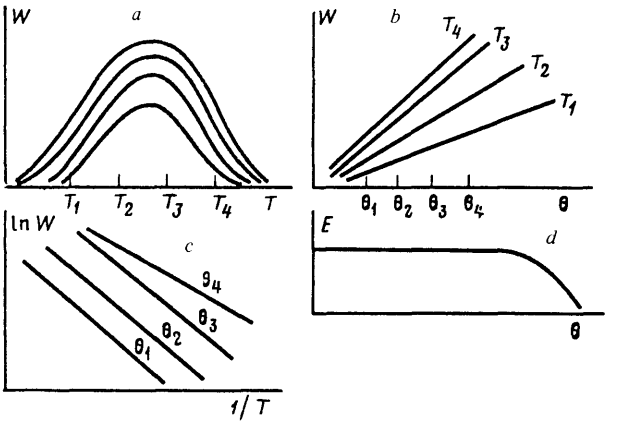

Figure 3. The method of "desorption isotherms": *a*) family of desorption curves for different original degrees of covering, *b*) desorption isotherms, *c*) Arrhenius relationships for constant degrees of covering, *d*) dependence of $E$ on the degree of covering.

The above methods for determining the kinetic parameters are applicable to the analysis of individual TD or TPSR peaks reflecting processes taking place on uniform surfaces. For the analysis of processes taking place on non-uniform surfaces, the so-called method of "desorption isotherms" has been proposed.[12,13] It is based on a series of thermal desorption experiments differing in the original degree of covering of the surface. The original data in this case can be represented in the form of a family of curves (this method is illustrated in Fig.3), each point of which corresponds to a definite rate of the process, temperature, and degree of covering of the surface $\theta$. These data are used to construct desorption isotherms (Fig.3*b*), that is the dependence of $W_{des}$ on $\theta$ (or $N$) for several constant temperatures. These relationships make it possible to determine the order of the process if the data are represented, for example, on coordinates $\ln W - \ln\theta$ (in Fig.3*b* the order of the reaction is 1).

The Arrhenius relationships are then constructed for a series of constant values of the degree of covering (Fig.3c), and finally the dependence of the activation energy on the degree of covering is calculated (Fig.3d). The great advantage of this method is that in the treatment of the data it is not necessary to know beforehand or to assume the kinetic order of the process. Moreover, the form of the $E = f(\theta)$ relationship shows clearly whether the surface is uniform or non-uniform.

Later, it was suggested that the heating rate be varied instead of the initial degree of covering;[14] this makes it possible to cover a wider temperature range for the process, and hence to calculate its kinetic parameters more accurately. It has been pointed out,[15] however, that if both $E$ and $k$ depend on the degree of covering, the dependence of the rate of the process on the concentration of adsorbed substance (Fig.3b) may not reflect the true order of the reaction.

In addition to the above methods for determining the order of the reaction, mention must be made of another method, based on the analysis of the shape of the TD or TPSR peaks. It has been proposed[16] that the order of the desorption be estimated using the so-called "shape index" $S$, which is the ratio of the slopes of the tangents to the TD peak at the points of inflection on the ascending and descending branches. The values of this parameter were subsequently calculated[8] for four cases: for first- and second-order desorption processes with and without re-adsorption. These calculations[8] were subsequently refined.[17] Here, however, it may be noted that according to the published data,[8] the parameters $S$ for first- and second-order processes in the absence of re-adsorption have different values and are independent of the original degree of covering. At the same time, the values of $S$ are similar for first-order desorption without re-adsorption and for second-order desorption with re-adsorption. This situation makes it difficult to determine the kinetic order of the process; moreover, since graphical differentiation of the TD (or TPSR) peak is necessary, the uncertainty of the determination of the parameter $S$ is high.

The kinetic parameters of the desorption or the surface reaction can be determined using appropriate mathematical programs which make it possible to select these parameters on the basis of a regression analysis to give best agreement with the experimental curve. This method can be used even for overlapping peaks,[18] although it is pointed out[18] that it is difficult to choose between different models. An undoubted advantage of this method is that it is possible to vary the dependence of $k$ and $E$ on the degree of covering; this was clearly demonstrated[19] in an analysis of the experimental TD spectra for but-1-ene from the surface of NaY zeolites.

The principal methods of determining the kinetic parameters of desorption have been examined. The most suitable methods for the treatment of single peaks are apparently the half-width method and the linearisation of the TD curves on Arrhenius coordinates. These methods are simple and sufficiently reliable. If the peaks overlap or if there is extensive non-uniformity of the surface, however, the method of "desorption isotherms" is preferred. Naturally, all the above methods for determining the kinetic parameters of thermal desorption are also applicable when chemical transformations take place on the surface. In this case the kinetic parameters obtained from the curves giving the time (temperature) dependence of the removal of the reaction products reflect both their desorption into the gas phase and the processes taking place on the catalyst surface. Moreover, the TPSR method makes it possible, in particular, to obtain information on the presence of active centres of different types, stepwise mechanisms, the limiting stage of the process, and intermediate compounds.

## III. REACTIONS ON CATALYST SURFACES

### 1. Active Centres of Different Types

In ordinary thermal desorption, when the interaction of the gas with the surface takes place without change in the chemical composition of the particles, the existence of adsorption centres of different types is indicated by the existence of several TD peaks. Similarly, in TPSR, the appearance of several peaks for the same reaction product may indicate non-uniformity of the active surface in the given reaction. In this case, however, there may be several factors responsible for this type of TPSR spectrum, so that additional experiments are required to prove the existence of active centres of different types. This is particularly necessary in the case of deposited catalysts.

Thus if it is assumed that there is only one type of centre on which the reaction takes place, but that the carrier contains pores with different dimensions, then in this case, even if the reaction takes place with the same rate constant on all the active centres, the removal of the products into the reaction space free from catalyst (where the concentration is properly measured) may be determined by the rate of diffusion from different pores and by re-adsorption. Thus the existence of several peaks will indicate not the existence of active centres of different types but a distribution of the pore sizes in the carrier. It is therefore first necessary to estimate the rates of diffusion and adsorption and to be satisfied that these processes do not influence the nature of the TPSR spectrum (the positions and half-widths of the peaks). This can be done experimentally by varying the particle size of the catalyst, the weight of catalyst, and the rate of evacuation (or the velocity of the stream of carrier gas), and hence changing the concentration of the reaction product over the catalyst.

A second and apparently more significant factor responsible for the existence of several peaks for a given product is related to the kinetic characteristics of the reaction. If it is assumed that the reaction on the surface takes place according to the simple scheme A → B → C → D, and if the adsorption of the compound A is carried out at a sufficiently high temperature, then at the start of the actual TPSR experiment the reaction may already have taken place to some extent, and the compounds A, B, and C may be present on the surface in definite concentrations. In this case, when the catalyst is heated, the appearance of the product D in the gas phase will be determined by the rate constants of three corresponding processes, namely A → B → C → D, B → C → D, and C → D, and this may lead to the appearance of several peaks for the product D in the TPSR spectrum. To determine whether this effect is present, it is necessary to carry out the adsorption at different, preferably lower, temperatures. In this case the transformation of the adsorbed substance A into B and C will naturally be hindered, and in the limiting case, only the substance A will be present on the surface at the start of the TPSR experiment. If change in the adsorption temperature does not lead to a decrease in the number of peaks for the product, this indicates that active centres of different types are in fact present on the surface.

Another method for proving the presence of different centres on a catalyst surface is by modifying the centres in some way and then analysing the TPSR spectra. This approach has been used, in particular, in a study[20] of the dehydrocyclisation of n-heptane on deposited platinum specimens with different degrees of dispersion (Fig.4). Fig.4 shows that there is a correlation between the intensity of the high-temperature peak of toluene and the degree of

dispersion of platinum. Thus the TPSR spectrum in this case does in fact characterise the catalyst. This spectrum can be used to determine the kinetic parameters of the process on centres of each type, and their concentration. Thus the TPSR method, in addition to providing a means of investigating the mechanism and kinetics of the reaction being studied, also makes it possible to characterise the catalyst itself.

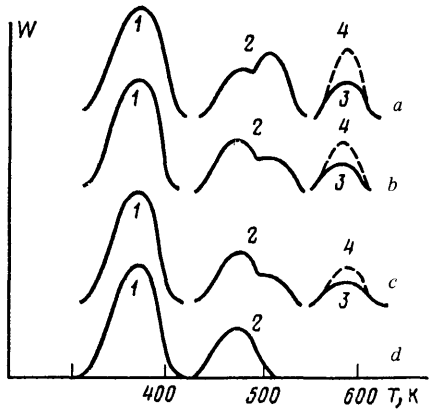

Figure 4. TPSR spectra of n-heptane on $Pt/Al_2O_3$ specimens with different platinum particle sizes, Å: *a*) 13, *b*) 17, *c*) 38, *d*) 1000; *1*) heptane, *2*) toluene, *3*) benzene, *4*) methane.[20]

## 2. Stepwise Mechanisms of the Surface Reaction and the Limiting Stage

The advantages of the TPSR method are possibly revealed to the greatest extent in the study of the mechanisms of catalytic reactions. Although such reactions as the recombination-desorption of diatomic molecules naturally are also surface reactions, the application of the TPSR method to more complex processes such as catalytic decomposition, oxidation, dehydrogenation, and dehydrocyclisation will be considered.

A study of the decomposition of hydrazine and ammonia on $Ir/Al_2O_3$ by the TPSR method and infrared spectroscopy[21] showed that the reaction of hydrazine with the catalyst surface leads to the appearance, in addition to the peaks of the main products, of an additional peak due to nitrogen remaining in the adsorbed state in the atomic form up to high temperatures. The high strength of the bond formed by the nitrogen atoms with the surface was regarded[22] as the factor responsible for the gradual decrease in the activity of the $Ir/Al_2O_3$ catalyst during the decomposition of $N_2H_4$ when the process was carried out under stationary conditions. As in the earlier studies,[21] a single nitrogen peak with $T_m \cong 670$ K was observed, whereas the formation of $NH_3$ takes place chiefly in the temperature range 300–500 K (Fig.5). The appearance of the nitrogen peak with $T_m = 670$ K in the decomposition of both $N_2H_4$ and $NH_3$ indicated[22] that the reaction of $N_2H_4$ with $Ir/Al_2O_3$ leads to rupture of the N–N bond in the hydrazine molecule.

Even this TPSR study[22] essentially used a procedure involving the preliminary adsorption of possible intermediate compounds (in this case $NH_3$, which is readily transformed into $NH_2$). This approach was apparently used in most complete form in studies[23,24] which showed that the principal route in the dehydrocyclisation of $C_6$–$C_7$ hydrocarbons on $Pt/Al_2O_3$ involves the stepwise dehydrogenation of the starting material.

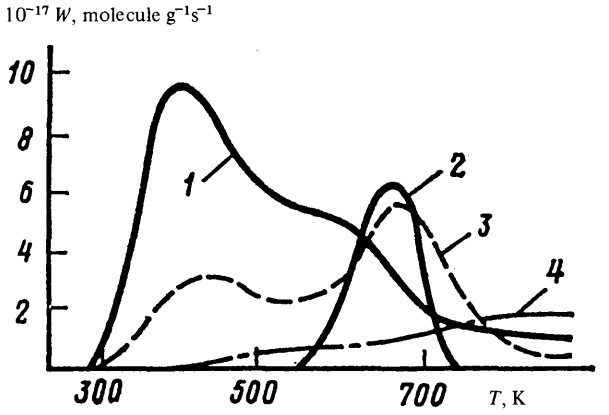

Figure 5. TPSR spectra of $N_2H_4$ on 0.38% $Ir/Al_2O_3$ (complete covering by $N_2H_4$ at 298 K); *1*) $NH_3$ (rate *W* increased by a factor of 1.3), *2*) $N_2$ (×2.1), *3*) $H_2$, *4*) $H_2O$ (×25).[22]

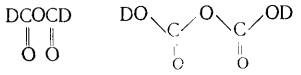
This approach can be examined in slightly more detail. If it is assumed that the reaction $A \xrightarrow{k_1} B \xrightarrow{k_2} C \xrightarrow{k_3} C_{gas}$ takes place on the surface and that the limiting stage is the transformation of B into C, then the parameters determined from the peak for the liberation of C into the gas phase should coincide for the adsorption of the substances A or B, but after the adsorption of the substance C the $C_{gas}$ peak should be displaced to lower temperatures. On the other hand, this approach makes it possible to determine the limiting stage of the process. On the other hand, if the rate constants for the formation of $C_{gas}$ from A and from B, determined by the TPSR method, coincide completely, this indicates that B is in fact an intermediate compound in the chain of successive transformations of A into $C_{gas}$.



Using this approach, it has been possible to show[23] that the dehydrogenation of cyclohexane on platinum catalysts takes place on centres of two types, corresponding to two benzene peaks (Fig.6). The limiting stage on centres of one type is the transformation of cyclohexane into cyclohexene, and that on the centres of the other type is the desorption of the firmly bound form of benzene.

The question naturally arises of whether the suggested intermediate substances in adsorption give the same surface forms as are produced during the reaction. It is difficult to answer this question unambiguously, and its solution requires the use of other independent methods, for example spectroscopy.

To investigate the reaction mechanism it is important to carry out a complete analysis of the thermal-desorption curves for all the reaction products. A detailed study carried out in this way made it possible[25] not only to determine the mechanism of the decomposition of methanol on pure tungsten but also to follow the change in the mechanism of this reaction as carbon was deposited on the catalyst surface. Other similar examples have been described.[26–29]

In particular, in a study of the decomposition of labelled formic acid DCOOH on a single crystal of nickel,[29] it was

shown (Fig.7) that the decomposition products $D_2$ and $CO_2$ are desorbed simultaneously at $T_m$ = 400 K, and that CO is desorbed at higher temperatures (the narrow CO peak in Fig.7 corresponds to a mass-spectrometric fragment of $CO_2$). The study of the adsorption of carbon monoxide itself showed that CO is desorbed at the same temperatures as the CO obtained by the decomposition of formic acid. The simultaneous removal of $CO_2$ and $D_2$ indicates that the desorption of these products is not the limiting stage (otherwise they would have different $T_m$). Quantitative analysis showed that $D_2$, $CO_2$, and CO are liberated in the ratio 1 : 1 : 1. Since $H_2O$ was formed and liberated at much lower temperatures, the following two possible forms were proposed for the adsorbed intermediate, from which the products indicated are obtained:

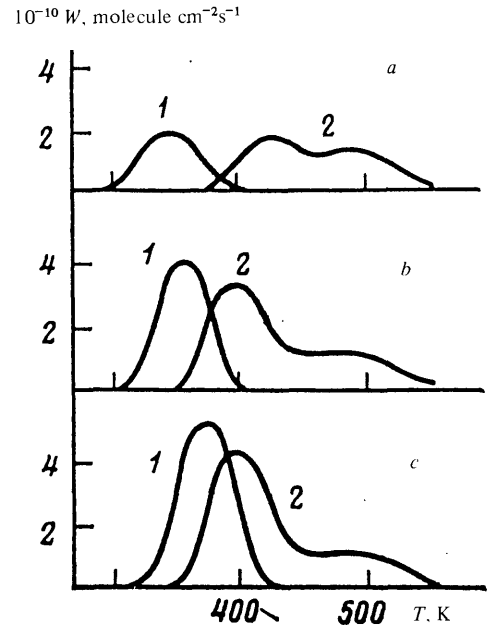


Figure 6. TPSR spectra after the adsorption of cyclohexane (*a*), cyclohexene (*b*), and cyclohexadiene (*c*) on $Pt/Al_2O_3$: *1*) original hydrocarbon, *2*) benzene.[23]

Labelled molecules were used in this study,[29] although attention was not concentrated on the distribution of isotopes in the reaction products. This approach, however, can give valuable information on the surface process. In a study of the oxidation of ethanol on a single crystal of silver,[29] $^{18}O_2$ and $CH_3CH_2OD$ were used to distinguish the hydrogen joined to hydrogen atoms from the hydrogen in the hydroxyl group. $D_2O$, $H_2$, $C_2H_4$, $CH_3CH_2OH$, and $CH_3CH_2O$ were detected in the reaction products. The TPSR spectra obtained, and the distribution of the isotopes in the reaction products, led to the following conclusions: 1) on adsorption, the hydroxyl group of the alcohol reacts with the surface $^{18}O$ atoms to give adsorbed $CH_3CH_2O$ and $D_2O$; 2) the simultaneous appearance of $CH_3CH_2OH$, $CH_3CHO$, and $H_2$ in the gas phase indicates that all these products are formed from the same intermediate, namely the adsorbed species $CH_3CH_2O$; and 3) the formation of $C_2H_2$, $D_2^{16}O$, and $H_2$ from $CH_3CH_2^{16}OD$ is associated with the decomposition of a surface complex consisting of two alcohol molecules.

An analysis[30] of the liberation of $D_2$ and deuteriated derivatives of benzene during the dehydrogenation of cyclohexane ($C_6D_{12}$ was used to distinguish the hydrogen liberated from the cyclohexane molecule from the hydrogen adsorbed during the reduction of the catalyst) confirmed the earlier conclusion[23] that this process takes place on centres of two types. On the low-temperature centres the process is limited by the removal of hydrogen, whereas on the high-temperature centres the slowest stage is the addition of surface hydrogen to the dehydrogenated form of benzene.

## IV. INTERMEDIATE REACTION PRODUCTS

In the great majority of cases, the intermediate products of the surface reactions are liberated into the gas phase in such small quantities that they cannot be detected by ordinary methods. This is due to the fact that the rate constant of the surface process is generally appreciably greater than the rate constant of the desorption of the intermediate substance. It has been shown,[31-33] however, that if the catalyst surface is heated very rapidly, it becomes possible to observe the intermediate and final reaction products simultaneously. Thus if for example the following transformations take place on the surface

and that the limiting stage is $A_{ads} \rightarrow B_{ads}$, then the liberation of the products $B_{gas}$ and $C_{gas}$ will be determined by the constant $k_1$. In this case they will appear almost simultaneously, and

the heating rate will have little influence on their relative quantities. If however the surface process is limited by the stage $B_{ads} \rightarrow C_{ads}$, then in this case the relative integral yield of the product $B_{gas}$ will increase sharply with increase in the heating rate. An example is provided in Fig. 8, which gives the dependence of the yield of the intermediate substance on the heating rate for various typical parameters of the separate stages.

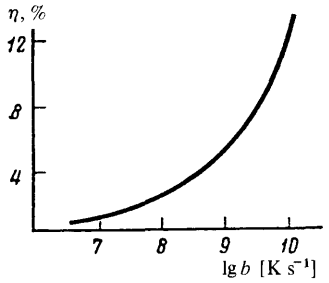

Figure 8. Dependence of the yield of intermediate substance $\eta$ on the heating rate $b$ at $E_{des}$ = 63 kJ mole$^{-1}$, $E_r$ = 42 kJ mole$^{-1}$, and $k^0_{des}/k^0_r = 10$.[33]

It has been suggested[31,32] that pulse laser sources be used to obtain high heating rates ($b > 10^4$–$10^5$ K s$^{-1}$). Because of the finite dimensions of the space of the drift of the desorbed species from the surface being studied to the analyser, the time resolution of the recording systems (mass spectrometers) was worse than $10^{-4}$–$10^{-5}$ s, that is the traditional TD or TPSR curves could not be obtained, and the mass-spectrometric analysis made it possible to determine only the integral yield of products. The approach developed in Ref. 33 made it possible to propose a method for determining the kinetic parameters of the desorption of intermediate products, based on the measurement of their integral yields at different heating rates.

Laser-stimulated thermal desorption has been used[34] to detect the intermediate products of the dehydrocyclisation of alkanes. It was shown that in the case of hexane, the reaction involves the intermediate formation of hex-2-ene and hexadiene. The same method has been used[35,36] to study the reaction of acetaldehyde with copper oxide catalysts. The change in the predominant direction of the transformations of the adsorbed species with change in the rate of heating of the catalyst was demonstrated for the decomposition of methanol on a nickel surface.[37] It was shown[37] that during slow TPSR ($b \cong 7$ K s$^{-1}$), less than 10% of the original methanol is liberated into the gas phase (in this case it must be regarded as an intermediate product), and the rest is in the form of $H_2$ and CO. In the case of laser TPSR, however, the opposite picture is observed, that is the chief product after the adsorption of methanol at low temperatures is $CH_3OH$.

The use of pulse lasers with a high quantum flux density per unit surface area can in principle lead to effective decomposition of the species on the surface. To verify this it is necessary to carry out additional experiments, as for example in a comparison[34] of the effect of laser radiation on hexane adsorbed on a $Pt/Al_2O_3$ catalyst and on the $Al_2O_3$ carrier. The decomposition of hexane was slight in both cases, but the liberation of reaction products, namely benzene, hexene, and hexadiene, was observed only in the experiments with $Pt/Al_2O_3$. These data indicate that a catalytic process is taking place, and that there are no chemical transformations of the molecules in the gas phase directly under the influence of the laser radiation.

---o0o---

The material reviewed showed that the TPSR method can be used to determine the kinetic parameters of a surface process and its limiting stage, to reveal non-uniformity of catalyst surfaces, and in a whole series of cases to establish the reaction mechanisms. Additional information can be obtained by combining the TPSR method with, for example, infrared spectroscopy or other methods for studying surfaces.† It is always necessary, however, to take account of a characteristic feature of TPSR, namely the absence of the original compounds from the gas phase. Thus when transferring data obtained by the TPSR method to ordinary catalysis, care is required, and it is necessary in every case to be satisfied that the introduction of the original substances into the gas phase does not change the reaction mechanism.

# The Chemisorption of Oxygen and the Oxidation of Carbon Monoxide on Metals

V.I.Savchenko

Data on the chemisorption of oxygen on a number of metals (Pt, Pd, Ir, Ru, Ni, etc.), obtained by SED, EAS, XES, etc., have been reviewed. The bond energies and principal properties of the two types of $O_{ads}$ on metals (non-reconstructive and reconstructive), and also the conditions for the realisation of each type of adsorption, have been examined.
The bibliography contains 84 references.

CONTENTS

I. Introduction 222
II. Mechanism of the adsorption of oxygen on metals 222
III. The oxidation of carbon monoxide on metals 226

## I. INTRODUCTION

The nature of the chemisorption compounds, the energy of the bonds formed, and hence the mechanism and kinetics of the reactions depend on the chemical composition and structure of the metal surface. Many authors[1-3] have noted a similarity between the properties of chemisorption compounds and complex compounds or oxides, carbides, and nitrides. For example, in the chemisorption of oxygen, a whole series of compounds may be formed, from molecular forms to three-dimensional oxides. The heats of adsorption of the molecular forms $O_{2ads}$ are 40–50 kJ mole$^{-1}$; their desorption temperature is low, $T_{des}$ = 120–150 K; and the reactivity of $O_{2ads}$ is low.[4] The forms of greatest interest for catalysis on metals are adsorbed atomic forms of oxygen at degrees of covering less than a monolayer, which are present on the surface at the temperatures of "real" catalysis (300–800 K).

One of the most important questions is whether the chemisorption of oxygen atoms takes place on the surface or whether they are inserted into the surface layer, with a simultaneous displacement of the metal atoms. The possibility of adsorption in the non-reconstructive (type I) or reconstructive (corrosion) (type II) forms was examined in Ref.1. Subsequently, as a result of the development of physical methods for studying surfaces (slow electron diffraction (SED), electronic Auger spectroscopy (EAS), X-ray electron spectroscopy (XES), thermal desorption (TD), low-energy electron characteristic loss spectroscopy, etc.), this question was discussed by a large number of authors. As emphasised by Boreskov,[5] "in a solid catalyst–reactant system, transformations are undergone not only by the reactants under the influence of the catalyst, but also by the catalyst as a result of chemical interaction with the reactants". The reaction medium will obviously have a greater effect on the catalyst when at least one of the reactants under the reaction conditions is chemisorbed in the reconstructive form (type II). Thus the phenomena of catalytic corrosion have been related to reconstructive adsorption.[6] The nature of the chemisorption (type I or II) apparently influences the reactivity of the species and the form of the kinetic relationships describing the adsorption and the catalytic reaction.

The present review examines data on the influence of the nature and structure of the surface on the state of adsorbed oxygen species and the oxidation of CO on a number of metals (Pt, Pd, Ir, Ru, Ni), obtained by SED, TD, and electron spectroscopy.

On all the above metals, carbon monoxide is adsorbed in molecular forms (linear and bridged) with approximately identical heats of adsorption $\Delta H$ between −100 kJ mole$^{-1}$ and −150 kJ mole$^{-1}$; the influence of the structure of the surface is even stronger than the influence of the nature of the metal. The bond between CO and the metals is a donor–acceptor bond. Photoelectron spectroscopy (PES) has shown[7,8] that the $CO_{ads}$ molecules are joined to the metal through the carbon atom and are arranged at right angles to the surface.

On the other hand, the energies of the bonds formed by oxygen with the above metals vary from 180–220 kJ mole$^{-1}$ (Pt) to 500 kJ mole$^{-1}$ (Ni). This indicates that a decisive role in the change in the catalytic activity in this series of metals is played by the change in the bond energy and state of the adsorbed oxygen. In the present review, therefore, particular attention is paid to the chemisorption of oxygen on metals.

## II. MECHANISM OF THE ADSORPTION OF OXYGEN ON METALS

When oxygen is chemisorbed on the surface of metal single crystals, the $O_{ads}$ atoms are not arranged randomly, but form definite structures. The diffraction patterns obtained by SED may result from the scattering of electrons on ordered oxygen atoms on the surface (adsorption of type I) or on metal atoms which have undergone ordered displacements on reconstructive (corrosion) chemisorption (adsorption of type II). It can also be said that in chemisorption of type II, surface oxides are formed, since a mixed layer consisting of oxygen and metal atoms is produced.

In the nineteen-sixties, on the basis of the concept of the once-only scattering of electrons (the kinematic theory of diffraction), it was concluded[9] that the adsorption of oxygen on nickel is reconstructive, for example, it was assumed that in the structure Ni(100)–c(2 × 2)O, every second nickel atom is replaced by an oxygen atom. Later calculations[10] carried out in accordance with the complete program of the dynamic theory of diffraction, that is with allowance for multiple scattering of the electrons, led to a model of the adsorption of type I in which the oxygen atoms are situated at a distance of 0.9 Å above the metal. This adsorption scheme, however, is not consistent with the data obtained by other methods, for example ion-neutralisation spectroscopy.[11] Thus in Ref.12

it was noted that the c(2 × 2)O structure can probably be produced in adsorption of both type I and type II.

Criteria for establishing the type of adsorption may be provided by the following data: 1) the change in the work function: $\Delta\phi \cong 0.5-1.0$ eV for adsorption of type I, and $\Delta\phi < 0$ eV for adsorption of type II; 2) the form of the EAS spectrum, namely the change in the ratio of the peaks in the Auger spectrum of oxygen. Thus the Auger spectrum of oxygen in the Ni(111)–(2 × 2)O structure practically consists of two peaks, whereas for reconstructive chemisorption and for oxygen in nickel oxide, the Auger spectrum shows three peaks: $KL_1L_1$, $KL_1L_2$, and $KL_2L_2$; 3) the temperature dependence of the intensity of additonal reflections. For reconstructive adsorption, this relationship approximately coincides with the temperature dependence of the principal reflections, for example for the structure W(100)–(2 × 1)O, whereas for non-reconstructive adsorption in the (4 × 1)O structure there is a sharp decrease in intensity with increase in temperature, due to the production of disorder in the adsorption layer.[13]

## 1. The Chemisorption of Oxygen on Pt, Pd, Ir, Ru, and Ni

### *a) Adsorption on nickel*

According to EAS data, the kinetic curve for the adsorption of $O_2$ on the (111), (110), and (100) faces of Ni at 300 K consists of two main regions:[14,15] the first corresponds to rapid chemisorption, and the second is associated with the nucleation of isolated regions of the phase NiO (induction period) and the subsequent growth of the isolated regions to form a continuous NiO film with a thickness of 2–3 monolayers.

A detailed study of the kinetics of the chemisorption of $O_2$ at a low pressure ($p(O_2) = 2 \times 10^{-7}$ Pa) on Ni(100) at 433 K showed[15] that after the p(2 × 2)O structure is completely filled with oxygen; a slight induction period is observed, followed by an increase in the rate of chemisorption with the growth of the isolated regions of the c(2 × 2)O structure. The topochemical character of the kinetics of the chemisorption with the formation of the c(2 × 2)O structure, analogous to the kinetics of the formation of NiO, indicates that the adsorption in this case is reconstructive, that is a two-dimensional oxide is formed. To investigate the nature of the adsorption when the Ni(100)–c(2 × 2)O structure is formed, oxygen was adsorbed at 170 K to a degree of covering $\theta = 0.5$.[16] A structure was not formed, but the work function increased by 0.5 eV. Next, the crystal was stepwise heated to 600 K. Formation of the c(2 × 2)O structure at 250–300 K was accompanied by a decrease of the work function by 0.3 eV in comparison with that of a clean Ni(100) surface. It may be noted that the "order–disorder" transformation in layers of type I does not lead to a change in the work function. This was shown in analogous experiments[17] for the non-reconstructive adsorption of oxygen on an Ru(0001) face. Thus the decrease in the work function when the Ni(100)–c(2 × 2)O structure is formed must be due to the insertion of $O_{ads}$ into the lattice, that is to the formation of a layer of type II.

It was found qualitatively (visual estimation) that there is no significant decrease in the intensity of the SED pattern on p(2 × 2)O and c(2 × 2)O when the crystal is heated to 700 K. It was recently found[18] that disorder is produced in the Ni(100)–c(2 × 2)O structure only at 900 K, and that simultaneously, judging from the EAS data, oxygen disappears from the surface, that is the production of disorder in the layers of this type is due to the breakdown of the lattice (2D) of the oxide and the solution of oxygen in the bulk of the metal.

Quantum-chemical calculations by the generalised valence bond method[19] led to the conclusion that two states of oxygen can exist on an Ni(100) surface: in the first, radical-like state ($O^-_{ads}$), the oxygen atom is at a distance $d = 0.9$ Å from the surface (adsorption of type I), and in the second state ($O^{2-}_{ads}$) the oxygen atom of the surface oxide is at distance $d = 0.23$ Å from the surface (adsorption of type II). The oxygen bond energy in state II is 60 kJ mole$^{-1}$ greater than that in state I. State I is possibly produced on Ni(100) at $T \leq 250$ K, and state II in the c(2 × 2)O structure. The change from $O_{ads}$(I) to $O_{ads}$(II) for a given degree of covering ($\theta = 0.5$) leads to appreciable suppression of the adsorption of CO.[20]

When $O_2$ is adsorbed on Ni(110), a succession of structures appears: (3 × 1)O, (2 × 1)O, (3 × 1)O again, p(9 × 4)O, and finally (100)NiO. Their ranges of existence are separated by short induction periods.[21] Ion-scattering spectroscopy showed[22,23] that the Ni(110)–(2 × 1)O structure consists of alternating (at intervals of one) rows of nickel atoms, as suggested in Ref. 9.

Fig. 1 gives a representation of the structural transformations taking place when $O_2$ is adsorbed on Ni(111).[24] The start of adsorption at 300 K gives the (2 × 2)O structure, in which oxygen is probably adsorbed according to type I, since the Auger spectrum differs from that of oxygen in NiO, the work function increases by 0.5 eV on adsorption, and the temperature at which disorder is produced in the layer is 480 K. The production of disorder in the layer is accompanied by the reversible transfer of some of the $O_{ads}$ into the

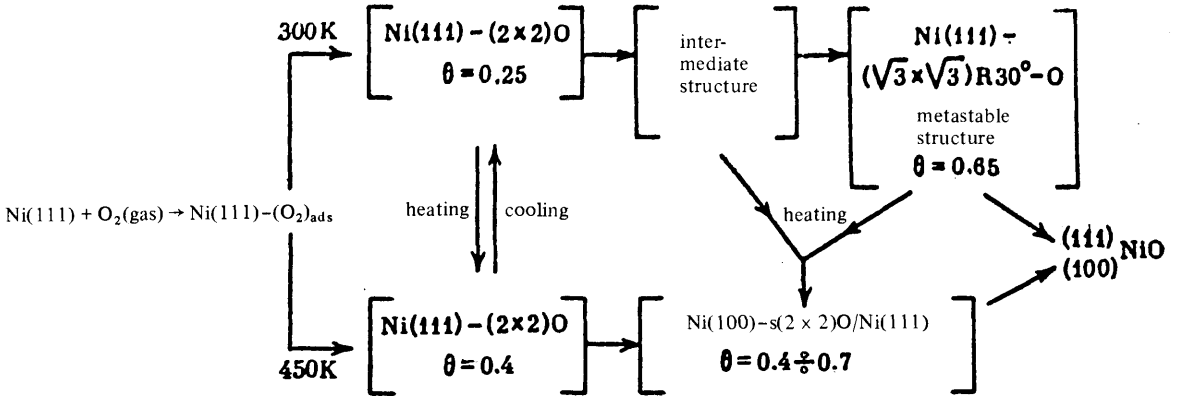

**Figure 1.** Structural transformations when $O_2$ is adsorbed on Ni(111).

surface region. With increase in the degree of covering ($\theta = 0.65$) at 300 K the structure ($\sqrt{3} \times \sqrt{3})R30°$–O appears. This structure is metastable, since on heating to 450 K it is transformed irreversibly into Ni(100)–c(2 × 2)O//Ni(111), that is for adsorption of type II, "reorientation" of the surface oxide into the most favourable configuration is possible, as a result of which the structure of the layer is the same, namely c(2 × 2)O on the (100) and (111) faces. A similar "reorientation" of the Ni(111) face was observed when sulphur is adsorbed.[25]

*b) Adsorption on ruthenium*

Oxygen adsorbed at 300 K on Ru(0001) is desorbed at $T_{des} = 1200–1300$ K; $E_{des}$/kJ mole$^{-1} = 400 - 80\ \theta$.[17,26] EAS has shown, however, that heating even at 400–600 K leads to an irreversible decrease in the magnitude of the Auger peak of oxygen. This can be attributed to the conversion of $O_{ads}(I)$ into the surface-oxide state (adsorption of type II) and the resulting shielding of the oxygen atoms by the ruthenium atoms and increase in the effective charge on the oxygen atom. The equation and kinetic constants were obtained for the transformation $O_{ads}(I) \rightarrow O_{ads}(II)$. The activation energy of this transformation is ~20 kJ mole$^{-1}$. The formation of $O_{ads}(II)$ leads to a decrease in the subsequent adsorption of carbon monoxide in the layer.[26,27]

*c) Adsorption on iridium*

The principal adsorption properties of the (111) and (110) faces of Ir have been described.[28] A clean Ir(110) surface, which has the (1 × 2) structure, after several oxygen adsorption and thermal desorption cycles is rearranged to give a (1 × 3) structure, due to micro-facetting of the surface by (111) faces.[29]

When $O_2$ is adsorbed on Ir(111), a (2 × 2) diffraction pattern is observed, due to the existence of (2 × 1)O domains with three orientations, since $\theta = 0.5$.[30] EAS data and contact potential difference measurements indicate that the adsorption of oxygen on Ir(111) is of type I. The development of the (2 × 2) structure on the Ir(111) face is delayed relative to adsorption, indicating that adsorption takes place on any surface centres, after which ordering of the layer takes place as a result of lateral interaction between the $O_{ads}$ atoms. Calculation of the energy of the lateral interaction from the temperature of the production of disorder in the (2 × 2)O layer ($T_c = 480$ K) in the Bragg–Williams approximation gave the value 4–8 kJ mole$^{-1}$.[30]

At $T \geqslant 450$ K on Ir(110), a non-stoichiometric surface oxide is formed,[14,28,29] and the (110)–(1 × 3) structure is converted into (110)–(1 × 1)O. The activation energy of the transformation is ~80 kJ mole$^{-1}$. As on Ni and Ru, on Ir the transformation $O_{ads}(I) \rightarrow O_{ads}(II)$ leads to a decrease in the heat of adsorption of carbon monoxide (by ~30 kJ mole$^{-1}$ according to Ref. 31).

*d) Adsorption on platinum*

On Pt(111) and on a stepped surface Pt(s), oxygen is adsorbed in the (2 × 2)O structure. In the initial stage on Pt(s), the structure 2(1D)O is formed, that is the atoms are adsorbed on platinum steps with intervals of one atom. The activation energy of desorption $E_{des} = 240 - 50\ \theta$ kJ mole$^{-1}$.[32]

The temperature dependence of the intensity of the (1/2, 1/2) reflections showed (curve *2* in Fig. 2*a*) that complete disordering of the (2 × 2)O layer on Pt(111) takes place even at 420 K.[33] For Pt(s), the graph consists of two regions (curve *3* in Fig. 2*a*): a region corresponding to a sharp decrease in the intensity of the reflections of the (2 × 2)O layer on terraces, similar to curve *2* for Pt(111), and a region corresponding to a relatively weak temperature dependence, associated with "bands" of the 2(1D)O structure, which pass through the positions of the (1/2, 1/2) reflections. Since the oxygen adsorbed on the steps in the 2(1D)O structure does not undergo disordering up to the desorption temperature, the adsorption on the steps is apparently reconstructive (type II).

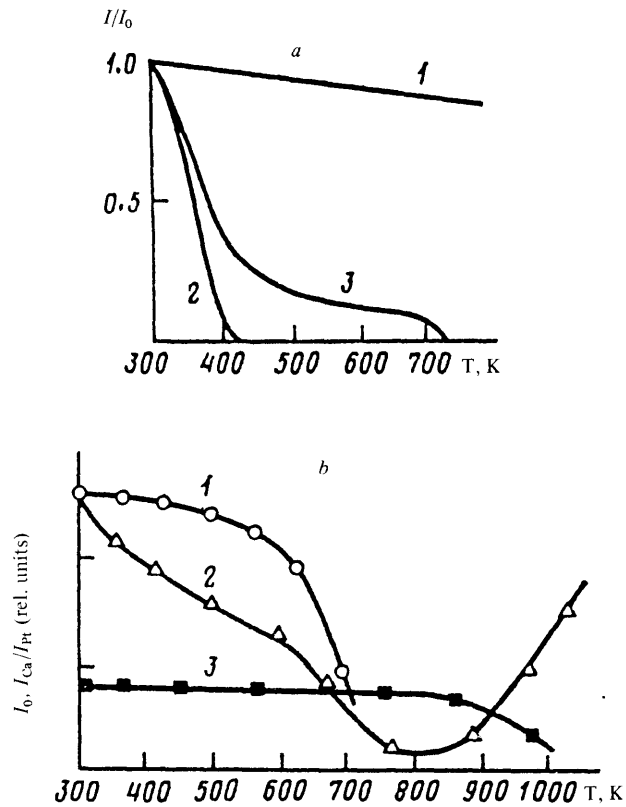

Figure 2. *a*) Temperature dependence of the intensity of the principal (1, 0) (*1*) and additional reflections of a layer of oxygen on Pt(111) (*2*) and Pt(s) (*3*); *b*) change in the magnitude of the Auger peak of oxygen on heating in a vacuum after the adsorption of $O_2$ on Pt at 300 K (*1*) and on heating in a flow of oxygen (*2*), and the temperature dependence of the concentration of calcium (*3*).

EAS has shown[34] (curve *1* in Fig. 2*b*) that when the (2 × 2)O layer on platinum is heated, no appreciable solution of oxygen takes place up to the desorption temperature, in contrast to the case of iridium[29] and rhodium.[35] If however platinum is heated in a stream of $O_2$ (curve *2*), then at high temperatures (800 K) the quantity of oxygen absorbed increases as a result of its solution in the surface layers of platinum. Thus the activation energy of the diffusion of oxygen in platinum is apparently greater than the activation energy of desorption. Thus in Ref. 36, the value given for the activation energy of the diffusion of oxygen in platinum is $E_{diff} = 330 \pm 100$ kJ mole$^{-1}$. The formation and thermal stability of surface oxides of platinum may be influenced by impurities (Si, Ca).[37] Thus a calcium concentration corresponding to

1–2% of a monolayer at 300 K decreases when surface oxides are formed (curve *3*).

If a high concentration of oxygen is produced on a platinum surface, particularly on an "open" (321) face, the TD spectra, in addition to the usual broad $O_{ads}(I)$ peak (second-order desorption), show a new narrow peak with $T_{max} = 700$ K, whose position remains unchanged with variation of the degree of covering, that is first-order desorption takes place.[38] The appearance of this peak may be related to the decomposition of surface (2D) oxides of platinum.

*e) Adsorption on palladium*

When $O_2$ is chemisorbed on Pd(111), [39] the (2 × 2)O structure is formed at 300 K, but disappears on heating in a vacuum to 600 K. Heating at $T \geqslant 600$ K in a stream of $O_2$ leads to saturation of the surface region with oxygen and to the reappearance of the (2 × 2)O structure, attributed[39] to the production of the surface oxide PdO. On thermal desorption, two oxygen peaks were observed: the first is due to the recombination of $O_{ads}$ on the surface, and the second to the decomposition of the surface oxide.

In a PES study using synchrotron radiation,[40] the position of the O2*s* line indicated three states of oxygen, analogous to those found for platinum:[33] 1) $O_{ads}$ on "smooth" regions of the Pd(111) surface; this is realised in "pure" form at 150 K; 2) oxygen inserted into the surface layer of the metal, apparently at points of structural breakdown (defects, etc.), this $O_{ads}$ (type II, together with $O_{ads}$ of type I) is observed on Pd(111) at 300 K; and 3) surface palladium oxides, formed at 600–700 K.

## 2. Properties of Adsorption Layers of Types I and II

The above data make it possible to put forward a general adsorption scheme. When oxygen reacts with metals, a succession of surface compounds is formed:[14]

$$M + O_2(gas) \rightarrow M\text{-}O_{2\,ads} \rightarrow M\text{-}O_{ads}(I) \rightarrow M\text{-}O_{ads}(II) \rightarrow MO(oxide)$$
$$\qquad\qquad\qquad

non-reconstructive state $O_{ads}(I)$ possibly increases in the position of maximum coordination.

Adsorption of type I is thermodynamically more favourable in the series Ag–Ir. For Ru, Ni, Co, and other metals, the principal state is $O_{ads}(II)$, but at low degrees of covering on the most closely packed faces, the existence of reactive oxygen in the intermediate state $O_{ads}(I)$ is possible, and the oxygen atoms may not be in the position of maximum coordination.

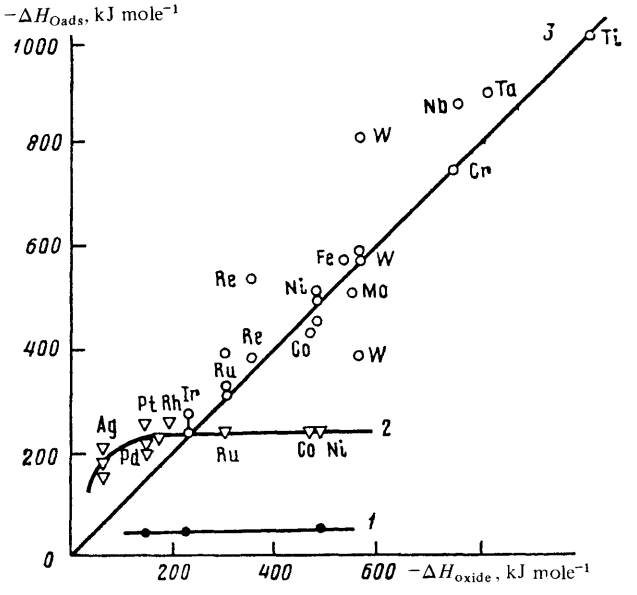

Figure 3. Plots of the heats of adsorption in the molecular (*1*), non-reconstructive (*2*), and reconstructive (*3*) forms against the heats of formation of the oxides of the corresponding metals.

The possibility of the transformation $O_{ads}(I) \rightarrow O_{ads}(II)$ depends on the energy of both the bonds being broken and the bonds being formed, and, in the general case, on the difference $\Delta H[O_{ads}(II)] - \Delta H[O_{ads}(I)]$. With decrease in the coordination number of the metal atoms in the series of structures: bulk (3D)–plane (2D)–step (1D), the heats of formation of the corresponding oxides apparently increase in the order:

$$|\Delta H[(1D)\text{oxide}]| > |\Delta H[(2D)\text{oxide}]| > |\Delta H[(3D)\text{oxide}]|$$

The insertion of an oxygen atom into a metal layer, that is the transformation $O_{ads}(I) \rightarrow O_{ads}(II)$, is accompanied by an increase in the effective charge on the atom, and its state changes from the radical-like state $O^{\delta-}_{ads}$ [19,55] to the state of oxygen in the surface oxide $O^{2-}_{ads}$. [19,40]

## III. THE OXIDATION OF CARBON MONOXIDE ON METALS

The investigation of the relationship between the kinetic and thermodynamic parameters of adsorption and heterogeneous-catalytic reactions is an important problem in the theory of heterogeneous catalysis.[56–58] The existence of a correlation between the heat of adsorption of oxygen and the catalytic activity of oxides in total oxidation reactions has been established.

The plot of the rate of the oxidation of CO against the energy of the bond formed by oxygen (Fig.4) is a curve with a maximum corresponding to the platinum group metals,[50] in agreement with the change in the rate of adsorption and the efficiency of the reaction in the same metal series.[59]

On metals for which the energy of the $M-O_{ads}$ bond is low (Ag, Au), the limiting stage is apparently the adsorption of oxygen. Thus a recent ESCA study[60] of the adsorption of oxygen on silver films (at an oxygen pressure up to 10 Pa) showed that the adsorption on the silver surface takes place with a low accommodation coefficient $s \cong 10^{-3}$ in a state characterised by a high reactivity towards CO (the efficiency of the reaction is close to 1). This agrees with published data.[61,62]

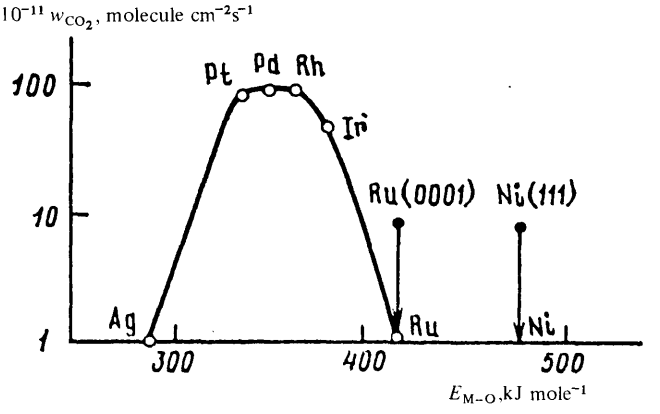

Figure 4. Plot of the rate of oxidation of carbon monoxide (520 K, $p(O_2) = p(CO) = 1 \times 10^{-5}$ Pa) against the energy of the bond formed by oxygen with metals; black points—catalytic activity of Ru(0001) and Ni(111) under non-stationary conditions.

For metals lying on the right-hand branch of the curve in Fig.4, the limiting stage is the reaction of CO with $O_{ads}$. Thus the adhesion coefficient of oxygen on Ru(0001) is 0.4, whereas the reaction rate at 520 K and $p(O_2) = p(CO) = 1 \times 10^{-5}$ Pa in the reaction mixture is only $2 \times 10^{11}$ molecule cm$^{-2}$ s$^{-1}$. [17] In Ref.63, the reaction rate on Ru(0001) under stationary conditions could not be measured at all ($w \leq 10^{11}$ molecule cm$^{-2}$ s$^{-1}$). Under stationary reaction conditions at pressures of oxygen and carbon monoxide of $1.3 \times 10^{-5}$ Pa on Ni(110), a layer of nickel oxide is formed.[64] Since it is highly endothermic ($\Delta H_p = 85$ kJ mole$^{-1}$), the reaction of $CO_{ads}$ with $O_{ads}$ on nickel takes place at a measurable rate only at temperatures above 600 K. The right-hand branch of the curve in Fig.4 agrees approximately with published data[65] which show that the rate of the oxidation of hydrogen decreases by a factor of $10^2$ on going from platinum to nickel.

An interesting feature is that under certain conditions at low temperatures, Ru(0001) and Ni(111) show a high but unstable activity (Fig.4).

### 1. The Influence of the Transformation $O_{ads}(I) \rightarrow O_{ads}(II)$ on the Activity of Ru, Ni, and Co

On the Ru(0001) face after a constant flux of the reaction mixture has been established ($p(O_2) = p(CO) = 1.3 \times 10^{-5}$ Pa)

with smooth increase in temperature (~1 K $s^{-1}$) from 300 K and above the formation of $CO_2$ is observed.[63,66] Fig.5 shows that the reaction rate is a maximum at 470 K. The catalytic activity is not constant, however, since keeping the specimen at any temperature leads to a decrease in the reaction rate. As already noted, oxygen is adsorbed on Ru(0001) at 300 K in a reactive form (type I), which on heating is converted into a surface oxide (type II), leading to the suppression of the catalytic activity. The kinetics of oxidation of CO on Ru(0001) have been described using the observed rate constants for the stage of the adsorption of $O_2$ and CO, the reaction $O_{ads}$ + $CO_{ads}$, and the stage corresponding to the irreversible transformation $O_{ads}(I) \rightarrow O_{ads}(II)$.[66]

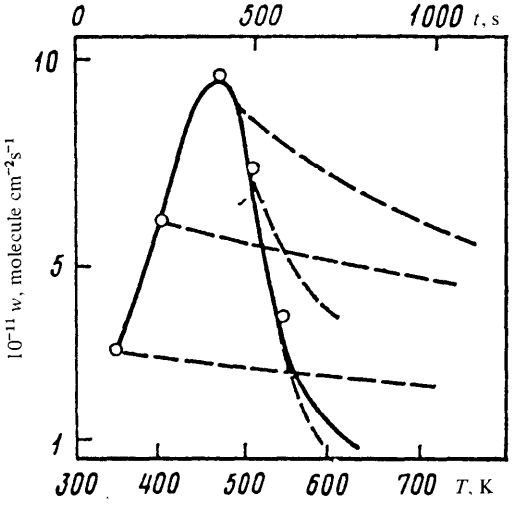

**Figure 5.** Temperature dependence of the rate $w$ of formation of $CO_2$ on the Ru(0001) face for a specimen heated at a rate of 1 K $s^{-1}$. The points correspond to the specimen heated at the given temperature, and the broken lines correspond to the change in $w$ with time.

When Ni(111) is cooled slowly from 800 K or kept under isothermal conditions at 450–500 K in the reaction mixture (5% $O_2$) a "burst" of catalytic activity is observed during the phase transformation Ni(111) → NiO.[14,67] In the case of Ni(100) under the same conditions, this "burst" is not observed. It is possible that on Ni(111) the reaction involves $O_{ads}(I)$, and that the surface region before the "burst" is gradually saturated with dissolved oxygen, preventing the diffusion of $O_{ads}(I)$ into the volume, so that the activity increases. The subsequent decrease in catalytic activity is due to the formation of a surface oxide. Essentially analogous data have been obtained[68] for the Co(0001) face.

Thus for metals such as Ru, Ni, Co, etc., the initial high catalytic activity associated with the production of $O_{ads}(I)$ gradually decreases as a result of the conversion of $O_{ads}(I)$ into the surface-oxide state (type II), in which the oxygen is unreactive under the given conditions.

## 2. The Oxidation of CO on Metals of the Platinum Sub-group

The oxidation of CO on metals of the platinum sub-group, which have a high catalytic activity under stationary conditions, can be considered.

### *a) Titration of the adsorbed oxygen with carbon monoxide*

The (111) and (110) faces of a single crystal of Ir show a high specificity in the titration, that is the differences between the faces are extremely marked. Thus on Ir(111) the initial rate of the titration ($w^0$) is low at 300–400 K [69] and with increase in temperature it increases in proportion to the decrease in the intensity of the reflections of the (2 × 2)O structure, that is the degree of disorder in the (2 × 2)O layer. On an Ir(110)–(1 × 3) surface micro-faceted by (111) faces, the initial rate remains high ($w^0 \cong 10^{12}$ molecule $cm^{-2}$ $s^{-1}$) at 300–400 K, that is at temperatures below the temperature at which disorder is produced in the (2 × 2)O layer. Thus on Ir(111) the reaction requires thermal disordering of the layer, whereas on Ir(110)–(1 × 3) the structure of the surface itself plays the role of the factor producing structural disorder. The high value of $w^0$ on Ir(110), from the viewpoint of formal kinetics, can be described in terms of the Eley–Rideal mechanism with $E$ = 2–4 kJ $mole^{-1}$, although in fact the reaction takes place in the adsorption layer,[70–72] possibly with the participation of oxygen adsorbed on the edges of the micro-facets.

If the stream of CO is interrupted during the titration of $O_{ads}$ on iridium and on a stepped platinum surface Pt(s), heating the specimen gives $CO_2$ as a result of the reaction $O_{ads}$ + $CO_{ads}$.

For Ir(111), one "low-temperature" α-$CO_2$ peak is observed. Conversion of the temperature dependence of the rate of formation of $CO_2$ at this peak to a straight line in the coordinates lg $w/[O][CO] = f(1/T)$ gives the values of the constants $E_a$ = 44 kJ $mole^{-1}$, $k_a^0 = 10^{-10}$–$10^{-11}$ $cm^2$ molecule$^{-1}$ $s^{-1}$. For Ir(110)–(1 × 3), two peaks are observed: an α-$CO_2$ peak with constants close to those found for Ir(111), and a "high-temperature" β-$CO_2$ peak, which can probably be related to oxygen introduced into the metal in the "valleys" of the micro-facets.

For a stepped platinum surface,[73] the following values were obtained: for α-$CO_2$, $E_a$ = 40 kJ $mole^{-1}$, $k_a^0 = 10^{-3}$ $cm^2$ molecule$^{-1}$ $s^{-1}$; for β-$CO_2$, $E_a$ = 80 kJ $mole^{-1}$, $k_a^0 = 10^{-6}$ $cm^2$ molecule$^{-1}$ $s^{-1}$. The β-$CO_2$ peak can be assigned to the reaction of $CO_{ads}$ with oxygen reconstructively adsorbed on the steps of the surface. Thus it has been shown[33] that the oxygen in the 2(1D)O structure on Pt(s) is less reactive than the $O_{ads}(I)$ on the terraces. Field-emission microscopy[74] previously showed that the reaction of CO with $O_{ads}$ on platinum points, the surface of which consists chiefly of "open" faces and faces with a high density of steps, takes place at temperatures of 400–500 K, in agreement with the temperature range of β-$CO_2$ formation. In the region of the Pt(201) faces, the boundary of the reaction was gradually displaced.

### *b) The oxidation of CO under stationary conditions*

The kinetics of the oxidation of CO on Ir(110) and platinum can be described by a two-path scheme (Langmuir–Hinshelwood and Eley–Rideal mechanisms) using the observed rate constants of the separate stages.[14,75] Agreement between the calculated (curve *1* in Fig.6) and experimental temperature dependence of the reaction rate could be achieved only if it was assumed that the activation energy of the desorption of CO corresponds to the most firmly bound form β-$CO_{ads}$, indicating the importance of the presence of steps (defects) for the reaction on metals of the platinum group. It can be seen from Fig.6 (curve *2*) that the increase in the rate over the range 480–525 K is effectively described by the Langmuir–Hinshelwood mechanism alone; the introduction of the Eley–Rideal mechanism is required to describe the reaction at

higher temperatures. It follows from the SED data at $T \geq 500$ K, however, that the Ir(110)–(1 × 3) surface is transformed into a surface oxide Ir(110)–(1 × 1)O, leading to a change in the constants for all the stages and to the appearance of hysteresis on going from the "forward" to the "reverse" change in temperature.

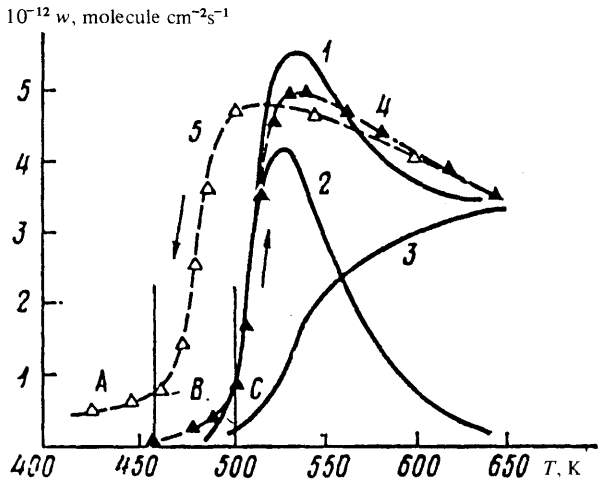

**Figure 6.** Temperature dependence of the rate of oxidation of CO on Ir(110) under stationary conditions (treatment for 5 min at each point; $p(O_2) = 1.6 \times 10^{-5}$ Pa, $p(CO) = 6.7 \times 10^{-6}$ Pa); *1–3*) calculated curves: *1*) overall rate, *2*) rate for the Langmuir–Hinshelwood mechanism, *3*) rate for the Eley–Rideal mechanism; *4, 5*) experimental curves: *4*) on heating, *5*) on cooling. The ranges of existence of the structures (1 × 3), 2(1D)O, and (1 × 1)O are denoted by the letters *A*, *B*, and *C* respectively.

On platinum in an excess of oxygen, for example at $p(O_2)/p(CO) = 5$, ($p(CO) = 2.6 \times 10^{-6}$ Pa), under stationary conditions (time of treatment at each point 5 min), hysteresis is also observed for the "forward" and "reverse" change in temperature (Fig. 7*a*).[73] This hysteresis is not truly kinetic in character, due to non-linearity of the stages involving the adsorption of $O_2$ and the reaction in the adsorption layer, as assumed in Ref. 76, since decrease in temperature from different initial points of the curve for the "forward" change in temperature gives different curves for the "reverse" change.[73] The hysteresis is evidently related to a change in the state of the oxygen on platinum.

Preliminary solution of oxygen at $T \approx 800$ K (see Fig. 2*c*) has no influence on the course of the $w = f(T)$ curves. Thus the hystersis is related to surface processes. Figs. 7*b* and 7*c* give the titration curves for oxygen adsorbed on platinum under stationary reaction conditions, obtained after the flow of oxygen had been stopped. Stopping the flow of $O_2$ at 430–460 K (Fig. 7*b*) leads to a sharp decrease in the rate, but at $T \geq 500$ K the curves are flat. The concentrations of $O_{ads}$ obtained from the titration curves at 445 K are less than $10^{12}$ atom cm$^{-2}$, and at 600 K the value obtained was ~$5 \times 10^{13}$ atom cm$^{-2}$. The order of magnitude of the last value ($\theta = 0.05$) agrees with the density of steps. Under stationary reaction conditions at 500–600 K and during the titration (flat regions), the SED patterns show "bands" of the 2(1D)O structure. On cooling (see Fig. 7*c*), the proportion of flat regions on the titration curves, and the stationary concentration of inserted $O_{ads}$(II), are much greater than those for the "forward" change (Fig. 7*b*).

Thus at 300–400 K, the $CO_{ads}$ molecules apparently block the Pt(s); at 400–460 K, the desorption of β-$CO_{ads}$ liberates the steps on which $O_2$ dissociates, and the $O_{ads}$(I) form reacts immediately with $CO_{ads}$. At $T \geq 480$ K, as a result of the transformation $O_{ads}(I) \rightarrow O_{ads}(II)$, the reaction no longer takes place on the steps (defects), but on the one-dimensional platinum oxide (1D)O.

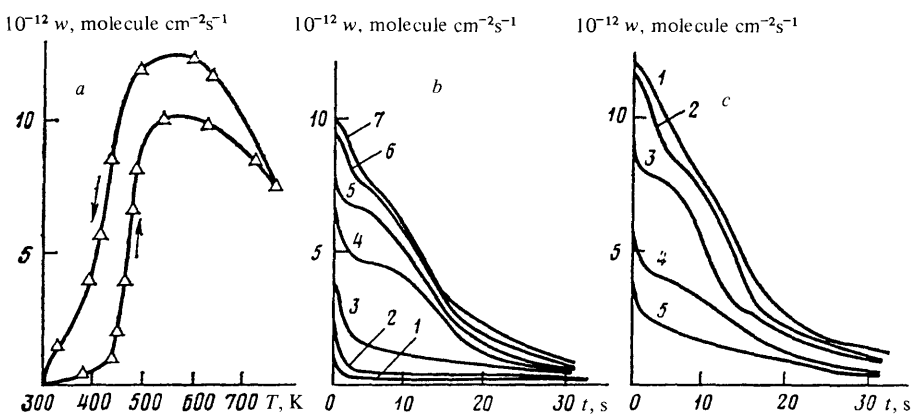

**Figure 7.** *a*) Temperature dependence of the rate of the oxidation of CO on platinum foil under stationary conditions ($p(O_2) = 1.3 \times 10^{-5}$ Pa, $p(CO) = 2.6 \times 10^{-6}$ Pa; *b*) titration curves for oxygen adsorbed under stationary reaction conditions (*a*), obtained after switching off the stream of $O_2$ during the "forward" change in temperature (heating). Temperatures of the titration, K: *1*) 430, *2*) 445, *3*) 460, *4*) 480, *5*) 495, *6*) 540, *7*) 600. *c*) The same for the "reverse" change in the temperature of the reaction (*a*). Temperatures of the titration, K: *1*) 535, *2*) 485, *3*) 450, *4*) 400, *5*) 340.

## 2. General Scheme for the Oxidation of CO on Metals

The equation for the reaction rate can be written in the following general form:[5]

$$w = k\mathrm{f}(c_i\theta_i)\,\varphi(c_i)\ .$$

The first term is determined by the stoichiometry of the active complex, and the second by the influence of the reaction medium on the properties of the catalyst. For the oxidation of CO, the set of stages determining the kinetics of the reaction on a non-changing surface (that is without allowance for the influence of the reaction medium) can be written as the four-stage scheme:[75-77]

$$O_2 + 2Z \xrightarrow{k_1} 2ZO \qquad (1)$$

$$CO + Z \underset{k_{-2}}{\overset{k_2}{\rightleftarrows}} ZCO \qquad (2)$$

$$ZO + ZCO \xrightarrow{k_3} CO_2 + 2Z \qquad (3)$$

$$ZO + CO \xrightarrow{k_4} CO_2 + Z \qquad (4)$$

Here, Z represents the adsorption centres on the metal surface. Stage (3) corresponds to the Langmuir–Hinshelwood mechanism, and stage (4) to the Eley–Rideal machanism. As already noted, the collision stage (4) in this model is introduced to describe the kinetics at high temperatures (see Fig.6), but oxidation of the metal already takes place under these conditions. In this scheme, ZO represents the radical-like[19,55] non-reconstructively adsorbed $O_{ads}(I)$.

The influence of the reaction medium ($\phi(c_i)$) is related to the oxidation of the metal in the stages:

$$ZO \xrightarrow{k_5} Z_{ox}O\,, \qquad (5)$$

$$Z_{ox}O + ZCO \xrightarrow{k_6} CO_2 + Z'_{ox} + Z\,. \qquad (6)$$

Here, $Z_{ox}$ represents the centre of the surface oxide associated with $O_{ads}(II)$, and $Z'_{ox}$ the same centre in the intermediate state after the removal of $O_{ads}(II)$ by reaction with $CO_{ads}$ (stage (6)).

For metals such as Ru and Ni, the rate constants of stage (6) are low compared with $k_3$ and $k_4$, so that the transformation $O_{ads}(I) \rightarrow O_{ads}(II)$ (stage (5)) leads to the suppression of the catalytic activity.

For the platinum metals, the constants $k_6$ and $k_3$ do not differ so greatly.[73] Thus for Pt(s) the ratio of the rate constants for the reaction of $CO_{ads}$ with $O_{ads}(I)$ and $O_{ads}(II)$ at 500 K is $k_3/k_6 = 10-10^2$, so that reaction is possible under stationary conditions. Oxidation of the metal naturally also changes the values of the constants of stages (1) and (2); the rates of the adsorption of $O_2$ and CO decrease slightly, and, which is more important, the heat of adsorption of $CO_{ads}$ decreases; as a result, $CO_{ads}$ blocks the surface at lower temperatures, and this is responsible for the hysteresis. Recently, a similar scheme (stages (1)–(6)) was used to obtain a quantitative description of the self-oscillations in the rate of the oxidation of carbon monoxide on platinum and iridium.[78,79]

Next, the displaced metal atoms ($Z'_{ox}$) formed in stage (6) apparently either return to their equilibrium position on the step (Z) or "roll out" on to a terrace, forming so-called adsorbed metal atoms $Z_{ads}$

$$Z'_{ox} \xrightarrow{k_7} Z\,, \qquad (7)$$

$$Z'_{ox} \xrightarrow{k_8} Z_{ads}\ . \qquad (8)$$

The appearance of thermodynamically unstable forms ($Z_{ads}$) under stationary conditions as a result of the heat of the reaction may have a significant influence on the catalytic properties of the metal.[80] The adsorbed atoms (or clusters) $Z_{ads}$ can act as new "active centres" for the adsorption of $O_2$, bringing about a branched-chain process.[81] The heat of the reaction $O_{ads} + CO_{ads}$ on platinum is $\Delta H_p = -(30-50)$ kJ mole$^{-1}$, that is it is even lower than the energy of a single Pt–Pt bond (85 kJ mole$^{-1}$).[82] In view of the high rate of the dissipation of energy in the metal lattice, it is difficult to imagine that the reaction between $CO_{ads}$ and $O_{ads}(I)$ can lead to the "ejection" of metal atoms, that is to the formation of $Z_{ads}$. In the case of reconstructive chemisorption, however, even at the stage of the insertion of oxygen into the layer of metal (stage (5)), displacement of platinum atoms (or at least a decrease in the strength of the Pt–Pt bond) takes place, so that the reaction stage (stage (6)) only facilitates the removal of platinum atoms. Thus the formation of $O_{ads}(II)$ is a necessary condition for the processes involved in the rearrangement of the surface.

Scanning microscopy has shown[83,84] that the oxidation of CO produces a marked change in the micro-relief of the surface of a platinum filament, although the adsorption of $O_2$ or CO alone has no significant influence on the surface. It is easy to imagine that if the rate of generation of $Z_{ads}$ is high, and the rate of their diffusion over the terraces is low, then "loosening" of the surface will take place. If however the rate of diffusion is high, the $Z_{ads}$ atoms will be able to migrate to the positions with minimum free energy, and completion of the most closely packed faces (facetting) will take place.

## 4. The Specific Features of the Faces in Catalysis and the Constancy of the Specific Catalytic Activity

The specific features of the faces and "active" centres in catalysis and the constancy of the specific catalytic activity have been examined.[5,14,59]

The rate of the reaction of $H_2$ with oxygen adsorbed in the Ni(111)–(2 × 2)O structure is 10–20 times the rate of the reaction with $O_{ads}$ in the Ni(100)–c(2 × 2)O structure. The rearrangement of Ni(111) to the Ni(100)–c(2 × 2)O//Ni(111) structure, however, leads to approximately equal reactivities of oxygen on the two faces.[14,59]

The reaction of CO with $O_{ads}$ on Ir(110) at 330 K is ten times that on Ir(111). In a reaction stream with relatively rapid heating of the specimens (~4 K s$^{-1}$), the Ir(110) to (1 × 3) face is 2.5 times more active than the Ir(111) face. Under stationary reaction conditions, surface oxides are formed, the Ir(110)–(1 × 3) surface at $T \geq 450$ K is rearranged to the (1 × 1)O structure, and the catalytic activities of the two faces become equal.[14,28,59]

Thus if under the reaction conditions (relative excess of CO, comparatively low temperatures) the oxygen on the surface is adsorbed as $O_{ads}(I)$, then the structure of the surface is important for the reaction, the steps act as "active" centres, and the actual reaction takes place via stages (1)–(4). At "high" temperatures with an "excess" of oxygen in the reaction mixture, $O_{ads}(II)$ is formed on the surface, stages (5)–(8) also take place, and rearrangement of the surface leads to the practical disappearance of the specific characteristics of the faces, that is the rule of approximate constancy of the specific catalytic activity is observed.

---o0o---

Thus examination of the properties of the two most important types of adsorbed oxygen, namely the non-reconstructive (I) and the reconstructive (surface-oxide) (II) types, has made it possible to explain a number of phenomena of oxidative catalysis on metals in a single scheme.

This approach may be more general, since in addition to adsorption layers of type I (sulphur, nitrogen, carbon), surface sulphides, nitrides, and carbides are also known for metals.

# The Application of Mössbauer Spectroscopy to the Study of Tin-containing Catalysts

E.N.Yurchenko

The principal problems arising in the study of tin-containing homogeneous and heterogeneous catalysts by Mössbauer spectroscopy are reviewed. The information provided by the parameters of the method, among which special attention has been devoted to the probability of the resonance absorption of $\gamma$-quanta by the specimen and its temperature variation, is analysed. The principal results obtained in the study of the structure and properties of various tin-containing catalysts are surveyed.
The bibliography includes 91 references.

CONTENTS

I. Introduction 232
II. Methodological problems in the study of catalysts by the Mössbauer method 233
III. The properties of tin-containing catalysts 242
IV. Conclusion 245

## I. INTRODUCTION

Specific types of tin(II)-containing compounds have now gained a firmly established place among homogeneous and heterogeneous catalysts of various processes in reductive media. $SnCl_3$-containing transition metal complexes are most widely used as homogeneous catalysts. Platinum metal complexes, both those in which the ligands are tin halide species alone and complexes containing $PR_3$, $P(OR)_3$ and CO molecules in addition to Cl and $SnCl_3$, exhibit catalytic properties in the hydrogenation reactions of various monoolefins and polyolefins as well as unsaturated organic acids, in their isomerisation, in olefin carboxylation processes, etc. Most detailed information on this question has been published by Matvienko.[1] On the other hand, industrial catalytic processes are mainly carried out on deposited Pt–Sn intermetallic compounds, which are used in reforming[2] and dehydrogenation[3] processes.

The unique possibilities of the Mössbauer method for securing information about the structure and properties of tin-containing compounds have been known for a long time.[4] However, its application to the study of such catalysts has been inadequately dealt with in review articles. One of the first reviews in which questions concerning the application of Mössbauer spectroscopy to catalysis were discussed dealt largely with iron compounds[5] and concentrated mainly on two possible aspects of the application of the Mössbauer effect: (1) the derivation of information about the electronic states of the atoms in catalysts and about the relation with their activity and selectivity; (2) the detection of intermediate complexes in catalysis. The only study considered by Gol'danskii and Suzdalev[5] was that of Skalkina et al.[6], who found that the relation between the rate of the oxidative ammonolysis of propene and quadrupole splitting $\Delta$ (for a constant chemical shift $\delta$) has an extremum for $SnO_2$ and its solid solutions in $Sb_2O_4$, $MoO_3$, and $Fe_2O_3$.

The most complete review, in the sense of coverage of problems involving catalysis, is that of Dumesic and Topsoe,[7] who discuss in detail the information contained in the parameters of the Mössbauer spectra, the characteristic features of the application of the method to the study of the structure of the catalyst surface, the adsorption of various molecules on such a surface, and the reactivity of molecules containing different Mössbauer atoms. Their review covers an even greater number of examples of the study of tin-containing catalysts, but these are mainly tin(IV) compounds. In a later review[8] dealing with the application of Mössbauer spectroscopy to catalysis, no information whatever is included about tin-containing catalysts. Finally, the compilations of communications on Mössbauer spectroscopy, regularly published in the journal Analytical Chemistry (R) (see, for example, Stevens et al.[9]) are concerned with all the aspects of the application of the method and do not analyse the characteristics of its application to the study of particular types of systems, including catalysts.

This position can be partly accounted for by the fact that the number of studies on tin-containing catalysts by the Mössbauer method has indeed been small. For example, the first investigation of the industrial tin-containing catalysts deposited on $\gamma$-$Al_2O_3$ appeared in 1975.[10] The authors[10] showed that the surface of the carrier contains a whole set of tin (IV), tin(II), and zerovalent tin compounds, although the main problem is their detailed identification. Studies of this kind have been partly discussed in a recently published review,[11] but the methodological aspect of the problem of the determination of the number of individual components of the catalyst, their composition, and their state on the basis of the complex overall Mössbauer spectrum remained inadequately dealt with.

The experience gained in the application of physical methods to catalysis, accumulated at the Institute of Catalysis of the Siberian Division of the USSR Academy of Sciences, has shown that a fairly profound understanding of the reaction mechanism and of the action of the active centre has been achieved in those cases where it was possible to obtain reliable information about its composition, structure, or the type of compound or phase constituting this centre. One must note that none of the reviews published hitherto has considered the outcome of the application of the Mössbauer effect to the study of tin-containing homogeneous catalysts. Here too it is necessary to obtain in the first place information about their composition and structure. In view of the foregoing, in the present review we shall consider primarily the structural aspect of the application of the Mössbauer method to the study of tin-containing homogeneous and heterogeneous catalysts.

## II. METHODOLOGICAL PROBLEMS IN THE STUDY OF CATALYSTS BY THE MÖSSBAUER METHOD

In this Section, no attempt is made to describe all the methodological problems of the application of the Mössbauer effect in chemistry; like the theory of the method, they have been described in detail elsewhere.[12–16] Here we shall deal only with those of their aspects which are most important for the investigation of catalysts.

### 1. Homogeneous Systems

As mentioned above, the homogeneous catalysts usually consist of $SnCl_3$-containing platinum metal complexes as well as clusters of the same metals incorporating $SnCl_3$, $SnCl_2$, and SnCl groups and Sn atoms.[1,17,18]

It has been shown[17–20] that the line form in the Mössbauer spectra of complex compounds frequently differs from the ideally symmetrical doublet; this can be caused by the non-equivalence of the positions (and hence the electronic structures) of the $SnCl_3$ ligands in the coordination sphere of the platinum metal or, which happens more frequently, by the presence in its coordination sphere of tin-containing ligands of different composition. The latter is typical for clusters.[17,18,21] In this case the determination of the parameters of the Mössbauer signal of each kind of tin-containing groups makes it necessary to resolve the overall spectrum into individual doublets with a Lorentzian line form. Fig. 1 (Yurchenko[18]) presents the Mössbauer spectrum of the $[Pd_3Sn_8Cl_{20}]^{4-}$ cluster obtained in the form of the tetraphenylphosphonium salt; the spectrum was interpreted on a BESM-6 computer. The line form of each quadrupole doublet was described by the expression

$$W_a(E) = \frac{1}{2\pi}\left[\frac{\Gamma_{nat}/2}{(E-E_0-\Delta)^2+(\Gamma_{nat}/2)^2}+\frac{\Gamma_{nat}/2}{(E-E_0+\Delta)^2+(\Gamma_{nat}/2)^2}\right], \quad (1)$$

where $E$ is the energy of the emission of $\gamma$-quanta, $E_0$ the energy of the resonance transition, and $\Gamma_{nat}$ the natural line width.

Later it was found that it was more rational to carry out an analogous resolution procedure with the aid of an SK-2 curve synthesiser,[18] which makes it possible to isolate simultaneously up to seven components of the spectrum. The area under the envelope of each doublet is related to the number of absorbing atoms $n$ by the familiar expression[14,15,17]

$$S_a = \frac{\pi}{2}\Gamma_{nat}\sigma_0 \varkappa f n f', \quad (2)$$

in which $\varkappa f$ can be determined by the black absorber method, which has been described for tin.[22] Yurchenko[18] adopted $f'_{77} = 0.22$ for the $SnCl_3$ ligand, 0.3 for SnCl, and 0.4 for Sn in the $Pd_3Sn$ alloy.[23] Taking into account these values of $f'$ for Sn in $[Pd_3Sn_8Cl_{20}]^{4-}$, it is found that the ratio of the areas of the two doublets in Fig. 1 corresponds to the ratio of the numbers of tin atoms in the ligands of the cluster, which is 3:1;[18,21] this constitutes one of the arguments in support of the representation of the composition of the cluster by $[Pd_3(SnCl_3)_6(SnCl)_2]^{4-}$.[21]

The study of the state of catalysts under the conditions of the catalytic process (*in situ*) is particularly valuable. For homogeneous systems, this requires the measurement of the Mössbauer effect for solutions, which, by virtue of the nature of the effect itself, becomes possible only when the latter are frozen. In those cases where the concentration of the catalytically active forms of the complex or intermediate states is high, freezing of the solutions has a conserving effect on these forms and makes it possible to identify them from the Mössbauer spectra. However, studies available hitherto on the Mössbauer spectroscopy of frozen solutions have been associated mainly with the analysis of complex formation processes.[24–27] In their methodological aspect, such studies require the availability of cells of appropriate design, which would not break on cooling the solution to the temperature of the liquid nitrogen and would retain their hermetic seal.

The use of Mössbauer parameters such as $\delta$ and $\Delta$ for the identification of the types of complexes predominating in solution required the accumulation of information about the characteristics of the Mössbauer effect for compounds of tin in various oxidation states and with different structure of its immediate environment. For tin(II) complexes, such a study has been carried out[18] and the relation between the observed changes in the Mössbauer parameters and the characteristics of the structure of the complex as a whole and of the tin(II)-containing ligands in it has been elucidated by simultaneous investigation of the crystals of the complexes by the X-ray diffraction and Mössbauer spectroscopic methods. Fig. 2 presents examples of the Mössbauer spectra of various tin compounds; evidently, the values of $\delta$, $\Delta$, the width of the components $\Gamma$, and the form of the spectra are sensitive not only to changes in the oxidation state of tin but also to the characteristics of the structure of the tin-containing compounds.[17] Thus the formation of a coordinate bond by the $SnCl_3$ group alters $\delta$ from 3.64–3.00 mm $s^{-1}$ and $\Delta$ from 0.90–1.73 mm $s^{-1}$ for the $SnCl_3^-$ ion[28] to 1.50–1.95 mm $s^{-1}$

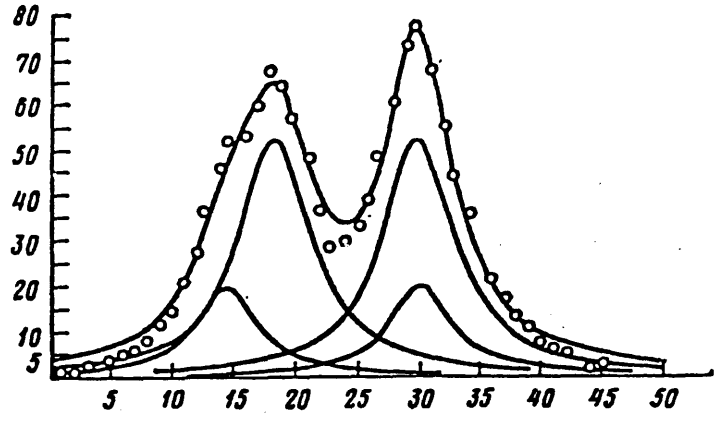

**Figure 1.** The Mössbauer spectrum of the $(Ph_4P)_4[Pd_3Sn_8Cl]_{20}$ cluster (in terms of the arbitrary units of the graph plotter.

and 1.60–2.10 mm $s^{-1}$ respectively.[29–35] If all the $SnCl_3$ ligands in the coordination sphere of the complex have equivalent positions and geometries, as, for example, in $[PdCl_3(SnCl_3)]^{2-}$ (Fig. 2, curve 3), then under these conditions a symmetrical doublet is observed with lines of equal and minimum width. If the ligands in the coordination sphere of the complex occupy non-equivalent positions, for example, the axial and equatorial $SnCl_3$ groups in $[Pt(SnCl_3)_5]^{3-}$, and therefore have different values of $\delta$ and $\Delta$, then the overall spectrum can be asymmetric and can have broader lines (Fig. 2, curve 4). Finally, the presence of tin(II)-containing ligands in the complex which are non-equivalent as regards composition and structure imparts a strongly asymmetric contour to the overall spectrum resulting from the doublets due to each ligand (Fig. 2, curve 5).

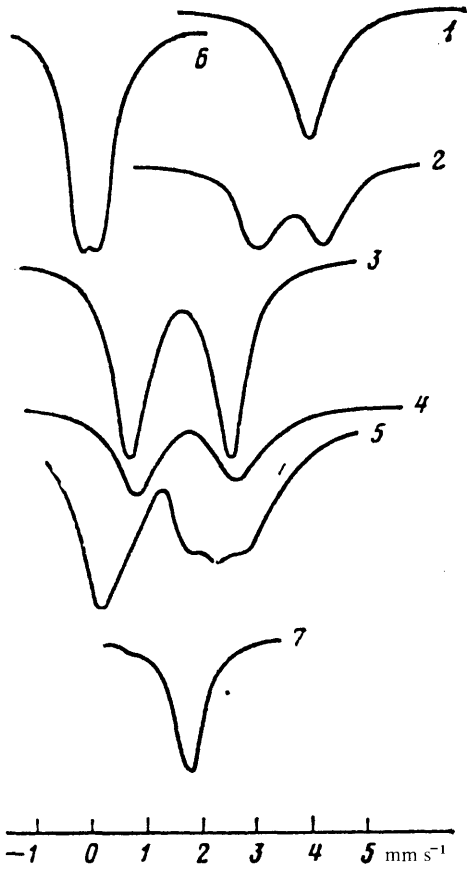

**Figure 2.** Mössbauer spectra: 1) $SnCl_2$(anh.); 2) $SnCl_2 \cdot 2H_2O$; 3) $(Ph_4P)_2[PdCl_3(SnCl_3)]$; 4) $(Et_4N)_3[Pt(SnCl_3)_5]$; 5) $Cs_4[Rh(Sn_4F_{15})(SnF_2(H_2O)_2]_2 \cdot 2H_2O$; 6) $SnO_2$; 7) PtSn.

The non-equivalence of the $SnCl_3$ ligands as regards their positions in the coordination sphere of the complex affects the form of the spectrum to a greater extent than the differences between the geometries of each of them. This has been demonstrated by an investigation[36] of the crystal structure and spectra of $[Me_4N]_4[OsCl(SnCl_3)_5]$. All ten crystallographically independent $SnCl_3$ ligands in the unit cell of the crystal of this compound have appreciably different SnCl bond lengths and Cl–Sn–Cl angles. Nevertheless, the Mössbauer spectrum of the powdered complex consists of a symmetrical doublet;[32] the above differences in the geometry of the $SnCl_3$ groups induce only a broadening of the line widths to 0.85 mm $s^{-1}$.

Thus the results of a number of studies[30–36] helped to discover how much structural information is contained in the Mössbauer characteristics of tin(II) compounds, such as the form and width of the components of the recorded spectrum and the values of $\delta$ and $\Delta$ for its individual components. Dynamic parameters, particularly $f'$, have not been used to characterise the structural features of tin-containing catalysts.

The quantity $f'$ is defined by the expression

$$f' = \exp\left(-\frac{\langle x^2\rangle}{\lambda^2}\right), \qquad (3)$$

where $\langle x^2\rangle$ is the mean square shift of the emitting nucleus at the crystal lattice site in the direction of the stream of $\gamma$-quanta. $\lambda = \lambda/2\pi$, and $\lambda = 0.52$ Å for $^{119}Sn$. One might expect that the characteristics of the structure of tin-containing compounds will be reflected in the value of $\langle x^2\rangle_{Sn}$ for the latter and hence in the value of $f'$.

The parameter $f'$ is, in principle, related to the macroscopic properties of the entire crystal containing the Mössbauer atom.[13,14] The value of $f'$ in the range $1 \leq f' \leq 0$ depends on whether there exist in the given crystal possibilities for the consumption of part of the energy of the $\gamma$-quanta, which is equal to the recoil energy of the Mössbauer nucleus. Such energy dissipation channels are provided by the excitation of the phonon spectrum and of the individual vibrations of the crystal in the optical branches.[37,38] In simplest cases of one- or two-atom lattices, the Debye model of the solid is used for the description of $f'$,[39] according to which we have in the temperature range above 77 K

$$f' = \exp\left(-\frac{6E_R T}{k\Theta^2}\right), \qquad (4)$$

where $\Xi$ is the characteristic Debye temperature for the crystal, $E_R$ the recoil energy, and $k\Xi = \hbar\omega_{max}$.[12–14] It has been suggested that, when the Mössbauer nucleus in the solid forms part of the composition of the molecule or ion having characteristic vibration frequencies $\omega_i$, Einstein's model of the solid be employed, according to which

$$f' = \prod_i \exp\left(-\frac{E_R}{\hbar\omega_i}\coth\frac{\hbar\omega_i}{2kT}\right). \qquad (5)$$

It has also been suggested[40] that $f'$ for molecular crystals be expressed as the product $f'_{ia}f'_{ir}$, where $f'_{ia}$ characterises the component of the probability of the absorption of a $\gamma$-quantum which depends solely on the intramolecular vibrations of the Mössbauer atom, while $f'_{ir}$ characterises the part which depends on the vibrations in the solid of the entire molecule containing the given atom. Eqn. (3) is then valid for $f'_{ia}$ and $f'_{ir}$ separately, $\langle x^2\rangle_{ir}$ is a result of the shift of the Mössbauer atom as a consequence of intermolecular vibrations, and $\langle x^2\rangle_{ia}$ is the result of the shift due to intramolecular vibrations. A number of compounds, for example organotin(IV) compounds, have high frequencies (300–400 $cm^{-1}$ and above) and, in conformity with Eqn. (4) or (5), $f'_{ia} \to 1$. Debye's model of the solid state is usually employed to describe $f'_{ir}$ and the following relation is analysed:

$$\frac{d\ln f'}{dT} = \frac{3E_i^2 k}{M_{eff}c^2\hbar^2\omega_i^2}, \qquad (6)$$

where $M_{eff}$ is the mass of the entire molecule and $\omega_i$ its

vibration frequency (the lowest lattice vibration frequency is adopted as $\omega_i$). In combination with the determination of $\omega_i$ from Raman spectra, this approach has been used in a whole series of studies, for example, for the determination of the molecular weights of tin-containing compounds.[41-45]

It follows from Eqns.(4)–(6) that the higher the effective mass of the vibrating molecule and the lower the vibrational frequency of the Mössbauer atom, the closer is $f'$ to unity and the weaker the dependence of $f'$ on $T$.

However, the above approach proved to be unsuitable for a whole series of systems. For example, in biological objects containing the $^{57}$Fe label a marked dependence of $f'$ on $T$ (over a limited temperature range) and of the absolute value of $f'$ on the water content in the protein has been observed.[46,47]

It is also noteworthy that, in an early study[48] of the Mössbauer effect in amorphous tin halide compounds, it was observed that the absorption of $\gamma$-quanta without recoil does not require the presence of a crystal structure as such. It is only necessary that an effective mechanism hindering the consumption of the energy of the $\gamma$-quanta in the form of the recoil energy in different kinds of low-frequency rotational and vibrational movements of the groups containing the Mössbauer atom should operate.

In terms of the structural aspects of the use of Mössbauer spectroscopy in which we are interested, it was extremely important to elucidate to what extent the parameter $f'$ itself and its dependence on $T$ are determined by the internal structure of the tin-containing molecule and why this is so. In order to solve such a problem, it is essential to have information about the crystal structures of various tin(II) halide complexes of transition metals. Such data have been obtained in a number of studies.[19,36,49-53] They show that all tin-containing halide complexes without exception are constructed according to the principle of molecular crystals, i.e. the interaction energies of the atoms within the complex anion and within the cation (short interatomic contact) greatly exceed the energy of interaction between them (long interatomic contact). The structure of the (Sn–F)-containing anion is such that four Sn atoms are linked via bridging F atoms. In the chlorine complexes tin is present in the form of the $SnCl_3$ ligand, but the geometry of the latter within the anion and within the unit cell and also in different compounds can vary significantly.

A study[17,54] of $f'$ and of its dependence on $T$ for the number of (Sn–F)-, (Sn–Cl)-, and (Sn–Br)-containing complexes has shown that the maximum values of $f'$ and its weakest temperature dependence ($f'_{77} = 0.5$, $f'_{77}/f'_{153} = 1.6$),† close to that obtained for platinum–tin and nickel–tin alloys, are observed for the fluorides. For the $SnCl_3$-containing complexes, the values of $f'$ are lower and their dependence on $T$ is more marked ($f'_{77} = 0.2$, $f'_{77}/f'_{153} \cong 4-5$). For the $SnBr_3$-containing analogues with the same cations, the values of $f'_{77}$ are somewhat greater (0.3), but the dependence of $f'$ on $T$ is steeper ($f'_{77}/f'_{153} \cong 6$). In a series of compounds of the same $SnCl_3$-containing complex anion, the increase of density from 1.8–2.2 g cm$^{-3}$ to 3.3 g cm$^{-3}$ on replacement of the bulky organic cation by $Cs^+$ entails an increase of $f'_{77}$ to 0.4 and a weakening of its temperature dependence ($f'_{77}/f'_{153} = 3$); however, in this case too $f'$ is smaller and its dependence on $T$ is stronger than for the fluorides. For frozen fluoride solutions, the values of $f'$ are also higher than for the chlorides. This demonstrates that the measured $f'_{eff}$ for the crystalline complexes investigated depend both on the internal properties of their tin-containing anions and on the characteristics of the interionic interaction in the crystal as a whole, i.e. both on $f'_{ia}$ and on $f'_{ir}$.

The components of the effective mean-square vibration amplitude of the tin atom in the crystal lattices of such ($\langle x^2\rangle_{eff}$) have been analysed:[55]

$$\langle x^2\rangle_{eff} = \langle x^2\rangle_{ia} \coth\frac{\alpha_{ia}}{T} + \langle x^2\rangle_{i\gamma} \coth\frac{\alpha_{i\gamma}}{T}, \qquad (7)$$

where $\alpha_{i(j)} = \hbar\omega_{i(j)}/2k$, $\omega_i$ the frequency of the lowest-frequency vibration of the Mössbauer atom within the molecule, and $\omega_j$ the frequency of its vibration together with the molecule. This equation was first used to analyse the dynamics of the behaviour of the tin atom on the silica gel surface.[56]

The observed[55] $\langle x^2\rangle_{eff}$–$T$ relations are illustrated in Fig.3; Table 1 presents the parameters and the temperature ranges in which these relations were fitted by Eqn.(7). The effective frequencies of the vibrations of the $^{119}$Sn atoms within the anion and of the associated vibrations have been calculated from the $\langle x^2\rangle$ obtained. The frequencies $\nu_{ir}$ are reasonably consistent with the vibrations of species having masses greater than 1000 a.m.u. and weakly linked to one another. They have similar values for all solid halides except complex 2. This is consistent with the crystallographic data, according to which the distances between the atoms in compound *1* are $R(Sn - Cs^+) > 4.5$ Å and $R(F - Cs^+) > 3$ Å and differ little from the distances between the atoms of the $SnCl_3$ and $(CH_3)_4N$ groups in compound *3*.[49-53] The effective intermolecular vibration frequencies decrease in the sequence F > Cl > Br, remaining higher in absolute magnitude than the observed low-frequency components of the spectrum.

**Table 1.** Parameters obtained by fitting Eqn.(7) to the curves in Fig.3.[55]

| Complex* | $T$, K | $10^{18}\langle x^2\rangle_{ia}$, cm$^2$ | $10^{18}\langle x^2\rangle_{ir}$, cm$^2$ | $\alpha_{ia}$, K | $\alpha_{ir}$, K | $\nu_{ia}$, cm$^{-1}$ | $\nu_{ir}$, cm$^{-1}$ |

*The numbers of the complexes correspond to the numbers of the curves in Fig.3.

The calculation,[55] based on the measured force constants of the $SnX_3^-$ anions[57] and the complex $[PdCl_3(SnCl_3)]^{2-}$ [50] as well as the available information about the geometry of the complexes,[19,36,49-53] made it possible to discover a series of important characteristic features of the compounds considered. Firstly, the number of low-frequency (up to 100 cm$^{-1}$) normal vibration modes increases in the sequence F, Cl, Br: 55 cm$^{-1}$ for the F-derivatives, 61, 66, 75, and 82 cm$^{-1}$ for the Cl-derivatives, and 44, 52, 73, 85, 90, 97 cm$^{-1}$ for the Br-derivatives. Secondly, in the presence of bridging F atoms, as in the fragment

$$F_3Sn\diagdown\!\!\diagup F \diagup\!\!\diagdown SnF_3,$$
$$\qquad\quad M$$

the calculated $\langle x^2\rangle$, corresponding to a frequency of 55 cm$^{-1}$, is $11.6 \times 10^{-20}$ cm$^2$, while without a bridging atom, as in the fragment, $F_3Sn–M–SnF_3$, it amounts to $30.6 \times 10^{-20}$ cm$^2$ at a

†The subscripts $f'$ correspond to the temperatures of the measurement (K).

frequency of 74 $cm^{-1}$. Thirdly, the tin atom undergoes the greatest shift in stretching vibrations [$\nu$(SnX) whose observed frequencies decrease in the same sequence of atoms X (524 $cm^{-1}$ for F, 316 $cm^{-1}$ for Cl, and 225 $cm^{-1}$ for Br). The calculated values of $f^*_{ia}$ at $T = 0$, expressed as the product of the $f'_{ia}$ for each of the frequencies quoted above, proved to be 0.64 for the fluorides, 0.58 for the chlorides, and 0.46 for the bromides.

Table 2 presents the values of $f'_{ia}$ and $f'_{ir}$ as well as their temperature variations obtained by Eqns. (3) and (7) and taken from Yurchenko et al.[55] Comparison of the values of $f'_{ia}$ at $T = 0$ with those of the $f^*_{ia}$ listed above shows that the analysis of the vibrations of the metal–tin halide complexes made it possible to estimate correctly their characteristic values of $\langle x^2\rangle_{ia}$ ($T = 0$) and the corresponding $f^*_{ia}$.

The analysis suggested[56] that all the low-frequency vibrational modes, including $\nu$(SnX), contribute effectively to the mechanism of the changes in $f'_{eff}$ in the series of tin(II) halide-containing complexes of transition metals, the increase of the number of such modes from X = F to X = Br and the decrease of $\nu$(SnX) in the same series having the greatest importance. The data of Yurchenko et al.[55] have shown that the values of $f'$ characteristic of the $SnX_3$ ligands occur in the range 77–140 K; they differ little in the series of metals and can be used to analyse the type of tin-containing halide complexes obtained. Table 2 also shows that at $T = 0$ the overall value of $f'_{eff}$ is approximately equally determined by the presence of zero-point vibrations of the tin atom in the anion and associated vibrations of the anion. An increase of temperature, within the limits where Eqn. (7) fitted to the relations shown in Fig. 3 holds, leads to a greater intensification of the internal vibrations of the tin atom, so that along these sections the temperature dependence of $f'$ is determined mainly by the internal properties of the anions. The characteristics of the packing and of the interionic interaction have a greater influence at higher temperatures.

**Table 2.** Temperature dependence of the parameters $f'_{ia}$ and $f'_{ir}$ for the complexes.

It was noted above that the establishment of the dependence of the rate and selectivity of a catalytic reaction on the electronic structure of the catalyst atoms was already identified in an earlier review[5] as one of the most important aspects of the application of the Mössbauer effect in catalysis. Unfortunately, so far the study of Skalkina et al.[6] is perhaps the only one where such an attempt was made in relation to a heterogeneous catalytic process. We are unaware of any studies on these lines in relation to homogeneous catalysis. The reason is primarily that, despite the extensive literature describing the catalytic reactions in the presence of $SnCl_3$-containing complexes,[1,18] not even the

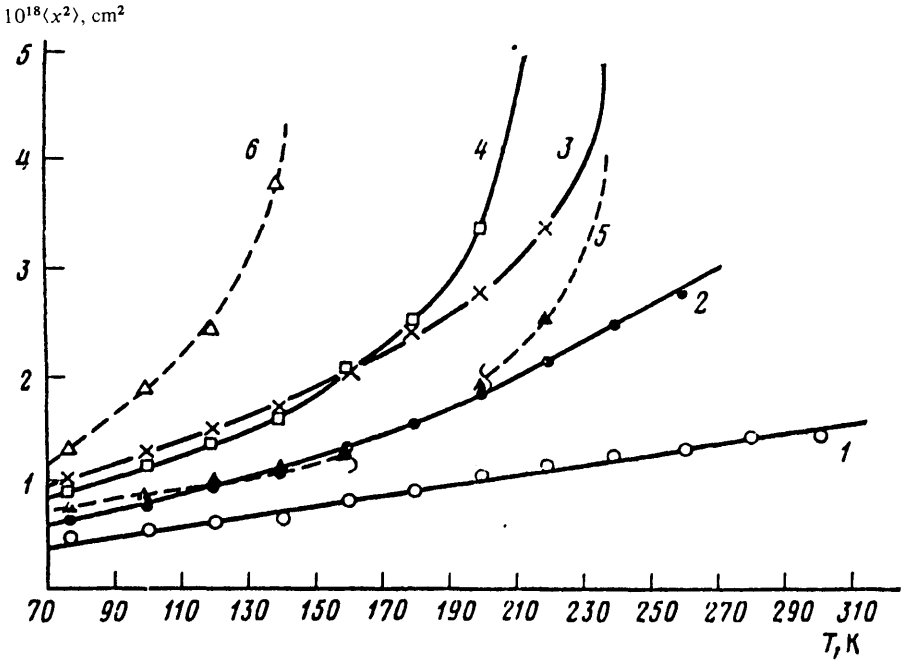

**Figure 3.** Temperature dependence of the effective mean square amplitudes of the shifts of the $^{119}Sn$ atoms in tin halide catalysts: *1*) $Cs_4\{Rh(Sn_4F_{15})[SnF_2(H_2O)_2]_2\}.4H_2O$; *2*) $Cs_3[Pt(SnCl_3)_5]$; *3*) $(Me_4N)_4[OsCl(SnCl_3)_5]$; *4*) $(Me_4N)_4[OsBr(SnBr_3)_5]$; *5*) $[RuSn_3F_{18}]^{4-}$ solution in 3 M HF (0.015 M); *6*) $[Pd(SnCl_3)_5]^{3-}$ solution in 3 M HCl (0.032 M).

composition of the complex functioning as the true catalyst has been elucidated in any of the studies except those in Refs.1, 18, 58. At the same time, other causes limiting the extensive possibilities for the determination of the electronic structure of the tin atoms in tin-containing homogeneous complexes provided by the analysis of Mössbauer spectroscopic parameters such as $\delta$ and $\Delta$ have also been noted.[18] The first parameter is related to the spherical symmetry of the electron density distribution around the nucleus of the tin atom:[14]

$$\delta = C\frac{\Delta r}{r}\Delta|\psi_{ns}|^2 , \qquad (8)$$

where $C$ is a constant characterising the Mössbauer nucleus, $\Delta r$ the difference between the radii of the nuclei in the ground and excited states, $r$ the radius of the nucleus in the ground state, and $\Delta|\psi_{ns}|^2$ the difference between the electron densities generated by the $ns$ electrons on the nuclei of the absorber and the source of $\gamma$-quanta.

Since the change in the population of the valence 5$s$ atomic orbitals (AO) of tin makes the main contribution to $\Delta|\psi_{ns}|^2$, the reason for the interest in the direct estimation of the latter from $\delta$ and conversely is fairly obvious.[13,14] However, two difficulties arose in the determination of the above quantities: the lack of an exact value of $\Delta r/r$ and the fairly considerable scatter in the estimates of the shielding influence of the 5$s$, 5$p$, and 5$d$ electrons on the 5$s$ electron of the tin atom.[18] The necessity to determine the exact value of $\Delta r/r$ has been discussed in detail.[14] However, hitherto there exists no unanimous view concerning the estimation of $\Delta r/r$, which has been well illustrated in the paper by Vertes et al.[16], where values of $\Delta r/r$ ranging from $0.73\times10^{-4}$ to $2.05\times10^{-4}$ are presented even on the basis of the very latest data.

Allowance for the shielding of the 5$s$ electron by the 5$s$, 5$d$, and 5$p$ electrons in the first studies on this question led to different estimates of its extent.[59,60] Subsequently numerous expressions relating the measured values of $\delta$ to the population of the 5$s$, 5$p$, and 5$d$ AO of tin in compounds were proposed[61-63] but none of them is sufficiently universal.[18] This situation is clearly demonstrated by Table 3, which lists the values of $\delta$ for tin species widely used in catalysis–$SnCl_4$ and $SnCl_3^-$; these values were calculated using the populations of the 5$s$ (S) and 5$p$ (P) AO obtained[17,18,64] from the three formulae proposed by Antoncik[61] and also from the formulae quoted by Gol'danskii and Makarov[59] and by Flin.[60] Evidently, within the framework of any of the approximations for the estimation of $S$ and $P$ for the same compound, the values of $\delta$ differ by a factor of 1.5–3. At the same time the data in Table 3 show that the parametrisation of the semi-empirical LCAO-MO method yields differences of the same order of magnitude. Whereas calculation for $SnCl_4$ yields as a rule values of $\delta$ which are much too high, within the framework of the same LCAO-MO approximation those obtained for $SnCl_3^-$ are too low. Here one must note that the dependences of $\delta$ on $S$, $P$, and $D$ have been obtained using different values of $\Delta r/r$. Thus Gol'danskii and Makarov[59] adopted $3.3\times10^{-4}$, while Antoncik[61] adopted $0.92\times10^{-4}$.

Thus neither the parametrisation of the LCAO-MO methods for tin compounds nor the estimation of the populations of the 5s, 5p, and 5d AO for the tin atom in such compounds on the basis of the measured $\delta$ are possible without refining and standardising the values of $\Delta r/r$ and the shielding parameters. However, within the framework of a narrow range of compounds, any of the proposed dependences of $\delta$ on $S$, $P$, and $D$ reproduce satisfactorily the principal characteristics of the changes in $\Delta|\psi_{5s}|^2$. Thus the populations of the 5$s$ and 5$p$ AO of the tin atom in $SnCl_3^-$ and the complexes obtained in terms of the Mulliken–Wolfsberg–Helmholtz (MWH) approximation[51] yield the following values of $\delta$ estimated by the formula quoted by Herber et al.[63]: 3.38 mm $s^{-1}$ for $SnCl_3^-$, 2.8 mm $s^{-1}$ for $[PtCl_3(SnCl_3)]^{2-}$, and 2.96 mm $s^{-1}$ for $[PtCl_2(SnCl_3)_2]^{2-}$. These results show that the MWH approximation can reflect fairly roughly the charge distribution in the complex but the principal features (the decrease of $\Delta|\psi_{5s}|^2$ for the tin atom on coordination and its greatest decrease for the complex with the M:Sn = 1:1 ratio) are reproduced correctly.[51]

Table 3. The parameters $\delta$ obtained in calculations of the populations of the 5$s$ and 5$p$ AO of the tin atom in terms of the LCAO-MO approximations.

| Method of calculation of $S$ and $P$ | $\delta$*($SnCl_4$) | | | | | $\delta$*($SnCl_3^-$) | | | | |
|---|---|---|---|---|---|---|---|---|---|---|
| | 1**–[63] | 2–[63] | 3–[63] | [59] | [60] | 1–[63] | 2–[63] | 3–[63] | [59] | [60] |
| CNDO (Ref.64) | 1.12 | 2.2 | 0.74 | 1.68 | 1.95 | — | — | — | — | — |
| CNDO-Cl (Refs.17, 18) | 2.05 | 3.44 | 2.16 | 2.63 | 3.03 | 3.19 | 5.27 | 3.31 | 2.62 | 4.24 |

*The parameters $\delta$ are given relative to $Ba^{119}SnO_3$: $\delta_e(SnCl_4) = 0.85$ mm $s^{-1}$;[65] $\delta_e(SnCl_3^-) = 3.64$ mm $s^{-1}$.[28]
**The numerals 1, 2, and 3 refer to the dependences of $\delta$ on $S$ and $P$ taken from Ref. 63 (in sequence).

Note. The numerals in square brackets denote references (Ed.of Translation).

Direct correlations between $\delta_e$ and $\Delta|\psi_{5s}|^2$ have been used in a number of studies and satisfactory results have been obtained.[16,64,66] They show that, at least in a series of related compounds, it is possible to interpret the differences in $\delta$ as a consequence of the changes in the population of the 5$s$ AO of the tin atom. This information is important for the study of the mutual influence of the ligands in the complex and also for the determination of the AO involved in the interaction of the homogeneous catalyst with the molecule being activated and in the change of the properties of the catalyst under various conditions.

In discussing the possibility of using the Mössbauer parameters to characterise the features of the electronic structure of tin halide complexes, it is essential to consider the problem of the use for this purpose of quadrupole splitting in a number of investigations. We have

$$\Delta = \frac{e^2qQ}{2}\left(1+\frac{\eta^2}{3}\right)^{1/2} , \qquad (9)$$

where $eq$ is the electric field gradient (EFG) at the nucleus in the direction of the emission of $\gamma$-quanta (the $z$ axis), $Q$ the quadrupole moment of the nucleus characterising the deviation of the distribution of the average charge density on the nucleus from spherical symmetry and $\eta = (q_{xx}-q_{yy})/.q_{zz}$ the asymmetry parameter.[13] The gradient $eq$ is determined for tin mainly by the population of the $5p_z$ AO. The expressions for the dependences of the EFG in the direction of the $x$, $y$, and $z$ axes ($q_{xx}$, $q_{yy}$, and $q_{zz}$ respectively) in terms of the populations of the $p_x$, $p_y$, and $p_z$ AO have been published.[13] Thus $\Delta$ can serve as a measure of the uniformity of the population of the $5p_{x,y,z}$ AO of the tin atom and is a parameter sensitive to the structure of the immediate environment of the atom.

The authors of one of the first studies[30] on the Mössbauer spectra of $SnCl_3$-containing complexes explained the increase of $\Delta$ on passing from salts of the $SnCl_3^-$ anion to complexes by electron transfer from the metal atom to the $\pi^*$ orbital of $SnCl_3$, incorporating the $5p_{x,\,y}$ AO of the tin atom with the simultaneous decrease of the number of electrons in the $5p_z$ AO owing to the formation of a $\sigma$-bond, which intensifies the non-equivalence of the populations of the $p$ AO of the tin atom. Subsequently the chage in $\Delta$ was regarded in certain studies, for example, those of Antonov and co-workers,[67,68] as a direct measure of the $\pi$-acceptor properties of the ligand $SnX_3$ (X = Cl or Br), i.e. a measure of the increase of the population of the $5p_{x,\,y}$ AO of the tin atom in the ligand.

The change in the distribution of electron density in the $SnX_3^-$ anions on $\sigma$-donor transfer of the electron pair from the highest occupied MO has been analysed.[17,18,34] The data presented show that such transfer does indeed entail a marked population decrease of the $5p_z$ AO of the tin atom, which induces the appearance of a negative $q_{zz}$, which increases in absolute magnitude from F- to I-derivatives. According to Yurchenko's estimate,[18] this effect leads to the following increments in $\Delta$ for the $SnX_3$ ligand compared with the $SnX_3^-$ ion: 0.83 mm $s^{-1}$ for $SnF_3$, 1.43 mm $s^{-1}$ for $SnCl_3$, 1.70 mm $s^{-1}$ for $SnBr_3$, and 2 mm $s^{-1}$ for $SnI_3$. The changes in $\Delta$ in the series of X observed for the $SnX_3$-containing complexes agree with these estimates, although they are somewhat lower in absolute magnitude.[50,51] This shows that the $\Delta$ cannot be used to estimate the $\pi$-acceptor properties of the ligands $SnX_3$ without taking into account the contribution to the changes in the population of the $5p_\sigma$ AO of the tin atom as a consequence of the $\sigma$-donor transfer $X_3Sn \rightarrow M$.

The values of $\delta$ and $\Delta$ for the $SnX_3$-containing complexes have been published mainly in Refs. 1, 18, 19, 29, and 31–36.

The inverse proportionality between $\delta$ and $\Delta$ can be usually traced in tin(II) compounds with donor–acceptor bonds.[13] In the case of a purely ionic bond between tin(II) and its environment (the $5s^25p^0$ configuration), we should have $\Delta = 0$ and an increase of the population of the $5p$ shell should lead to $\Delta \neq 0$. According to Shpinel's estimate,[13] one unbalanced $p$ electron in the $z$ axis direction should then give rise to $\Delta = 3$ mm $s^{-1}$. However, for coordinated $SnX_3$ ligands such a relation between $\delta$ and $\Delta$ has not been observed, as for the tin compounds mentioned above; this serves as yet another piece of evidence demonstrating the complexity of the redistribution of the population of the $5p_{x,\,y,\,z}$ AO of the tin atom on coordination of the $SnX_3$ groups.

Thus it is at present impossible to predict beforehand which precise changes in $\delta$ and $\Delta$ will be undergone by particular tin(II) compounds and the structural identification of the latter can be achieved in only one way—by determining the boundary values and other characteristics of the Mössbauer parameters by studying compounds of different types but with known structures established by X-ray diffraction, which has been partly done in two investigations.[17,18]

## 2. Heterogeneous Systems

Two applications of tin-containing compounds in heterogeneous catalysis have now arisen: (1) the immobilisation of $SnCl_3$-containing transition metal complexes on the surfaces of carriers;[18] (2) the deposition on the surfaces of carriers of either these complexes or of tin-containing compounds and transition metal compounds (usually platinum) separately with subsequent high-temperature reduction until M–Sn alloys are formed.[3] In both cases a series of specific complications arise in the application of the Mössbauer effect for the identification of tin compounds on the surfaces of carriers and for the characterisation of their state.

Thus it has been shown[69] that some of the tin compounds formed on the $ZnAl_2O_4$ surface are readily oxidised by oxygen, which requires the preparation of the specimens and the recording of the spectra under conditions where access of air can be ruled out. Flat sealed bulbs made of thin molybdenum glass have proved very useful for this purpose.[70] In preparing such bulbs, one must keep their flat sides parallel and the distance between them should ensure an effective thickness of the specimen $C_a$ less than unity.[13] Such cells have been used[26,27,54,69–72] to record the Mössbauer effect in the temperature range 77–300 K.

When $SnCl_3$-containing complexes and other tin(II) compounds, for example $SnCl_2$, are fixed on the carrier, the Mössbauer parameters change appreciably;[26,27,54,73] there is a particularly pronounced alteration of $f'$. Fig. 4 illustrates the changes in $f'$ for different tin(II) compounds when they are deposited on $\gamma$-$Al_2O_3$.[54,55,73] Since the tin(II) compounds were deposited by impregnating the carrier with their solutions in organic solvents, after the removal of the solvent and drying of the specimen, the tin(II) compounds were present on the specimen surface in the form of molecules linked to specific centres on the carrier.[74] In this case the conclusion reached by Yurchenko et al.[55] that an increase of $f'$ (Fig. 4) implies a strong chemical interaction of the $SnCl_3$ ligands in the complex or of the $SnCl_2$ molecules with the surface as a consequence of the partial hydrolysis of the Sn–Cl bond by the acid OH groups,[55] i.e.

$$\left|-OH + Cl_2Sn{-}ML_n \rightarrow \right| -O{-}SnCl_2{-}ML_n + HCl\,, \qquad (10)$$

can be used to explain the changes in $f'$.

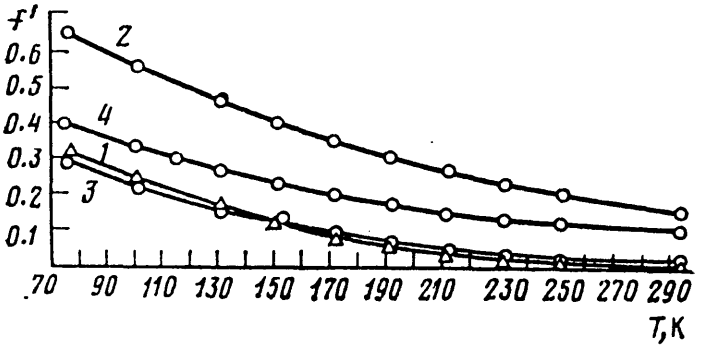

**Figure 4.** Temperature dependence of $f'$: *1*) $SnCl_2.2H_2O$; *2*) $SnCl_2$ on $\gamma$-$Al_2O_3$; *3*) $(Et_4N)_2[PtCl_2(SnCl_3)_2]$; *4*) $[PtCl_2(SnCl_3)_2]^{2-}$ on the surface of $\gamma$-$Al_2O_3$.

After treating these specimens under the reaction conditions ($H_2$ atmosphere, temperature 773 K), a set of tin compounds are as a rule formed on the surface, giving rise to very complex overall spectra (Fig. 5, curves *1*, *2*, *5*, and *6*). The identification of individual tin compounds on the catalyst surface requires in such cases the resolution of

the complex contour of the Mössbauer spectrum into individual components. In this case the problem is much more complex than in the analysis of individual Lorentzian components in the spectra of clusters (cf. Fig. 1). Similar complex spectra are observed when different carriers and when different methods of preparation of the catalysts are used.[10,69–72,75–77]

As each of the tin compounds identified can be chemically bound to the surface or can exist in a finely dispersed state, where most of the Mössbauer atoms do not interact with the surface and compounds of this kind do not as a rule exist in an individual state, some uncertainty arises about the selection of the parameters ($\delta$, $\Delta$, and $f'$) of the individual components of the spectrum. Two approaches arose in the consideration of the question of the permissible variation of the Mössbauer parameters of the individual components. In the first, the values of $\delta$ and $\Delta$ for the individual components remain close to those for the individual substances in the massive state. Clearly such resolution is closer to the true one the coarser the dispersion of the test substances and the weaker their interaction with the surface. If such resolution cannot be carried out, the parameters can be altered somewhat, for example, $\Delta$ can be increased, but within the limits of the values encountered for individual systems. The parameter $f'$ is not then measured.[10,70–72]

The second approach consists in the investigation of the changes in $\delta$, $\Delta$, and $f'$ when various tin compounds, whose formation may be expected, interact with the surface, and in the resolution of the overall spectrum into components with parameters corresponding to the interaction of the individual compounds with the surface. It is then implied that the compounds do not interact with one another or that this interaction is not reflected in the Mössbauer

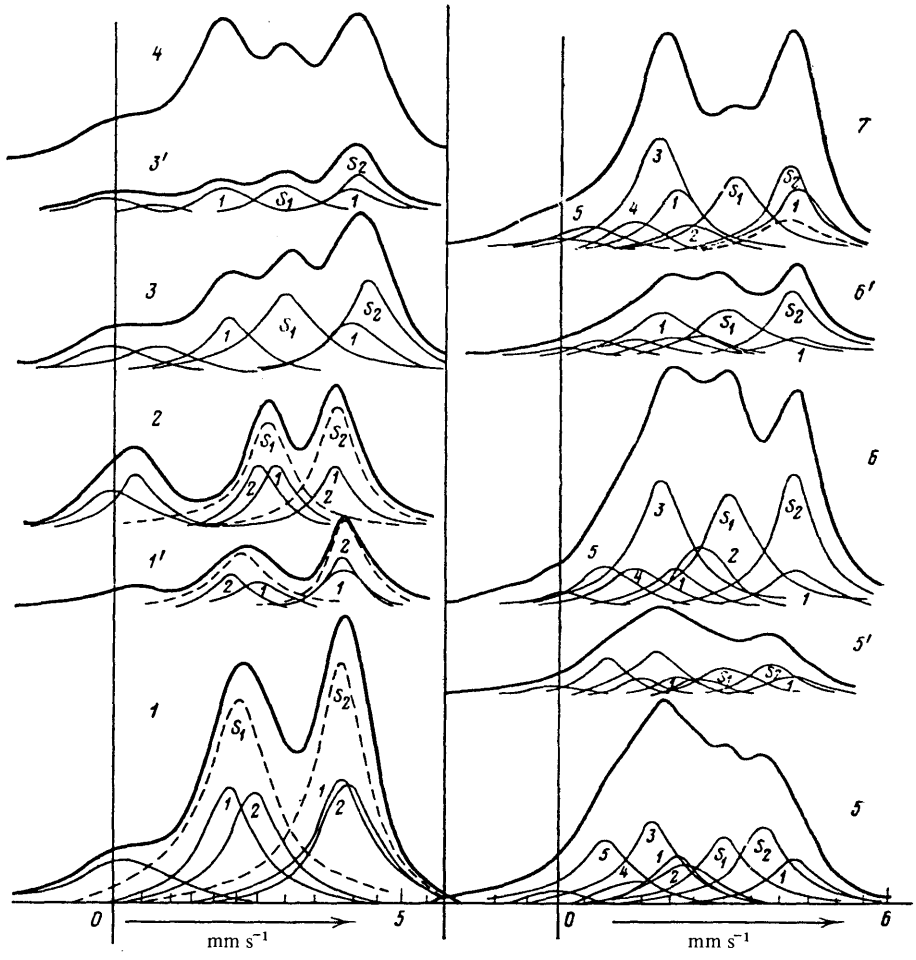

**Figure 5.** Mössbauer spectra resolved into individual components on an SK-2 synthesiser: *1*) and *1'*) $SnCl_2$ on $\gamma$-$Al_2O_3$; *2*) $SnCl_2$ on $\gamma$-$Al_2O_3$ chlorinated beforehand [$\gamma$-$Al_2O_3$(Cl)]; *3*) and *3'*) specimen 2 reduced in a stream of $H_2$ (773 K); *4*) overall spectrum of specimen 3 and Pt–Sn alloys; *5*) and *5'*) Pt–Sn/$\gamma$-$Al_2O_3$; *6*), *6'*), and *7*) Pt–Sn/$\gamma$-$Al_2O_3$(Cl); specimens 5 and 6 were obtained by depositing the complex $[PtCl_2(SnCl_3)_2]^{2-}$ and were reduced in a stream of $H_2$; specimen 7 was obtained after repeated oxidation-reduction cycles; spectra *1*–*7* were recorded at 77 K and spectra *1'*–*6'* at 295 K.

parameters. This approach has been used by Yurchenko and Kuznetsov[73]# and, to a limited extent, without analysis of the values of $f'$, by Gray and Fahra[75] and Berndt et al.[76] However, in this case too it is frequently impossible to achieve a unique resolution and one must consider all the alternative interpretations of the spectra. Such data have been reported.[73,76]

A major complication in the selection of the initial values of $\delta$, $\Delta$, and $f'$ for the resolutions arises from the influence of the degree of dispersion of the compounds on the parameters of the Mössbauer spectra. Analysis of the characteristic features of the Mössbauer spectra of molecular crystals has shown[18,55,73] that the differences between the electronic structures and the dynamics of the movement of the tin atom in a complex molecule are determined predominantly by the molecular structure. Thus the transfer of a molecule from the crystal to the solution hardly influences $\delta$ and $\Delta$ and entails merely a decrease of $f'$. The physical adsorption of tin-containing molecules on the carrier surface should therefore not alter $\delta$ and $\Delta$ either. The observed[26,27,54,73] changes in $\delta$ and $\Delta$ on deposition of tin compounds on a carrier are in fact associated with the partial alteration of the chemical composition of the molecule, illustrated in Scheme 10, i.e. with the partial replacement of the Cl atom by O in the coordination sphere of tin. One can also assume that tin(IV) compounds ($SnO_2$, $SnCl_4$, etc.) and tin(II) compounds ($SnCl_2$, $SnCl_2.nH_2O$, SnOHCl, SnO) have (when their molecular composition is retained) values of $\delta$ and $\Delta$ on the carrier surface close to those characteristic of the individual compounds.

The changes in $\delta$ and $\Delta$ owing to the possible chemical reactions on the surface can be modelled by investigating the parameters of the spectra of the pure substances analogous to the products of such reactions. The situation is more complex as regards the parameters of the phases with closer packing such as β-tin and Pt–Sn alloys. For example, the study of the dependence of $f'$ on the degree of dispersion of β-tin showed that $f'$ for the surface atoms diminishes markedly.[78] Specimens with particle sizes ranging from 1500 to 200 Å have been investigated,[78] but, from the standpoint of catalysis, even the latter are coarsely dispersed specimens. Information about the changes in $f'$ when the particle size is varied from 200 to 10 Å is essential for catalysis. This problem has not been studied rigorously; the main difficulty in this instance involves the preparation of highly dispersed specimens with a uniform distribution of particles with respect to size.

It follows from general considerations (see, for example, Suzdalev[15]) that the frequency of the phonon spectrum increases for a very small particle size and this can actually lead to an increase of $f'$ for the particles. The transition to clusters (particle size 10–30 Å) should alter not only $f'$ but also the parameters $\delta$ and $\Delta$ of the Mössbauer atom. Such finely dispersed formations should appear only as a consequence of an intense interaction with the surface and there is no reason to regard them as finely dispersed particles having the properties of the phase present in the coarsely dispersed state. It is more reasonable to regard them as new compounds incorporating carrier atoms in their composition. Such a system ($Pt–Sn/SiO_2$) has been investigated;[70] the size of particles containing only platinum and tin was $10 \pm 3$ Å and the Mössbauer effect due to the tin atoms was manifested by a doublet with $\delta = 1.43$ mm $s^{-1}$ and $\Delta = 2.32$ mm $s^{-1}$.

Thus the final result of the fragmentation of the Pt–Sn alloy particles on the carrier is the formation of clusters, in which the platinum atoms interact with the tin bound to the surface. The parameters $\delta$ and $\Delta$ of such tin atoms then assume values approaching $\delta$ and $\Delta$ for the tin(II) complexes with transition metals. At least under the conditions of such dispersion, there is no possibility of a very large increase in $\Delta$, unaccompanied by a significant change in $\delta$, which has been postulated[77] in the resolution of the Mössbauer spectrum of the $Pt–Sn/Al_2O_3$ catalyst.

A finely dispersed phase of the Pt–Sn alloy, whose parameter $\delta$ varies within the limits 1.85–2.13 mm $s^{-1}$ ($\delta = 1.97$ mm $s^{-1}$ for the massive alloy) and $\Delta$ varies from 0.3 to 5.26 mm $s^{-1}$, has been identified[71] on specimens with different platinum contents. The last value should correspond to a difference between the populations of the $5p_\sigma$ and $5p_\pi$ AO of the tin atom of 1.75 electrons. Such a difference has not been observed even for the $SnB_9C_2H_4$ structure, where the coordination of the tin atom models effectively a purely surface disposition on the carrier;[62] it is even more unrealistic for the coordination of the tin atom to the symmetrically arranged electron-saturated Pt(0).[79]

The differences between the permissible variations in $\delta$ and $\Delta$, which can be identified on the surfaces of compounds, have been one of the causes of the discrepancies in the descriptions of the state of tin(IV) and tin(II) and of the types of alloys on the surface of $\gamma$-$Al_2O_3$ in the studies of Bacaud and co-workers,[10,77] on the one hand, and Yurchenko and co-workers,[72,73] on the other. In our view, the initial resolution of the spectra for fixed values of $\delta$ and $\Delta$ for the individual components of the Mössbauer spectrum, corresponding to individual tin compounds, is methodologically correct. When $\delta$ and $\Delta$ are varied in an arbitrary manner, the resolution ceases to be in any way definite. Simultaneously with this procedure, one should deposit all the necessary individual substances on the carrier, the specimen should be treated under the same conditions as the catalyst, and the variation of $\delta$, $\Delta$, and $f'$ should be investigated, and then the parameters of the individual components obtained on resolution of the spectra of the catalyst should be appropriately corrected. It has been shown[55,73] that in many cases information of decisive importance for the identification of the state of the Mössbauer atom on the surface is provided by the analysis of the temperature variation of $f'$. The ratio $f'_{77}/f'_{295}$ can be used as the simplest and most convenient parameter of the dependence of $f'$ on $T$.

In view of the special sensitivity of the parameter $f'$ to the type of the tin-containing compounds, investigation of the specimens at least at 77 and 295 K and the maintanence of the ratios $f'_{77}/f'_{295}$ for all the components on resolution of the spectrum within specific characteristic limits make such resolutions significantly more rigorous as regards the identification of the number and types of different tin-containing formations on the surface. The range of variation of $\delta$ and $\Delta$ as well as $f'_{77}/f'_{295}$ for the tin compounds identified on the $\gamma$-$Al_2O_3$ surface has been indicated by Yurchenko and Kuznetsov[73]§ and Yurchenko.[18]

The ratios $f'_{77}/f'_{295}$ for different tin(II) and tin(IV) halides, oxides, and sulphides,[80] for massive PtSn and $PtSn_2$ [81,82] alloys, and for $SnX_3$-containing complexes[55] have been published.

#The analysis of the Mössbauer spectra of such systems is discussed in detail in the paper by V.I.Kuznetsov, A.S.Belyi, and E.N.Yurchenko, J.Catal (in the Press).

§See the previous footnote concerning the report of Yurchenko and Kuznetsov.[73]

## III. THE PROPERTIES OF TIN-CONTAINING CATALYSTS

### 1. Homogeneous Catalysts

Matvienko[1] gave a systematic account of most of the studies published up to 1978 where platinum metal compounds with the $SnCl_3$ ligand have been used as catalysts of the reactions of various organic substances. In the same communication and also in Yurchenko's thesis,[18] it is noted that the state of the $SnCl_3$-containing complexes in the reaction medium has not been established in any of these catalysts. Mössbauer spectroscopy has not been used for such purposes.

Later, several communications, also dealing with the catalytic properties of $SnCl_3$-containing complexes, were published. It has been reported[83] that, in the presence of the complex $Rh(PPh_3)_3.(SnX_3)$ (X = Cl or Br), catalytic hydrogenation of olefins takes place. The authors concluded that an unidentified hydride complex exhibits a hydrogenating activity. It has been found[84] that the rhodium(I) complex $[Rh_2Cl_2(SnCl_3)_4]^{4-}$ is active in the isomerisation of olefins, but it has been concluded[67] that the complex should be regarded as a rhodium(III) compound, apparently having the composition $[RhCl_4(SnCl_3)_2]^{3-}$.[85] Antonov et al.[67] investigated $SnCl_3$-containing rhodium(III) compounds ranging from $[Rh(SnCl_3)_2Cl_4]^{3-}$ to $[Rh(SnCl_3)_5Cl]^{3-}$ (by the Mössbauer method), but their state in the presence of olefins was not characterised. Borunova et al.[86] examined the catalytic properties of the complexes $[MX(SnX_3)_5]^{n-}$ (M = Pt, Rh, Ir, Ru, or Os, X = Cl or Br) in the hydrogenation and isomerisation of olefins. The initial compounds were characterised by Mössbauer spectroscopy mainly in the study of Yurchenko et al.[32] However, in this case the authors concluded that the complex undergoes a change in composition in solution and that hydride forms are active, for example, in isomerisation, but these two were not identified or investigated by Mössbauer spectroscopy either. This applies likewise to the complex $[Ru(PPh_3)_2.(SnCl_3)Cl]$, in the presence of which catalytic hydrogenation of olefins takes place.[87]

Thus only the initial $SnCl_3$-containing complexes, forming the intrinsic catalytically active species under the conditions of the catalysis, have been characterised by the Mössbauer method in the studies enumerated above. The lack of Mössbauer spectroscopic data for the intrinsic catalytically active forms precludes the analysis of the relation between their $\delta$ and $\Delta$, on the one hand, and the catalytic activity of such compounds, on the other. This situation can be avoided perhaps only in the case of the chlorocarbonyltin complexes $[IrClCO(SnCl_3)_2]^{2-}$ (I), $[RhClCO(SnCl_3)_2]^{2-}$ (II), $[PtCl_2CO(SnCl_3)]^{-}$ (III), and $[IrCl_3CO(SnCl_3)_2]^{2-}$ (IV), which have been investigated by a series of physical methods, including Mössbauer spectroscopy.[34] It has been shown[1,18] that these complexes are in fact the catalytically active forms in the homogeneous dehydrogenation of HCOOH. In this connection, one may note that for the first three complexes in which the transition metal has the $d^8$ configuration, the reaction rate constants $k$, $\delta$, and $\Delta$ vary in parallel: $3\times10^{-3}$ $s^{-1}$, 1.73 mm $s^{-1}$, and 2.15 mm $s^{-1}$ for compound (I), $1.2\times10^{-4}$ $s^{-1}$, 1.64 mm $s^{-1}$, and 1.92 mm $s^{-1}$ for compound (II), and $1.5\times10^{-5}$ $s^{-1}$, 1.58 mm $s^{-1}$, and 1.60 mm $s^{-1}$ for compound (III).[1] On passing to the iridium(III) compound with the $d^6$ configuration, $k$ diminishes appreciably ($4.5\times10^{-5}$ $s^{-1}$), but $\delta$ and $\Delta$ for the Sn atom in the $SnCl_3$ ligands in this complex increase (1.83 and 2.08 mm $s^{-1}$ respectively).

Thus the direct relation between the Mössbauer parameters and the rate constants for catalytic reactions in such systems can hardly be regarded as adequately universal. Analysis of the mechanism of the catalytic dehydrogenation of HCOOH, proposed by Yurchenko and Anikeenko,[88] and also valid for $SnCl_3$-containing complexes,[1] showed that the properties of this ligand influence two stages of the process: the substitution of one $SnCl_3$ ligand by $HCOO^-$ and the rate-limiting stage involving the rupture of the H—C bond. The role of the intrinsic properties of the ligand in cases where the central atom of the complex is Ir(I) or Ir(III) is indeed found to be different.[18,88]

The first tin-containing zerovalent palladium clusters which have been obtained and characterised[21] proved to be catalytically active in the conversion of olefins into the cyclic esters of polyhydric alcohols (anhydroalditols).[1] In this case Mössbauer study of the clusters made it possible to refine their composition.[21] It was mentioned above why the parameters $f'$ were used for this purpose (Fig. 1). For all the palladium clusters, the values of $\delta$ and $\Delta$ for the individual Lorentzian components were analysed together with $f'$. In particular, it was shown that the observed $\delta$ for the second type of tin(II)-containing ligand satisfy the condition of a linear decrease of the 5*s* electron density in the sequence $PdSnCl_3 > Pd_2SnCl_2 > Pd_3SnCl > Pd_4Sn$.[21] Anions having the composition $[Pd_2(SnCl_2)_2(SnCl_3)_4]^{2-}$, $[Pd_3(SnCl)_2.(SnCl_3)_6]^{4-}$, and $[Pd_4(Sn)_2(SnCl_3)_8]^{4-}$ have been identified.[1,21] A communication has been published recently[89] whose authors, repeating Matvienko's study,[1] found other compositions of clusters containing four palladium atoms: $[Pd_4(SnCl_2)_2(SnCl_3)_8]^{5-}$ and $[Pd_4(SnCl_2)_2(SnCl_3)_4Cl_2]^{6-}$. The communication[89] contains no arguments justifying this difference nor a discussion of the structure of the clusters obtained. The measured parameters of the Mössbauer spectra of the above compounds, which differ from the parameters quoted for clusters by Elizarova et al.[21], do not prove that Antonov et al.[89] obtained compounds having a composition different from those found by Matvienko[1] because $\delta$ and $\Delta$ for familiar palladium(II) complexes, in particular $[Pd(SnCl_3)_5]^{3-}$, obtained by Antonov et al.[89] differ from those found in other studies[1,21,33,34] by an amount greatly exceeding the experimental error.

The Mössbauer method occupies a notable place in studies where questions concerning the formation and stability of $SnCl_3$-containing complexes and the mutual influence of the ligands in them, which are important for homogeneous catalysis, are investigated. The formation of such complexes in methanolic and aqueous HCl solution was first investigated by the Mössbauer method in the $H_2PtCl_6.H_2O$–$SnCl_2.2H_2O$ system.[24] The authors observed the reduction of platinum(IV) to platinum(II) by bivalent tin, demonstrated the coordination of the platinum(II) atom to $SnCl_3$, and attempted to determine the composition and stability of the complex formed in solution from saturation curves. Later it was shown[25] that the inflections in the saturation curves for such systems do not yield reliable information about the composition of the complexes formed. In the given study of complex formation in the system comprising $K_2PtCl_4$ in 0.5 M HCl solution and $SnCl_2.2H_2O$, the composition of the dominant complexes was determined from the characteristic values of $\delta$ and $\Delta$ for the individual components after the resolution of the spectrum into the Lorentzian doublets. Two complexes with the Pt : Sn = 1 : 2 ratio and a 1 : 5 complex were identified. It was observed that in solution tin(IV) appears rapidly for low Pt : Sn ratios (1 : 1–1 : 2), which might have indicated the reduction of platinum(II) to the zerovalent state with formation of the $[Pt_3Sn_8Cl_{20}]^{4-}$ state.[1]

Yurchenko et al.[26] investigated analogously the formation of complexes between $RuCl_6^{2-}$ and $SnCl_2$ in aqueous 3 M HCl

solution. The composition of the complex was also not determined from the point of inflection in the relation between the concentration of the tin bound in the complex and the Sn:Ru ratio in the system, but was found from the parameters $\delta$ and $\Delta$, which were compared with their values for the individual species $[RuCl(SnCl_3)_5]^{4-}$. In view of their identity over the entire range of Sn:Ru ratios, it was concluded that only this complex is formed under the conditions considered.

The complex formation reaction between $IrCl_6^{3-}$ and $SnCl_2$ in aqueous 3 M HCl solution has been investigated by Antonov et al.[90] who obtained the same Mössbauer parameters of the complex $[IrCl(SnCl_3)_5]^{3-}$ as those discussed previously[34] and this finding, and not the Sn:Ir ratios at which inflections were observed on the saturation curves, confirms the validity of the determination of the composition of this complex in solution.

Thus the saturation curves for the formation of complexes of $SnCl_3$ with a transition metal, plotted from data obtained by any of the physical methods, do not constitute a reliable means of determining the composition of the complex and, when Mössbauer spectroscopy is used for this purpose, it is essential to compare the parameters of the differentiated doublets with those of the spectra of the individual compounds. It has been shown[33] that the variation of the nature of the cations in the latter affects to some extent only the magnitude of $\Delta$, which makes it possible to compare $\delta$ and $\Delta$ for complex anions in solutions with the corresponding parameters of their salts. In view of the foregoing, the identification of the complex $[IrCl_4(SnCl_3)_2]^{3-}$ by Antonov et al.[90] appears controversial.

The investigation of the state of the $SnCl_3$-containing complexes in solution was subsequently continued.[21,26,27] Analysis of frozen $PdCl_4^{2-}$ and $SnCl_2$ solutions in methanol and in aqueous 2.4 M HCl solution, after standing for a long time in an inert atmosphere, confirmed that the rapid process involving the formation of palladium(II) complexes with the $SnCl_3$ ligand is accompanied by the reduction of palladium(II) to zerovalent palladium, which forms, at a specific instant, clusters whose composition was discussed above.

The complex formation reaction between $H_2PtCl_6$ and $SnCl_2$ in aqueous acetone solution containing HCl has been studied[27] and the dynamics of the behaviour of two types of complexes, namely $[PtCl_3(SnCl_3)]^{2-}$ (A) and $[PtCl_2.(SnCl_3)_2]^{2-}$ (B) was followed. It was found that, apart from the reduction of platinum(IV) to platinum(II) and the formation of platinum complexes indicated above, there is a slow increase of the amount of tin(IV) in the system. After a time, the complex (B) was converted into the complex (A) and the platinum in the latter was reduced to the zerovalent state.¶ The formation of a platinum(II) chloride complex with $SnCl_2.2H_2O$ in isopropyl alcohol has been investigated[21] by Mössbauer spectroscopy. Two types of complexes, namely $[Pt(SnCl_3)_5]^{3-}$ and $[PtCl_2(SnCl_3)_2]^{2-}$, were found. Depending on the HCl content, they can be interconverted. The platinum(II) complexes of the first type are stabilised at high HCl concentrations. After a time, the successive transformation $[Pt(SnCl_3)_5]^{3-} \rightarrow [PtCl_2(SnCl_3)_2]^{2-} \rightarrow [PtCl_3.(SnCl_3)]^{2-} \rightarrow$ Pt–Sn alloy takes place. The alloy is present in solution in an ultradispersed state in a mixture with the last two complexes.

¶Unfortunately, as a result of an error by the Publishing House, in the issue of the journal React.Kinet. Catal.Letters containing Refs.26 and 27, Fig.1 from Ref.26 and Fig.2 from Ref.27 were transposed. Readers are requested to take this fact into account.

Thus Mössbauer studies of the state of the platinum and palladium complexes of the $SnCl_3$ ligand in various solutions revealed their important feature—their tendency towards slow inner-sphere conversion by an oxidation-reduction reaction into clusters of zerovalent metals or into intermetallic compounds.

We shall consider briefly the results of the application of Mössbauer spectroscopy to the study of the mutual influence of ligands. It has been shown[17,34] that a combination of Mössbauer spectroscopy, NMR, RyPES [Rydberg photoelectron spectroscopy?], and, for carbonyl complexes, infrared spectroscopy is useful. The overall results of such studies have shown that the relative $\sigma$-donor and $\pi$-acceptor capacities of the $SnCl_3$ ligand vary markedly as a function of the nature of the partners in the coordination sphere. Thus, in complexes of the type $PtCl(SnCl_3)L_2$ and $Pt(SnCl_3)_2L_2$ with $L = P(OR)_3$, the $SnCl_3$ *cis*-ligand diminishes competitively with the $\pi$-acceptor interaction $M \rightarrow P(OR)_3$. When $L = PR_3$, the influence of the $SnCl_3$ *cis*-ligand consists in a marked weakening of the $\sigma$-donor interaction $R_3P \rightarrow M$. In compounds of the type $[MCl_3CO(SnCl_3)_2]^{2-}$, where M = Rh(III) and Ir(III), the $SnCl_3$ ligands have the same influence on CO and the charge state of M as $PR_3$ in $MCl_3CO(PR_3)_2$, but in the complex $[MClCO(SnCl_3)_2]^{2-}$ the $SnCl_3$ ligand exhibits more pronounced $\sigma$-donor and $\pi$-acceptor properties than $PPh_3$ in $MClCO(PPh_3)_2$, such properties being more marked in the iridium(I) complex than in the rhodium(I) complex.

For this reason, in complexes of various types, the $SnCl_3$ ligand occupies different positions in the series based on the *trans*- or *cis*-influence and, depending on the nature of the other ligands, the influence itself is manifested unequally in the sense of the involvement in it of the $\sigma$-donor and $\pi$-acceptor interactions of M with $SnCl_3$. As a general characteristic of the mutual influence of ligands in such complexes, one may mention the tendency of $SnCl_3$ to have the minimum number of *trans*-partners L with $\sigma$-donor and $\pi$-acceptor properties [$L = PR_3$, $P(OR)_3$, CO, or $SnCl_3$]. *cis*-$SnCl_3$ exerts a dominant influence on the most pronounced properties of the ligand L ($\sigma$-donor or $\pi$-acceptor).

The influence of the central metal atom M on the state of the ligand $SnCl_3$ in a wide range of compounds cannot be investigated, since they differ significantly in composition and structure. For the complexes $[MX(SnX_3)_5]^{n-}$ and $[M(SnX_3)_5]^{m-}$ (X = Cl or Br), the 5*s*-electron-accepting capacities of $d^6$ and $d^8$ metals decrease in the sequences Ir(III) > Os(II) ≥ Ru(II) [32] and Pt(II) > Pd(II) > Rh(I) [33] respectively.

## 2. Heterogeneous Catalysts

As stated above (Section I), the main type of industrial heterogeneous catalytic systems comprises Pt–Sn alloys on various carriers. As mentioned above, apart from the alloys, the surface of the carriers contains also a whole series of tin(II) and tin(IV) compounds, each of which can play a definite role in complex catalytic processes. For example, in the case of catalysts consisting of a solid solution of $SnO_2$ in $MoO_3$ on the $SiO_2$ surface, the Mössbauer spectroscopic method demonstrated that the propene oxidation reaction leads to the formation of an adsorption complex of acroleine and tin(II),[91] which indicates unambiguously the involvement in the reaction of not only molybdenum(VI) compounds but also of tin(IV) and tin(II) compounds.

The results of the study of the Pt–Sn catalysts on various carriers[69–72,75,76] show that the composition of the compounds formed in a reductive medium on the surface is determined by

the composition of the deposited compounds and the properties of the carrier.

Mössbauer spectroscopic study of the phase composition of the Pt–Sn/$ZnAl_2O_4$ catalyst at all stages of its preparation as a function of the composition of the solution containing platinum and tin(II) compounds showed that, after deposition on the surface of the zinc–aluminium spinel, the main bulk of tin is present as $SnO_2$ and in a smaller proportion as the complex containing Pt–$SnCl_3$; when $SnCl_2$ is present in solution in an excess, tin(II) is formed on the surface with $\delta = 3.25$ and $\Delta = 1.85$ mm $s^{-1}$, indicating a strong interaction with the surface of the tin not bound to platinum.[69,71] In the course of the dehydrogenation of n-butane in a reductive medium, some of the tin(II) (both bound and not bound in the complex) forms alloys with platinum. The alloy composition depends on the Pt:Sn ratio in the complex predominating in the impregnating solution.[18,71] For Pt:Sn ratios of 1:1 and 1:2 in the complex, mainly the $Pt_3Sn$ alloy, which exhibits the highest catalytic activity among all Pt–Sn alloys and ensures a fairly high stability of the catalyst, is formed preferentially on $ZnAl_2O_4$.[18,71] The ratio $f'_{77}/f'_{293}$ for $SnO_2$ in such a catalyst is 7.7, which is appreciably higher than the corresponding parameter for massive $SnO_2$ and can indicate a high degree of dispersion of the particles on the carrier surface. The Mössbauer parameters of the alloys are close to those for the massive specimens, which was explained by the lower degree of dispersion of the particles of the Pt–Sn alloys compared with the state of $SnO_2$.[18]

Taking into account the values of $f'$ for the individual components of a similar catalyst, the kinetics of the formation of specific tin compounds on the surface have been investigated[75] by the Mössbauer method and a mechanism has been proposed for the oxidative dehydrogenation of paraffins. In the above study data were obtained for the first time demonstrating the strong interaction of part of the tin(II) with the carrier surface, leading to the formation of $SnAl_2O_4$.

When tin(II) and platinum(II) compounds with organic ligands were deposited on the $SiO_2$ surface with subsequent reduction, the formation of $SnSiO_3$ was observed by the Mössbauer method, which can also be regarded as a result of the insertion of tin(II) in the $SiO_2$ lattice with its subsequent partial reorganisation.[70] A detailed study has been made[76] of the genesis of the phase composition of the Pt–Sn catalyst on the $\eta$-$Al_2O_3$ carrier. A strong interaction of tin(II) with the surface was also observed and it was shown that the deposition of platinum(II) and tin(II) on the carrier in the form of an $SnCl_3$-containing platinum complex leads to their more intense interaction in the catalyst than in the case where the chlorides $PtCl_4^{2-}$ and $SnCl_4$ are deposited separately. It was found that the parameter $\delta$ for the alloys decreases linearly with increase of their platinum content and that the activity in dehydrocyclisation is associated with the modification of the properties of platinum atoms by tin.

The methodological problems arising in the analysis of the complex Mössbauer spectra of such catalysts were discussed above. In this connection the details of the identification of the types of compounds in the Pt–Sn catalyst deposited on $\gamma$-$Al_2O_3$, quoted by Bacaud and Bussiere,[77] must be treated critically. However, it is true that, as in catalysts incorporating other carriers, on the $\gamma$-$Al_2O_3$ surface there are several states of the tin(IV) and tin(II) atoms and several types of Pt–Sn alloys. This is also confirmed by the Mössbauer spectra of the Pt–Sn/$\gamma$-$Al_2O_3$ systems[18,73] resolved into the individual Lorentzian components by the second method (see above), which are illustrated in Fig. 5 (spectrum 5). Two states of tin(IV) [one close to $SnO_2$ and the other close to $SnCl_4$ and giving rise to a singlet (curve 5); both states interact with the carrier], two states of tin(II) [$SnAl_2O_4$ giving rise to a doublet (curve *1*) and $SnCl_2$ interacting with oxygen on the surface via Scheme (10) and giving rise to an $S_1$–$S_2$ doublet], and a series of Pt–Sn alloys ($Pt_3Sn$, singlet *4*; PtSn, singlet *3*; $PtSn_4$, singlet *2*) have been identified on the surface of this catalyst.[18]

Pt–Sn reforming catalysts, obtained by depositing $SnCl_3$-containing platinum complexes on $\gamma$-$Al_2O_3$ chlorinated beforehand [$\gamma$-$Al_2O_3$(Cl)] have been investigated by the Mössbauer method.[18,72,73] The Mössbauer spectra were analysed by Kuznetsov et al.[72] using the first resolution procedure and by Yurchenko[18] and Kuznetsov[73] using the second procedure (see above), according to which a preliminary study was made of the interaction of $SnCl_2$ with $\gamma$-$Al_2O_3$ and $\gamma$-$Al_2O_3$(Cl) during the preparation of the catalyst (Fig. 5, curves *1–4*). It was shown that prolonged treatment of the catalyst under conditions close to those during catalysis alters appreciably the quantitative composition of the tin-containing components (cf. spectra *6* and *7* in Fig. 5) and intensifies the interaction of part of tin(II) and $Al_2O_3$(Cl) with formation of tin(II) having $\delta$ close to that of anhydrous $SnCl_2$ (the singlet shown dashed in spectrum *7* in Fig. 5). More detailed characteristics of the state of tin(II) not bound to platinum on the surface were obtained by using for this purpose the temperature dependence of the parameter $f'$,[18,73] the extent of which can be deduced by comparing the Mössbauer spectra in Fig. 5 at 77 K (spectra *1–7*) and 293 K (spectra *1′–7′*). Otherwise, the two methods of analysis of the Mössbauer spectra yielded similar results not only as regards the identification of the principal tin containing components of the catalyst (cf. spectra 5 and *6* with Fig. 1 in Ref. 72) but also as regards their amounts on the surface.[18,73] It has been shown[18,72,73] that the modification of the carrier by introducing Cl atoms into the latter entails a significant change in the state of the tin(II) compounds in the catalyst.

The fundamental difference between the carriers based on $\gamma$-$Al_2O_3$ and $ZnAl_2O_4$ is that the former ensures a more ready susceptibility of tin(IV) to reduction and stabilises the state of tin(II) in tin-containing components of the catalyst.[18,72]

Thus the composition of the catalyst might have differed appreciably in different investigations as a consequence of the differences in the methods used to deposit platinum and tin, the conditions in the preliminary preparation of the $Al_2O_3$ surface, and, mainly, owing to the different nature of the carrier itself: $\gamma$-$Al_2O_3$,[10,72,73,76] $\eta$-$Al_2O_3$,[76] Zn–Al spinel,[69,71,75] and $SiO_2$;[70] they might also have differed owing to the differences between the procedures used in the analysis of the complex Mössbauer spectra of such systems discussed above.

Apart from the Pt–Sn alloys on carriers, which catalyse processes at high temperatures, the possibilities of the immobilised $SnCl_3$-containing complexes as heterogeneous catalysts of low-temperature processes have been attracting increasing attention recently. The first steps on these lines have already been taken. Thus it has been shown[85] that $[RhCl_4(SnCl_3)_2]^{3-}$ fixed on an anion-exchange resin catalyses the dimerisation of ethylene at 50–70 °C but the states of the complex on the anion exchanger and after exposure to the reaction conditions have not been investigated by the Mössbauer method. It has been shown[18] that carbonyltin halide complexes, which are active in the homogeneous-catalytic dehydrogenation of HCOOH (see Section III), can be immobilised on the $\gamma$-$Al_2O_3$ and $SiO_2$ carriers without loss of their catalytic properties. The Mössbauer parameters of the immobilised complexes indicate the interaction of a proportion of their $SnCl_3$ ligands via Scheme 10 with the surface OH groups; for example, such interaction of the complex [$PtCl_2$.

$.(SnCl_3)_2]^{2-}$ entails a change of $\delta$ from 1.64 to 1.52 mm $s^{-1}$ and of $\Delta$ from 2.11 to 2.2 mm $s^{-1}$; $f'$ increases and its temperature variation becomes less marked (Fig. 4). The Mössbauer parameters of the carbonyltin chloride complexes enumerated vary analogously.

## IV. CONCLUSION

Extensive information has thus been accumulated about the Mössbauer effect involving the $^{119}Sn$(II, O) nuclei in various tin halide complexes, clusters, and intermetallic compounds. Tin(IV) compounds, including organotin compounds, have been studied even more vigorously.[11] All these data have created a basis for a wider-scale employment of the Mössbauer method in the study of the structure and properties of various homogeneous and heterogeneous tin-containing catalysts.

The lack of exact values of $f'$ and of their temperature variation for many individual compounds and (especially) for the products of the interaction with the carrier constitutes a major problem, which has inhibited extensive quantitative studies of tin-containing catalysts by the Mössbauer method. It would be useful to obtain general quantitative relations between $f'$ and the parameters characterising the degree of interaction of tin-containing molecules with the carrier surfaces, particularly the relations for the corresponding equilibrium constants and force constants of the adsorbent–adsorbate bonds, using additional information from their vibrational spectra. Studies of the temperature dependence of $f'$ at lower temperatures, down to the temperature of liquid helium, are essential. In general, whereas the parameters $\delta$, $\Delta$, and $\Gamma$ have been used fairly widely in the study of the state of tin-containing catalytic systems, the parameter $f'$ has not as yet become a widely used means for the investigation of the properties of real catalysts. However, modern technology and the need to develop precise methods for the investigation of the state of heterogeneous M–Sn catalysts will probably correct this situation in the immediate future.

Finally, the greatest problem in heterogeneous catalysis is that of the development of methods for the investigation of the properties of the surfaces of real catalysts. The Mössbauer effect could, in principle, become a basis for such a method. However, a recent international conference on the application of the Mössbauer effect (Alma-Ata, 1983) demonstrated that so far the different versions of the method make it possible to investigate a surface layer which is not less than tens and even hundreds of angstroms thick, whereas for catalysis one requires information about the state of the Mössbauer atoms and the depth equivalent to several monolayers, i.e. up to 10 Å. Presumably Mössbauer spectroscopy, which is already a unique method for the investigation of the state and properties of homogeneous and heterogeneous catalysts containing Mössbauer atoms, will in future occupy a leading position in the study of such systems.

# The Nature of the Active Component in Deposited Sulphide Catalysts

Yu.I.Ermakov

The use of various physical methods (high resolution electron microscopy, Mössbauer spectroscopy, X-ray photoelectron spectroscopy, X-ray radial distribution of atoms, infrared spectroscopy, and the study of the long-range fine structure of X-ray absorption) for the elucidation of the structure of the active component in deposited sulphur catalysts is examined. The data obtained by these methods show that the active component in the catalysts considered has an $MoS_2$ (or $WS_2$) layer structure, while cobalt (or nickel) ions are distributed on the lateral faces of the dispersed sulphide particles.
The bibliography includes 63 references.

## I. INTRODUCTION

The catalysts used in practice usually consist of a complex mixture of bulk-phase and surface compounds. As a rule the catalytically active centres are incorporated in highly dispersed phases. The composition of the catalyst varies under the influence of the reaction medium. All these factors are responsible for the difficulties which arise in the solution of the problem of which of the compounds (or their combination) is essential for the manifestation of catalytic activity (i.e. is an active component of the catalyst). For the majority of the important industrial catalysts, this problem is still controversial. The most likely controversy in recent years arose in the discussion of the mechanism of the action of hydro-purification catalysts. Industrial catalysts for the refining of petroleum products by treating them with hydrogen at high temperatures contain molybdenum (or tungsten) compounds combined with cobalt (or nickel) compounds in a highly dispersed state on a carrier (alumina). Under the conditions of the reaction medium, the catalysts combine with sulphur (the formation of surface metal sulphides). In the course of hydro-purification at high temperature (350–450 °C) under a high hydrogen pressure (50–100 atm), C–S, C–N, and C–O bonds undergo hydrogenolysis (which leads to the removal of hetero-atoms from the petroleum products—in the first place the removal of sulphur in the form of hydrogen sulphide), metallic impurities are removed from the petroleum crude, and hydrogenation and isomerisation processes take place. Hydro-purification is one of the largest-scale catalytic processes (hundreds of millions of tonnes of petroleum products are processed). The annual production of hydro-purification catalysts runs into tens of thousands of tonnes. The scale of the employment of hydro-purification processes and of the manufacture of catalysts for this purpose will increase with increasing extent of the processing of petroleums having a high sulphur content (and, in future also, of the liquid products of the processing of coal). For example, in the USA these catalysts occupy the first place as regards the rate of growth of production and sales.[1–3] Industrial hydro-purification catalysts contain 12–20% of transition metal oxides on a carrier. The cost of the metals forming part of the composition of these catalysts is rapidly increasing. For example, the world prices of cobalt rose by a factor of 4 during the period from 1970 to 1976.[4] This makes it necessary to create active and stable catalysts with a low metal content. For the solution of this problem, it is important to understand the nature of the active component in the catalyst. Nevertheless, there is no unanimous view in the literature concerning the nature of such a component in sulphide catalysts. The most important of the proposed hypotheses are illustrated in Figs. 1–4.

The monolayer model (Fig. 1) has been put forward by Lipsch and Schuit[5] to account for the structure of the active component in hydrosulphurisation catalysts and improved models of this type have been considered in other studies.[6,7] This model is based on the hypothesis that surface oxide sulphides are formed in the monolayer of the surface aluminium molybdate when the latter combines with sulphur. The molybdate is produced in accordance with the mechanism

Cobalt is located within the $Al_2O_3$ lattice, but its role in the catalytic process remains obscure.

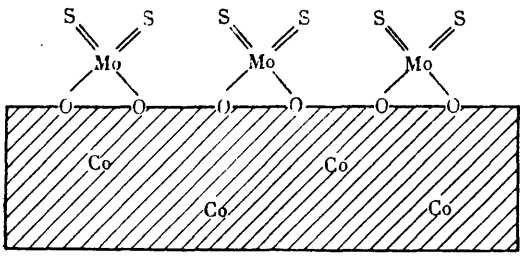

**Figure 1.** The monolayer model designed to account for the structure of the active component in hydrodesulphurisation catalysts.[5–7]

The intercalation model (Fig. 2) has been proposed by Voorhoeve and Stuiver[8] and improved by Farragher and Cossee.[9] According to this model, different metal ions can be inserted (intercalated) between sulphide packets linked by weak van der Waals forces. Farragher and Cossee[9] believe that intercalation of the Ni(Co) ions between

$MoS_2(WS_2)$ layers is confined to the surface of the lateral face. Thus the active centre is produced on the lateral face of the sulphide crystal; there is also a possibility of the formation of bimetallic active centres, including those incorporating $Mo^{3+}$ and $W^{3+}$ ions after the partial elimination of sulphur from the surface layer. Fig. 2 illustrates schematically the structure of the $MoS_2$ layer crystals; a similar scheme is valid for $WS_2$. The crystals of these sulphides consist of packets having the composition $MS_2$ and each packet comprises a layer of metal (M) atoms and two layers of sulphur atoms. A metal atom within the layer is coordinated to six sulphur atoms.

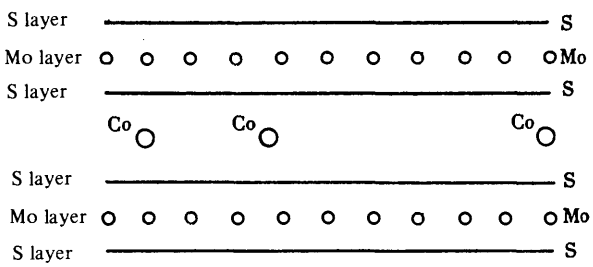

**Figure 2.** The intercalation model.[8,9]

The contact synergism model, proposed by Delmon and co-workers,[10-12] presupposed (Fig. 3) that two separate (albeit very disperse) sulphide phases are formed in mixed sulphide catalysts. These phases are in contact or are close to one another on the carrier. The active centres proper are distributed on the $MoS_2$ phase. The presence of cobalt sulphide activates the hydrogen.

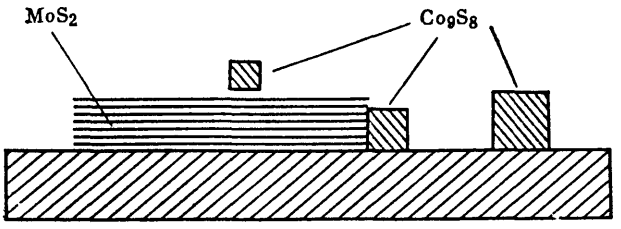

**Figure 3.** Delmon's "contact synergism" model.[10-12]

The insertion model has been put forward recently by Ratnasamy and Sivasanker.[13] In this model it is assumed that the cobalt atom is located on the lateral face of the $MoS_2$ crystal. Fig. 4 illustrates the lateral face of a single $MoS_2$ packet with inserted cobalt atoms. This model was put forward[13] without experimental justification on the hypothesis that the location of cobalt on the lateral face decreased the excess charge on the sulphur atoms adjoining the lateral face.

The application of a combination of physical methods has led in recent years to significant progress in the elucidation of the composition of the active component of hydropurification catalysts. The aim of the present review is not a complete retrospective consideration of all the data obtained in the study of hydrodesulphurisation catalysts (frequently extremely contradictory), since many excellent reviews covering this field already exist (see, for example, Refs. 13–17). Here we shall deal with the results of recent studies of two catalytic systems: $(Ni+W)/SiO_2$ (studies performed at the Institute of Catalysis of the Siberian Division of the USSR Academy of Sciences[18-36]) and $(Co+Mo)/Al_2O_3$ (studies carried out by Topsøe and co-workers[14,37-54]).

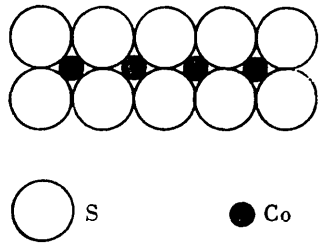

**Figure 4.** The insertion model.[13]

## II. RESULTS OF THE STUDY OF THE $(Ni+W)/SiO_2$ SYSTEM

### 1. Characteristic Features of the Preparation of the Catalysts

Silica gel was used as the carrier for the preparation of the catalytic system, because it ensures a more uniform surface composition (compared with catalysts based on $Al_2O_3$) and a lesser degree of interaction of the deposited components with the carrier.

In order to attain the maximum degree of dispersion of the sulphide particles, the surface sulphides were obtained from attached organometallic complexes. The preparation of the catalyst is illustrated schematically in Fig. 5.

The preparation of catalysts incorporating only one metal (such catalysts are referred to below as monometallic) involved states in which the allyl complexes of tungsten and nickel interacted with the surface hydroxy-groups, the resulting attached complexes were treated with hydrogen, and the reduced forms of nickel (finely dispersed metallic nickel) and tungsten ($W^{2+}$ ions) were subsequently converted into sulphides. The catalysts obtained in this way (henceforth such catalysts will be referred to as organometallic) were 5–20 times more active than the catalysts prepared by the standard method involving impregnation with $Ni(NO_3)_2$ and $(NH_4)_2WO_4$ solutions.[18,31] This difference in activity is associated mainly with the higher degree of dispersion of the sulphide particles and catalysts prepared from organometallic complexes (organometallic catalysts).

The monometallic sulphide catalysts $Ni/SiO_2$ and $W/SiO_2$ (the sulphur incorporated in the catalysts when it combines with them will not be indicated in the formulation of the catalyst composition either here or henceforth) exhibited approximately equal activities in the hydrogenolysis of thiophen at 300–350 °C. Analogous data indicating similar activities of cobalt and molybdenum sulphide deposited on charcoal have been published by De Beer et al.[55] Thus it

would not be useful to regard the sharp increase in the activity of the mixed sulphide systems (such systems are referred to below as "bimetallic") as "promotion" (this term is suitable for the case where one of the components is inactive or its activity is low). The mutual enhancement of activity in mixed sulphide systems is usually treated in the literature as a manifestation of synergism.

The most active bimetallic catalysts on $SiO_2$ have been obtained when the second component was deposited in the form of an organometallic compound on the dispersed sulphide of the first component (see Fig. 5). It is important to note that the $(Ni+W)/SiO_2$ sulphide catalysts of "organometallic" origin were more active than catalysts of analogous composition on alumina.[31]

The activity of the catalysts depends on the atomic ratio of the deposited metals (Fig. 6). The dependence of the overall activity $a$ on $\lambda = Ni/(Ni+W)$ is analogous for organometallic hydrodesulphurisation catalysts and the specimens obtained by the usual procedures.[10,42,56]

The maximum activity per unit weight of the deposited metals in the "organometallic" catalysts is observed at $\lambda \cong 0.3$; the activity referred to 1 g of nickel increases with decrease of its content and reaches a maximum at $\lambda \leq 0.2$. Presumably for these values of $\lambda$ the entire nickel (or at least a constant fraction of the latter) is incorporated in the composition of the active centres. We may note that analogous results have been obtained for the $(Ni+Mo)/SiO_2$ system.[24]

## 2. High Resolution Electron Microscope Data

The morphology of the sulphide particles in the $(Ni+W)/SiO_2$ catalysts has been investigated[22,24,32] with the aid of a JEM-100CX electron microscope with a point resolution of 2 Å (Figs. 7 and 8). The photomicrographs of the monometallic $Ni/SiO_2$ and $W/SiO_2$ sulphide catalysts obtained from organometallic complexes show, against the background of $SiO_2$ globules, individual particles with dimensions <10 Å.

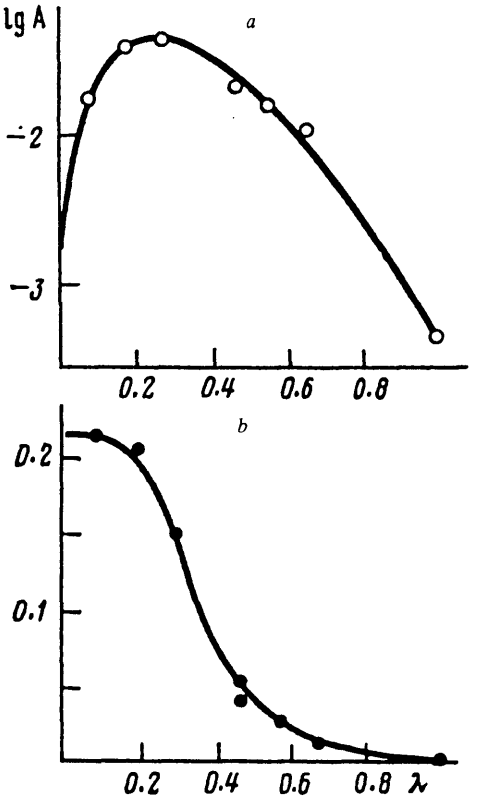

**Figure 6.** Dependence of the catalytic activity of the $(Ni+W)/SiO_2$ sulphide catalysts on the atomic ratio $\lambda = Ni/(Ni+W)$; the activity was measured in the hydrogenolysis of thiophen at 350 °C and 20 atm: *a*) activity (rate of reaction) referred to 1 gram-atom of both metals (Ni + W) ($10^2$ mol $s^{-1}$); *b*) activity referred to 1 gram-atom of nickel ($10^2$ mol $s^{-1}$).

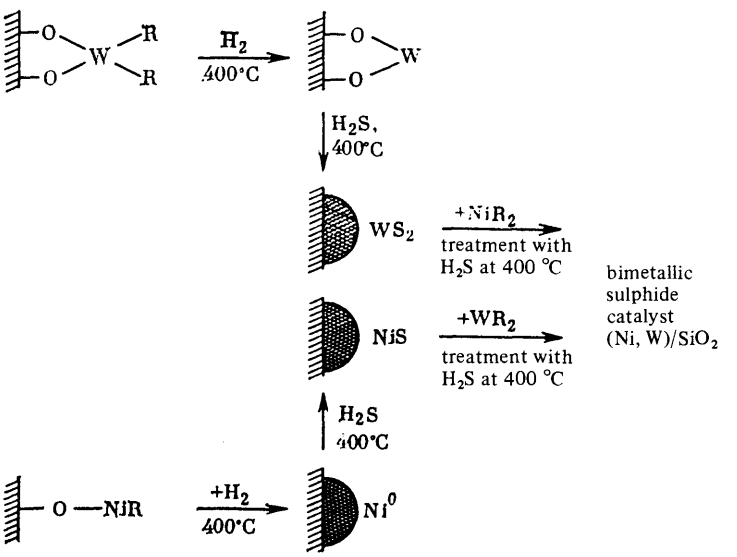

**Figure 5.** Schematic illustration of the preparation of deposited mono- and bimetallic catalysts using organometallic complexes.

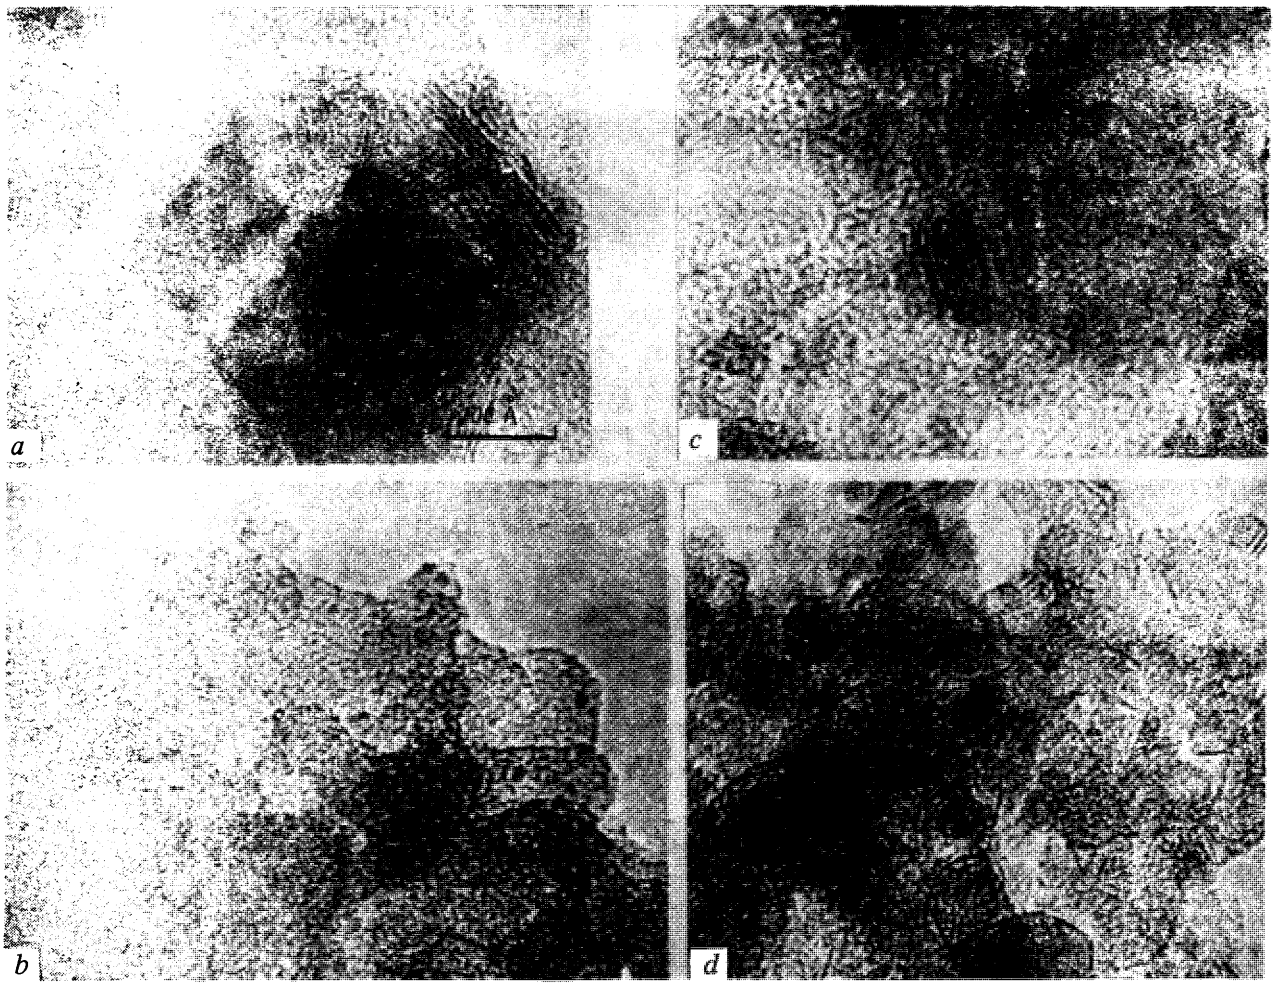

**Figure 7.** Electron photomicrographs of deposited sulphide catalysts: *a*) $WS_2/SiO_2$ catalyst obtained by the standard impregnation method; *b*) $W/SiO_2$ catalysts obtained from organometallic compounds fixed to the carrier; *c*) $(Ni+W)/SiO_2$ catalysts obtained by the standard method involving simultaneous impregnation with aqueous $Ni(NO_3)_2$ and $(NH_4)_2WO_4$ solutions; *d*) $(Ni+W)/SiO_2$ catalyst obtained by treating a $W/SiO_2$ specimen with the allyl complex of nickel and subsequent sulphiding at 400 °C.

In the case of catalysts obtained by "standard" impregnation methods, particles of nickel and tungsten sulphides can be seen. Thus the photomicrographs of the catalyst containing $WS_2$ show formations whose size ranges from 20 to several hundred angstroms. These agglomerates have a layer structure with interlayer distances of ~6 Å, which corresponds to a distance $d_{002} = 6.2$ Å between individual layers of tungsten atoms in the $WS_2$ crystal. Comparison of the dimensions of the sulphide particles in the "standard" and "organometallic" catalysts shows that the higher activity of the latter can be accounted for in the main by the higher degree of dispersion.[22,32]

A different morphology of the surface particles is characteristic of the bimetallic sulphide catalysts compared with that of the monometallic $W/SiO_2$ specimens of "organometallic" origin. Instead of particles approximately 10 Å in size, linear structures (strips) 20–50 Å long appear in the sulphur-treated $(Ni+W)/SiO_2$ catalyst. The photomicrographs of the "organometallic" specimens show mainly single strips; when packets of strips are formed, the distance between the strips "layers" is about 6 Å. Evidently the individual strips are projections of the $WS_2$ layers onto the lateral surface.

The numbers of layers in the surface particles of the "organometallic" and "standard" catalysts differ significantly (Fig. 8). The dominant type of particles in the most dispersed organometallic catalyst consist of single-layer formations. In the "standard" catalysts the sulphide particles contain 6–10 layers.[32] Comparison of the activities of the "organometallic" and "standard" catalysts with the morphology of the sulphide particles in them provides evidence in support of the view that the active centres are located on the lateral faces of the sulphide particles (Fig. 9). The activity of the "organometallic" catalysts is ~3 times higher than that of the "standard" catalysts. We shall assume that the active centres are located on the basal plane. In this case a greater difference should be observed between the activities, since, on passing from the "organometalic" to "standard" specimens, the fraction of the surface of the basal planes per unit mass of the active phase (and

hence the catalytic activity) should fall approximately in proportion to the increase of the number of layers in the particles of the surface sulphide.

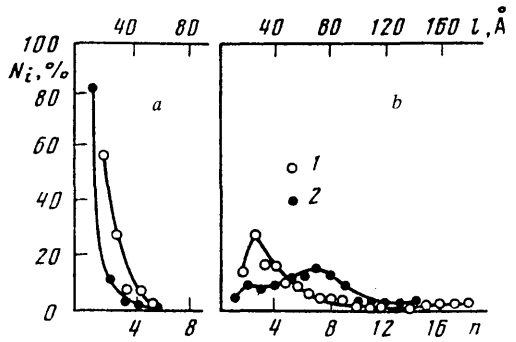

**Figure 8.** Distribution of particles with respect to size in the $(Ni+W)/SiO_2$ sulphide catalysts according to electron microscope data: *a*) catalyst obtained from organometallic compound; *b*) catalyst obtained by the standard impregnation method; *1*) length of layers *l*; *2*) number of layers *n*; $N_i$ = fraction of particles (%).

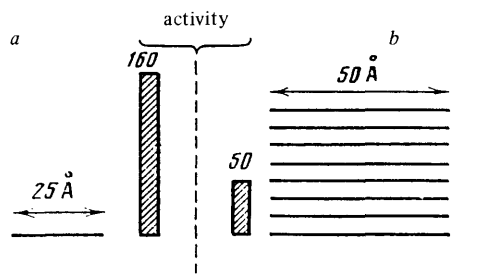

**Figure 9.** Comparison of the typical surface structures in the deposited sulphide catalysts $(Ni+W)/SiO_2$ according to electron microscope data; the lines correspond to individual $WS_2$ layers; the catalytic activity is expressed as the rate of hydrogenolysis of thiophen at 350 °C [$10^{-4}$ mol (Ni + W g-atom)$^{-1}$ $s^{-1}$]: *a*) catalyst obtained from organometallic compounds; *b*) catalyst obtained by the standard impregnation method.

It follows from the results that (a) layer structures characteristic of massive $WS_2$ or $MoS_2$ sulphides are formed in the bimetallic sulphide catalysts. The most dispersed "organometallic" catalysts with an enhanced activity contain single-layer formations (single packets). This finding is inconsistent with the intercalation model[8,9] which presupposes not less than two layers of packets for the formation of active centres. (b) The most probable site at which the active centres for the hydrogenolysis of the C–S bond are located on the lateral faces of $WS_2$ or $MoS_2$ crystals.

The results of electron microscope studies do not, however, permit an unambiguous conclusion about the formation of mixed compounds from nickel and tungsten sulphides.

### 3. X-Ray Photoelectron Spectroscopic (XPES) Data

When dispersed nickel or tungsten (molybdenum) sulphides are formed on the surface of silica gel, an appreciable increase of the electron binding energy $E_b$ at the $Ni2p_{3/2}$ and $W4f_{7/2}$ levels is observed in the XPE spectra (Fig. 10) compared with the massive sulphides.[19,33] This indicates the interaction of the dispersed sulphides with the carrier with a consequent decrease of the electron density on the deposited metals. When mixed catalysts are prepared, a further increase of $E_b$ at the $Ni2p_{3/2}$ levels and a decrease of $E_b$ at the $W4f_{7/2}$ and $(Mo3d_{5/2})$ levels takes place. Thus the introduction of nickel into the composition of dispersed sulphide catalysts leads to its interaction with tungsten (molybdenum), which entails the transfer of electron density from nickel to W(Mo) atoms. We may note that the absolute values of $E_b$ at the $Ni2p_{3/2}$ and $W4f_{7/2}$ levels for the catalysts and the thiotungstate and thiomolybdate complexes containing the $[Ni(MS_4)_2]^{2-}$ anion, where M = Mo or W, are similar. In these compounds nickel is surrounded by sulphur atoms:

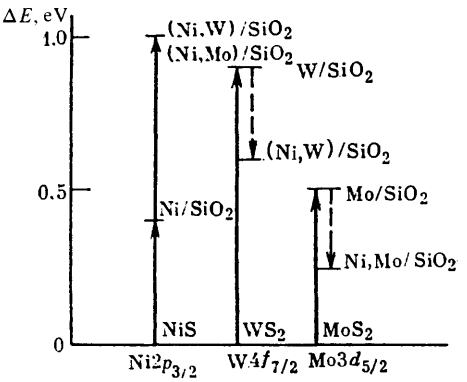

**Figure 10.** The change in the energies of the $Ni2p_{3/2}$, $W4f_{7/2}$, and $Mo3d_{5/2}$ electronic levels in deposited mono- and bi-metallic sulphide catalysts relative to the NiS, $WS_2$, and $MoS_2$ massive sulphides.

Thus the application of the XPES method established that mixed sulphide compounds are indeed formed in the bimetallic catalysts. In order to elucidate the structure of the mixed compounds produced, it is necessary to resort to structural data.

### 4. Data Obtained by Structural Methods

Deposited sulphide catalysts obtained from attached organometallic compounds are amorphous to X-rays. Information about the interatomic distances in the highly dispersed particles of the deposited catalysts can be obtained by the X-ray atomic radial distribution (XARD) method.[57,58] The XARD curves for deposited sulphide catalysts are presented in Fig. 11. The following interatomic distances, which are satisfactorily correlated with the values characteristic of $WS_2$, have been determined for the $(Ni+W)/SiO_2$

sulphide catalysts:[34] ~2.5 Å (W–S distances in the $WS_2$ layer amounting to 2.48 Å; ~3.2 Å (W–W distance amounting to 3.187 Å); ~4.1 Å (distance between the W atoms and the S atoms in the second coordination sphere amounting to ~4.04 Å). At the same time the XARD curves for the deposited catalysts show a peak at ~3.8 Å, which was not observed in the study of the $WS_2$ structure.

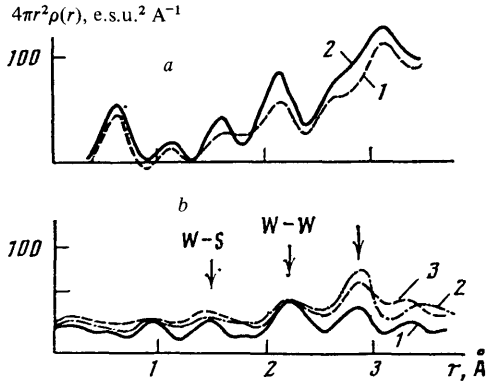

**Figure 11.** *a*) radial distribution curves for the carrier ($SiO_2$) (curve *1*) and the sulphur-treated $W/SiO_2$ catalyst prepared from organometallic precursors (curve *2*); *b*) differential radial distribution curves for the sulphur-treated catalysts obtained after subtracting the curve corresponding to the carrier: *1*) $W/SiO_2$ specimen obtained from organometallic precursors; *2*) $(Ni+W)/SiO_2$ specimen obtained from organometallic precursors; *3*) $(Ni+W)/SiO_2$ specimen obtained by the standard impregnation method.

The same interatomic distances have been found for the bimetallic sulphide catalysts as for the monometallic catalysts. Thus the surface compounds in the deposited $W/SiO_2$ and $(Ni+W)/SiO_2$ sulphide catalysts have the structure of massive $WS_2$. An analogous conclusion is valid for the deposited molybdenum catalysts.

The introduction of nickel does not entail the appearance of new peaks on the X-ray plots (or XARD curves) for the deposited sulphide; only the intensities of certain maxima, characteristic of the $W/Si_2$ catalysts, increases. The increase of the intensity of the maxima can also be associated with the formation of $WS_2$ layers ~25 Å long (instead of the more dispersed formations).

If nickel ions are intercalated between $WS_2$ layers, one might have expected the appearance of the maximum corresponding to an Ni–W distance of 3.45 Å. Since this peak was not observed, one may conclude that intercalation compounds are not formed in the mixed sulphide catalysts; the Ni–Ni distance characteristic of nickel sulphides (3.4 Å) is also absent.

It is noteworthy that the peaks corresponding to the W–W distances between the atoms in different packets of the $WS_2$ structure are not manifested on the XARD curves for the deposited sulphide catalysts. These results are consistent with electron microscope data, according to which single $WS_2$ packets are formed preferentially on the surface and, when aggregates are produced, the layers in the latter are not arranged in parallel.

The appearance of a maximum of 3.8 Å, which does not correspond to the interatomic distances in the $WS_2$ structure, has been explained[34] by the appearance of a chemical bond between the deposited sulphides and the carrier with formation of Si–O–W–S fragments. In these fragments the Si...W distance is ~3.8 Å. Comparison of the $WS_2$ structure with that of the $SiO_2$ surface layers shows that the W–W and S–S interatomic distances in $WS_2$ are close to the O–O interatomic distances in two neighbouring $SiO_4$ tetrahedra forming the $SiO_2$ structure. The surface layer sulphide compounds of tungsten can therefore be formed without distorting the structure of the layer.

Thus it follows from the XARD data that (a) the $WS_2$ layer structure is retained in the deposited sulphide catalysts without the formation of a regular three-dimensional structure; (b) the appearance of the maximum corresponding to an interatomic distance of 3.8 Å, which is not observed in $WS_2$ and $SiO_2$, may be due to the formation of chemical bonds between the deposited sulphides and silica gel.

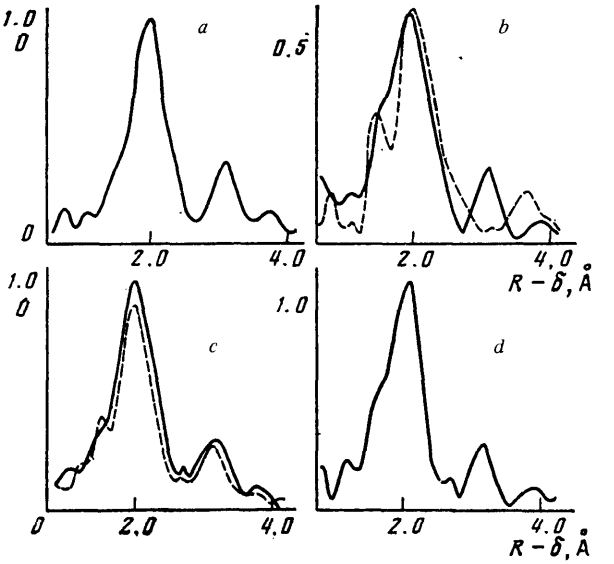

**Figure 12.** Radial distribution curves obtained by the EXAFS method in the measurement of the $L_{III}$ spectrum of tungsten in the sulphided catalysts: *a*) massive $WS_2$ sulphide; *b*) $W/SiO_2$; *c*) $(Ni+W)/SiO_2$, $\lambda = 0.3$; *d*) $(Ni+W)/SiO_2$, $\lambda = 0.5$; the dashed lines correspond to specimens brought into contact with air; $U$ = relative intensity (arbitrary units); $R$ = interatomic distance; $\delta$ = phase shift.

Additional data for the structure of the surface sulphide compounds have been obtained by the EXAFS method (the principles of the method in relation to the study of catalysts have been described by Mastikhin and Zamaraev[59]).

In order to determine the interatomic distances characteristic of the environment of the tungsten atom, the $L_{III}$ absorption spectra of this element have been recorded.[35] The radial distribution curves are illustrated in Fig. 12. Peaks corresponding to the W–S (~2.46 Å) and W–W (~3.19 Å) interatomic distances characteristic of the $WS_2$ packet were found for the $W/SiO_2$ catalyst. A maximum at $R-\delta = 1.61$ Å was also observed, which may be due to the presence of oxygen in the coordination spheres of the tungsten ions (Si–O–W fragments linking the ultradispersed particles of tungsten sulphide to the carrier

surface). The introduction of nickel into the composition of the catalyst increases the intensity of the peaks at $R-\delta = 2.05$ and 3.09 Å. It has been suggested[35] that this may be caused by the additional scattering by nickel ions. When account is taken of the phase correction for the scattering by nickel ions, the W–Ni distances should be 2.38 and 3.42 Å in this case. Analysis of the *K* absorption spectra of the nickel in the mixed sulphide catalyst showed that there are sulphur ions in the immediate environment of nickel. The Ni–S distance is 2.22 Å, which is significantly less than the Ni–S distance in α-NiS (2.38 Å). These data confirm the conclusion that the Ni–S phase is absent from the bimetallic catalysts. The Ni–S distance of 2.22 Å is close to that characteristic of the Ni–S bond length in $[Ni(WS_4)_2]^{2-}$, where the nickel is present in a planar square made up of sulphur ions.

### 5. The Structure of the Active Component of the $(Ni+W)/SiO_2$ Sulphide Catalyst

By the active component, we understand surface structures containing the active centres for the catalytic reaction. The active centre should be understood as the minimum number of surface atoms necessary for the occurrence of the catalytic cycle.

When models of the active component and of the active centre in deposited sulphide hydrosulphurisation catalysts are considered, account must be taken of the following experimental facts observed in the course of the investigation of the $(Ni+W)/SiO_2$ system prepared from organometallic compounds: (a) highly dispersed sulphide particles are present on the catalyst surface mainly in the form of monolayer structures comprising individual packets with linear dimensions of ~25 Å; (b) mixed compounds of two metals (nickel and tungsten in the case considered) are formed on the surface; (c) the interatomic W–S (2.46 Å) and W–W (3.20 Å) distances in the highly dispersed sulphide particles correspond to the layer structure of the massive tungsten sulphide; (d) maxima, which can be referred to the W–O (1.93 Å) and Si–W (3.8 Å in the Si–O–W fragment) distances, are observed on the radial distribution curve; (e) sulphur ions are present in the first coordination sphere of nickel at a distance of ~2.22 Å. Nickel ions are apparently distributed at distances of 2.32 and 3.42 Å from the tungsten ions.

It follows from the data obtained that the active component has the layer structure typical for $WS_2$ (or $MoS_2$) crystals. The active component may be a single packet comprising two layers of sulphur atoms and a layer of W (or Mo) atoms between them. This packet can be arranged either parallel to the carrier surface [can adjoin the carrier via its basal plane (Fig. 13*a*)] or at right angles to the surface, i.e. can adjoin the carrier via its lateral face (Fig. 13*b*). According to electron microscope data, the second possibility is more likely. A cross section for such a packet is illustrated in Fig. 14. Some of the tungsten atoms are linked to the oxygen atoms on the carrier surface. The appearance of the more negative (compared with sulphur) oxygen in the coordination sphere of the tunsten ion leads to a difference between the positions of the electronic levels of tungsten in the dispersed surface particles compared with massive $WS_2$. The nickel atoms are located on the lateral face of the active component, being distributed in the same plane as the tungsten atoms. Fig. 14 illustrates two possibilities for the adsorption of a thiophen molecule: on a bimetallic active centre (Fig. 14*a*), after the removal of a single sulphur atom from the surface of the active component, and on a monometallic active centre (Fig. 14*b*).

The structure presented in Fig. 13*b* contains Si–O–W fragments with an Si–W distance of ~3.8 Å, which corresponds to the peak on the XARD curve.

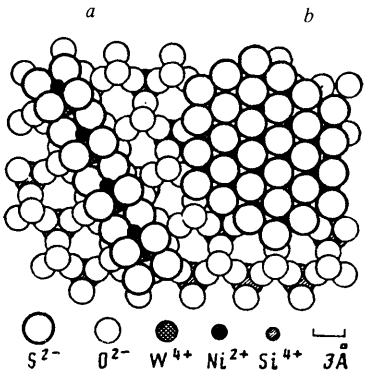

**Figure 13.** Distribution of the $WS_2$ packets on the silica gel surface: *a*) packet arranged at right angles to the $SiO_2$ surface, adjoining it via its lateral face; *b*) packet in contact with the $SiO_2$ surface via its basal plane.

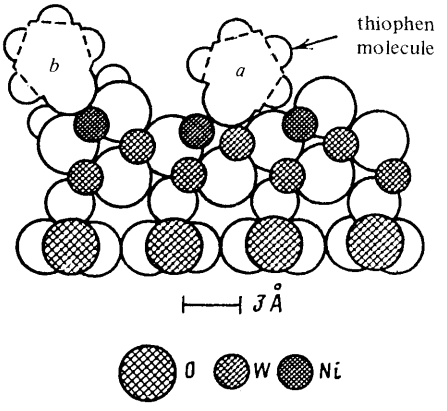

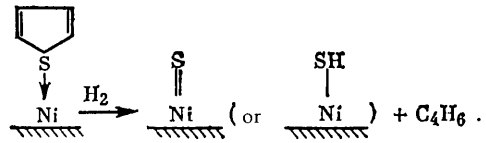

**Figure 14.** The possible structure of the active component in the sulphide hydrodesulphurisation catalysts.

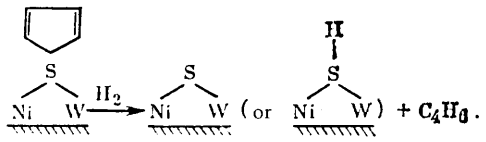
In the study of the structures of the active centres on sulphide catalysts, it is important to determine the location of the nickel (or cobalt) ions in the layer structure of the active component. The possible structures formed when the nickel atoms are distributed on the lateral face of the $WS_2$ crystal have been examined in detail.[36] The best correspondence with structural data has been observed on the hypothesis that the nickel atom substituting a tungsten atom is surrounded by sulphur atoms on the lateral face (Fig. 14). Findings such as the appearance of shortened Ni–S distances and two types of interatomic Ni–W distances can then be explained.

We shall examine the possible types of active centre.



(a) A monometallic active centre—a coordination-unsaturated nickel ion. After the adsorption of thiophen and its hydrogenolysis on such a centre, the sulphur atom is bound

to one metal ion:

The role of tungsten sulphide then reduces to providing the lateral faces of its crystal as a matrix for the accommodation of the coordination-unsaturated nickel ions.

(b) A bimetallic active centre. In this case $WS_2$ plays the role not only of the matrix for the stabilisation of the nickel ions but also participates directly in catalysis. In the course of the hydrogenolysis of thiophen, a sulphur atom is bound to two metal ions:

It has been shown[36] that the removal of surface sulphur, bound to two metal atoms, require a significantly greater energy expenditure than the removal of the sulphur bound to one nickel (or cobalt) atom. The successive removal and addition of sulphur to the monometallic active centre in the catalytic cycle is therefore more likely. The existence of the optimum ratio $\lambda = Ni/(Ni+W) = 0.3$ can be explained with the aid of the above model of the binding of nickel ions on the tungsten sulphide surface. The above value is close to the atomic fraction of the nickel stabilisation centres on the lateral faces of tungsten sulphide packets with a size of 20–50 Å. When the nickel content is above the optimum value, the activity falls (for example, down to 10% of the maximum activity for $\lambda = 0.6$), apparently as a consequence of the shielding of the active centres by nickel sulphide.

The model of the active component considered above has certain features of the "monolayer model" (retention of the bond between the sulphide species and the carrier), the Cossee model (distribution of the ions of the second metal on the lateral face of the sulphide), and the Ratnasamy "insertion" model (distribution of nickel on the lateral plane of a single sulphide packet; square coordination of the nickel ion), but is inconsistent with Delmon's synergistic model (Fig. 3). The results of the study of the $(Ni+W)/SiO_2$ system confirmed the principal postulates of the hypothesis put forward by Topsøe concerning the nature of the active component on cobalt plus molybdenum sulphide/alumina desulphurisation catalysts.

## III. RESULTS OF THE STUDY OF THE $(Co+Mo)/Al_2O_3$ SYSTEM

The $(Co+Mo)/Al_2O_3$ system is used widely as an industrial hydropurification catalyst (nickel is sometimes used instead of cobalt). The catalysts are usually prepared by the successive impregnation of the carrier with aqueous solutions of the components followed by heat treatment in air at 500 °C and conversion into the sulphide form. A number of studies have been made on this system (see the relevant reviews[14–17,53]), but these did not yield unambiguous data owing to the inhomogeneity of the surface composition of the given system (particularly in the oxidised state) and the high degree of dispersion of the active component. As a result of the systematic studies by Topsøe and co-workers[14,37–54] by various physical methods, more reliable information about the nature of the active component in this system has been obtained only in recent years.

### 1. Mössbauer Emission Spectroscopic Data

Systematic application of this method to the study of sulphide systems yielded important information about the nature of the active component in the system considered. It has been noted[14,39] that this is associated with the following features of the method: (a) the Mössbauer parameters (the isomer shift $\delta$, the quadrupole splitting $\Delta E_Q$) are very sensitive to the oxidation state and the composition of the immediate environment of the element investigated; (b) Mössbauer spectra can be measured directly under reaction conditions (at an elevated temperature and in the reaction medium with the necessary composition).

The principal data have been obtained using Mössbauer emission spectroscopy (MES). In the study of sulphide catalysts, mainly specimens into which $^{57}Co$ had been introduced were used. The details of the method have been described in detail elsewhere.[38,39,60] The advantage of the MES method compared with another method [X-ray photoelectron spectroscopy (XPES)] which makes it possible to obtain information about the electronic state of a given element, are evident from a comparison of the spectra (Fig. 15). Whereas the XPE spectra of metallic cobalt and its compounds are virtually identical, the ME spectra differ sharply.

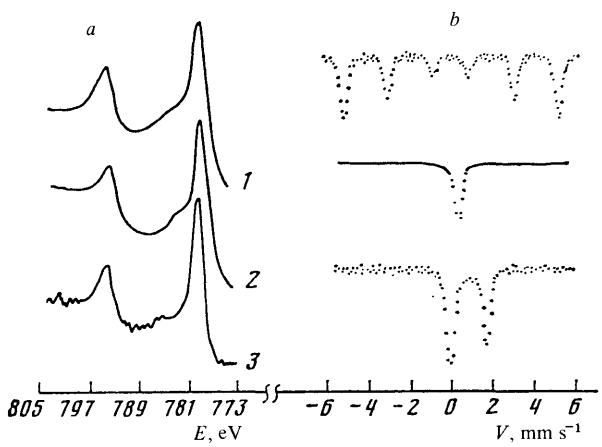


**Figure 15.** X-Ray photoelectron Co2*p* spectra (*a*) and Mössbauer absorption spectra of the individual compounds (b); $E$ = bond energy (eV); $V$ = velocity; *1*) metallic cobalt; *2*) $Co_9S_8$; *3*) $CoMo_2S_4$.[14]

In the first studies[37,38] involving the application of MES, the authors already concluded that in the cobalt–molybdenum sulphide catalysts cobalt is present in a compound different from $Co_9S_8$ and $CoMo_2S_4$; the compound has been called the "Co–Mo–S phase". The ME spectrum of this phase is characterised by a doublet $Q_1$ (Fig. 16), whose parameters differ from those of the individual compounds. The spectra of the sulphide catalysts show, together with the doublet $Q_1$, a weak signal (a doublet $Q_2$) corresponding to the same state of cobalt in which it existed before being converted

into the sulphide (apparently these are cobalt ions bound to the carrier).

A detailed study of the formation of the "Co–Mo–S phase" as a function of the composition and conditions in the preparation of the catalysts[40–48] permitted the following principal conclusions:[47,53]: (a) the "Co–Mo–S phase" is not a stoichiometric compound of definite composition; (b) the cobalt atoms in the "Co–Mo–S phase" are surrounded by sulphur atoms; (c) the "Co–Mo–S phase" is present in both deposited catalysts, obtained using various carriers ($Al_2O_3$, $SiO_2$, activated charcoal), and in massive mixed catalysts; (d) the cobalt atoms are present on the surface, since their environment changes after the adsorption of oxygen; (e) there is a correlation between the content of the "Co–Mo–S phase" in both deposited and massive catalysts and the catalytic activity in hydrodesulphurisation.

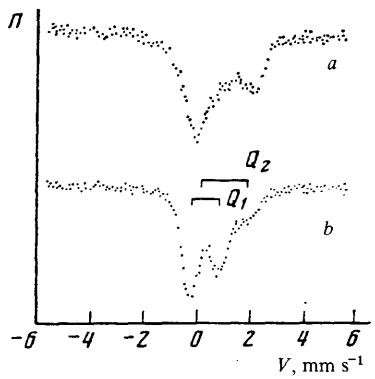

**Figure 16.** Mössbauer emission spectra of the $(Co+Mo)/Al_2O_3$ catalysts:[42] *a*) catalyst in the oxidised state; *b*) after treatment with the $H_2S+H_2$ mixtures; П = absorption.

The content of the "Co–Mo–S phase" reaches a maximum for the optimum Co : Mo ratio. At low cobalt concentrations the fraction of this element entering into the composition of the "Co–Mo–S phase" is close to 100%; with increase of the cobalt concentration, the fraction falls and the content of the inactive sulphide $Co_9S_8$ increases.[42]

## 2. X-Ray Photoelectron Spectroscopic Data

The position of the Co2*p* level in the cobalt catalysts deposited on molybdenum sulphide is higher by 0.5 eV than in massive $Co_9S_8$.[46] The position of the Co2*p* peak for the remaining catalysts is close to that characteristic of $Co_2Mo_2S_4$. This led to the conclusion that the electronic states of cobalt in the "Co–Mo–S phase" and in $CoMo_2S_4$ are similar. Thus cobalt is present in the mixed catalysts in the form of Co(II) in a low-spin state. This interpretation of the XPES data differs from that proposed by Brinen and Armstrong,[61] who concluded that metallic cobalt is present in the sulphide catalysts. The study of the XPE spectra of $Co_9S_8$ [46] and $CoS_2$ [62] showed that the absence of satellite peaks is characteristic of the state of Co(II) in the sulphide systems.

## 3. EXAFS Data

According to EXAFS data,[48] only one peak on the radial distribution curve is observed for the oxide catalysts $Mo/Al_2O_3$ and $(Co+Mo)/Al_2O_3$. The absence of a second ordered coordination sphere shows that the coordination of the molybdenum ions in the catalysts investigated is greatly distorted. As a result of the conversion of the catalyst into the sulphide phase, more regular structures are produced. Comparison of the EXAFS data for $MoS_2$ and the sulphided catalyst led to the conclusion[48] that molybdenum ions enter into the composition of the dispersed $MoS_2$ particles, whose size is independent of the presence of cobalt in the catalyst. In the same study the authors concluded that oxygen ions are absent from the coordination sphere of molybdenum (i.e. the oxide sulphide groups are not formed in the system considered). The immediate environment of cobalt ions contains sulphur atoms and there is no order in the second coordination sphere of the cobalt ions. The Co–S distance in the "Co–Mo–S phase" differs from that between the same atoms in $Co_9S_8$ or $CoMo_2S_4$. The composition of the coordination sphere of cobalt changes when the catalyst comes into contact with air.

## 4. Infrared Spectroscopic Data

Bands corresponding to the hydroxy-groups of the carrier are not observed in the infrared spectra of the catalysts sulphided at 320 °C.[49] Such groups are manifested in the spectra of catalysts sulphided at 600 °C. This indicates the formation of three-dimensional sulphide particles when the catalysts are subjected to a high-temperature treatment, which is also confirmed by electron microscope data. It is believed[50] that the absence of bands due to the OH groups of the carrier from the infrared spectra indicates the retention in the catalysts subjected to a low-temperature treatment (320 °C) of the bond between the active component and the carrier (although the character of this bond remains undefined).

The use of NO as the probe molecule in the study of the surface compounds in the $(Co+Mo)/Al_2O_3$ oxide catalysts revealed the formation of a mixed compound (the "Co–Mo–O phase"). This compound can apparently be regarded as the precursor of the active component formed after treatment with sulphur.[30] The intensity of the absorption bands of the NO adsorbed on the "Co–Mo–O phase" was proportional to the activity of the sulphided catalyst. The amount of adsorbed nitric oxide is also correlated with the catalytic activity.[29] It is noteworthy that the structure of the "Co–Mo–O phase" differs from that of cobalt molybdate.

The infrared spectra of the adsorbed nitric oxide make it possible to distinguish two types of adsorption centres in the sulphided $(Co+Mo)/Al_2O_3$ catalysts—on molybdenum and cobalt.[54] It was found that, with the increase of the cobalt content in the catalyst, the number of adsorption centres containing Mo ions falls. A correlation has been observed between the catalytic activity and the amount of nitric oxide adsorbed on cobalt ions. This permitted the important conclusion that cobalt ions enter directly into the composition of the active centres.

## 5. The Structure of the Active Component of the $(Co+Mo)/Al_2O_3$ Sulphide Catalyst

The MES and EXAFS data are inconsistent with the oxide sulphide and intercalation models and also the synergistic model. On the basis of the set of data obtained, Topsøe

and co-workers[14,50,54] proposed a model, according to which the active component (the "Co–Mo–S phase") consists of highly dispersed particles having the $MoS_2$ structure (usually a single-layer packet). The cobalt atoms are present on the lateral faces of these packets. According to Candia et al.[54], the cobalt atoms block the coordination-unsaturated molybdenum ions distributed on the lateral face. A structure of the active component corresponding in essence to the Ratnasamy model[13] has been put forward by Topsøe et al.[40] For a high degree of dispersion of the active phase (sulphide particle size ~10 Å), the maximum concentration of cobalt ions distributed on the lateral force of the $MoS_2$ crystal can correspond to a stoichiometry with Co : Mo ≅ 0.5.[40] An increase of the cobalt content above the optimum value entails the formation of the inactive sulphide $Co_9S_8$. In conformity with the model proposed by Topsøe and co-workers,[14,50,54] the increase of the activity of the catalyst as a consequence of the deposition of cobalt is associated with the formation of new centres. The degree of dispersion of the molybdenum sulphide particles does not change when cobalt is introduced into the catalyst and the "Co–Mo–S phase" is formed.

## IV. CONCLUSION

The study of the (Ni +W)/$SiO_2$ and (Co +Mo)/$Al_2O_3$ catalytic systems of different composition by a combination of physical methods led various groups of investigators to similar conclusions concerning the nature of the active compounds in the hydrodesulphurisation catalysts: the active component in the sulphide catalysts consists of highly dispersed sulphide particles retaining the layer structure characteristic of the massive sulphides ($MoS_2$ or or $WS_2$); the active centres, incorporating the atoms of the second transition element (nickel or cobalt), are distributed on the lateral faces of the highly dispersed sulphides; the increased activity of the mixed catalytic systems is due to the formation of a surface compound containing the atoms of both transition elements. The atomic activity of the centres in the mixed catalysts is appreciably higher (apparently by about two orders of magnitude) than that of the centres in catalysts containing only one metal.

There is some discrepancy in the data obtained in the study of the above systems as regards the estimation of the degree of interaction with the carrier. For the (Ni +W)/$SiO_2$ catalysts obtained from organometallic compounds, there exist data demonstrating the retention of a bond between tungsten and the oxygen of the carrier. It may be that this is due to the method of preparation of the catalyst via the stage in which the organometallic complexes are fixed on the carrier. Oxygen atoms were not detected by the EXAFS method in the first coordination sphere of molybdenum in the (Co +Mo)/$Al_2O_3$ catalysts. However, one cannot rule out the possibility that a small number of chemical bonds between $MoS_2$ and the carrier are retained in this catalyst too, which is the reason for the retention of a high degree of dispersion of the deposited sulphides under severe conditions of the operation of the catalyst.

Thus important features of the active formations in the mixed sulphide catalysts were elucidated recently as a result of the application of a combination of physical methods. However, the role of the individual components of the catalyst remains obscure. Different causes of the promoting influence of Group VIII metals ($M^{VIII}$) added to Group VI metal ($M^{VI}$) sulphides have been discussed in the literature (see, for example, Pratt and Sanders[63]). These causes can be divided into two groups:

(1) The introduction of the metal $M^{VIII}$ leads to the structural modification (an increase of the degree of dispersion and stability) of the sulphide $M^{VI}S_2$;

(2) The introduction of the metal $M^{VIII}$ increases the number of the active centres in the $M^{VI}S_2$ phase (anionic vacancies, reduced $M^{VI}$ ions) as a result of the activation of hydrogen.

Data obtained by electron microscopy[22,32] have shown that the introduction of nickel into the W/$SiO_2$ catalyst can increase the degree of dispersion of the sulphide particles, but this is not the main cause of the sharp increase of the activity of the mixed catalysts. An increase of the degree of dispersion of the sulphide particles as a consequence of the introduction of cobalt has not been observed in the Mo/$Al_2O_3$ system.[54]

The study of catalysts obtained by depositing $Ni(C_3H_5)_2$ on massive tungsten disulphide has shown[28,29] that the activity referred to one nickel atom is approximately constant regardless of the nickel concentration and also of the morphology and area of the $WS_2$ surface. The same atomic catalytic activity is characteristic of deposited catalysts at low nickel concentratons (below the optimum value of λ). This suggests that nickel enters directly into the composition of the active centres. There exist different views concerning the ions ($M^{VI}$ or $M^{VIII}$) which constitute the centres for the activation of thiophen. A scheme for the hydrogenolysis of thiophen on the "Co–Mo–S phase", according to which thiophen is activated on molybdenum ions, has been put forward.[14] It has been suggested[14] that the presence of cobalt weakens the Mo–S bond, which facilitates the removal of sulphur under the reaction conditions with formation of coordination-unsaturated molybdenum ions on which thiophen is adsorbed. It has been concluded[54] that the active centres in the mixed sulphide catalysts incorporate directly the atoms of the Group VIII–VI element.

Analysis of the possible strength of the bonds between sulphur and surface centres of different composition has led to the hypothesis[36] that the active centre contains $M^{VIII}$ ions. The layer sulphide $M^{VI}S_2$ serves as a matrix for the stabilisation of $M^{VIII}$ in the sulphide environment. The role of the Group VI metal may also consist in altering the reactivity of the centre containing the $M^{VIII}$ ion (for example, in facilitating the removal of the sulphur bound to $M^{VI}$ as a result of the formation of the $M^{VI}$–$M^{VIII}$ bond).

Despite the fact that significant progress has been made in recent years in the elucidation of the nature of the active component in sulphide hydropurification catalysts, a whole series of questions concerning the mechanism of the action of these catalysts still awaits an answer. One of these questions is why a specific combination of two metals (namely the location of cobalt or nickel in the layer structures of tungsten or molybdenum sulphides) actually ensures a high activity in the hydrogenolysis of the C–S bond. The mechanism of the activation of the C–S bond and of the hydrogen molecule on sulphide catalysts remains unelucidated. Further studies should provide an answer to these questions and should also yield additional data on the structure of the active centres in one of the most important classes of industrial catalysts—the hydropurification catalysts.

# The Application of Deuterium in the Study of Heterogeneous Organic Catalysis

B.S.Gudkov

The use of deuterium for the study of the mechanisms of heterogeneous-catalytic organic reactions and of the adsorption of organic molecules on the surface, the structure of the active centres and properties of catalysts, as well as other aspects of catalysis is examined. The possibilities of employing data obtained by measuring the rate of deuterium exchange, by the analysis of the isotope distribution in the products, and by the determination of kinetic isotope effects are demonstrated. The bibliography includes 168 references.

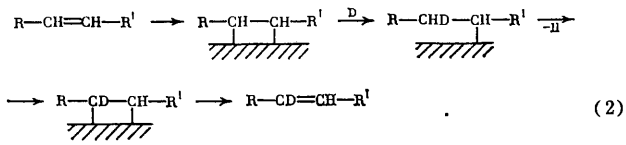
III. Isotope distribution 262
IV. Kinetic isotope effect 265

## I. INTRODUCTION

Increased attention to the reaction mechanism is a characteristic feature of present day studies in the field of heterogeneous catalysis. Among the numerous methods used to solve problems associated with this factor, the isotope methods, in particular those based on the use of deuterium, occupy a notable place. The employment of deuterium in catalysis began as early as the 1930s–1940s in the well known studies by the brothers Farkas, Grinev, and Polanyi. However, it began to be used widely and comprehensively only after the publication in the 1950s of a cycle of the fundamental studies by Kemball, which have since become classical.[1] Extensive literature data have been surveyed in the existing reviews[2-4], but the methodological procedures which assist in the determination of the mechanism of a particular heterogeneous-catalytic reaction by the introduction of the deuterium label have never been examined systematically. Nevertheless the number of studies on catalysis using deuterium has been growing continuously and the attempt at this kind of systematic account undertaken in this review has been fairly urgently needed. As a consequence of the limited space available in the review, we shall deal only with organic heterogeneous catalysis.

It is possible to differentiate three main methods of using deuterium in the study of organic heterogeneous-catalytic reactions: (1) measurement of the rate of deuterium exchange involving compounds participating in the reaction, frequently combined with its comparison with the rate of the main reaction of the compounds; (2) analysis of the isotope distribution in the initial reactants or the final products of the catalytic reaction; (3) measurement of the kinetic isotope effects when hydrogen is replaced by deuterium in one or several components of the reaction mixture. Depending on the specific features of the catalytic system investigated, each of these methods is used in different versions.



## II. RATE OF DEUTERIUM EXCHANGE

A heterogeneous-catalytic reaction is known to have more than one elementary stage. In the study of the reaction mechanism the queston of which stage is the slowest always arises. If hydrogen participates in the reaction, important information about this stage can be obtained by measuring the rate of deuterium exchange involving the initial compounds. A bond with a hydrogen atom must be broken in the deuterium exchange and a new bond must be formed with a deuterium atom. In the case of saturated hydrocarbons, the main pathway leading to the breaking of the C–H bond in deuterium exchange is dissociative adsorption on the catalyst:

(1)

For unsaturated compounds, there is yet another pathway, namely the addition of a deuterium atom to the multiple bond with formation of a semihydrogenated form and subsequent elimination of a hydrogen atom:

(2)

Since dissociative adsorption or the formation of the semihydrogenated form can occur as stages in other reactions of hydrocarbons, for example, in dehydrogenation or hydrogenation, comparison of the rates of deuterium exchange [processes (1) and (2)] with the rate of the given reaction investigated helps to establish the rate-limiting stage.

### 1. Determination of the Rate of Deuterium Exchange

Thus the problem arises of the correct estimation of the rate of deuterium exchange. If the reaction proceeds in a static system, Kemball's equations are used:[1]

$$k_0 = \frac{100 - d_{0,\infty}}{t} \ln \frac{100 - d_{0,\infty}}{d_0 - d_{0,\infty}}, \quad (3)$$

where $k_0$ is the initial rate of consumption of the non-deuteriated organic molecules, $d_0$ the fraction (as a percentage) of the non-deuteriated molecules at time $t$, $d_{0,\infty}$ their equilibrium fraction (as a percentage), and

$$k_\varphi = \frac{\varphi_\infty}{t} \ln \frac{\varphi_\infty - \varphi_0}{\varphi_\infty - \varphi}, \quad (4)$$

where $k_\phi$ is the number of deuterium atoms entering 100 molecules of the organic compound per unit time, $\phi = \sum_{i=1}^{m} i d_i$ ($d_i$ is the fraction of the organic molecules $C_mH_n$ containing $i$ deuterium atoms), $\phi_0$ is the initial value of $\phi$, and $\phi_\infty$ its

equilbrium value, defined by

$$\varphi_\infty = \frac{100n \cdot 2y}{n+2y}$$

($y$ is the ratio of the initial molar concentrations of $D_2$ and $C_mH_n$).

If the initial deuterium content in the organic molecule is zero ($\phi_0 = 0$), which is usually the case, the gaseous deuterium is present in the system in an excess so that $d_{0,\infty} \cong 0$, then Eqns.(3) and (4) simplify and become respectively

$$k_0 = \frac{100}{t} \ln \frac{100}{d_0}$$

and

$$k_\varphi = \frac{\varphi_\infty}{t} \ln \frac{\varphi_\infty}{\varphi_\infty - \varphi} \quad .$$

Having plotted $\ln d_0$ against $t$ and $\ln(\phi_\infty - \phi)$ against $t$, it is possible to find $k_0$ and $k_\phi$ respectively from the slopes of the straight lines.

It is seen from Eqn.(3) that $k_0$ has the dimensions of the reciprocal of time, i.e. it is a relative quantity indicating the fraction of the molecules (as a percentage) involved in the exchange per unit time. The rate of disappearance of non-deuteriated molecules can be obtained by multiplying $k_0/100$ by the concentration of the organic compound. The rate of incorporation of deuterium into organic molecules can be obtained in exactly the same way from $k_\phi$. The quantities $k_0$ and $k_\phi$ may not be identical because several hydrogen atoms of one organic molecule can be substituted by deuterium simultaneously. The ratio

$$M_D = k_\varphi / k_0 \qquad (5)$$

characterises the multiplicity or extent of the exchange, i.e. the number of D atoms entering one organic molecule per reaction step.

Isotope exchange is a first-order reaction with respect to the isotope,[5] i.e. in any specified initial mixture involved in deuterium exchange in the static system the rate of consumption of the hydrogen-containing molecules on all gaseous deuterium is described by the first-order Eqn.(3). At the same time the form of the kinetic equation describing the rate of deuterium exchange as a function of the concentration of the reaction components is determined by the mechanism of a specific process. The rate of exchange usually increases with increasing concentration of hydrocarbon molecules, while an increase in the deuterium concentration entails a retardation of the exchange.[2]

The estimation of the rate of deuterium exchange in a flow-circulation system has certain specific features. In contrast to the usual reactions where a chemical transformation takes place, in deuterium exchange a molecule which has reacted once is not "removed from play" and can undergo new isotope exchange steps. The experimental degree of reaction (exchange) is then too low. In the usual formula for the calculation of the rate of reaction in a flow-circulation system one therefore introduces a correction which takes into account the possibility of such repeated exchange:[6]

$$r_{об} = \frac{u_0 x_{exch} M_{av}}{g M_D} \quad ,$$

where $u_0$ is the flow rate of the exchanging molecules, $x_{exch} = (100-d_0)/100$ the degree of exchange, $g$ the weight of the catalyst sample, $M_{av}$ the average number of D atoms in the exchanging molecules after the experiment, and $M_D$ the number of D atoms entering one molecule in one exchange step.

The quantity $M_{av}$ can easily be determined from the results of the mass-spectrometric analysis of the products and $M_D$ can be found from Eqn.(5). One must bear in mind in the calculation of $k_\phi$ and $k_0$ in Eqn.(5), that the quantities $d_0$ and $\phi$ are determined in the given instance at only two points—the initial point and the time $t$, and the accuracy of the estimate can therefore be low. In order to improve the accuracy, one can set up special experiments, but the rate of exchange and the rate of the main reaction usually differ sufficiently and there is no doubt which of these processes predominates.

The methods for the determination of the rate of exchange when the molecule contains hydrogen atoms which are not equivalent as regards reactivity are described below.

## 2. The Use of Data for the Rate of Deuterium Exchange

In the first place we shall consider specific examples where information about the mechanism of the catalytic reaction can be obtained by comparing its rate with that of deuterium exchange.

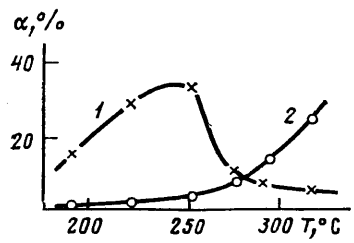


**Figure 1.** Temperature dependence of the degrees α of exchange involving cyclohexane (curve *1*) and of its dehydrogenation (curve *2*) on the nickel catalyst.[7]

The mechanism of the dehydrogenation of cyclohexane and the related benzene and cyclohexene hydrogenation reactions on a nickel catalyst has been investigated[7] with the aid of deuterium. It was found that the deuterium exchange involving cyclohexane begins at a lower temperature and is much faster than its dehydrogenation. However, with increase of temperature, the rate of dehydrogenation (which in the given case, in a flow-circulation system, is proportional to the degree of reaction) increases and the rate of exchange falls after passing through a maximum (Fig.1), so that dehydrogenation now becomes the faster process. The high rate of deuterium exchange at the beginning of the experimental temperature range evidently demonstrates that the dissociative adsorption stage, which is common to both reactions, cannot limit the rate of dehydrogenation. An increase of temperature promotes a further reaction (dehydrogenation) of the dissociatively adsorbed cyclohexane and the suppression of the competing process involving its desorption with substitution of the eliminated H atoms by D (i.e. the deuterium exchange is retarded). This entails the reversal of the ratio of the rates of the exchange process and the cyclohexane dehydrogenation reaction. A similar phenomenon has been observed also in the deuterium exchange involving a series of paraffinic hydrocarbons on nickel under the conditions of hydrogenolysis and dehydrocyclisation.[8]

The rate of deuterium exchange involving the potential intermediate of this reaction, namely cyclohexene, is extremely low under the same conditions and is much lower than the rate of its hydrogenation.[7] Presumably the adsorption of cyclohexene (probably with dissociation of the double bond) is in this instance virtually irreversible and the intermediate surface compound formed reacts further rapidly.

The deuterium exchange involving benzene, which has been investigated in both flow-circulation[7] and static[9] systems, is faster than the hydrogenation of benzene. However, comparison of the temperature variations of the rates of both reactions (Fig. 2) shows that they proceed independently via different surface intermediate species.

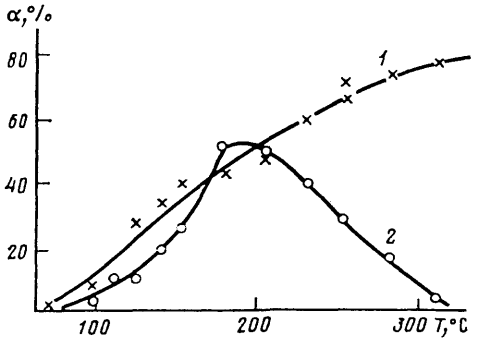

Figure 2. Temperature dependence of the degrees α of exchange involving benzene (curve *1*) and of its hydrogenation (curve *2*) on the nickel catalyst.[7]

Analysis of the relations obtained using kinetic, adsorption, and other data made it possible to develop a fairly convincing general mechanism of the reactions in the benzene–cyclohexane system on a nickel catalyst.[7] Analogous conclusions have been reached by comparing the rates of exchange and deuteriation also for the reaction with participation of toluene.[10]

One may point to a series of other studies in which comparison of the rates of deuterium exchange and a chemical reaction yielded valuable information about the mechanisms of the processes investigated. Such data have been obtained for the hydrogenation of ethylene on $Al_2O_3$,[11] propene on rhodium,[12] isoprene on palladium,[13] benzene on a series of metals,[14] and mesityl oxide on palladium,[15] for the hydrogenation of a series of alkanes on titanium dioxide,[16] n-decane on alumir.oplatinum[17] and platinum–tin[18] catalysts, and isopentene on the calcium–nickel–phosphate catalyst,[6] for the conversion of cyclohexanol into cyclohexanone on a copper–magnesium catalyst,[19] for the hydrogenolysis of thiophen on an industrial aluminonickel–molybdenum catalyst,[20] for the hydrogenation and isomerisation of hexenes on "sulphided" palladium,[21] for the hydrogenolysis and isomerisation of propane and butane on platinum[22] and n-pentane on nickel, platinum,[23] and platinum–lead and platinum–copper catalysts,[24] for the hydrogenolysis and dehydrogenation of cyclohexanes on platinum and nickel,[25] for the *cis–trans* isomerisation and migration of the double bond in butenes on nickel,[26] and for a number of other processes.

The measurement of the rate of deuterium exchange involving not only the starting materials but also the reaction products can also be of considerable interest. Thus the high rate of exchange involving the methane formed in the hydrogenolysis of hydrocarbons on sputtered iron films[27] and on rhodium–iridium catalysts[28] made it possible to reject the hypothesis that the rate-limiting stage in this reaction is the desorption of its products. However, there exist also contradictory data according to which the rate of hydrogenolysis of hydrocarbons on iridium, rhodium, ruthenium[29,30] and on palladium–silver alloys[31] is determined precisely by the rate of the desorption stage.

The rate of deuterium exchange is not measured solely in order to compare it with the rate of the chemical reaction investigated to establish the process mechanism. Deuterium exchange has proved to be a sensitive instrument for the investigation of the catalysts themselves. By estimating the influence of the composition of the catalyst, of the degree of its dispersion and its genesis, of its treatment by various substances, etc., on the rate of deuterium exchange, it is possible to obtain information about the nature, structure, and properties of the active centres of the catalysts. Thus it has been possible to establish with the aid of deuterium exchange involving ethylene that the active centres of catalysts containing chromium in a magnesium oxide matrix are $Cr^{2+}$ ions.[32] Deuterium exchange has been used also to investigate a series of other oxide catalysts.[33–36] Measurement of the rate of deuterium exchange involving hydrocarbons made it possible to elucidate the way in which the temperature of the preliminary treatment influences the activity of $\gamma$-$Al_2O_3$ [37] and barium oxide[38] and to obtain data on the active centres in these catalysts.

In many studies the active centres have been investigated by treating the catalysts with various substances, mainly sulphur-containing substances, which influence the rate of deuterium exchange and other reactions of organic molecules. The unequal effects of the treatment of molybdenum sulphide with hydrogen sulphide on the hydrogenation of ethylene and on the exchange between the latter and $C_2D_4$ led to the conclusion that two types of active centres exist on the surface of this catalyst[39] and differ in the degree of coordination unsaturation of the molybdenum atoms.[40] Similar data have been obtained also for nickel sulphide.[41] Different active centres, responsible for the isomerisation of n-butene and for the deuterium exchange involving benzene and n-butene, have been detected also on the surface of alumina: the former incorporate $Al_2^{3+}$ and sometimes also $O_2^-$ and the latter incorporate $O_2^-$ ions differing from those participating in isomerisation.[42] The influence of the poisoning of the $Pt/Al_2O_3$ catalyst with hydrogen sulphide, sulphur dioxide, and other poisons on the hydrogenation, hydrogenalysis, and deuterium exchange reactions of certain hydrocarbons.[43,44]

Investigation of the dependence of the rate of deuterium exchange involving ethane,[45] cyclopentane,[46] and cyclohexane[47] on the degree of dispersion of platinum led different investigators to different conclusions, so that the question of the structural sensitivity of these reactions remains controversial. The assignment of the reaction to a particular type is believed[48] to depend on the degree of reaction and, after the attainment of complete surface coverage of the catalyst, the structure-sensitive reaction can become "structure-insensitive". Doubt have been cast on the validity of the usual methods for the determination of the structural sensitivity of catalytic reactions on metals[49] in view of the results of the study of the deuterium exchange involving 2,2-dimethylbutane on platinum and palladium.

The rate of deuterium exchange involving benzene proved to be different on different crystallographic faces of a platinum single crystal,[50] in contrast to the rate of its hydrogenation, which constitutes an additional argument in support of the view that the mechanisms of these reactions are different.[7]

The measurement of the rate of deuterium exchange involving hydrocarbons is used particularly widely in comparisons with the rates of other reactions, in the study of bimetallic catalysts. This usually makes it possible to estimate the role of the cluster and ligand effects in such systems.

It has been postulated[51-54] and confirmed by calculation[55] by Dalmon's method[56] that deuterium exchange takes place in clusters smaller than those required for hydrogenolysis. The fact that the rate of hydrogenolysis of hydrocarbons (dissociation of C–C bonds) depends more strongly on the composition of nickel–copper[51-53] and platinum–gold[54] alloys than the rate of deuterium exchange (dissociation of C–H bonds) has been interpreted as evidence for the decisive role of the size of the *ensembles*, i.e. of the geometrical factor, in these and similar systems. However, in subsequent studies using deuterium exchange involving cyclohexane and n-hexane on nickel–copper alloys,[55] ethane and neopentane on ruthenium–copper and ruthenium–silver alloys,[57] and methane and neopentane on palladium–gold alloys[58] it was emphasised that, together with the geometrical factor, account must be taken also of the electronic factor. It is appropriate to mention, if only selectively, also certain other studies in which deuterium exchange involving various hydrocarbons has been used to investigate the catalytic properties of Pt–Re,[56-60] Pt–Ir, Ir–Os,[60] Pt–Pd,[61] Pd–Ni,[62] Ni–Mo,[63,64] Ni–Cu,[65] and Pd–Ag [31] alloys. The isotope exchange between methane and deuterium has been suggested as a method for the determination of the composition of the surfaces of platinum–palladium alloys.[61]

Finally the measurement of the rate of deuterium exchange can be used to estimate the strength of the C–H bonds and the reactivities of the hydrogen atoms in various groups in organic molecules. It was found that the rate of deuterium exchange in a series of cycloalkanes is correlated with the "bond indices" calculated by quantum-chemical methods and characterising the strength of the C–H bonds after adsorption on nickel.[66] The reactivities of all the hydrogen atoms in cycloalkanes are approximately equal, which follows from the linearity of the relation plotted in terms of the variables of Eqn.(4) over a fairly wide range of degrees of exchange. However, there are many compounds in the molecules of which the hydrogen atoms are not equivalent. Such non-equivalence leads to a break in the straight line plotted in terms with the variables of Eqn.(4), as shown for toluene in Fig. 3.

A method is known whereby it is possible to determine separately the rate of exchange in each group.[67] For the initial section of the curve illustrated in Fig. 3, the quantity $k_\phi = k_A + k_B$, which corresponds to the overall rate of exchange in groups A and B, is found by equations of type (4). The second section of the curve, beyond the break, corresponds to the exchange of hydrogen in the less reactive group B (the exchange in group A has already terminated by this time). The constant $k_B$ for the second group of atoms can be found from the second section by means of the equation

$$k_B = \frac{\varphi_{B,\infty}}{t} \ln \frac{\varphi_{B,\infty} - \varphi_0}{\varphi_\infty - \varphi} .$$

However, for this purpose, it is necessary to know the quantity $\phi_{B,\infty}$ which corresponds to $\phi_\infty$ but refers only to the second group. The quantity $\phi_{B,\infty}$ is calculated from the relations

$$\varphi_\infty = \varphi_{A,\infty} + \varphi_{B,\infty} ,$$

$$\varphi_{A,\infty}/\varphi_{B,\infty} = n_A/n_B ,$$

where $n_A$ and $n_B$ are the numbers of hydrogen atoms in groups A and B respectively. The quantities $n_A$ and $n_B$ are found by analysing the molecular structure and the dynamics of the time variation of the concentrations of the various deuterio-products.[68] Thus it is possible to determine the rate of deuterium exchange in each of the groups A and B.

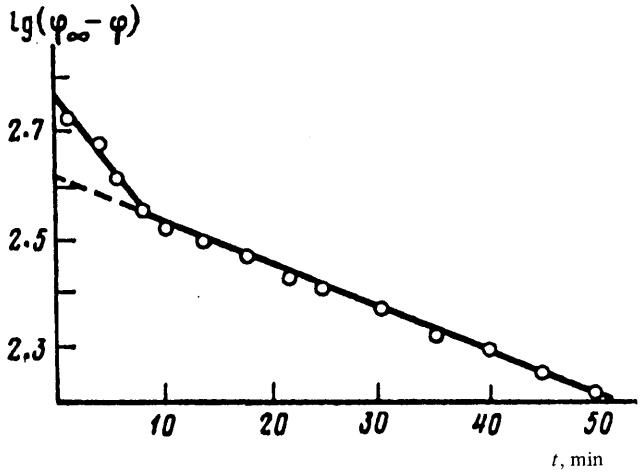

**Figure 3.** Time variation of the rate of deuterium exchange involving toluene in terms of the variables of Eqn.(4).[68]

The rates of exchange of the hydrogen atoms in the ring and in the side groups in alkylbenzenes have been measured by this procedure.[68,69] It is of interest that, whereas the rate of hydrogenation varied consistently as a function of the positions and numbers of the alkyl substituents, the rate of exchange within each group (in the ring and in the substituents) remained fairly constant for the entire series of compounds investigated. Correlations between the rate of exchange and the quantum-chemical quantities characterising the average population of the C–H bonds after the adsorption of hydrocarbons on nickel were found from these data:[70] the higher the population, the lower the rate of exchange.

The unequal reactivities of the α- and β-hydrogen atoms in the thiophen molecule[71] and of the hydrogen atoms in the methyl, methylene, and methylidyne groups in saturated hydrocarbons[72] were demonstrated in a similar way.

## III. ISOTOPE DISTRIBUTION

The determination of the isotope distribution in the reaction products is a widely used procedure, which is at the same time difficult to subject to a formal treatment. It is used in the study of catalytic processes involving deuterium. In each specific case different aspects of the distribution can be of greatest interest: the type of exchange (simple or multiple) in the initial and final products and the possible intermediates, the most probable site where deuterium enters the molecule, the dependence of the distribution

on the molecular structure, reaction temperature, other conditions, etc.

We shall examine initially the possibilities for the theoretical calculation of the isotope distribution in deuterium exchange products.

## 1. Calculation of the Distribution

Deuterium–hydrogen exchange processes are usually subdivided into simple and multiple. In the former case one hydrogen atom is substituted by deuterium in each reaction step and the quantity $M_D$ calculated by Eqn.(5) is unity. When $M_D > 1$, the occurrence of multiple exchange is indicated, where more than one hydrogen atom is replaced by deuterium in at least some of the molecules. When the molecule contains only equivalent hydrogen atoms, the simple exchange is a statistical process and is readily susceptible to calculation. Up to a certain degree of exchange $x$, the fraction of each isomer $d_i$, whose molecule contains $i$ deuterium atoms, can be found from the formula[73]

$$d_i = \frac{n!}{i!\,(n-i)!}\, x^i (1-x)^{n-i} \quad , \qquad (6)$$

where $n$ is the number of hydrogen atoms capable of exchange and $x$ the average fraction of hydrogen atoms in the hydrocarbon molecules substituted by deuterium. However, there exist compounds whose molecules contain groups of hydrogen atoms which are not equivalent as regards reactivity. Although the exchange in each group can be of the simple type, nevertheless one must not calculate the overall distribution of the deuterioisomers by Eqn.(6) in this instance. For such compounds, a method of calculating the distribution,[74] based on the statistical analysis of the independent exchange processes in two different groups A and B, has been developed. Agreement between calculated and experimental distributions is achieved by selecting the appropriate ratio of the rates of deuterium exchange in these groups $k_A/k_B$. If reliable independent evidence showing that the exchange does in fact proceed via a non-equivalent substitution mechanism is available, then $k_A/k_B$ can be calculated from the distribution data, i.e. the relative reactivities of different hydrogen atoms in a given process can be estimated quantitatively as a function of the process conditions.[74,75]

The situation is much more complex as regards the theoretical calculation of the distribution in multiple deuterium exchange. Attempts at such a calculation have been made,[76–79] but they are all based on an artificial selection of parameters, which are not determined directly from experimental data; their value is therefore fairly limited.

Another approach, namely the kinetic approach, has been used by Nekrasov et al.[80] The study of the kinetics of deuterium exchange makes it possible to find a series of rate constants $k_n$ for the formation of products with the composition $d_n$. Taking into account the statistical probabilities of the formation of the exchange products of the initial molecule $d_0$ and from molecules which have already been partly substituted, it is possible to derive an expression for the rate of formation of any deuterium-substituted molecule $d_n$, which assumes the following form when the molecule contains, for example, 12 equivalent hydrogen atoms:[80]

$$r_n' = k_n d_0 + \sum_{i=1}^{n-1} C_{12-i}^{n-i} \sum_{m=0}^{i} \frac{C_i^m}{C_{12}^{n-i+m}}\, k_{n-i+m} d_i \quad ,$$

where the symbol $C$ denotes the number of combinations. The equation for the rate of consumption of deuterium-substituted molecules can be obtained similarly:

$$r_n'' = \left( k_0 - \sum_{i=1}^{n} k_i C_n^i / C_{12}^i \right) d_n \quad .$$

The observed rate of accumulation of each product containing $n$ deuterium atoms is defined by the expression

$$r_n = r_n' - r_n'' \quad .$$

Knowing the constant $k_n$, the concentrations of all the deuterium-substituted products at any instance can be calculated by means of these equations. The experimental distribution of the products of the deuterium exchange involving cyclohexane on nickel[80] and platinum[81] agrees satisfactorily with the calculated distribution.

The distribution, redistribution, and transfer of isotopic atoms both in the "pure" exchange and under the conditions of the occurrence of another accompanying reaction have been subjected to mathematical analysis in a general form in a series of investigations.[82–85] Unfortunately this analysis has not so far found application in research, possibly because of its complexity.

## 2. The Use of Isotope Distribution Data

As can be seen from the foregoing discussion, analysis of the isotope distribution is of a specific character in each case and it is extremely difficult to achieve a general classification of the procedures used for this purpose. One can only conclude that the character of the distribution in deuterium exchange usually serves as an indication of a particular form of adsorption of the test compound. Simple exchange, which is typical for oxide catalysts, occurs in one-point adsorption, while multiple exchange, which is more characteristic of metals, presupposes multipoint adsorption.[86] Incidentally, both simple and multiple exchange can take place on metals depending on the size of the *ensembles*.[87] A noval concept concerning the mechanism of the deuterium exchange involving alkanes and alkenes on metals, based on the hypothesis of the formation of intermediates of the carbene type, has been recently proposed by Dolgoplosk and co-workers.[88]

It was already stated above that a monotonic isotope distribution curve is as a rule observed in those cases where the hydrogen atoms are approximately equivalent as regards their reactivities.[7,13,19,23,89] On the other hand, if the hydrogen atoms can be subdivided into separate groups differing in their positions in the molecule and reactivities, characteristic deviations from monotonic variation appear on the distribution curve, which has been observed, for example, in the exchange involving methyl-substituted aromatic molecules,[10,67–69] cyclohexane,[80,81] and other compounds.[20,51,72,75,90] Incidentally, one should exercise a certain amount of caution as regards this problem, because the non-uniformity of the distribution can be caused in some cases also by purely kinetic factors (for further details about this, see Vlasveld and Ponec[62] and Nekrasov et al.[81]).

Among the characteristics of deuterium exchange of more or less general importance, one may name also the lower degree of exchange involving unsaturated compounds compared with the related saturated hydrocarbons.[4,6,13,91] It is of interest that the deuteriation of olefins is usually accompanied by the appearance in the initial instant of the reaction of a considerable amount of saturated molecules with the composition $d_0$ and $d_1$,[4,91–93] although the simple insertion of deuterium in the double bond should have yielded

only $d_2$ molecules. This can be explained by the slowness of the dissociative adsorption of deuterium in the presence of unsaturated compounds and also by the addition to the adsorbed molecule of the protium evolved in the dissociative adsorption of other hydrocarbon molecules,[4] i.e. by the redistribution of hydrogen.

We shall now proceed to the consideration of specific examples illustrating the possibility of employing hydrogen isotope distribution data for the elucidation of the mechanisms of catalytic reactions.

The study of the thiophen hydrodesulphurisation reaction yielded fairly unexpected results, which led the authors[94] to the conclusion that the hydrogen sulphide evolved in the presence of deuterium does not have the composition $D_2S$, as should have been the case when sulphur is abstracted by deuterium, but $H_2S$. This served as a basis for the hypothesis of an intramolecular mechanism of this reaction, according to which the dissociation of the C–S bonds is followed by the addition to the sulphur atom of the less mobile β-hydrogen atoms of thiophen and the "external" hydrogen (deuterium) is consumed only in the hydrogenation of hydrocarbon residues. This hypothesis was, as it were, supported by data for the isotope composition of the hydrogen sulphide in the deuteriolysis of thiophen containing deuterium in the α-positions and hydrogen in the β-positions.[20] Examination of the mass spectrum also demonstrated in this instance that mainly hydrogen sulphide having the composition $H_2S$ is formed in the reaction. However, subsequent careful investigation under conditions including also low degrees of reaction, in which the very first portions of the hydrogenolysis products evolved were analysed, demonstrated that the conclusion concerning the intramolecular mechanism was incorrect.[95] In fact the main sulphur-containing product of the deuteriogenolysis of thiophen on five different hydrodesulphurisation catalysts proved to be $D_2S$. This was confirmed also by the analysis of the isotope composition of the products of the hydrogenolysis of perdeuteriothiophen. The intense mass-spectrometric peak corresponding to a mass number of 34 (which formally corresponds to the mass of $H_2S$) was indeed observed, but it was of secondary origin. Its appearance is probably associated with the hydrogenolysis of the thiophen decomposition products, because an increase in the degree of hydrogenolysis entails also an increase in this peak. The above example demonstrated the necessity to resort to the greatest possible amount of additional evidence in assessing the isotope distribution data.

Another example is associated with the skeletal isomerisation of n-pentane. The results of a kinetic study of this reaction suggested that it involves hydrogen, although the latter does not enter into the stoichiometric equation. As a test, the isomerisation of n-pentane on a platinum catalyst was carried out in the presence of deuterium.[23] It was found that the reaction product (isopentane) contains significantly more deuterium than was present in the initial n-pentane. This effect was shown even more strikingly on platinum–lead and platinum–copper catalysts.[24] These results served as important evidence in support of the hypothesis of the direct involvement of hydrogen in skeletal isomerisation. Similar evidence indicating the participation of hydrogen has also been obtained by the deuterium exchange method for the double bond migration reaction[96] and the *cis–trans* isomerisation of hydrocarbons.[96,97]

There are reactions which cannot be detected at all without an isotope label because of the identity of the chemical properties of the initial reactants and final products. Thus the metathesis of olefins, for example of propene:

$$2CH_3{-}CH{=}CH_2 \rightarrow CH_3{-}CH{=}CH{-}CH_3 + CH_2{=}CH_2, \quad (7)$$

must inevitably be accompanied also by a process in which the methylene group is replaced not by an ethylene group but by a methylene group from another molecule. The replacement of some of the molecules of normal propene by the deuteriated analogues makes it possible to detect this "degenerate" or "latent" metathesis:

$$CH_3{-}CH{=}CH_2 + CD_3{-}CD{=}CD_2 \rightarrow CH_3{-}CH{=}CD_2 + CD_3{-}CD{=}CH_2. \quad (8)$$

Furthermore, the metathetical reaction of ethylene, in which products of a different chemical composition cannot be formed in principle, becomes accessible to observation:[98–100]

$$CH_2{=}CH_2 + CD_2{=}CD_2 \rightarrow 2\,CH_2{=}CD_2, \quad (9)$$

The appreciable difference between the rates of the explicit and latent metathesis of propene [reactions (7) and (8)] compared with the rate of reaction (9) served as important evidence[100] in support of the view that the reaction proceeds under the conditions of heterogeneous catalysis via a carbene chain mechanism, which has been proved for homogeneous systems.[101] Deuterium-labelled olefins have been used also in the metathetical reaction for the study of its stereospecificity[102,103] and its relation with the isomerisation reaction[104,105] and also for the determination of the mechanism of the formation of the intermediate carbene complex.[106]

Not only the isotope distribution in the products as such but also the position of the deuterium atoms in the molecule is important for the elucidation of the mechanism of this and other reactions. The isotope distribution, i.e. the relative contents of different deuterium-containing molecules, is usually determined mass-spectrometrically, most frequently by analysing the spectrum of molecular ions. Other methods, including microwave spectroscopy,[12,107–110] NMR,[111–118] and infrared spectroscopy[19] are used to determine the location of deuterium atoms in the molecule.

The study of the detailed distribution of deuterium yielded valuable information about the mechanism of the isomerisation of hydrocarbons,[107,108,110] the hydrogenation of propene,[118] butadienes,[116] cyclopentene,[115] substituted cyclohexenes,[112] various ketones,[117] and ethers,[114] the selective hydrogenation of dimethylethynylmethanol,[111] the dehydrogenation of cyclohexanol,[19] and other reactions.[109,113]

However, in certain cases mass-spectromatic analysis also provides certain definite possibilities for the determination of the position of the deuterium atoms. The point is that the mass spectrum usually represents not only molecular but also fragment ions formed as a result of the abstraction of entirely definite groups, for example, methyl groups from the molecule. Comparison of the isotope compositions of the molecular and fragment ions can yield some information about the part of the molecule in which deuterium atoms are preferentially located. For example, Fig. 4 shows that the isotope distribution of the fragment ions of *cis*-1,2-dimethylcyclohexane, formed by the abstraction of one methyl group, exactly reproduces the distribution of the molecular ions and that characteristic breaks in the monotonic variation of one curve correspond to analogous breaks in the monotonic variation of the other.[119] Since the difference between the mass numbers of these characteristic points is 18, the implication is that the hydrogen in the abstracted methyl groups has been fully replaced by deuterium, i.e. that they have the composition $CD_3$. The difference between the isotope compositions of the methyl groups in *cis*- and *trans*-1,2-dimethylcyclohexanes observed from the mass spectra[97] served as confirmation of the hypothesis that the molecules are arranged in different ways on the catalyst surface.

Comparative analysis of the mass spectra of the molecular and fragment ions of 5-methylfurfural and the products of its simultaneous decarbonylation and hydrogenation, 2-methylfuran and 2,5-dimethylfuran respectively, made it possible to determine the way in which the molecules are adsorbed on the palladium catalyst and to elucidate important details of the reaction mechanisms.[120] A similar approach has been used also to separate the hydrogen atoms of ethylbenzene into groups differing in their reactivity.[68]

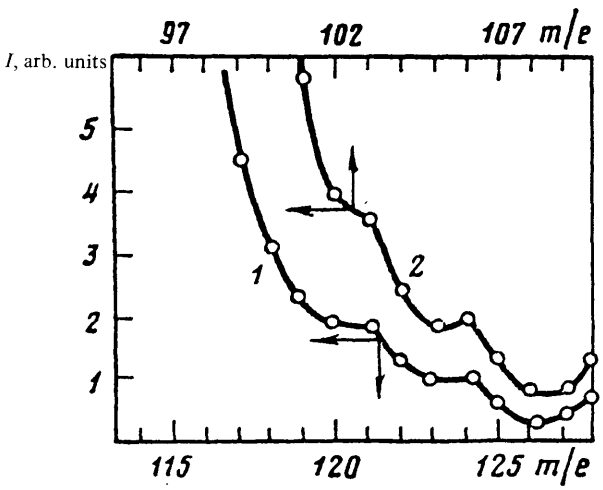

**Figure 4.** Isotope distribution of the products of the deuterium exchange involving *cis*-1,2-dimethylcyclohexane on platinum:[119] the intensities *I* of the peaks of the molecular (*1*) and fragment (*2*) ions.

Sometimes the intensity of the molecular ion peaks is so low that the isotope composition must be wholly estimated from fragment ions.[19]

One of the widely used procedures in isotope investigations involves the study of the reactions of certain compounds on the surface of a catalyst subjected to a preliminary treatment with deuterium. Information about the active centres on alumina catalysts,[121–125] niobium hydride,[126] molybdenum disulphide,[127] aluminosilicates,[122] and zeolites[128] has been obtained by this procedure. Evidently, this method is particularly useful for the study of catalysts with acid or basic centres but it is also useful in the study of the mechanisms of reactions on metals. Thus it has been shown[129,130] that intense deuterium exchange involving benzene takes place in the absence of deuterium from the gas phase on the surface of a nickel catalyst saturated with deuterium, but deuteriation hardly occurs.

Only after the introducton of deuterium into the gas phase, is the rapid formation of cyclohexane observed. Consequently hydrogen in a molecular form must participate in the benzene hydrogenation reaction, while in deuterium exchange it is involved in an atomic form, which confirms the mechanism proposed previously.[7]

There exist many other examples of the use of isotope distribution data for the investigation of the mechanisms of catalytic processes. We shall mention only some of them. Comparison of the observed calculated isotope distributions of the products on the hypothesis of a particular mechanism has been suggested[131] as a procedure for the determination of the rate-limiting stage of a process consisting of a series of parallel-consecutive reactions. The calculated and observed distributions have also been compared in the study of the hydrogenation of methylacetylene on platinum-group metals:[132] complete agreement between the calculated and experimental data has been noted only for reactions on palladium, platinum, and nickel.

Isotope distribution data have led to conclusions about the associative mechanism of the hydrogenation of methylene on magnesium oxide[133] and the involvement of dissociatively adsorbed intermediates in olefin hydrogenation reactions on the $Al_2O_3$ catalyst[134] and in their isomerisation on iron.[135] Data have also been obtained for the mechanisms of the selective hydrogenation of conjugated dienes,[91,136] the hydrogenation[137–139] and isomerisation[139,140] of olefins, the hydrogenolysis of paraffins,[141,142] and the dehydrogenation of n-decane[17,18] and isobutane[143] on platinum catalysts. A not altogether usual instance of the slow exchange involving a saturated hydrocarbon (isobutane) on a metal up to a fairly high temperature (400 °C) and conversely a rapid exchange involving an olefin (isobutene) has been observed.[143] These data and also comparison of the isotope distributions in the initial and final products led to the conclusion that the dissociative adsorption cannot be the slow stage of the dehydrogenation reaction in this instance.

Analysis of the isotope distribution in the methane and ethylene formed when carbonaceous deposits on the $Co/Al_2O_3$ and Co/C catalysts are treated with deuterium showed that they include both the $CH_2$ fragments and carbide carbon.[144] The adsorption-chemical equilibrium involving methane on nickel has been studied by a similar procedure with the aid of perdeuteriomethane.[145]

## IV. KINETIC ISOTOPE EFFECT

Measurement of the kinetic isotope effect (KIE) is the simplest way of using deuterium for the study of catalytic reactions. Here there is no need to determine the isotope composition and hence there is no need to employ the mass-spectrometric or another complex analytical method. One compares the rate of the reaction with participation of the usual reactants with its rate after the replacement of hydrogen by deuterium in one or several components or in specific sites in the initial molecule: the non-identity of these rates indicates the involvement of the corresponding hydrogen atoms in the slow stage of the reaction. However, in practice the measurement of the KIE is associated with certain difficulties.

The theory of kinetic isotope effects in homogeneous systems has been fairly highly developed,[146] which unfortunately cannot be said of heterogeneous-catalytic processes. This is not an appropriate place for the consideration of the theoretical aspects of the problem and it is sufficient to say that, in the measurement of the KIE in heterogeneous catalysis, one may encounter, apart from the trivial experimental errors associated, for example, with the different degrees of purification of the deuteriated and non-deuteriated reactants, also difficulties due to the incorrect estimation of the reaction rates, the deactivation of the catalyst, the influence of side processes, an incorrect interpretation of the reverse effects, their dependence on temperature, etc.

The kinetic isotope effect is characterised by the ratio $\beta$ of the rates of the processes occurring with participation of the light and heavy isotopes under identical conditions and for the same composition of the reaction mixture (for identical degrees of reaction):

$$\beta = r_H/r_D .$$

If the kinetic equation for the reaction is known and the rate constants involved in it has been determined for the reactions with participation of hydrogen and deuterium, then the constancy of the degree of reaction is not an obligatory condition, because the rate of reaction can be easily calculated for any composition. However, as a rule, such data are not available and the failure to meet this requirement may be a source of errors. In the case of kinetic power equations the ratio of the rates is equal to the ratio of the rate constants.

The reverse values of the KIE, i.e. the increase and not the decrease of the rate of reaction following the replacement of the light isotope by the heavy isotope, at first sight conflict with the elementary theory of isotope effects based on the transition state method.[146] This phenomenon has been explained[147] by the multistage nature of the hetereogeneous-catalytic processes and the swamping of the decrease of the rate in the slow stages by the shift of the equilibrium in the fast stages, including the adsorption and desorption stages, and also by the specific shift of the zero-point energy levels of the activated complexes in the slow stages on isotope substitution. We may note that, in principle, one cannot rule out the complete compensation of the forward effect by the reverse effect, which would outwardly appear as the absence of a KIE. It is therefore useful to carry out measurements under different conditions by altering, for example, the temperature.

The true KIE, i.e. the change in the rate constant for the slow stage after the replacement of one isotope by another, can be masked by the thermodynamic effects of the preceding fast stages. The change in the contribution to the overall process by side reactions whose rates are different in the presence of hydrogen and deuterium can also be reflected in the observed KIE for the reaction investigated.[148]

As a result, for the same reaction under similar conditions, different investigators have frequently obtained markedly different values of the KIE. Thus in a study of the hydrogenation of benzene on the $Ni/SiO_2$ catalyst at 240 °C, measurements were made of the rates of the following reactions:

$$C_6H_6 + 3H_2 \xrightarrow{r_1} C_6H_{12},$$
$$C_6H_6 + 3D_2 \xrightarrow{r_2} C_6H_6D_6,$$
$$C_6D_6 + 3D_2 \xrightarrow{r_3} C_6D_{12},$$
$$C_6D_6 + 3H_2 \xrightarrow{r_4} C_6H_6D_6.$$

The following values of the KIE were obtained: $r_1/r_2 = 0.60$, $r_1/r_4 = 0.53$, $r_4/r_3 = 0.55$, and $r_1/r_3 = 0.28$. On the other hand, in another study[149] the KIE obtained on a similar catalyst at 85 °C were respectively 0.7, 1.1, 0.8, and 0.9. Evidently the discrepancies are fairly considerable, particularly for the ratio $r_1/r_4$ and $r_1/r_3$. This may be partly associated with the difference between the temperatures; for example, according to Kiperman et al.[7], the ratio $r_1/r_2$ changed from 0.60 to 0.51 when the temperature increased from 240° to 270 °C. If the comparison has been made solely on the basis of only one ratio, for example $r_1/r_4$, then the results obtained in the two studies[7,149] might have led to opposite conclusions. The authors' interpretations in the two cases are based on fairly extensive experimental data and the role of random conclusions is reduced to a minimum. One can therefore assume that at 240 °C, i.e. in the region where the reaction is reversible, the ratio of the rates of the individual stages is different than at 85 °C, where "pure" hydrogenation takes place.

In the reverse reaction involving the dehydrogenation of cyclohexane, the replacement of hydrogem by deuterium in $C_6H_{12}$ led to the observation of the direct KIE ($\beta = 2.3$ at 293 °C).[7]

On the platinum catalysts, the rates of hydrogenation of benzene were identical whatever the combination of the deuteriated and light molecules, i.e. there were no KIE.[149] However, one should note that the measurements were performed at only one temperature (85 °C). Comparison of the rates of the exchange reactions in the $C_6H_6 + D_2$ and $C_6D_6 + H_2$ systems showed that the KIE is then fairly large and that $\beta$ ranges from 6.0 to 7.0 on both nickel and platinum.[149]

An example of the discrepancies between the estimates of the KIE can also be provided by the data of an investigation[100] where the disproportionation of propene on rhenium oxide was studied and of one[106] where the same reaction was carried out on a molybdenum catalyst. In the former case no KIE was observed, while in the latter the rate of reaction changed in the presence of deuterium at specific sites in the molecule. The absence of the KIE in the hydrogenolysis of n-pentane on platinum and nickel[23] conflicts with the significant isotope effect in the hydrogenolysis of various paraffins on the oriented crystal faces of platinum.[150]

The reverse KIE are not rare in hydrogenation reactions when $H_2$ is replaced by $D_2$.[147] They have been noted in the hydrogenation of acetone,[151] toluene,[10] and 2-methylfuran [152] on nickel and of 5-methylfurfural on palladium,[120] in the reaction between methane and carbon monoxide on the ruthenium,[153] nickel,[154,155] and palladium [156] catalysts, and in the synthesis of methanol on the $ZnO-Cr_2O_3$ and $Cu-ZnO-Al_2O_3$ catalysts.[157] The reverse KIE in the hydrogenation of benzene was already mentioned above. However, the manifestation of the reverse KIE in hydrogenation can be in no way regarded as a general rule. Reverse KIE have been observed, for example, in the hydrogenolysis[150] and skeletal isomerisation[23,150] of paraffins on platinum. On the other hand, the direct effects have been observed in the hydrogenation of isoprene,[13] hexene,[21] cyclopentadiene,[91] mesityl oxide,[15] and dimethylethynylmethanol [111] on various palladium catalysts, of cyclohexanone on the copper–magnesium catalyst,[19] of isoprene on the calcium–nickel phosphate catalyst,[6] and of piperylene on the NaY zeolite.[158] In all the studies quoted the occurrence of the KIE was regarded as evidence for the involvement of hydrogen in the slow stage of the reaction. On the other hand, the absence of the KIE in the hydrogenation of n-decane,[17] the dehydrogenation of cyclohexanol $C_6H_{11}OD$,[19] the hydrogenolysis of thiophen[20] and n-pentane,[23] and the disproportionation of propene[100] is regarded as proof that hydrogen is not involved in the slow stages of these processes.

The measurement of the KIE when hydrogen is replaced by deuterium in specific positions in the molecule constitutes a very effective procedure. This makes it possible not only to infer the very fact of the involvement of a bond with hydrogen in the slow stage of the reaction, but also makes it possible to determine the location of such bonds. For example, a KIE has been observed in the hydrogenation of toluene when fully deuteriated or ring-deuteriated molecules were made to react (the values of $\beta$ at 216 °C were 0.73 and 0.85 respectively), whereas the KIE was absent when hdyrogen was replaced by deuterium in the methyl group,[10] i.e. as was to be expected, the hydrogen in the methyl groups is not involved in the slow stage.

In the study of the *cis–trans* isomerisation of mixtures of *cis*-but-2-enes having the compositions $C_4H_8$ and $C_4D_8$ and also of $CH_3CDCDCH_3$ and $C_4D_8$ on aluminophosphate catalysts, an appreciable KIE was observed ($\beta \cong 2.5$).[140] On the

other hand, the coisomerisation of a mixture of *cis*-but-2-enes $C_4H_8$ and $CH_3CDCDCH_3$ took place without an isotope effect. Hence follows the conclusion that the methyl groups of but-2-ene participate in the slow stage.

Similar examples are known also for oxidation reactions. In the extensive oxidation of perdeuteriopropene and propene having the formula $CD_3CHCH_2$ on the irridium catalyst, a large isotope effect was observed following the oxidation of $CH_3CDCH_2$ and especially $CH_3CHCD_2$ molecules. $\beta \cong 1$ was obtained.[159] Consequently the slow stage of this reaction involves the dissociation of a C–H bond in the methyl group. Comparison of the rates of oxidation of the methanols $CH_3OH$, $CH_3OD$, and $CD_3OD$ to formaldehyde on molybdate catalysts also showed that here the rate-limiting stage is the abstraction of hydrogen from the methyl group.[160] The dissociation of a C–H bond also limits the rate of oxidation of butanol on platinum,[161] because a KIE was observed only in the presence of deuterium in the hydrocarbon component of the molecule but not in the hydroxy-group.

The extensive oxidation reactions of cyclohexene, acetaldehyde,[161] and formic acids[162] on platinum also occurred with a large isotope effect. On the other hand a KIE was not observed in the oxidation of acetic acid,[162] benzene,[161] and aniline.[163]

As already mentioned, the magnitude of the KIE depends on the reaction temperature: $\beta$ usually approaches unity as the temperature increases,[15,24,150] but a linear increase of the KIE has also been observed—in the reaction between methane and carbon monoxide on the nickel catalyst.[155] The temperature dependence of the KIE in the hydrogenolysis and isomerisation of saturated hydrocarbons has been studied.[150] The pressure of the reactants can also influence the magnitude of the effect.[148,150] A change in the sign of the effect, from direct to the reverse, has been observed with decrease of the ratio $H_2(D_2)$/hydrocarbon in the dehydrocyclisation of isooctane on platinum.[148,164] This emphasises yet again that it is insufficient to measure the KIE under only one set of arbitrarily selected conditions.

-o0o-

To what has been said above, we may add that an important feature of many studies carried out in recent years is the use of isotope methods in combination with other procedures for the investigation of the mechanisms of catalytic reactions. This results in a mutual enrichment of their possibilities and promotes a deeper understanding of the characteristics of the reactions of organic molecules on the surfaces of catalysts. In particular, analysis of the isotope composition of the products formed when hydrogen is replaced by deuterium has been applied successfully to the study of catalysis by the thermal desorption and programmed temperature reaction methods[165–167] and also by the mass spectrometry of secondary ions.[168] The use of deuterium in the study of the mechanisms of catalytic reactions by the non-stationary response method has also proved very useful.[148]

The great interest aroused in the mechanism of catalysis will undoubtedly promote a wider adoption of isotope methods involving the use of deuterium, especially in combination with other procedures.

# Computer Chemistry

A.A.Ovchinnikov and A.I.Boldyrev

The state, problems, and prospects of a new branch of chemistry, computer chemistry, associated with the application of computers to the solution of chemical problems is described. The application of computers in quantum chemistry, in solution theory, in the search for new medicinal drugs, in the identification of chemical compounds from spectroscopic data, and in the development of the syntheses of new chemical compounds is examined. The level of the problems solved in the above fields of computer chemistry is demonstrated for specific examples.
The bibliography includes 64 references.

## I. INTRODUCTION

We are now witnessing a major revolution in natural sciences associated with the wide-scale introduction of computers into all their branches, both experimental and theoretical. This process has taken place particularly vigorously during the last decade, a period during which there has been a considerable growth in the manufacture of fast computers and virtually all those investigators who are interested have gained access to powerful computers. The most important consequence of the introduction of computers into natural sciences has been the appearance of new branches of these sciences. Thus, together with experimental and theoretical physics, computer physics has appeared and in chemistry we have computer chemistry.† The time when we shall be able to speak of computer biology is apparently not distant. Whereas until recently there existed two ways of securing knowledge, either by carrying out experiments or by creating a theory, nowadays one may speak of the appearance of a third way associated with the use of computers.

The study of the physical and chemical properties of molecules, atoms, radicals, and ions in the gas, liquid, and solid phases with the aid of computers is the subject of computer chemistry. Some experience has already been gained in the solution of these problems with the aid of computers and in this review we shall characterise briefly the level of the problems solved at present by the methods of computer chemistry and we shall discuss the advances, problems, and prospects of this branch of science.

## II. QUANTUM CHEMISTRY

Computer quantum chemistry constitutes the most developed branch of computer chemistry. Quantum chemists were some of the first to initiate the use of computers in their research; as a result, quantum chemists engaged in calculations are as a rule highly qualified programers and quantum-chemical programs are some of the most complex among scientific and technical programs# together with programs for nuclear physics and programs for the calculation of the trajectories of space devices.

The need to use computers in quantum chemistry is due to the fact that, although the Schrödinger equation has been known for more than fifty years, nevertheless it has been possible to solve it analytically only for the simplest cases—the hydrogen atom and the $H_2^+$ molecular ion. Successful quantum-chemical calculations involve the use of a whole series of approximations for the solution of the Schrödinger equation. Nevertheless, even the approximate equations obtained for any complex atoms and molecules can be solved only with the aid of computers. The most logical methods in quantum chemistry are the non-empirical (or *ab initio*) methods. This term is understood to embrace a fairly wide set of approximate methods for the solution of the Schrödinger equation for atoms and molecules. It is not fortuitous that the Latin term "*ab initio*" which can be translated as "from the beginning" has found extensive applications in all languages for the designation of these computation methods, because it emphasises that the *ab initio* methods do not use any additional experimental data (ionisation potentials, atomisation energies, etc.) apart from fundamental physical constants (the velocity of light, the Planck constant, and nuclear and electronic charges and masses) and have been devised on the basis of the Schrödinger method by introducing various physically justified approximations. By the successive abandonment of such approximations, it is possible to increase the rigour and accuracy of these calculations.

The simplest version of the *ab initio* approach consists in the solution of the system of Hartree–Fock–Roothaan (HFR) equations:

$$\sum_{\nu=1}^{n} c_{i\nu}(F_{\mu\nu} - \varepsilon_i S_{\mu\nu}) = 0, \text{ where } \mu = 1 \ldots n \ . \qquad (1)$$

In this approach the wave function is used in the form of a Slater determinant and the delocalised molecular basis orbitals (MO) are expanded in terms of one-centre atomic orbitals (AO) and the self-consistent field approximation is employed:

†A series of international journals (Computers and Chemistry, Journal of Computational Chemistry, and Journal of Chemical Information and Computer Sciences), devoted to computer chemistry are already being published.

#For example, the GAUSSIAN-80 program consists of one hundred thousand FORTRAN operators.[1]

$$\Psi^{MO} = \sum_{\mu=1}^{n} c_\mu \varphi_\mu . \qquad (2)$$

At the present time there are already tens of non-empirical programs applying the HFR method. Among foreign programs, these are GAUSSIAN, HONDO, IBMOL, POLYATOM, MOLECULE, DISCO, and others while among Soviet programs mention may be made of SPUSH) Moscow State University, KVANT (Institute of General Chemistry of the USSR Academy of Sciences), and others.

It is at present difficult to estimate what are the largest molecular systems susceptible to calculations by the HFR method. Fairly accurate calculations for molecules of the type $C_6F_6$ are possible even on minicomputers of the NORD-500 type.[2] Naturally, on large computers the scope for calculations is significantly greater and calculations have already been made for the $Fe[C_5(CH_3)_5]_2$ molecule[3] containing 51 atoms and 176 electrons, a complex of the prophyrin ring with an iron atom and an ammonia molecule adsorbed on it,[4] and a cluster of 13 copper atoms.[5]

In the limiting case where the basis set of AO is complete, it is possible to obtain by this method the exact total Hartree–Fock energy of the molecule, which constitutes a fairly good approximation to the exact non-relativistic value ($\geqslant$99.9% of the exact value). However, the residual error is comparable to the energies of chemical bonds and the HFR method therefore provides a poor description of the dissociation energies of chemical bonds. The example involving the dissociation energy of the $F_2$ molecule, where the HFR method yields a negative value, is well known. Nevertheless, many molecular characteristics can be obtained with satisfactory accuracy in calculations by the HFR method. The experience gained in calculations for several hundreds of molecules, ions, and radicals has shown that in this approach the calculated equilibrium intermolecular distances as a rule differ from the experimental values by 0.02–0.05 Å, the valence angles differ by 1–3°, the force constants differ by 10–15%, the vibration frequencies differ by 5–10%, the energies of isodesmic reactions, in which the number of bonds is kept constant (for example, HCCH + $H_2$ → $H_2CCH_2$), differ by 5–10 kcal mol$^{-1}$, the barriers to intramolecular rearrangements differ by 2–5 kcal mol$^{-1}$, the valence ionisation potentials differ by 1–2 eV, and the dipole moments differ by 0.2–0.5 D.[6–8] These data show that the HFR method is entirely suitable for semi-quantitative estimations of many molecular characteristics. Although the cost of calculations by the HFR method is still high, nevertheless, bearing in mind that the calculations yield a large number of molecular characteristics which are not accessible simultaneously to any one experimental method, such calculations may be justified economically.

The second group of computational *ab initio* methods, which have developed particularly vigorously during the last five years, makes it possible in principle to obtain a virtually exact solution of the non-relativistic Schrödinger equation. In these methods account is taken of the correlation energy of the electrons, which is equal to the difference between the Hartree–Fock energy and the exact non-relativistic adiabatic energy of the molecule. A large set of such methods, both methods adapted for the solution of specific problems such as the calculation of ionisation potentials and electron affinities (the method of Green functions, the method of equations of motion, etc.) and more general computational methods for the calculation of the total energy and the wave function (the method of configuration interaction, the multiconfiguration self-consistent field method, and perturbation theory), have now been developed.

The configuration interaction (CI) method is most frequently used to take into account the electron correlation energy in *ab initio* calculations.[9–11] In it the total wave function is formulated as a linear combination of Slater determinants corresponding to different electronic configurations:

$$\Psi_{tot} = \sum_{k=1}^{M} a_{kl}\varphi_k , \qquad (3)$$

where $M$ is the number of configurations taken into account. The calculation reduces to the computer solution of the following system of equations:

$$\Sigma a_{kl}(H_{kl} - E_l\delta_{kl}) = 0 . \qquad (4)$$

In calculations by the CI method several approaches are used for the selection of the configurations to be taken into account. One of the approaches, involving a limited CI expansion (3), is based on the estimation of the coefficients $a_{kl}$ in terms of perturbation theory. Only the determinants whose coefficients $a_{kl}$ are greater than a certain quantity are then left in expansion (3). In this approach it is possible to select the most significant configurations and, using not unduly long expansions, account can be taken of most of the electronic correlation energy.[11] Another approach, in which account is taken of the complete set of configurations of any type, for example singly and doubly excited configurations (CI-SD) or only doubly excited configurations (CI-D), is also widely used.[12] This method of taking into account the correlation energy uses the fact that electrons are mainly correlated in pairs. Indeed, in CI-SD and CI-D calculations it is possible to include 85–95% of the valence correlation. Many programs using this CI method are now available; the first approach is employed, for example, in the SPUSH (Moscow State University) program and the second in the GAUSSIAN-80 program.

Another widely used method whereby the electron correlation energy is taken into account is that of perturbation theory (PT).[12–14] This approach is based on seeking the solution of the exact Schrödinger equation:

$$H\Psi = E\Psi$$

on the basis of the known solutions of the Schrödinger equation

$$H^{(0)}\varphi^{(0)} = E^{(0)}\varphi^{(6)}$$

with a model Hamiltonian $H^{(0)}$ which differs from the exact equation by a small perturbation $W$. The wave function $\Psi$ and the energy $E$ are sought in the form of the series

$$\Psi = \varphi^{(0)} + \varphi^{(1)} + \varphi^{(2)} + \ldots$$
$$E = E^{(0)} + E^{(1)} + E^{(2)} + \ldots .$$

In quantum-chemical calculations the Hartree–Fock–Roothaan Hamiltonian is chosen as $H^{(0)}$ and the perturbation $W$ is the operator describing the electronic correlation:

$$W = \sum_{i>j} \frac{1}{r_{ij}} - \sum_{i>j} (2J_{ij} - K_{ij}) .$$

For this choice of $H^{(0)}$ and $W$, $E^{(1)}$, i.e. the first correction to the electronic energy of the molecule, vanishes and the first non-zero contribution comes from the second-order perturbation theory (the energy $E^{(2)}$).

The contributions to the energy by each order of the perturbation theory can be formulated by means of a diagrammatic representation, which has proved extremely useful for the construction of algorithms for the corresponding program. Because of this, programs taking into account fully four PT orders were devised immediately in several laboratories in the world. One such program is the POLYCOR program developed at the Bratislava university (Czechoslovakia); the Gaussian-82 program, developed at the Carnegie-Melon university (USA), also includes the corresponding set of subprograms. It is of interest to discover how rapidly the

members of the PT series diminish. Table 1 presents the corrections to the total energies of the $LiBH_4$ and $Li_2BeH_4$ molecules arising from the second-, third-, and fourth-order perturbation theories. We may note that a slow decrease of the members of the PT series might have been expected for these molecules owing to the quasidegeneracy of the 2*s* and 2*p* shells of the Be and B atoms. Nevertheless, Table 1 shows that successive members of the PT series decrease rapidly. For the $LiBH_4$ and $Li_2BeH_4$ molecules, the contribution by the second-order perturbation theory is 90–95% of the valence correlation energy and calculations for the HF, $H_2O$, and BH molecules have shown[16,17] that the sum of the contributions by the second-, third-, and fourth-order perturbation theories takes into account 98–99% of the valence correlation energy. It must be emphasised that, for molecules having low-lying excited states, the PT series can diverge, as happens, for example, for the $C_4$ molecule.[18]

**Table 1.** The contributions to the total energies of the $LiBH_4$ and $Li_2BeH_4$ molecules by different orders of perturbation theory.[15]*

| Molecule | $E^{HFR}$, a.u. | $E^{(2)}$, a.u. | $E^{(3)}$, a.u. | $E^{(4)}$, a.u. |
|---|---|---|---|---|
| $LiBH_4$ | −34.4535 | −0.1379 | −0.0211 | −0.0068 |
| $Li_2BeH_4$ | −31.8522 | −0.0787 | −0.0178 | −0.0063 |

*DE + P + D basis set.

Since we are unable to consider other methods for taking into account the electronic correlation energy, we shall deal briefly with the new possibilities provided by *ab initio* methods with allowance for electronic correlation in quantitative calculations of molecular characteristics.

*Ionisation potentials.* The results of the calculations of ionisation potentials (IP) by the method of Green functions have been summarised[19] and it has been concluded that the maximum error in the calculated IP is between 0.1 and 0.25 eV depending on the basis set used in the calculations. Table 2 presents the calculated experimental IP of the ethylene molecule as a typical example.

**Table 2.** Calculated* and experimental ionisation potentials (eV) of the ethylene molecule.[20]

| Symmetry of MO | Calcn. | Expt. |
|---|---|---|
| $1b_{2u}$ | 10.44 | 10.51 |
| $1b_{2g}$ | 13.04 | 12.85 |
| $2a_g$ | 14.70 | 14.66 |
| $1b_{3u}$ | 16.07 | 15.87 |

*The time required to calculate one ionisation potential by the method of Green functions on the IBM 360/91 computer is only 4–5 min.

*Electronic transition energies.* Either the standard CI method or the CI method based on several initial configurations (CI-SIC) are most often used to calculate the electronic transition energies. As for the ionisation potentials, here the error in the determination of the energies of vertical electronic transitions does not exceed 0.1–0.2 eV and is in fact within the limits of the error of their experimental determination. As an example, Table 3 presents the calculated electronic transition energies for the *trans*-butadiene molecule.

**Table 3.** The energies of the electronic transitions (eV) in the *trans*-butadiene molecule.[21]

| Symmetry of state | Calcn.* | Expt. |
|---|---|---|
| $^3B_u$ | 3.31 | 3.2; 3.22; 3.3 |
| $^3A_g$ | 4.92 | 4.93; 4.9; 4.8 |

| $3^1A_g$ | 7.53 | 7.481 |

*Calculation by the CI method taking into account all the valence-excited configurations.

*Dissociation energies.* It is known that the determination of the dissociation energies of molecules to within the experimental accuracy presents the greatest difficulty for *ab initio* calculations. Table 4 lists the dissociation energies of certain molecules for which the HFR method introduces large errors; however, it is seen that allowance for the correlation energy within the framework of perturbation theory diminishes the errors in the calculated dissociation energies of these molecules to approximately 5 kcal $mol^{-1}$. These results show that, for small moelcules and especially for radicals, ions, and other chemically active species, whose experimental study involves considerable difficulties, computer calculation can constitute an alternative approach to the determination of their dissociation energies.

**Table 4.** The calculated and experimental dissociation energies (kcal $mol^{-1}$) of the $H_2$, $N_2$, and $NH_3$ molecules.[22]

| Method* | $H_2 \rightarrow 2H$ | $N_2 \rightarrow 2N$ | $NH_3 \rightarrow N + 3H$ |
|---|---|---|---|
| HFR | 83.7 | 114.8 | 200.8 |
| HFR + PT(2) | 103.7 | 231.2 | 290.5 |
| HFR + PT(2-3) | 107.2 | 207.7 | 288.1 |
| HFR + PT(2-4) | 108.1 | 223.6 | 292.4 |
| Experiment | 109.4 | 228.4 | 297.3 |

*PT(2), PT(2–3), and PT(2–4) are corrections to the correlation energy calculated within the framework of second-, second- and third-, and second, third-, and fourth-order perturbation theory respectively.

*Vibration frequencies.* At the present level of the accuracy of the calculations of vibration frequencies, one may hope to achieve results with an error of 1–2%. Table 5 lists the fundamental frequencies of the water molecule calculated by the CI method for several configurations.

Table 5. The calculated and experimental fundamental vibration frequencies ($cm^{-1}$)* of the $H_2O$ molecule.[23]

| Method of determination | $\nu_2$ | $\nu_1$ | $\nu_3$ |
|---|---|---|---|
| MC-CISD* | 1623 | 3667 | 3752 |
| Experiment | 1595 | 3657 | 3756 |

*The method of configuration interaction based on an initial multiconfiguration function.

*Equilibrium geometrical parameters.* Allowance for the correlation energy makes it possible to increase the accuracy of the determination of the calculated geometrical parameters to within 0.01 Å for internuclear distances and 0.1° for valence angles. Such accuracy in the above quantities is comparable or even greater than the accuracy of their determination for molecules, radicals, and ions with more than two atoms.

The high accuracy of the *ab initio* calculations of many molecular characteristics has made them a powerful instrument, independent of experiment, for the investigation of molecules and the application of these methods has significantly expanded our ideas. We shall quote only two examples. In chemistry one of the firmly established postulates is that the maximum valence of carbon is four and, in relation to univalent ligands, its maximum coordination number is therefore also four. However, in 1982–1983, Schleyer and co-workers[24,25] predicted by means of *ab initio* calculations the existence of the stable molecules $CLi_5$ and $CLi_6$. In their equilibrium configurations these molecules have the structure of a regular trigonal bipyramid and an octahedron respectively. In addition, on the basis of non-empirical calculations, Schleyer and co-workers concluded that the hyperlithium molecules $NLi_5$, $OLi_5$, $NLi_4$, $OLi_4$, $FLi_4$, $OLi_3$, $FLi_3$, and $FLi_2$ and also the hypersodium molecules $ONa_3$, and $ONa_4$ are stable with respect to unimolecular dissociation.[24–26] The existence of some of these molecules has been confirmed experimentally. Thus the $CLi_5$ molecule has been detected mass-spectrometrically in the interaction of $CCl_4$ with lithium atoms in the gas phase. When lithium atoms diffused through a graphite membrane, $CLi_6$ and $CLi_5$ were also detected mass-spectrometrically. Mass-spectrometric measurements also led to the detection of $OLi_5$, $OLi_4$, $ONa_3$, and $ONa_4$ (for further details, see Schleyer[25]). The theoretically predicted discovery of this new class of hyperlithium and hypersodium molecules has extended our ideas concerning the possible valence states and coordination numbers of atoms and molecules.

Non-empirical calculations of the potential surfaces for a large number of structurally non-rigid molecules showed that our ideas about molecular structure are limited. The point is that modern ideas about molecular structure constitute a complex conglomerate of quantum and classical concepts. Whereas the concept of wave functions has been rapidly introduced into chemistry for the description of the electronic subsystem of the molecule as the foundation of quantum mechanics, for the nuclear subsystem the classical description has to a large extent persisted to this day. There are objective reasons for this: in the first place these are the much greater mass of the nuclei and the shape of the potential surfaces (PS) for many molecules, where a deep minimum in the PS corresponds to the equilibrium configuration (in this case one minimum on the PS is sufficient for the description of the molecular structure). For the lowest vibrational levels of such molecules, a quasi-rigid rotator–harmonic oscillator model is satisfactory. This molecular model makes it possible to retain all the classical ideas concerning the length, energy, and force constant of the chemical bond and the subdivision of all interactions into valence and non-valence types. For quasi-rigid molecules, the vibration amplitudes of the nuclei are small compared with the chemical bond lengths and the transition from the classical sphere-rod or sphere-spring model to the quantum model by the introduction of nuclear density functions does not lead to any significant modification of the classical ideas.

Nevertheless it is clear that the quantum nature of nuclei must be manifested in the molecular structure and for many problems it is essential to resort to the nuclear density functions. One can indicate several fields where the introduction of the concept of nuclear density functions is necessary for the description of the structure. In the first place these are highly excited vibrational states and "activated" or "transition" complexes in reactions. Finally, there exists a large class of molecules for which the approach restricted to one minimum in the PS is insufficient even for the lowest vibrational levels. These are the so-called structurally non-rigid or polytopic molecules on the PS of which there are at least several minima having similar energies and separated by low barriers. Such molecules have been known since the 1930s; they include organic molecules in which there is a possibility of hindered rotations about single bonds, amines in which inversion takes place, pentacoordinate $MX_5$ molecules with pseudorotation, etc. However, in these molecules "movements" with a large amplitude occur between atoms which are not linked by valence bonds and the classical subdivision of interactions into valence and non-valence types is not therefore infringed.

Non-empirical calculations of the PS for tens of molecules have shown[27] that large-amplitude movements (of the order of the chemical bond length) of molecules are possible also for atoms which are linked by valence bonds from the classical standpoint. The movements of the $Li^+$, $Na^+$, and $K^+$ cations around the $CN^-$, $BH_4^-$, and $BF_4^-$ anions,[28–33] rearrangements with intramolecular decomposition of anions in the salts $Li_2BeH_4$ and $Li_2BeF_4$,[34,35] and the intramolecular movement of the $H^+$ cations along the carbon skeletons of carbonium ions[36] and of $H^-$ anions along the beryllium and boron skeletons of hydroberyllates and hydroborates[37] may be quoted as examples. In order to describe such molecules, it is necessary to consider large regions of PS along "non-rigid" coordinates. In the vibrational adsorption spectra the lines are split owing to tunnelling through low barriers[38] and the vibrational states of these molecules must be classified in terms of irreducible representations of either the complete transposition-inversion groups or their subgroups. Curves describing the temperature variation of the thermodynamic functions of structurally non-rigid molecules show inflections and the rigid rotator–harmonic oscillator must not be used to calculate the thermodynamic functions. However, the presence of a number of maxima in the nuclear density function greater than the number of atoms in the molecule, which cannot be described within the framework of classical ideas, must be recognised as the most unusual manifestation of the structural non-rigidity of molecules.

The examples presented show that computer quantum chemistry provides an alternative approach to the study of molecules and makes it possible to discover new classes of molecules, to achieve a deeper understanding of molecular structure, and to obtain numerical values of molecular characteristics.

## III. MODELLING OF SOLUTIONS

As mentioned above, the quantum chemistry of gas-phase molecules has already in fact reached the level of computer experiments. However, the majority of chemical reactions take place in solution and allowance for solvation effects constitutes an extremely difficult problem and again new significan progress has been achieved as a result of the employment of computers.

Several approaches have been developed in solution theory. In the most logical approach, the calculation is carried out by one of the quantum-chemical methods described in the previous section for a solute molecule surrounded by the maximum possible number of solvent molecules. This approach is referred to as supermolecular,[39] but it is evident that its realisation involves considerable computational difficulties, although for comparatively simple molecules such calculations have in fact been carried out.

Approximate methods are used in the study of solutions of complex organic and biological molecules: the direct optimisation method,[40] the molecular dynamics method,[41,42] the Monte Carlo method,[43,44] and others. Owing to the small amount of space available in this review, we shall confine ourselves to the consideration of the description of the structure and thermodynamics of solutions by the Monte Carlo method, which has come to be widely employed in recent years. The Monte Carlo (MC) technique is a procedure for the estimation of multiple integrals with the aid of random numbers. The average energy of a liquid system, obtained by averaging the energy values over a canonical *ensemble*, is a multiple integral of this kind. The kinetic energy is known and, for the determination of the potential energy $v(q_1 \ldots q_n)$, it is necessary to calculate its average value:

$$\langle v \rangle = \int v(q_1 \ldots q_n)\, p(q_1 \ldots q_n)\, dq_1 \ldots dq_n \quad , \qquad (5)$$

where

$$p(q_1 \ldots q_n) = \frac{\exp[-v(q_1 \ldots q_n)/kT]}{\int \exp[-v(q_1 \ldots q_n)/kT]\, dq_1 \ldots dq_n} \quad . \qquad (6)$$

The potential of the interaction between $n$ molecules can be represented as follows:

$$V = \sum v(ij) + \sum v(ijk) + \ldots \sum v(ij \ldots n) \quad . \qquad (7)$$

In real calculations only the first sum is left in expansion (7).

The parameters of the pair potential can be determined either by *ab initio* calculations or from experimental data. The first procedure is more effective because *ab initio* calculations make it possible to investigate the interactions of molecules for any orientations, whereas experimental information refers to the equilibrium configurations. Clementi[39] examined 50 classes of atoms (H, C, O, N, and certain other atoms most frequently encountered in organic and biological molecules) as a function of the valence state of the given atom and of its environment. For these classes of atoms, he determined the parameters of the atom–atom potentials from his *ab initio* calculations; these parameters are most frequently used in calculations by the MC method.

The study of the structure and thermodynamics of solutions by the MC method reduces to the random generation of the configurations of the solvent molecules around the solute molecule, which is placed at the origin of coordinates. In order to obtain statistically reliable information, it is necessary to sort through $10^9$ configurations, many of which are energetically unfavourable and therefore very improbable. In order to exclude such configurations, one employs the Markov chain technique which selects configurations taking into account the Gibbs distribution. Evidently, the larger the number of solvent molecules considered, the more reliable is the information which can be obtained concerning solvation effects. In the calculations carried out a present, account is taken as a rule of between 100 and 500 water molecules.

One of the first systems investigated by the *ab initio* MC method, was water.[45] These calculations showed that the radial distribution function for the oxygen atoms in water calculated *ab initio* without using empirical data agrees well with the experimental curve (Fig. 1). The average energy of the interaction of the molecule with the remaining molecules is approximately 7 kcal $mol^{-1}$ according to the calculations by the MC method. Apart from pure water, aqueous solutions of LiF,[46,47] and glycine, certain other aminoacids, and other biologically important molecules[39] were investigated. The MC method was applied even in the study of the hydration of the complex DNA molecule; in these calculations a fragment of the DNA double helix was placed in a hydration shell made up of 477 water molecules.[39]

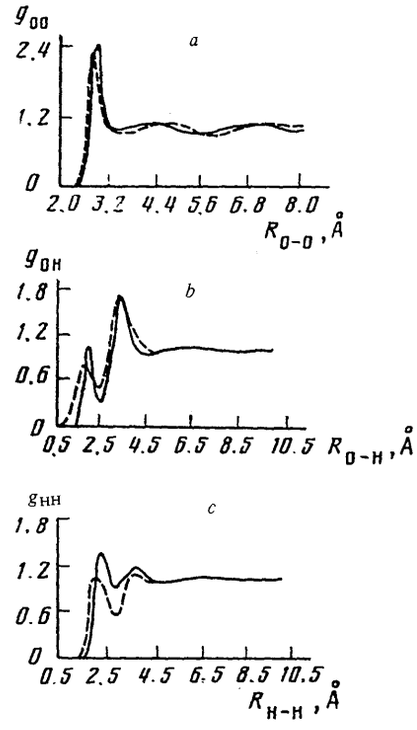

**Figure 1.** Comparison of the experimental (continuous lines) and calculated by the *ab initio* method (dashed lines) radial distribution functions: a) $g_{OO}$; b) $g_{OH}$; c) $g_{HH}$.[45]

The influence of solvation on the tautomerism of 4-hydroxypyridine and 4-pyridone has been investigated within the framework of the MC method.[48] In these calculations, the Clementi potentials were used and account was taken of 110 water molecules; it was found that the solvation energy of

4-pyridone is greater by ~5 kcal $mol^{-1}$ than that of 4-hydroxypyridine, which agrees with the experimental value (~5 kcal $mol^{-1}$). Naturally, one must not overestimate such good agreement between the calculated and experimental quantities because 110 water molecules is not a very large number for a reliable modelling of the solvation of these molecules. We may note that the MC method permits the investigation of the influence of temperature on the structure and thermodynamics of solutions.[44]

A very interesting aspect of solution theory involves the combination of the supermolecular and Monte Carlo methods, in which the geometrical structure of the solvation shell is determined by the MC method, while a quantum-chemical calculation makes it possible to determine the influence of solvation on the electronic structure of the solute molecule, which influences in its turn the electronic structure of the solvent molecules.

## IV. MOLECULAR DESIGN OF MEDICINAL DRUGS

The major advances in medicine achieved during the last decade are to a large extent due to new highly effective medicinal drugs. However, in order to introduce new drugs into medical practice, it is necessary to synthesise and test the physiological activities of approximately 20000 chemical compounds, which requires up to 7–10 years of work by investigators and a large financial outlay. The use of the computer-aided molecular design of new chemical compounds makes it possible to overcome these difficulties and leads to great possibilities in the purposeful search for medicinal preparations.

The essential feature of the new approach is that the physiological action of a medicinal drug is related to its stereospecific interaction with a receptor, which can be hydrophobic or of the type involving hydrogen bonding between the active fragment of the drug molecule (pharmacophor) and the biologically important centre of the receptor. At the molecular level, the problem therefore reduces to isolating the active and toxic fragments of the drug molecule and to the determination (by considering both the short-range and long-range environment) of the optimum chemical composition and structure of the molecule such that the useful interaction between the pharmacophor and the receptor is most favourable, while toxic fragments are as far as possible absent. The isolation of such active and toxic fragments can be achieved by comparing the useful biological activities and toxicities of a large number of compounds in which individual fragments are substituted in succession.

After this stage of the research has been carried out, the problem of increasing the physiological activity and of decreasing the toxicity of the preparation can be solved in several ways. The most logical procedure involves a direct non-empirical quantum-chemical calculation of the electronic structures of a set of different derivatives of the initial molecule with the receptor model. The results of such calculations can be compared with, for example, the strength of the hydrogen bond between the active centre of the preparation and the receptor, which might serve as a basis for the selection of molecules with the highest physiological activity. However, such an approach nevertheless requires much computational effort in the case of complex biologically important molecules and therefore so far other simpler procedures are used.

The structure of the receptor for biologically active compounds of a given series as well as the mechanism of their interaction are usually unknown *a priori* and must be determined together with the identification of the pharmacophor molecule and the determination of its optimum steric and electronic structures. An essential condition for the solution of this problem is the availability of extensive experimental data reflecting the relation between the structures and biological activities of the chemical compounds investigated. The molecules of biologically active substances are conformationally labile and an important feature of such investigations must therefore be the determination of biologically active conformations in which there is a possibility of interaction with the receptor. The selection of the total number of low-energy conformations of each molecule investigated can be carried out both by semiempirical quantum-chemical methods and on the basis of model force fields, whose parameters are determined either empirically or from non-empirical calculations for simple molecules. In the field under consideration, the method of atom–atom potentials, which makes it possible at present to investigate fairly complex molecules (for example, those of oligopeptides), has come to be most widely used among the theoretical methods of conformational analysis.

Biologically important molecular conformations contain information about the topography of the receptor and can therefore be used in the purposeful search for new compounds with a high affinity for the receptor. Apart from the steric structure of the pharmacophor, one can therefore optimise also its electronic structure.

One of such methods reduces to the calculation of the electrostatic potential surface of an isolated molecule on the assumption that the electrostatic potential reflects the ability of the active centre of the therapeutic model to form a hydrogen bond. This approach requires a preliminary quantum-chemical calculation, which, however, is carried out only for an isolated molecule. Programs for the electrostatic potential have now been developed and are included in the sets of programs for both non-empirical and semiempirical (of the CNDO, MINDO/3, MINDO, etc.) methods of calculation.

Thus the problem of the analysis of the biological activity of the drug molecule reduces to the determination of the most stable molecular conformation in which the atoms in the active centre are accessible to interaction and the environment is complementary with respect to the corresponding receptor atoms. The relevant programs have been developed and are already widely used for the solution of specific problems. We shall quote below several examples of the successful purposeful search for medicinal drugs with the aid of the methods described above.

One of the known examples is provided by a series of theoretical studies which led to a preparation analogous to somatostatin in its physiological activity but remaining active for a longer period. We may recall that somatostatin increases the susceptibility to insulin in patients suffering from diabetes, but natural somatostatin molecules retain their physiological activity in the human body for only a short time. A group of investigators led by Weber[49] analysed a series of somatostatin conformations by the molecular modelling method and identified the active component of the molecule with the aid of computer graphics. Next, nine aminoacids were removed from somatostatin in a computer experiment and it was thus possible to stabilise the structure, which was in Weber's view most complementary to the corresponding receptor atoms. When the molecule for which the calculations had been made was synthesised in the laboratory and its effect on animals was tested, it was found that the new preparation retained its activity in the animal organism 40 times longer, whilst retaining the physiological activity of the natural hormone.

Another example involves the theoretical study of cardiac glucosides used in medicine to treat heart failure. In therapeutic doses the glucosides increase the strength of the contractions of the myocardium, reduce the frequency of the

contractions of the heart, and diminish the excitability of the myocardium. A major disadvantage of the cardiac glucosides employed hitherto is their high toxicity, to the overcoming of which investigators have devoted much effort. A complete theoretical conformational analysis of 46 cardiosteroids with known biological activity and a wide variety of monosaccharide residues in the corresponding monoglycosides has been carried[50,51] by the method of atom–atom potential functions. These calculations led to the determination of the biologically active conformations of the cardiac glycosides, which made it possible to understand the steric structure of the digitalis receptor and the mechanism of the glycoside–receptor interaction and also it permitted the prediction of a series of configurations of drug molecules which should exhibit an enhanced affinity for the receptor. These studies may serve as a basis for the purposeful synthesis of new highly effective preparations.

The advances achieved by means of computer molecular design in the development of new effective medicinal drugs give rise to the hope that the use of computers will contribute also to the development of antitumour preparations.

## V. "ARTIFICIAL CHEMICAL INTELLECT"

As computers came to be used on an increasingly wide scale, it became understood that the computer can compete with man even in fields which have been traditionally regarded as intellectual. It is possible to identify two fields in chemistry where one can already speak in a certain sense of the creation of an "artificial chemical intellect". Firstly, these are problems associated with the recognition of the structure of a molecule from the available experimental spectroscopic data. Secondly, these are problems concerning the development of a strategy for the synthesis of complex organic molecules.

The development of chemistry and especially the application of physical methods to the study of molecular structure has led to an information explosion during the last decades. It is frequently much simpler to synthesise a compound than to identify it. One of the ways of solving the complex problem of the identification of a new compound consists in the recognition of a chemical compound by comparing its spectrum with one available in the literature. However, since information about the spectra of more than 100000 organic and inorganic compounds has already accumulated in the world and the amount of this information is increasing, it follows that realistically such a comparison can be made effectively only with the aid of a computer. Such computer recognition systems for chemical compounds have already been developed by Koptyug and co-workers and have been used for a number of years in the Siberian Division of the USSR Academy of Sciences.[52,53]

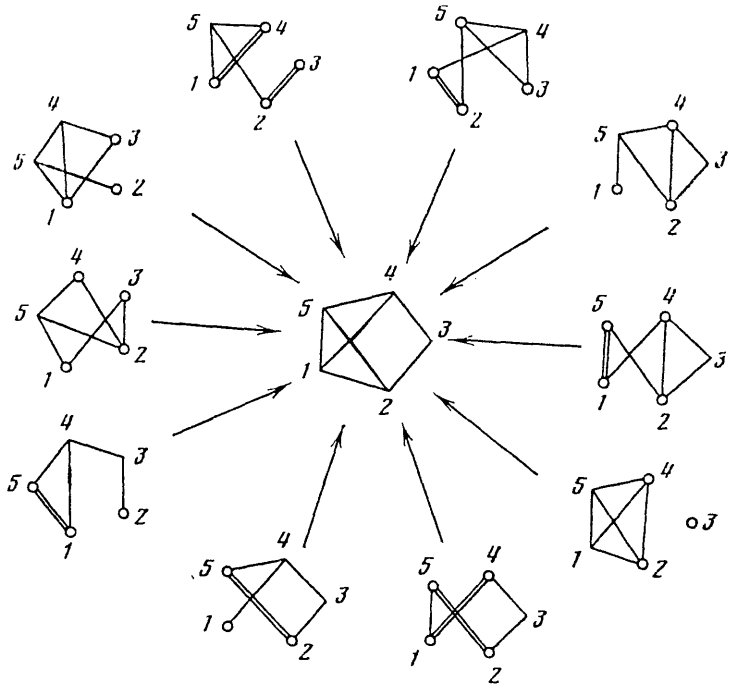
In another approach to the identification of compounds from spectra, the molecule is represented as a set of separate structural fragments such as aromatic rings, methyl groups, amino-groups, etc. which have characteristic spectral features. In each specific spectrum of the compound to be identified one isolates features which are regarded as characteristic. After such characteristic spectral features have been found, each is brought into correspondence with a set of competing structural fragments. Next, for any permissible set of fragments, all the possible molecular structures satisfying the overall formula and the requirements of the classical theory of valence are constructed. Among all the structures thus found, a further selection is now made on the basis of spectroscopic parameters, which are calculated, for example, in the case of infrared spectra, from the force constants of the fragments. Information about the experimental spectroscopic parameters of the fragments is stored in the computer—in a library of standard fragments. The closeness of the calculated spectrum of a particular structure to the experimental spectrum of the molecule to be identified provides the basis for a conclusion concerning the correctness of the recognition of its structure. Evidently, when several spectroscopic methods, such as mass spectrometry and infrared, Raman, NMR, and ultraviolet spectroscopy are used in the identification process, the reliability of the determination of the molecular structure increases significantly. Sets of programs for carrying out such computer analysis have been developed under Gribov's supervision[54,55] and have already been used successfully for several years.

Apart from the problem of the recognition of molecules from the spectra, computers are being introduced into another field of "chemical thinking", namely the development of a strategy in synthesis. So far several trends have been established in the computer synthesis of organic compounds.

One of them is based on the determination of the possible ways of synthesising the required compound on the basis of thoroughly investigated organic reactions. The corresponding programs have been developed in several laboratories. One of the most popular programs, LHASA, was developed at Harvard University.[56] It consists of approximately 50000 FORTRAN operators and its data bank contains information about approximately 1000 reactions. In developing a strategy for synthesis, the LHASA program as it were solves the converse problem, i.e. it begins with the molecule which is to be synthesised and then, by "breaking" the bonds in it via a series of reactions, it arrives at comparatively simple initial compounds which are either commercially available or can be readily obtained in the laboratory.

Another trend involves a formal logical approach based on the classical theory of valence, which regards a reaction as an intermolecular or intramolecular redistribution of bonds (cyclic electron transfer). In this case the ways of obtaining a given compound can be determined from its structure by the methods of graph theory and the combinatorial theory (for further details, see Zefirov and co-workers[57,58]). The advantage of this approach consists in the fact that it makes it possible to generate on a computer processes which have no direct analogues among the known reactions. The program FLAMINGO has been developed on this unique logical basis under Zefirov's supervision and has been designed to find all possible single-state processes with cyclic electron transfer in both closed and open systems taking into account specified conditons.

The application of this program to the computer synthesis of tricyclo[2.1.0.$0^{2,5}$]pentane has been described.[58] All single-stage many-centre reactions with cyclic electron transfer directed towards the synthesis of this compound were found with the aid of a computer. The following initial data were specified: (1) the graph representing the skeleton of tricyclo[2.1.0.$0^{2,5}$]pentane with numbered atoms (Fig.2); (2) information about the molecular symmetry; (3) information necessary to select the possible reactions. The computer sorted through all the possible processes involving the redistribution of bonds between the carbon atoms on the basis of the initial graph and predicted 6 three-centre, 12 four-centre, and 11 five-centre reactions with cyclic electron transfer. On the basis of special criteria, 19 reactions were then rejected and the remaining 10 (Fig.2) were recommended as possible ways of synthesising tricyclo[2.1.0.$0^{2,5}$]pentane. Some of them have not so far been applied; we may note that, since the publication of the above communication, a reaction prediced by the computer has already been carried out under laboratory conditions.[58]



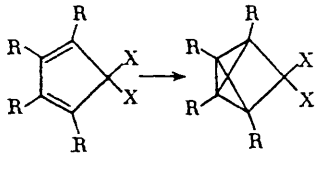


**Figure 2.** Schematic representation of the possible ways of constructing the tricyclo[2.1.0.$0^{2,5}$]pentane system found with the aid of a computer.

The field in which the "artificial chemical intellect" is developing is nowadays undergoing a vigorous growth and industrial firms interested in this problem already participate in the creation of similar programs. The computer programs described in this Section apparently simulate the thinking process of a research chemist, which in fact makes it possible to classify the operation of such programs as "artificial chemical thinking". An advantage of the computer over the human brain is that it can memorise an enormous amount of information and can manipulate it fairly rapidly.

## VI. PROSPECTS FOR THE DEVELOPMENT OF COMPUTER CHEMISTRY

Within the framework of a single review, it is at present already difficult to deal even briefly with all the fields of the rapidly developing new science—computer chemistry, which has arisen at the junction of chemistry, physics, mathematics, and computer technology. For example, apart from the applications considered above, one can point out also other important applications of computer chemistry such as the solution of the problem of optimising chemical technology with the aid of a computer and the solution of dynamic problems in the theory of elementary chemical processes. Evidently, as computers become more available to chemists, new fields of computer chemistry will arise.

The development of computer chemistry is in many respects determined by the advances in computer technology, which have been very great during recent years. Supercomputers capable of performing 100–200 million operations per second exist and, towards the end of the 1990s, the creation of supercomputers capable of 1–10 billion operations per second are expected. At the same time the size of both the operating memory of computers and the capacity of peripheral storage devices has been increasing. Discs with a capacity of one gigabyte have already been created and work on the creation of videodiscs is being completed.

The use of these new possibilities makes it possible to solve fundamentally new problems in computer chemistry, to raise the level of accuracy in the problems already dealt with, and to extend the range of applications. In quantum chemistry this involves taking into account the relativistic effects in molecules and calculations for large systems taking into account electron correlation; in principle, one may expect the appearance of dialogue programs, which would enable the chemist, before synthesising any one compound, to investigate theoretically its energy stability and the properties of its molecules. In solution theory, the supermolecular approach will become available for large organic molecules as the computer technology is improved and in methods of the Monte Carlo type it will be possible to take into account tens of thousands of solvent molecules, which will permit the investigation of bimolecular reactions in solution. In studies on molecular design, it will be possible to consider a large number of medicinal drug molecules and to take into account tens of their parameters in identifying the active centres, which will significantly increase the reliability of the prediction of the activities of new preparations. In studies on the "artificial chemical intellect", the data banks

will increase to tens of thousands of reactions, which will enable us to increase fundamentally the effectiveness of the synthetic procedures being developed; in problems on molecular structure recognition, the increase in the number of spectra in the data bank will also raise the reliability of the identification of new compounds. The development of chemistry is nowadays no longer imaginable without computers.

---o0o---

During the preparation of the review for the press, a number of other review articles, devoted to various branches of computer chemistry were published.[59-64] Clementi[59] described new results obtained in the *ab initio* modelling of water (three- and four-particle interactions, and also corrections associated with zero-point vibrations were taken into account), the hydration of a DNA fragment (30 pairs of bases surrounded by 1500 water molecules), and the transport of $Na^+$ and $K^+$ ions through membrane channels. The results of the application of supercomputers to the calculation of the structure of the solvated electron and the structures of liquid sulphur, amorphous nickel, and silicon in crystalline, liquid, and low-temperature amorphous states have been discussed in a review.[60] Other communications[61-64] have been devoted to the prospects for the creation and use of supercomputers in chemistry, the computational aspects of the determination of crystal structures, and non-empirical quantum-chemical methods.

# Experimental Study of Chemical Processes under Dynamic Compression Conditions

G.A.Adadurov

The results are given of studies on the creation of a set of systems for the preservation of specimens of condensed substances subjected to dynamic pressures with different types of stress applied to the specimens: with single and stepwise shock compression and also with nearly isentropic compression. The conditions in the compression of substances in protective tubes using cylindrical and planar compression schemes are examined. Examples of various chemical processes under these conditions are given, attention being concentrated on the reactions of organic substances.
The bibliography includes 90 references.

## I. INTRODUCTION

New methods for the generation of high pressures in a condensed medium, based on the use of powerful shock waves (SW), have been proposed and developed in recent years. In particular, shock waves have been generated in the test substance by the action of detonation waves from a chemical explosive on a specimen in contact with the explosive charge or as a result of impact by bodies accelerated to high velocities by the detonation products of the explosive. In condensed (solid or liquid) explosives, up to $8\times10^6$ kJ $m^{-3}$ of chemical energy can be concentrated per unit volume; the energy is liberated under detonation conditions, i.e. in the course of the ultrasonic propagation of the front of an exothermic chemical reaction in the explosive. After the sharp increase of pressure at the shock wave front, the pressure diminishes owing to the chemical process in the reaction zone. At the end of the reaction zone the detonation products expand and are accelerated in the direction of propagation of the reaction zone. The mixture of gaseous products at the end of the reaction zone has a density of up to 2.5 g $cm^{-3}$. The detonation wave propagates at a constant velocity, so that the energy losses by the SW are continuously made good by the energy liberated as a result of the chemical reaction in new portions of the explosive.

The detonation wave excited SW in the adjoining medium whose intensity depends on the power of the explosive and the dynamic rigidity of the medium $\rho_0 D$, where $\rho_0$ is the initial density of the material of the specimen and $D$ the velocity of the SW front. For example, in the detonation of an explosive at a rate of $\sim8\times10^3$ m $s^{-1}$, pressures of ~45 GPa develop in a steel bar in contact with the charge. Experiment shows that, when a steel plate is accelerated by the detonation of the same explosive, its impact against steel can generate pressures in the specimen which are three times as great.

The behaviour of gases and condensed substances on compression by means of SW shows significant differences. When SW are propagated in a gas, even low pressures induce a marked compression and a considerable increase of temperature by virtue of the high compressibility of the gas. The pressure in the gas has a thermal origin and is always proportional to the temperature. At high temperatures various physicochemical processes occur in gases: excitation of molecular vibrations, dissociation, ionisation, and chemical reactions.

On compression by SW, a condensed substance behaves differently, because the repulsive forces between atoms must be overcome in order to increase density. For this reason, an internal pressure of non-thermal character arises on shock compression in addition to the "thermal" pressure. With increased compression, the first component of the pressure associated with the thermal movement of atoms increases; this leads to limiting degrees of compression. This does not occur under isentropic or isothermal compressions, where an increase of pressure always entails an increase of density.

The first studies showed that the use of shock compression is productive in the study of dynamic compressibility (shock adiabats) of metals, the determination of null isotherms, and the derivation of semi-empirical equations of state in the range of pressures up to several hundreds of GPa and temperatures of $\sim10^4$ K.[1,2] We may note that a break in the shock adiabat for iron has been noticed for the first time[3] at 13 GPa which is the first evidence for a possible change in the structure of the substance during shock compression.

The methods used to measure shock adiabats are based on the measurement of the velocity of the wave front $D$ and the mass velocity of the test substance behind the front $u$ (in practice measurements are made of the velocity of the free surface of the specimen, which is close to twice the mass velocity). Knowing these kinematic parameters of the SW, it is possible to determine the thermodynamic characteristics of the substance (its density $\rho = 1/V$, the pressure $P$, and the increase in specific internal energy $\Delta E$) from the laws of conservation of mass, momentum, and energy:

$$\rho=\frac{1}{V}=\rho_0\frac{D}{D-u},\quad P=\rho_0 Du,\quad \Delta E=\frac{1}{2}P(V_0-V)$$

$D$ and $U$ are measured with the aid of electrical contacts in the central part of the specimen which is unaffected by stress relaxation waves (for the details of the method, see Al'tshuler's review[1]).

Careful investigations of the dynamic compressibilities of complex inorganic compounds have been carried out at the Institute of Chemical Physics of the USSR Academy of Sciences since 1957. Many such compounds have very high dynamic yield points—up to 10 GPa and above. The propagation of elastic waves with such amplitudes precluded the investigation of the compressibilities of such substances in the monolithic state over a wide pressure range by the methods known at the time, based on the measurement of the velocities of the SW and of the free surface. A "mixed" method,[4] based on the study of the compressibility of a mixture of particles of the test substance in a plastic medium, for example, paraffin, the shock adiabat for which is known, was therefore proposed and applied. This method made it possible to investigate the volume dynamic compressibilities of stable substances such as crystalline quartz,[5] glass,[6] and feldspar[7] also at low pressures.

In order to investigate the complex structure of the SW front in the elastic-plastic region or in phase transitions, an electromagnetic method,[6] previously employed to measure the velocities of the detonation products, was applied. This method made it possible to follow the evolution of the complex wave structures as they are propagated in glass,[6] potassium bromide and chloride,[8] and fused quartz.[9]

The investigations showed that all the substances mentioned above as well as marble[10] undergo structural changes during compression, i.e. in a period shorter than $10^{-6}$ s. The study of the impact compressibility of graphite[11] demonstrated that this important substance exhibits an anomalous compressibility at pressures of 20–40 GPa, which was interpreted as its conversion into diamond. The break at 60 GPa, caused, according to the authors,[11] by the transition of carbon to a metallic state, is a result of a methodological error, which was demonstrated in later investigations, for example, those of Pavlovskii and co-workers.[12,13] This erroneous result served as a basis for the construction of a phase diagram for carbon[14] in the region of high parameters which unfortunately has been used in the past by many investigators.

The aim of the above method was not to preserve the specimens: after recording a particular parameter, the specimen of the test substance disintegrated and was lost. For this reason, although these methods do in fact yield information about the pressure range in which the state of the test substance changes, about the structure of the SW front, and about the change in the electrical and optical parameters of the test substance, we obtain in essence only indirect data about the reactions which the test substance has undergone. These reactions are responsible for the anomalous behaviour of the shock adiabats observed for a whole series of substances.[3–16] In the first studies[3–11] it was already found that the anomalies on the shock adiabats, associated with the possible structural transformations in the test substances, occurred at relatively low pressures in the range 10–40 GPa, at which the preservation of the specimens was entirely possible; further studies were therefore developed with the aim of creating special devices (preservation tubes).

The difficulty of preserving the specimens after shock compression, particularly at ultrahigh pressures, is due to the presence in the decompression waves of powerful extending stresses which lead to the rupture of metallic containers and the loss of the test specimens. In constructing the retaining devices, the main task is to discover the region of the working volume within which the decompression waves do not interact and there is no appreciable macroplastic deformation. The appropriate positioning of the tubes with the specimens largely determines the success in devising preservation methods.

The first studies on substances preserved after impact compression were published at the end of the 1950's. In the first place one should mention the investigation[17] of the physicochemical transformations of substances under the influence of SW. This communication describes experiments on the shock compression of substances placed in cylindrical preservation tubes. It was shown that compression resulted in the partial decomposition of paraffin, NaCl, $CuSO_4$, $MgCO_3$, and $Pb(NO_3)_2$; on the other hand, sulphur underwent a phase transformation. Other investigations of preserved substances revealed the decomposition $Fe_2O_3 \rightarrow Fe_3O_4$ with decrease in the valence of the metal[18] and the conversion of $SiO_2$ into an amorphous form.[19] An important result has been obtained:[20] after the shock compression of graphite in a cylindrical tube, a small amount of finely dispersed diamonds was isolated. The results of investigations of metallic specimens (iron, steel, copper, and aluminium) and certain other technically important materials, preserved after shock compression, have been published.[21,22] Studies on the strengthening and welding of metals by an explosion have also begun to develop since 1960 (see the relevant monograph[23]). Much attention has been devoted to the explosive pressing of powdered materials.

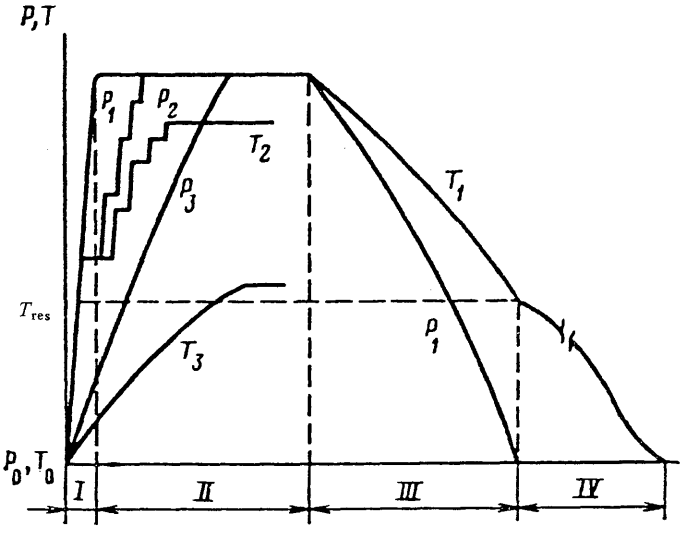

Figure 1. Idealised time variations of $P$ and $T$ at a certain point in the specimen in single ($P_1$, $T_1$) and multiple ($P_2$, $T_2$) shock compression and in dynamic isentropic compression ($P_3$, $T_3$). The rate of cooling of the substance along section III is not less than $10^8$ K $s^{-1}$.

In the studies quoted the experimental details and the conditions in the shock compression of specimens as well as the degree of macroplastic deformations of the tubes were inadequately described. The character of the interaction of the SW with the test substance had not yet been investigated at that time.

For a better understanding of the questions considered in this review, we shall deal with the general character of the changes in the pressure and temperature in the specimen in experiments with preservation, i.e. when the specimen is acted upon by the entire shock compression cycle, including rarefaction waves.

Fig.1 presents the idealised temperature and time variations of the pressure under the conditions of dynamic compression, by which we understand the compression of the test substance subjected to different types of stress; from compression by single-step and multistep SW to dynamic isentropic compression (DIS) or more precisely compression approaching isentropic compression. In the case of a single compression of the test specimen, the $P$ and $T$ increase simultaneously and very rapidly (over a period of $10^{-12}$ and $10^{-9}$ s) in the SW front (region I); the compression phase continues for $10^{-6}$ s (region II). The pressure is then removed by the isentropic decompression waves and (owing to the irreversibility of the shock compression) the temperature diminishes to a certain value $T_{res}$ (region III). Further cooling of what is now an unstressed specimen takes place in accordance with the usual thermal conductivity laws (region IV). The high residual temperatures in region IV can lead to the liquefaction (annealing) of the phase formed on compression and (or) to the occurrence of chemical reactions.

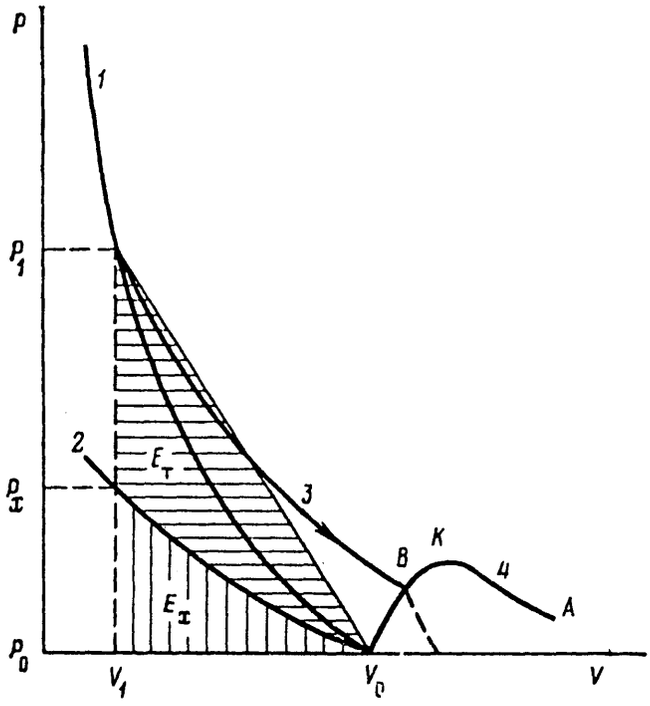

**Figure 2.** The $P-V$ relation on shock compression of the test substance and its relaxation: *1*) shock adiabat; *2*) cold (elastic) compression curve; *3*) rarefaction adiabat. The shaded regions correspond to the cold ($E_c$) and hot ($E_h$) components of the total energy of the compressed specimen; *4*) curve separating the regions of the single- and two-phase states of the substance.

Fig.2 illustrates the shock adiabat (curve *1*), the cold compression curve (curve *2*), the decompression adiabat (curve *3*), and curve *4* separating the regions of single-phase and two-phase states of the substance; its $V_0K$ branch before the critical point $K$ represents the boiling point curve (the onset of vaporisation) and the branch $KA$ represents the saturated vapour curve (the onset of condensation).

If the amplitude of the SW is not high, then, as a result of compression, the test substance passes from the initial $P_0V_0$ state to, for example, the state $P_1V_1$ (Fig.2). After decompression, the states of the system follow the isentropic decompression curve [shown by an arrow in Fig.2 (curve *3*)], which intersects the boiling point curve at point $B$, after which the solid should, in principle, boil. However, the rate of this process is negligible at temperatures of the order of hundreds and even thousands of degrees (for metals) and in reality the solid expands and cools to zero pressure along the "superheated liquid" adiabat shown dashed in Fig.2.

If the SW is very powerful and the internal energy of the heated substance is many times greater than the bond energy between the atoms (equal to the heat of vaporisation at $T = 0$), then, following its expansion to $P = 0$ in the region below the point $K$, the substance can completely vaporise. This problem has been analysed in detail in a book[2] (p.550).

Various designs of the preservation tubes for the dynamic compression of condensed substances with the aim of carrying out various physicochemical transformations are examined below. Attention has been concentrated on the conditions in the compression of the test substance following the application of different kinds of stress; certain results illustrating the possibility of the method based on dynamic influences are presented.

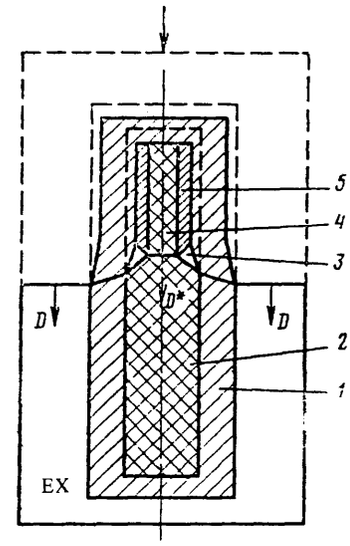

**Figure 3.** Schematic diagram of the compression of a substance in a cylindrical tube; $D$ = rate of detonation of explosive (EX); $D^*$ = rate of propagation of head SW: *1*) metallic tube; *2*) test substance; *3*) and *4*) regions of single compression behind the front of the incident and head SW; *5*) region of double compression behind the front of the incident and reflected SW. The dashed lines indicate the initial positions of the explosive, the tube, and the specimen.

## II. THE BEHAVIOUR OF SUBSTANCES COMPRESSED BY CONVERGING WAVES

Cylindrical preservation tubes are the principal means of carrying out dynamic experiments for chemical purposes. Fig.3 illustrates a cylindrical metallic tube and the test

substance placed in it; the tube is arranged along the axis of the explosive charge. As a result of the detonation of the explosive, the detonation wave passing around the cylinder excites a conical converging shock wave in it and in the test substance. The wave undergoes a transition to a three-shock configuration which is propagated in the stationary region at a rate equal to the rate of detonation of the explosive employed.[24] The three-shock configuration arises in solid (continuous and porous) substances and in liquids.

The details of the investigation have shown[25] that there is a linear relation between the diameter of the head wave (the Mach wave), occupying the central part of the three-shock configuration, and the diameter of the specimen. It is significant that in the central part of the tube the test substance undergoes a single shock compression by the head wave, while at the walls of the tube it undergoes a double compression by the incident and reflected SW; as a result of this, for the same final pressure, the shock heating of the test substance in the centre of the specimen is much greater than at the walls of the tube. The compression conditions also differ along the length of the specimen. It is almost always possible to differentiate three zones: the region where a three-shock configuration is produced, the region of the stationary propagation of the wave, and the region at the bottom of the tube where additional compression of the test substance by the SW reflected from the bottom can take place. Thus in a single experiment the substance located in different zones of the cylindrical specimen is subjected to stresses of different kinds.

The observed relation between the rate of propagation of the three-shock configuration and the rate of detonation of the explosive charge employed made it possible to determine the pressures developed without special direct measurements (when the shock adiabat for the test substance is known). It was found that it is very simple to achieve pressures of several hundreds of GPa. Thus the use of an explosive whose detonation velocity is $\sim 8 \times 10^3$ m s$^{-1}$ generates maximum pressures of ~500, 60, and ~35 GPa in monolithic specimens of tungsten, sodium chloride, and perspex respectively. In order to increase the pressure, for example, in salt, it is sufficient to mix and compact tungsten and salt powders. With a low sodium chloride content, pressures close to 500 GPa can be reached as a result of repeated compression and equalisation of the pressure in the specimen.

The next important factor was the occurrence of very intense plastic deformations in the working volume of the cylindrical tubes with axial filling.[26] The particles of the test substance can migrate under such conditions relative to one another over considerable distances in the direction of propagation of the three-shock configuration, particularly in the central part of the tube. Evidently such conditions should promote the decomposition of chemical compounds, should significantly accelerate the fusion processes, and should facilitate chemical interactions of substances. An attempt has been made to separate the decomposition products using intense plastic flows.[26] For this purpose, a very small amount of the test substance (0.5 wt.%), for example, an oxide, was mixed with ground quartz and the mixture was subjected to shock compression. After the experiment the metallic shell was dissolved in hot hydrochloric acid and the remaining monolithic quartz bar was ground and polished. The ground sections were investigated under a microscope. This method revealed traces of the movement of the particles of the material of the tube into the test specimen and also traces of plastic deformations shown by a change in the colour of the test substance following the chemical reaction. In order to protect the test substances from contamination, quartz or glass inserts were used, which completely prevented the migration of the contaminant into the specimen. It was shown in these experiments that, during the plastic flows in the preservation tubes under shock compression, the particles of the test substance can migrate in the direction of the SW over a distance of 2–3 and more centimetres.

The behaviour of more than 60 oxides has been investigated by this method under identical shock compression conditions. Special measurements showed that in porous quartz ($\rho_0 = 1.48$ g cm$^{-3}$) and hence also in the test oxides a pressure of ~48 GPa developed; the concentration of energy was then $E = 1.2 \times 10^4$ kJ kg$^{-1}$. The capacity of oxides for decomposition under shock compression was determined by the enthalpy $\Delta H^0_{298}$ of the process involving the elimination of one gramme-atom of oxygen. Oxides with $\Delta H^0_{298}$ ranging from 62.8 kcal g-atoms$^{-1}$ ($Ag_2O$) to 211.0 kcal g-atom$^{-1}$ (CaO) were investigated. It was found that the decomposition limit of the substance subjected to the influences indicated corresponds to a quantity which is only 20% below the overall energy of the shock compression.[26]

In order to ensure the chemical purity of the experiments, it was necessary to determine the degree of contamination of the test substances by the materials of the walls of the tubes as a function of the properties of the substances and the conditions of the dynamic influence. For this purpose, the contamination of sodium chloride and alumina, placed in steel-65 tubes, was determined by chemical analysis. Sodium chloride was used in the form of a powder or was fused *in vacuo* on the inner part of the tube. After the experiment, the tube was opened, the test substance was extracted, and the distribution of iron along the length and radius of the tube was investigated. The results showed that, when the test specimen is monolithic, then the material of the walls hardly penetrates the test substance. On the other hand, if the tube is filled with a powder, particularly one which is difficult to compact, such as $Al_2O_3$ (in the experiments the initial density of $Al_2O_3$ was 1.1 g cm$^{-3}$, while that of powdered NaCl was 1.9 g cm$^{-3}$), then the degree of contamination of the specimen by iron reached several tenths per cent.[27] In the above study it was shown that, if for any reason, it is not possible to employ a monolithic specimen, then one can subject the specimen to preliminary impact compression using the detonation of a low power explosive charge which causes only an insignificant contamination of the test substance but ensures its effective compaction. At the same time a sharp decrease of the maximum temperature developed on repeated compression is achieved, because the specimen had been subjected to preliminary compaction.

The influence of SW on porous substances as a rule leads to the formation of more or less monolithic cylinders having in most cases a characteristic structure: along the axis, there is a filamental cavity 0.1–0.5 mm in diameter. Its formation is due to the interaction of the rarefaction waves. A cavity 1–3 mm in diameter is sometimes formed in the lower part of the specimen.

Under certain conditions (high pressures and a low crystal lattice energy of the test substance), the substance may not only melt but may evaporate at the centre of the tube. The migration of the test substance in the direction opposite to that of the propagation of the SW has been demonstrated by the radioactive isotope method.[28]

After the completion of the process, a characteristic microstructure, usually arising during the radial crystallisation of the fused metal in the tube during its uniform external cooling, can arise throughout the volume of the cylindrical specimen. This feature of the shock compression of the test substance in cylindrical tubes is associated with the difference

between the residual temperatures of the substance and the walls of the metallic tube. This difference is particularly large in the study of specimens in a porous state where the residual temperature of the substance can reach several thousands of degrees, while that of the metallic tube is hundreds of degrees. As a result, conditions are created for the rapid cooling and quenching of the test substance. For example, estimates for niobium pentoxide have shown[29] that the total crystallisation time of the melt is ~0.3 s, while the linear rate of crystallisation is 0.05 m $s^{-1}$; for tungsten, these quantities are 0.005 s and 0.3 m $s^{-1}$ respectively.

In most cases specimens with a reduced density, whose pores contain air at atmospheric pressure, are investigated in cylindrical tubes. One can assume that during the shock compression of such systems with a small particle size $k$, the pressure is equalised but thermal equilibrium is not established. Owing to the small weight fraction of air, its contribution to the temperature is small and the average temperature of the mixture differs little from that of the solid component, although in the initial instant of the compression the air in the pores was heated to a much greater extent. After intense shock compression, the porous medium undergoes a major volume deformation and hence is heated more than a continuous substance compressed to the same final pressure.[1] Even after the shock compression of porous specimens subjected to preliminary evacuation the temperature developed may amount to tens of thousands of degrees and part of the substance passes to the state of plasma;[30] thermal emission of electrons can take place under these conditions.[31]

The shock compression of porous substances does not entail major difficulties in the solution of the problem of the preservation of the compression products. Difficulties arise when the test substances decompose or react with the evolution of a large amount of gas and especially when the pores have been filled beforehand with gases which have been compressed to high pressures or liquefied. As a rule, the usual tubes are ruptured under these conditions by the high internal pressure. In order to preserve the tube without rupture, it is necessary to develop special designs. Evidently the preservation of the tube should be promoted by the situation where the gas reacts partly or fully with one of the components of the specimen on compression to form a solid product. It has been shown[27] that the compression of the oxides, fluorides, chlorides, iodides, and sulphates of univalent, bivalent, quadrivalent, and hexavalent elements did not lead to the rupture of the tubes. Comparatively readily decomposed substances such as copper sulphate, barium chloride dihydrate, paraffin, phosphorus oxide nitride, and nickel fluoride hydrate and substances which are highly volatile under the usual conditions such as sulphur and mercury were also satisfactorily preserved in specially developed tubes. The tubes were preserved without rupture also on compression of the substances listed below. Far-reaching hydrolysis on shock compression of nickel fluoride hydrate resulted in the evolution of a considerable amount of free water and hydrogen fluoride; phosphorus oxide nitride decomposed almost completely into nitrogen and phosphorus and layer phosphorus oxides, and copper sulphate partly decomposed to free copper.

Systematic studies have been made to develop cylindrical preservation tubes which would permit the shock compression of solid–condensed gas mixtures in order to carry out various chemical interactions.[32] The task of preserving condensed gases after their compression in SW involves considerable difficulties. Firstly, metals become brittle at low temperatures, which increases the probability of the rupture of the tubes. Secondly, the high compressibility of condensed gases leads to considerable deformations of the tubes on compression and decompression which leads to the rupture of the tube under the conditions of increased brittleness of the material. Thirdly, even if the liquefied gas does not vaporise during compression, the effect of high residual temperatures after rarefaction causes its transition to the gaseous state, which creates high pressures within the tube capable of rupturing it. However, special tube designs, providing for the removal of the excess gases, made it possible to preserve the solid product. As a result of the investigations carried out, the interactions of various substances with liquid nitrogen and solid carbon dioxide have been achieved. In particular, the possibility of the formation of niobium nitride and carbide on shock compression of a mixture of powdered niobium with liquid nitrogen and carbon dioxide has been demonstrated.[32] The interaction of various metals with hydrogen yielded hydrogen-containing titanium and manganese compounds as well as other substances. It has been shown that saturated hydrocarbons and water can be used as sources of hydrogen in such interactions.[33]

In order to obtain $CO_2$ in the solid state under normal conditions, attempts have been made to oxidise SiC under the conditions of shock compression.[34] Mixtures of powdered SiC with gaseous or liquid oxygen were subjected to shock compression in preservation tubes. The study of the compression products by X-ray diffraction and infrared spectroscopy showed that the interaction of oxygen with SiC involves the oxidation of the latter and the formation of a non-molecular lattice structure. Heating of oxidised SiC to 800–1300 K removes carbon oxides. The cylindrical tube can be improved; in order to simplify the pattern of wave interactions and to eliminate the head wave, it is sufficient to insert a metallic rod along the axis of the tube. In this case the specimen in the form of a cylindrical layer is subjected to shock compression. This design can be used to achieve structural transformations[35] and also in technological processes—for the pressing of tubes.

Thus the generation of very high pressures, temperatures, and macroplastic deformations of specimens in cylindrical preservation tubes has a positive influence on many physicochemical processes. However, these conditions and the complex pattern of wave interactions in the test specimens restrict the scope of studies of the behaviour of substances under dynamic compression, whose class is limited mainly to metals and refractory compounds.

## III. PLANAR DYNAMIC COMPRESSION

The creation of devices for the preservation of substances subjected to compression by planar SW ensured the possibility of dynamic compression at a lower maximum pressure but with a simpler pattern of wave interactions than in the cylindrical scheme. Planar compression also has the advantage over compression by converging waves because the SW parameters are susceptible to measurement and the compression conditions are controllable.

### 1. Experimental Technique

Fig. 4 illustrates schematically the designs for the preservation of substances after shock compression using a planar compression scheme. The shock waves in the tube and in the specimen are generated by a planar detonation wave of an explosive charge in contact with the tube (Fig. 4*a*) or as a result of the impact of a metallic

plate accelerated by the detonation product (Fig.4*b*).[33] After an appropriate selection of experimental conditions, the shock compression pressures in the test substance and in the material of the tube are equalised by repeated reflections of the SW from the bottom and lid of the tube when the latter is made of a material whose dynamic rigidity is greater than that of the test substance.[33] The scheme in Fig.4*b* is more convenient because impact by plates generates SW with a rectangular profile. A change in the thickness of the impact plate makes it possible to measure or calculate more rigorously the residence time of the test substance in the compression phase. In order to obtain more information, several specimens of different test substances were placed in a planar cassette (Fig.5*b*), which was in its turn inserted in the tube (Fig.5*a*), which made it possible to study the behaviour of different substances in a single experiment under comparable conditions. Such formulation of the experiment permits in addition the variation of the number of reflections of the SW in the specimen by using different thicknesses of the latter (Fig.5*c*).

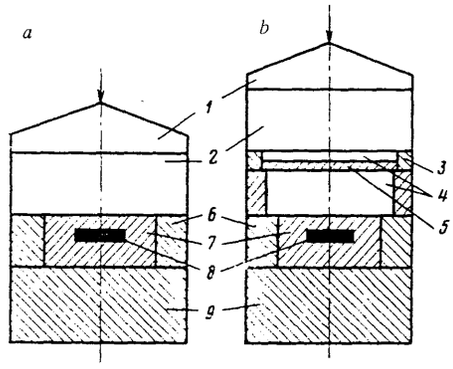

**Figure 4.** Schematic illustration of devices for planar shock compression: *1*) generator of planar detonation wave; *2*) explosive charge; *3*) metallic ring; *4*) air gaps; *5*) impactor; *6*) protective ring; *7*) tube; *8*) test substance; *9*) metallic support.

The pressures developed in the specimens depend on the dynamic rigidity of the material of the tube and the compression conditions and can range from 1 to 150 GPa.[33]

Despite the simpler compression pattern of the test substance when planar SW are used compared with the cylindrical compression scheme, the determination of the characteristics of the substance as a function of pressure requires a larger number of independent experiments with preservation of the specimen, also the compression conditions can be different in different experiments. A method has therefore been developed whereby it is possible to achieve in a single experiment the shock compression of one or several different substances over a wide range of fixed pressures with subsequent preservation of the specimens for physicochemical analyses.[36] Under the conditions created in this method, as the SW is propagated in a metallic block, the maximum pressure and temperature fall sharply after the wave has travelled a relatively short distance. A calibration relation between the pressure and the thickness of the metallic layer has been determined with the aid of special measurements.

The shock wave was generated in a copper block by the impact of an aluminium plate 1 mm thick accelerated by the products of a planar detonation of a thin layer of explosive; the distance traversed by the impactor was 2.5 cm. (We may note that at 45.5 GPa the maximum temperature of the copper reached 670 K, while the residual temperature $T_{res}$ (Fig.1) was 480 K; at 13.2 GPa the corresponding temperatures were 380 and 330 K respectively.) The metallic block was then replaced by a set of plates of the required thickness, between which thin specimens of the test substance were placed. They were subjected to repeated shock compression at different fixed pressures.

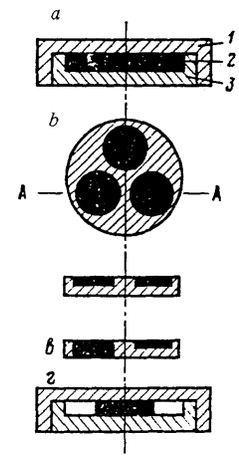

**Figure 5.** Design of the preservation tubes: *a*) preservation tube: *1*) lid; *2*) test substance; *3*) bottom of tube; *b*) cassette with three specimens which can be inserted in the tube instead of specimen *2*; *c*) section through the cassette along the AA line; *d*) preservation tube permitting a specified degree of deformation of the specimen as a result of its movement into the free volume on compression.

Comparison of the data obtained for the compression of the test substance in a layered container of this kind, where the shock compression times are short, with data obtained in independent experiments at the same pressures but for specified and longer compression times made it possible to obtain the dependence of the physicochemical characteristics on the shock compression time. In the experiment described the duration of the compression phase was determined from the instant of the appearance of the rarefaction wave arriving from the direction of the impactor; the pressure decreased over a period of 1.5–2.0 μs.

The specimens of the organic substances investigated, in the form of discs up to 0.7 mm thick at 15 mm in diameter or in the form of plates 50–100 μm thick, were placed within sockets in copper plates or were positioned between plates. In each layer several specimens of different substances could be placed. By selecting copper plates of a suitable thickness, it is possible to obtain up to 15 maximum pressures in the SW in the range from 10 to 40 GPa for several test substances in a single experiment. Since the thicknesses of the specimens are small, one can assume that there is no significant distortion of the wave front. The final pressure in the specimen after repeated compression is close to the

pressure in the copper plate, since the time of a single pass of the SW through the specimen is ~0.02 μs.

It is noteworthy that the contact of the thin layer of the test substance, which has been more compressed and heated to a higher temperature, with the metal heated to a lower temperature promotes the rapid removal of the residual heat from the specimen, ensuring a kind of quenching. Estimates have shown that, when a layer container is used for the shock compression of specimens of organic substances ~100 μm thick, the time required to equalise the temperature between the specimen and the metal is ~0.35 s. This design permits experiments at an initial temperature of 77 K, which improves the quenching conditions.

The planar compression scheme was used to study various substances and processes on shock compression. It proved to be most useful in the investigation of substances with a low thermal stability, such as, for example, organic substances.

## 2. Chemical Reactions of Organic Substances

Studies on the chemical reactions in organic substances which have undergone shock compression were initiated at the Institute of Chemical Physics of the USSR Academy of Sciences in 1965. The experiments performed using planar compression schemes revealed,[37] and this was subsequently confirmed in relation to many monomers, that exposure to a shock wave induces rapid polymerisation.[38] Polymerisation was observed for different classes of monomers which usually polymerise via radical (acrylamide) or ionic (trioxan) mechanisms. In addition, many monomers (tolane) which are extremely difficult to polymerise under the usual conditions do polymerise in the SW. The investigations showed that polymer chains are formed when the amplitude of the SW reaches a specific value, which differs for different monomers. The yield of the polymer formed and its average molecular weight initially increase with the SW amplitude and then diminish owing to the thermal degradation of the polymers. With increase of pressure, not only the length of the macromolecules changes but there is also a possibility of a change in the structure of the polymer chain. It has been shown[38] that these chemical reactions under the influence of SW cannot be reduced to a trivial thermal process and fusion or to a combination of static compression and heating.

The possibility of the formation of macromolecules as a result of polycondensation has also been considered. It has been demonstrated that the action of a SW in a mixture of α-aminoacids with silica gel can entail the formation of polypeptide molecules.[39] The authors[39] attribute a dehydrating role to silica gel, which displaces the reaction equilibrium towards the formation of polypeptides.

The first studies on the effect of SW on polymer systems (butadiene–nitrile, butadiene–styrene, natural and other raw rubbers) showed that in this case there is a possibility of the cross-linking of the macromolecules with formation of a three-dimensional network and their partial degradation.[40,41] The study of polymers with saturated bonds, such as poly(metyl methacrylate), polypropylene, polyethylene, and polystyrene showed that, regardless of the initial supermolecular structure (spherolitic, fibrillar, and quenched structureless) the effect of the SW leads to the formation of an isotypical fine spherolitic structure.[42] The use of a layer container permitted the study of the structural changes in polymer films at pressures differing by only 1.0–1.5 GPa in the range 10–40 GPa.[43] It was shown that the transition to the fine spherolitic structure takes place at pressures of 13.5, 23, 25, and 27 GPa for polybutylene, polypropylene, polyacrylonitrile, and Lavsan respectively. The degree of deformation of the specimens was estimated from the relation $\varepsilon(\%) = 100(R - R_0)/R_0$, where $R_0$ and $R$ are the radii of the specimen before and after shock compression: it did not exceed 1%. Comminution of the supermolecular formations and an increase of the microhardness in the surface layers have been noted in a study[44] of the shock compression to 10 GPa of crystalline polycaprolactam and amorphous poly(methyl methacrylate).

A more detailed analysis of the above results was carried out in other investigations.[45,46] The efforts of many investigators, mainly Soviet scientists, were subsequently directed towards a more detailed study of the physicochemical properties of organic substances subjected to shock compression in preservation tubes and towards the elucidation of the mechanisms of the chemical reactions which occurred.

Three fields of study have now arisen. Firstly, we have the investigation of the reactions of low-molecular-weight organic substances, which include isomerisation, for example, the conversion of *trans*-stilbene into *cis*-stilbene,[47] condensation—the formation of polypeptides from α-aminoacids,[39] the dimerisation of polynuclear compounds such as anthracene, phenanthrene, and pyrene,[48] intramolecular rearrangements, for example, the formation of poly-β-alanine together with the usual vinyl polymerisation of acrylamide,[49] and finally the degradation reactions which partly accompany the processes enumerated above.

The data on the degradation of aromatic and cyclic compounds by SW proved to be the most informative.[50,51] It has been shown that shock compression of benzene disrupts the benzene ring and leads to the formation of a considerable amount of ethane and hydrogen, greatly exceeding the amount of the degradation products formed on compression of the less thermally stable hexane and cyclohexane. The authors of these investigations suggest that the disruption of the molecular structure is of a non-thermal character and that a change in the valence angles in the rigid benzene ring is impossible without the breakdown of the latter. On the other hand, aliphatic groups in cyclohexane can undergo a change in valence angles with subsequent relaxation. It has been concluded that the decomposition of benzene molecules takes place directly in the SW front where the most intense microplastic deformations take place.

Presumably the formation of defects, active centres, etc. in the SW front constitutes the "initiating" stage of the subsequent reactions. The isomerisation and condensation reactions can also be considered from this standpoint.

The second field of study involves the investigation of polymerisation reactions and demonstration of the activating role of the SW front in this process. The initiating role of the SW front in the polymerisation of acrylamide (AA) under the conditions of shock compression was first noted by Adadurov et al.[52] The experiments were performed at 77 K and a pressure where the polymer is not yet formed. Next, when not more than 30 s had elapsed since the experiment, the tube was cooled with liquid nitrogen, opened at this temperature, and the physicochemical analyses of the specimens were begun also at 77 K. The presence of active polymerisation centres at a concentration of $10^{20}$–$10^{21}$ $kg^{-1}$ in the compressed AA specimens was confirmed by EPR. The SW front was regarded as a generator of active centres. The subsequent rise in the temperature of the SW-activated specimens led to an explosive AA polymerisation process, which was investigated calorimetrically. The data obtained and calculations led to the conclusion[52] that, depending on the temperature conditions established in the compression stage and obtaining after the removal of pressure, polymerisation can take place

either as a slow after-effect or as a thermal explosion. At high shock compression pressures, accompanied by the development of high concentrations of active centres and high temperatures, the polymer can be formed in the compression stage during a period shorter than $10^{-6}$ s. The presence of active polymerisation centres in AA compressed by a SW of brief duration has been confirmed by EPR.[53] The polymers were formed on subsequent dissolution of the specimen in tetrahydrofuran.

γ-Irradiation of the majority of solid monomers at low temperatures is known to lead to the formation of stable active centres which initiate the polymerisation process on subsequent temperature rise. A study has been made[54] in which AA specimens γ-irradiated in doses up to 6.3 Mrad were subjected to shock compression at 16 GPa and 77 K. It was shown that, for the dose indicated, the yield of the "purely radiation" polymer was 20%. The shock compression of non-irradiated AA led to the formation of 5% of the polymer, while that of the irradiated AA afforded 40% of the polymer. This yield exceeds by a factor of almost 2 the simple sum of the contributions by both influences and is almost an order of magnitude higher than the yield of the polymer due to the action of the SW alone. In the next Section of the review, in the analysis of new possibilities in dynamic investigations, direct proof of the decisive role of the SW front in the polymerisation of AA will be given.

We may note that the polymerisation mechanism under the conditions of shock compression described above is not the only one possible. Thus study of the polymerisation of trioxan[55] showed that the structural changes in the monomer during the compression stage are decisive for the formation of polyformaldehyde. The propagation of trioxan chains in microcrystalline and single crystal specimens has been investigated[56] as a function of the variable pressure and duration of the shock compression. It was concluded that the polymerisation takes place during shock compression and that the growth of polymer chains is virtually limited to this period. An increase of pressure entails an appreciable acceleration of the chain growth. The polymer chain propagation process is influenced significantly by the degree of perfection of the crystal lattice. Analysis of the changes in the characteristics of the products of the polymerisation of single-crystal trioxan under different conditions of compression by SW [57] showed that the molecules undergo a deformation which accelerates all the stages of the polymerisation process. Active centres are formed on partial degradation of the monomer molecules in the SW front, whereupon their number increases with increase in the degree of deformation.

The study of the transformations in polymers subjected to shock compression can be regarded as the third field of study. The observed degradation and cross-linking reactions[40,41] can also be accounted for from the standpoint described above in connection with the consideration of the mechanism of the polymerisation reaction. It is noteworthy that the long chains in the polymer macromolecules should be more sensitive to deformations in the SW front and the breaks in these chains should entail the formation of radicals. The subsequent reactions of these radicals can lead either to the degradation of the macromolecules or to their cross-linking with formation of a three-dimensional structure depending on the characteristics of the polymer, the presence of double bonds in the chain, etc.

In the study of the changes of the supermolecular structures of polymer specimens subjected to shock compression, the radiothermoluminescence (RTL) method was resorted to in addition to optical microscopy and X-ray diffraction.[43] Polypropylene (PP), in which any initial structure is converted into a fine spherolytic structure at a threshold pressure of 23 GPa, has been studied in greatest detail. It has been shown by the RTL method that, at a pressure below the threshold value the crystal structure breaks down and the fraction of the amorphous phase increases. It has been suggested that the compression in the SW front induces the formation of defects in the polymer structure and the annealing of defects or the rearrangement of the supermolecular structure at the elevated residual temperatures increases the fraction of the amorphous phase. The low-temperature luminescence peak observed by the RTL method for PP specimens compressed at 77 K indicates the possibility of the breakdown of the supermolecular structures. This low-temperature transition can be due to the local relaxation of the ends of the macromolecular chains along the boundaries of the cracks formed and on the surfaces of the lamellae. It has been suggested that the structural changes take place in polymers "activated" by the SW front immediately after the removal of pressure owing to the effects of the residual heat and can only be interpreted when account is taken of all the factors accompanying shock compression.

Studies of the chemistry of the shock compression of organic substances in which the observed effects were also explained have been published in recent years.[58-60] The conclusions reached are close to our ideas described above and reduce to the fact that shock compression can induce chemical reactions, including unusual reactions, which cannot occur for equivalent combinations of static pressures and temperatures and that the reactions can take place in the SW front itself. It has been suggested that the "anomalous" effects can be the result of "catastrophic shock".[58] According to this concept, the shock waves generate a high concentration of defects and cause the mechanical rupture of chemical bonds and the relative displacement of neighbouring groups in the SW front. As in the present author's investigations discussed above, the author[58] states that much more attention should be devoted to the possible processes in the SW front, such as the generation of a non-equilibrium state and defects, the breaks in chemical bonds, etc.

## IV. THE REALISATION OF SPECIFIED THERMODYNAMIC CONDITIONS IN THE DYNAMIC COMPRESSION OF CONDENSED SUBSTANCES

The interrelation between the pressure in the SW front and the temperature developed there, limits the possibility of achieving sufficiently high pressures without the accompanying marked heating of the test substance. Shock compression of a precooled substance also does not lead to an appreciable reduction of this temperature. In other words, the region of the $P-T$ diagram immediately adjoining the $P$ axis is in principle inaccessible in experiments with SW.

The attainment of this region under the conditions of dynamic compression at pressures up to 100 GPa and above is essential for the study of the metallation of dielectrics, including condensed gases, for the reduction of residual temperatures after intense dynamic compression, and for the prevention of the annealing of the high-pressure phases formed and the decomposition of the newly formed chemical compounds, etc. Despite certain advances in the technique of high static pressures, at the present time pressures in excess of 50 GPa can be obtained only on compression of extremely small amounts of test substances. Under dynamic conditions, the above restrictions are not limiting.

### 1. Stepwise Compression and Dynamic Isentropic Compression

The possibility, in principle, of a decrease in the temperature rise of the test substance on shock compression by organising a stepwise compression of the specimen by a series of successive SW of lower amplitude is known from the SW theory. For the same final pressure, the final temperature of the specimen is reduced in stepwise compression and the degree of compression of the test substance increases (because of the decrease of the thermal component of the pressure). As a result, the states located on the shock adiabat for repeated stepwise compression should approach the states on the compression curve at the absolute zero. Experiments in which shock adiabats have been recorded with double shock compression of certain substances have been described in the literature. An X-ray diffraction method for the investigation of regular regimes involving the oblique reflection and oblique collision of SW as well as the head on collision of SW introduced to achieve the double compression of magnesium, aluminium, perspex, paraffin and water have been described.[61] It has been shown that double compression states correspond to comparatively low temperatures and small thermal components of the pressure. For example, double shock compression of aluminium to a density of 1.57 g $cm^{-3}$ results in the heating of the specimen to ~1100 K; on the other hand, in a single compression to the same density, the temperature reached is ~3800 K. The thermal components of the pressure in single and double compressions reach 20 and 6 GPa respectively.

P–V diagrams have been determined[62] for marble subjected to double shock compression. The shock wave emerging from marble was reflected from a copper plate with a high dynamic rigidity and was propagated through the marble specimen already subjected to compression by the first wave. It has been shown that at pressures in excess of 15 GPa the state arising in double compression significantly differs from the state in single compression and approach the "cold" compression curve.

It is seen from the examples presented that double shock compression makes it possible to reduce the temperature developed in the test substance. Repeated SW compression or "smooth" dynamic compression should make the process even closer to an isentropic process. Repeated SW compression of water and boron nitride to pressures of 100 GPa has been carried out[63] in order to measure their electrical conductivities. The compression of test specimens placed between two copper plates was achieved by creating shock counterwaves of identical amplitude, which were generated by the synchronous collision of aluminium plates accelerated by the explosion products. It was shown in these experiments that in the region of 80 GPa boron nitride exists in a semiconducting state. The electrical conductivity of water is ionic and at a pressure of 30 GPa the specific conductance reaches a plateau as a result of the attainment of the total dissociation of water molecules.

The dynamic isentropic compression (DIS) of fused quartz and liquid hydrogen to ~500 GPa has been achieved[64] with the aid of an explosive magnetic flux compression technique. It was shown that, up to pressures of 500 GPa, quartz does not become an electrical conductor. At 200 GPa liquid hydrogen has a density of ~1 g $cm^{-3}$ and at this pressure its transition to a metallic state was not observed. The density of hydrogen subjected to repeated shock compression has been measured[65] by the $\gamma$-ray diffraction method; the density was determined by measuring the diameter of a cavity converging towards the centre of a cylindrical shell (accelerated by detonation products) in which hydrogen was present initially in the gaseous state. It was shown that, at pressures in excess of 280 GPa, the density of hydrogen increases from 0.8 to 1.3 g $cm^{-3}$, which the authors suggest is due to the transition of hydrogen to the metallic state.

Several studies postulating various schemes (not realised experimentally hitherto) for the achievement of the isentropic compression of a substance under dynamic conditions have been published. Thus Yampol'skii,[66] who also carried out a general analysis of the state of the problem, suggested that the "smooth" compression of the specimen be effected by the products of the detonation of a charge located at some distance from the target; the period of increasing pressure then depends on the size of the gap. It has also been suggested that media with variable dynamic rigidities be employed. In the propagation of SW through such media there is a possibility of the transformation of the SW into a wave with a smooth increase of pressure in the front.[66] A gas-dynamic method for the low-temperature compression of solid hydrogen placed in a copper cooling conductor has been proposed.[67] The isentropic compression of hydrogen can be achieved in this method by transmitting pressure to the cooling conductor via a gas which is compressed by a metallic cylinder moving towards the centre as a result of being acted upon by a descending detonation wave.

All the proposed methods have been designed to record the low-temperature states of substances in the course of shock compression or DIS and do not provide for the preservation of the specimens of the test substances. In the above methods the test specimens break down after compression and fly apart in the form of a plasma, particles, fragments, etc. One should also note the difficulty and high cost of creating a cylindrical converging detonation wave and reproducible strong magnetic fields.[68]

### 2. The Generation of Low-Temperature States of Condensed Substances in Dynamic Compression in Experiments with Preservation of the Specimens

Systematic studies designed to generate experimental conditions ensuring low-temperature dynamic compression were initiated in 1970 at the Institute of Chemical Physics of the USSR Academy of Sciences. Attention was concentrated on the development of simple schemes for the compression of substances placed in preservation tubes and ensuring a closer approach to the isentropic regime compared with the stepwise shock compression.

Since the temperature on the isentropic curve corresponding to the given degree of compression is linearly related to the initial temperature of the test substance, it follows that, in order to be able to carry out experiments at lower temperatures, it was necessary to develop also designs for preservation tubes permitting experiments with the specimens cooled to 4.2 K. Evidently dynamic isentropic compression at low temperatures should lead to the appearance of states of the test substance which are located in the immediate vicinity of the compression curve at the absolute zero. Estimates have shown,[66] that, for example, in the shock compression of lead to 100 GPa, the maximum temperature reaches ~9200 K, while the residual temperature is 1800 K. Isentropic compression to the same pressure of the specimen initially at room temperature should heat lead by not more than ~900 K and from 4.2 K only up to 12 K.

We shall consider briefly below the principal experimental schemes developed for the achievement of low-temperature dynamic compression and shall discuss the differences in the states of various substances whose specimens were

preserved after repeated shock compression and after DIS.[33,69-73]

Analysis of the propagation of SW in media with variable density indicates the possibility of their transform ion into smooth isentropic compression waves.[63,73] Since it is very difficult to prepare a medium with a continuously varying medium density, systems consisting of layers of substances having different dynamic rigidities, which made it possible to reduce significantly the amplitude of the first SW and to increase the number of subsequent waves in the repeated SW compression of the test specimen, have been used.[69,70] Organic substances having low thermal stabilities were employed as a kind of thermoindicators.

In one of the methods proposed, a decrease of the amplitude of the first SW was achieved by placing a buffer system of plates (screens) made up of different materials in front of the specimen.[69] In these experiments it was possible to reduce the amplitude of the first SW in acrylamide and polypropylene to ~3 GPa for a final pressure of 50 GPa. In the case of repeated shock compression for the same pressure in the absence of screens, the amplitude of the first wave was ~13 GPa and for the specimen initially at room temperature AA underwent total thermal degradation and PP underwent a thermal structural transformation. On the other hand, under conditions close to DIS, i.e. in the presence of screens, there was only partial degradation of AA and the structural transformation of PP did not take place.

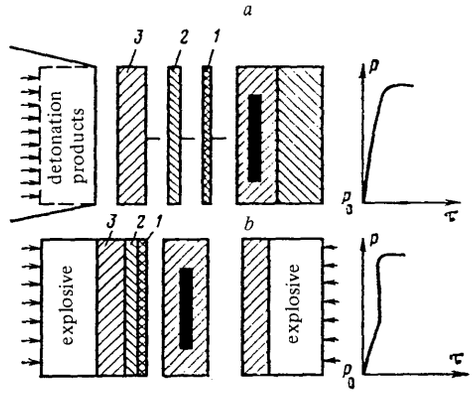

**Figure 6.** Schematic illustration of devices ensuring the dynamic isentropic compression (*a*) and successive compression of the test substance by the isentropic wave and then the shock wave (*b*); the three layer impactor is made up of perspex (*1*), aluminium (*2*), and copper (*3*) plates. The time variation of the pressure in the specimen during compression is shown on the right.

The compression scheme illustrated in Fig.6, which permits the achievement of "smooth" compression of the test substances placed in preservation tubes by successive impacts against the tube by plates (impactors) with increasing dynamic rigidity, proved to be the most rational.[33,70] By a planar detonation of an AA charge, SW are generated and propagated in this method over a system of plates, made, for example, of copper, aluminium, and perspex; when the shock wave reaches the free surface, it initiates at first the motion of the perspex plate, which acquires the highest velocity by virtue of its high compressibility. Impactors made of aluminium and copper require lower velocities and the velocity of the plate is lower the greater the dynamic hardness of its material. The final pressure in the target is generated after impact by the copper plate.

Qualitative analysis of this method leads to the conclusion that, when the distance between the layer impactor and the target is varied, it is possible to achieve a wide variety of different profiles of the compression waves accompanied by a longer period of increasing pressure at the given point in the specimen compared with the usual repeated SW compression. It is significant that, when the law governing the decay in the target (the lid of the tube) of the shock wave generated as a result of the impact by the first thin plate is known, it is possible to select the thicknesses of the materials in such a way that after the first impact the test substance is acted upon by a SW with a very low amplitude.

A series of experiments have been carried out[73] on the repeated shock compression and DIS of an organic monomer—acrylamide, using various compression schemes (Figs.4*b* and 6*a*), up to 40 GPa at initial temperatures of 293, 77, and 10 K. After the experiments, the tubes were cooled to 77 K in order to fix the products formed, then opened at the same temperature, and the properties of the specimens were investigated also starting with 77 K. It was found that repeated shock compression of AA at 293 K led to its complete degradation or at 77 K it gave rise to a 30% yield of the polymer. On raising the temperature of the cooled specimens, postpolymerisation was not achieved, apparently as a consequence of the annealing of the active centres. In the course of compression at 10 K, 10% of the polymer was formed and the concentration of active centres remained the same, so that, on raising the temperature of the specimen to 293 K, vigorous polymerisation took place; the final yield of the polymer reached 40%.

Under DIS conditions at 293 K and 77 K, 20 and 3% of the polymer were formed respectively; at 10 K the yield of the polymer was virtually zero. On raising the temperature, polymerisation did not occur apparently owing to the inadequate number of active centres, the possibility of the appearance of which was reduced probably as a consequence of the lack of high pressure gradients in the SW front. Degradation was not observed over the entire experimental range. The results obtained indicate a significant decrease of temperature in DIS compared with repeated shock compression.

The development of methods for the DIS of substances at low initial temperatures in experiments with preservation of the specimen created a possibility for the investigation of frozen gases or systems in which they are included. Tube designs were developed which permit the preservation of the above specimens after their dynamic isentropic compression to 50 GPa. Carbon dioxide, chlorine, water, a mixture of water and carbon dioxide, and a mixture of n-heptane and chlorine were investigated.[33] In order to observe the changes in the state of the substances at low temperatures, the RTL method was used. It was found that the RTL spectra of many substances subjected to compression differ from the initial spectra. For example, after the compression of $CO_2$, new peaks appear on the luminescence curve. The $C_7H_{16} + Cl_2$ mixture subjected to DIS loses its capacity for a rapid reaction in the region of the phase transition (at about 153 K), which is characteristic of an untreated mixture of these reactants.

The demonstration of the possibility of carrying out experiments with condensed gases under dynamic compression conditions with preservation of the specimens and of the

direct observation of their properties must be regarded as the principal result of studies of this kind carried out hitherto.

As research expands, an increasing number of processes which are favourably influenced by low-temperature dynamic compression are being discovered. For example, the low-temperature dynamic compression to 20 GPa of trioxan subjected to preliminary $\gamma$-irradiation induces a much greater increase in the yield of the polycrystalline polymer and of the number of chains that might have been produced by the simple summation of the compression and irradiation effects.[74] In order to increase the yield of the dense boron nitride phase, two-layer cylindrical tubes made of different materials have been used,[75] which led to an increase of the multiplicity of the shock compressions and to a decrease of the temperature developed in the specimen. When the molybdenum–iron pair was used, it was possible to attain a 70% yield on compression of boron nitride without additives. A layer of liquid hydrogen, which served simultaneously as the cooling agent, was used[76] as a light pressure transmitting substance. It was shown that, in the zone where DIS is active in copper, brass, and nickel specimens, a significant decrease of microhardness and of the density of traces of deformation was observed compared with the corresponding characteristics in the region of shock compression. The profiles of the compression waves in DIS are being investigated[77,78] and various schemes for the practical employment of layer systems have been proposed.[79]

We should like to draw attention to the following possibility which appears in connection with the development of methods for the attainment of DIS. In DIS the microshear deformations at the front and the temperatures developed are significantly reduced even by comparison with repeated shock compression, whereas the duration of action, the character of the decrease of pressure, and the degree of macroplastic deformations of the tubes with the specimen are virtually the same in both cases. DIS by itself does not as yet allow the separation of the role of microshear deformations and of the temperature factor, since a weakening of the influence of the former induces also a decrease of the temperature of the substance behind the front. However, preliminary heating of the substance under DIS conditions makes it possible to obtain $P-T$ conditions identical with those in the usual repeated shock compression and hence to isolate the influence of the SW front in a "pure form".

Two processes of different kinds, occurring on shock compression, have been investigated: the structural transformation of boron nitride into a dense diamond-like modification[80] and polymerisation of AA.[33] It has been shown that, when the experiments are carried out at low temperatures or at room temperature, the replacement of repeated SW compression by DIS prevents the structural transition in boron nitride. On the other hand, preliminary heating above 400 K is sufficient for the dense form of boron nitride to be produced both on DIS in 70% yield and on repeated shock compression. It has been shown in relation to the polymerisation of AA that the SW front is in fact responsible for the process, because preliminary heating of AA specimens up to the melting point did not increase the yield of the polymer, which remained an order of magnitude lower on DIS than on repeated shock compression.

### 3. The Attainment of Ultrahigh Pressures as a Result of the Head-on Collision of Shock Waves

The collision of planar SW and the attainment of ultrahigh pressures in specimens and their subsequent preservation for analysis have been achieved.[81] This became possible as a result of the construction of a symmetrical apparatus (Fig.7) in which two specimens of the test substance are subjected to two identical initial SW directed towards one another. We may note that modern explosive experimental technique makes it possible to synchronise with high accuracy the detonation of two identical explosive charges which accelerate identical impactors. An important requirement is the displacement of the test substance within the apparatus into the region not subjected to negative pressures which arise as a result of the interaction of the rarefaction counterwaves. When the layer 5 is made of a very dense material, for example, tungsten, it can promote a considerable increase of pressure in the reflected wave. If the shock adiabats for the materials and the velocities of the impactors are known, then the maximum pressure in the test substance can be estimated beforehand.

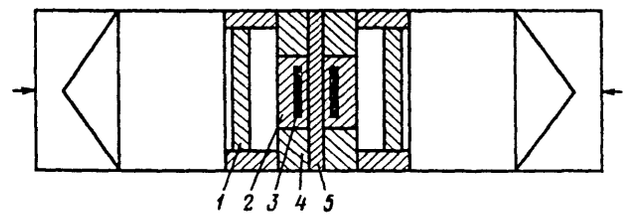

**Figure 7.** Schematic illustration of the experimental apparatus for the attainment of ultrahigh pressures on collision of planar shock waves: *1*) impactor (may be a multilayer impactor); *2*) preservation tube; *3*) test substance; *4*) protective ring; *5*) layer of a hard material.

The use of the method described for the treatment of substances by dynamic pressures makes it possible to increase greatly the maximum attainable pressures without complicating the existing systems and devices designed for the creation of high pressures in a one-sided impact. For example, at the velocities of the copper impactors usually employed, amounting to $\sim 2.0 \times 10^3$ and $2.5 \times 10^3$ m s$^{-1}$, pressures of ~50 and ~65 GPa respectively are developed in copper (or steel). The head-on collision of such impactors generates pressures of ~120 and ~170 GPa. The use of powerful explosives and greater charges makes it possible to increase the velocities of copper impactors to $\sim 3.5 \times 10^3$ m s$^{-1}$, whereupon pressures up to ~300 GPa can be achieved in a head-on collision.

Experiments have demonstrated[81] that the usual tubes with test substances withstand effectively pressures up to ~100 GPa. Above this pressure, changes in design are necessary in order to eliminate considerable macroplastic deformations. Experiments on the dynamic compression of polyethylene (PE) and polystyrene (PS) at pressures up to ~120 GPa have been carried out.[81] In order to achieve DIS, the head-on collision of two compound impactors made of perspex, aluminium, and copper has been used. Copper impactors, which determined the final pressure, had a velocity of $\sim 2 \times 10^3$ m s$^{-1}$. Analysis of the PE and PS specimens preserved after compression showed that they remained monolithic and semitransparent and were free from traces of degradation. A gel fraction was formed in PS in 100% yield owing to the formation of cross links, but, judging from the infrared spectrum, the decomposition of the benzene ring was not observed. We may note that

repeated shock compression of PS to 50 GPa leads to only partial formation of the gel fraction. It is known that $\gamma$-irradiation of polystyrene with a dose of 100 Mrad is necessary for the formation of 30% of the gel fraction.

The methods examined and the results show that both shock and isentropic compression waves or their various combinations can be used in head-on collisions. For example, a specimen subjected to preliminary DIS can be then acted upon by SW (Fig. 6*b*). The possibilities of this method have already been described.[33] In other words, it is now possible to achieve a controlled dynamic compression of specimens of different kinds and also to follow the variation of the state of the substance both in the course of compressing, by employing high-speed recording apparatus, and directly during the analysis of the preserved specimens.

## V. CHEMICAL SYNTHESES AND THE PREPARATION OF ULTRAHARD MATERIALS DIRECTLY IN THE DETONATION WAVE

Until recently dynamic methods for the preparation of ultrahard materials (UHM) such as diamonds and the dense modifications of boron nitride were based solely on the use of SW.[82] The initial materials are placed in flat or cylindrical preservation tubes which are penetrated by SW generated by a detonating explosive placed on the outside. Thus the detonation of explosives is used indirectly as a mixed external source of energy for the generation of SW. It has been shown in recent years that the detonation of charges made of a mixture of explosives and materials to be transformed (carbon or graphite-like boron nitride) entails the formation of UHM.[82] For this purpose, free mixed charges were detonated in stationary repeatedly reuseable hollow hermetically sealed containers, which made it possible to avoid the employment of disposable preservation tubes. It is significant that the detonation parameters (pressures up to 50 GPa and temperatures up to 6000 K) correspond to the region of the synthesis of UHM on static presses and overlap the part of the phase diagram which is difficult to attain, in which carbon and boron nitride exist in the liquid state.

The detonation synthesis[82] makes it possible to obtain diamond from various modifications of carbon, including amorphous modifications, with different fractional compositions. Depending on the experimental conditions, it is possible to synthesise the cubic modification or a mixture of the cubic and hexagonal modifications of diamond. Detonation diamond is a highly dispersed material with a high specific surface (20–150 $m^2\ g^{-1}$) and small coherent scattering regions (60–200 Å).

It has been shown that dense modifications of boron nitride can be obtained by detonation synthesis from both crystalline graphite-like and high-temperature boron nitride. Furthermore, depending on the detonation parameters of mixed charges, it is possible to achieve the specific synthesis of wurtzite-like or cubic modifications of boron nitride. As in the case of diamond, the particle size of the dense modifications of boron nitride is small—ranging from 0.05 to 5 μm, while the density is significantly lower than its theoretical value: 3.15–3.30 $g\ cm^{-3}$.

In considering the possible mechanisms of the formation of UHM, the hypothesis that carbon and boron nitride melt with subsequent crystallisation of the UHM from the melt appears to be of greatest interest. In particular, this hypothesis is supported by the synthesis of diamond from amorphous forms of carbon.

The question of the possibility of the synthesis of oxides, nitrides, and carbides directly in the detonation wave has been examined in a review.[33] The examples quoted indicate extensive new possibilities for the dynamic methods for acting on matter.

## VI. THE ROLE OF PLASTIC DEFORMATION IN DYNAMIC EXPERIMENTS AND THE POSSIBILITY OF COMPARING THE RESULTS OF DYNAMIC AND STATIC INFLUENCES

In discussing the questions concerning the role of plastic deformations, it is essential to differentiate two types of information obtained in the dynamic compression of matter. These include various characteristics recorded in the course of shock compression in the central region of the specimen, which is not yet affected by rarefaction waves, and the data obtained from them, for example, compressibility, electrical properties, etc. When the specimen is compressed by a planar shock wave, its central region is subjected to a one-dimensional compression without transverse deformations. The compression of a substance by powerful SW, whose amplitude greatly exceeds the yield point, makes it possible to neglect the effect associated with the hardness of solids. One can therefore assume that compression to a given pressure is the same as that which would have been achieved under a hydrostatic pressure of the same magnitude. This hypothesis is confirmed by the fact that in most cases the characteristics obtained by the shock compression methods merge smoothly, on extrapolation, with the characteristics obtained by static methods at lower pressures. For a number of substances, a satisfactory agreement has been observed as regards the onset of reactions in static and single shock compressions.[83,84] This applies, for example, to substances such as Fe, Bi, Si, Ge, P, I, Sb, Se, FeC, KCl, CdS, and GaAs.

It has been suggested that the martensite mechanism of the transformation predominates on compression by SW, whereas the change in the lattice is based on the cooperative displacement of many atoms over short distances. Such a transformation, which does not require an activation energy, can take place at very low temperatures at sonic rates of propagation, so that the particles of the new phase, with micron dimensions, are formed in the course of $10^{-7}$–$10^{-8}$ s. It has been suggested[84] that a complete identity of the phase transition pressures is possible for coordination crystals and layer structures with few defects. However, highly defective layer structures require higher pressures on compression by a SW than under static compression.

The specific features of shock compression are determined by the SW front in which the strongest microplastic deformations take place simultaneously with a sharp increase of the pressure and temperature. Despite the fact that the duration of the action of high pressure is only a fraction of a microsecond, i.e. is shorter by a factor of $10^7$ than in static compression, there is sufficient time for the occurrence of a wide variety of physicochemical processes in the test substances. The acceleration of processes in the SW has been compared by many investigators with the results obtained at high static pressures in combination with shear deformation (HP + SD)—see the relevant review.[85] However, the difficulty of comparing these two methods consists in the fact that under static conditions one investigates as a rule $P$–$T$ diagrams, while under dynamic conditions one obtains relatively simply and with a high accuracy $P$–$V$ diagrams. On the other hand, the temperature can be in the main estimated only by calculation subject to various simplifying assumptions. Furthermore, the pressure range in dynamic

experiments greatly exceeds that in static experiments. The question of the possibility of a comparison has been analysed in greatest detail in the review of Dremin and Breusov.[86]

Information about the influence of the rarefaction waves on chemical and phase transformations of a given substance in the course of shock compression is virtually lacking in the literature. Certain considerations concerning the role of rarefaction waves in the formation of active polymerisation centres and their contribution to the residual temperature have been published.[33]

When questions associated with the comparison of the changes in the properties of substances preserved in tubes after shock compression or after DIS are discussed, the situation is different. As already mentioned, in this case the specimen is acted upon by the full phase of the SW, including the rarefaction waves. Under these conditions, the specimen in the preservation tube inevitably undergoes major plastic deformations which depend on the compression conditions and the formulation of the experiment.

In considering the experiments in which specimens were compressed in cylindrical tubes, attention was drawn above to the complex pattern of the wave interactions and to the occurrence of the intense uncontrollable plastic deformations of the substance, leading to additional heating of the specimen. Nevertheless, it is sometimes possible to carry out a qualitative comparison of the results of static and dynamic experiments. We shall consider this in relation to the formation of polymeric molecules from unsaturated carboxylic acids—maleic (MA) and fumaric (FA), which are *cis*- and *trans*-isomers. Under the usual conditions, these acids do not polymerise owing to steric hindrance. However, it has been shown[87] that under HP + SD conditions at 6 GPa they undergo oligomerisation. The oligomers have a molecular weight of 700–800, which corresponded to a chain consisting of 6–7 molecules.

These objects behave differently on shock compression. Whereas both oligomers with a chain length of 5–7 units and polymeric products with a molecular weight (MW) of $3 \times 10^4$ (chain length of 250 units) are formed in MA on compression in flat and cylindrical tubes, in FA polymeric products are detected only under the conditions of enhanced deformations in the cylindrical tubes.

When special precautions are taken, the use of a planar compression scheme makes it possible to alter specifically and within wide limits the degree of radial macroplastic deformations of the specimens. Fig.5 illustrates the design of tubes in the usual formulation of the experiment (*a*) and in an experiment where the degree of deformation is specified beforehand (*d*), in which the specimen is capable of being deformed during the period of the operation of the high pressure ($\sim 10^{-5}$ s) and of filling the free volume in the tube. Such conditions were first used in the study of the influence of the degree of macroplastic deformations as a function of pressure on the polymerisation of acrylamide in a layered tube.[88] An increase of the degree of deformation of the specimens from 1 to 17% at the same pressure led to an appreciable increase of the number of polymer chains formed and of the yield of the polymer.

The scheme for the creation of specified macroplastic deformations has been used also in the study of the possible abiogenic syntheses of aminoacids in nature from nitrogen-containing organic compounds using as an example the reactions of the ammonium salts of unsaturated carboxylic acids under dynamic compression[89] and on their deformation under the conditions of a high static pressure up to 6 GPa.[90] The dynamic compression of the specimens was achieved in five different regimes. Shock compression, shock compression with a specified degree of deformation (up to 160%), DIS by the usual method, and DIS with a specified degree of deformation of the specimens were achieved in the planar arrangement, while in the cylindrical version the system was also subjected to shock compression. The pressure was varied from 5 to 11 GPa and the initial temperatures were varied from 77 to 300 K.

It has been shown[89,90] that, both in the HD + SD method and on dynamic compression, the ammonium salts of acrylic, methacrylic, crotonic, fumaric, and maleic acids can be converted into aminoacids. The yield of aminoacids on dynamic compression depends on the pressure, the initial temperature, and especially on the compression regime. The maximum yield has been attained in the presence of enhanced macroplastic deformations (Fig.5d) in planar compression under DIS conditions and in the cylindrical compression scheme.

It is to be hoped that the proposed schemes for compression with a specified degree of deformation will make it possible to compare quantitatively the results obtained in the HP + SD method and in different dynamic compression regimes and to discover the role of the SW front, plastic deformations, kinetic factors, etc. in various physicochemical processes.

---o0o---

The technique of dynamic experiments in which provision is made for the preservation of the test specimens after compression in order to investigate the changes which they have undergone made it possible to extend the range of thermodynamic parameters compared with the traditional studies of the state of substances in the course of shock compression with subsequent breakdown of the specimen. Treatment of specimens in the pressure range 10–100 GPa and above and at temperatures up to $10^4$ K has become a realistic possibility. The useful volume of the specimens of the test substances is not limited at much higher pressures, in contrast to static apparatus.

The set of systems for the preservation of substances which have undergone dynamic (shock or isentropic) compression developed has made it possible to achieve various physicochemical transformations.

Methods permitting the attainment of controllable changes in the character of the dynamic compression and of the degree of deformation and also experiments at very low initial temperatures permitted in many instances the determination of the mechanism of the action of the SW and the role of its front. These experiments should promote the joint employment of the results of dynamic and static investigations, particularly in the HP + SD method. The possibilities of the dynamic method have not as yet been fully elucidated, as shown, for example, by the synthesis of ultrahard materials directly in the detonation wave.

# Inorganic Chemistry of High Dynamic Pressures

S.S.Batsanov

The causes and history of the appearance of a new field in the physical chemistry of high pressures, namely the chemistry of shock compression, are examined. Cases of phase transitions under the influence of high dynamic pressures which in principle cannot occur on static compression, namely transformations involving a decrease of density, are also described. Various types of chemical reactions, mainly syntheses, in condensed inorganic substances under the influence of shock waves are examined. Attention is concentrated on the mechanisms of chemical reactions and on the synthesis of new compounds and solid solutions, including those with atoms in unusual oxidation states. The prospects for the further development of the inorganic chemistry of shock compression are assessed.
The bibliography includes 231 references.

## I. INTRODUCTION

Together with variation of temperature, the nature of solvents, and the state of aggregation of the reactants, the high pressure technique has come to be used on an increasingly wide scale in recent years in synthetic methods of modern chemistry in order to influence specifically the structure and composition of the given substance. By varying the pressure, it is possible to influence various levels of the organisation of matter. It has been established experimentally that plastic deformation of the majority of materials is observed in the pressure range 1–10 kbar, polymorphic transformations take place in the range 10–100 kbar, while in the range 100–1000 kbar the outer electronic structure of atoms changes. Although the van der Waals, atomic, and electronic interactions can be separated only to a first approximation, it is evident that an increase of the level of pressures gives rise to new possibilities for influencing matter.

It is known that the technique employed in generating high static pressures suffers from two important limitations. Firstly, the pressure attained in presses is limited by the mechanical strength of the working material of the apparatus; record static pressures (1–2 Mbar) have now been obtained using diamond anvils. Secondly, an increase of pressure is accompanied by a decrease of the working space within the presses. As a result, in laboratory diamond presses the useful volume is now reckoned in microns and experiment makes it possible to obtain only new information about the given substance and not to synthesise materials with new properties.

The above limitations led to the need for a fundamentally new method of generating high pressures which would be free from the above disadvantages. Such an alternative procedure proved to be the dynamic methods for compressing matter with the aid of shock waves. It is noteworthy that the general theoretical questions of the physics of shock waves have been inadequately developed. The gas-dynamic principles of the theory of shock waves have been described in familiar monographs[1–3] and we shall therefore confine ourselves merely to a description of the principal terminology of this branch of physics.

Shock waves are formed as a result of the collision of molecules and particles travelling at an ultrasonic velocity with a stationary or moving barrier. The shock waves formed in the barrier are propagated at a rate $D$ and cause the migration of the bulk of the substance at a rate $u$. The dynamic pressure developed in the given body is

$$p=\rho_0 Du\ , \qquad (1)$$

where $\rho_0$ is the initial density of the compressed substance.

The energy source of shock waves may be provided by the detonation of explosives, an electric discharge, the work of the evaporation of solids on irradiation with a powerful light source, an electron beam, etc. The period of the increase of pressure from the normal value (1 atm) to the maximum value is $10^{-10}$–$10^{-12}$ s, the period of the high pressure is of the order of $10^{-6}$ s, and the period of the decrease of the pressure (relaxation) is $10^{-5}$–$10^{-6}$ s. The region in which the pressure increases is called the shock wave front and extends from tens to thousands of angstroms depending on the state of aggregation of the substance of the specimen.

Precisely because of the concentration of energy in space and time, it is possible to increase greatly the pressure by the dynamic method. However, the brevity of the duration of the dynamic pressure has posed new questions—is there sufficient time during such a brief period for the atoms in the structure of the solid to undergo a rearrangement and, even more so, is there sufficient time for a chemical reaction to occur in a mixture of the substances compressed by the shock wave. Only when these questions are resolved in a positive sense, will it be possible to claim that chemists have acquired a new instrument for influencing matter.

Evidently, the above problem can be solved only provided that the specimen subjected to the action of powerful shock waves is preserved (in a mechanical sense) so that is can be investigated by traditional physicochemical methods. Since the temperature also increases on shock compression, the study of the substance exposed to a shock wave would make it possible to compare its properties with the characteristics of the same substance heated to the corresponding temperatures at the normal pressure. If the results proved to be the same, then, from the chemical standpoint, the shock wave

is simply a means of heating the substance, but, if a difference is observed, then the new physical procedure has novel aspects. The solution of this problem, the protection of specimens against mechanical breakdown, and their careful physicochemical study, were the main topic investigated during the initial stage of the development of the chemistry of shock compression.

We shall consider briefly the sources of the appearance of this new field of study, namely the level of knowledge from which extensive experimental studies began in the 1960's in the field of the chemistry of shock compression. In 1938 to 1949 Michel-Levy and co-workers[4-6] described experiments in which the formation of silicates was noted on detonation of a mixture containing metal silicon oxides. In 1944, when two brass discs were exposed to a detonation pulse, they were found to be joined together (welded).[7] In 1948 Carrington and Gayler[8] described the change in the real structure of iron, duralumin, and silver after pulsed compression, namely an increase in the number of defects and in the strength of the metals was observed.

The next major step was taken in 1954 by Walsh,[9] who suggested, on the basis of the form of the shock adiabat for iron, the possibility of a phase transition under the conditions of dynamic compression. The study of the real structure of iron after its shock compression confirmed this hypothesis.[10,11] In 1956 Bancroft et al.[12] investigated experimentally the dynamic compressibility of iron and observed at 130 kbar a break on the curve relating the volume to pressure and detected ε-iron in the shock compression products, which indicated unambiguously the polymorphic transformation of iron in shock waves.

Non-metallic objects were first investigated in 1956 by Ryabinin,[13,14] who studied chemical compounds subjected to dynamic compression in cylindrical tubes; he observed the appearance of defects and processes involving the total or partial decomposition of organic and inorganic substances. In 1958 a technique for shock pressing, particularly in relation to aluminium and iron oxides, was described.[15] A marked distrotion of the structure, up to the complete conversion into the amorphous form (vitrification) of crystalline quartz was observed by De Carli and Jamieson.[16] Finally in 1961 the same workers[17] observed, after the shock compression of graphite (at $p \cong 300$ kbar), minute crystals of diamond in the specimen, in full agreement with the equation of state for carbon published by Leipunskii[18] in 1939.

In our view, the study of De Carli and Jamieson[17] completed the series of investigations which led to the establishment of the principal elements in the new scinetific discipline—the physical chemistry of shock compression. In the Soviet Union this was formally recognised at the Novosibirsk Scientific Centre of the Siberian Division of the USSR Academy of Sciences by the organisation of the Division of the Physical Chemistry of Pulsed Pressures. The results of the investigations in this Division have been described;[19] an analogous series of physicochemical laboratories have been established in Moscow at the Institute of Chemical Physics of the USSR Academy of Sciences. The combination of the physics of shock waves, the "preservation technique", and the chemistry of the solid state has in fact led to the attainment of very high values of thermodynamic parameters, made it possible to ensure the mechanical preservation of the product of the exposure of the given substance to explosion, and permitted the optimum selection of the objects of study.

An extensive literature on the chemistry of shock compression has already accumulated and it is virtually impossible to consider it in a single review. In the present article we shall therefore summarise the development of only the inorganic chemistry of high dynamic pressures and in our treatment we shall deal consistently with all the deeper levels of the structural changes in matter under the influence of shock waves and the corresponding molecular-physical and chemical consequences of these changes. This approach cannot naturally reflect all the studies on the problems considered. Additional literature may be found in other review articles.[20,21]

## II. THE CHANGE IN REAL STRUCTURE

When shock waves are propagated through a crystalline specimen, fragmentation and disorientation of the crystallites take place at the boundary between the compressed and unperturbed substance as a consequence of the steep pressure gradient. This results in an increase of the density of dislocations and of the microhardness of the specimen. This was first observed by Klein and co-workers[22-27] (in relation to MgO).

The present author investigated[28-31] single crystals of alkali metal halides in fluorite, preserved after a dynamic stress, and in a number of instances the dislocation densities and microhardness were determined for different orientations of the crystals. It was observed that, after dynamic compressions up to 60–80 kbar, the dislocation density in alkali metal halide specimens increases by 5–6 orders of magnitude. The increase of the density proved to be minimal for the <110> direction, while during annealing the decrease of the number of dislocations and of the microhardness was faster along the <111> direction. The latter factor can apparently be accounted for by the anisotropy of the plasticity of the crystals. The disorientation of the blocks in the single crystals subjected to shock compression which we investigated varied in the range from 40' to 3°.

The experimental surface dislocation densities ($10^{10}$–$10^{11}$ $cm^{-2}$ for alkali metal halides and $10^{12}$ $cm^{-2}$ for MgO) can be accounted for with the aid of the following estimates. The size of the crystal blocks [coherent scattering regions (CSR)] in single crystals subjected to shock compression is $\geq 100$ Å.[30,32] If it is supposed that dislocations constitute the boundaries of these blocks, then the maximum number of surface dislocations per $cm^3$ is ~$10^{18}$–$10^{19}$ and the dislocation density is therefore ~$10^{12}$–$10^{13}$ $cm^{-2}$. As a consequence of the residual heat, some of the dislocations disappear and the density is reduced by 1–2 orders of magnitude. Thus the residual dislocation density should not exceed $10^{11}$–$10^{12}$ $cm^{-2}$, as has in fact been observed experimentally.

In the study of dislocation structures by the method of etch figures, an interesting feature was observed[30]—the inheritance of the properties of the initial material by the substance subjected to shock compression. Thus, after shock compression, LiF, NaCl, and CsI crystals retain the initial dislocation structure, against the background of which new dislocation networks appear. On the other hand, in the case of KBr, which undergoes a phase transition under the conditions of the dynamic stresses employed, a new dislocation pattern was found after compression, which is apparently due to the breakdown of the initial structures as a consequence of the migration of atoms. It has been suggested[33] that a polymorphic transformation should altogether destroy the crystallinity of the given body, but experiment has shown that a single crystal can be preserved even after phase rearrangement.

At the same time, quartz[16] and silicate crystals undergo a complete or partial conversion into the amorphous form under the influence of shock waves. The latter phenomenon has been studied in greatest detail[34,35] by optical and X-ray

methods. It has been shown that sections (submicroscopic inclusions) of a disordered amorphous phase arise in the bulk of the crystals; as a result, the anisotropy of the properties of the shock-compressed crystal diminishes and its parameters approach those of isotropic bodies.

X-Ray studies of the dynamic compression of single crystals have shown that crystalline order is immediately established behind the shock wave front in LiF,[36–38,41,44,45] Al,[39,43] and BN[40,42] and that the shock compression at a high pressure is isotropic at the level of the unit cell. After the phase transition, the X-ray reflections for KCl[43] were appreciably weakened and broadened, which indicated the fragmentation of the blocks to dimensions of ~100 Å. After the shock compression of NaCl,[44] a monoaxial deformation was observed and the existence of crystalline order in the course of a microsecond behind the shock wave front was noted. The lines on the X-ray diffraction patterns for NaCl and KCl proved to be broader than for the initial single crystal and the intensity of the reflections was lower; however, the lines were more distinct than for a typical powder. The boradening of the lines can be accounted for by the fragmentation of the grains and the increase of the dislocation density. The reflections on the X-ray diffraction patterns of specimens of shock-compressed NaCl disappear 0.8 μs after the pressure peak as a consequence of the distortion of the crystal by plastic deformation.

Thus, according to X-ray diffraction data, the shock compression of single crystals at high pressures takes place isotropically, at moderate pressures deviations from the isotropic behaviour are observed, while at low pressure monoaxial compression takes place. In the region where a high pressure operates ordering of the material is observed and relaxation is accompanied by its deformation and disordering. This factor enabled American[36,40] and German[44] investigators to suggest that the fragmentation of the grains and in general the change in the real structure take place as a consequence of extensive stresses in the decompression wave and not at the front of the shock wave.

At the same time, the present authors' first experiments on the real structure of single crystals[28,30] showed that, with increase of the weight of the explosive charge, i.e. with increase of the smoothness of the decompression, and with decrease of the effects of the extensive stresses, the dislocation density either does not change or actually increases somewhat. Hence it follows that the shock wave front plays an important role in the formation of defects, while during decompression the material either becomes more defective owing to plastic deformations or less so as under the influence of temperature (see below).

Simultaneously with the study of single crystals, much attention has also been devoted to the investigation of the real structure of polycrystalaline materials subjected to the action of dynamic stresses. The pattern of the distribution of shock waves in powders is more complex than in single crystals, since in the former case the effects on the surfaces of crystalline grains are also manifested—repeated reflections, splits, contact fusion, surface evaporation, etc. Table 1 presents the minimal dimensions of the CSR of shock-compressed polycrystalline materials according to the present authors' data;[46] the substances are arranged in order of decreasing degree of dispersion of the material attained in a single step on shock compression.

The minimum CSR cannot be reduced by subjecting the same material to repeated shock compression. Thus single compression of $CaF_2$ and $BaF_2$ resulted in the appearance of anisotropic (in conformity with the different strengths in different directions) crystalline blocks whose size was 180–600 and 220–380 Å in the <110> and <111> directions respectively.[47] As a result of repeated compression, the crystallites became fragmented only along the major axes; the dimensions of the maximum axes of the ellipsoidal CSR in the $CdF_2$ and $BaF_2$ specimens diminished to 380 and 260 Å respectively, while the lengths of the minimum axes did not change on repeated compression. An analogous picture was obtained also in the shock compression of magnesium and aluminium oxides. This approach to isometric CSR corresponds to the enhancement of the isotropic nature of the properties on shock compression observed in relation to single crystal silicates (see above).

Table 1. Dimensions of the crystallites in shock-compressed powders.

| Substance | CSR, Å | Substance | CSR, Å |
|---|---|---|---|
| C, $TiO_2$ | 100 | $UO_2$ | 230 |
| $Al_2O_3$ | 130 | $Al_2SiO_5$ | 250 |
| BN, AlN, Mo | 150 | Ni, $LaB_6$ | 270 |
| LiF, MgO | 160 | Cu | 350 |
| $CdF_2$ | 180 | ZrC | 370 |
| $CaF_2$ | 190 | NaF | 440 |
| $BaF_2$ | 220 | | |

The results of the determination of the distribution of grain sizes in powders are also consistent with X-ray diffraction data for the degree of dispersion of polycrystalline materials: it has also been observed that large crystalline grains are fragmented more intensely than small ones.[48,49]

The above findings suggest that the "fragmenting effect" of shock waves has a definite limit (as if the crystalline powder were forced through the openings in a "sieve" of specific size). We shall consider the mechanism of the operation of this "sieve" and the factors which determine the size of the openings in it. If we turn back to the pattern in the propagation of a shock wave in a crystalline specimen, then it is easily seen that the crystals experience the maximum stresses (pressure gradient) only in the shock wave front, since ahead of the latter the unperturbed substance is present, while the region behind it contains the compressed substance. The depth of the front is usually estimated as equal to approximately ten unit cell parameters, i.e. ~100 Å.[50] Thus the minimum opening in the "sieve" is determined simply by the structure of the shock wave front. It has been shown[51] that, under the influence of shock waves, the crystalline grains in various types of steel assume a form close to an ellipsoid with the minor axis perpendicular to the shock wave front.

Generally speaking, the mechanism of the fragmentation of crystals can be various. If the size of the crystallites $l$ is much greater than the depth of the shock wave front $h$, the situation is favourable for the appearance of pronounced distortions (deformations) of the blocks, which promotes further (in the relaxation wave) cleavage of the crystal along the "weakened" directions. If the size $l$ is comparable to $h$, then deformations or even microsplits of the grain boundaries appear under the influence of the high pressure. For $l \leq h$, the high pressure region does not distort or fragment the crystal blocks.

Consequently the crystalline grains are deformed mainly during the compression or decompression of the substance and that, after the crystal has been exposed to the high

pressure zone, the defects acquired previously do not disappear. The mechanism of such memory is apparently associated with the disorientation of the crystallites caused by the intense vibrational movements in the shock wave front and observed from the asterism of the X-ray reflections from the preserved crystals.

In fact the contraction of the polycrystalline specimens in the high compression region can abolish micropores and cracks and can increase the apparent size of the grains, i.e. can improve the crystallinity of the material but cannot bring the disoriented crystallites into contact to form a single crystal. All the defects and distortions which had arisen in a crystal during the shock wave stress or which had been present in the initial material, therefore reappear after the decrease of pressure. One may expect that, as a result, microstresses are more likely to arise in large grains than in small crystallites and the dislocation density will correspondingly increase in direct proportion to the size of the CSR and not in inverse proportion, as always happens in the usual grinding of powders. An analogous picture of this type of unusual dependence of the concentration of microstresses on the size of crystallites has been observed in the study of the influence of radiation on crystals.[52] An analogy between the effects of shock waves and radiation has been observed also in other cases, as will be seen from further exposition. Annealing of defects induced by shock waves and radiation restores the real structure of the substance to the state of equilibrium.

Table 2. Dependence of the microstresses on the dimensions of crystallites.

| Substance | CSR, Å | $10^3\langle\varepsilon^3\rangle^{1/3}$ | Substance | CSR, Å | $10^3\langle\varepsilon^3\rangle^{1/3}$ |
|---|---|---|---|---|---|
| $CaF_2$ | 330 | 1.2 | $Al_2O_3$ | 810 | 3.3 |
| $CaF_2$ | 370 | 1.4 | $Al_2O_3$ | 1500 | 3.6 |
| $CdF_2$ | 180 | 1.6 | Mo | 145 | 1.8 |
| $CdF_2$ | 380 | 1.8 | Mo | 185 | 2.5 |
| $CdF_2$ | 650 | 1.9 | Mo | 265 | 3.4 |
| $Al_2O_3$ | 660 | 2.4 | | | |

Table 2 presents the results of the study of real structures for a series of shock compressed polycrystalline substances by the present author and his co-workers[47] (the size of the microstresses is $\langle\varepsilon^2\rangle^{3/2} = \Delta d/d$, where $d$ is the interplanar spacing). Examples of the equilibrium relations between $\langle\varepsilon^2\rangle^{1/2}$ and CSR are not quoted here owing to their trivial nature. Comparison of the products of shock compression extracted, for example, from different parts of the preservation tube and exhibiting different types of dependence of the microstresses on the size of the crystallites makes it possible to obtain additional information about the temperature field in the given tube.

The accumulation of microstresses within large grains leads to their splitting during relaxation. As a result of the decomposition of the crystals, the substance evolves the excess free energy. When the critical dislocation density is exceeded, the crystals undergo brittle breakdown. We shall consider this density subsequently in the description of processes involved in the shock pressing of powders.

The dispersion of particles and the appearance in the latter of considerable microstresses after shock compression leads to an increase of the free energy and therefore affects the molecular-physical properties of the substance. Thus, in recording heating curves, it was observed that endothermic effects (fusion of powders) are weaker, while exothermic effects (chemical combination of atoms) are more intense than for the same mixtures before exposure to dynamic action.[53] Data obtained from the determination of the energy stored after exposure to shock waves in relation to magnesium and aluminium oxides agree with this result.[49]

The activation of powders by treatment with shock waves is technologically important (see below). The study of the real structure of the powders proved useful in the investigation of the topography and characteristics of the strengthening of solids, in the determination of the mechanisms of phase transitions, and even in the solution of problems concerning the construction of preservation systems. The procedure followed nowadays in the study of the real structure on the basis of the analysis of the form of X-ray lines constitute an extremely important stage in the investigation of the processes involved in dynamic action on a substance and in the analysis of the results.

## III. THE CHANGE IN ATOMIC STRUCTURE

The change in the atomic structure of a substance in the course of a long period has been the main aim of high pressure physics (for example, the conversion of graphite into diamond). At the present time, the aims and possibilities of the technique of high dynamic pressures have expanded, but polymorphic transformations still constitute a very important field with which investigators are concerned.

In the first stage of the study of the physical chemistry of shock compression attention was concentrated on the very fact of the presence or absence of phase transitions and then on the stage involving the determination of the pressures of these transformations—the results of dynamic and static experiments began to be compared, and finally the time came to discover the characteristics of the polymorphic transformations in the course of dynamic stress. Accordingly, we shall divide all the dynamic phase transitions investigated into three groups: transitions whose parameters are close to those of static transitions; transitions differing in the character or properties of products; extremely specific phenomena manifested only in shock wave processes.

We shall consider initially a qualitative picture of the compression of a solid. This process is known to begin with the compaction of the substance at the macroscopic level: air is forced out of pores, cracks are healed, and vacancies and dislocations are abolished. Next begins the compaction process involving the shortening of interatomic distances, first within the framework of the initial structure, giving rise to isomorphic compression. With decrease of the distances, the structure of the substance departs to an increasing extent from the region of thermodynamic stability. Finally the time comes when the given substance with the initial structure can no longer exist under the new thermodynamic conditions and its structure undergoes an abrupt rearrangement, i.e. a first-order phase transition takes place. If the compression process continues then at the next level of pressures a new phase transition can occur, etc. The sequence of polymorphic transformations under pressure, leading to an increase of density, i.e. to the coordination of atoms, has been studied in greatest detail in relation to dioxides ($MO_2$): the quartz ($SiO_2$) structural type, which has the coordination number C.N. = 4, is followed, in terms of increasing density, by the $TiO_2$ structural type, which has C.N. = 6; then we have the $ZrO_2$ structural type (C.N. = 7), which is converted into the

$CaF_2$ structural type (C.N. = 8), and finally we have the $PbCl_2$ structural type (C.N. = 9).[54]

Thus there is a series of minima on the potential surface of the crystal corresponding to different packing densities of atoms in space.

Apart from the principal minima, there is a possibility of the presence of subsidiary additional minima on the potential curves in the region of the thermodynamic stability of the main structures. Under the conditions of static compression, where the stress and its relaxation take place comparatively slowly, it is not possible to detect these states. A sharp decrease of the dynamic pressure and temperature makes it possible to "quench" and preserve the compressed state of the substance (without altering the symmetry of the crystal), which was first observed by the present author.[55,56] We call this type of structural change an isomorphic transition. It is noteworthy that, generally speaking, isomorphic transitions have been known also in the physics of static pressures.[57] Thus the imposition of static pressures on lanthanide compounds entailed an increase of the oxidation state of the metal and the corresponding reduction of the unit cell parameters without alteration of their symmetry. However, in dynamic compression a decrease in cell size has been observed also for compounds of metals which do not have higher oxidation states (naturally together with the classical cases of isomorphic compression accompanied by a change in valence).

**Table 3.** The isomorphic decrease of unit cell parameters.

| Substance | C.N. | Unit cell parameters, Å | | $\Delta a$, Å |
|---|---|---|---|---|
| | | initial | after compression | |
| BN | 3 | 6.66 | 6.56 | 0.1000 |
| CuBr | 4 | 5.690 | 5.643 | 0.0470 |
| $MnCr_2O_4$ | 6 | 8.422 | 8.414 | 0.0080 |
| $CaF_2$ | 8 | 5.4620 | 5.4592 | 0.0028 |
| $CdF_2$ | 8 | 5.3839 | 5.3819 | 0.0020 |

Table 3 presents the results of the determination of the unit cell parameters of isomorphic decompressed polycrystalline materials.[55] Evidently the degree of isomorphic compression increases with the looseness of the structure, which is as a rule inversely proportional to the coordination number. It is of interest that the observed isomorphic transitions precede the usual phase transitions, i.e. constitute, as it were, a preparatory stage for the geometrical rearrangement of the crystal structure. At any rate, we have never been able to detect in the preserved substance changes in the unit cell parameters in the pressure ranges where polymorphic transformations of the test substances are not manifested. Analogous isomorphic changes in parameters were found later also by other investigators.[58,59]

Although the changes in the unit cell parameters are small, nevertheless they have a marked influence on the physical properties of substances. Thus the decrease of the unit cell parameter of fluorite was only 0.01% of the bond length, while the dielectric constant of the substance increased under these conditions from 7.1 to 7.9, i.e. by more than 10%. In the case of CuBr the dielectric constant of the initial specimen, which was 10.0, increased after isomorphic compression to 17.8, i.e. by 80%, while the unit cell parameter decreased by only 0.8%. Such a sharp increase in the polarisability of the crystals of isomorphically compressed substances is due to the overlap of the electron shells of the atoms approaching one another.

When the state of the system under conditions of increasing pressure corresponds to the principal minimum on the potential surface, the usual phase transition with a total change in the structure of the substance takes place. If the compressed body does not then have defects (or their number is small), then the transition pressures in the static and dynamic experiments are found to be very close (Table 4).

**Table 4.** The phase transition pressures.[60]

| Substance | Pressure, kbar | | Substance | Pressure, kbar | |
|---|---|---|---|---|---|
| | static | dynamic | | static | dynamic |
| Fe | 130 | 130 | Ge | 120 | 125 |
| P | 90 | 100 | GdS | 27 | 28 |
| Bi | 25 | 27 | KCl | 20 | 19 |
| I | 240 | 270 | Si | 115 | 130 |
| Sb | 85 | 88 | $CaF_2$ | 100 | 120 |
| Se | 130 | 150 | GaAs | 193 | 203 |

The observed difference between the phase transition pressures (in Table 4) is caused not only by the possible experimental errors, including the chemical and structural differences between the test materials, but also by the dynamic compression temperature factor. In fact, in static compression it is possible to influence independently the temperature of the compressed specimen, cooling or heating it to a specific temperature (unless otherwise stipulated, this means that the compression was carried out at room temperature). On the other hand, in shock compression the stressed substance is simultaneously heated and the "dynamic" transition compression is therefore found to be higher than the "static" value. If the dynamic and static compression of the test substance are carried out at the same temperature, one may expect even better agreement between the pressures of the phase transitions carried out by the different methods.

The substances listed in Table 4 have one common feature—it is impossible to generate in them a sufficiently high concentration of defects. By applying various influences, the densities of these substances can be reduced only slightly, at most by 10%, while the densities of graphite and boron nitride can be reduced by 50%, for example by creating structural defects. The cause of this difference is the homodesmic character of the structures and in many instances (for P, Bi, I, and KCl) also the high plasticity of the crystals, which promotes the rapid drift of dislocations during the deformation and baring of the specimen even at room temperature.

In many substances with a heterodesmic structure, in particular a structure of the layer type (graphite, boron nitride), the phase transformation pressure under the conditions of dynamic compression can greatly exceed the "static" value, when the initial material has a sufficiently high concentration of defects.[61,62] As will be shown below, at a very high concentration of defects the break in the

shock compressibility curve can be altogher absent[63,64] and the shock compression products do not contain the high-pressure phase.

The thermodynamic cause of the increase of the phase transition pressure in the dynamic compression of a defective crystal is then reduced density, which leads to an increase of the effective porosity of the specimen (at the atomic level) and hence to an increase of the shock compression temperature, which makes it essential to increase the pressure in the system. At a very high concentration of defects, i.e. for substances close to the amorphous state, the spreading of the phase transition boundary owing to the structural inhomogeneity of the specimen is observed, a classical example being provided by the softening temperatures of glasses.

Defects also influence the kinetics of the transformation. Evidently vacancies, dislocations, and disorientations of the blocks in the crystal structure lead to the breakdown of the coherence of the rearrangement and to the retardation of the transformation. In order to eliminate defects, it is necessary to perform work, which is executed under high pressure conditions by increasing the duration and intensity of the stress. Since on exposure to shock waves the duration of the dynamic pressure is limited, only the second procedure remains—one involving the increase of the pressure corresponding to the onset of the phase transition.

This effect obtains also in static compression. Thus in a study of the polymorphism of potassium and rubidium halides, we observed[65] that consecutive compression of the same specimen (accompanied by an increase of the concentration of defects) entails a constant growth of the pressure corresponding to the onset of the transformation, which can exceed the standard value almost by 100%. Thus, when the specimen is enriched in defects, the phase transition may not be observed at the standard pressure, for example, in the shock compression of certain kinds of graphite and boron nitride.[63,64]

It is noteworthy that the increase of the pressure of the onset of the transition is always accompanied by a decrease of the pressure of the end of the transformation, as a result of which the average phase transition pressure remains approximately constant. Thus, when the specimen is enriched in defects up to a certain critical value, the lower branch of the hysteresis loop reaches the normal pressure region. In other words, at the normal pressure it is possible to preserve the high pressure phase. This is in fact the reason for the existence over a specific period of structures of the CsCl type in alkali metal halides forced through draw plates at high pressures.[66]

Presumably, under the conditions of shock compression, where the increase and decrease of pressure take place over a very short time (i.e. the most favourable conditions are created for maximum hysteresis), the high-pressure phases are retained to an extent which is impossible under static conditions. This factor is extremely important for experiments with preservation of shock-compressed specimens, where it is possible to achieve not only the usual polymorphic transformations, which occur also under static compression, but also unusual transformations characteristic only of high dynamic pressures.

We shall begin the examination of the experimental results with the usual first-order phase transitions. The study of lanthanide and actinide compounds subjected to the action of explosion has occupied a significant place in Soviet research into the chemistry of shock compression. Thus in 1965 we carried out a physicochemical investigation of the products of the shock compression of the *C*-forms of lanthanide oxides and in 1966 evidence was obtained for the $C \rightarrow B$ transformations of all $Ln_2O_3$ for which such modifications had been unknown under normal conditions.[19] It is noteworthy that in 1964 the *B*-forms of a number of lanthanide oxides were obtained in static experiments,[67] but the physical properties of these substances were not investigated. In our communication[68] we therefore quoted the X-ray parameters, densities, refractive indices, and infrared spectra of *B*-$Ln_2O_3$ and also the temperatures at which these modifications are annealed (in the range 350–500 °C) with reformation of the *C*-form, which indicates unambiguously the physical nature of this transformation. The comparatively low annealing temperature of the *B*-forms necessitated special measures to reduce the influence of the thermal factor in dynamic compression: in order to achieve polymorphic transformations, cylindrical tubes with a central metallic rod were used.[68] Subsequently the transitions of lanthanide oxides from a *C*-type structure to the *B*-form were confirmed in other investigations.[69,70]

In 1966 phase transitions were observed in the compounds $MF_4$, where M = Ce, Th, or U, and were subsequently investigated in detail.[19,71–74] Whereas the initial tetrafluorides had a structure of the type of $ZrF_4$, after shock compression structures of the type of $LaF_3$ were obtained, where 25% of the sites in the cationic sublattice are vacant (for this reason, the formulae of the new modification should be more correctly written as $M_{0.75}F_3$). Refractometric studies confirmed the increase of the coordination number of the atoms in the crystal structures of these compounds under the influence of shock waves. The structure where together with the compaction of the substance atoms are "subtracted" from the metallic sublattice is also apparently formed as a consequence of the quenching of the shock-compressed substance. The absence of an analogous phase transition under static compression agrees with this hypothesis,[75] although the author[75] does not rule out the possibility that the required pressure may not have been attained in this instance. A phenomenon which is in essence analogous was subsequently observed in other studies[76,77] where the shock compression of $Nb_2O_5$ and $Ta_2O_5$ led to the formation of a structure of the $TiO_2$ type with a very slight change in composition.

Classical polymorphic transformations involving an increase of density as a result of the application of high dynamic pressures were achieved in our studies for lanthanide sulphides $Ln_2S_3$.[78] Like the oxides, the sulphides of light and heavy lanthanides differed in their structures and before dynamic experiments phase transformations involving an increase of density were achieved under the conditions of static compression.[79] Dynamic compression of terbium, dysprosium, holmium, erbium, and yttrium sulphides also led to a transition from the monoclinic form (of the type of $Ho_2S_3$) to a denser cubic form (of the type of $Th_3P_4$).

Transitions resulting from the shock compression of the hexagonal (quartz-like) $GeO_2$ also belong to classical polymorphic transformations involving an increase in the coordination numbers of the atoms.[80,81] It is known that under normal pressure $GeO_2$ exists in two forms—the low-temperature form of the type of rutile (C.N. = 6) and the high-temperature form of the type of quartz (C.N. = 4). At temperatures above 1000 °C a transformation of the $6 \rightarrow 4$ type takes place, while below 1000 °C there is a $4 \rightarrow 6$ transformation and static pressure does not exert a significant influence on the limits of the thermal transition.[82] Furthermore, in the absence of heating, solely under the influence of a moderate static pressure, the transformation of the $4 \rightarrow 6$ type in pure $GeO_2$ proceeds extremely slowly owing to the low rate of diffusion.[83] On the other hand, under the influence of dynamic pressures, the transition involving an

increase of the C.N. in $GeO_2$ proceeds very readily. If an intense shock wave is employed, then polymorphic transformations in the crystalline phase are accompanied by the formation of the yellow vitreous $GeO_2$. When the compression conditions were altered, a dense glass was obtained in which both four- and six-coordination of the germanium atom was observed by infrared spectroscopy. Such a rutile-like structure in vitreous germanium dioxide was obtained for the first time by ourselves.[81]

When the usual vitreous $GeO_2$ was exposed to an intense shock wave, not only the rutile phase but also a still denser (by 5%) crystalline modification was subsequently found.[84] It is of interest that the static compression of vitreous $GeO_2$ also entails the formation of a new, denser phase.[85] According to Ahrens,[86] the vitreous phase is the most convenient source of stishovite (for further details, see below).

As already stated, the vitrification of silicon dioxide under the influence of shock compression was first observed by De Carli and Jamieson.[16] The phase transformations in silicon dioxide involving an increase of density have been investigated in two studies;[87,88] the first study led to the detection of stishovite and the second revealed the presence of coesite. Subsequently this system was investigated by Dremin and Breusov.[89–91] We may also note a study[92] whose authors concluded that a phase transition of the 4 → 6 type in quartz occurs at such a high temperature that it involves the formation of a dense glass with the $SiO_6$ group in the first coordination sphere. In this connection we shall note the results of investigations of meteorites from craters in which both coesite and stishovite were discovered,[93,94] and dense forms have been frequently detected as inclusions in a mixture of crystalline and vitreous silicon dioxide.[95] This finding assisted us in selecting a natural method for the synthesis of dense forms of $SiO_2$, namely intense shock compression of quartz and subsequent separation of the products of the dynamic treatment with the aid of heavy liquids. Coesite and stishovite can be readily obtained by this procedure as a result of the shock compression of α-quartz.[96]

The question of the stabilisation of shock phase transitions is of fundamental importance but is still far from being solved. Even in those cases where it is possible to preserve the new phase after the explosion, there is no certainty that this is the precise phase formed under the conditions of high dynamic pressures. For example, a break at 330 kbar has been observed[97] on the compressibility curve for $TiO_2$ and the change in the volume of the specimen in the phase transition was by 21%. However, in the preserved specimen, the new modification having a distorted fluorite structure proved to be significantly less dense. The authors suggested that, at the instant when the substance was acted upon by the shock wave, a structure of the $PbCl_2$ type was formed and that the degree of coordination of the atoms and the density of the substance decreased during decompression; the dense modification decomposed under the influence of the residual heat. The rapid annealing of the dense modification at 550 °C has been noted.[98]

Various procedures are used to diminish the effect of annealing under the influence of residual heat. The most obvious method is to reduce the degree of filling of the tubes or one can even proceed to the shock compression of single crystals, which has been successfully demonstrated in two investigations.[58,99] The "chemical" procedure involving the wetting of the powder in the preservation tube with water, which by filling the pores displaces air and because of its higher heat capacity induces a sharp decrease of the residual temperature of the evolved heat, also proved extremely useful. The degree of decomposition of $PbO_2$ in the phase transition has been reduced in this way[100] and transitions known from static experiments for CdS and $CaCO_3$ were observed. After the shock compression of an aqueous suspension of HgO, a new (brown) modification of mercury(II) oxide was obtained,[101,102] differing appreciably in its properties from the known red and yellow forms. Despite the significant differences in the molecular-optical properties and in the density of the brown form of HgO, the X-ray characteristics of this phase proved to be virtually indistinguishable from those of the known modifications. The X-ray absorption spectrum and the $L_{III}$ absorption edge of the brown form has undergone a bathochromic shift.[103,104] On this basis, the authors[101,102] suggested the occurrence of local changes in the coordination of the oxygen atoms in the brown modification although the large difference between the atomic numbers of mercury and oxygen precluded the detection of an inclusion of the new phase by X-ray methods. A neutron diffraction study of the brown modification of HgO yielded some evidence in support of this hypothesis.[105]

As already stated above, in layer structures such as those of graphite and boron nitride, the transition to the diamond structure in specimens with a high content of defects under the influence of shock waves is hindered ("smeared") or is even altogether absent. Shock wave experiments with graphite have been carried out since 1961 (see above and also Trueb[106] and Gust[107]), while boron nitride was first subjected to shock compression and was preserved for subsequent study as late at 1965 in our laboratory.[108]

The shock compression with the aid of a cylindrical scheme of pyrolytic low-density BN led only to a slight increase of the density of the specimen, although small transparent crystals with a density of 2.5–2.6 g $cm^{-3}$ were observed along the axis of the cylindrical tube; their X-ray diffraction pattern contains, among others, lines due to the wurtzite modification of BN: 2.20 (m.), 2.08 (m.), 1.95 (m.), 1.54 (w.), 1.26 (v.w.), and 1.17 (v.w.) Å. The presence of reflections from other interplanar spacings did not allow us to claim that the new phase (we called it the "E-phase") contains a diamond-like modification as a component, although the lines quoted above undoubtedly indicate a geometrical relationship between the E-phase and the dense forms of boron nitride. In 1976 this modification was produced by Japanese investigators in the shock compression of BN (using a planar scheme) to 600 kbar, the initial materials being subjected to two (in succession) dynamic compressions.[109] This factor is extremely significant, since, after the first shock compression, a multiplicity of defects arise in the material and the structure of the latter approaches that of the pyrolytic state, i.e. conditions very close to those in our experiments are realised. The E-phase has also been obtained[110] in a pulsed discharge between boron rods in a nitrogen atmosphere, being detected after a short exposure to these conditions, whereas an increase of the duration of the exposure (of the number of pulses) led to the formation of the classical diamond modification. Hence it was concluded that the formation of the E-phase is the first stage in the transformation of the graphite structure into the diamond structure. Finally, the E-phase has been recently obtained when the graphite-like boron nitride was subjected to laser irradiation and an increase of the duration or the intensity of the irradiation again led to the formation of the wurtzite-like modification of BN.[111]

The simplest explanation of the nature of the E-phase would involve the hypothesis that a mixture or a solid solution (for example, the type of block isomorphism) of the graphite and diamond phases of BN is formed. However, the identity of the properties of the E-phase specimens obtained by different procedures and also the change of

only its concentration and not of its characteristics when the applied dose of the given influence is changed indicate the individuality of the product. Unfortunately, owing to the low quality of the crystals, only the unit cell parameters could be determined: $a = 7.2$, $b = 8.1$, and $c = 18.9$ Å.[112]

Later Kurdyumov and Pilyankevich[113] obtained a polycrystalline carbon with similar properties, which they regard as an analogue of the E-phase. Although the above phase was called simply the dense modification (of the diamond type) in a well known review,[114] we believe it to be useful to differentiate it as an intermediate structure in which the graphite networks may be connected by diamond bridges in a specific sequence (see Noda and Inagaki[115]).

The diamond forms of BN have been obtained by the shock method[116,117] and it has been shown[117] that the yield of the dense forms increases in parallel with the increase of the density (i.e. of the degree of perfection of the crystals) of the initial graphite-like boron nitride. At the same time we demonstrated independently[80] that the structural perfection of the hexagonal BN is essential for the success of the phase transition. Next we obtained dense forms of BN by the shock compression of a fairly perfect initial material.[118] The crystallographic aspect of the transition of the hexagonal boron nitride to the tetragonal or cubic modifications has been examined in detail.[119] The mechanism of the phase transformation of the graphite-like modification to the diamond modification was later investigated[113] from the standpoint of the real structure of the initial and shock-treated boron nitride.

In conclusion of the description of the polymorphic transformations on shock compression, we shall consider certain unusual phase transitions, which cannot occur on static compression of the test substance. We have in mind the phase transitions involving a decrease of density. Generally speaking, the annealing of the dense modifications under the influence of the residual heat, which was already discussed above, can be regarded as the formal outcome of the dynamic compression of the given body. However, for substances which undergo phase transformations with compaction of the structure after heating under normal pressure (AgI, PbO, MnS, $Ln_2O_3$, etc.), the temperature and even more so a high pressure can no longer promote a decrease of density. In other words, the dense modifications of substances of this class cannot be converted into the loose modifications for any kind of change in the thermodynamic parameters. The study of precisely such substances in our laboratory, starting from 1965, revealed phase transitions involving a decrease of density, i.e. the exposure to shock waves led to a change from irreversible to reversible transitions. The first review of the literature devoted to this topic was written by the present author[19] and more detailed information can be found in other communications.[60,112]

After the discovery of phase transitions involving a decrease of density on shock compression, analogous transformations were achieved in experiments involving the irradiation of substances,[120] in the comminution of crystals in a ball mill,[121] and on static compression with shear.[122] In all these processes the generation of a large number of defects entails partial or total conversion of the substance into the amorphous form, which leads to the activation of the powder and the creation of conditions for the appearance and rapid growth of the nuclei of a new phase which is stable under the given thermodynamic conditions†. Thus, under the influence of shock waves, the initial structure breaks down and the residual heat induces the crystallisation of a new phase, which is initially less dense, while further heating leads to the formation of the densest phase.

According to the model developed above, the physical cause of the decrease of density is the decrease of the coordination number of the atoms as the crystalline grains are fragmented. Since the fragmentation of crystals entails an increase of the fraction of surface atoms, which have smaller coordination numbers than in the bulk of the crystal, comminution is always accompanied by a decrease of the static (effective) coordination number of the atoms. Estimates have shown that, when account is taken of the decrease of the coordination numbers owing to the formation of vacancies and dislocations, fragmentation to a size of 50–100 Å is sufficient to reduce the effective coordination number by 1–2. In this case the energy of the comminution (which appears as an increase of surface energy) is comparable to the heat of the phase transition.

It is of interest to analyse the polymorphic transformations in steels from the standpoint described. It is known that the heating of iron is accompanied by the $\alpha \rightarrow \gamma$ (or $\beta \rightarrow \gamma$) transition involving an increase of density. The reverse transition takes place under the influence of various kinds of deformations, including those induced by the dynamic compression.[123] It is significant that the polymorphism of pure iron is of the reverse character and only after the introduction of carbon or other "hard" additives does the phase transition under the influence of any kinds of deforming forces become possible. Leaving to one side the possible (slight) change in the composition of steels in the polymorphic transformation, the role of alloying additives can be naturally accounted for by a decrease of the rate of elimination of defects as a consequence of the decrease of the plasticity of the material. As soon as this rate becomes lower than the rate of deformation of the material, conditions are immediately generated for the accumulation of defects, i.e. for the conversion of the substance into an amorphous form.

In the first stages the unusual phase transformations were investigated mainly by optical methods and also by measuring the density and by recording heating curves. In all cases the loose modifications were converted after annealing into dense modifications with an exothermic effect, which indicated the absence of a change in the chemical composition on exposure to shock waves. Table 6 presents the structures and densities $\rho$ of certain lanthanide compounds which have undergone a phase transition with decrease of density under the influence of dynamic pressures.

Apart from polymorphic transformations, it was possible to obtain as a result of exposure to shock waves modifications which differed from the initial forms only in the size but not the symmetry of the unit cell.[55] Such transformations were called isomorphic by analogy with the physics of static pressures, where appreciable changes in the parameters without a change in the structural type have been observed in relation to lanthanide metals and their compounds.[57] Whereas such transformations have been induced under static conditions by a change in the oxidation state of the lanthanides, with the aid of the dynamic method the isomorphic transitions have been achieved for compounds of a wide variety of metals, including those which have only one oxidation state. Furthermore, phases involving an increase in the unit cell parameters, caused by a weakening of the chemical bonds as a result of the dynamic pressure, have been obtained on exposure to shock waves.

If account is taken of the fact that, with increase of the density, isomorphic compression precedes the polymorphic transformation, the isomorphic expansion of the parameters

†In the case of α-spodumene, the intermediate amorphous phase was detected experimentally.[124]

can be naturally correlated with the phase transitions involving a decrease of density which have just been discussed. Table 5 presents the X-ray diffraction data for the isomorphically expanded materials. The average differences of the unit cell parameters ($\Delta a$) are quoted for anisotropic substances.

Table 5. The increase of unit cell parameters in isomorphic transitions.

| Substance | $\Delta a$, Å | Refs. |
|---|---|---|
| $SiO_2$ | 0.013 | [125] |
| $SiO_2$ | 0.067 | [125] |
| Ni | 0.04 | [126] |
| $NdF_3$ | 0.027 | [127] |

Table 6. The properties of polymorphic modifications.

| Substance | Initial phase | | After shock compression | |
|---|---|---|---|---|
| | structure | $\rho$, g cm$^{-3}$ | structure | $\rho$, g cm$^{-3}$ |
| $SmF_2$ | $LaF_3$ type | 6.93 | $YF_3$ type | 6.64 |
| $HoF_2$ | $LaF_3$ type | 7.83 | $YF_3$ type | 7.64 |
| $Tm_2S_3$ | $Ho_2S_3$ type | 6.27 | new phase | 6.06 |
| $Nd_2S_3$ | A-form | 7.42 | C-form | 6.29 |

In conclusion of this Section, we shall attempt to answer the question how the phase transitions occur under shock compression. One should apparently consider separately two types of transformations—those in which there is a possibility of a coherent shift of all the lattice atoms over a short distance (the so-called martensite transitions) and transformations which require the preliminary rupture of the initial structure. Since the changes in bond lengths associated with the usual changes in coordination numbers are within the limits of the vibration amplitudes, the martensite transition can be readily accounted for in terms of a vibrational mechanism, i.e. it should occur at the velocity of sound. The presence of an amorphous phase as an intermediate state is essential for transitions of the second type. In this state the atoms are probably extremely mobile, since they are not linked to their neighbours and resemble free radicals. Thermodynamically, the state corresponds to the disappearance of the potential barrier between the two modifications.

The conversion into the amorphous form gives rise to the possibility of the formation of a phase with a reduced density. Furthermore, in the amorphous (vitreous) initial material the phase transition should take place more readily. Indeed, in many instances the phase traosformation of glasses has been observed at lower pressures than in the corresponding single crystals.[84,85,86,128] It is shown below that the reconstructive phase transitions and the active intermediate state involved in them play an important role also for chemical processes.

## IV. CHEMICAL REACTIONS

Processes involving the synthesis and decomposition of chemical compounds have been investigated from the very beginning of the development of the new scientific discipline; furthermore, the very name, shock compression chemistry, presupposes the preservation of the specimen exposed to shock waves for further study.

The chemical investigations have been carried out in terms of two aspects—in order to solve problems of practical importance and to obtain specific substances, on the one hand, and in order to develop the method itself and to elucidate the mechanism and the characteristics of the chemical reactions under the conditions of shock compression, on the other.

We shall consider initially the second question, which is in essence fundamental for the entire chemical component of the dynamic method. The most important task is to determine the period of the reaction, i.e. to determine the possibility of the completion of the reaction under the conditions of a high pressure during $10^{-6}$–$10^{-5}$ s.

There is as yet no evidence that the compounds produced under the conditions of shock compression and preserved for further experiments were obtained in the high pressure zones; this can be inferred only from indirect features. However, our present day knowledge about the processes occurring on shock compression of powders permits the conclusion that the character of the chemical processes under these conditions is non-trivial.

A specific feature of the chemical interaction under shock compression is that, under the influence of the shock wave, the crystalline grains are fragmented and a multiplicity of structural defects, namely vacancies, dislocations, and atoms with altered oxidation states, are generated in the particles; the particles of the mixture components interpenetrate one another during migration behind the shock wave front (owing to the differences between the mass velocities of the components), are deformed, and are pressed into a monolithic form. After the establishment of a uniform pressure in a mixture of fairly small particles, the components of the shock-compressed specimens can be compressed in different ways (owing to the differences between the mechanical properties of the reactants) and hence can be heated in different ways. Estimates have shown[129] that the difference between the temperatures of the "hot" and "cold" points in a shock-compressed mixture reaches hundereds of degrees.

If one takes into account further the fact that the plastic deformations occurring on pressing the powders will also cause unequal heating of different mixture components and even different parts of the grains,[130] then it becomes evident that the additional effect may amount to a further several hundred degrees.[131] Thus the overall temperature difference between adjoining sections of the mixture can exceed 1000° and can lead to diffusion and even the evaporation of individual particles. This factor constitutes a fundamental difference between the heating of the reaction mixture by the shock wave and the homogeneous heating of the same composition in the usual furnaces.

Finally, the rapid migration of the shock wave front promotes the rapid propagation of the chemical reaction zone. For highly exothermic reactions, this process can be analogous to high-speed combustion or even detonation.

The characteristic features of the shock compression method gave rise to the hope that unusual results might be obtained. Certain conclusions from the investigations made can now be reached.

The first shock syntheses of substances from the elements were performed by Japanese workers. Thus in 1963 Horiguchi and Nomura[132] reported the synthesis of TiC (see also Ref.133). The same investigators subsequently obtained WC[134] and $Al_4C_3$.[135] Suzuki et al.[136] synthesised TiC, ZrC, and SiC; all these substances are of interest for the preparation of ultrahard materials. Simultaneously with the solution of practical problems, studies were made of the characteristics and mechanism of the reactions. Thus Horiguchi and Nomura[133] suggested that the shock wave leads to te mechanochemical activation of the reactants and compresses the mixture in which "hot" points, initiating the chemical reactions, are distributed. The subsequent development of the chemical process takes place as a consequence of the liberation of heat at the active centres. Suzuki et al.[136] noted the dependence of the thermodynamic parameters in the cylindrical preservation tube on the location of the specimen and showed that the reactions proceed with the maximum intensity in the axial region of the cylinder.

Adadurov et al.[137] synthesised by the shock compression method a number of silicides from the elements—FeSi, $FeSi_2$, and $V_3Si$. Otto and co-workers[138,139] obtained the intermetallic compounds $Nb_3Sn$ and $Al_3Nb$, which are of interest for the study of superconductivity. These workers used copper tubes to improve (as a result of the high plasticity of copper) the compression of the materials; in addition, they employed evacuated preservation tubes before the dynamic experiment. According to these workers, the mechanism of the formation of the intermetallic compounds involves the shock fusion of one of the components, for example, tin, and the dissolution of the other component in it.

The shock compression of Nb–Ge, Nb–Sn, and Nb–Pb mixtures has been described.[140] The syntheses of $Nb_3Si$ and $Ta_3Si$ have been reported.[141,142] Savitskii et al.[143] carried out the shock compression of 3Nb + Y (Y = Si, Ge, Sn, Pb, or In) mixtures and observed that the synthesis occurred only in the axial region of the cylindrical tube.

Elementary syntheses in our laboratory have been carried out in order to investigate mainly the characteristic features of the duration of the shock synthesis of transition metal chalcogenides. In the synthesis of chromium chalcogenides the influence of fine shock dispersion of the powders on the endothermic effects of the fusion process and the exothermic effects of the chemical reactions was observed.[53] Modifications of chromium monochalcogenides with reduced density and with retention of the type of crystal structure were obtained in the same study (see above).

Batsanov et al.[144] determined the temperature of the Sn + S reaction mixture 0.05–0.1 s after dynamic compression, which proved to be 1100 °C. The residual temperature in the case of SnS, synthesised beforehand by the usual method and then shock-compressed under the same conditions, was only 130 °C. Bearing in mind that the residual temperature during the measurement (after 0.05–0.1 s) only decrease, one can conclude that the reactons have been completed by this time. The same paper describes an interesting instance of the influence of particle size on the degree of reaction and even on the direction of the reaction in shock synthesis. An equimolar Sn + S mixture consisted of powders with particle sizes ranging from 0.06 to 0.4 mm; all the experiments were performed with the tube filled to the same extent and with all other conditions kept the same. It was found that, in the range 0.06–0.2 mm, the yield of SnS increased with decrease of the particle size. The grain diameter increased to 0.2–0.4 mm and the degree of conversion of sulphur rose from 45 to 80%. This was caused by the change in the composition of the product: the reaction product proved to be $SnS_2$. This unusual fact can be explained by taking into account the thermal instability of tin disulphide at temperatures above 600 °C. Since the amount of heat evolved increases with increase of the surface energy of the powder (see the synthesis of chromium chalcogenides described above[53]), there exists a critical particle size above which $SnS_2$ is stable.

The interaction of the chalcogens sputtered in the form of thin films on the surfaces of plates, under the influence of shock waves directed at right angles to the plane of the plate, has also been studied.[145] The chemical compound is formed as a result of the mutual diffusion of the tin and chalcogen atoms. An increase in the duration of the shock pulse entails the growth of the diffusion zones: for example, for a 3.2 km $s^{-1}$ pulse, the thickness of a tin sulphide layer is 1 μm whereas for a 7.8 km $s^{-1}$ pulse it increases to 3 μm. It is significant that treatment with shock waves promotes also the usual thermal diffusion. Thus, when specimens compressed by a 3.2 km $s^{-1}$ pulse for 50 h are heated, the diffusion zone is 9 μm thick, whereas for the non-compressed specimens the diffusion zone is only 4 μm thick in such heat treatment.

The characteristic features of the diffusion of atoms in a solid subjected to shock compression have been investigated.[146] The authors showed that, in the pulsed compression of a metal, the rate of diffusion can be actually higher than in its melt. It is also of interest that the rate of diffusion was higher in the dense γ-iron lattice (of the face-centred type) than in the less dense α-iron (of the body-centred type), which the authors explained by the sharp increase of the number of point defects in the case of the face-centred lattice. The acceleration of the movement of atoms in the shock-compressed materials has been explained[147] by the decrease of the activation energy for diffusion owing to the decrease in size of the particles and the corresponding decrease of their melting point.

A sharp increase of the rate of the chemical reaction of the elements can be achieved by employing the method of detonation synthesis.[148,149] The absence of metallic tubes leads to close contact between the energy carrier and the material being treated, as a result of which very high temperatures and pressures are generated by this method. Calorimetric and X-ray studies have shown that, during a period of ~$10^{-5}$ s, the synthesis of zinc chalcogenides takes place quantitatively.[149]

Compounds in known structural forms were obtained in all the studies enumerated above. On the other hand, compounds in new crystalline forms were produced in the synthesis of lanthanide sesquichalcogenides, for example, those of holmium and erbium.[78] The shock synthesis of neodymium and samarium monochalcogenides[150] yielded a series of new solid solutions with an intermediate (between 2 and 3) oxidation state of the metal.

Reactions of the type metal + the oxide form of the compound have also been achieved under the conditions of shock compression. The first publication on this topic concerned the reactwon Cu + $CuBr_2$ → 2CuBr[55] with reduction of the unit cell parameters (Table 3). A decrease of the oxidation state of titanium via the reaction Ti + $TiO_2$ → 2TiO has been achieved by Ruchkin et al.,[151] while a decrease of the oxidation state of indium in $InF_3$ in the interaction of the latter with metallic indium has been carried out by Batsanov et al.[152] The interaction of lanthanide trifluorides with various lanthanides, which yielded both pure[153] and mixed[154] fluorite

phases, has been studied in detail. The doubly charged state of the lanthanide in these compounds has bee confirmed by optical and magnetic data.[155,156] The oxidation state of the metal could be reduced only in copper[157] and chromium[158] oxides and in the latter case a chromium(II) compound was detected by means of a special system in which two reactants were separated in space within the tube and only one was subjected to shock compression, as a result of which one reactant was swept onto the other by the Mach wave. The reaction mixture is very rapidly cooled in such a system, which promotes the quenching of the metastable compound. We recently synthesised neodymium monoxide by the reaction $Nd + Nd_2O_3 \rightarrow 3NdO$, the mixture of components being initially repeatedly subjected to the action of shock waves and then heated at 600 °C for 100 h;[159] this compound has a structure of the NaCl type, but its unit cell parameter proved to be 5.096 Å, i.e. greater than that for NdO obtained on static compression of the same mixture,[160] which suggests the formation in our case of a compound of neodymium in an oxidation state less than 3.

Apart from the processes involving a decrease of the oxidation state of the metal by some other metal in a free state, the reactions involving the reduction of oxides by other elements have been investigated. Thus the shock interaction of $Ln_2O_3$ with B yielded[69] $LnB_6$. The authors[69] believe that the reaction proceeds after the completion of the shock compression due to the residual heat in the preservation tube. The shock reduction of $SnO_2$ by carbon, silicon, and aluminium, accompanied by the mechanochemical treatment of the mixtures in ball mills, has been described.[161] The importance of the area of the contact surface and of the local temperature ("hot" spots) has been noted.

The shock reactions of metals with Teflon, which proceed in accordance with one of the two equations

$$M + (CF_2)_n \rightarrow MF_x + C,$$
$$M + (CF_2)_n \rightarrow MF_y + MC$$

have been investigated recently.[162] Fluorite phases have been obtained with the aid of these reactions for scandium and yttrium. The reaction of metals with water led to the synthesis of a number of metal oxides, hydroxides, and peroxides.[163,164] The aim of these studies was to elucidate the question of the possible completion of the chemical reaction during the period of shock compression. These experiments were based on the following reasoning. Since water at high pressures has the properties of an acid, the shock compression of the metal + water mixture can lead to the displacement of hydrogen, provided that the metal is electrochemically more active than water (or when the water remains chemically "inert" if the metal is more passive). It is important that the reaction should proceed only in the high pressure zone where water has acid properties. Experiment fully confirmed these hypotheses, but the question of the residual temperature in such a suspension remains open, since in the case of heating to a high temperature there is a possibility of simple pyrolytic decomposition of water by the metal.

We shall now proceed to the description of the results of studies of the reactions of oxides and compounds with one another. In 1963 the shock compression of an equimolar mixture of zinc and iron oxides yielded zinc ferrite[165] (see also Adadurov et al.[166]), while in 1966 zinc orthosilicate was synthesised from a mixture of zinc oxide and silica.[167]

Lanthanide mono- and tri-hydroxides, LnOOH and $Ln(OH)_3$ were synthesised in 1967 by the reaction of lanthanide sesquioxides with water.[168] Tubes with a reduced strength, which remained integral during the experiment if all the water combined with the oxide and were ruptured if water was taken in excess, were used in the above study. Thus the stoichiometry of the chemical reaction can be inferred even from the mechanical behaviour of the tubes. Dremin and Breusov[89] described the syntheses of silicates, double fluorides, and garnets. Subsequently barium titanate was synthesised by the shock compression of a mixture of $BaCO_3$ and $TiO_2$.[169] Data on the shock synthesis of magnesium and calcium metasilicates as a result of the compression of mixtures of the corresponding oxides and silica have been published.[170]

Lanthanide oxides or chalcogen fluorides have been obtained in our laboratory[171] as a result of the dynamic compression of mixtures of fluorides with lanthanide oxides or chalcogenides. It has been shown for samarium oxide fluorides that, in the presence of a slight excess of the fluoride in the initial mixture, a tetragonal oxide fluoride is produced, whereas in the presence of an excess of the oxide the product is the rhombohedral modification, the cubic SmOF phase being formed only on compression of a stoichiometric mixture. As a result of the movement of masses in the course of shock compression, for example, in a cylindrical tube, there is a possibility of the local breakdown of the reaction stoichiometry as a consequence of the distillation of the mixture components, i.e. the "polymorphic transformation" of complex compounds becomes possible. The $PbO + TiO_2$, $PbO + ZrO_2$, and $2PbO + TiO_2 + ZrO_2$ interactions have been investigated under the conditions of shock compression.[172] The stoichiometry of lead zirconate-titanate (LZT), which is an extremely important piezoceramic material, is infringed in its usual thermal synthesis owing to the unequal volatilities of the components. On the other hand, in the shock compression of the initial mixture of oxides, synthesis, pressing, and shaping of the compound produced take place simultaneously.

Complex formation in accordance with the equations $2KX + PtY_2 \rightarrow K_2PtX_2Y_2$, where X and Y are halogens of different kinds, has been described.[173] We believe this reaction to be promising from the standpoint of the synthesis of inner sphere complexes of coexisting ligands, which cannot be combined [in the same coordination shell] by the usual methods of synthesis. We synthesised by the reaction $SmO + TiO_2 \rightarrow SmTiO_3$ a compound in which there is a definite competition between the Sm(II) and Ti(IV) oxidation states.[129] Evidently analogous compounds can be obtained also by the reaction of titanium monoxide with lanthanide sesquioxides. It is entirely likely that a kind of valence isomerism can occur in this instance. We obtained compounds of the type $Ln_2O_3.MO_2$ and $Ln_2O_3.2MO_2$ by the reaction of lanthanide sesquioxides with $TiO_2$, $ZrO_2$, and $HfO_2$ [59,174] and investigated the dependence of their structure on composition. We recently studied the shock reaction occurring via the mechanism $Ln_2O_3 + Ln + 3/2I_2 \rightarrow 3LnOI$, the Ce, Gd, Ho, and Lu compounds having been obtained and investigated for the first time.

In conclusion of this Section, we shall consider the formation of substitutional solid solutions as a result of shock compression. The feature of the majority of substitutional solid solutions is that their densities are lower than those of the initial mixtures and is of methodological interest. The formation of stable solutions should therefore be caused by the temperature factor and, conversely, phase transitions or other structural changes in the solid solutions formed should take place under the influence of pressure. Indeed the synthesis of KCl–KBr solid solutions yielded[80] a substance with an increased density and the annealing of the product was accompanied by a decrease of density with the simultaneous evolution of heat (exothermic effect on the thermogram).[80] The shock compression of the RbCl–CsCl mixture

leads to the formation of solid solutions with a structure of the NaCl type, but their density again proved to be higher than the standard values.[175] It is significant that the composition of the solid solution did not depend on the component ratio in the initial mixture: the shock compression of a wide variety of compositions yielded a solid solution of the same composition.

The corresponding solid solutions were synthesised for the first time from $NH_4X$–$CsX$ mixtures by dynamic compression of the latter.[176,177] Solid solutionsof the $NH_4X$–$KX$ and $NH_4Br$–$NH_4I$ systems have also been obtained by the dynamic method, their compressibility increasing with the atomic number of the halogen.[178] A change in the intensity of the shock wave entails a change in the compositions of the solid solutions formed, which is characteristic of the chemistry of berthollides. Finally, shock compression of the KCl–CsCl mixture led to a decrease of the phase transformation temperature of CsCl from 469° to 305 °C, while the X-ray diffraction pattern of the mixture remained unaltered. A detailed study showed that the solid solution formed in this system remains in the X-ray-amorphous state at room temperature.[179]

Solid solutions of another type have been investigated in a series of studies. Thus Gryaznov et al.[180] investigated the saturation of iron by carbon under the influence of pressure pulses and showed that at 425 kbar carbon penetrates to a depth of 0.05 mm as a result of dissolution in a layer of melt on the surface and subsequent crystallisation. Kozorezov et al.[181] observed a considerable miscibility (greater by a factor of 7 than in the usual thermal synthesis) of tungsten and iron. Adadurov et al.[76] obtained a continuous series of solid solutions with compositions ranging from $Nb_2O_5$ to $NbO_2$ on the basis of the rutile structure. Such solid solutions were formed only for high intensities of the shock waves where the specimens were known to be in a fused state. A solution of gallium in copper with a concentration greatly exceeding the "thermal" value has been obtained by shock compression.[182] Finally, the ZnS + Se shock interaction led to the formation of a continuous series of ZnS–ZnSe solid solutions which have the sphalerite structure in the presence of ZnS contents from 0 to 50% and the wurtzite structure for higher ZnS contents.[183]

In conclusion of the description of shock syntheses, we shall now turn to the question of the duration of the chemical reactions. The usual objection against the possibility of the occurrence of reactions during such short periods arises from the relatively low rate of diffusion in solids, especially under high pressure conditions. However, experiments carried out in the authors laboratory, involving the measurements of the electrical conductivities of powders under pressure, have shown that the conductivity of ionic polycrystalline substances is fairly high under these conditions and does not increase with increase of pressure but increases until the attainment of the monolithic state. Furthermore, it increases sharply at the instant of the phase transformation of the chemical compound.[184] We believe the latter factor to be extremely important because it has been suggested[195] that the chemical reaction can take place during the period of high dynamic pressure, provided that at least one of the reactants undergoes a reconstructive phase transition under the given thermodynamic conditions. A direct experimental test of this hypothesis by investigating the phase transformations in the reacting systems is of interest.

Apart from syntheses under conditions of high dynamic pressures, studies have also been made of chemical decomposition reactions of substances and these had begun earlier than the synthetic experiments. Thus the appearance of metallic sodium as a result of the shock compression of NaCl has been noted.[14] Subsequently Nicholls et al.[186] observed a disproportionation under dynamic pressure into iron and lead oxides.

Batsanov et al.[187] undertook a systematic study of the possibility of the shock decomposition of complex oxygen compounds. A thermodynamic criterion was established, namely the enthalpy of formation of the compound above which the crystal structure is improved under the influence of a specific shock influence, while below it the substance decomposes.

The shock decomposition of alkali metal bromates and nitrates has been described.[188] In the former case an analogy has been observed between shock and radiation decompositions, while for nitrates the process is more complex. The formation of defects as a consequence of the action of an explosion on nitrates has been studied in detail in the present authors' laboratory and a definite analogy has been observed between the formation of shock and radiation defects.[19,189] Symons[190] studied by EPR the formation of radicals when binary oxides and sulphides and complex oxygen compounds are exposed to shock waves; a correlation with radiation defects (produced by $\gamma$- and $n$-irradiation) was not observed. An analogous study has been carried out by Nelson and Hartley.[191]

Lapshin et al.[192] investigated the chemical properties of $K_2S_2O_8$ subjected to dynamic compression and observed that the compression leads to the formation of the same paramagnetic centres as those produced during irradiation.

The decomposition of sillimanite into $Al_2O_3$ and $SiO_2$ has been observed.[193] Here an interesting result is the isolation of stishovite when intense shock waves are applied. This justifies the hypothesis that the compound decomposes under the conditions of high pressure.

It has been shown[194] that the CO and $CH_4$ shock adiabats can be described satisfactorily only if it is assumed that these molecules decompose at high pressures (in excess of 200 kbar) into diamond particles and gaseous $O_2$, $CO_2$, $H_2$, $CH_n$, and $C_2H_2$ molecules. We may note that the decomposition of $CO_2$ into diamond and $O_2$ has been observed at high pressures under the conditions of the static compression of $CO_2$.[195] Hence it follows that finely dispersed diamond can be obtained by the dynamic compression of hydrocarbons and carbonates.

Together with the usual decomposition of compounds as a consequence of shock compression, shock structure-breaking in substances exposed beforehand to hard radiation has been investigated.[192,196,197] Thus $K_2S_2O_8$ powder has been subjected to the influence of detonation[192] after its preliminary treatment with $\gamma$-radiation (from a $^{60}Co$ source). The $F$ centres were retained in the test substance after the shock compression, although the absorption spectrum changed appreciably compared with the substance which was simply irradiated. After the irradiation of alkali metal halide crystals and also $CaF_2$, $SiO_2$, and $(NH_4)_2S_2O_8$, the appearance of colloidal intralattice metal was observed.[196] Single crystal and polycrystalline NaCl specimens have been studied in greatest detail,[197] the intensity of irradiation and of the dynamic compression being varied within fairly wide limits. It has been established that the formation of a colloidal metal is characteristic of the single crystals, the size of the colloidal particles varying in parallel with the degree of distortion of the specimens; the $F$ centres are retained in the polycrystalline specimens. The latter fact is apparently caused by the higher rate of diffusion of atoms and the higher temperature in the shock compression of powders

compared with single crystals, which leads to the decomposition of colloidal particles on relaxation with formation of *F* centres. It is significant that the concentration of free sodium in the shock-compressed NaCl specimens proved to be higher than that of the *F* centres, which is probably caused by the additional injection of electrons in the course of the shock compression from the material of the preservation tube and from the impurities in the initial specimen. One should note further that the *F* centres in shock-compressed materials are unstable at room temperature—crystals can be decolorised by natural light in the course of several minutes or even seconds.

The first stage of any decomposition is accompanied by a decrease of the oxidation state of the metal owing to the dissociation of chemical bonds. The increase of the magnetic susceptibility of zinc sulphide on shock compression as a consequence of the Zn(II) → Zn(I) transition has been observed by Nomura and Tobisawa.[198] In 1967 the present author and his co-workers studied the Ti(IV) → Ti(III) transition[199] and then the Eu(III) → Eu(II) transition.[200,201] The change in the oxidation state of other lanthanides on shock compression was dealt with above.

The practical application of the shock method for the generation of structural defects, in particular the decrease of the oxidation state of the metal, involves the modification of catalysts by exposure to shock waves. Thus the influence of dynamic compression on the catalytic properties of transition metal oxides has been studied;[199] shock treatment led to an increase of the catalytic activities of ZnO, $TiO_2$, and $BaTiO_3$ by 2–3 orders of magnitude. This result was confirmed in another study.[202] We established that the increase of the catalytic activity of $TiO_2$ and other titanium compounds took place as a result of the formation of electronic defects, especially $Ti^{3+}$ centres. The shock compression has been used[203] to activate pyrites catalysts used in the liquefaction of coals. It has been shown[204] that, after the shock-wave treatment of $CaF_2$, which catalyses the dehydration and dehydrogenation of isopropyl alcohol, the temperature of the onset of the reaction diminished and the selectivity of the catalyst action increased. Increase of selectivity carried by dynamic influence has now been observed also for other catalysts.

Finally, we shall indicate yet another, analytical aspect of the shock compression chemistry. Since the substance treated is enclosed in a strong metallic tube and, generally speaking, there should be no loss of material in the course of the dynamic experiment, there is no need for the usual chemical analysis. The physical methods for the determination of the phase composition and the possible structural changes play an analytical role in this instance. However, the compressed substance may be contaminated by the material of the walls of the tube, which has been investigated.[205,206] It has been found that, when the substance is contaminated by iron in a cylindrical tube, the bulk of the impurities enter the compressed substance from the lower stopper at the centre of which a crater is usually formed as a consequence of the effect of the reflected shock wave.[206] The overall concentration of the impurities is correlated with the packing density of the powder before the experiment, the parameters of the shock wave entering the substance, and the presence or absence of phase transformations involving a change in the volume and compressibility of the given body.[207]

Thus spectroscopic analysis of a shock-compressed substance can serve as an indication of the physicochemical transformations which have occurred as a result of dynamic compression (including reversible transformations which cannot be observed in the preserved specimen).

## V. CONCLUSION

The new method whereby the composition and structure of a given substance can be actively influenced, namely shock compression, has immediately found extensive practical application. The fundamental studies and technical applications developed in parallel. Below we shall consider briefly the practical aspects.

We shall begin with the physical and mechanical manifestations of the changes in the real structure. The hardness of the material increases as a result of the fragmentation of the crystalline grains and the increase of the dislocation density under the influence of the dynamic compression, which has already been dealt with at the beginning of the review. Naturally the increase of hardness and hence in the strength of metals is of practical importance. The first review devoted to the metallurgical effect of shock waves is that of Appleton.[208] Subsequently monographs were devoted to this topic.[209–211]

The technical problems of the dynamic strengthening of metals are extremely varied and even a simple list of the results obtained would occupy far too much space. New data concerning different mechanisms of the thermal and shock strengthening of metals, which may lead to new prospects in this field of materials science, are noteworthy (see also Bekrenev and Naumov[212]).

The second major field in which the shock wave techniques are used is that of the pressing of powders. The advantages of the dynamic method compared with static pressing consists in the easier attainment of high pressures and the absence of limitations as regards the size of the treated articles. Several international conferences have been devoted to the application of dynamic pressures in the pressing of powders[213–215] and such pressures have also been considered at the All-Union Symposia on Pulsed Pressures.[216–221] In addition, shock pressing has been described in the above reviews[208,209] and in the original articles by foreign[48,49] and Soviet[222–224] workers.

At the same time, dynamic pressing suffers from serious limitations at the present time due to the specific features of the shock compression itself. We have in mind the phenomenon of "overpressing", which leads to the saturation of specimens by cracks and pores or even its fragmentation into small pieces. This phenomenon is due to the fact that the dynamic compression of the crystal increases the dislocation density of the latter and under certain experimental conditions the concentration of the defects can exceed the critical value for the given substance, after which the crystalline grain disintegrates into smaller particles. In order to prevent disintegration, one either heats the specimen between dynamic treatments in order to increase its plasticity or the maximum plastic deformation of the material is ensured.

The most important practical application of polymorphic transformations under the influence of dynamic pressures is the shock synthesis of diamond and borazone [boron nitride]. The main task here is the rapid removal of heat during (or after) decompression, since diamond and borazone are annealed to the graphite modification at $T \geq 1000$ °C. It is difficult to solve this problem, which has led to the following paradoxical situation: transformations of the graphite → diamond type take place quantitatively in the shock wave, but in the decompressed system the concentration of diamond is only several per cent. Numerous methods and patents have been devoted to the development of various procedures for the solution of this problem.

The application of synthetic methods involves in practice mainly the pulsed welding of metals, which leads to the formation (in the region of the join) of intermetallic compounds, including those which are not obtained in the traditional methods of synthesis. The pulsed welding of metals has found applications in various branches of industry for the large-scale manufacture of bimetallic plates and coatings for tubes and the flat surfaces of machines and mechanisms.[210,225] At the present time the manufacture of welded and strengthened constructions in our country has reached a rate of 100 tonnes annually and shows a tendency to increase.

The methods for the shock synthesis and modification of materials with the aid of a dynamic treatment have also found practical applications in a new branch of science and engineering—the synthesis of superconductors. Apart from the studies quoted above,[138–143] the newest investigations should be mentioned.[226–231] Dynamic experiments make it possible to include in this vigorously developing field methodological features such as high-speed deformation, rapid thermal quenching, and instantaneous increase and relaxation of pressure. In many instances these procedures can be used in technology.

Apart from the direct applications of the dynamic pressure techniques, the latter are used also for the preliminary treatment of materials in the usual technology—for the activation of powders or sintering, pressing, catalytic processes, etc.

Thus we have outlined the most general limits to the applications of the chemistry of shock compression. As regards the prospects for the employment of this method, the unusual nature of the temperature pattern of shock compression, deformation, electrical phenomena, and the enormous pressure gradients create a unique set of physical influences on matter. By varying the energy carriers, the duration of the pulse, the density, and the temperature of the ambient medium and by the joint or consecutive operation of various factors, it is possible to widen significantly the horizons in the application of the shock-wave techniques in chemistry. At the very beginning of the development of shock wave chemistry, its prospects seemed to be limitless; however, in the present author's view, even now the peak in the development of this field has not been passed.

We may note certain problems which have not found a practical solution. This concerns in the first place the synthesis of high pressure phases. Hitherto it has not been possible to obtain such phases chemically; the reason is that the reaction of solids takes place over period $\geq 10^{-6}$ s, i.e. when the high pressure has ceased to operate. The rate-limiting stage is naturally diffusion processes. However, if special measures are taken and the mixture components are comminuted to give a particle size of 0.1–1 μm, then the diffusion time is reduced by 1–2 orders of magnitude and there is sufficient time for the reaction to occur in the high pressure zone. By varying the sizes of the particles of individual components, it is possible, in principle, to "involve" wholly the various parts of the reaction in the chemical process. The successive employment of various pulsed influences—self-perpetuating high-temperature synthesis, electric discharge, shock waves, and radiation can be used for the same purpose. Additional possibilities arise in the inorganic synthesis of high pressure phases under the conditions of the technical application of ultrafast quenching (detonation synthesis "into space") or following the instantaneous imposition of a static pressure after shock compression (for example, in hermetically sealed tubes with water or other gas evolving substance).

The problem of the synthesis of complex and organometallic compounds by-passing the liquid phase appears to be extremely promising. At the present time many substances (with covalent bonds) cannot be directly involved in a chemical process, since they do not dissolve in the known solvents without decomposition and cannot be congruently fused (for example, NaH, $PtCl_2$, $CaC_2$, $CrO_3$, etc.). The chemical interaction under the conditions of shock wave compression in strong containers makes it possible to insert directly into the initial matrix additional atoms and molecules and to obtain new clathrate compounds (for example, silicates with neutral metal atoms incorporated in their vacancies) or complexes with unusual combinations of ligands [for example, $PtF_2Br_2$, $LnF_2I$, $K_2Ni(CN)_2Cl_2$, etc.]. The problem of the polymerisation of inorganic gases, which, as it now appears, can be solved on the basis of solid solutions or clathrate compounds, is also of interest.

These are the nearest prospects for the inorganic shock-wave chemistry, but, as this science develops, new even more interesting tasks may arise.

# Diffraction Methods for the Investigation of the Electron Density and Dynamics of Crystal Lattices

V.G.Tsirel'son, Yu.Z.Nozik, and V.S.Urusov

Precision diffraction methods for the investigation of the electron density, electrostatic potential, and dynamics of crystal lattices are described. Data concerning the fine details of the chemical bonds in compounds of various classes obtained with their aid are discussed. The forms in which the data on the distribution of electron density and electrostatic potential in crystals can be represented and interpreted are examined.
The bibliography includes 96 references.

## I. INTRODUCTION

Two approaches to the description of the structures of molecules and crystals have arisen hitherto. The first of these, namely the quantum-chemical approach, reduces to seeking (in terms of a particular type of approximation) the solution to the Schrödinger equation and their chemical interpretation constitutes an exceptionally difficult problem. In the other, crystal-chemical approach, the structure of the substance is described on the basis of a simple geometrical model and the concepts of the effective charges and radii of atoms.

The two approaches have now come together to some extent owing to factors dictated by practical chemical problems. Qualitatively, the new level of these problems required a fairly rigorous description of the structure and detailed properties of crystals with a complex structure of chemical bonds. Such a description has been achieved by introducing the function $\rho(\mathbf{r})$ characterising the total electron density in the molecule or crystal. This function contains an appreciable proportion of the chemical information about the system, can be related to chemical concepts, can be visualised by graphical representation, and finally its values can be measured directly by X-ray diffraction. The last factor is of fundamental importance because, instead of abstract parameters, determined by wave functions, it makes it possible to describe the electronic structure of the substance with the aid of the experimental function $\rho(\mathbf{r})$.

Together with a brief description of the modern methods for the interpretation of diffraction data and the estimation of their accuracy, the aim of the present review is to demonstrate for a series of examples in what way the results obtained with the aid of precision X-ray measurements can be interpreted in terms of the language of quantum chemistry and crystal chemistry. It is particularly important that the data obtained by this method concern complex chemical compounds which are not susceptible to modern quantum-chemical computational methods.

The use of diffraction methods normally reduces to the determination of the coordinates and parameters of the thermal vibrations of atoms in the crystal lattice. However, by virtue of the significant increase in accuracy of structural analysis as a result of the wide-scale introduction of automatic diffractometers and the development of methods for the accurate interpretation of experimental data, detailed investigation of charge distribution and potential near the equilibrium positions of the atoms in crystals has become possible in recent years. The application of the neutron diffraction method in addition to X-ray data has significantly expanded the range of information obtained.

The qualitative imporvement of the apparatus for the diffraction methods has entailed a change in all the stages of the experiment and of the treatment of the results of measurements. We therefore thought it useful to describe concisely all the stages of the accurate measurement and interpretation of diffraction data. The expansion of experimental possibilities has sharply increased the number of studies based on diffraction methods. They have been devoted to the experimental refinement of the traditional ideas of structural chemistry and the theoretical interpretation of the data obtained. These questions, together with the description of the principles of the precision X-ray and neutron diffraction methods and the analysis of the accuracy of the results, the methods of their representation, and their comparison with data derived by quantum-chemical calculations, are examined in this review. The review does not deal with questions of the determination of spin and momentum densities by diffraction methods in molecules and crystals, which have been considered in detail in a collected volume.[1]

## II. EXPERIMENTAL STUDY OF THE DISTRIBUTION OF ELECTRON DENSITY

In terms of the adiabatic approximation,[2] it is possible to separate with adequate accuracy the movements of electrons and nuclei and to examine the electron subsystem for the nuclear configuration fixed by the thermal equilibrium positions. The structure and properties of the $N$-electron subsystem in the ground state are then described by the many-electron wave function $\Psi(\mathbf{x}_1, \ldots, \mathbf{x}_N)$, which depends on the three-dimensional coordinates and spins of all the electrons. This function can be found as the solution of the Schrödinger equation on the basis of the variational principle. This mathematically cumbersome procedure yields results which depend on the level of the approximations adopted and on the quality of the basis functions used.

For this reason, it is exceptionally difficult to obtain the complete wave function $\Psi$ which reproduces correctly all the properties of the many-electron system;[3] furthermore, the practical determination of such characteristics from $\Psi$ is fairly difficult. However, it is possible to use for the description of the majority of the physicochemical properties of molecules and crystals a one-electron density distribution function $\rho(\mathbf{r})$ with a simpler structure, the function depending solely on the three-dimensional coordinates of the point at which the charge density is to be determined. This function is related to $\Psi$ by the expression[2]

$$\rho(\mathbf{r}) = N \int \ldots \int \Psi(\mathbf{x}_1, \ldots, \mathbf{x}_N) \cdot \Psi^*(\mathbf{x}_1, \ldots, \mathbf{x}_N)\, d\mathbf{x}_2 \ldots d\mathbf{x}_N d\mathbf{s}_1, \qquad (1)$$

where $\mathbf{x}_i = \mathbf{r}_i \mathbf{s}_i$, $\mathbf{r}_i$ being the three-dimensional coordinates, $\mathbf{s}_i$ the spin coordinates of the $i$th electron, and $N$ the number of electrons in the system.

The theoretical interpretation of the function $\rho$ is significantly simpler than that of the wave function $\Psi$ and Eqn.(1) makes it possible to determine it.

The wave function $\Psi$ (with its numerical characteristics) can be calculated with the aid of one of the approximate versions of the solution of the Shcrödinger equation, for example, by the self-consistent field method in terms of the Hartree–Fock approximation, the configuration interaction method, and also the methods based on the band theory of solids. However, the problem of the correct description of the electron density distribution at all points in the test system is very difficult and such description has been achieved (with an error of approximately 0.1 $e\text{Å}^{-3}$) only for simple 2–6 atom molecules.[4,5] For more complex many-electron systems and especially for crystals, the realistically attainable accuracy of the theoretical calculations of electron density is to within approximately 0.3 $e\text{Å}^{-3}$, which is clearly inadequate for the solution of many chemical problems.

On the other hand, the function $\rho$ can be measured experimentally because elastic (Bragg) X-ray scattering by the crystal entails the interaction of the radiation with the electrons and the signal contains information about their distributions. Having measured the intensities of the X-ray reflections for various atomic planes with the *hkl* indices, it is possible to obtain the time-average electron density function† at any point with the coordinates $xyz$ in a unit cell having the volume $V$ (Vainshtein[6]):

$$\rho(\mathbf{r}) \equiv \rho(xyz) = \frac{1}{V} \sum_{hkl} F(hkl) \exp[-2\pi i(hx + ky + lz)] \qquad (2)$$

where $F(hkl)$ is the structural amplitude related to the reflection intensity measured in the X-ray diffraction experiment. Thus Eqn.(2) makes it possible to determine directly the electron density distribution in the crystal (Fig.1). The accuracy of the determination of $\rho$ depends on a number of factors and will be examined in detail below. Here we shall only note that in many instances the error can be only 0.02 $e\text{Å}^{-3}$.

The classical X-ray diffraction analysis of structure is based on the hypothesis that the maxima in the function $\rho$ correspond to the centres of gravity in the electron densities of the atoms; approximate values of these maxima can be found by special methods.[6] The coordinates of the atoms and the parameters of their anisotropic vibrations are then refined by the method of least squares based on minimising the functional

$$\Phi = \sum_{hkl} [F(hkl) - F_{\text{calc}}(hkl)]^2. \qquad (3)$$

The model of the structure to be refined is specified by the expression for the structural amplitude:

$$F_{\text{calc}}(hkl) = \sum_{n=1}^{m} f_n W_n(hkl) \exp[2\pi i(hx + ky + lz)],$$

where the atomic amplitude $f_n$ describes the scattering capacity of the $n$th atom with the coordinates $x_n$, $y_n$, and $z_n$ and the temperature multiplier $W_n$ takes into account the thermal parameters.

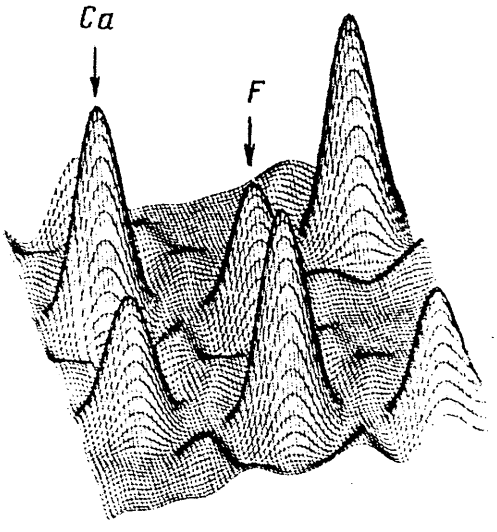

Figure 1. The map of the total electron density in the $CaF_2$ crystals; the maxima of the $\rho$ function correspond to the positions of the atoms.

The atomic amplitude $f_n$ is related by the Fourier transformation to the function of the static electron density of the atom. For an atom in the crystal, this function is never known accurately; to a first approximation, it is assumed that a crystal made up of spherically symmetrical atoms constitutes a satisfactory *a priori* model. This made it possible to describe and tabulate the values of $f$ for all atoms on the basis of the calculation of their spherically symmetrical electron densities by quantum-chemical methods; these $f$ curves are in fact normally used in practice.[7] The errors of their calculation are less than 0.5% (somewhat more for heavy atoms). However, one should note that the above error is not a criterion of the suitability of the spherical atom model for the refinement by the method of least squares. In fact, the modification of the atomic electron density through chemical interaction disturbs the spherical symmetry of the atom and leads to a dependence of the atomic amplitude on the direction of scattering of X-rays. The structural parameters found within the framework of the traditional approach can therefore contain errors associated with this factor.

†The averaging arises because the measurement takes place over a period of time.

In order to take into account the thermal movement of the crystals, one uses the approximation according to which the electron density $\rho$ "smeared" by the atomic vibrations is represented by the convolution of the theoretical static density and the distribution function $t(\mathbf{R})$ for the positions of the centres of gravity of the vibrating atoms $\mathbf{R}$.[8] For an individual atom, this can be formulated as follows:

$$\rho_n(\mathbf{r}) = \int \rho_n(\mathbf{r}, \mathbf{R})\, t_n(\mathbf{R})\, d\mathbf{R}. \quad (5)$$

The specific form of the function $t_n$ depends on the characteristics of the crystal field potential near the point of thermal equilibrium of the atom. In early studies, this potential was assumed to be harmonic and the function was represented by a three-dimensional Gaussian distribution function. However, in a real case the atomic vibrations are anharmonic and the anharmonicity parameters can be determined experimentally, which is done by introducing additional terms into the $t_n$ refined by the method of least squares.[8] An example of such a description is provided by the cumulative expansion of this function when the temperature multiplier assumes the form[6]

$$W_n = \overline{\exp}\left[-\sum_{ij}\beta^{ij}h_ih_k - \sum_{ijk}\gamma^{ijk}h_ih_jh_k + \sum_{ijkl}\delta^{ijkl}h_ih_jh_kh_l + \ldots\right], \quad (6)$$

where $\beta^{ij}$, $\gamma^{ijk}$, and $\delta^{ijkl}$ are the elements of the tensors describing the harmonic and anharmonic (third- and fourth-order) thermal vibrations of the atoms and the $h$'s are the Miller indices. Other expansions of the functions $t_n$ can also be encountered.[8]

A relation of type (2) can be obtained likewise for the distribution of nuclear density; in this case the structural amplitudes $f(hkl)$ are measured in a neutron diffraction experiment and the maxima of the density function correspond to the centres of gravity of the ellipsoids of the thermal vibrations of the nuclei. Owing to the small dimensions of the nuclei, the neutron scattering by the atom is spherically symmetrical. The amplitude of the coherent scattering of neutrons $b_n$ is determined by the properties of the given nucleus and, in contrast to the atomic amplitude $f_n$, is independent of both the magnitude and direction of the scattering vector, i.e. $b_n = \text{const}$.[9]

In terms of the adiabatic approximation, the parameters of the thermal vibrations of the atomic nuclei and of their electron shells are identical. In terms of this approximation, one can assume that the information obtained by the X-ray and neutron diffraction methods (taking into account their specific features—see below) is identical. However, one should note that at the present time the data produced by accurate diffraction experiments show that in certain cases the use of the adiabatic approximation is inadmissible; for example, highly delocalised valence electrons and conductivity electrons do not obey this approximation. On the other hand, if this approximation is adopted, then certain inaccuracies, mentioned above, in the determination of the structural parameters from X-ray data owing to the non-spherical nature of the electron density of the atoms can be eliminated in the subsequent analysis of the electron distribution. The analogous parameters obtained from neutron diffraction measurements can be used instead of the X-ray parameters.

The joint application of various diffraction methods can be generally speaking extremely useful. For example, the scattering of electrons is determined by the electrostatic potential of the atom, which depends on the charge distribution in the crystal. We have the relation[6] between the amplitude of the scattering of electrons and X-rays:

$$f_{el}[(\sin\theta)/\lambda)] = \frac{8\pi^2me^2}{h^2}\cdot\frac{Z - f_p[(\sin\theta)/\lambda]}{[(\sin\theta)/\lambda]^2}, \quad (7)$$

where $h$ is the Planck constant, $e$ and $m$ are the charge and mass of the electron, and $Z$ is the atomic charge. Using the values on the X-ray $f$ curves refined on the basis of experimental data (see below), it is possible to calculate $f_{el}$ more accurately by Eqn.(7), which permits an improvement of the accuracy of the structural information.

In order to make use of the information derived from the diffraction experiments in the study of electron density, it is essential to relate $\rho$ directly to the measured radiation intensity. This can be done within the framework of the kinematic theory of diffraction taking into account the corresponding dynamic corrections.[6,9] If the homogeneous monochromatic X-ray beam is incident on a crystal, then the total measured intensity of the scattered radiation can be formulated as follows:

$$T(\mathbf{q}) = JK(e^2/mc^2V)^2v\lambda^3LP(1+\alpha)\cdot|yDF(\mathbf{q})|^2 + \sum_m p_m I_m(\mathbf{q}) + B, \quad (8)$$

where $\mathbf{q}$ is a vector whose coordinates are the Miller indices, $h$, $k$, and $l$ [it is the scattering vector $|\mathbf{q}| = 4\pi(\sin\theta)/\lambda$], $K$ a multiplier which takes into account the drift of the primary beam over a long period, $A(\mu)$ the transmission function which depends on the absorption coefficient $\mu$, $\alpha$ a correction for the thermal diffuse scattering, $V$ the volume of the unit cell, $B$ the background intensity, $p_m$ are coefficients taking into account the energy exchange between the incident and reflected beams with the intensities $I_m$ under the conditions of repeated scattering, $J$ is the intensity of the incident radiation with a wavelength $\lambda$ per unit area, $e^2/mc^2$ the electron multiplier, $v$ the volume of the crystal involved in the reflection, $P$ the polarisation multiplier, $L$ the Lorentz factor, $y$ the correction for extinction, and $D$ the correction for anomalous scattering.[6]

The formula for the intensities of neutron diffraction can be formulated analogously.[9] In this case the multiplier $e^2/mc^2$ is omitted from Eqn.(2) and, in view of the lack of polarisation of the neutrons, $P = 1$.

Eqn.(8) can be conveniently rewritten in the form

$$T(\mathbf{q}) = I(\mathbf{q})/M + \sum_m p_m I_m(\mathbf{q}) + B, \quad (9)$$

where $1/M = \text{KLP}(1+\alpha)A(\mu)$ and $I(\mathbf{q}) = |yDF(\mathbf{q})/k|$. The fact that $1/k^2 = J(e^2/mc^2V)^2\lambda^3$ is independent of $\mathbf{q}$ was used here; the quantity $K$ is a scaling factor. Evidently, the intensity of the Bragg reflection can be represented by the expression

$$I = M\left(T - \sum_m p_m I_m - B\right). \quad (10)$$

The factors influencing the accuracy of the determination of the intensities of the diffraction reflections and the moduli of the structural amplitudes can be divided into two types. The factors unrelated to the type of radiation (X-rays and neutrons) or depending on a given type but in terms details which are insignificant should be assigned to the first type. For example, as a result of repeated scattering, due to the fact that the reflecting site can contain simultaneously several inverse lattice sites, the intensity of the measured reflection changes. Such a change can be avoided when the crystal is rotated around the direction of the scattering vector until all the inverse lattice sites, except that for which the measurement is made, have passed out of the Ewald sphere. Factors of the first type also include the geometry of the measurement taken into account by the Lorentz multiplier.[6]

Factors of the second type, associated with various mechanisms of the interaction with X-rays and neutrons with the crystal, have to be taken into account in different ways (absorption, extinction, thermal diffuse scattering). The principal difficulties in the accurate determination of the structure amplitude arise in absorption when the test crystal has an arbitrary geometrical shape, in extinction in the case where the shape and size of the coherent scattering blocks in the specimen are markedly anisotropic, and in thermal diffuse scattering for crystals with a low symmetry.

The allowance for absorption when the radiation passes through the crystal reduces to the calculation of the integral[9]

$$A(\mu) = \frac{1}{v}\int_{v} \exp[-\mu(r_1 + r_2)]\, dv, \qquad (11)$$

in which $r_1$ and $r_2$ are the distances traversed by the beam in the crystal before and after diffraction. Here the accuracy of the determination of the average effective length of the path of the beam in the crystal for each *hkl* reflection is the most significant. For a spherical specimen, the corrections for absorption have been tabulated; for a polyhedral crystal, they can be calculated by a method which has been described.[7] The absorption coefficients for X-rays are in the range ~$10^2$–$10^3$ $cm^{-1}$, while those for neutrons are significantly smaller ($\mu \cong 10^{-1}$ $cm^{-1}$ for $\lambda \leq 1$ Å). Lithium, boron, cadmium. and certain lanthanides ($\mu_{neutr} \cong 10$–$100$ $cm^{-1}$) as well as substances whose composition includes a large number of hydrogen atoms ($\mu_{neutr} \cong 2$–$5$ $cm^{-1}$) are exceptons.[9]

Allowance for the deviations from kinematic diffraction due to the presence of excited states in the crystal lattice in the radiation field, which entails non-elastic coherent scattering by acoustic phonons or thermal diffuse scattering (TDS) is extremely important.[8,10] Allowance for this effect is especially important in neutron diffraction, where the energy of the neutrons used in the diffraction experiment is close to that of the thermal vibrations of the lattice atoms. The contribution by TDS to individual reflections in molecular crystals can reach 30% of the intensity of the Bragg peak.

For certain relations between the velocities of the thermal neutrons and sound in the crystal, the effective cross-sections for the TDS of neutrons and X-rays can become comparable. For example, for lead and similar "soft" materials, the TDS for neutrons and X-rays become similar when $\lambda_{neutr} \leq 1.70$ Å while for "hard" materials (tungsten and others) this happens already for $\lambda_{neutr} \leq 0.77$ Å.

The correction for TDS can be represented in the form

$$1 + \alpha = \exp[2\Delta U[(\sin\theta)/\lambda]^2], \qquad (12)$$

where $\alpha$ is the ratio of the intensities of the thermal diffuse and Bragg scattering and $\Delta U$ is the effective temperature coefficient common to all the atoms of the structure. Evidently the neglect of the TDS effect leads to errors in the determination of the atomic thermal parameters manifested by their apparent decrease.

Several methods have been proposed for the calculation of corrections for TDS which are suitable in the case of crystals of any symmetry.[8,10] The effect can also be diminished by reducing the experimental temperature. For example, $\Delta U \cong 0.1$ Å$^2$ for ammonium oxalate $(NH_4)_2C_2O_4$ at room temperature, while at $T = 110$ K the quantity $\Delta U$ decreases to 0.04 Å$^2$. However, the use of low temperatures presupposes the thermal stability of the crystal and the absence of phase transitions in the latter. One should note that the contribution of TDS depends significantly on the conditions of the measurements: the divergence and the non-monochromatic nature of the primary beam, the aperture of the detector, the size of the crystal investigated, and the methods used to correct the background and the quantity q.[10]

As an example, Fig. 2 presents the dependence fo the TDS contribution on $(\sin\theta)/\lambda$ and the aperture of the counter for the scattering of X-rays by a ruby single crystal.[10] Such data make it possible to select the optimum strategy for precision intensity measurements.

After the above corrections have been introduced, it is possible to formulate a formal expression for the estimation of the variance of the measured intensity:

$$\sigma^2(I) = Q^2\sigma^2_{cr} + Q^2p^2I_0^2 + s^2(Q)\, I_0^2, \qquad (13)$$

where $\sigma^2_{st}$ takes into account the statistical components of the variance (the radiation quanta registered by the counter obey the Poisson distribution[11]), $Q$ is determined by comparing the intensities of periodically measured references reflections, $s^2(Q)$ is the random variance of $Q$, the multiplier $p$ takes into account the instrumental instability of the error associated with the application of the corrections and partly with the random errors that have not been taken into account. An estimate of the accuracy of the measurement is also provided by averaging the symmetrically-equivalent reflections measured over the total Ewald sphere; the extent of the scattering is an index of the accuracy of the experimental determination of the extent of diffraction intensities.[12]

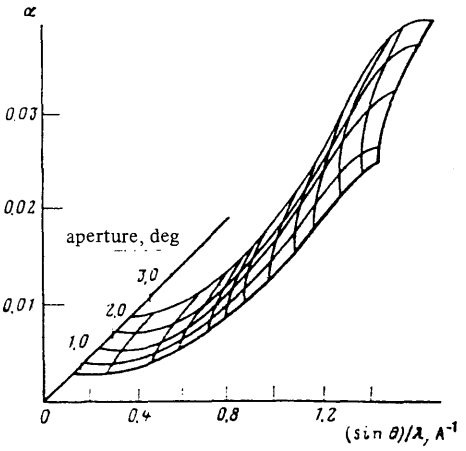

**Figure 2.** The influence of thermal diffuse scattering on the intensity of X-ray diffraction by a ruby single crystal.[10]

The primary treatment of diffraction data described above makes it possible to proceed to the elucidation of the structure of the crystal and then to its refinement by the method of least squares. Here it is necessary to take into account extinction and anomalous scattering. The correction for extinction allows for the change in the reflection intensity owing to the phase relations between the rays scattered by different points in the crystal. The correction is applied by introducing in Eqn. (8) the multiplier $y = y_1y_2$. The correction for the primary extinction $y_1$ takes this effect into account in each of the mosaic blocks and the correction for the secondary extinction $y_2$ takes it into account for the entire collection of these blocks. Corrections of the two types are inter-related—in particular $y_2 \approx f(y_1)$,[12] and only the quantity $y_2$ is therefore usually included among the parameters refined by the method of least squares.[13]

Anomalous scattering arises when the frequency of the incident radiation is comparable to the intrinsic frequencies of the vibrations of the scattering atom in the crystal. In this case the expression for the atomic amplitude is[7]

$$f=f_0+\Delta f'+i\Delta f'', \qquad (14)$$

where $f_0$ is the normal scattering component and $\Delta f'$ and $\Delta f''$ are corrections taking into account the anomalous scattering. The values of these corrections at the X-ray wavelengths normally employed in the structural analysis for light atoms are small, but for heavy atoms they can reach 5–10% of $f_0$. In neutron diffraction the correction for anomalous scattering is significant only for nuclei such as $^6$Li, $^{10}$B, $^{113}$Cd, and certain lanthanides. The methods used to apply this correction have been described in detail and the corresponding tables of the values of $\Delta f'$ and $\Delta f''$ have been published.[14,15]

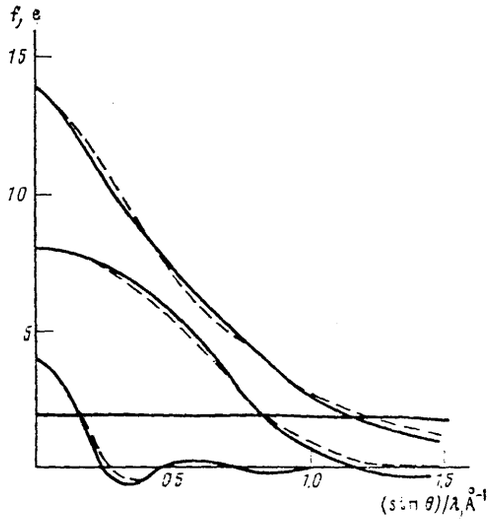

Figure 3. The atomic [$f = f_K + f_L + f_M$ (1)] and partial [$f_K$ (2), $f_L$ (3), and $f_M$ (4)] scattering amplitudes for the Si atom calculated using Slater orbitals (continuous lines) and Hartree–Fock orbitals (dashed lines).[16]

We shall now consider certain features of the procedure involved in the application of the method of least squares in connection with the problem of the determination of the electron distribution in crystals. The positional (coordinates) and thermal parameters of atoms, the scaling factor $k$ which converts the experimental data to values in terms of the absolute scale, and the correction for extinction are refined by this method. The deficiencies of the model of spherically symmetrical atoms have already been mentioned above. The error in the refinement procedure can be diminished, for example, by taking into account the fact that the electrons of the valence subshells deformed by chemical bonds scatter X-rays mainly in the "short-range" region of the inverse space. Fig.3 presents the atomic amplitude calculated using Slater type orbitals (STO) in terms of the orthogonal basis set and the basis set of the Hartree–Fock (HF) orbitals for the silicon atom[16] having the electronic configuration $1s^22s^22p^63s^23p^2$. It is also seen from Fig.3 that, when the basis set is altered, the partial amplitudes indicate an apparent "flow" of densities from one shell to another. This must be taken into account by comparing the experimental and quantum-chemical results of the determination of electron density distribution: the application of identical basis functions in both cases is an obligatory condition for the correct interpretation of the results.

The coordinates and thermal parameters of atoms are usually refined on the basis of "long range" reflections where the contribution due to spherically symmetrical (undeformed) inner electron subshells is mainly manifested.[17] Here it is assumed that the boundary between the "long-range" and "short-range" regions of the inverse space is located at $(\sin\theta)/\lambda \cong 0.7–0.8$ Å$^{-1}$. However, one should bear in mind that the non-spherical characteristics of the valence subshells (for example, the unshared electron pairs) make an appreciable contribution to the scattering up to $(\sin\theta)/\lambda \leqslant 1.0$ Å$^{-1}$.[5] Instead of refining the thermal and positional parameters of atoms, we can also determine them in an independent neutron diffraction experiment.

In accurate studies the modification of the electron density of atoms in the crystal is taken into account approximately by introducing into the radial part of the function describing the density of valence electrons the multiplier $\kappa$ which characterises its "contraction" or "expansion" compared to the free atom.[18] In this case the scattering amplitude for valence electrons is defined by the expression

$$f_{val}(\varkappa, q)=f'(q/\varkappa), \qquad (15)$$

where $f'$ is the amplitude of the scattering by the free atom.

The parameter $\kappa$ and the populations of the valence shells of atoms are included among the parameters refined by the method of least squares. An even greater flexibility can be achieved by employing a multipolar model. Within the framework of this model, the electron density of the bound atom in the crystal is represented by the expansion in terms of the angular harmonics $y_{\ell}(\theta, \phi)$ satisfying the local symmetry of the environment (see below). This model diminishes significantly the $R$ factor#[13] and other criteria for the statistical estimation of the reliability of the results.[19]

Allowance for a series of physical and chemical requirements, such as the electroneutrality of the crystal, the equality of the parameters referring to chemically equivalent parts of the molecules, and the imposition of limitations on the components of the thermal vibrations owing to the rigidity of the bond,[20] is also extremely useful and makes it possible to reduce the error of the results.

## III. METHODS FOR THE REPRESENTATION OF ELECTRON DENSITY

In the study of the characteristics of the electron distribution in a system made up of atoms linked by chemical interactions, it is convenient to make use of difference functions of the type

$$\delta\rho(r)=\rho_1(r)-\rho_2(r), \qquad (16)$$

where $\rho_1$ and $\rho_2$ are functions corresponding to two different

---

#The unreliability factor $R$ is used to estimate the relative error in the refinement of the structure of the crystal and is calculated from the formula $R = \sum_q[F_{exp}(q) - F_{calc}(q)]/\Sigma F_{exp}(q)$, where $F_{exp}$ and $F_{calc}$ are the measured and calculated structural amplitudes respectively.

versions of the determination of the electron distribution. The experimental electron density $\rho_{exp}$ is normally employed as $\rho_1$.

The function of the deformation electron density

$$\delta\rho(\mathbf{r}) = \rho_{exp}(\mathbf{r}) - \sum_n \rho_n(\mathbf{r}), \qquad (17)$$

is most convenient for the analysis of the redistribution of electrons in the system caused by the involvement of atoms in chemical bonding. Here the sum represents the electron density for a set of spherically symmetrical atoms located at the same point as the atoms in the crystal (the electron density of the "promolecule").[21]

If only the inner electrons (electronic skeletons) of atoms are involved in the summation, then the function $\delta\rho$ describes the valence electron density of the crystal.

Eqn.(17) can be rewritten in terms of the series

$$\delta\rho(\mathbf{r}) = \frac{1}{V}\sum_{\mathbf{q}} \delta F(\mathbf{q}) \exp(-i\mathbf{qr}), \qquad (18)$$

where $\delta F(\mathbf{q}) = F_{exp}(\mathbf{q}) - F_{calc}(\mathbf{q})$ and $F_{calc}(\mathbf{q})$ is the Fourier transform of the electon density of the promolecule.

The theoretical calculation should be performed using modern quantum-chemical methods[3] taking into account the relativistic effect and multiconfiguration interaction; otherwise the low accuracy of the calculation can hinder the interpretation of $\delta\rho$. However, since this is not always feasible, one can employ wave functions calculated with the aid of the relativistic version of the Hartree–Fock method; the corresponding $f$ curves have been tabulated.[7]

The function $\delta\rho$ can be regarded as one describing the redistribution of electrons in the system due to chemical bonding. Naturally the diffraction data must be interpreted in terms of the same basis set as in the calculation for the promolecule taking into account the modification of the wave functions of the valence electrons.

The graphical representation of the cross-sections of the deformation electron density function for the test molecules makes it possible to determine whether the chemical bonds are straight or bent (strained) and directional or of the many-centre type, what their shape is in cross-section, where the unshared electron pair density maxima are located, how the deformation of the electron density of the atom depends on its environment, etc.

As an example, Fig.4 presents the results of a precision study of a ruby crystal having the composition $Al_2O_3$ + Cr(0.46 wt.%).[22] Fig.4*a* illustrates the map of the deformation electron density of a fragment of the structure of ruby containing characteristic Al–O bonds 1.970 and 1.856 Å long. The map contains excess deformation (covalent) peaks whose height is approximately 0.27 eÅ$^{-3}$ which have undergone a shift towards the more electronegative O atom and which have been displaced from the line of the bond. This map shows that the Al–O bonds in ruby and also in corundum $Al_2O_3$ are partly covalent and strained and the shift of the deformation peak from the line of the bond is a consequence of the electrostatic interaction of the electrons in the region of the bond with the nearest "foreign" positively charged ion. It can be seen that distinctly directional individual chemical bonds characteristic of ionic crystals are absent from the structure, while the electron density is highly localised. These features of the electronic structure are reflected in the properties of ruby such as, for example, its mechanical strength.

In the study of ruby[22] an attempt was made to determine by X-ray diffraction the positions of the $Cr^{3+}$ ions. Refinement by the least squares method ($R$ = 0.0068) showed that the chromium ion, substituting the $Al^{3+}$ ion in the structure isomorphously, is not located exactly at the position of the latter but is displaced along the hexagonal $z$ axis by 0.13 Å towards an octahedral vacancy. A difference electron density map has been constructed (Fig.4*b*) on which the admixture of $Cr^{3+}$ ions appears in the form of an excess peak 0.3 eÅ$^{-3}$ high in the vicinity of the $Al^{3+}$ ions. The possibility of determining such a small amount of the admixture is characteristic of the actual attainable accuracy of modern diffraction methods.

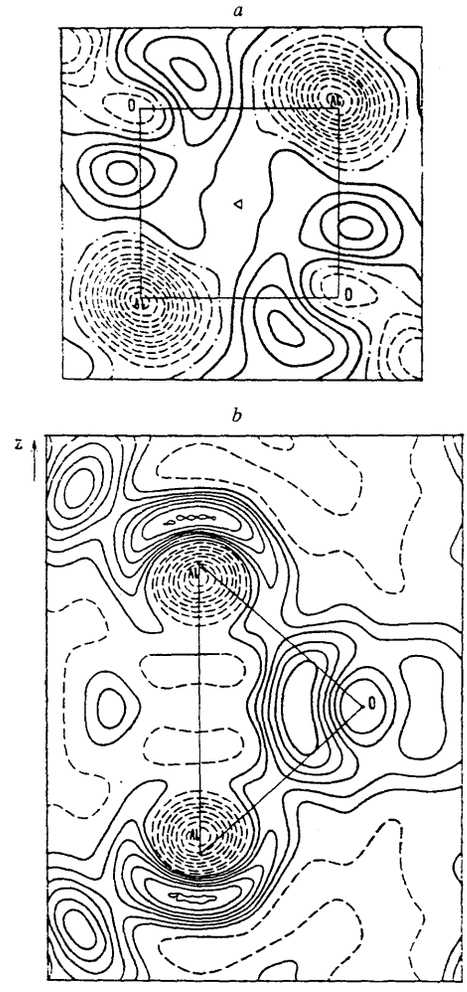

**Figure 4.** Fragments of deformation electron density in the ruby crystal.[22] (Here and henceforth the continuous lines on the map connect points with excess electron density, the dashed lines connect points with deficient electron density, and the dash-dot lines connect points with zero electron density): *a*) sections through the Al and O atoms and the centre of symmetry; the spacing between lines 0.07 eÅ$^{-3}$; *b*) the (0110) [sic] plane; the Cr atom was not removed in the synthesis and can be seen as a peak above and below Al; the spacing between lines is 0.05 eÅ$^{-3}$.

The deformation electron density function can be constructed in accordance with two schemes.[23,24] In the first of these all the parameters for the calculation of $F_{calc}$ were

obtained by refining the X-ray diffraction data corresponding to high experimental values of $(\sin\theta)/\lambda$ (the $X-X$ method). In the second $F_{calc}$ is determined with the aid of parameters obtained from a neutron diffraction experiment (the $X-N$ method). As stated above, the advantage of the latter consists in the absence of a dependence of the results of the measurements of the model of the electronic structure of the crystal and in the reliability of the determination of the positional and thermal parameters of light atoms (in the first place hydrogen) in the presence of heavy atoms.

The application of the $X-N$ approach requires allowance for the specific features of both diffraction methods and also for the possible difference between the temperatures of the two experiments.[12,23] A check on the temperature can be carried out by calculating the unit cell parameters of the crystal, which should be identical at identical temperatures. It is more difficult to take into account other effects. For example, TDS is manifested in different ways in experiments of the two types: in neutron scattering the contribution of TDS is greater. This reduces the thermal parameters of the atoms obtained in neutron diffraction experiments by approximately 10% relative to the X-ray experiments. Next, discrepancies arise in the results due to the differences in the allowance for the background in the calculation of the contribution of elastic scattering to the intensity. Furthermore, the different sizes of the crystals and the difficulty of an adequate description of the X-ray and neutron scattering processes also lead to errors which cannot be always fully corrected. Practical procedures used in such corrections can be found in a number of communications.[1,12,23]

In order to obtain reliable results in the analysis of the function $\delta\rho$, the error in the deformation density $\sigma(\delta\rho)$ must be less than the significant details in the function $\delta\rho$. On the basis of the standard deviations of the parameters obtained as a result of the least squares refinement and $\sigma^2(F_{exp})$, the variance of the deformation electron density can be represented in the form[23,25]

$$\sigma^2(\delta\rho) = \frac{2}{V^2}\sum_{|q|>0}[\sigma^2(\delta F)\cdot\cos^2\alpha + \delta F^2\cdot\sin\alpha\cdot\sigma^2(\alpha) + \\ + \sin 2\alpha\cdot\delta F\cdot\sigma(\delta F)\cdot\sigma(\alpha)\cdot\gamma(\delta F,\alpha)], \qquad (19)$$

where $\alpha = qr - \beta$, $\beta$ is the $\delta F$ phase, and $\gamma$ the correlation coefficient.

As a result of a careful study, it is possible to express $\sigma^2(\delta\rho)$ in terms of $\sigma^2(F)$, $\sigma^2(F_{calc})$, and $\sigma^2(k)$ and to show that (1) the error due to $\sigma^2(F)$ and $\sigma^2(F_{calc})$ is approximately constant throughout the cell and does not exceed 0.04 eÅ$^{-3}$ for centrosymmetrical structures with light ($Z \leq 16$) atoms and 0.06 eÅ$^{-3}$ for non-centrosymmetrical structures and (2) the error due to $\sigma^2(k)$ and the errors in the structural parameters is significant only in the vicinity of the centres of atoms and for heavy ($Z \geq 50$) atoms reaches in this instance 6–8 eÅ$^{-3}$, while for light atoms it is 0.1–0.8 eÅ$^{-3}$. In the $X-N$ scheme the error associated with the inaccurate selection of the amplitude of the coherent neutron scattering can also have an effect; in the vicinity of the centres of atoms it is comparable in magnitude to the errors due to other factors and must be taken into account.[26]

The average error of the determination of the deformation electron density, constructed on the basis of precision diffraction data, is usually less than 0.05 eÅ$^{-3}$ in the region of the chemical bond.[1] This makes it possible to investigate at the present time the details of the electron distribution in crystals containing heavy atoms (up to $Z = 78$). Such accuracy and the potential set of objects, including complex molecules with heavy atoms, are so far inaccessible to theoretical calculations.

Another field where diffraction data are used involves the determination of the numerical characteristics of the electron distribution. Several methods have been proposed for the solution of this problem and these have been described in detail, for example, by Tsirel'son and Ozerov.[23] The simplest method of parametrising the function $\rho(\mathbf{r})$ consists in determining the electronic charge concentrated in a certain volume by the direct integration of the function $\rho$ over this volume. In particular, it is possible to estimate in this way the effective atomic charges. Usually the volume over which the integration is carried out is represented by a sphere bounded by the minimum of the function $\rho$; this approximation is justified only for a simple ionic compound.[24] In the case of atoms involved in covalent bonds, it is useful to employ more complex methods for charge separation. In the integration, account must also be taken of the fact that the function $\rho$ is constructed on the basis of data obtained in a diffraction experiment in which only a limited number of terms of the Fourier series are measured; the appropriate correction must therefore be applied to the final results.[27]

Table 1. The atomic charges in certain silicates.[28]

| Atom | $Mg_2Si_2O_6$ | $Co_2Si_2O_6$ | $Fe_2Si_2O_6$ | $Mg_2SiO_4$ | $Co_2SiO_4$ | $Fe_2SiO_4$ |
|---|---|---|---|---|---|---|
| Metal, $M(1)$ | +1.84 (4) | +1.29 (11) | +1.14 (12) | +1.76 (3) | +1.60 (11) | +0985 (8) |
| Metal, $M(2)$ | +1.79 (4) | +0.81 (12) | +1.10 (13) | +1.74 (3) | +1.54 (7) | +1.45 (11) |
| $Si^A$ | +2.20 (4) | +1.79 (9) | +2.21 (11) | +2.11 (3) | +2.21 (10) | +2.43 (6) |
| $Si^B$ | +2.36 (4) | +2.76 (9) | +2.16 (11) | — | — | — |
| $O(1)^A$ | −1.51 | −1.10 | −1.04 | −1.52 | −1.24 | −1.13 |
| $O(1)^B$ | −1.37 | −1.14 | −1.19 | — | — | — |
| $O(2)^A$ | −1.36 | −1.12 | −1.09 | −1.29 | −1.24 | −1.21 |
| $O(2)^B$ | −1.43 | −1.16 | −1.20 | — | — | — |
| $O(3)^A$ | −1.31 | −0.84 | −0.92 | −1.40 | −1.39 | −1.24 |
| $O(3)^B$ | −1.22 | −1.10 | −1.18 | — | — | — |
| ⟨Metal⟩ | +1.82 | +0.95 | +1.12 | +1.75 | +1.57 | +1.15 |
| ⟨Si⟩ | +2.28 | +2.28 | +2.19 | — | — | — |
| ⟨O*⟩ | −1.42 | −1.43 | −1.13 | — | — | — |
| ⟨O**⟩ | −1.27 | −1.05 | −0.97 | — | — | — |
| ⟨O⟩ | −1.37 | −1.08 | −1.10 | −1.40 | −1.29 | −1.19 |

Notation: The angular brackets indicate that average quantities are quoted; $M(1)$ and $M(2)$ are two types of octahedral and $A$ and $B$ are two types of tetrahedral positions in the structure.

*Non-bridging oxygen atoms.

**Bridging oxygen atoms.

The effective charges on the atoms in certain oxides and silicates obtained in this way[27,28] are listed in Table 1. In conformity with modern ideas concerning the semicovalent character of the chemical bond, the charges on the oxygen ion in the oxide compounds are in the range from −0.8 to −1.5 e and those on the silicon atoms are from +1.8 to +2.8 e.

Another way of estimating the atomic charges from diffraction data consists in the application of the method of least squares.[29] For this purpose, the atomic electron shells are assumed to consist of a constant inner part to which a fixed number of electrons are bound and of the valence part whose electron population is to be refined. Simultaneously with the refinement of the number of valence electrons, it is possible to take into account, using the parameter $\kappa$ and Eqn.(15), the radial modification of the valence electron shell associated with the charge redistribution in the system.[18]

A correlation has been observed between the charge on the atom and the parameter $\kappa$,[18] which agrees well with the familiar Slater rules for the selection of the exponential multipliers in the radial parts of the orbitals. Fig.5 shows that these simple rules make it possible to determine quite satisfactorily the charge on the N atom in various organic compounds; this can also be said of the C and O atoms.

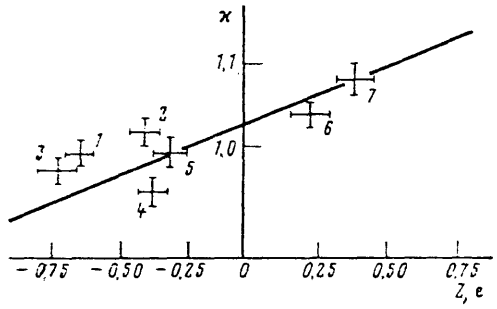

Figure 5. Dependence of $\kappa$ on the atomic charge according to Coppens et al.:[18] 1) and 2) glycylclycine; 3) formamide; 4) cyanuric acid; 5) tetrasulphotetranitride; 6) sulphamic acid; 7) *p*-nitropyridine *N*-oxide; the result of the calculation by the Slater method is indicated by the straight line.

We shall consider the multipolar procedure for the refinement of structural parameters by the least squares method. In this approach the electron density of the crystal is represented in the form

$$\rho(\mathbf{r}) = \sum_j \left\{ \rho_j(\mathbf{r}) + \sum_i c_{ij} R_{ij}(\mathbf{r}) \Phi_{ij}(\theta, \varphi) \right\} \qquad (20)$$

where $\rho_j$ is the electron density on the $j$th atom, according to Hirshfeld and Harel,[30,31] or on the skeleton of this atom, according to Stewart,[32] and the $c_{ij}$ are the coefficients of the expansion (the electron "populations") of the multipoles.

Eqn.(20) represents the expansion of the deformation of the valence electron density in terms of functions whose angular component $\Phi_{ij}$ describes the multipolar (dipolar, quadrupolar, octapolar, etc.) deformation of the atom in the crystal, determined by the symmetry of the environment and the effects of the chemical interaction. The radial functions usually have the form

$$R_{ij}(r) \sim r_{ij}^n \exp(-2\alpha_{ij} r_{ij}),$$

where $r_{ij}$ is the current coordinate reckoned from the nucleus of the $j$th atom.

Thus the electron density of the crystal is represented by the sum of the multipolar terms ("pseudoatoms"[32]) and the coefficients and the experimental multipliers of the multipoles $\alpha_{ij}$ are included among the parameters refined by the least squares method. This model is very flexible, and its flexibility can be increased still further by combining the multipolar expansion method with the use of the parameter $\kappa$.[19] The electron populations of the monopolar terms are usually interpreted as the electronic charges on the atom. A direct interpretation of the remaining multipolar parameters of the electron density distribution in terms of the LCAO-MO approximation is difficult.

The multipoles linked by the *d* orbitals of transition metal atoms are an exception.[33] Information of this kind is of considerable interest. Thus it follows from the refinement of the above populations of the cobalt atom in (*meso*-tetraphenylporphyrinato)cobalt(II) ($C_{44}H_{28}N_4Co$),[34] carried within the framework of the crystal field theory, that the cobalt atom in this compound exists in a low-spin state, in conformity with the results of magnetic measurements (Table 2).

Table 2. The electron populations of the *d* levels of cobalt in $C_{44}H_{28}N_4Co$.[34]

| Atomic orbital | Electron populations | | | |
|---|---|---|---|---|
| | I | II | III | III |
| $b_1 (d_{x^2-y^2})$ | 1.4 | 0.0 | 1.0 (2) | 0.25 |
| $a_1 (d_{z^2})$ | 1.4 | 1.0 | 1.0 (2) | 1.06 |
| $b_2 (d_{xy})$ | 1.4 | 2.0 | 1.3 (2) | 1.76 |
| $c (d_{xz}, d_{yz})$ | 2.8 | 4.0 | 3.7 (3) | 3.91 |

Notation: I) the expected high-spin state; II) the ideal low-spin state; III) results of refinement on the basis of diffraction data; IV) theoretical calculation by the configuration interaction method.

The observed deviation from the expected values indicates the limited applicability of the one-determinant approximation for the description of the observed picture. Comparison with theoretical calculations (Table 2) show that, when the additional excitations of the electronic configurations are taken into account, the theoretical populations of the 3*d* orbitals vary in parallel with experimental data. Another important result of Stevens' study[34] is the demonstration of the limited character of the crystal field theory, which is frequently used to interpret the state of the metal ion in organometallic [sic] compounds.

In particular, the unduly high populations of the $d_{x^2-y^2}$ orbital which follow from the diffraction data are a consequence of the failure to take into account the metal–ligand $\sigma$-bond by this theory, while the neglect of the $\pi$ interaction leads to reduced populations of the $d_{xy}$ and $d_{yz}$ orbitals.

The large number of parameters of the multipolar model entails their strong mutual correlation in the equations of the least squares method. In order to increase the reliability of the results of the multipolar method of calculation, it is useful to introduce certain additional conditions relating the parameters being refined to one another. For example, it is possible to carry out the refinement in such a way that agreement is ensured between the electric field gradient at one of the atomic nuclei and the value derived from NQR experiments. A refinement of this kind, carried out for aluminium phosphate ($AlPO_4$)[35] showed that the above procedure makes it possible to attain a deeper minimum in the functional (3) for the charges on the Al, P, and O atoms; values of +1.4, +1.0, and −0.60 e respectively were obtained. These charges indicate a significant covalence of the P–O bond, which has also been confirmed by the cross-sections of the deformation electron density function constructed by Schwarzenbach and Ngo Thong.[35]

The multipolar analysis of the distribution of electron density in diamond and graphite has shown that the exponential multiplier in the radial function $\alpha_{exp}$, found by least

squares refinement, is 1.56 for diamond[36] and 1.58 for graphite,[37] whereas for the free carbon atom $\alpha = 1.59$.[38] Comparison of these data with the molecular optimised value $\alpha_m = 1.72$, obtained for the carbon atom by averaging the results of quantum-chemical calculations in terms of the minimal basis set for a series of simple organic molecules,[38] has shown that the calculated $\alpha$ corresponds to a more "contracted" atom. An analogous situation has been observed for silicon ($\alpha_{exp} = 1.6$; $\alpha_m = 1.75$).[38] Comparisons of this kind are useful for semiempirical quantum-chemical calculations where there is a possibility of choosing the optimum values of the exponential multipliers, defining the basis functions, depending on the level of the approximations adopted. Thus one may conclude that in quantum-chemical calculations where the overlap of orbitals of neighbouring atoms is neglected it is possible to compensate for the failure to allow for the shift of part of the electron density to the interatomic space by reducing the values of $\alpha$ in terms of the minimal basis set.

Maps of the deformation electron density can be constructed on the basis of the results of the multipolar refinement. Such "synthesised" maps filter out the "noise" associated with the errors in the diffraction data and are to a large extent free from the defects due to the cut-off of the Fourier series.[19] As an example, we shall consider the compound $C_{44}H_{28}N_4Co$ mentioned above.[34] Fig. 6*a* presents the cross-section of the multipolar function $\delta\rho$ in the plane of the pyrrole ring averaged with respect to the chemically equivalent parts of the molecule. The distribution of errors for the non-averaged case is illustrated in Fig. 6*b*; the error in the determination of the distribution of the centres of atoms reaches 0.7 eÅ$^{-3}$ according to the estimates made above. The "multipolar filtration" and averaging reduce this error by a factor of 3–4. Ultimately the characteristics $\delta\rho$ become even more pronounced: $\delta\rho > 3\sigma(\delta\rho)$. The peak on the C(2)–C(3) bond on the map, which significantly exceeds the peaks on other covalent bonds in the porphyrin molecule, is striking. This finding has been analysed[34] and accounted for in terms of the localisation of the $\pi$ electrons at this bond.

Another quantitative approach to the analysis of the electron distribution in crystals is based on the representation of $\rho(\mathbf{r})$ with the aid of the linear combination of atomic orbitals (LCAO) in the following form:

$$\rho(\mathbf{r}) = 2\sum_{ij} P_{ij}\varphi_i(\mathbf{r})\,\varphi_j^*(\mathbf{r}) \qquad (21)$$

where $\phi_i$ are the analytical atomic orbitals (for example, the orthogonalised Slater orbitals) and $P_{ij}$ are the elements of the charge–bond order matrix characterising the electronic structure of the system investigated. Having calculated the Fourier transform of formula (21), it is possible to find the matrix elements $P_{ij}$ assuming them to be adjustable parameters and minimising the functional (3). However, the attempt to apply such an approach in conjunction with the least squares matrix encountered computational difficulties associated with the correlation between the parameters to be refined.[39–44] This led to the use of the palliative methods mentioned above,[29] in which either certain matrix elements $P_{ij}$ were not refined, being selected *a priori*, or the electron populations of the valence shells of each atom were refined as one parameter. Nevertheless, the idea of the above approach is extremely primising because it leads to the possibility of a direct comparison of the experimental results with data obtained from quantum-chemical calculations in terms of the LCAO approximation involving the same matrix *P*.

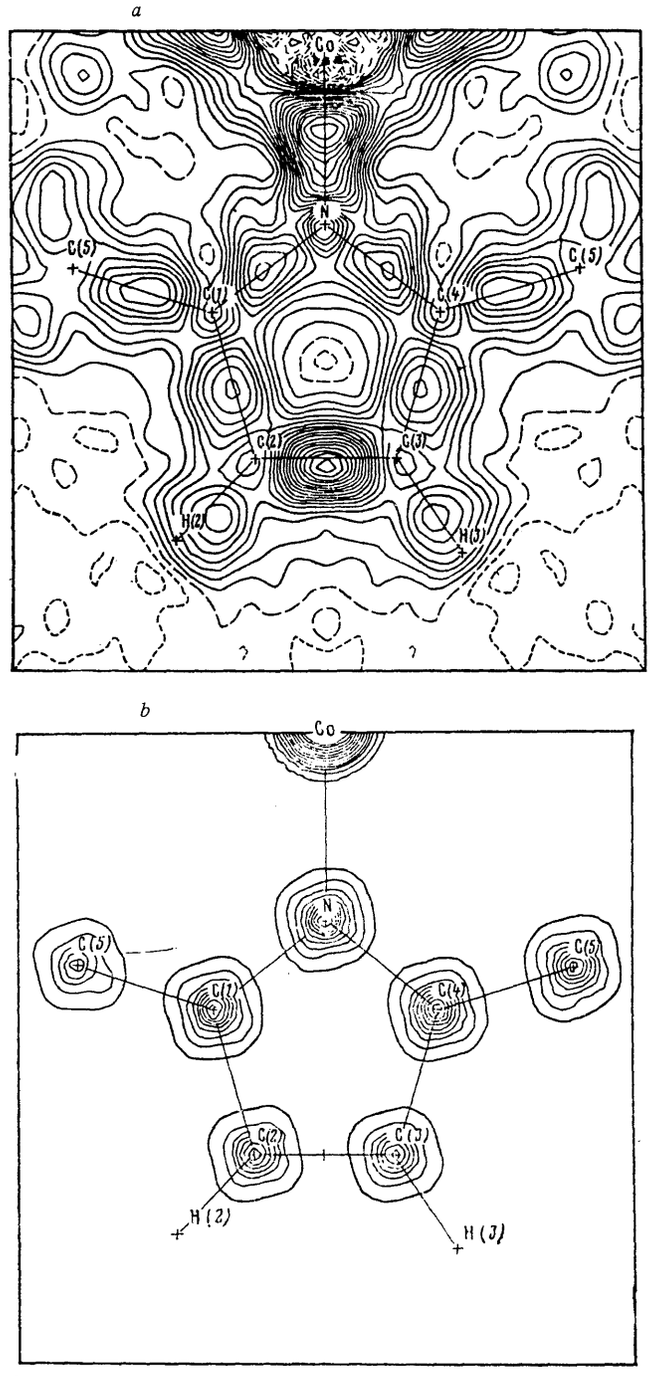

**Figure 6.** Deformation electron density for the $C_{44}H_{28}N_4Co$ crystal according to Stevens:[34] *a*) section in the plane of the pyrrole ring (spacing between lines 0.05 eÅ$^{-3}$); *b*) distribution of errors on the deformation electron density map (spacing between lines 0.02 eÅ$^{-3}$).

Analysis[45–47] has shown that, when the matrix elements $P_{ij}$ are sought, account must be taken of the quantum character of the electron distribution. In particular, it is essential that the quantities found should describe the distribution of electron density consistent with the Pauli

principle. Neglect of this fact can lead to negative electron densities in the vicinity of the nucleus or to populations of molecular orbitals exceeding 2e.[48] Allowance for it[47] led to equations for $P_{ij}$ having the same form as the equations for the same matrix in quantum chemistry (the Hartree–Fock–Roothaan equations). Thus the rigorous analysis made it possible to reduce to a single formal basis the experimental and theoretical approaches to the study of the distribution of electron density.

Table 3. The effective atomic charges in $HCOOLi.D_2O$.[49]

| Atom | Atomic charges, e | | |
|---|---|---|---|
| | experiment | *ab initio* calculation | EHM calculation |
| | Lithium ion | | |
| Li | 0.82 | 0.70 | 0.55 |
| | Formate ion | | |
| C | 0.04 | −0.01 | −0.01 |
| O (1) | −0.53 | −0.34 | −0.30 |
| O (2) | −0.46 | −0.34 | −0.26 |
| H | 0.13 | −0.02 | −0.02 |
| | Water molecule | | |
| D (1) | 0.11 | 0.06 | 0.08 |
| D (2) | 0.07 | 0.06 | 0.07 |
| O (3) | −0.18 | −0.12 | −0.10 |

Table 4. The intermolecular interaction energy $U_M$ and the heat of sublimation $\Delta H_S$ for the $HCOOLi.D_2O$ crystal.[50]

| Method of calculation | $U_C$, kcal mol$^{-1}$ | $U_M$, kcal mol$^{-1}$ | $\Delta H_S$, kcal mol$^{-1}$ |
|---|---|---|---|
| Diffraction data | 34.78 | 50.02 | 49.05±0.05 |
| Extended Hückel method | 8.36 | 24.10 | — |
| *Ab initio* calculation | 8.48 | 23.72 | — |

Remarks: $U_C$ is the Coulombic interaction energy; $\Delta H_S$ was measured on a Calvet microcalorimeter.

Calculations for the lithium formate deuterate ($HCOOLi.D_2O$) crystal[49] have shown (Table 3) that, although the experimental results agree with quantum-chemical data, there are also differences reflecting the effect of the crystal environment (both types of calculations have been carried out in terms of the same basis set). This has been manifested distinctly in the calculation of the intermolecular interaction energy in the $HCOOLi.D_2O$ crystal.[50] Calculation of this quantity by the method of atom–atom potentials taking into account the Coulombic interaction in terms of the "experimental" and quantum-chemical (for individual molecules) charges in the atoms revealed a satisfactory agreement with the results of thermodynamic measurements only when the "experimental" charges were used (Table 4). On this basis, one may conclude that the $P_{ij}$ matrix obtained from diffraction data describes satisfactorily the distribution of electron density in the crystal investigated. Theoretical calculations taking into account the crystal environment are not so effective.

## IV. THE ELECTROSTATIC FIELD IN THE CRYSTAL

The methods involving the "point" and parameteric representations of the electron density function using diffraction data were examined above. A concept according to which diffraction data are used to determine the electrostatic potential in crystal has developed recently.

The analytical expression relating the charge density functions for the electrons and nuclei of a system to the electrostatic potential of the point **r** is defined by the Poisson equation and assumes the following form:

$$\varphi(\mathbf{r}) = \sum_i (Z_i/|\mathbf{R}_i - \mathbf{r}|) - \int_{-\infty}^{\infty} \frac{\rho(\mathbf{r}')}{|\mathbf{r}' - \mathbf{r}|}\, d\mathbf{r}, \qquad (22)$$

where $Z_i$ is the charge on the atomic nucleus located at the point $\mathbf{R}_i$. The first term in Eqn.(22) describes the contribution to $\phi(\mathbf{r})$ by the nuclei in the system and the second describes the contribution by the electron distribution. The function $\phi(\mathbf{r})$ characterises the electrostatic interactions between the unperturbed system and the positive unit charge at the point **r**. Eivdently the potential $\phi(\mathbf{r})$ can be useful in the description of the chemical interaction when the molecules are separated by large distances, whereupon one can neglect the polarisation, charge transfer, and exchange effects.

Numerous chemical applications of this approach have been dealt with in detail in a communication.[51] However, the deformation electrostatic potential (DESP), introduced by Varnek et al.[52] and Spackmann and Stewart,[53] contains no less information and is defined by the expression

$$\delta\varphi(\mathbf{r}) = \int_{-\infty}^{\infty} \frac{\delta\rho(\mathbf{r}')}{|\mathbf{r} - \mathbf{r}'|}\, d\mathbf{r}' = -\frac{4\pi}{V} \sum_{\mathbf{q}} \frac{\delta F(q)}{|q^2|} \exp(-i\mathbf{q}\mathbf{r}). \qquad (23)$$

From the physical point of view, DESP characterises the electrostatic field, which, when superimposed on the electrostatic field of the promolecule, ensures a stable equilibrium configuration of the system.

Fig.7, obtained for ruby, shows that DESP reflects its physical properties.[22] In particular, the delocalisation of electron density discussed above leads to an unusual distribution of the electrostatic potential in the ruby crystal. The regions near the centres of the aluminium atoms, where the positive potential of the incompletely shielded nuclei predominates in the crystal, giving rise to quasi-continuous bands between which are included regions of negative potential extended along the Al...Al bond. Such distribution of DESP reproduces the characteristics of the electrostatic interaction of the ions in the ruby crystal and can be associated with its mechanical strength.

The electrostatic potential determines the electric field and its gradient at any point within the crystal. The knowledge of the latter is particularly important at the sites where the nuclei of the system are located, because this makes it possible, in principle, to calculate the nuclear quadrupole moment from the diffraction data without resorting to its measurement by the NQR method of with the aid of the Mössbauer effect.[54] Comparison of such results, obtained with the aid of various methods, can serve as a significant criterion of the quality of the determination of the electron distribution. The joint application of both methods in the multipolar refinement was discussed above for $AlPO_4$.[35]

The most promising applications of the experimental electrostatic potential were apparently associated with the development of the concept of a density functional based on the Hohenberg–Kohn theorem[55] and its generalisation.[56,57] According to this theorem, the energy and other characteristics of the many electron system are fully determined by

the function $\rho$. The exact form of this functional has not been established, but there exist many approximate relations which enable one to express the energy of the system as a functional of $\rho(\mathbf{r})$[58] or $\phi(\mathbf{r})$.[59] The first attempt to include diffraction data within the framework of such an approach[52,60] indicates that this procedure is promising for the study of the properties of crystals.

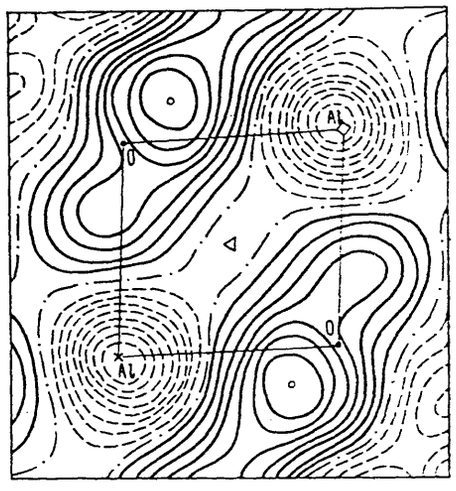

Figure 7. Experimental electrostatic deformation potential in ruby.[22]

## V. THE ATOMIC (ONE-PARTICLE) POTENTIALS

The deration of the elementary step of the interaction of radiation with matter is approximately $10^{-18}$ s and the characteristic time of thermal vibrations of lattice atoms is $10^{-12}$–$10^{-13}$ s. However, in real measurements the diffraction experiment yields a time-average picture of the crystal structure. As mentioned above, thermal movement is taken into account by introducing individual atomic temperature multipliers $W(\mathbf{q})$, which are the Fourier transforms of the distribution function $t(\mathbf{R})$ for the positions of the nuclei (neutrons) or the centres of gravity of the electron shells of the atom (X-rays). In the high-temperature limit (classical approximation), the above function can be written in the following form having replaced the time average by the average with res0ect to the ensemble:

$$t(\mathbf{R}) = \frac{\exp(-V(\mathbf{R})/kT)}{\int_{-\infty}^{\infty} \exp(-V(\mathbf{R})/kT)\,d\mathbf{R}}, \qquad (24)$$

where $V(\mathbf{R})$ is the potential energy of the atom vibrating in the effective force field of its neighbours. Such a one-particle model[61] constitutes a development of Einstein's model of independent oscillators.[62] If $V(\mathbf{R})$ is expanded in a power series in terms of displacements reckoned from the equilibrium position and the quasi-harmonic approximation is used,[61] then the expansion coefficients characterise the effective potential of the given atom. They can be included among the parameters capable of being refined by the least squares method and hence one can obtain important information about the dynamics of the crystal lattice. We may note that the above expansion is not restircted to the harmonic terms of the series and can be extended to higher-order terms associated with the asymmetry of the potential well.

There exists a fundamental relation between the function $\rho(\mathbf{r})$ and the effective atomic potentials, established by the Gel'man–Feynman theorem.[63,64] According to the latter, the force acting on each nucleus in the system is determined by the distribution of electron density and other nuclei. For the equilibrium configuration, this force becomes zero, which can serve as a criterion of the accuracy of the experimental distribution of electron density.

Diffraction analysis of the detailed characteristics of the lattice dynamics has become possible only very recently. Its first applications were associated with the study of the ionic conduction in solids.[65–68] For example, the form of the effective potential in lithium nitride ($Li_3N$) has been established[67,68] from X-ray diffraction data obtained over a range of temperatures. The above compound crystallises in the *P6/mmm* group, the N atom being surrounded by eight Li atoms in the form of a hexagonal bipyramid. Having applied the 6th-order Gram–Charlier expansion§, Schulz and Zucker[66,67] showed that the height of the potential barrier between the lithium atoms located in a plane perpendicular to the c axis is $0.29 \pm 0.04$ eV. Thus, the appearance of ionic conduction requires that the activation energy for the ion should be in the range 0.25–0.33 eV, which agrees with the results of the experimental measurement of this quantity (approximately 0.29 eV).[68]

Another application of the approach considered has been described in a study[69] where the concept of the effective atomic potential was applied in a correct interpretation of the deformation electron density maps for the $KCuF_3$ crystal subjected to Jahn–Teller distortion. In particular, it has been shown that the Coulombic attractive interaction between the $Cu^{2+}$ and $F^-$ ions exerts a greater influence on the anharmonicity of the vibrations of the $Cu^{2+}$ ion than the repulsion between the atomic skeletons.

The concept of effective atomic potentials has proved to be extremely useful also in other fields of study of the properties of crystals. Thus the parameters of the potentials can be related to the force constants of the chemical bonds and their characteristic frequencies, which makes it possible to relate the diffraction and spectroscopic analytical methods. Furthermore, knowledge of potential function character in the vicinity of atomic centres combined with knowledge of the details of the electron distribution in crystals is essential for understanding the mechanism of chemical reactions in the solid phase and also for controlling these reactions.[70] The establishment of relations of this kind is a task for the future and the immediate development of this field holds out very much promise.

## VI. CHARACTERISTICS OF THE ELECTRONIC STRUCTURE OF CRYSTALS OF DIFFERENT TYPES

The possibilities of modern diffraction methods for the study of the electronic structure and properties of crystals were demonstrated above. It is important, in principle, that $\rho$ is the observed experimental quantity which can be visualised by a graphical representation. This function contains important information about the properties of matter and with its aid it is possible to formulate a number of tasks

§ Other versions of the expansion of the potential are also possible—see, for example, Zucker and Schulz.[65]

involving the properties of the ground states of molecules and crystals.[71] The first attempts to apply this approach to the determination of certain magnetic and optical properties of crystals have already demonstrated its effectiveness.[71]

Analysis of the electron density function makes it possible to reinterpret the classical concepts of crystal chemistry. This applies particularly to the problem of the "dimensions" of atoms in the crystal and the possibility of an experimental estimation of their "radii" and "charges". In crystals with maximum covalent and metallic character, the atomic radius is determined simply as half the shortest interatomic distance and the effective charge within the limits of a sphere defined by such a radius can be logically assumed equal to zero.

However, analysis of the electron density distribution even in such simple crystals indicates a deviation of the form of the atoms in the crystal from the spherical shape. For covalent crystals of the type of diamond, the existence of electron density "bridges" between the atoms, surrounding one another in a tetrahedral arrangement has long been established. This picture corresponds to the model involving the $sp^3$ hybridisation of the valence orbitals of carbon and its analogues proposed by Pauling as early as 1929. It has recently been found that a situation similar to that already described is observed in metals and that a fraction of the valence electrons are localised along the length of the M–M bond.[72] The problem of the determination of the size of atoms in complex chemical compounds gives rise to even greater difficulties even when data concerning the distribution of electron density are available.

In order to obtain the dimensions of the ions from the function $\rho$, the criterion of the electron density minimum, characterised by the optimum separation radius $R_{sep}$, has been put forward.[27] It was found that the experimental values of $R_{sep}$, determined along the line of the bond, are intermediate between the classical and ionic and covalent (atomic) radii even in the most ionic compounds such as halides and oxides.[24] There are two main reasons which can account for this phenomenon:[73] (1) the anisotropic expansion of the electron shell of the cation and the contraction of the electron shell of the anion in the crystal and (2) the incompletely ionic character of the chemical bond. The first factor, which was initially predicted theoretically, was subsequently repeatedly confirmed also experimentally and with the aid of accurate calculations for alkali metal halides, where the bond can be regarded as virtually purely ionic. For these compounds, the experimental radii of the cations are greater by approximately 0.2 Å and those of the anions are smaller by the same amount from the classical ionic radii. This systematic difference is confirmed by the data presented in Table 5. It can be attributed wholly to the effects of the "contraction–expansion" of the ion in the crystal field and of the transfer of charge ensuring the fulfilment of the Pauli principle.

For multicharged ions in halides, oxides, and chalcogenides, these effects cannot be regarded as the only cause of the difference between the experimental maximum separation radii and the classical ionic radii. This is also indicated by the experimental estimates of the effective atomic charges obtained from the distribution of electron density, which were described above. In conformity with data obtained by other methods, these results indicate a semicovalent character of the chemical bond in the oxide and silicates of bivalent and tervalent elements. Experiment has shown that the Si–O bonds in silicates are more than half-covalent. On the other hand, chalcogenides are more correctly regarded as covalent compounds with a proportion of ionic character. This means that the concept of ionic radii cannot be strictly speaking applied at all to compounds of this group. Indeed, the results of numerous studies have shown that the optimum separation radii for the oxides and silicates are intermediate between the ionic and atomic radii and in many instances (Si, Al, Co, and Ni) they are closer to atomic radii than to ionic radii.

**Table 5.** Comparison of the radii of optimum separation of the electron densities of ions with the classical ionic radii ($R_i$) and atomic radii ($R_{at}$) in certain halides.

| Element | $R_i$, Å | $R_{sep}$, Å | $R_{at}$, Å | Refs. |
|---|---|---|---|---|
| $Na^+$ | 1.02 | 1.21±0.05 | 1.80 | [74] |
| $Cl^-$ | 1.81 | 1.61±0.05 | 1.00 | |
| $K^+$ | 1.38 | 1.45±0.07 | 2.20 | [74] |
| $Cl^-$ | 1.81 | 1.70±0.07 | 1.00 | |
| $Ag^+$ | 1.15 | 1.03±0.05 | 1.60 | [74] |
| $Cl^-$ | 1.81 | 1.74±0.05 | 1.00 | |
| $Ag^+$ | 1.15 | 1.13 | 1.60 | [75] |
| $Br^-$ | 1.46 | 1.76 | 1.15 | |
| $Mg^{2+}$ | 0.72 | 0.90 | 1.50 | [76] |
| $F^-$ | 1.33 | 1.25 | 0.50 | |

The idea of the continuous variation of the effective atomic size as the character of the chemical bond is varied between two limiting values—the ionic radius for the limiting ionic bond and the covalent radius for the covalent bond—is permissible. A linear variation of the radius with the amount of the ionic character of the chemical bond has been postulated. It was later shown that the variation of the dimensions of the electron shells (the so-called orbital radii) with the charge is not strictly linear.[73] Having adopted this model, one must not forget that the atomic and ionic radii are of a completely different character; the former are characterised by the distance from the centre of the atom to the maximum electron density of the valence electrons or, since these maxima overlap on formation of the chemical bond, to the maximum density of the electron overlap between the atoms, while the ionic radii are equal to the distance to the electron density minimum in the direction of the bonds between the atoms.

The dependence of the size of the atom on the effective charge can be regarded as semiempirical. For example, for silicon it can be described by the simple expression $r = r_k - 0.05Z^2$, where $r_k$ is the covalent radius and $Z$ the atomic charge. The theoretical values of the orbital radii of $Si^+$ (1.08 Å) and $Si^{2+}$ (0.90 Å) are distributed between the covalent (1.16 Å) and ionic (0.40 Å for a coordination number of 6) radii.[24] It is important to emphasise that the average experimental radius of the silicon ion (0.96 Å), found for silicates, corresponds to a charge of +1.5 e. In its turn the estimated effective charge on the silicon atom agrees closely with the results of the analysis of the distribution of the electron density of silicon discussed above and with numerous data obtained by other physical methods.

Thus the description of the atom as a spherical body for significantly covalent compounds greatly simplifies the radial picture of chemical bonds. The study of the distribution of electron density in various polymorphic modifications of $SiO_2$ is extremely instructive in this sense. In the $SiO_2$ crystal with the rutile structure (stishovite),[77] the chains of $SiO_2$ octahedra having common edges are arranged along the $c$ axis. Each chain is linked to four other chains via oxygen

atoms. It follows from the ionic model that the Si–Si and O–O repulsion in stishovite should lead to a longer Si–O bond directed along the common edge of the octahedra.[77] Experiment has shown that the deformation electron density peaks for the two bonds are respectively 0.47 and 0.30 eÅ$^{-3}$ (Fig. 8*a*) and are somewhat displaced towards oxygen atoms. The distance from them to Si is 1.1 Å, which agrees fairly well with the Slater atomic radius of silicon.[78] The Si–O bonds in the four-membered ring are strained, which is indicated by the shift of the peaks to the outside from the line of the bond (Fig. 8*b*). It is striking that in this plane the peaks are linked by bridges; such distribution of deformation electron density is apparently preferable on energy grounds. In this case the electrons of the bridges shield the nuclei of the cations interacting via the common edge and for this reason, contrary to the ionic model, the corresponding Si–O bonds are shorter.

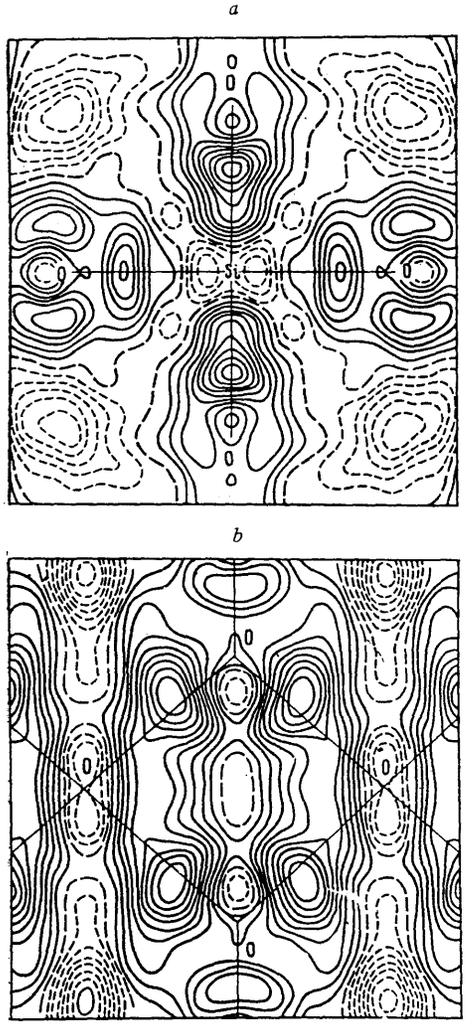

**Figure 8.** Deformation electron density in the stishovite ($SiO_2$) crystal:[72] *a*) section illustrating the non-equivalent Si–O bonds (the Si atom is in the centre); *b*) section through a four-membered ring made up of O atoms; the contour lines are drawn at 0.05 eÅ$^{-3}$ intervals.

As in stishovite, the deformation electron density peaks have been found from the Si–O bonds in α- and β-quartz to one side of the line connecting the atoms.[79] In these $SiO_2$ modifications the deformation of the electron cloud is more complex. We may note the appreciable delocalisation of the electrons along the O–Si–O fragment and the displacement of the centres of gravity of the covalent peaks towards the oxygen atoms. Individual bonds are also linked by bridges, which may be interpreted as evidence for partial double bond character of the Si–O bond. Estimation of the atomic charges by the least squares method using the multipolar expansion showed that the effective charge on silicon in various $SiO_2$ modifications is in the range 1.0–1.7 e, while the charge on oxygen is between −0.5 and −0.85 e.[28] The charge on silicon with a coordination number (C.N.) of 4 is close to 1.0 e and for C.N. = 6 in stishovite it increases to 1.7 e. This indicates an increase of the amount of ionic character of the Si–O bond with increasing C.N. Using the parameter κ, it has been found that the silicon atom in the crystal has contracted while the oxygen atom has expanded relative to the dimensions of the free atoms.

A correlation has been observed experimentally in recent times between the charge on the silicon atom and its coordination number. In particular, it has been found for the compound $K_2Si^{VI}Si_3^{IV}O_9$, where the silicon atoms occupy both tetrahedral and octahedral positions,[80] that the charge on silicon increases with increasing C.N. Refinement of the populations of the valence shells yielded the charges +3.29(15) e for $Si^{VI}$ and +2.52(11) e for $Si^{IV}$, which can be interpreted as an indication of an increase in the amount of ionic character of the bonds in which a Si atom participates as the coordination number of atoms increases.

Estimation of the atomic charges is the simplest method for finding an approximation to the experimental electron distribution. For this purpose, one usually employs either numerical integration of the electron density (for example, for cations over the volume of a sphere whose radius is equal to the radius of optimum separation[27]) or the refinement of the valence electron population of the atoms (as a rule with the aid of the κ technique[18] by the method of least squares). Both methods suffer from a series of disadvantages. Thus the result of the integration depends on the selected volume and that of the refinement procedure on the functions with the aid of which one calculates the scattering amplitude for the valence electrons. Furthermore, the data obtained by these methods agree poorly with one another (Table 6).[81] The estimated values for transition metal atoms in various coordination compounds quoted in Table 6 approach the formal oxidation state only in oxides and silicates (ionic crystals). In organometallic compounds they are appreciably below the formal oxidation states owing to the significant covalent contribution of the metal–ligand bonds. Thus the above estimated charges can hardly be regarded as characteristic of the valence state of the central atom in coordination compounds. More detailed information can be derived from the maps, which make it possible to identify the characteristics of the electronic structure of metal atoms in various crystals.

The study of dinuclear transition metal complexes is of great interest. The character of the chemical bond between the transition metal ions is in this case strikingly different both from the simple picture observed in covalent bonds involving light atoms without d electrons and from the metal–ligand bond. The observed large difference between the lengths of the quadruple M–M bonds (approximately 0.7 Å) shows that the distribution of electron density in various compounds containing such bonds can have significantly different details. The extensive experimental and theoretical studies proved useful for the understanding of the specific

features of these details. The dihydrate of dichromium tetra-acetate $Cr_2(O_2C_2H_3)_4.2H_2O$ has been investigated.[82] In this crystal the moelcule is located at the crystallographic centre of inversion and has an intrinsic $D_{4h}$ symmetry. This made it possible to obtain fairly accurate results by averaging the experimental $\delta\rho$ maps over the chemically equivalent parts of the molecule. According to classical views, a quadruple metal–metal bond is formed in this compound, where the distance between the chromium atoms is 2.36 Å: a single $\sigma$-bond (described by the $d_{z^2}$ orbital), two equivalent $\pi$-bonds ($d_{xz}$ and $d_{yz}$), and a single weak $\delta$-bond ($d_{xy}$) are formed. The contributions of each component differ very greatly in magnitude and the bond order indicated above therefore merely reflects the fact that it can be formally described by four molecular orbitals occupied by eight electrons. The experimental data (Fig.9) show that the deformation electron density in the region of the metal–metal $\sigma$-bond is diffuse and significantly smaller in magnitude than in the Cr–O, C–O, and C–H bonds (approximately 0.1 eÅ$^{-3}$ to within 0.02 eÅ$^{-3}$); on the other hand, somewhat higher peaks (0.12–0.3 eÅ$^{-3}$) are manifested in the region of $\pi$- and $\delta$-bonds. These data agree well with theoretical calculations of the deformation electron density functions for $Cr_2(HCO_2)_4$ in terms of an expanded basis set taking into account configuration interaction.[82] Comparison of the electron populations of the 3*d* orbitals of the free chromium atom (spherically averaged) and the chromium atom in a molecule has shown that the population of the $d_{z^2}$ orbital forming a $\sigma$-bond changes very insignificantly on formation of a molecule and the peaks in the corresponding region are therefore small. The more appreciable change in the populations of other orbitals is accompanied by the appearance of peaks far from the line of the bond. One should note that the 4*s* valence orbital in the molecule is almost unoccupied and this also entails a decrease of the deformation electron density between the metal atoms.

**Table 6.** Charges on transition metal atoms estimated from diffraction data.[81]

| Atom | Atomic charge, e | | Oxidation state | Compound |
|---|---|---|---|---|
| | I | II | | |
| Co | +0.7 (1) | +0.06 (6) | +3 | $[Co(NO_2)_6]^{3-}$ |
| Co | +0.7 (3) | +0.8 (1) | +3 | $[Co(NH_3)_6]^{3+}$ |
| Co | +0.2 (3) | +0.4 (1) | +3 | $[Co(CN)_6]^{3-}$ |
| Cr | +0.15 (12) | — | 0 | $[Cr(Co)_6]$ |
| Cr | +0.1 (1) | +2.78 (6) | +6 | $CrO_4^{2-}$ |
| Co | — | +1.5 (1) | +2 | $CoAl_2O_4$ |
| Mn | +1.58 (1) | — | +2 | MnO |
| Mn | +0.21 (6), +1.49 (6) | — | +2 | $Mn_2SiO_4$ |
| Fe | +0.85 (8), +1.54 (7) | +1.3 (1), +1.9 (1) | +2 | $\alpha$-$Fe_2SiO_4$ |
| Mn | +1.21 (6), +1.49 (6) | +1.3 (1), +2.2 (2) | +2 | $\alpha$-$Mn_2SiO_4$ |

Remarks: The charges quoted in column I were found by the numerical integration of the electron density within the limits of the sphere defined by the optimum separation radius, while column II lists the charges found by the $\kappa$-refinement using the method of least squares.

When configuration interaction was taken into account, it was found[82] that the $\sigma^2\delta^2(\delta^*)^2(\sigma^*)^2$ configuration makes a considerable contribution to the energy of the structure; the contribution of the highly bonding $\sigma^2\pi^4\delta^2$ configuration is only 18%. Thus the antibonding configurations diminish with formal bond order, increasing the bond length.

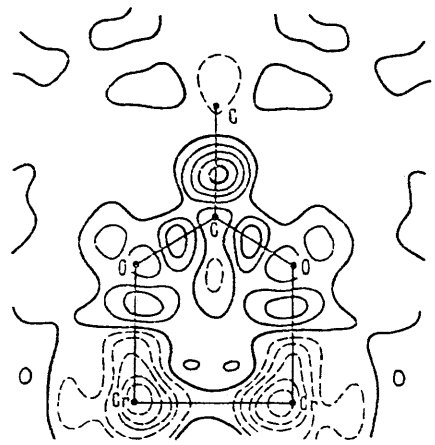

Figure 9. Experimental map of the deformation electron density in the $Cr_2(O_2C_2H_3)_4.2H_2O$ crystal; the section containing the Cr–Cr bond is shown; spacing between lines 0.1 eÅ$^{-3}$.

The characteristic features of the $\delta\rho$ map in $Mo_2(O_2C_2H_3)_4$ in the region of the Mo–Mo bond, whose length is 2.10 Å, are qualitatively similar to the picture described above. However, more intense peaks have been observed[83] between the metal atoms (approximately 0.2 eÅ$^{-3}$) also to one side of the Mo–Mo line (approximately 0.4 eÅ$^{-3}$). Calculated data for the changes in the electron populations of molybdenum[83] suggest that the explanation of the causes of the increase of $\delta\rho$ in the region of the $\pi$- and $\delta$-bonds adduced above in connection with the consideration of $Cr_2(O_2C_2H_3)_4.2H_2O$ is valid also in the case under discussion. Next it was found for $Mo_2(O_2C_2H_3)_4$ that the transfer of electrons from Mo to the neighbouring atoms is accompanied by the appearance of negative minima in the vicinity of the Mo atom on the $\delta\rho$ map in directions corresponding to a decrease of electron density in the antibonding $d_{x^2-y^2}$ orbital. This is characteristic of a transition metal ion in a crystal field with $D_{4h}$ symmetry. It is noteworthy that, in contrast to $Cr_2(O_2C_2H_3)_4.2H_2O$, the contribution of the configuration of the ground state $\sigma^2\pi^4\delta^2$ in this compound is 66% and allowance for the excited configuration hardly alters the deformation electron density map.

The refined features of the electron density in the "ultrashort" quaternary Cr–Cr bond in $[Cr_2(mhp)_4]$, whose length is 1.879 Å at 74 K, have been studied in detail.[84]¶ A $\delta\rho$ peak 0.41 eÅ$^{-3}$ high, extending over the $\pi$- and $\delta$-regions, has been observed between the metal atoms (Fig.10*a*). This peak is so diffuse that it is linked by $\delta\rho$ bridges 0.15 eÅ$^{-3}$ high with the peaks on the metal–ligand

¶ Here mhp = μ-2-hydroxy-6-methylpyridine.

bond. Quantum-chemical calculation for the $Cr_2[H_2P(CH_2)_2]_4$ molecule has shown[84] that the contribution of the δ-component to such a quadruple bond is relatively small and that the σ- and π-interactions play the main role. Negative δρ regions approximately −0.37 eÅ$^{-3}$ deep are directed towards the ligand; this indicates a smaller electron population of the $d_{x^2-y^2}$ orbital compared with the $d_{xy}$ orbital. This is why the $d_{x^2-y^2}$ orbital in fact serves as an acceptor for the unshared electron pairs of the ligands, promoting the formation of a donor–acceptor bond. The theoretical δρ map (Fig. 10*b*), calculated taking into account configuration interaction (the contribution of the $\sigma^2\pi^4\delta^2$ configuration is 55%), agrees well with the experimental map: for example, the height of the peak on the M–M bond is in this case 0.30 eA$^{-3}$. Excess density peaks are observed in both cases when the line of this bond is produced (0.3–0.45 eÅ$^{-3}$), which is caused, according to the authors,[84] by the contraction of the 3*p* and 3*s* shells. Such peaks have also been observed for $Mo_2(O_2C_2R_3)_4$, but could not be interpreted reliably.

Thus experiment has shown that formally identical quadruple metal–metal chemical bonds have, apart from common features, all the characteristic features associated with the specific composition and structure of the compound. This conclusion has been confirmed and supplemented by theoretical calculations. Thus the cases discussed above indicate a tendency towards an increase of the δρ peak located between the metal atoms with decrease of the bond length. On the other hand, the observed small population of the $d_{x^2-y^2}$ orbital changes from compound to compound depending on the nature of the metal atoms and the type of ligand, which alters the ligand–metal–metal angle, changing at the same time the geometry of the compound as a whole. Allowance for the interelectron interaction in binary complexes, which significantly reduces the energy of the system, has different effects on the deformation electron density in various compounds, sometimes leading merely to changes in insignificant details.

In interpreting the deformation electron density maps, one should bear in mind that the construction of difference electron density maps always involves an arbitrary element, because they depend on the choice of the model of the promolecule,[85] which can be made up, in principle, of the electron densities of the free atoms or spherically averaged atoms forming part of the molecule. In the former case the atoms with incompletely occupied *p* and *d* shells have non-zero angular moments and possess a characteristic symmetry. As a consequence of this, differences arise between the electron densities along the chemical bond and at right angles to it and are manifested on the δρ maps. In particular,[85] if the B and C atoms in the ground state are included in the promolecule, then the values of the δρ function along the line of the bond are smaller than in the case where the electron densities of these atoms are spherically averaged. The opposite picture is observed for O and F atoms. For this reason, it is recommended[85] that the promolecule be defined as the set of the electron densities of spherically symmetrical atoms; this reference state has since become generally adopted.

In the calculation of the valence electron density, the separation of electrons into "inner" and "outer" is usually carried out on the grounds of energy considerations. It is then assumed that the densities (and energies) of the "inner" electrons in the molecules and in the free atoms are virtually the same. However, it is known from calculations that, when atoms are involved in a chemical bond, the energies of the inner shells change somewhat.[86] This is also indicated by photoelectron spectroscopic data.[87] Another deficiency of the energy approach to the separation consists in the fact that is is not clear how it can be applied to the electrons of the *s* orbitals located not only in the valence region but also in the vicinity of atomic nuclei.

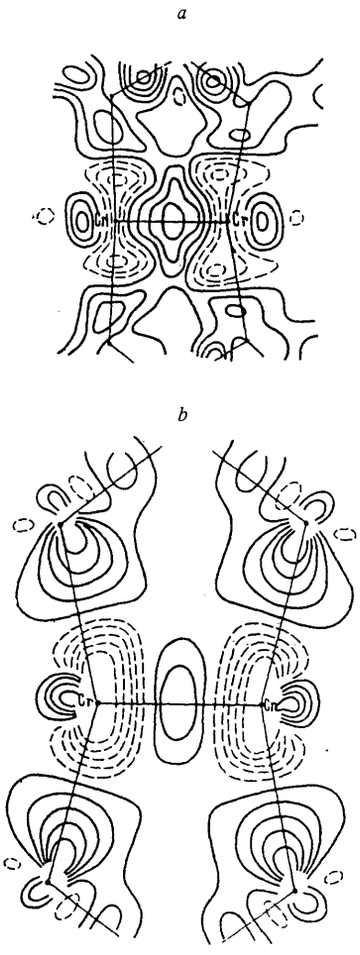

**Figure 10.** Experimental (*a*) and theoretical (*b*) maps of the deformation electron density in the "ultrashort" quadruple Cr–Cr bond;[84] spacing between lines 0.1 eÅ$^{-3}$.

At the same time, it has been noted[88] that points where the radial distribution of the electron density has local minima, whose number is equal to the number of nodes in the radial wave function, exist in atoms. It has been suggested[89] that these minima be regarded as the boundaries between the *K*, *L*, ... layers in the electron shells of atoms. This provides a natural criterion for the subdivision of electrons into skeletal and valence electrons. In molecules the spherical symmetry of the atom breaks down and its electron skeleton is polarised: the skeleton contracts along the bond and expands in a perpendicular direction (dipolar polarisation).[90] However, this polarisation is relatively insensitive to the nature of the other atoms involved in the

chemical bond and the above definition of the skeleton is therefore very suitable for the identification of valence electrons.

Careful analysis[21] made it possible to elucidate the role of the nodes in wave functions in the formation of a chemical bond. An increase of their number in σ orbitals weakens the role of the σ-electron density in the formation of chemical bonds; at the same time the contribution to the electron density described by the π, δ, and other orbitals increases. For this reason, the covalent bonds involving the C, N, and O bonds are apparently stronger than the bonds involving the Si, P, and S atoms.[21]

On the basis of the foregoing, one can conclude that positive peaks on the δρ maps will be manifested in the bonding and non-bonding regions of the molecule and the crystal, while the negative peaks will occur in the regions where the atomic orbitals whose contribution to the molecular orbitals are small are localised. Comparison of the spatial characteristics of the atomic orbitals with the observed electron distribution permits a qualitative interpretation of the latter in terms of the LCAO-MO approximation. Here it is essential to note that the absence of positive δρ peaks in the bonding region does not indicate the absence of a covalent bond. For example, we can imagine a molecular orbital, describing the region of the bond, in the form of a linear combination of the hybrid orbitals of atoms in close proximity each of which supplies one electron to the bond. If these atoms contain more than half-occupied valence shells, then, after spherical averaging, there will be more than one electron per hybrid atomic orbital. In the calculation of the δρ function, this cannot only compensate for the corresponding peaks but can also lead to their negative values in the region of the bond.

Indeed the results of the experimental and theoretical studies have confirmed these considerations. The above picture has been observed, for example, in the N–N bond of diformylhydrazide,[91] the O–O bond in hydrogen peroxide,[92] the C–F bond in tetrafluoroterephthalodinitrile,[93] and also in certain M–M bonds discussed above. We may note the choice of the reference state in a form different from the promolecule (see, for example, Heijser et al.[94]) makes it possible to identify the characteristics of the distribution of the deformation electron density also in such cases, which are difficult to interpret by the standard procedure.

The above refers also to the regions where the unshared electron pairs are located, their peak diminishing and being observed nearer to the centres of the atoms with increase of the electronegativity of the latter.[93] Thus, in the interpretation of the deformation electron density maps, one must take into account the distribution of electrons among the orbitals in the atoms of the promolecule averaged over the orientations.

---o0o---

It is seen from the data presented that modern diffraction methods make it possible to obtain a clear and detailed picture of the structures of crystalline substances which had been inaccessible hitherto. The new data sometimes agree with the existing crystal-chemical and quantum-chemical views, supplementing and refining them, and sometimes contradict them. At the present time experimental data for a wide range of systems are accumulating rapidly. The electron densities in the fragments of complex biological molecules, medicinal drugs, the organometallic compounds involved in catalytic processes, substances used in instrument making, and minerals are being investigated. A general treatment of these data will enable us to move from qualitative correlations to the establishment of quantitative relations between the electronic structures of substances and their physicochemical properties. So far only the first attempts have been made to seek such relations in the solution of problems concerning complex formation[95] and in the study of materials for non-linear optics;[96] a further development of this approach appears extremely promising.
